Preface

Each of the first two editions of *The Prokaryotes* took a bold step. The first edition, published in 1981, set out to be an encyclopedic, synoptic account of the world of the prokaryotes—a collection of monographic descriptions of the genera of bacteria. The Archaea had not yet been formalized as a group. For the second edition in 1992, the editors made the decision to organize the chapters on the basis of the molecular phylogeny championed by Carl Woese, which increasingly provided a rational, evolutionary basis for the taxonomy of the prokaryotes. In addition, the archaea had by then been recognized as a phylogenetically separate and distinguishable group of the prokaryotes. The two volumes of the first edition had by then expanded to four. The third edition was arguably the boldest step of all. We decided that the material would only be presented electronically. The advantages were obvious and persuasive. There would be essentially unlimited space. There would be no restrictions on the use of color illustrations. Film and animated descriptions could be made available. The text would be hyperlinked to external sources. Publication of chapters would be seriati—the edition would no longer have to delay publication until the last tardy author had submitted his or her chapter. Updates and modifications could be made continuously. And, most attractively, a library could place its subscribed copy on its server and make it available easily and cheaply to all in its community. One hundred and seventy chapters have thus far been presented in 16 releases over a six-year period. The virtues and advantages of the online edition have been borne out. But we failed to predict the affection that many have for holding a bound, print version of a book in their hands. Thus, this print version of the third edition shall accompany the online version.

We are now four years into the 21st century. Indulge us then while we comment on the challenges, problems and opportunities for microbiology that confront us.

Moselio Schaechter has referred to the present era of microbiology as its third golden age—the era of "integrative microbiology." Essentially all microbiologists now speak a common language. So that the boundaries that previously separated subdisciplines from each other have faded: physiology has become indistinguishable from pathogenesis; ecologists and molecular geneticists speak to each other; biochemistry is spoken by all; and—mirabile dictu!—molecular biologists are collaborating with taxonomists.

But before these molecular dissections of complex processes can be effective there must be a clear view of the organism being studied. And it is our goal that these chapters in *The Prokaryotes* provide that opportunity.

There is also yet a larger issue. Microbiology is now confronted with the need to understand increasingly complex processes. And the modus operandi that has served us so successfully for 150 years—that of the pure culture studied under standard laboratory conditions—is inadequate. We are now challenged to solve problems of multimembered populations interacting with each other and with their environment under constantly variable conditions. Carl Woese has pointed out a useful and important distinction between empirical, methodological reductionism and fundamentalist reductionism. The former has served us well; the latter stands in the way of our further understanding of complex, interacting systems. But no matter what kind of synoptic systems analysis emerges as our way of understanding host–parasite relations, ecology, or multicellular behavior, the understanding of the organism as such is sine qua non. And in that context, we are pleased to present to you the third edition of *The Prokaryotes*.

Martin Dworkin
Editor-in-Chief

Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These four volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors many of the strategies and tools as well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the "organism approach" has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of the *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and

prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the “nitrosome,” a unique nitrogen-fixing organelle. Study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become “dog-eared” and worn as students seek basic information for the hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, i.e., from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator these volumes should generate excitement.

Happy hunting!

Volume 1

1. Essays in Prokaryotic Biology

1.1 How We Do, Don't and Should Look at Bacteria and Bacteriology 3
CARL R. WOESE

1.2 Databases 24
WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER and ERKO STACKEBRANDT

1.3 Defining Taxonomic Ranks 29
ERKO STACKEBRANDT

1.4 Prokaryote Characterization and Identification 58
HANS G. TRÜPER and KARL-HEINZ SCHLEIFER

1.5 Principles of Enrichment, Isolation, Cultivation, and Preservation of Prokaryotes 80
JÖRG OVERMANN

1.6 Prokaryotes and Their Habitats 137
HANS G. SCHLEGEL and HOLGER W. JANNASCH

1.7 Morphological and Physiological Diversity 185
STEPHEN H. ZINDER and MARTIN DWORKIN

1.8 Cell-Cell Interactions 221
DALE KAISER

1.9 Prokaryotic Genomics 246
B. W. WREN

1.10 Genomics and Metabolism in *Escherichia coli* 261
MARGRETHE HAUGGE SERRES and MONICA RILEY

1.11 Origin of Life: RNA World versus Autocatalytic Anabolism 275
GÜNTER WÄCHTERSHÄUSER

1.12 Biotechnology and Applied Microbiology 284
EUGENE ROSENBERG

1.13 The Structure and Function of Microbial Communities 299
DAVID A. STAHL, MEREDITH HULLAR and SEANA DAVIDSON

2. Symbiotic Associations

2.1 Cyanobacterial-Plant Symbioses 331
DAVID G. ADAMS, BIRGITTA BERGMAN, S. A. NIERZWICKI-BAUER, A. N. RAI and ARTHUR SCHÜßLER

2.2 Symbiotic Associations Between Ciliates and Prokaryotes 364
HANS-DIETER GÖRTZ

2.3 Bacteriocyte-Associated Endosymbionts of Insects 403
PAUL BAUMANN, NANCY A. MORAN and LINDA BAUMANN

2.4 Symbiotic Associations Between Termites and Prokaryotes 439
ANDREAS BRUNE

2.5 Marine Chemosynthetic Symbioses 475
COLLEEN M. CAVANAUGH, ZOE P. MCKINESS, IRENE L.G. NEWTON and FRANK J. STEWART

3. Biotechnology and Applied Microbiology

3.1 Organic Acid and Solvent Production 511
PALMER ROGERS, JIANN-SHIN CHEN and MARY JO ZIDWICK

3.2 Amino Acid Production 756
HIDEHIKO KUMAGAI

3.3 Microbial Exopolysaccharides 766
TIMOTHY HARRAH, BRUCE PANILAITIS and DAVID KAPLAN

3.4 Bacterial Enzymes 777
WIM J. QUAX

3.5 Bacteria in Food and Beverage Production 797
MICHAEL P. DOYLE and JIANGHONG MENG

3.6 Bacterial Pharmaceutical Products 812
ARNOLD L. DEMAIN and GIANCARLO LANCINI

3.7 Biosurfactants 834
EUGENE ROSENBERG

3.8 Bioremediation 850
RONALD L. CRAWFORD

3.9 Biodeterioration — 864
JI-DONG GU and RALPH MITCHELL

3.10 Microbial Biofilms — 904
DIRK DE BEER and PAUL STOODLEY

Index — 939

Volume 2

1. Ecophysiological and Biochemical Aspects

1.1 Planktonic Versus Sessile Life of Prokaryotes — 3
KEVIN C. MARSHALL

1.2 Bacterial Adhesion — 16
ITZHAK OFEK, NATHAN SHARON and SOMAN N. ABRAHAM

1.3 The Phototrophic Way of Life — 32

3. Proteobacteria

Introduction to the Proteobacteria — 3
KAREL KERSTERS, PAUL DE VOS, MONIQUE GILLIS, JEAN SWINGS, PETER VAN DAMME and ERKO STACKEBRANDT

3.1. Alpha Subclass

3.1.1 The Phototrophic Alpha-Proteobacteria — 41
JOHANNES F. IMHOFF

3.1.2 The Genera *Prosthecomicrobium* and *Ancalomicrobium* 65
GARY E. OERTLI, CHERYL JENKINS, NAOMI WARD, FREDERICK A. RAINEY, ERKO STACKEBRANDT and JAMES T. STALEY

3.1.3 Dimorphic Prosthecate Bacteria: The Genera *Caulobacter*, *Asticcacaulis*, *Hyphomicrobium*, *Pedomicrobium*, *Hyphomonas* and *Thiodendron* 72
JEANNE S. POINDEXTER

3.1.4 The Genus *Agrobacterium* 91
ANN G. MATTHYSSE

3.1.5 The Genus *Azospirillum* 115
ANTON HARTMANN and JOSE IVO BALDANI

3.1.6 The Genus *Herbaspirillum* 141
MICHAEL SCHMID, JOSE IVO BALDANI and ANTON HARTMANN

3.1.7 The Genus *Beijerinckia* 151
JAN HENDRICK BECKING

3.1.8 The Family Acetobacteraceae: The Genera *Acetobacter*, *Acidomonas*, *Asaia*, *Gluconacetobacter*, *Gluconobacter*, and *Kozakia* 163
KAREL KERSTERS, PUSPITA LISDIYANTI, KAZUO KOMAGATA and JEAN SWINGS

3.1.9 The Genus *Zymomonas* 201
HERMANN SAHM, STEPHANIE BRINGER-MEYER and GEORG A. SPRENGER

3.1.10 The Manganese-Oxidizing Bacteria 222
KENNETH H. NEALSON

3.1.11 The Genus *Paracoccus* 232
DONOVAN P. KELLY, FREDERICK A. RAINEY and ANN P. WOOD

3.1.12 The Genus *Phenylobacterium* 250
JÜRGEN EBERSPÄCHER and FRANZ LINGENS

3.1.13 *Methylobacterium* 257
PETER N. GREEN

3.1.14 The Methanotrophs—The Families Methylococcaceae and Methylocystaceae 266
JOHN P. BOWMAN

3.1.15 The Genus *Xanthobacter* 290
JÜRGEN WIEGEL

3.1.16 The Genus *Brucella* 315
EDGARDO MORENO and IGNACIO MORIYÓN

3.1.17 Introduction to the Rickettsiales and Other Intracellular Prokaryotes 457
DAVID N. FREDRICKS

3.1.18 The Genus *Bartonella* 467
MICHAEL F. MINNICK and BURT E. ANDERSON

3.1.19 The Order Rickettsiales 493
XUE-JIE YU and DAVID H. WALKER

3.1.20 The Genus *Coxiella* 529
ROBERT A. HEINZEN and JAMES E. SAMUEL

3.1.21 The Genus *Wolbachia* 547
MARKUS RIEGLER and SCOTT L. O'NEILL

3.1.22 Aerobic Phototrophic Proteobacteria 562
VLADIMIR V. YURKOV

3.1.23 The Genus *Seliberia* 585
JEAN M. SCHMIDT and JAMES R. SWAFFORD

3.2. Beta Subclass

3.2.1 The Phototrophic Betaproteobacteria 593
JOHANNES F. IMHOFF

3.2.2 The *Neisseria* 602
DANIEL C. STEIN

3.2.3 The Genus *Bordetella* 648
ALISON WEISS

3.2.4 *Achromobacter*, *Alcaligenes* and Related Genera 675
HANS-JÜRGEN BUSSE and ANDREAS STOLZ

3.2.5 The Genus *Spirillum* 701
NOEL R. KRIEG

3.2.6 The Genus *Aquaspirillum* 710
BRUNO POT, MONIQUE GILLIS and JOZEF DE LEY

3.2.7 *Comamonas* 723
ANNE WILLEMS and PAUL DE VOS

3.2.8 The Genera *Chromobacterium* and *Janthinobacterium* 737
MONIQUE GILLIS and JOZEF DE LEY

3.2.9 The Genera *Phyllobacterium* and *Ochrobactrum* 747
JEAN SWINGS, BART LAMBERT, KAREL KERSTERS and BARRY HOLMES

3.2.10 The Genus *Derxia* 751
JAN HENDRICK BECKING

3.2.11 The Genera *Leptothrix* and *Sphaerotilus* 758
STEFAN SPRING

3.2.12 The Lithoautotrophic Ammonia-Oxidizing Bacteria 778
HANS-PETER KOOPS, ULRIKE PURKHOLD, ANDREAS POMMERENING-RÖSER, GABRIELE TIMMERMANN and MICHAEL WAGNER

3.2.13 The Genus *Thiobacillus* 812
LESLEY A. ROBERTSON and J. GIJS KUENEN

3.2.14 The Genera *Simonsiella* and *Alysiella* 828
BRIAN P. HEDLUND and DAISY A. KUHN

3.2.15 *Eikenella corrodens* and Closely Related Bacteria 840
EDWARD J. BOTTONE and PAUL A. GRANATO

3.2.16 The Genus *Burkholderia* 848
DONALD E. WOODS and PAMELA A. SOKOL

3.2.17 The Nitrite-Oxidizing Bacteria 861
AHARON ABELIOVICH

3.2.18 The Genera *Azoarcus*, *Azovibrio*, *Azospira* and *Azonexus* 873
BARBARA REINHOLD-HUREK and THOMAS HUREK

Index 893

Volume 6

3. Proteobacteria

3.3. Gamma Subclass

3.3.1 New Members of the Family Enterobacteriaceae 5
J. MICHAEL JANDA

3.3.2 Phylogenetic Relationships of Bacteria with Special Reference to Endosymbionts and Enteric Species 41
M. PILAR FRANCINO, SCOTT R. SANTOS and HOWARD OCHMAN

3.3.3 The Genus *Escherichia* 60
RODNEY A. WELCH

3.3.4 The Genus *Edwardsiella* 72
SHARON L. ABBOTT and J. MICHAEL JANDA

3.3.5 The Genus *Citrobacter* 90
DIANA BORENSHTEIN and DAVID B. SCHAUER

3.3.6 The Genus *Shigella* 99
YVES GERMANI and PHILIPPE J. SANSONETTI

3.3.7 The Genus *Salmonella* 123
CRAIG D. ELLERMEIER and JAMES M. SLAUCH

3.3.8 The Genus *Klebsiella* 159
SYLVAIN BRISSE, FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.9 The Genus *Enterobacter* 197
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.10 The Genus *Hafnia* 215
MEGAN E. MCBEE and DAVID B. SCHAUER

3.3.11 The Genus *Serratia* 219
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.12 The Genera *Proteus*, *Providencia*, and *Morganella* 245
JIM MANOS and ROBERT BELAS

3.3.13 *Y. enterocolitica* and *Y. pseudotuberculosis* 270
ELISABETH CARNIEL, INGO AUTENRIETH, GUY CORNELIS, HIROSHI FUKUSHIMA, FRANÇOISE GUINET, RALPH ISBERG, JEANNETTE PHAM, MICHAEL PRENTICE, MICHEL SIMONET, MIKAEL SKURNIK and GEORGES WAUTERS

3.3.14 *Yersinia pestis* and Bubonic Plague 399
ROBERT BRUBAKER

3.3.15 *Erwinia* and Related Genera 443
CLARENCE I. KADO

3.3.16 The Genera *Photorhabdus* and *Xenorhabdus* 451
NOEL BOEMARE and RAYMOND AKHURST

3.3.17 The Family Vibrionaceae 495
J. J. FARMER, III

3.3.18 The Genera *Vibrio* and *Photobacterium* 508
J. J. FARMER, III and F. W. HICKMAN-BRENNER

3.3.19 The Genera *Aeromonas* and *Plesiomonas* 564
J. J. FARMER, III, M. J. ARDUINO and F. W. HICKMAN-BRENNER

3.3.20 The Genus *Alteromonas* and Related Proteobacteria 597
VALERY V. MIKHAILOV, LYUDMILA A. ROMANENKO and ELENA P. IVANOVA

3.3.21 Nonmedical: *Pseudomonas* 646
EDWARD R. B. MOORE, BRIAN J. TINDALL, VITOR A. P. MARTINS DOS SANTOS, DIETMAR H. PIEPER, JUAN-LUIS RAMOS and NORBERTO J. PALLERONI

3.3.22 *Pseudomonas aeruginosa* 704
TIMOTHY L. YAHR and MATTHEW R. PARSEK

3.3.23 Phytopathogenic Pseudomonads and Related Plant-Associated Pseudomonads 714
MILTON N. SCHROTH, DONALD C. HILDEBRAND and NICKOLAS PANOPOULOS

3.3.24 *Xylophilus* 741
ANNE WILLEMS and MONIQUE GILLIS

3.3.25 The Genus *Acinetobacter* 746
KEVIN TOWNER

3.3.26 The Family Azotobacteraceae 759
JAN HENDRICK BECKING

3.3.27 The Genera *Beggiatoa* and *Thioploca* 784
ANDREAS TESKE and DOUGLAS C. NELSON

3.3.28 The Family Halomonadaceae 811
DAVID R. ARAHAL and ANTONIO VENTOSA

3.3.29 The Genus *Deleya* 836
KAREL KERSTERS

3.3.30 The Genus *Frateuria* 844
JEAN SWINGS

3.3.31 The Chromatiaceae 846
JOHANNES F. IMHOFF

3.3.32 The Family Ectothiorhodospiraceae 874
JOHANNES F. IMHOFF

3.3.33 *Oceanospirillum* and Related Genera 887
JOSÉ M. GONZÁLEZ and WILLIAM B. WHITMAN

3.3.34 *Serpens flexibilis*: An Unusually Flexible Bacterium 916
ROBERT B. HESPELL

3.3.35 The Genus *Psychrobacter* 920
JOHN P. BOWMAN

3.3.36 The Genus *Leucothrix* 931
THOMAS D. BROCK

3.3.37 The Genus *Lysobacter* 939
HANS REICHENBACH

3.3.38 The Genus *Moraxella* 958
JOHN P. HAYS

3.3.39 *Legionella* Species and Legionnaire's Disease 988
PAUL H. EDELSTEIN and NICHOLAS P. CIANCIOTTO

3.3.40 The Genus *Haemophilus* 1034
DORAN L. FINK and JOSEPH W. ST. GEME, III

3.3.41 The Genus *Pasteurella* 1062
HENRIK CHRISTENSEN and MAGNE BISGAARD

3.3.42 The Genus *Cardiobacterium* 1091
SYDNEY M. HARVEY and JAMES R. GREENWOOD

3.3.43 The Genus *Actinobacillus* 1094
JANET I. MACINNES and EDWARD T. LALLY

3.3.44 The Genus *Francisella* 1119
FRANCIS NANO and KAREN ELKINS

3.3.45 Ecophysiology of the Genus *Shewanella* 1133
KENNETH H. NEALSON and JAMES SCOTT

3.3.46 The Genus *Nevskia* 1152
HERIBERT CYPIONKA, HANS-DIETRICH BABENZIEN, FRANK OLIVER GLÖCKNER and RUDOLF AMANN

3.3.47 The Genus *Thiomargarita* 1156
HEIDE N. SCHULZ

Index 1165

Volume 7

3. Proteobacteria

3.4 Delta Subclass

3.4.1 The Genus *Pelobacter* 5
BERNHARD SCHINK

3.4.2 The Genus *Bdellovibrio* 12
EDOUARD JURKEVITCH

3.4.3 The Myxobacteria 31
LAWRENCE J. SHIMKETS, MARTIN DWORKIN and HANS REICHENBACH

3.5. Epsilon Subclass

3.5.1 The Genus *Campylobacter* 119
TRUDY M. WASSENAAR and DIANE G. NEWELL

3.5.2 The Genus *Helicobacter* 139
JAY V. SOLNICK, JANI L. O'ROURKE, PETER VAN DAMME and ADRIAN LEE

3.5.3 The Genus *Wolinella* 178
JÖRG SIMON, ROLAND GROSS, OLIVER KLIMMEK and ACHIM KRÖGER

4. Spirochetes

4.1 Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta* 195
SUSAN LESCHINE, BRUCE J. PASTER and ERCOLE CANALE-PAROLA

4.2 The Genus *Treponema* 211
STEVEN J. NORRIS, BRUCE J. PASTER, ANNETTE MOTER and ULF B. GÖBEL

4.3 The Genus *Borrelia* 235
MELISSA J. CAIMANO

4.4 The Genus *Leptospira* 294
BEN ADLER and SOLLY FAINE

4.5 Termite Gut Spirochetes 318
JOHN A. BREZNAK and JARED R. LEADBETTER

4.6 The Genus *Brachyspira* 330
THADDEUS B. STANTON

5. Chlorobiaceae

5.1 The Family Chlorobiaceae 359
JÖRG OVERMANN

6. Bacteroides and Cytophaga Group

6.1 The Medically Important *Bacteroides* spp. in Health and Disease 381
C. JEFFREY SMITH, EDSON R. ROCHA and BRUCE J. PASTER

6.2 The Genus *Porphyromonas* 428
FRANK C. GIBSON and CAROLINE ATTARDO GENCO

6.3 An Introduction to the Family Flavobacteriaceae 455
JEAN-FRANÇOIS BERNARDET and YASUYOSHI NAKAGAWA

6.4 The Genus *Flavobacterium* 481
JEAN-FRANÇOIS BERNARDET and JOHN P. BOWMAN

6.5 The Genera *Bergeyella* and *Weeksella* 532
CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE

6.6 The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella* 539
BARRY HOLMES

6.7 The Order Cytophagales 549
HANS REICHENBACH

6.8 The Genus *Saprospira* 591
HANS REICHENBACH

6.9 The Genus *Haliscomenobacter* 602
EPPE GERKE MULDER and MARIA H. DEINEMA

6.10 *Sphingomonas* and Related Genera 605
DAVID L. BALKWILL, J. K. FREDRICKSON and M. F. ROMINE

6.11 The Genera *Empedobacter* and Myroides — 630
CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE

6.12 The Genera *Chryseobacterium* and *Elizabethkingia* — 638
JEAN-FRANÇOIS BERNARDET, CELIA J. HUGO and BRITA BRUUN

6.13 The Marine Clade of the Family Flavobacteriaceae: The Genera Aequorivita, Arenibacter, Cellulophaga, Croceibacter, Formosa, Gelidibacter, Gillisia, Maribacter, Mesonia, Muricauda, Polaribacter, Psychroflexus, Psychroserpens, Robiginitalea, Salegentibacter, Tenacibaculum, Ulvibacter, Vitellibacter and Zobellia — 677
JOHN P. BOWMAN

6.14 Capnophilic Bird Pathogens in the Family Flavobacteriaceae: Riemerella, Ornithobacterium and Coenonia — 695
PETER VAN DAMME, H. M. HAFEZ and K. H. HINZ

6.15 The Genus *Capnocytophaga* — 709
E. R. LEADBETTER

6.16 The Genera *Rhodothermus*, *Thermonema*, *Hymenobacter* and *Salinibacter* — 712
AHARON OREN

7. Chlamydia

7.1 The Genus *Chlamydia*—Medical — 741
MURAT V. KALAYOGLU and GERALD I. BYRNE

8. Planctomyces and Related Bacteria

8.1 The Order Planctomycetales, Including the Genera *Planctomyces*, *Pirellula*, *Gemmata and Isosphaera* and the Candidatus Genera *Brocadia*, *Kuenenia* and *Scalindua* — 757
NAOMI WARD, JAMES T. STALEY, JOHN A. FUERST, STEPHEN GIOVANNONI, HEINZ SCHLESNER and ERKO STACKEBRANDT

9. Thermus

9.1 The Genus *Thermus* and Relatives — 797
MILTON S. DA COSTA, FREDERICK A. RAINEY and M. FERNANDA NOBRE

10. Chloroflexaceae and Related Bacteria

10.1 The Family Chloroflexaceae — 815
SATOSHI HANADA and BEVERLY K. PIERSON

10.2 The Genus *Thermoleophilum* — 843
JEROME J. PERRY

10.3 The Genus *Thermomicrobium* — 849
JEROME J. PERRY

10.4 The Genus *Herpetosiphon* 854
NATUSCHKA LEE and HANS REICHENBACH

11. Verrucomicrobium

11.1 The Phylum Verrucomicrobia: A Phylogenetically Heterogeneous Bacterial Group 881
HEINZ SCHLESNER, CHERYL JENKINS and JAMES T. STALEY

12. Thermotogales

12.1 Thermotogales 899
ROBERT HUBER and MICHAEL HANNIG

13. Aquificales

13.1 Aquificales 925
ROBERT HUBER and WOLFGANG EDER

14. Phylogenetically Unaffiliated Bacteria

14.1 Morphologically Conspicuous Sulfur-Oxidizing Eubacteria 941
JAN W. M. LA RIVIÈRE and KARIN SCHMIDT

14.2 The Genus *Propionigenium* 955
BERNHARD SCHINK

14.3 The Genus *Zoogloea* 960
PATRICK R. DUGAN, DAPHNE L. STONER and HARVEY M. PICKRUM

14.4 Large Symbiotic Spirochetes: *Clevelandina*, *Cristispira*, *Diplocalyx*, *Hollandina* and *Pillotina* 971
LYNN MARGULIS and GREGORY HINKLE

14.5 *Streptobacillus moniliformis* 983
JAMES R. GREENWOOD and SYDNEY M. HARVEY

14.6 The Genus *Toxothrix* 986
PETER HIRSCH

14.7 The Genus *Gallionella* 990
HANS H. HANERT

14.8 The Genera *Caulococcus* and *Kusnezovia* 996
JEAN M. SCHMIDT and GEORGI A. ZAVARZIN

14.9 The Genus *Brachyarcus* 998
PETER HIRSCH

14.10 The Genus *Pelosigma* 1001
PETER HIRSCH

14.11 The Genus *Siderocapsa* (and Other Iron- and Maganese-Oxidizing Eubacteria) 1005
HANS H. HANERT

14.12 The Genus *Fusobacterium* 1016
TOR HOFSTAD

14.13 Prokaryotic Symbionts of Amoebae and Flagellates 1028
KWANG W. JEON

CHAPTER 1.1

Planktonic Versus Sessile Life of Prokaryotes

KEVIN C. MARSHALL

Because of the extremely small size of most prokaryotic organisms, the limits on what is meant by the terms planktonic and sessile require definition. According to the *Oxford English Dictionary*, planktonic refers to "drifting or floating organic life found at various depths in the ocean or fresh water." At the micrometer level, a planktonic habitat for prokaryotes can also encompass water films around soil particles, saliva in the mouth, fluids in the intestinal lumen, serum in blood vessels, and urine in the bladder and urinary tract. Sessile, on the other hand, means "immediately attached, without a footstalk." Again, one can extend this definition to include those prokaryotes directly adhering to surfaces, those attaching by means of a holdfast at the end of a prostheca (e.g., *Caulobacter*), those embedded in biofilms developing as a result of extracellular polymer production by bacteria colonizing surfaces, and those colonizing mucus excreted by higher organisms (as in the gastrointestinal tract and the mucigel of plant roots).

Most microbiologists, oriented by their training to the study of pure cultures, regard suspension culture as the normal state for growth of these organisms. This is particularly true for research into the physiology and biochemistry of bacteria, whereby homogeneous suspensions of bacteria are readily harvested and manipulated for experimental purposes. The reality of prokaryotic life in natural habitats is that many organisms spend part or all of their life spans attached to surfaces (Marshall, 1976). However, recently there has been a veritable explosion in research devoted to understanding the behavior of bacteria at surfaces (Beachey, 1980; Bitton and Marshall, 1980; Marshall, 1984; Savage and Fletcher, 1985).

Many questions arise regarding the association of bacteria with surfaces. It is my aim in this chapter to consider the current state of knowledge concerning the following questions: How do prokaryotes adhere to surfaces? Is there a single, all-embracing mechanism or a range of mechanisms of adhesion in different organisms? Are some prokaryotes especially adapted to a sessile existence? Are particular organisms homogeneous in their adhesive characteristics or are they variable in their response to surfaces? Once attached to a surface, do prokaryotes always remain in a sessile state or do they return to the planktonic state at some stage? Do prokaryotes gain any real advantage from being associated with surfaces? Are certain prokaryotes specifically adapted to the colonization of excreted mucous layers? Are sessile bacteria in a different physiological state from planktonic organisms; that is, do prokaryotes exhibit a physiological response to contact with a surface? If they show such responses, what physicochemical factors are responsible for inducing the responses?

Mechanisms of Adhesion to Surfaces

Full details of proposed mechanisms of adhesion of prokaryotes to solid surfaces have been presented elsewhere (Marshall, 1985, 1986a) so only a brief outline will be presented in this paper.

Transport Processes

Water currents induced by temperature and gravity (fluid dynamic forces) provide the major mechanism for the transport of planktonic bacteria over large distances. When bacteria and other particles in flowing water are transported to the region of the boundary layer near a solid surface, a lift force directs the bacteria toward the surface where fluid frictional forces slow them down (Characklis, 1981a) and deposit them in the vicinity of the surface.

Sedimentation is of significance only when bacteria are aggregated together or are attached to particles. Individual bacteria behave essentially as colloidal particles (Marshall, 1976) and tend to remain in suspension. Nutrient gradients may become established across the boundary layer near some surfaces and these may provide opportunities for chemotactic responses towards the surfaces by motile bacteria. Brownian motion can account for random movement of very small bacteria within the quiescent water of a boundary layer near a surface (Marshall, 1976).

Long-Range Forces

Bacteria in the vicinity of a solid-liquid interface frequently show an instantaneous but reversible attraction to the interface (Marshall et al., 1971a), and an attempt has been made to explain this reversible attraction by means of the colloid stability (DLVO named for the originators—Derjaguin, Landau, Verwey, and Overbeek) theory. That this attraction is reversible is shown by the fact that the bacteria can be removed from the solid surface by gentle shearing forces. The DLVO theory accounts, at least in part, for the attraction of a negatively charged bacterium to a negatively charged substratum surface at the "secondary attraction minimum" resulting from the interaction between London-van der Waals attraction forces and electrical repulsion forces in the overlapping double layers of cations surrounding the negatively charged surfaces. In terms of the DLVO theory, a bacterial cell would be held at a distance of some 10 nm from the surface by repulsion forces.

Problems in applying DLVO theory to biological systems have been raised by Pethica (1980) and Rutter and Vincent (1980), especially when the complexity of the bacterial cell envelope and the extracellular components are taken into account. However, Busscher and Weerkamp (1987) have argued strongly in favor of such long-range forces in the initial attraction of bacteria to surfaces.

Short-Range Forces

Certain bacteria irreversibly attach to surfaces very rapidly (Fletcher, 1980), whereas other bacteria require a significant time of exposure to the surface before becoming firmly attached (Marshall et al., 1971a). Irreversible attraction is shown by the fact that the bacteria cannot be removed by moderate shear forces. What is the mechanism of this firm adhesion of bacteria to surfaces? Early observations indicated that polymer bridging by extracellular components of cells to the substratum surface (Fig. 1) resulted in firm adhesion (Marshall and Cruickshank, 1973; Fletcher and Floodgate, 1973), and these observations have been confirmed for many systems (Corpe, 1980; Costerton et al., 1981). These extracellular polymers have a small radius of curvature and can overcome any repulsion barrier near a surface and, thus, can bind the cell to the surface using a variety of short-range forces. These forces include: 1) chemical bonds (electrostatic, covalent, and hydrogen); 2) dipole interactions (dipole-dipole, dipole-induced dipole, and ion-dipole); and 3) hydrophobic interactions (Rutter and Vincent, 1980).

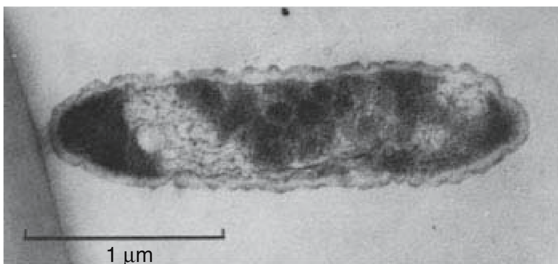

Fig. 1. Perpendicular adhesion of a marine bacterium to a solid plastic surface. The extracellular polymeric substances bridging between the cell and the surface are present only at the adhesive pole of the cell. (Courtesy of R. H. Cruickshank.)

Adhesion to surfaces in nature is generally considered to be *nonspecific*. That is, the bacteria adhere to a wide variety of different inanimate, and possibly animate, surfaces with varying degrees of adhesive strength. Bridging polymers involved in most cases of nonspecific adhesion are either extracellular polysaccharides, proteins, or glycoproteins. The precise mechanisms whereby such polymers interact with a range of substratum surfaces is not known, but it almost certainly involves various combinations of the short-range forces listed above.

Specific adhesion involves lectin-receptor-type mechanisms, in which a proteinaceous substance (lectin) on the bacterial surface reacts with a complementary carbohydrate receptor on another cell type (Switalski et al., 1989). The best-described examples of specific adhesion involve the attachment of pathogenic bacteria to the host cell surfaces they infect. However, specific attachment of bacteria to the heterocysts of the cyanobacterium *Anabaena* has been described (Lupton and Marshall, 1981).

Thermodynamic Approach to Bacterial Adhesion

Various workers have attempted to relate the extent of bacterial adhesion to the variation in surface free energy of the substratum, with very variable results (Dexter et al., 1975; Fletcher and Loeb, 1979). More detailed studies revealed that, in addition to the substratum-surface free energy, it was necessary to consider the bacterium-surface free energy and the surface tension of the liquid (Absolom et al., 1983; Pringle and Fletcher, 1983). The change in free energy associated with bacterial adhesion (ΔF_{adh}) is given by:

$$\Delta F_{adh} = \gamma_{BS} - \gamma_{BL} - \gamma_{SL}$$

where γ_{BS}, γ_{BL}, and γ_{SL} are the bacterium-substratum, bacterium-liquid, and substratum-liquid interfacial tensions, respectively. Bacterial adhesion is favored if the process results in a free energy decrease. In general, Absolom et al. (1983) found good agreement between bacterial adhesion to a variety of substrata and the adhe-

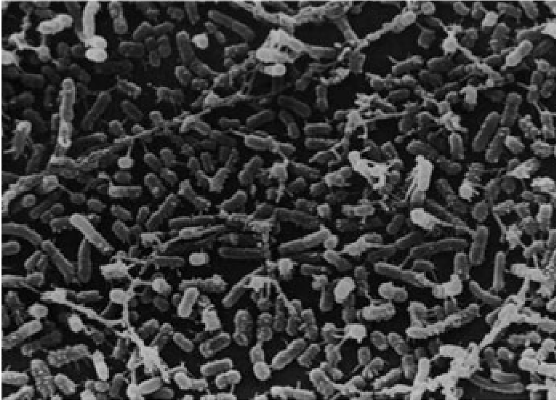

Fig. 2. Colonization of a glass surface, rendered hydrophobic by treatment with silane, by a marine bacterium after 16 h exposure. The condensed extracellular polymeric substances are clearly visible, as a result of drying on a cold stage. (Courtesy of T. Neu.)

sion behavior predicted by the thermodynamic model.

Detachment of Bacteria from Surfaces

Not all cells remain adherent at the surface. Mechanisms of detachment include fluid shear forces (Marshall et al., 1971a), changes in surface free energy of the substratum (Busscher et al., 1986) or the organism (Rosenberg et al., 1983; Fattom and Shilo, 1984), reproductive mechanisms (Power and Marshall, 1988), and enzymatic degradation of adhesive structures. In most cases, however, the majority of adhering bacteria remain at the surface, where they are capable of growth, reproduction (Fig. 2) (Lawrence and Caldwell, 1987; Power and Marshall, 1988; Szewzyk and Schink, 1988), and even biofilm formation. A *biofilm* consists of cells immobilized at a substratum surface and frequently embedded in an organic polymer matrix of microbial origin (Characklis and Marshall, 1990). Other practical aspects of bacterial detachment from surfaces will be considered in later sections.

Occurrence of Sessile Prokaryotes

Microbial Succession at Surfaces

Early reports indicated that very small bacteria were the primary colonizers of surfaces immersed in seawater and were succeeded by conventional rod-shaped and, somewhat later, by prosthecate bacteria (Marshall et al., 1971b). It was realized that the initial colonizing organisms were starvation-survival forms (Morita, 1982) that eventually produced cellular growth at surfaces and thus gave rise to rod-shaped forms (Dawson et al., 1981; Power and Marshall, 1988). Early colonizing organisms tend to be Gram-negative bacteria, particularly species of *Pseudomonas*, *Flavobacterium*, and *Achromobacter*, followed later by prosthecate bacteria (Corpe, 1973). Gram-positive bacteria have rarely been recorded on surfaces in aquatic habitats, although there have been recent reports of significant numbers of Gram-positive bacteria on surfaces associated with groundwater (Kölbel-Boelke and Hirsch, 1989) and on the seagrass *Zostera capricorni* (Angles, 1988). The numbers, overall biomass, and diversity of attached microorganisms increased with increasing time of immersion of a surface (Jordon and Staley, 1976). Scanning electron microscopic studies also have revealed a progression from rod-shaped primary colonizers, to prosthecate forms, and then to a complex biofilm whose composition varies with the nature of the exposed surface and with time (Gerchakov et al., 1977; Marszalek et al., 1979; Dempsey, 1981). Even in illuminated waters, microalgae are not primary colonizers of surfaces (Marshall et al., 1971b; Corpe, 1973; Jordon and Staley, 1976), but extensive development of diatoms, fungi, and protozoa has been observed following bacterial biofilm formation (Gerchakov et al., 1977; Marszalek et al., 1979).

Biologically inert substrata, such as stainless steel or glass, were colonized rapidly following immersion in seawater and produced a complex, two-tiered, microfouling layer (Gerchakov et al., 1977; Marszalek et al., 1979; Dempsey, 1981). The first stage of colonization consisted mainly of bacteria followed by nonmotile diatoms and fungi, whereas the second stage, which appeared after a 5-week exposure, consisted of large, colonial, motile diatoms, other diatoms, flagellates, and ciliates. On the other hand inhibitory substrata, such as copper-nickel alloys or brass, were slowly fouled by bacteria capable of secreting mucoid extracellular polymeric substances (EPS). Such substrata eventually developed a much less diverse biofilm community than inert ones.

Sequential establishment of sessile populations also occurs in freshwater streams (Geesey et al., 1977, 1978) and lakes (Paerl, 1980); in soils where the complexity and variability of the solid matrix makes adequate study difficult (Marshall, 1975; Stotzky, 1986); in the oral cavity (Bowden et al., 1979; Newman, 1980); in the gastrointestinal tract, where the normal sessile biota plays an important role in preventing colonization by bacterial pathogens (Lee, 1980, 1985; Savage, 1980, 1984); and in the colonization of prosthetic devices employed in human patients (Gristina, 1987).

Biofilm Formation

The combined effects of continuous adhesion and both growth and reproduction at surfaces

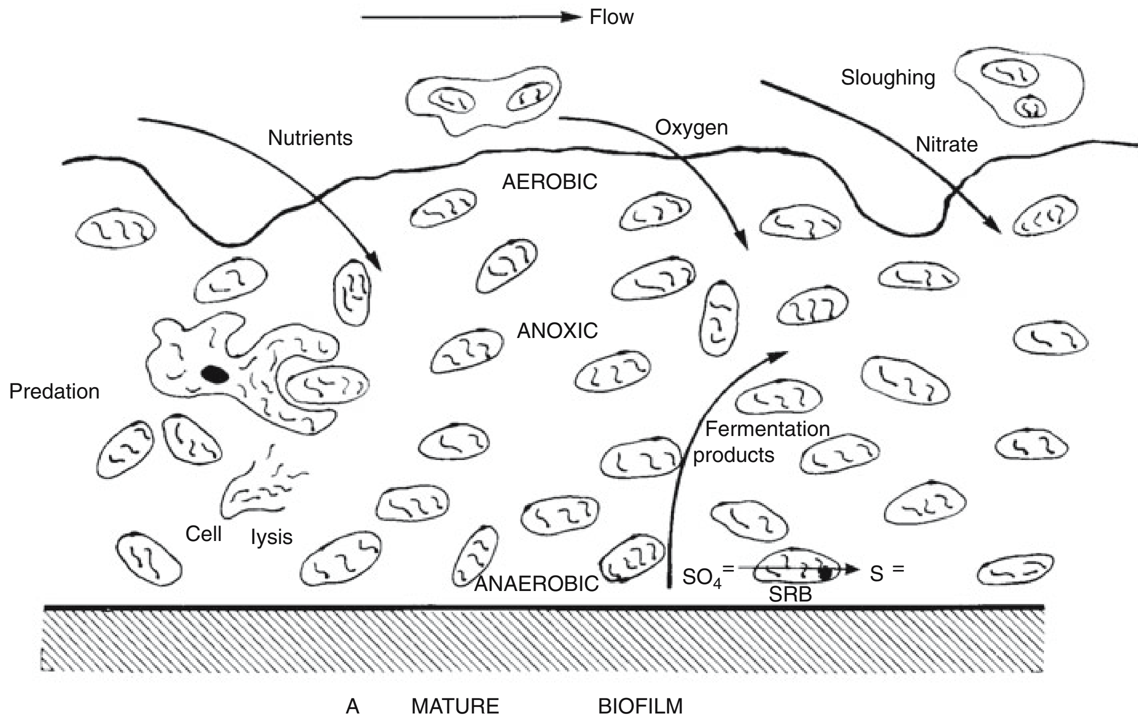

Fig. 3. Diagram of a section through a well-developed biofilm, showing bacteria embedded in an EPS matrix and the direction of decreasing gradients (arrows) of nutrients, oxygen, nitrate, and fermentation products. A predatory amoeba within the biofilm is shown at the left. SRB = sulfate reducing bacterium.

eventually gives rise to a macroscopic slime, or biofilm (Fig. 3).

Biofilms are of considerable nuisance on artificial structures, such as ship hulls, hydroelectric pipelines, water reticulation systems, heat exchangers, oil rigs, and floating oceanographic equipment, but find useful applications in wastewater trickling-filter plants and other fixed-film systems, as well as in fluidized-bed fermenters.

The development of a biofilm on a surface subjected to high shear rates may be described by a sigmoid-shaped curve, where the phase of biomass increase is a function of growth of attached bacteria along with further accretion of cells to the developing biofilm. The plateau of the curve represents the point at which the film penetrates the boundary (or viscous) sublayer (Characklis, 1981b). The final biofilm thickness is dependent on the magnitude of the fluid shear rate. Any protrusion of film irregularities above the viscous sublayer creates turbulence in the water flowing past the biofilm surface leading to frictional flow resistance.

The colonization of mucous excreted by higher organisms (e.g.) the mucous blanket of the animal gastrointestinal tract (Lee, 1985); and the mucigel of plant roots (Rovira et al., 1979), leads to a partial or complete immobilization of cells in the mucous adjacent to the organism's tissue. The final product in this instance bears a superficial resemblance to a biofilm but its mode of origin is entirely different. Certain organisms, particularly spiral bacteria (Phillips and Lee, 1983), appear to have a selective advantage in penetrating and colonizing this viscous habitat.

Methods of Studying Sessile Prokaryotes

Because of the inherent difficulty in directly observing the behavior of microorganisms at surfaces, a wide range of semidirect and indirect techniques have been employed to study adhesion, growth, biofilm development, and detachment from surfaces. Because of the different techniques needed for different surfaces and ecosystems, no attempt will be made here to give detailed instructions for the many techniques available but, rather, references to the descriptions of the original techniques will be provided.

Microscopy

Many of the applications of various forms of microscopy in the study of sessile bacteria have been reviewed (Marshall, 1986b). Most studies involve the use of transmitted or incident light microscopy, or of transmission (TEM) or scanning (SEM) electron microscopy. For transmit-

ted light microscopy, the use of transparent substrata (glass, mica, cellophane, polystyrene, etc.) as test surfaces is essential. Epifluorescence microscopy is necessary for translucent and opaque substrata (Zvyagintsev, 1962; Hobbie et al., 1977). Sessile bacteria may be observed by washing the exposed substratum to remove debris and loosely attached cells and then either staining, with conventional bacteriological stains or fluorescent dyes, or viewing directly with phase-contrast optics. The advantages and disadvantages of such techniques have been presented by Marshall (1986b).

Novel techniques involving light microscopy include the use of submerged microscopy (Staley, 1971), capillary microscopy (Perfil'ev and Gabe, 1969), computer-enhanced image analysis (Caldwell and Germida, 1985), interference reflection microscopy (Fletcher, 1988), dialysis microculture (Duxbury, 1977), marked slides (Bott and Brock, 1970), soil films (Harris, 1972), transparent sections in tubular reactors to study biofilm development (Characklis, 1980), and light section microscopy to measure biofilm thickness (Loeb, 1980).

Other Methods of Study

During the early stages of colonization of surfaces, and particularly if glass, plastic, metal, or wooden slides are immersed in an aqueous phase, bacteria adhering firmly to the surface may be cultured by washing the slides or coupons to remove loosely adhering organisms and then smearing the slide or coupon over the surface of a suitable agar plate (Marshall et al., 1971a). If a distinct biofilm has formed on a surface, the biofilm may be scraped from the surface, suspended in a suitable diluent, homogenized, a dilution series prepared, and aliquots of each dilution plated on an appropriate agar medium. Such methods suffer from the normal problems of selectiveness of the medium employed, and it is likely that some colonizing species (e.g., *Caulobacter*, *Hyphomicrobium*) are never obtained by such techniques. Often the use of special selective media is required in order to isolate particular organisms that may be obvious microscopically. In some cases, it may be necessary to resort to micromanipulation techniques to separate slow-growing or sensitive organisms from more aggressive or resistant species. The simple micromanipulation system devised by Skerman (1968) is especially recommended for this purpose.

A variety of other methods have been adapted to estimate numbers of microorganisms or the total biomass found in a sessile state at surfaces. These include: measurement of radioactivity following the uptake of labeled substrates (Brock, 1971; Lupton and Marshall, 1981), autoradiography (Fletcher, 1979; Bright and Fletcher, 1983), ATP determinations for total biomass (La Motta, 1976), muramic acid determinations for bacterial biomass (Moriarty, 1977), bacterial growth rates using thymidine incorporation (Moriarty, 1986), and determination of bacterial types at surfaces by phospholipid fatty acid signature analysis (Guckert et al., 1985) and by 16S rRNA sequence analysis (Pace et al., 1986; Weller and Ward, 1989). Other techniques that may prove valuable in analyzing biofilm composition and function include the use of Fourier transform infrared spectrophotometry (Nichols et al., 1985) and the use of microelectrodes to measure various gradients with depth of biofilms (Revsbech and Jørgensen, 1986) (Fig. 3).

Adaptation to the Sessile State

Are certain prokaryotes uniquely adapted to a sessile form of life? The answer to this question is not simple because of the very wide range of bacteria that can be found on various surfaces. Several examples of different modes of sessile behavior will be considered in order to illustrate the complexity that may be encountered in natural habitats.

Although many bacteria are capable of adhering to a wide variety of surfaces (nonspecific adhesion), the extent of adhesion on the various surfaces varies considerably. Some bacteria adhere best to hydrophobic surfaces (Fletcher and Loeb, 1979), some adhere best to hydrophilic surfaces (Dexter et al., 1975), whereas others adhere best to surfaces of more intermediate surface-free-energy values (Pringle and Fletcher, 1983). The conditions under which the bacteria are grown also modify the adhesive ability of various bacteria on a range of different surfaces (McEldowney and Fletcher, 1986).

Many bacteria that require relatively high nutrient concentrations (copiotrophic bacteria) exist planktonically in oligotrophic waters in a state of starvation. These starvation-survival forms are characterized by a significant reduction in size and by lower endogenous respiration and heat output, and are often more adhesive than actively growing cells (Morita, 1982; Dawson et al., 1981; Humphrey and Marshall, 1984). Adhesion to surfaces by these starvation-survival forms provides access to nutrients accumulated at the surfaces. The starved bacteria are able to scavenge these nutrients and metabolize them (Kefford et al. 1982; Kjelleberg et al., 1983), thereby leading to cellular growth and reproduction (Kjelleberg et al., 1982; Power and Marshall, 1988; Szewzyk and Schink, 1988). In

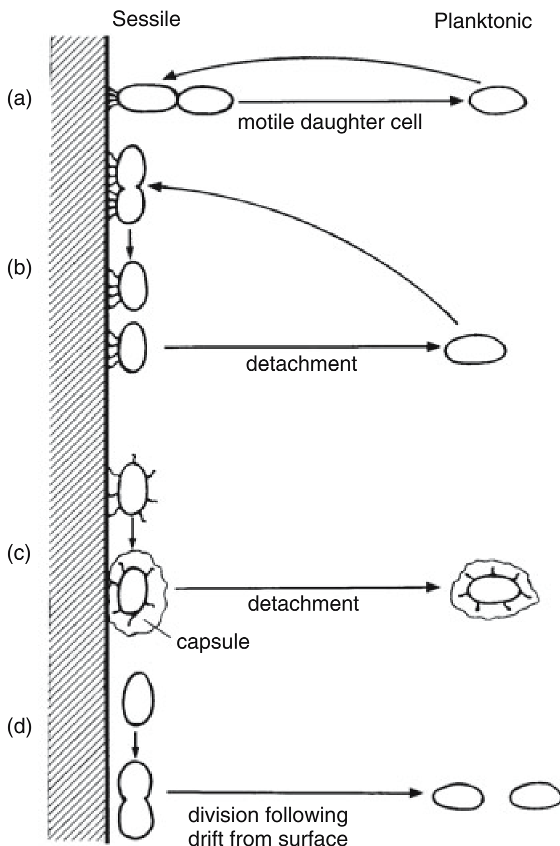

Fig. 4. Four mechanisms for alternating between the planktonic and sessile states: (a) a perpendicularly attached mother cell releases a motile daughter cell, as in *Vibrio* sp. DWI; (b) division of a cell adhering in a face-to-face manner, and release of a cell on utilization of a bound hydrophobic substrate, as in *Pseudomonas* sp. JD8; (c) detachment of a fimbrial-attached organism following the production of a hydrophilic capsule, as in *Acinetobacter calcoaceticus*; and (d) growth of a reversibly adhering organism at a surface and completion of the division phase following drift of the cell from the surface, as in *Vibrio* sp. MH3.

many marine environments, it appears that such small, starved bacteria are the primary colonizers of freshly immersed surfaces (Marshall et al., 1971b).

Some copiotrophic bacteria seem unable to adhere firmly to surfaces, yet, under oligotrophic conditions, any starvation-survival forms approaching a surface are able to metabolize surface-bound substrates (Hermansson and Marshall, 1985) and exhibit both cellular growth and reproduction (Power and Marshall, 1988). Thus, nonadhesive bacteria do exist in the planktonic state but it is still possible for such organisms to benefit from association with surfaces.

A particularly effective adaptation to the sessile state is the ability of many bacteria in nature to adhere in an orientation perpendicular to the surface (Fig. 4a; see also Fig. 1). Such prokaryotes appear to have either a specialized holdfast (*Caulobacter*) or a particularly adhesive portion at one pole of the cell (*Hyphomicrobium*, *Flexibacter*, and *Leucothrix*). Such an orientation allows a very efficient contact both with the solid and the aqueous phases, as well as providing an effective means of releasing daughter cells into the planktonic state. An examination of this mode of orientation at solid surfaces revealed that both *Hyphomicrobium* and *Flexibacter* exhibited the same perpendicular orientation at air-water and oil-water interfaces (Marshall and Cruickshank, 1973). It was postulated that the pole of the cell approaching the interface was hydrophobic while the bulk of the cell was hydrophilic, and the hydrophobic pole was rejected from the water phase and aligned at the nonaqueous phase, regardless of whether it was solid, air, or oil (Marshall and Cruickshank, 1973).

Some bacteria are adapted to growth at surfaces, yet possess various mechanisms to ensure that some cells return to the planktonic state. For instance, cells of the marine species *Vibrio* DW1 adhered to a surface in a perpendicular manner (Fig. 4a) and, following cellular growth of the starved cells to normal size, motile daughter cells were released at regular intervals (approximately 57 min) from the attached mother cells (Kjelleberg et al., 1982). Cells of the marine *Pseudomonas* sp. JD8 adhered in a face-to-face manner (Fig. 4b) and, following cellular growth and one division cycle the daughter cells slowly (about 0.15 μg/min) began to migrate away from each other while still adhering to the surface. After subsequent division cycles, similar migration patterns were observed but, eventually, some of the daughter cells detached from the surface (Power and Marshall, 1988). This slow migration was explained in terms of the cells being initially irreversibly attached to the hydrophobic stearic-acid-covered surface but, upon utilization of the fatty acid in the microenvironment around the cell, the cells became reversibly attached to the underlying hydrophilic substratum (Busscher et al., 1986) and were capable of some form of movement. As soon as the cells moved a short distance, however, they encountered more hydrophobic stearic acid and adhered irreversibly again until that substrate was utilized, and the cycle was repeated. When the bound substrate was essentially exhausted, cells detached from the underlying hydrophilic surface (Power and Marshall, 1988). Even the nonadhesive *Vibrio* MH3 (Fig. 4d) was able to grow from the small starvation-survival form to normal size and then begin the division cycle when exposed to surface-bound stearic acid (Power and Marshall, 1988). The dividing cells drifted away from the surface and completed the division cycle in the planktonic state.

An interesting adaptation ensuring reversibility of the sessile state has been described in *Acinetobacter calcoaceticus*, which adheres

reversibly to epithelial cells and oil by means of thin fimbriae (Fig. 4c). The adhesion of this bacterium is reversed as a result of the production of an excessive amount of extracellular emulsan that surrounds and thus masks the adhesive properties of the fimbriae (Rosenberg et al., 1983). Another example of reversible adhesion has been described in the cyanobacterium *Phormidium*, which in its sessile state possesses a hydrophobic surface but under certain conditions produces a hydrophilic capsule, thus allowing the organism to revert to the planktonic state (Fattom and Shilo, 1984).

These studies emphasize the ability of some prokaryotes to take advantage of substrates adsorbed to surfaces, as well as revealing a variety of strategies for releasing daughter cells from the sessile to the planktonic state. As pointed out by Pedros-Alio and Brock (1983), a simple division into sessile and planktonic forms is overly simplistic. Different bacteria have a variety of mechanisms to attach at surfaces but they also possess a range of mechanisms for detachment in order to return to a planktonic existence.

Advantages of the Sessile State

Nutrient Availability

When a clean surface is immersed into a natural habitat, a molecular film rapidly forms on the surface as a result of adsorption of macromolecules and smaller hydrophobic molecules. This film serves to "condition" the surface, causing alterations in surface charge (Neihof and Loeb, 1974) and surface free energy (Baier, 1980). One of the most obvious advantages of the sessile state is the increased probability of access to nutrients accumulating at surfaces, particularly in flowing, oligotrophic conditions. ZoBell (1943) was the first to suggest that complex macromolecules adsorbed at surfaces would serve as concentrated sources of nutrients for organisms adhering at those surfaces. It was clearly demonstrated by Jannasch (1958) that the beneficial effect of surfaces in the presence of added complex nutrients only occurred at very low nutrient concentrations, where the level of nutrient in the aqueous phase was negligible and the nutrients had adsorbed to the surfaces.

Many investigators comparing the activities of bacteria in the sessile and planktonic states have employed simple soluble substrates such as glucose and amino acids (Azam and Hodson, 1977; Berman, 1975; Berman and Stiller, 1977; Campbell and Baker, 1978; Ferguson and Palumbo, 1979; Fletcher, 1979, 1986; Hanson and Wiebe, 1977; Kirchman and Mitchell, 1982; Pedros-Alio and Brock, 1983; Riemann, 1978). In natural habitats, and particularly in low nutrient situations, such soluble substrates would be rapidly utilized by planktonic bacteria and would rarely encounter a substratum surface. Similarily, many of these low-molecular-weight substrates cannot adsorb to surfaces and would not be expected to concentrate these. If the substrates do adsorb, their availability for bacterial utilization is often reduced substantially (Gordon and Milero, 1985). In many field studies, filtration has been used to separate sessile and attached bacteria, but filtration can lead to problems in that: 1) shear forces involved in filtration are sufficient to remove some reversibly attached bacteria that are feeding at surfaces (Hermansson and Marshall, 1985); and 2) such reversibly attached bacteria may have fed, grown, and reproduced at the surface and then returned to the aqueous phase at some time prior to filtration (Power and Marshall, 1988).

A more logical method of studying the activity of bacteria at surfaces is to provide substrates such as macromolecules or lower molecular weight hydrophobic molecules that are likely to adsorb at surfaces. Using surface-bound stearic acid as a model substrate, Kefford et al. (1982) and Kjelleberg et al. (1983) clearly demonstrated that a range of bacteria were capable of scavenging ^{14}C-labeled stearic acid from a surface. In particular, a reversibly adhering *Leptospira* species rapidly utilized the labeled fatty acid, and ^{14}C-labeled bacteria were readily recovered from the planktonic state. A similar result was obtained with the nonadhesive marine *Vibrio* MH3 (Hermansson and Marshall, 1985), a result that emphasizes the fact that bacteria do not need to firmly adhere to surfaces in order to utilize substrates adsorbed at the surface. Subsequent studies have shown that starved bacteria adhering to surfaces where nutrients have accumulated not only metabolize the nutrients but are capable of cellular growth and reproduction (Kjelleberg et al., 1982; Power and Marshall, 1988; see also Fig. 4 a–d).

Protection from Harmful Factors

Sessile bacteria appear to be more resistant to the inhibitory effects of antibacterial agents, such as antibiotics, chlorine, and heavy metals (Costerton et al., 1981). In relatively thick biofilms, this apparent resistance may be the result of the reaction of the agents with the outer layers of cells and, in the case of chlorine and heavy metals, reaction with the extracellular polymer that makes up the matrix of the biofilm. There is increasing evidence, however, that bacteria attached to surfaces are inherently more resistant to certain antibacterial agents than are planktonic forms, but the mechanism of this increased resistance is not understood. Bacteria below the biofilm-water interface are also pro-

tected from external grazing by protozoa and metazoa. In addition, association of prokaryotes with various sizes of particles or colloidal clays can provide a degree of protection from parasitism by bacteriophage and *Bdellovibrio*, as well as from predation by amoebae and the lytic effects of certain gliding bacteria (Roper and Marshall, 1974, 1978).

Disadvantages of the Sessile State

Sedimentation

Although bacteria attached to particle surfaces may gain an advantage by utilization of adsorbed nutrients or by the dissolution of organic particles, such bacteria would sink to the sediments and would be unable to colonize new particle surfaces if mechanisms did not exist for their release or the release of daughter cells from the particle surfaces. As seen above, such mechanisms are common among sessile forms of bacteria (Fig. 4). It is precisely these phenomena of bacterial attachment, nutrient utilization, and recycling, and detachment that are continually occurring within "marine snow" in the pelagic zone of oceans (Alldredge, 1989).

Grazing

Zooplankton are capable of ingesting planktonic bacteria but detritus feeders have been found to consume the bacteria growing on detritus particles rather than ingest the particles themselves (Fenchel and Jørgensen, 1977). Fenchel (1986) reported that the flagellate *Bodo* sp. spends about 45 sec ingesting a bacterium from a surface, during which time the flagellate does not move. *Bodo* normally slides over the substratum at a velocity of 3.5 µm/sec and only detects and ingests bacteria lying in a 1.0 µm wide band along the path of the flagellate. Zooplankton grazing on biofilm surfaces, however, may play a useful role in maintaining the bacteria near the biofilm surface in an active state of growth. Amoebae have been observed grazing well within the matrix of a biofilm (Mack et al., 1975) (see Fig. 3).

Gradients

Decreasing gradients of nutrient and oxygen availability develop with increasing depth of a biofilm (Fig. 3) (Christensen and Characklis, 1990). Such gradients form as a result of diffusional resistance within the biofilm and of utilization of the nutrients and oxygen by microorganisms within the biofilm. Consequently, aerobic organisms near the biofilm-water-interface tend to be actively growing and create anoxic conditions at greater depths within the biofilm. If nitrate is present then some microorganisms at depth in the biofilm are capable of using the nitrate as an alternative to oxygen as an electron acceptor. Other aerobic organisms tend to be inactive, or even lyse, within the anoxic zone, whereas strict anaerobes and fermentative bacteria may be active in such sites. In biofilms developed on metallic surfaces, the activity of sulfate reducing bacteria (SRB) have been implicated in corrosion processes (Little et al., 1990).

Physiological Responses by Bacteria at Surfaces

Observed Responses

Probably the most obvious physiological response observed in bacteria associated with surfaces is cellular growth and, in some instances, reproduction (Jannasch, 1958; Bott and Brock, 1970; Kjelleberg et al., 1982; Pedros-Alio and Brock, 1983; Power and Marshall, 1988). Another possible response in bacteria to the physical presence of a surface is the time-dependent appearance of firm adhesion, which may indicate the induction of suitable bridging polymer production by the surface-associated bacteria (Marshall et al., 1971a).

The best documented response to a surface is the change observed in certain marine vibrios from a single, sheathed, polar flagellum in the planktonic stage to the production of multiple, lateral flagella when plated on an agar surface (Golten and Scheffers, 1975; de Boer et al., 1975; Belas and Colwell, 1982). Other reported responses include a reduction in size and an increase in endogenous respiration and in heat output by starving marine bacteria at interfaces in the absence of exogenous nutrients (Kjelleberg et al., 1982, 1983; Humphrey et al., 1983; Humphrey and Marshall, 1984). Also, attached bacteria show an increase in resistance to antibacterial substances (Costerton et al., 1981).

Control of Responses

Silverman et al. (1984) have described two possible control mechanisms regulating bacterial responses at surfaces, namely, "responsive" and "variable" control (Fig. 5). Essentially, responsive control involves information processing, whereby the bacterium senses some environmental signal and responds accordingly. In the case of *Vibrio parahaemolyticus*, the response to a shift from an aqueous medium to an agar surface is to deregulate lateral flagella production

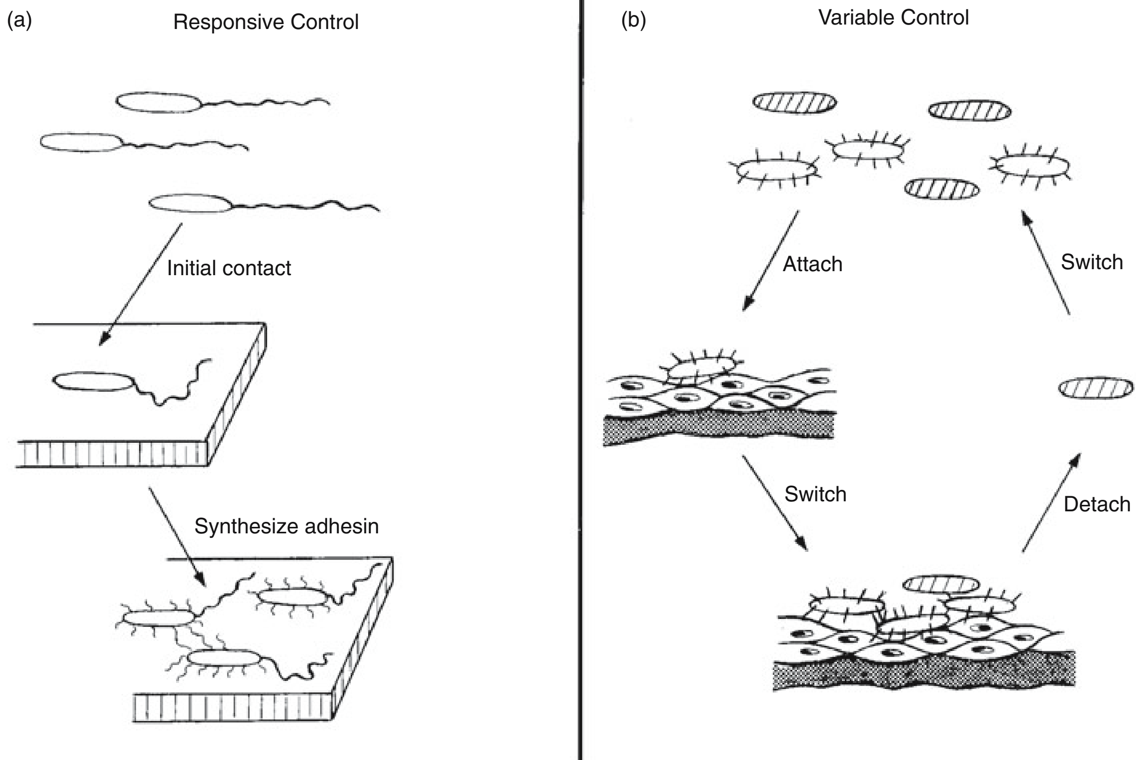

Fig. 5. Strategies for responsive and for variable control of adhesive substance expression. (a) Responsive control, as shown by a shift from polar to lateral flagella in *Vibrio parahaemolyticus*. (b) Variable control, in which a fraction of the cells are preadapted to the fimbriated state, and attach to epithelial cells. Nonfimbriated variants detach and return to the aqueous phase. (From Silverman et al., 1984.)

(Fig. 5a). In the case of variable control, a fraction of the cells are preadapted, for example, to adhere to a particular surface, and individuals within the population are constantly switching among a variety of forms. For instance, a portion of the population may produce fimbriae and attach to epithelial cells (Fig. 5b). Nonadhesive variants of these cells arise and detach to return to the aqueous phase. Such phase variation in certain salmonellae results from a rearrangement of the DNA structure involving the inversion of part of the molecule containing a transcriptional control element.

Physicochemical Triggering of Responses

Using *lux* gene fusion mutants, Belas et al. (1986) studied the responsive control of lateral gene expression when *Vibrio parahaemolyticus* was transferred from liquid to agar medium. They were able to show conclusively that the physicochemical factor triggering lateral flagella production was increased viscosity. Whether this surface effect was entirely the result of viscosity or whether it was also related to a reduction in water activity has not been tested.

Another important factor at surfaces that would result in metabolic, as well as cellular growth and reproduction responses, is the adsorption of organic nutrients at surfaces (Kefford et al., 1982; Kjelleberg et al., 1981; Hermansson and Marshall, 1985; Power and Marshall, 1988). Enhanced phosphorus uptake by attached bacteria has also been reported by Paerl and Merkel (1982). A further situation involving possible adsorption phenomena at surfaces is the finding by Humphrey and Marshall (1984) that changes in size, endogenous respiration, and heat output in starving marine bacteria at surfaces could be reproduced in the presence of surfactants and even when no surface was present. Many bacteria in nature produce surfactants, and these surfactants could adsorb to surfaces where they might trigger various responses in other bacteria adhering to the surfaces.

Other possible explanations for the triggering of physiological responses in bacteria at surfaces include alterations in the proton motive force on the face of the cell nearest the surface (Ellwood et al., 1982) and possible cell deformation near a surface (Fletcher, 1984).

Conclusions

Although the sessile state is very common in bacteria in natural habitats, it is not a state limited to particular groups of organisms. All sessile bacteria are derived from the planktonic state and, in addition to active growth and metabolism at surfaces, these sessile organisms have also evolved a variety of methods to ensure that representatives of the population can return to the planktonic state. Such mechanisms include direct release of daughter cells, changes in the hydrophobicity of the sessile cells or of the substratum surface, exclusively reversible adhesion (subject to removal by gentle shear forces), and, possibly, enzymatic degradation of adhesive bridging polymers.

Planktonic bacteria, on the other hand, possess a wide range of mechanisms whereby they can adhere to a variety of surfaces. In some instances these bacteria possess preformed adhesive polymers, whereas in other cases the bacteria appear to produce appropriate polymers following association with the surface. There is increasing evidence for responsive control of a number of physiological functions evident only at surfaces, but more detailed investigations are required to elucidate the nature of these physicochemical triggering mechanisms.

CHAPTER 1.2

Bacterial Adhesion

ITZHAK OFEK, NATHAN SHARON AND SOMAN N. ABRAHAM

Introduction

It is now well established that to initiate infection at a particular site bacteria must adhere to host cells or to layers covering these cells (Ofek and Doyle, 1994f). The mucosal surfaces of the respiratory, gastrointestinal and urogenital tracts are the most common portals by which infectious bacteria enter the deeper tissues of a mammalian host. Thus, adhesion to the epithelial cells of these mucosal surfaces and then colonization of the mucosal tissue are considered the first stages on the infectious process. In numerous cases the adhesion is mediated by special protein molecules (known as adhesins) associated with proteinaceous organelles (known as fimbriae or pili). These adhesins, which are on the surface of the infectious bacteria, combine with complementary structures on the mucosal surfaces. Adhesion to mucosal surfaces offers the infectious agent a number of advantages. It allows the bacteria to firmly attach and thereby resist dislocation by the hydrokinetic forces that typically act on these surfaces. And it gives better access to nutrients as well as more protection from deleterious effects of antimicrobial agents in the surrounding milieu (Zafriri et al., 1987).

Although adhesion is an important determinant of mucosal colonization, especially with respect to the animal and tissue tropism of the invading organism, several critical post-adhesion events are required for bacterial colonization. Triggered by the adhesion of the bacteria to their complementary receptors, these events include upregulation of virulence factor expression in the bacteria on the one hand and induction of physiological changes in the host cells on the other. Among the latter are cell proliferation, increased mucus secretion, endocytosis of adherent bacteria, and release of pro- and anti-inflammatory mediators by mucosal and sub-mucosal cells.

In the present article, we review the current state of knowledge of bacterial adhesins and their mucosal cell receptors. We then discuss selected post-adhesion events and describe how they influence mucosal colonization and subsequent symptomatic infection. Finally, we show how the knowledge gained provides a basis for the development of anti-adhesion agents that can block and even reverse bacterial colonization of mucosal surfaces before tissue damage.

Bacterial Adhesins and Their Cognate Receptors

Types of Adhesin-Receptor Interactions

The adhesive interactions of over 100 bacterial pathogens of humans and farm animals have been studied (Ofek and Doyle, 1994a; Karlsson, 1995). Based on these studies, three main types of adhesin-receptor interactions can be distinguished (Table 1). The first type, probably shared by the majority of bacterial pathogens is due to lectin-carbohydrate recognition. Many of the bacterial adhesins are lectins, a class of sugar-binding proteins that link the bacteria to carbohydrate moieties of glycoproteins or glycolipids on the mammalian host cell (Table 2). In some cases bacterial surface polysaccharides of either the capsule or the outermembrane lipopolysaccharides binds to cognate lectins on host cell's (e.g., macrophage) surface (Ofek et al., 1995). The second type involves recognition of a protein on the bacteria by a complementary protein on the mucosal surface. The third type, and the one least well characterized, involves binding interactions between hydrophobic moieties of proteins on one cell with lipids ion the other cell, or between lipids on either cell (Ofek and Doyle, 1994b).

Gents differ only in a single hydroxyl group, present on the acyl of the 4-NH group in the piglet-associated compound but absent in the pig-associated compound as well as in the glycolipids of humans. The subtle age-related change in the glycolipids may explain why *E. coli* K99 can cause diarrhea in piglets, but not in adult pigs or humans.

Multiple Adhesins

A number of common themes have emerged regarding the interactions between bacteria and

Table 1. Molecular features of adhesin-receptor interactions in bacterial adhesion to host cells.

Type of interaction	Bacterial ligand (and example)	Receptor on host cell (and example)	References
Lectin-carbohydrate	Lectin (type 1 fimbriae)	Glycoprotein (uroplakin on bladder cells)	Wu et al., 1996
	Polysaccharide (Klebsiella capsule)	Lectin (mannose receptor of macrophages)	Ofek et al., 1995
Protein-protein	Fibronectin binding proteins (F protein of *S. pyogenes*)	Fibronectin (fibronectin on respiratory cells)	Hanski et al., 1992; 1996
Hydrophobin-protein	Glycolipid (lipoteichoic acid of *S. pyogenes*)	Lipid receptors? (lipid-binding region of fibronectin on epithelial cells)	Courtney et al., 1990 Hasty et al., 1992
	Lipid binding proteins (surface protein of *Campylobacter* spp.)	Membrane lipids (phospholipids and sphingolipids of cells)	Szymanski et al., 1996 Sylvester et al., 1996

mucosal cells. The most notable is the concept that pathogenic bacteria attach to mucosal cells typically through multiple adhesive interactions. Thus, a bacterial cell may express several adhesin moieties, each one specific for a distinct receptor molecule on the epithelial cell surface (for examples see Table 4). Interactions may be mediated by multiple bacterial adhesins that are structurally similar but may exhibit different binding specificities such as the type 1 and P fimbriae of uropathogenic *E. coli* (Table 3). Alternatively, adhesins may be structurally and chemically dissimilar, as is the case with the lipoteichoic acid (LTA) and proteinaceous adhesins of *Streptococcus sanguis*. Some pathogens (e.g., *Neisseria gonorrhoeae*) produce two surface lectins, each specific for distinct carbohydrate structures, one found in glycolipids and the other in glycoproteins.

In many instances, different sub-populations of a bacterial clone express these distinct adhesins. By generating several phenotypic variants each expressing adhesins of distinct specificities, a given bacterial clone will increase the reper-

Table 2. Examples of carbohydrates as attachment sites for bacteria colonizing mucosal surfaces.

Organism	Target tissue	Carbohydrate structure	Form[b]
E. coli type 1	Urinary tract	Manα3[Marα3(Manα6)	Glycoprotein

[a]A. Target host cell express one receptor molecule that contain three attachment sites fro three different adhesins produced by three clones of bacteria; B. Two bacterial species express two distinct adhesins that bind the bacteria to the same receptor molecule on target host cell; C. The same bacterial clone produce a fimbrial structure comprised of two subunits, each bind the bacteria to distinct receptor on host target cell; D. The same adhesin bind the bacteria to similar attachment sites contained in different receptor molecules (isoreceptors) expressed by various host target cells.

[b]Baorto et al., 1997; [c]Wu et al., 1996.

Gp, Glycoprotein.

toire of its target tissues and perhaps also acquire antigenic variability that will enhance its ability to withstand the multifaceted defenses of the host (Ofek and Doyle, 1994b). This notion is exemplified by pyelonephritic isolates of *E. coli* which express either P fimbrial or type-1 fimbrial adhesin at any given time. Because transmission from one host to another is via the feacal-oral route, it was postulated that the pyelonephritogenic isolates may need the type 1 fimbriae mainly to transiently colonize the upper respiratory tract. Such colonies might then provide a constant source of bacteria entering the stomach and thus increase the chances for the incoming bacteria to colonize the intestine (Bloch et al., 1992). Once in the urinary tract, the bacteria seem to need the P fimbrial adhesins to adhere to the urinary tissues (Roberts et al., 1994; Winberg et al., 1995). In fact, the diverse types of fimbrial adhesins carried by various enterobacteria may determine by virtue of their distinct receptor specificity which of the unique niches along the intestine are colonized (Edwards and Puente, 1998).

In those instances where multiple adhesins are expressed simultaneously on the same organism, each adhesin appears to complement the other functionally. For instance, the cell surface LTA and the M protein co-expressed on the surface of *Streptococcus pyogenes* have both been implicated in mediating bacterial binding to Hep-2 cells (Hasty et al., 1992; Courtney et al., 1997). Adhesion of *S. pyogenes* appears to involve a two-step process. The first step is mediated by the interaction of LTA with fibronectin molecules on the host cells (Hasty et al., 1992) and the second

Table 4. Selected bacterial clones expressing multiple adhesins.

Bacterial clone	Source of isolation	Adhesin	Characteristics
E. coli	Pyelonephritis	Type P	Fimbrial lectin
		Type 1	Fimbrial lectin
S. saprophyticus	Urinary	Gal-GlcNAc	Peripheral lectin
		Lipoteichoic acid	Fibrillar hydrophobin
N. gonorrhea	Urogenital	Pilus	Pilin adhesin
		Opa protein	Outermembrane
S. sanguis	Dental plaque hydrophobin	Protein	Peripheral
		Fimbriae	Fimbrial adhesin
		Protein	Peripheral lectin
		Lipoteichoic acid	Fibrillar hydrophobin

by binding of the M protein to an as yet unidentified receptor on these cells (Courtney et al., 1997).

Adhesins as Lectins

Table 2 presents a list of bacterial lectins, their molecular forms and their sugar specifities. Whenever known, their animal and organ specificities are also included. Methods are available for the detection and identification of sugar specificities (Goldhar, 1994, 1995; Sharon and Ofek, 1995). For further details the reader is referred to the review literature (Cassels and Wolf, 1995; Karlsson, 1995; Ofek and Doyle, 1994c).

The lectin-mediated adhesion can be inhibited both in vitro and in vivo by either simple or complex carbohydrates that compete with the binding of the lectins to host-cell glycoproteins or glycolipids. In general the affinity of simple sugars (e.g., mono- or disaccharides) to the adhesins or lectins is low, in the millimolar range. Affinity can be increased several orders of magnitude by suitable chemical derivatization (Firon et al., 1987). Increase also can be obtained by attachment of the mono- or disaccharides to polymeric carriers, to form multivalent ligands (Lindhorst et al., 1997; Sharon, 1996; Sharon and Lis, 1997).

Some bacterial lectins recognize not only terminal sugars but internal sequences as well. For example, the tip adhesin Pap G of P fimbriae recognizes internal Galα (1-4)-Gal sequences on cell surface glycolipids (Table 2). When the bacterial adhesin binds the pathogen to a cognate glycolipid, the ceramide group of the latter may contribute to the affinity of the interaction in some cases (e.g. *Helicobacter pylori*; Table 3).

The study of bacterial lectins or adhesins, especially when these molecules are associated with fimbriae that are multi-subunit structures, has been hampered by difficulties in obtaining lectins in pure soluble form. Recently, however, a major breakthrough was achieved by preparing fusion proteins from the ZZ polypeptide of staphylococcal protein A and the amino terminal region of either PapG I, PapGII or PapGIII (Hansson et al., 1995). The three fusion proteins exhibited distinct fine sugar specificities identical with those of the parent fimbriae. It is anticipated that many of the fimbrial lectins will be purified and their combining sites identified using fusion to stabilize the proteins and preserve their carbohydrate-binding activity.

Bacterial Glycoconjugates as Adhesins

Mammalian macrophages express lectins, which recognize complementary carbohydrate structures on bacterial surface and mediate nonopsonic phagocytosis of bacteria. Although phagocytosis, termed lectinophagocytosis, of a number of bacterial species was found to involve macrophage lectins, the surface glycoconjugates that mediate binding to the macrophage lectin have been identified for only a few bacteria. The mannose receptor of macrophages was found to recognize *K. pneumoniae* capsules that contain Manα2/3Man or Rhaα2/3Rha sequences and *Mycobacterium tuberculosis* that have arabinomannan on the surface (Athamna et al., 1991; Schlesinger et al., 1994). For comprehensive reviews on macrophage lectin and bacterial polysaccharide interaction in the infectious process, see Ofek et al. (1995), Ofek and Sharon (1988), Speert (1992, 1988); and Zwilling and Eisenstein (1994).

It was suggested that lipo-oligosaccharide/lipopolysaccharide (LOS/LPS) on the outer membrane of Gram-negative bacteria mediates adhesion to nonprofessional phagocytes (including mucosal cells) as well as to mucus constituents (Jacques, 1996; Nassif and Magdalene, 1995). The evidence for this effect is not conclusive and is based on the following observations: (1) epithelial cells bind less mutant strain (lacking the O side chain of LPS) than they do parental strains, and isolated LPS acts as inhibitor of the binding; (2) LPS isolated from *Vibrio mimicus* causes agglutination of rabbit erythrocytes (Alam et al., 1996); (3) the heptose-3-deoxy-D-manno-2-octulosonic acid disaccharide present in the inner core of LPS is recognized by a lectin-like molecule on the plasma membrane of rat hepatocytes (Parent, 1990); and (4) the binding and internalization of *Pseudomonas aeruginosa* by corneal epihtelial cells requires intact inner-core LPS with a terminal glucose residue (Zaidi et al., 1996). In a few cases interaction between a lectin on one bacterial cell and the lipo-oligosaccharide on another cell may mediate aggregation of the bacteria (Blake et al., 1995). The animal lectin galectin-3 was found to recognize bacterial lipopolysaccharides of Gram-negative bacteria (Mey et al., 1996). In no case, however, has there been definitive proof presented or identification made of a mucosal cell lectin that binds carbohydrates from pathogenic bacteria.

Adhesin-Receptor Relationship

The adhesins of a number of bacterial pathogens and their cognate receptor on the host cells has been characterized in a considerable number of pathogenic organisms (reviewed in Ofek and Doyle, 1994b; Sharon and Lis, 1997). Several general features are notable (Table 2). One receptor may contain more than one attachment site that is specific for two or more adhesins. This is illustrated by the Dr blood group glycoprotein, which acts as receptor on host cell membrane for

three different clones of *E. coli* each one produces a distinct adhesin that binds to a different region of the Dr group molecule (Ofek and Doyle, 1994e).

Another general feature is that two different pathogens, each expressing structurally distinct adhesins, can exhibit the same receptor specificity. This is the case with *Staphylococcus aureus* and *S. pyogenes*, both of which bind to the amino terminal region of fibronectin on mucosal cells. The adhesin on *S. aureus* is a fibronectin-binding protein, whereas that of *S. pyogenes* is lipoteichoic acid (Table 3). The finding that several different respiratory tract pathogens recognize the disaccharide GalNAcβ4Gal is yet another example of the above (Table 2). It has been suggested that the GalNAcβ4Gal sequence is preferentially accessible in glycolipids of the respiratory epithelium and this allows firm binding of a diverse group of respiratory pathogens bearing the suitable adhesins. In some cases, however, distinct adhesins share specificity but are carried by different bacteria that colonize different tissues and animal hosts, as is the case for the Galα(1-4)Gal-specific lectins of the uropathogenic P-fimbriated *E. coli*, the pig pathogen *Streptococcus suis* (Tikkanen et al., 1995), and the respiratory/enteropathogenic P-like fimbriated *K. pneumoniae* (Prondo-Mordarska et al., 1996).

Conversely, the same bacterial adhesin can bind to several distinct receptors on different cell types; such receptors are called isoreceptors. For instance several glycoproteins ranging in size from 110–45 kDa have been described as receptors for type 1 fimbriae on different cell types (Table 2). All these isoreceptor glycoproteins share a common oligomannose-containing attachment site for FimH, the adhesin subunit of type 1 fimbriae. Another situation is when an adhesin molecule contains multiple domains, each with distinct receptor specificity as is the case of the filamentous hemagglutinin adhesin of *Bordetella pertussis*. This hemagglutinin, which has been cloned and sequenced, contains at least three domains: (1) an arginine-glycine-aspartate (RGD)-containing sequence which binds the bacteria to a CR3 integrin present on pulmonary macrophages (Relman et al., 1989); (2) a carbohydrate-binding domains specific for galactose (Tuomannen et al., 1988) and (3) a carbohydrate-binding domain specific for sulfated sugars (Menozzi et al., 1994).

Interaction of Bacterial Adhesins with Extracellular Matrix

Mucosal cells are often covered by a layer referred to as extracellular matrix (ECM), which is a heterogeneous assembly of proteins, mainly glycosylated but to different extents. Included are structural glycoproteins that are typical constituents of the ECM such as collagens, elastin, fibronectin, fibrinogen, laminin, chondriotin sulfate proteoglycans and heparan sulfate proteoglycans. Many mucosal colonizers express adhesins that specifically recognize one or more of these substances. The same three categories of adhesin-receptor interactions, presented in Table 1, occur between bacteria and ECM components. They may be interactions between proteins only, between lipids and proteins, or between lectins and carbohydrates. A more thorough discussion of these ECM-bacteria interactions may be found in excellent reviews (Patti and Höök, 1994; Hasty et al., 1994; Patti et al., 1994; Wadstrom et al., 1994). Among the various ECM components, interactions with fibronectin have been studied the most at both the molecular and cellular levels. Because this multifunctional glycoprotein is found on the surface of many types of cells including mucosal ones, fibronectin probably acts as a receptor for bacterial adhesion and colonization. The adhesion of bacteria to extracellular matrix components other than fibronectin is becoming more appreciated. Examples of recent studies describing specific structures that mediate binding of bacteria to such beta-components are shown in Table 5. A remarkable feature is that many of the bacterial species studied express on their surfaces at least two proteins that bind a specific ECM component. Thus, *Helicobacter pylori* expresses a laminin-specific adhesin that may be either a 25 kDa sialic-acid-binding lectin, which recognizes sialyl residues of laminin, or a lipopolysaccharide which recognizes other, as yet unidentified, regions in laminin (Valkonen et al., 1994, 1997). Many studies have established fibronectin as an important receptor for *S. pyogenes* and other bacteria on mucosal surfaces (Ofek and Doyle, 1994e; Courtney et al., 1990). At least six different molecules on *S. pyogenes* surfaces were found to recognize fibronectin, including LTA, protein F/Sfb, a 28 kDa fibronectin-binding protein, glyceraldehyde-3-phosphate dehydrogenase, serum opacity factor and a 54 kDa fibronectin-binding protein (FBP54; reviewed in Hasty and Courtney, 1996). It is not clear whether all these fibronectin-binding entities mediate the adhesion of streptococci to mucosal surfaces.

Consequences of Bacterial Adhesion to Cells and Tissues

Recently it has been shown that adhesins not only enable colonization of mucosal surfaces but also elicits a variety of distinct responses in the

Table 5. Examples of bacterial adhesins mediating binding of the bacteria to ECM glycoproteins.

Bacteria	Bacterial adhesin	ECM component	References
Borrelia burgdorferi	19 and 20kDa proteins	Proteoglycan decorin	1, 1a
	Protein A (Osp A) and 70kDa protein	Plasminogen	2
H. influenzae	P2 and P5 outermembrane proteins	Respiratory mucin	3, 3a, 3b
N. gonorrhea	Opa protein	Proteoglycan	4
P. aeruginosa	57 and 59kDa outermembrane proteins	Laminin	5

host cells as well as in the bacteria which can markedly affect the course of the infectious process (reviewed in Finlay and Cossart, 1997). In this section, selected examples are presented to illustrate the above notion.

Induction of Bacterial Virulence Genes

The urinary tract is relatively refractory to bacterial colonization. In addition to resisting the constant hydrokinetic forces acting in this organ, a potential pathogen must multiply fast enough in urine to compensate for the diluting effects of the latter. Urine is a complex fluid containing a variety of excreted products but is growth limiting for bacteria, in part, because it is low in free iron. The intrinsic iron acquisition machinery of uropathogenic *E. coli* is activated upon complex formation between the PapG fimbrial adhesin with its Galα (1-4)Gal-containing globoseries receptor (Zhang and Normark, 1996). When P-fimbriated bacteria attached to immobilized receptor, transcriptional activation of a sensor-regulator protein, AirS, was detected. This sensor protein, located in the cytoplasmic membrane, belongs to the two-component family of signal transduction factors. The precise mechanism of AirS action is as yet not known. It is believed to regulate the bacterial iron acquisition system and iron-regulated membrane proteins to facilitate the translocation of iron into the bacterium. Uropathogenic *E. coli*, in which the *airS* gene was knocked out, lost its capacity to grow in urine. It would appear that uropathogenic bacteria can "sense" receptors (e.g. of the globoseries) in the urinary tract environment via PapG and respond by colonizing this body site. These findings point to an intriguing new function for bacterial P fimbriae, namely, that of a sensory organelle. The strategic location of PapG at the distal tips of the peritrichously arranged fimbriae probably facilitates this purported role. This finding is one of an increasing number of cases showing that bacterial pathogens are intrinsically capable of responding to cues from host cells following interactions between complementary cell-surface molecules (Cotter and Miller, 1996; Finlay and Cossart, 1997). In addition, these observations provide a molecular basis for earlier findings. Various bacteria obtain a growth advantage after attachment to host cells, as demonstrated for type 1 fimbriated *E. coli* and *N. gonorrhoeae*, which exhibit shorter lag periods when adhering to tissue culture cells (Zafriri et al., 1987; Bessen and Gotschlich, 1986).

Induction of Cytokine Release from Mucosal Cells

In addition to evoking responses in the adherent bacteria, the specific coupling of the bacterial adhesins with their receptors also elicits a range of mucosal cell responses (Bliska and Falkow, 1992). For example, adhesion of the P-fimbrial adhesin to its receptors on mouse uroepithelial cells elicits the release from these cells of several immunoregulatory cytokines including inter-

leukins (ILs)-1α-, β, -6 and -8 (Svanborg et al., 1996). It also triggers intracellular release of ceramides that may be derived from the globoseries receptor itself or from neighboring sphingomyelin molecules by the action of endogenous sphingomyelinases (Hedlund et al., 1996; Svanborg et al., 1996). Ceramide is known to be a critical second messenger in signal transduction processes capable of activating the Ser/Thr family of protein kinases and phosphatases and leading eventually to cytokine production. This bacterial adhesin- mediated mechanism of signaling is reminiscent of that utilized by immunoregulatory cytokines such as tumor necrosis factor alpha (TNFα) and IL-1 when evoking cellular responses (Svanborg et al., 1996). Thus bacterial adhesin appears to be functionally mimicking the host's immunoregulatory molecules. Although the type 1 fimbriae of uropathogenic *E. coli* also stimulate a cytokine response from uroepithelial cells, the array of cytokines released is different from those elicited by P fimbriae (Connell et al., 1996b). The transmembrane signaling pathway of cytokine release by type 1 fimbriae has not been investigated but its clarification could benefit from the recent identification of uroplakin as the putative FimH-receptor on epithelial cells (Wu et al., 1996). Adhesion of Gram-positive bacteria to epithelial cells may also cause release of cytokines from the cells. For instance, group A streptococci adherent to HEp-2 cells via both M protein and LTA adhesins cause release of IL-6 from the target cells (Courtney et al., 1997). Perhaps more interesting are the findings that interaction of bacteria with ECM constituents may also trigger signal transduction in the underlying host cells (Juliano and Haskill, 1993).

Induction of Cytokine Responses in Inflammatory Cells

The capacity of bacterial adhesins to elicit cytokine responses is not confined to mucosal cells. Lectinophagocytosis mediated by fimbriae such as type 1 fimbriae of *E. coli* or of type 2 fimbriae of *Actinomyces viscosus* is associated with stimulation of the phagocytic cells (Sandberg et al., 1988; Ofek et al., 1995). Indeed, type 1 fimbriae of uropathogenic *E. coli* are capable of binding to and eliciting immunoregulatory products from a wide range of inflammatory cells including macrophages, neutrophils, mast cells, and B and T lymphocytes in vitro (reviewed in Connell et al., 1996a). That these interactions may occur in vivo with significant physiologic effects is suggested by experiments in which mice injected intraperitoneally with type 1 fimbriated *E. coli* generated lysosomal β-N-acetylglucosaminidase and a large spike of TNFα in the peritoneal fluid (Bernhard et al., 1992; Malaviya et al., 1996). The fimbrial adhesin, FimH, plays a key role in this exposure because intraperitoneal challenge with a FimH-minus isogenic mutant resulted in only a limited TNFα response (Malaviya et al., 1996). The source of TNFα in the mouse peritoneum was determined to be mast cells because mice genetically deficient in these cells exhibited a limited TNFα response following intraperitoneal injection of type 1 fimbriae. Notably, this TNFα response was accompanied by a large influx of neutrophils into the peritoneum, consistent with the fact that TNFα is a potent neutrophil chemoattractant (Malaviya et al., 1996). Thus, one of the immediate outcomes of type 1 fimbriae-mediated activation of mast cells is recruitment of neutrophils to sites of bacterial challenge. Because mast cells are found preferentially in mucosal surfaces, the interaction of type 1 fimbriae of *E. coli* with such cells could contribute to the influx of neutrophils from surrounding blood vessels leading to the translocation of the bacteria through the epithelial barrier and subsequent entry into the lumen. The excessive transepithelial migration of neutrophils during infections may predispose this barrier to increased bacterial penetration (Finlay and Cossart, 1997) and raises the possibility that facets of the host's immune response may be co-opted by pathogenic bacteria to enhance their virulence.

Impact of Bacteria-Elicited Inflammatory Responses

Evaluating the physiologic effects of some of the adhesin-elicited cytokines at sites of bacterial infection is difficult because these effects are numerous and complex (Abraham and Malaviya, 1997; Henderson et al., 1996). Some of the responses evoked in the mucosa following the adherence of pathogenic bacteria include increased mucus secretion, proliferation of epithelial cells and recruitment and activation of a variety of phagocytic cells. All of these responses could potentially affect the early elimination of the pathogen (Abraham and Malaviya et al., 1997; Henderson et al., 1996). However, some of the adhesin-triggered secreted products of host cells may have severe pathophysiologic effects on the surrounding tissue, particularly when released in excess or at inopportune times (Abraham and Malaviya, 1997). Although direct evidence is still lacking, considerable circumstantial evidence supports the notion that the many proteases, oxygen radicals, and cytotoxic cytokines secreted after inflamatory cells are activated by type 1 fimbriated *E. coli* (Tewari et al., 1994; Malaviya et al., 1994, 1996) are detrimental to the host and foster bacterial pathogenesis. For example, the elastases, oxygen radicals and other

cytotoxic agents, released from neutrophils following their interaction with type 1 fimbriae of *E. coli* in the kidney, are major contributors to renal scarring (Steadman et al., 1988; Topley et al., 1989). Whether an inflammatory response favors the host or pathogen may depend on other prevailing factors including the host's immune status and the intrinsic virulent capabilities of the pathogen. The number of bacteria at the site of infection may be another critical factor in light of the recent findings that certain bacteria have "quorum sensing" ability (Passador et al., 1993; i.e., they sense their population density at a given site and, upon reaching a critical density, coordinately turn on the expression of a battery of new virulence factors.)

Bacterial Uptake by Phagocytes

In addition to inducing the release of pharmacologically active mediators from various host cells, bacterial adhesins also elicit the phagocytic uptake of bacteria under serum-free conditions (reviewed in Ofek et al., 1995). The process involves a number of molecular mechanisms; as mentioned this process has been termed lectinophagocytosis, in analogy to opsonophagocytosis (Ofek and Sharon, 1988; Ofek et al., 1995). The best-characterized system of lectinophagocytosis is that of bacteria carrying the mannose-specific type 1 fimbrial lectins. The fact that a bacterial adhesin that promotes bacterial colonization and infection may also promote ingestion by phagocytic cells would seem a paradox. Although earlier work showed that bacteria are occasionally killed by the phagocytes, new evidence has emerged to suggest that type 1 fimbriae-elicited bacterial phagocytosis by macrophages may actually benefit the bacterial population (Baorto et al., 1997). In vitro survival assays in macrophages revealed that, unlike *E. coli* phagocytized via opsonin-mediated processes, *E. coli* phagocytized via type 1 fimbriae survived much of the intracellular killing. It has been suggested that by associating with CD48, a glycosylphosphoinositol-linked moiety on the surface of macrophages, the bacteria gain access to a lipid processing pathway that bypasses the normal phagocytic killing mechanisms of the macrophages (Baorto et al., 1997). This finding provides a molecular basis for earlier observations showing that, compared to bacteria ingested via opsonophagocytosis, bacteria subjected to lectinophagocytosis are often markedly less sensitive to killing by phagocytes (reviewed in Ofek et al., 1995). It is noteworthy that lectinophagocytosis comes into play only at body sites where opsonizing is poor such as in the urinary mucosa.

Internalization by Nonphagocytic Cells

Contact between bacterial adhesins and complementary receptors on so called nonphagocytic cells can trigger internalization of adherent bacteria (reviewed by Finlay and Falkow, 1990, 1997; Marra and Isberg, 1996). This has been demonstrated with such classical intracellular pathogenic species as *Listeria*, *Yersinia*, *Shigella*, *Salmonella* and *Bartonella* (Table 7). These organisms enter and proliferate in nonphagocytic cells in vitro and in vivo. Probably because of the development of highly sensitive and reproducible techniques to measure bacterial entry into mammalian cells (Tang et al., 1993), several well-known "extracellular" pathogens have recently been reported to be capable of penetrating nonphagocytic cells (e.g., epithelial and endothelial cells) and of surviving for a limited period and, in some cases, even of proliferating intracellularly. Unlike the classical or professional intracellular pathogens, entry of the extracellular pathogens is usually limited to a subset of bacterial strains within the same species, probably because entry into requires the co-expresion of multiple components such as adhesins and constituents of the secretory system (De Vries et al., 1996). Furthermore, the capacity to enter nonphagocytic cells is not necessarily associated with virulence of the extracellular pathogen. For example, isolates from carrier-state or nonencapsulated strains of *S. pyogenes* can invade epithelial cells, whereas pharyngitis isolates (Sela, 1998) or virulent encapsulated strains (Schrager et al., 1996) invade poorly. Excluding the classical intracellular pathogens, the list of bacterial species capable of invading nonphagocytic cells includes *Actinobacillus actinomycetemcomitans* (Meyer et al., 1996), *Pseudomonas aeruginosa* (Fleiszig et al., 1995, 1996), *Burkholderia* (*Pseudomonas*) *cepacia* (Burns et al., 1996), *E. coli* (Meier et al., 1996; Jouve et al., 1997; Donnenberg et al., 1997; Goluszko et al., 1997), *K. pneumoniae* (Oelschlaeger and Tall, 1997), *N. gonorrhoeae* (Weel et al., 1991), *N. meningitidis* (Virji et al., 1993), *Porphyromonas gingivalis* (Weinberg et al., 1997), *Streptococcus agalactiae* (Hulse et al., 1993; Valentin-Weigand et al., 1997; Gibson et al., 1993), *S. aureus* (Vann et al., 1987; Hamill et al., 1986) and *S. pyogenes* (Greco et al., 1995; LaPenta et al., 1994). Conceivably, the ability to enter nonphagocytic cells is an integral part of the pathogenic process of many infectious bacteria. While the classical intracellular pathogens utilize this ability to spread from cell to cell and to penetrate into deep tissue, other pathogens may utilize this trait to temporarily hide from the host's immune cells or from antibiotics. Thus, bacteria surviving within nonphagocytic cells

serve as a critical reservoir from which reinfection of the host can take place.

The mechanisms employed by various bacteria to gain access into nonphagocytic cells are diverse and often complex (see range of molecules implicated in bacterial invasion of host cells in Table 7). For example, *Yersinia enterolitica* employs a single cell surface protein, invasin, whose cognate receptors on the host cell membrane are β integrins (Isberg, 1996). When invasin binds with high affinity to β integrins, the close association between the integrins and cytoskeletal elements of the cell membrane triggers the bacterial uptake. Particles that are

coated with invasin proteins (or functionally relevant portions of the protein) and exposed to tissue culture cells are readily internalized by the cells. More complex modes of entry requiring specific secretion systems of the bacteria have been reported for certain enteropathogenic *E. coli* (Javris et al., 1995) and species of *Shigella* (Allaoui et al., 1993), *Salmonella* (Ginocchio et al., 1992) and *Bartonella* (Minnick et al., 1996). Perhaps the most remarkable of these systems involves enteropathogenic *E. coli* (EPEC) where the type III secretory system of the bacteria inserts into the host cell membrane a protein (HP90) that serves in turn as the receptor for the bacterial adhesin (Kenny et al., 1997; Nataro and Kaper, 1998). The process of internalization involve sequential interactions between EPEC and the host cell. The first step of adhesion occurs via bundle fimbria and is followed by intimate contact via a second adhesin termed intimin. The receptor on the host cell for the intimin is HP90, which is produced by the bacteria, phosphorylated, and then inserted into the host cell membrane by the type III secretory system of the bacteria. With the binding of intimin, the bacteria become internalized by the host cells. A similar mechanism was described for the internalization of pathogenic Neisseria by nonphagocytic cells (Dehio et al., 1998). In another recently reported mechanism, the bacteria after adhesion to their cognate receptor initiate a signaling cascade resulting in activation of phosphatidylcholine-specific phospholipase C and acidic sphingomyelinase, to allow entry of *N. gonorrhoeae* into nonphagocytic cells (Grassme et al., 1997). Finally, in some cases the molecular mechanism utilized by the bacteria to gain entry into nonphagocytic cells appears to be the same as that involved in the uptake of bacteria by phagocytes. A case in point is the specific interaction between CD66 on the mammalian cell surface and the *N. gonorrhoeae* Opa proteins that triggers the uptake of bacteria by both epithelial cells and polymorphonuclear cells (Gray-Owen et al., 1997; Virji et al., 1996; Chen et al., 1997; Sauter et al., 1993).

Concluding Remarks

Experiments in animals have proven that it is possible to prevent infections by blocking the adhesion of the pathogen to target tissue. These findings have stimulated the development of anti-adhesion drugs for preventing and treating microbial infections in humans (reviewed in Kahane and Ofek, 1996). New classes of these drugs are greatly needed because of the increasing incidence of pathogenic organisms resistant to conventional antibiotics. It is believed that strains with genotypic resistance to the anti-adhesion agents will spread much slower than strains resistant to conventional drugs, such as antibiotics aimed at killing the organisms. The reason is that both anti-adhesion-sensitive and -resistant strains are shed to continue transmission from host to host, whereas only antibiotic-resistant strains are transmitted following therapy.

Because lectin-mediated adhesion is a mechanism shared by many pathogens most investigators have focused their efforts to prevent bacterial infections on blocking the pathogen's lectins. The preferable target site is the mucosal surfaces where phagocytic cells are scarce and where most infections are initiated. A number of strategies have been suggested including enhancement of mucosal immunity by s-IgA anti-adhesin antibody induction, use of metabolic inhibitors of adhesin expression (e.g. sublethal concentration of antibiotics), and of dietary inhibitors, in particular receptor analogs (reviewed in Ofek and Doyle, 1994b; Kahane and Ofek, 1996). In the latter strategy, the lectin or adhesin is inhibited by sugars for which the lectin is specific (Table 6). This was first demonstrated in the late 1970s, when it was shown that methyl α-mannoside can protect mice against urinary tract infection by type 1 fimbriated *E. coli*; methyl α-glycoside which is not recognized by the bacteria, was not effective (Aronson et al., 1979). Subsequent studies by many other groups have proven beyond any doubt the drug potential of anti-adhesive compounds (Table 6; Beuth et al., 1995; Sharon, 1996; Ofek and Sharon, 1990; Zopf and Roth, 1996). Thus, derivatives of galabiose that inhibit the adhesion of P fimbriated *E. coli* to animal cells in vitro, prevented bacterial infections in the urinary tract of mice and monkeys. Antibodies against mannose-containing compounds present on epithelial cells prevented urinary tract infection in mice by type 1 fimbriated *E. coli*. in mice, and orally administered sialylated glycoproteins protected colostrum-deprived newborn calves against lethal doses of enterotoxigenic *E. coli* K99. In a clinical trial in humans, patients with otitis externa (a painful swelling with secretion from the external auditory canal) caused by *P. aeruginosa* were treated with a solution of galactose, mannose and N-acetylneuraminic acid (Beuth et al., 1996). The results were fully comparable to those obtained with conventional antibiotic treatment. An attractive candidate is oligosaccharides such as those found in human milk and other body fluids, that have been shown to inhibit the adhesion to cells and tissues of strains of *H. pylori* and *S. pneumoniae* (Zopf et al., 1996; Simon et al., 1997).

Human milk is a potential source of inhibitors of bacterial adhesion because it is rich in disac-

charides that may act as receptor analogs (Ashkenazi, 1996). However, other dietary constituents also may exhibit anti-adhesion activity and may be used to prevent bacterial infections. For example, cranberry juice contains at least two inhibitors of uropathogenic *E. coli* (Ofek et al., 1991) and according to one well documented report, it reduced the incidence of urinary tract infections in elderly women (Avorn, et al., 1994).

These findings illustrate the great potential of inhibitors of adhesion in the prevention and perhaps also treatment of bacterial infections. Moreover, they raise hopes for the development of anti-adhesive drugs for human use. The development of anti-adhesion therapy targeted at the microbial lectins has been hampered by the great difficulty in large-scale synthesis of the required inhibitory saccharides. An alternative is glycomimetics, compounds that structurally mimic the inhibitory carbohydrates, but which may be more readily obtainable. Eventually, a cocktail of inhibitors, or a polyvalent one, will have to be used, since many infectious agents express multiple specificities. The design of such drugs will certainly benefit from more detailed information about the specificity of the microbial surface lectins and the elucidation of the atomic structure of their combining sites, none of which is yet known.

CHAPTER 1.3

The Phototrophic Way of Life

JÖRG OVERMANN AND FERRAN GARCIA-PICHEL

Introduction

Photosynthesis is the utilization of radiant energy for the synthesis of complex organic molecules. The phototrophic way of life implies the capture of electromagnetic energy (see Light Absorption and Light Energy Transfer in Prokaryotes in this Chapter), its conversion into chemical energy (see Conversion of Light into Chemical Energy in this Chapter), and its use for cellular maintenance and growth (see Efficiency of Growth and Maintenance Energy Requirements in this Chapter). Photosynthesis may encompass the reduction of carbon dioxide into organic molecules, a mode of growth defined as photoautotrophy. The solar electromagnetic energy reaching the Earth's surface (160 $W \cdot m^{-2}$; see Light energy and the spectral distribution of radiation) surpasses the energy contributed by all other sources by four to five orders of magnitude (electric discharge, radioactivity, volcanism, or meteoritic impacts; ~0.0062 $W \cdot m^{-2}$ on primordial Earth; Mauzerall, 1992; present day geothermal energy ~0.0292 $W \cdot m^{-2}$; K. Nealson, personal communication).

At present the flux of electromagnetic energy supports a total primary production of 172.5×10^9 tons dry weight·year^{-1} (168 g $C \cdot m^{-2} \cdot year^{-1}$; Whittaker and Likens, 1975). If this global primary production is converted to energy units (39.9 kJ·g C^{-1}, assuming that all photosynthetic products are carbohydrate), 0.21 $W \cdot m^{-2}$ and thus 0.13% of the available solar energy flux are converted into chemical energy. Even at this low efficiency, the chemical energy stored in organic carbon still exceeds geothermal energy by at least one order of magnitude. As a consequence, photosynthesis directly or indirectly drives the biogeochemical cycles in all extant ecosystems of the planet. Even hydrothermal vent communities, which use inorganic electron donors of geothermal origin and assimilate CO_2 by chemolithoautotrophy (rather than photoautotrophy), still depend on the molecular O_2 generated by oxygenic phototrophs outside of these systems (Jannasch, 1989).

Several lines of evidence indicate that in the early stages of biosphere evolution, prokaryotic organisms were once responsible for the entire global photosynthetic carbon fixation. Today, terrestrial higher plants account for the vast majority of photosynthetic biomass; the chlorophyll bound in light-harvesting complex LHCII of green chloroplasts alone represents 50% of the total chlorophyll on Earth (Sidler, 1994). In contrast, the biomass of marine primary producers is very low (0.2% of the global value). However, the biomass turnover of marine photosynthetic microorganisms is some 700 times faster than that of terrestrial higher plants. Thus, marine photosynthetic organisms contribute significantly to total primary productivity ($55 \cdot 10^9$ tons dry weight·year^{-1}, or 44% of the global primary production). Because the biomass of cyanobacterial picoplankton (see Habitats of Phototrophic Prokaryotes in this Chapter) can amount to 67% of the oceanic plankton, and their photosynthesis up to 80% in the marine environment (Campbell et al., 1994; Goericke and Welschmeyer, 1993; Liu et al., 1997; Waterbury et al., 1986), prokaryotic primary production is still significant on a global scale. A single monophyletic group of marine unicellular cyanobacterial strains encompassing the genera *Prochloroccoccus* and *Synechococcus* with a global biomass in the order of a billion of metric tons (Garcia-Pichel, 1999) may be responsible for the fixation of as much as 10–25% of the global primary productivity. Additionally, prokaryotic (cyanobacterial) photosynthesis is still locally very important in other habitats such as cold (Friedmann, 1976) and hot deserts (Garcia-Pichel and Belnap, 1996) a nd hypertrophic lakes.

Today, the significance of anoxygenic photosynthesis for global carbon fixation is limited for two reasons. On the one hand, phototrophic sulfur bacteria (the dominant anoxygenic phototrophs in natural ecosystems) form dense accumulations only in certain lacustrine environments and in intertidal sandflats. The fraction of lakes and intertidal saltmarshes which harbor anoxygenic phototrophic bacteria is unknown, but these ecosystems altogether contribute only 4% to global primary production (Whittaker and Likens, 1975). In those lakes harboring pho-

totrophic sulfur bacteria, an average of 28.7% of the primary production is anoxygenic (Overmann, 1997). Consequently, the amount of CO_2 fixed by anoxygenic photosynthesis must contribute much less than 1% to global primary production. On the other hand, anoxygenic photosynthesis depends on reduced inorganic sulfur compounds which originate from the anaerobic degradation of or ganic carbon. Since this carbon was already fixed by oxygenic photosynthesis, the CO_2-fixation of anoxygenic phototrophic bacteria does not lead to a net increase in organic carbon available to higher trophic levels. The CO_2-assimilation by anoxygenic phototrophic bacteria has therefore been termed "secondary primary production" (Pfennig, 1978). Therefore, capture of light energy by anoxygenic photosynthesis merely compensates for the degradation of organic carbon in the anaerobic food chain. Geothermal sulfur springs are the only exception since their sulfide is of abiotic origin. However, because sulfur springs are rather scarce, anoxygenic photosynthetic carbon fixation of these ecosystems also appears to be of minor significance on a global scale.

The scientific interest in anoxygenic phototropic bacteria stems from 1) the simple molecular architecture and variety of their photosystems, which makes anoxygenic phototrophic bacteria suitable models for biochemical and biophysical study of photosynthetic mechanisms, 2) the considerable diversity of anoxygenic phototrophic bacteria, which has implications for reconstructing the evolution of photosynthesis, and 3) the changes in biogeochemical cycles of carbon and sulfur, which are mediated by the dense populations of phototrophic bacteria in natural ecosystems.

All known microorganisms use two functional principles (both mutually exclusive and represent two independent evolutionary developments) for the conversion of light into chemical energy. Chlorophyll-based systems are widespread among members of the domain Bacteria and consist of a light-harvesting antenna and reaction centers. In the latter, excitation energy is converted into a redox gradient across the membrane. In contrast, the retinal-based bacteriorhodopsin system is exclusively found in members of a monophyletic group within the domain Archaea. These prokaryotes lack an antenna system and use light energy for the direct translocation of protons across the cytoplasmic membrane. In both systems, photosynthetic energy conversion ultimately results in the formation of energy-rich chemical bonds of organic compounds.

The advent of modern genetic and biochemical methods has led to a considerable gain in knowledge of the molecular biology of phototrophic prokaryotes. At the same time, microbial ecologists have found these microorganisms of considerable interest and now frequently use molecular methods to investigate natural populations. The present chapter is limited to the discussion of phototrophic bacteria and attempts to link the physiology, ecology, and evolution of phototrophic bacteria to a molecular basis. Emphasis is laid on those molecular structures or functions that have evident adaptive value. This integrating view may provide a more solid foundation for understanding the biology of photosynthetic prokaryotes.

Taxonomy of Phototrophic Prokaryotes

The capacity for chlorophyll-based photosynthetic energy conversion is found in five of the 36 currently recognized bacterial lineages (Fig. 1; Hugenholtz et al., 1998): the *Chloroflexus* subgroup, the green sulfur bacteria, the *Proteobacteria*, the *Cyanobacteria*, and the *Heliobacteriaceae*. With the exception of the *Cyanobacteria*, phototrophic bacteria perform anoxygenic photosynthesis, which is not accompanied by photochemical cleavage of water and therefore does not lead to the formation of molecular oxygen. Based on their phenotypic characters, anoxygenic phototrophic bacteria had been divided previously into the five families Rhodospirillaceae, Chromatiaceae, Ectothiorhodospiraceae, Chlorobiaceae, and Chloroflexaceae (Trüper and Pfennig, 1981). However, 16S rRNA oligonucleotide cataloguing and 16S rRNA sequence comparisons have reveale d that the *Proteobacteria* and the *Chloroflexus*-subgroup both contain nonphototrophic representatives (Woese, 1987; Fig. 1). Therefore the use of light as an energy source for growth is not limited to phylogenetically coherent groups of bacteria. However, nonphototrophic representatives of the green sulfur bacterial and the cyanobacterial lineages have not been isolated to date.

Within the *Chloroflexus*-subgroup, three different species (*Chloroflexus aurantiacus*, *Chloroflexus aggregans* and *Heliothrix oregonensis*) of filamentous multicellular phototrophs have been described. All three are thermophilic and grow photoorganoheterotrophically. In addition four mesophilic species (*Oscillochloris chrysea*, *Oscillochloris trichoides*, *Chloronema giganteum*, *Chloronema spiroideum*) have been affiliated with the *Chloroflexus*-subgroup based on their multicellular filaments, gliding motility, and the presence of chlorosomes containing bacteriochlorophylls c or d (Pfennig and Trüper, 1989). The phylogenetic position of these latter bacteria

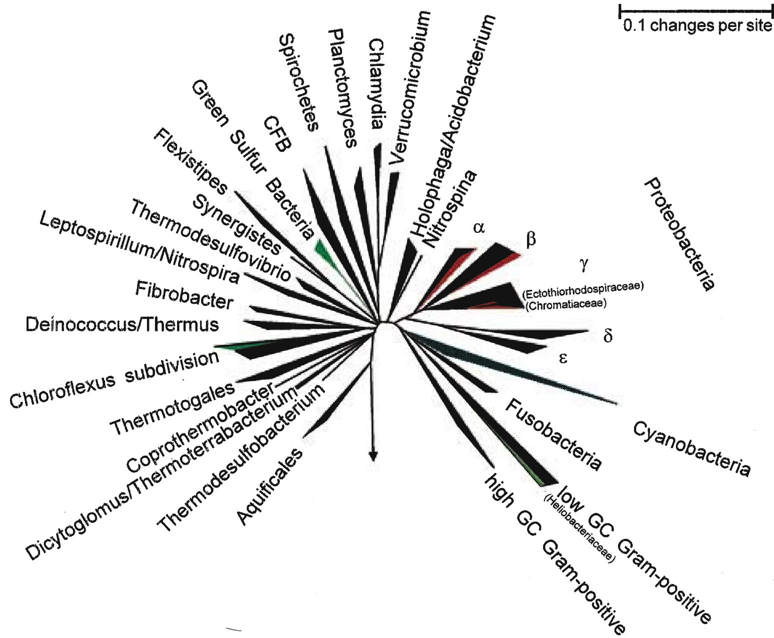

Fig. 1. Phylogenetic tree based on 16S rRNA sequences. All bacterial divisions containing culturable representatives were included in the analyses so that the phototrophic nature of the bacterial strains could be confirmed. Alignments were obtained with CLUSTAL W and pairwise distances calculated with the algorithm of Jukes and Cantor using the DNADIST program of PHYLIP 3.57c. The tree was constructed from evolutionary distances employing the least-squares algorithm of Fitch and Margoliash as implemented by the FITCH program of the package. The Archaeon *Methanopyrus kandleri* DSM 6324 was used as an outgroup to root the tree. (light green) Bacteria containing chlorosomes as light-harvesting antenna. (red) Bacteria containing antenna complexes within the cytoplasmic membrane and quinone/pheophytin-type reaction centers. (medium green) Gram-positive phototrophic bacteria with FeS-type reaction centers. (dark green) Bacteria containing the two types of reaction centers. Width of colored wedges indicates the phylogenetic divergence.

has not been investigated so far. With the exception of *Heliothrix oregonensis* all species mentioned contain chlorosomes as distinct light-harvesting structures (Fig. 2). Yet to be cultivated axenically, non-thermophilic "*Chloroflexus*-like" organisms are known from intertidal and hypersaline benthic environments (Pierson et al., 1994) and from cold freshwater sulfidic springs (F. Garcia-Pichel, unpublished observation). At least in the case of the hypersaline enrichments, the organisms are closely related to *Heliothrix* in terms of their 16S rRNA sequence (B.K. Pierson, personal communication to FGP). This, together with recent descriptions of *Oscillochloris trichoides* (Keppen et al., 1994) from freshwater sediments indicates a larger diversity and more widespread occurrence of the *Chloroflexaceae* and allied organisms than was previously recognized.

Green sulfur bacteria (see The Family Chlorobiaceae Volume 7) represent a coherent and isolated group within the domain Bacteria. They are strict photolithotrophs and contain chlorosomes (Fig. 3A). During the oxidation of sulfide, elemental sulfur is deposited extracellularly. Another typical feature of this group is the very limited physiological flexibility (see Docile Reaction). In the *Proteobacteria*, the α- and β-Proteobacteria comprise photosynthetic representatives (often also called the purple nonsulfur bacteria), which do not form separate phylogenetic clusters but are highly intermixed with various other phenotypes. Characteristically, members of these two groups exhibit a high metabolic versatility and are capable of photoorganotrophic, photolithoautotrophic and chemoorganotrophic growth. Photosynthetic pigments are bacteriochlorophyll *a* or b and a variety of carotenoids. Light-harvesting complexes, reaction centers, and the component s of the electron transport chain are located in intracellular membrane systems of species-specific architecture (Fig. 2; see Light Absorption and Light Energy Transfer in Prokaryotes in this Chapter).

Several members of the α-Proteobacteria are capable of bacteriochlorophyll *a* synthesis but cannot grow by anoxygenic photosynthesis. This physiological group has therefore been designated "aerobic anoxygenic phototrophic bacteria" (Shimada, 1995; Yurkov and Beatty, 1998), "aerobic phototrophic bacteria" (Shiba, 1989), or "quasi-photosynthetic bacteria" (Gest, 1993) and comprises a considerable number of species. So far, the marine genera *Erythrobacter* and

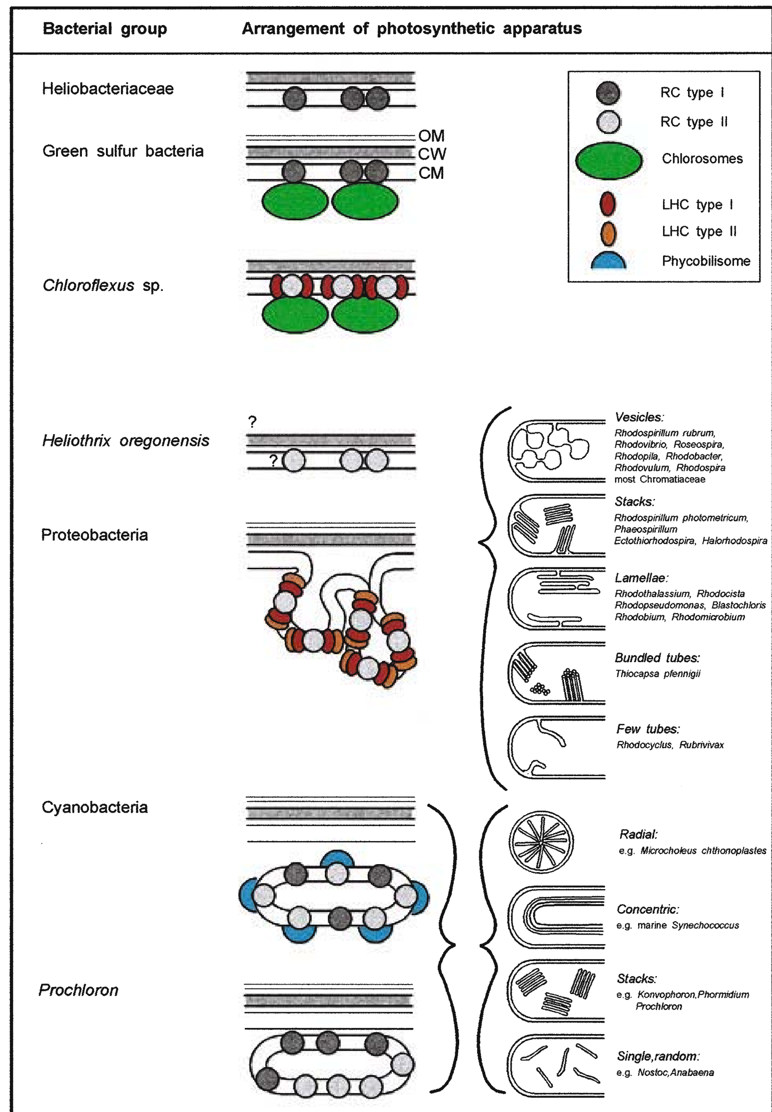

Fig. 2. Organization of the phototrophic apparatus in different groups of phototrophic bacteria. *OM* = outer membrane, *CW* = cell wall, *CM* = cytoplasmic membrane, *RC* = reaction center, *LHC* = light-harvesting complex. Question marks indicate that the organization of the cell envelope and the organization of the photosynthetic apparatus in *Heliothrix oregonensis* is not exactly known.

Roseobacter and the six freshwater genera *Acidiphilium*, *Erythromonas*, *Erythromicrobium*, *Porphyrobacter*, *Roseococcus*, *Sandarcinobacter* (Yurkov and Beatty, 1998) have been described. This group also includes some aerobic facultatively methylotrophic bacteria of the genus *Methylobacterium* and a *Rhizobium* (strain BTAi1; Evans et al., 1990; Shimada, 1995; Urakami and Komagata, 1984). The oxidation of organic carbon compounds is the principal source of metabolic energy. Photophosphorylation can be used as a supplementary source of energy, with a transient enhancement of aerobic growth following a shift from dark to illumination (Harashima et al., 1978; Shiba and Harashima, 1986). Aerobic bacteriochlorophyll-containing bacteria harbor a photosynthetic apparatus very similar to photosystem II of anoxygenic phototrophic Proteobacteria (Yurkov and Beatty, 1998). Photochemically acti ve reaction centers and light-harvesting complexes are present, as are the components of cyclic electron transport (e.g., a cytochrome *c* bound to the reaction center and soluble cytochrome c_2). In contrast to anoxygenic phototrophic bacteria, however, the aerobic phototrophic bacteria cannot grow autotrophically. Intracellular photosynthetic membrane systems as they are typical for anoxygenic phototrophic *Proteobacteria* are absent in most aerobic photosynthetic bacteria; *Rhizobium* BTAi1 being a possible exception (Fleischman et al., 1995). The presence of highly polar carotenoid sulfates and C_{30} carotenoid glycosides is a unique property of this group. All aerobic bacteriochlorophyll *a*-containing species group with the α-subclass of the Proteobacteria, but are more closely related to aerobic non-

bacteriochlorophyll-contain ing organisms than to anoxygenic phototrophs (Stackebrandt et al., 1996).

The γ-subclass comprises two families of phototrophic species, the *Chromatiaceae* and *Ectothiorhodospiraceae* (also called purple sulfur bacteria). *Chromatiaceae* accumulate sulfur globules within the cells and represent a conspicuous microscopic feature of these bacteria. With one notable exception (*Thiocapsa pfennigii*), the intracellular membrane system is of the vesicular type (Figs. 2 and 3B). In contrast, members of

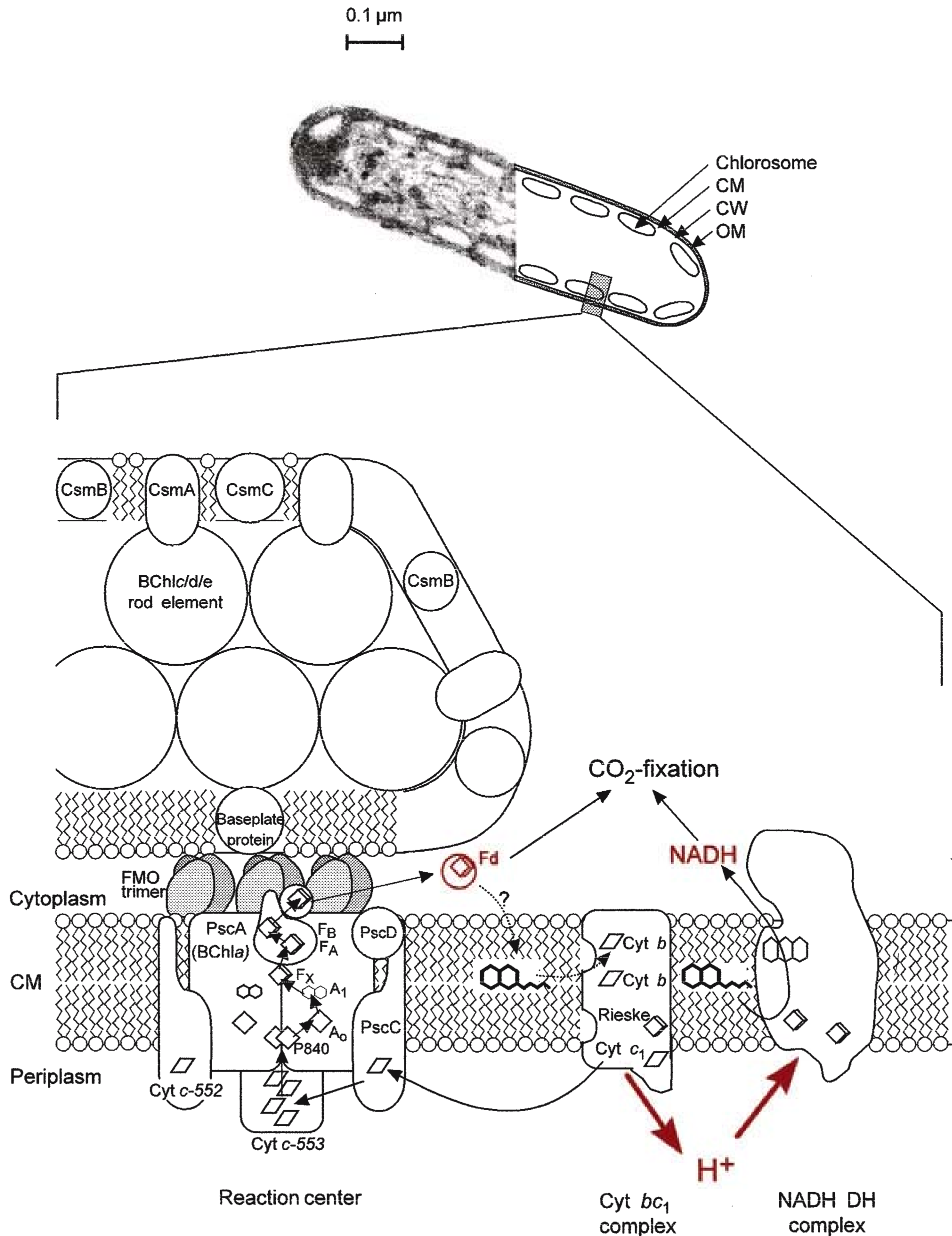

Fig. 3. Localization and organization of the photosynthetic apparatus in three major groups of phototrophic bacteria. Electron-donating enzyme systems, like flavocytochrome or sulfide quinone reductase, and ATP formation by the membrane-bound ATP synthase are not shown. A. Green sulfur bacteria (Chlorobiaceae). B. Purple nonsulfur bacteria and Chromatiaceae. C. Cyanobacteria. *OM* = outer membrane; *CW* = cell wall; *CM* = cytoplasmic membrane; *Cyt* = cytochrome; *P840* and *P870* reaction center special pair = primary electron donor; *B800, B850, B875* = bacteriochlorophyll molecules bound to light-harvesting complexes II and I; A_0 = primary electron acceptor in green sulfur bacteria = Chl *a*; A_1 = secondary electron acceptor in green sulfur bacteria = menaquinone; Q_A, Q_B = ubiquinone; F_X, F_A, F_B = FeS-clusters bound to the reaction center; *Fd* = ferredoxin; *FMO* = Fenna-Matthews-Olson protein; *FNR* = ferredoxin $NADP^+$ reductase; *PQ* = plastoquinone; *PC* = plastocyanin; *PS* = photosystem.

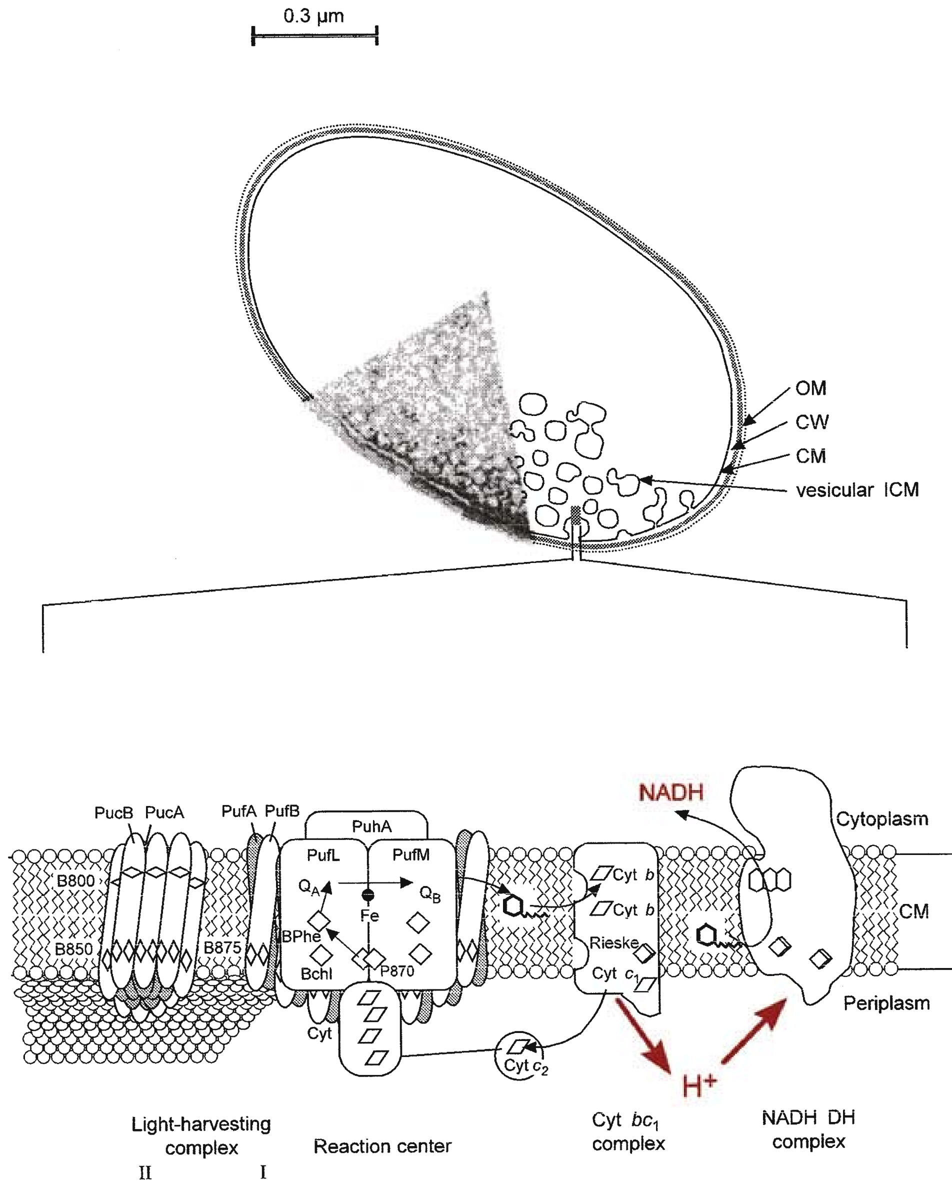

Fig. 3. *Continued*.

the *Ectothiorhodospiraceae* deposit elemental sulfur outside of the cells and contain lamellar intracellular membrane systems. Like their relatives of the α- and β-subclass of Proteobacteria, the purple sulfur bacteria contain bacteriochlorophylls *a* and *b*, and all components of the photosynthetic apparatus are located in the intracellular membrane.

No photosynthetic species have been described for the δ- or ε-subclass of the *Proteobacteria*.

Heliobacteriaceae differ from other anoxygenic phototrophic bacteria by their unique light-harvesting and reaction center pigment, bacteriochlorophyll g, and by their phylogenetic affiliation (Fig. 1). The first member of this group, *Heliobacterium chlorum* was described in 1983 by Gest and Favinger (Gest and Favinger, 1983b). Based on peptidoglycan structure studies (Beer-Romero et al., 1988), their high proportion of branched-chain fatty acids (Beck et al., 1990) and 16S rRNA sequencing, the *Heliobacteriaceae* belong to the Gram-positive low GC lineage. A close relatedness can also be deduced from the capability of *Heliobacterium modesticaldum* and *Heliobacterium gestii* to form endospores. However, a detailed phylogenetic analysis also indicated a close relatedness of

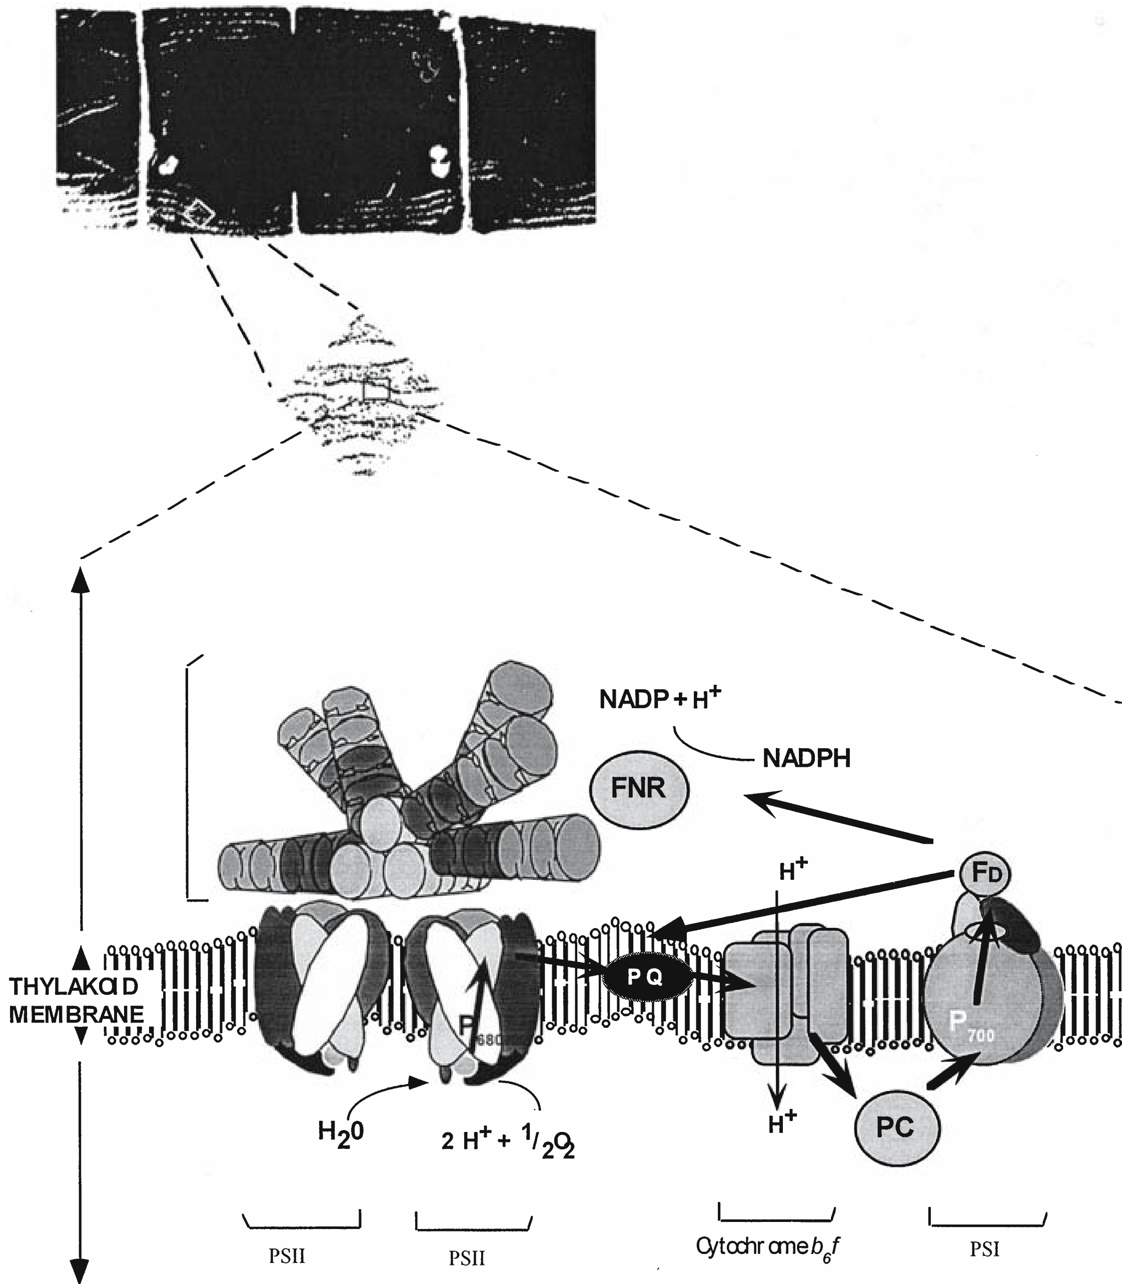

Fig. 3. *Continued*.

Heliobact eriaceae to the *Cyanobacteria* (Vermaas, 1994). *Heliobacteriaceae* do not contain distinct intracellular structures of the photosynthetic apparatus and the reaction centers are located in the cytoplasmic membrane. Bacteriochlorophyll g confers to the cells a near infrared absorption maximum at 788 nm, which is unique among photosynthetic organisms. The known species of *Heliobacteriaceae* all grow photoheterotrophically and are strict anaerobes.

Oxygenic photosynthesis is only found in members of a single bacterial lineage out of the five that contain phototrophs (Fig. 1). The *Cyanobacteria* by far comprise the largest number of isolated strains and described species (Table 1). The *Cyanobacteria* (= oxyphotobacteria) are defined by their ability to carry out oxygenic photosynthesis (water-oxidizing, oxygen-evolving, plant-like photosynthesis) based on the coordinated work of two photosystems (Fig. 3C). Phylogenetically, they constitute a coherent phylum that contains the plastids of all eukaryotic phototrophs. They all synthesize chlorophyll *a* as photosynthetic pigment, and

Table 1. Groups of photosynthetic prokaryotes and their characteristics.

Taxon		Preferred growth mode	Light harvesting	Photochemical reaction
Chloroflexus subdivision	(3)[a]	Anoxygenic photoorganoheterotroph(cls);	BChl *c*, car	Type II reaction center
		Aerobic chemoorganoheterotroph	—	—
Green sulfur bacteria	(15)	Anoxygenic photolithoautotroph	cls; BChl *cldle*, car	Type I reaction center
α-Proteobacteria	(31)	Anoxygenic photoorganoheterotroph	icm; BChl *alb*, car	Type II reaction center
		Aerobic chemoorganoheterotroph	—	—
α-Proteobacteria (aerobic photosynthetic)	(23)	Aerobic chemoorganoheterotroph	BChl *a*	Type II reaction center
β-Proteobacteria	(4)	Anoxygenic photoorganoheterotroph	icm; BChl *a*, car	Type II reaction center
		Aerobic chemoorganoheterotroph	—	—
Chromatiaceae Ectothiorhodospiraceae	(31) (9)	Anoxygenic photolithoautotroph	icm; BChl *alb*, car	Type II reaction center
Heliobacteriaceae	(5)	Anoxygenic photoorganoheterotroph	BChl *g*, car	Type I reaction center
Cyanobacteria	(>> 1000)	Oxygenic photolithoautotroph	thy; Chl *a* + PBS or Chl *b*, or Chl *d*; car	Type I + II reaction center
Prochloron, *Prochlorothrix*	(2)		thy; Chl *a/b*,car

Acaryochloris	(1)		thy; Chl*a,d*, car (PBS)	
Halobacteria	(3)	Aerobic chemoorganoheterotroph	Purple membrane; bacteriorhodopsin	Bacteriorhodopsin

[a]The numbers of photosynthetic species described for each taxon are given in parenthesis.
BChl = bacteriochlorophyll, car = carotenoids, Chl = chlorophyll, cls = chlorosomes, icm = intracellular membranes, PBS = phycobilisomes, thy = thylacoids.

most types contain phycobiliproteins as light-harvesting pigments. These multimeric proteinaceous structures are found on the cytoplasmic face of the intracellular thylakoid membranes and contain phycobilins as light-harvesting pigments. All *Cyanobacteria* are able to grow using CO_2 as the sole sou rce of carbon, which they fix using primarily the reductive pentose phosphate pathway (see Carbon Metabolism of Phototrophic Prokaryotes in this Chapter). Their chemoorganotrophic potential typically is restricted to the mobilization of reserve polymers (mainly starch but also polyhydroxyalkanoates) during dark periods, although some strains are known to grow chemoorganotrophically in the dark at the expense of external sugars. Owing to their ecological role, in many cases indistinguishable from that of eukaryotic microalgae, the cyanobacteria had been studied originally by botanists. The epithets "blue-green algae," "Cyanophyceae," "Cyanophyta," "Myxophyceae," and "Schizophyceae" all apply to the cyanobacteria. Two main taxonomic treatments of the *Cyanobacteria* exist, and are widely used, which divide them into major groups (orders) on the basis of morphological and life-history traits. The botanical system (Geitler, 1932 recognized 3 orders, 145 genera and some 1300 spe cies, but it has recently been modernized (Anagnostidis and Komárek, 1989, Komárek and Anagnostidis, 1989). The bacteriological system (Stanier, 1977; Rippka et al., 1979; Castenholz, 1989), relies on the study of cultured axenic strains. It recognizes five larger groups or orders, separated on the basis of morphological characters. Genetic (i.e., mol% GC, DNA-DNA hybridization) as well as physiological traits have been used to separate genera in problematic cases.

Previously, a separate group of organisms with equal rank to the cyanobacteria, the so-called "Prochlorophytes" (with two genera, *Prochloron*, a unicellular symbiont of marine invertebrates, and *Prochlorothrix*, a free-living filamentous form) had been recognized (Lewin, 1981). They were differentiated from cyanobacteria by their lack of phycobiliproteins (Fig. 2) and the presence of chlorophyll *b*. The recently recognized genus *Prochlorococcus* of marine picoplankters could be included here, even though the major chlorophylls in this genus are

divinyl-Chl *a* and divinyl-Chl *b*. Fourteen *Prochloron* isolates from different localities and hosts have been found to belong to a single species by DNA-DNA hybridization studies (Stam et al., 1985; Holtin et al., 1990). Some of the original distinctions leading to the separation of the Chl *b*-containing oxyphotobacteria from the cyanobacteria are questionable, since at least in one strain of *Prochloroccoccus marinus*, functional phycoerythrin (Lokstein et al., 1999), and genes encoding for phycobiliproteins have been detected (Lokstein et al., 1999). Additionally, phylogenetic analysis of 16S rRNA genes indicate that the three genera of Chl *b*-containing prokaryotes arose independently from each other and from the main plastid line (see Evolutionary Considerations in this Chapter), a result that is supported by the comparative sequence analysis of the respective Chl *a*/*b* binding proteins (Laroche et al., 1996; Vanders taay et al., 1998). Thus "Prochlorophytes" are just greenish cyanobacteria, and are not treated separately here. The recent discovery of Chl *d*-containing symbionts in ascidians (*Acaryochloris marina*, Miyashita et al., 1996) once again demonstrates the evolutionary diversification of light-harvesting capabilities among oxyphotobacteria (see Competition for Light in this Chapter). While the phylogenetic affiliation of *Acaryochloris marina* has not been presented as yet, ultrastructural and chemotaxonomic characters predict that *A. marina* belongs to the cyanobacterial radiation as well.

According to phylogenetic analysis of 16S rRNA sequences, the *Cyanobacteria* are a diverse phylum of organisms within the bacterial radiation, well separated from their closest relatives (Giovanonni, 1988; Wilmotte, 1995; Turner, 1887; Garcia-Pichel, 1999; Fig. 1). These analyses support clearly the endosymbiotic theory for the origin of plant chloroplasts, as they place plastids (from all eukaryotic algae and higher plants investigated) in a diverse, but monophyletic, deep-branching cluster (Nelissen et al., 1995). Phylogenetic reconstructions show that the present taxonomic treatments of the cyanobacteria diverge considerably from a natural system that reflects their evolutionary relationships. For example, separation of the orders *Chroococcales* and *Oscillatoriales* (Nelissen et al., 1995; Reeves, 1996), and perhaps also the *Pleurocapsales* (Turner, 1887; Garcia-Pichel et al., 1998) is not supported by phylogenetic analysis. The heterocystous cyanobacteria (comprising the two orders *Nostocales* and *Stigonematales*) form together a monophyletic group, with relatively low sequence divergence, as low as that presented by the single accepted genus *Spirulina* (Nübel, 1999). A grouping not corresponding to any official genus, the *Halothece* cluster, gathers unicellular strains of diverse morphology that are extremely tolerant to high salt and stem from hypersaline environments (Garcia-Pichel et al., 1998). A second grouping, bringing together very small unicellular ope n-ocean cyanobacteria (picoplankton) includes only marine picoplanktonic members of the genera *Synechococcus* and all *Prochlorococcus*. Several other statistically well-supported groups of strains that may or may not correspond to presently defined taxa can be distinguished. The botanical genus "*Microcystis*" of unicellular colonial freshwater plankton species is very well supported by phylogenetic reconstruction, as is the genus *Trichodesmium* of filamentous, nonheterocystous nitrogen-fixing species typical from oligotrophic marine plankton of the tropics. The picture that emerges from these studies is that sufficient knowledge of ecological and physiological characteristics can lead to a taxonomic system that is largely congruent to the 16S rRNA phylogeny.

A different principle of conversion of light energy into chemical energy is found in the Halobacteria. These archaea are largely confined to surface layers of hypersaline aquatic environments and grow predominantly by chemoorganoheterotrophy with amino or organic acids as electron donors and carbon substrates, generating ATP by respiration of molecular oxygen. In the absence of oxygen, several members are capable of fermentation or nitrate respiration. At limiting concentrations of oxygen, at least three of the described species of Halobacteria (*Halobacterium halobium*, *H. salinarium*, *H. sodomense*) synthesize bacteriorhodopsin (Oesterhelt and Stoeckenius, 1973), a chromoprotein containing a covalently bound retinal. Bacteriorhodopsin is incorporated in discrete patches in the cytoplasmic membrane ("purple membrane"). However, these prokaryotes have only a very limite d capability of light-dependent growth. Only slow growth and one to two cell doublings could be demonstrated experimentally (Hartmann et al., 1980; Oesterhelt and Krippahl, 1983). The fact that rhodopsin-based photosynthesis has been found only in the phylogenetically tight group of Halobacteria may indicate that, because of its lower efficiency, this type of light utilization is of selective advantage only under specific (and extreme) environmental conditions. Further information on the biochemistry, physiology and ecology of this group may be found in the chapters, *Introduction to the Classification of Archaea* and *The Family Halobacteriaceae*.

During the past years, culture-independent 16S rDNA-based methods have been used for the investigation of the composition of natural communities of phototrophic prokaryotes. These studies have provided evidence that more than

one genotype of *Chloroflexus* occur in one hot spring microbial mat and that four previously unkown sequences of cyanobacteria dominate in the same environment (Ferris et al., 1996; Ruff-Roberts et al., 1994; Weller et al., 1992). Similarly, nine different partial 16S rDNA sequences of *Chromatiaceae* and green sulfur bacteria, which differed from all sequences previously known, were retrieved from two lakes and one intertidal marine sediment (Coolen and Overmann, 1998; Overmann et al., 1999a).

However, 16S RNA signatures from natural populations were indistinguishable from those of cultured strains in the case of cyanobacteria with conspicuous morphologies, such as the cosmopolitan *Microcoleus chthonoplastes* (Garcia-Pichel et al., 1996) from intertidal and hypersaline microbial mats or *Microcoleus vaginatus* from desert soils (F. Garcia-Pichel, C. López-Cortés and U. Nübel, unpublished observations). In a similar manner, the 16S rRNA sequence of an isolated strain of *Amoebobacter purpureus* (*Chromatiaceae*) was found to be identical to the environmental sequence dominating in the chemocline of a meromictic salt lake (Coolen and Overmann, 1998; Overmann et al., 1999a). Obviously, the limited number of isolated and characterized bacterial strains rather than an alleged "nonculturability," at least in some cases, accounts for our inability to assign ecophysiological properties to certain 16S rRNA sequence types. This point is illustrated for extremely halotolerant unicellular cyanobacteria by the fact that only after a physiologically coherent group of strains was defined on the basis of newly characterized isolates (Garcia-Pichel et al., 1998) could the molecular signatures retrieved from field samples be assigned correctly.

It has to be concluded that 1) the numbers of species listed in Table 1 do not reflect the full phylogenetic breadth at least in the four groups of anoxygenic phototrophic prokaryotes as well as in morphologically simple *Cyanobacteria*, and 2) that the physiology and ecology of those species of phototrophic prokaryotes that are dominant in the natural environment in some cases may differ considerably from known type strains.

Habitats of Phototrophic Prokaryotes

Bacteria of the *Chloroflexus*-subgroup form dense microbial mats in geothermal springs, often in close association with cyanobacteria. *Chloroflexus aurantiacus* is a thermophilic bacterium which grows optimally between 52 and 60°C and thrives in neutral to alkaline hot springs up to 70–72°C. Of all anoxygenic phototrophic bacteria isolated so far, only *Chloroflexus aurantiacus* is capable of growth up to 74°C. In contrast to the domain Archaea, no hyperthermophilic species are known from the domain Bacteria. The phylogenetically related *Heliothrix oregonensis* grows optimally between 50 and 55°C and is abundant as a flocculant surface layer in a few alkaline springs in Oregon. Hydrothermal springs of 56–66°C, which contain sulfide of geothermal origin, are dominated by a surface layer or a "unispecific" mat of *Chloroflexus* (Castenholz and Pierson, 1995). Because of the absence of cyanobacteria in some of these systems, *Chloroflexus* presumably grows autotrophically (Pierson and Castenholz, 1995). In the presence of O_2, the mats exhibit an orange color whereas they are green under anoxic conditions (Castenholz and Pierson, 1995). The orange color is the result of the enhanced carotenoid biosynthesis under oxic conditions (see Chemotrophic Growth with O_2 in this Chapter). In the absence of sulfide, *Chloroflexus* is present as a distinct orange layer beneath a surface layer of cyanobacteria and may utilize their exudates or the fermentation products generated during decomposition of cyanobacteria. Molecular oxygen represses bacteriochlorophyll synthesis in *Chloroflexus* and often is present at saturation levels in the orange layers. Since bacteriochlorop hylls a and c are still present in this layer, however, it must be assumed that bacteriochlorophylls are synthesized at anoxic conditions during nighttime (Castenholz and Pierson, 1995).

Green and purple sulfur bacteria often form conspicuous blooms in non-thermal aquatic ecosystems (Figs. 4, 5A, 5B), although moderately

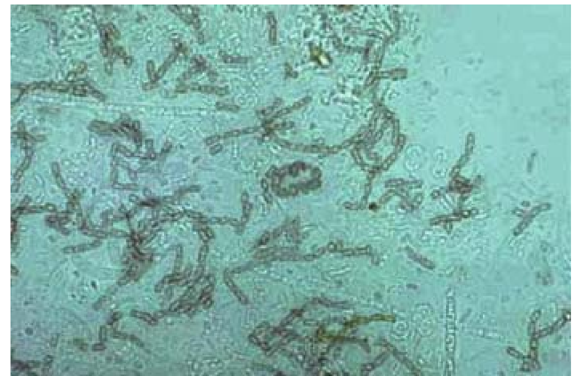

Fig. 4. Bright field photomicrograph of the bacterioplankton community thriving in the chemocline of the meromictic Buchensee (near Radolfzell, Germany) during autumn. The dominant anoxygenic phototroph at this time of the year is the green sulfur bacterium *Pelodictyon phaeoclathratiforme* (brown cells, which appear in chains or netlike colonies). In addition, phototrophic consortia ("*Pelochromatium roseum*," one consortium in the center) are found. Similar to *Pld. phaeoclathratiforme*, most of the colorless bacterial cells found in the chemocline contain gas vesicles as is evident from their highly refractile appearance in the bright field.

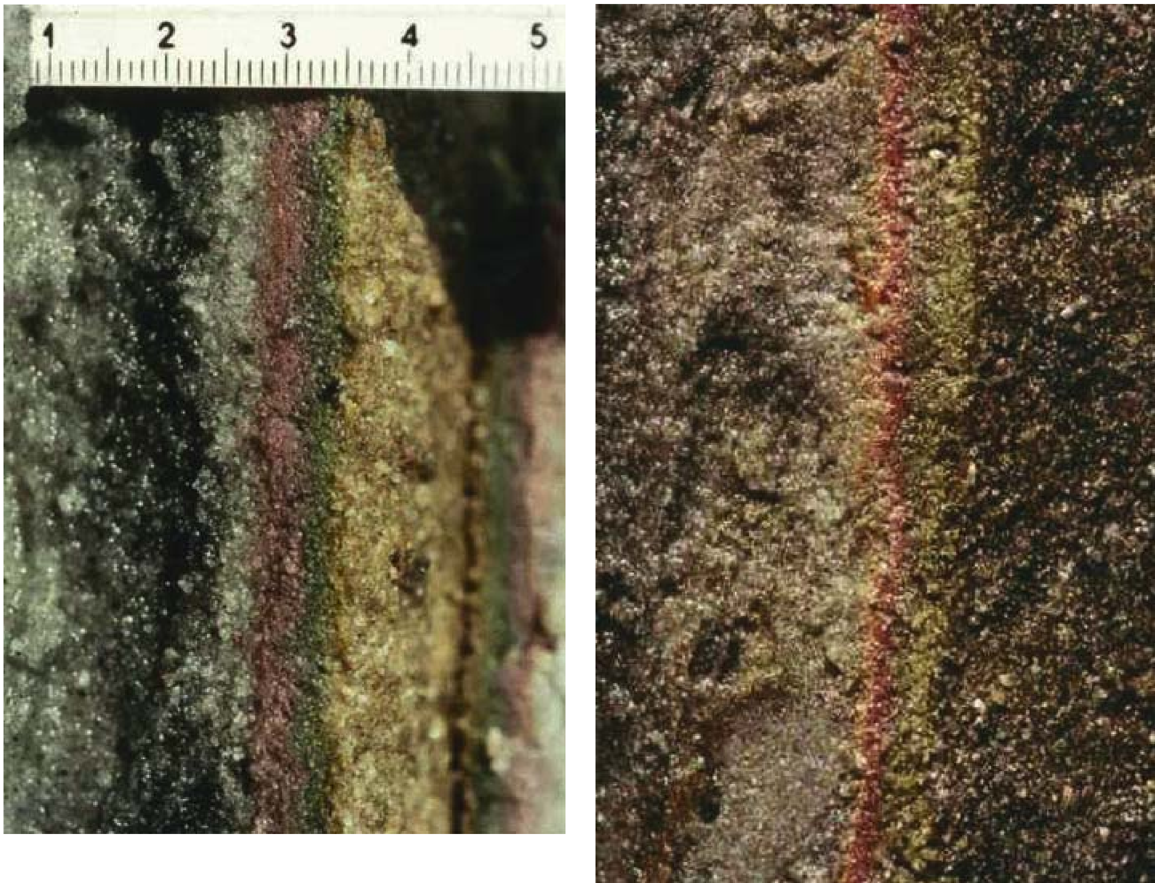

Fig. 5. Multilayered microbial mat as it is regularly found in the sandflats of Great Sippewissett Salt Marsh (Cape Cod, Massachusetts, USA). A. In most instances, the mats consist of a top green layer, an intermediate purple layer, and a grayish to blackish bottom layer. B. Fully developed microbial mats consist (from top) of an olive-green layer of diatoms and cyanobacteria, a green layer consisting mostly of cyanobacteria, a purple layer of purple sulfur bacteria, a peach-colored layer formed by BChl *b*-containing purple sulfur bacteria (morphologically similar to *Thiocapsa pfennigii*), and a greyish to blackish bottom layer.

thermophilic members of the genera *Chromatium* and *Chlorobium* have been described from hot spring mats (Castenholz et al., 1990). *Chlorobium tepidum* occurs in only a few New Zealand hot springs at pH values of 4.3 and 6.2 and temperatures up to 56°C. *Chromatium tepidum* was found in several hot springs of western North America at temperatures up to 58°C and might represent the most thermophilic proteobacterium (Castenholz and Pierson, 1995). In a recent compilation (van Gemerden and Mas, 1995), 63 different lakes and 7 sediment ecosystems harboring phototrophic sulfur bacteria were listed. Cell densities between 10^4 and $10^7 \cdot ml^{-1}$ and biomass concentrations between 10 and 1000 µg bacteriochlorophyll$\cdot l^{-1}$ are common in pelagic habitats. Of the purple sulfur bacteria, *Chromatiaceae* are typically found in freshwater and marine environments (Fig. 5A, B) whereas *Ectothiorhodospiraceae* inhabit hypersaline waters. The phototrophic sulfur bacteria grow preferentially by photolithoautotrophic oxidation of reduced sulfur compounds and are therefore limited to those environments where light reaches anoxic, sulfide-containing bottom layers. Because light and sulfide occur in opposing gradients, growth of phototrophic sulfur bacteria is confined to a narrow zone of overlap and is only possible if the chemical gradient of sulfide is stabilized against vertical mixing. In pelagic environments like lakes or lagoons, chemical gradients are stabilized by density differences between the oxic and anoxic water layers. Such density differences are either the result of thermals tratification and mostly transient (as in holomictic lakes) or are caused by high salt concentrations of the bottom water layers, in which case stratification is permanent (meromictic lakes). Pelagic layers of phototrophic sulfur bacteria extend over a vertical distance of 10 cm (van Gemerden and Mas, 1995; Overmann et al., 1991a) up to 30 m (Repeta et al., 1989) and reach biomass concentrations of 28 mg bacteriochlorophyll$\cdot l^{-1}$ (Overmann et al., 1994).

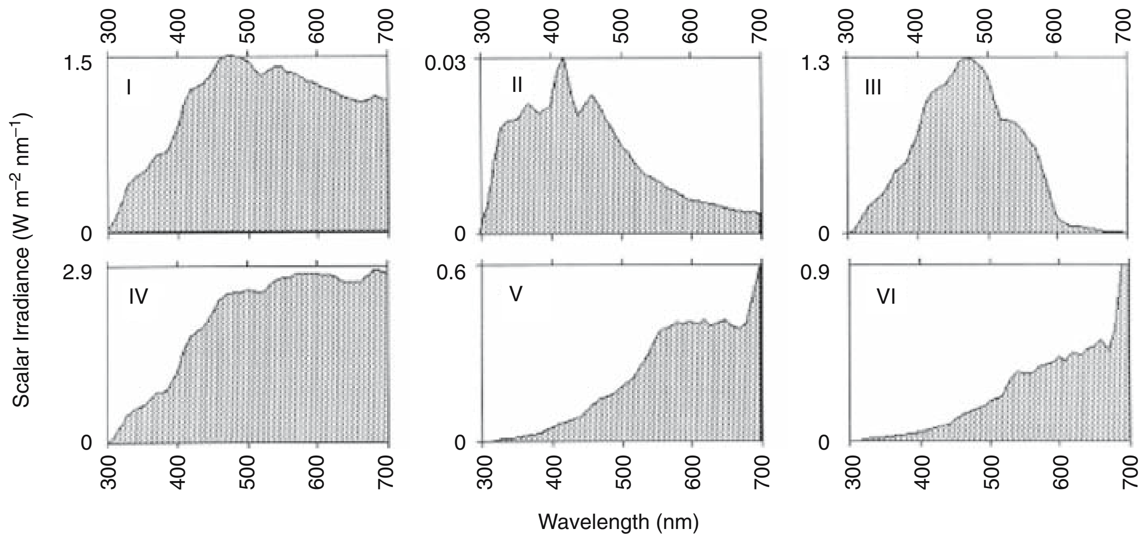

Fig. 6. Effects of the habitat on the physical exposure of cyanobacteria. The spectral scalar irradiance (sun and sky radiation) incident at ground level at noon in a clear midsummer day at 41°N is plotted in Plate I. The rest of the plates depict the in situ scalar irradiance experienced by cyanobacterial cells thriving in several habitats exposed to the incident fluxes in plate I (note different scales). Plate II: a "strong shade" habitat (North-facing surface illuminated by extremely diffuse sky radiation only), where scalar irradiance is very low but the relative importance of UV is enhanced. Plate III: a planktonic habitat (under 1 m of clear open-ocean water), where all fluxes remain fairly high and UVB and visible are more strongly attenuated than UVA. Plate IV: the surface of beach (quartz, feldspar) sand, where all UVB, UVA, and visible are higher than incident (by 120, 150, and 205%, respectively) due to light trapping effects. Plate V: 300-m deep in a wet topsoil, where UVB and U VA have been attenuated below 5% of incident but ca. 20% of the visible light remains. Plate VI: scalar irradiance within the thallus of the terrestrial cyanobacterial lichen *Collema* sp. Modified from Castenholz and Garcia-Pichel, 1999, after data from the following sources: F. Garcia-Pichel (unpublished observation); Garcia-Pichel, 1995; Büdel et al., 1997; and Smith and Baker, 1981.

Littoral sediments represent the second type of habitat of phototrophic sulfur bacteria. In these systems, turbulent mixing is largely prevented by the sediment matrix, and diffusion is the only means of mass transport. Gradients of light and sulfide are much steeper, and the fluxes of sulfide much larger compared to the pelagic environment. These conditions allow layers of phototrophic sulfur bacteria in sediments to reach much higher biomass densities (up to 900 mg bacteriochlorophyll·dm^{-3}; van Gemerden et al., 1989) than in lakes. At the same time, the layers are very narrow (1.3–5 mm; van Gemerden and Mas, 1995; Fig. 5A). This vertical distribution of anoxygenic phototrophic biomass ultimately determines the significance of microbial sulfide oxidation for the sulfur cycle in these ecosystems (see Significance of Anoxygenic Photosynthesis for the Pelagic Carbon and Sulfur Cycles in this Chapter). The spectral compos ition of light available for anoxygenic photosynthesis is considerably different between pelagic and benthic habitats (Fig. 6) and selects for different species of anoxygenic phototrophic bacteria. Whereas light of the blue to yellow-green wavelength bands dominates the depths of most lakes, infrared light is an important source of energy in benthic microbial mats (see Light Energy and the Spectral Distribution of Radiation in this Chapter).

The dominance of certain species of green sulfur bacteria (Fig. 4) or *Chromatiaceae* in pelagic environments in many cases can be explained by their specific light-harvesting capabilities (see Light Absorption and Light Energy Transfer in Prokaryotes and Competition for Light in this Chapter) and other phenotypic traits. Typically, those species that have been isolated from natural blooms in lakes are obligately photolithotrophic, lack assimilatory sulfate reduction, cannot reduce nitrate, and assimilate only few organic carbon sources (see Carbon Metabolism of Phototrophic Prokaryotes in this Chapter). This applies not only to all green sulfur bacteria but also to the dominant species of *Chromatiaceae*. Obviously, in the chemocline of lakes the metabolic versatile *Chromatiaceae* species have no selective advantage. As judged from the physiological characteristics of strains of phototrophic sulfur bacteria isolated from sediments, the pronounced diurnal variations in oxygen concentrations and salinity, together with the different light quality, select for different species composition in benthic microbial mats. The purple sulfur bacterium *Chromatium* (and the multicellular gliding colorless sulfur bacterium *Beggiatoa*) are found in many microbial mats

and exhibit diurnal vertical migrations in response to the recurrent changes in environmental conditions (Jørgensen, 1982; Jørgensen and Des Marais, 1986). Microbial mats of intertidal sediments are typically colonized by the immotile purple sulfur bacterium *Thiocapsa roseopersicina* and small motile thiobacilli (van den Ende et al., 1996).

In contrast to the phototrophic members of the γ-Proteobacteria, purple nonsulfur bacteria of the α- and β-subclasses of *Proteobacteria* do not appear to form dense accumulations under natural conditions (Biebl and Drews, 1969; Swoager and Lindstrom, 1971; Steenbergen and Korthals, 1982). However, purple nonsulfur bacteria can be readily isolated from a wide variety of marine, lacustrine and even terrestrial environments (Imhoff and Trüper, 1989; J. Overmann, unpublished observation). While comprehensive comparative quantitation of the ecological importance of purple nonsulfur bacteria is still lacking, as many as ca. 10^6 c.f.u. of purple nonsulfur bacteria could be cultivated per cm^3 of sediment in coastal eutrophic settings (Guyoneaud et al., 1996).

Generally, aerobic phototrophic bacteria thrive in eutrophic marine environments. Obligately aerobic bacteria containing bacteriochlorophyll *a* have been isolated from beach sand and seaweeds (thalli of *Enteromorpha linza* and *Sargassum horneri*; Shiba et al., 1979), and in some cases also from freshwater ponds and microbial mats. At least some of the aerobic phototrophic bacteria apparently can survive in situ temperatures of up to 54°C (Yurkov and Beatty, 1998). Aerobic phototrophic bacteria were isolated from hydrothermal plume water of a black smoker 2000 m below ocean surface (Yurkov and Beatty, 1998); acidophilic strains could be isolated from acidic mine drainage. Typically, *Methylobacterium* species are isolated from foods, soils and leaf surfaces (Shimada, 1995). Photosynthetic *Rhizobium* strains are widely distributed in nitrogen-fixing stem nodules of the tropical legume *Aeschynomene* spp. where they are present as symbiosomes. Similar strains have also been found in root and hypocotyl nodules of *Lotononis bainesii* (Fabaceae). These photosynthetic rhizobial and regular symbiosomes differ in that the former contains only one large spherical bacteroid. The photosynthesis of these endosymbionts may provide energy for nitrogen fixation and permit a more efficient growth of the host plant, since up to half of the photosynthate produced by legumes is allocated to nitrogen fixation (Fleischman et al., 1995).

Heliobacteriaceae appear to be primarily soil bacteria and have been isolated from dry paddy fields or other soils throughout the world (Madigan and Ormerod, 1995). Bacteria of this family may even represent the dominant anoxygenic phototrophic bacteria in soil (Madigan, 1992). Occasionally, strains also have been isolated from lakeshore muds and hot springs (Amesz, 1995; Madigan and Ormerod, 1995). *Heliobacterium modesticaldum* grows up to 56°C (Kimble et al., 1995). Spore formation may offer a selective advantage to *Heliobacterium modesticaldum*, *Heliophilum fasciatum*, and *Heliobacterium gestii* in their main habitat (rice field soil), which undergoes periodic drying and concomitantly becomes oxidized (Madigan, 1992). During growth of the rice plants, organic compounds excreted by their roots could provide sufficient substrates for photoheterotrophic growth of the *Heliobacteriaceae*.

Cyanobacteria as a group exhibit the widest range of habitats of all phototrophic prokaryotes due to the ubiquity of water, their preferred electron donor for the reduction of CO_2. In principle, cyanobacteria can thrive in any environment that has, at least temporarily, liquid water and sunlight. They are known from Antarctic endolithic habitats and from hot springs. More than 20 species of cyanobacteria (Castenholz and Pierson, 1995) are thermophilic. Effectively, however, no cyanobacteria are known from acidic environments (below pH 4.5) and competition with eukaryotic microalgae or higher plants may restrict their growth in other environments. Cyanobacteria are found in the plankton of coastal and open oceans and in freshwater and saline inland lakes. They thrive in the benthos of marine intertidal (Fig. 5B), lacustrine and fluvial waters and in a large variety of terrestrial habitats (soils, rocks, trees). Symbiotic associations are common.

In the marine plankton, the phycoerythrin-containing *Synechococcus* often represents a major fraction of all primary producers. The same holds true for *Prochlorococcus* (Campbell and Vaulot, 1993; Chisholm et al., 1988; Olson et al., 1990b). Compared with the high number of cyanobacterial species found in freshwater plankton, intertidal areas, and hypersaline environments, the diversity of this group is very limited in the open ocean (Carr and Mann, 1994). The predominant group invariably consists of small (<2 m) mostly nonmotile, non-nitrogen-fixing single cells assigned to the genus *Synechococcus*, which is found in the photic zone of all oceans except in the coldest areas. As a characteristic feature, the cells contain phycoerythrin as accessory photopigment which confers an orange autofluorescence on the cells. Despite their similar phenotype, marine *Synechococcus* strains are genetically heterogenous (Waterbury et al., 1986). An important component of the phytoplankton in tropical and subtropical oceans are the filamentous *Trichodesmium* spp. (Carr

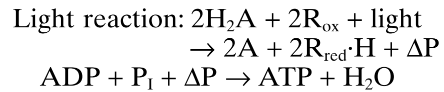
and Mann, 1994). The bundle and aggregate forming *Trichodesmium* typically develop into blooms that can extend kilometers long and are detected on the surface of oligotrophic tropical and subtropical oceans with the naked eye or with satellite imagery from space. The success of *Trichodesmium* can be mainly traced to the highly efficient nitrogen-fixing capacity of these nonheterocystous cyanobacteria. Their activities attain global magnitude for the nitrogen cycle (Capone et al., 1977). Heterocystous, nitrogen-fixing cyanob acteria of the genera *Nodularia*, *Anabaena*, and *Aphanizomenon* bloom in mesotrophic and eutrophic fresh and brackish waters. Together with the blooms of the nonheterocystous genus *Microcystis*, these cyanobacteria have become a real environmental concern, not only because of their effects of overall water quality but also because of their ability to produce toxins, which are known to have caused the deaths of humans and cattle. In the chemocline of stratified lakes, deep blooms of cyanobacteria occur frequently.

Edaphic cyanobacteria are also distributed worldwide, especially in soils of basic pH; sheathed oscillatorian forms (*Microcoleus vaginatus*, *"Schizothrix"* spp.), along with heterocystous ones (*Nostoc*, *Scytonema*) are of major ecological relevance in arid and semiarid regions where growth of higher plants is restricted. In such environments, cyanobacteria adopt a life strategy of resistance to desiccation (Potts, 1994) making use of the few occasions in which liquid water is available from rain or dew. Very intense productivity spurts occur in a matter of minutes after wetting (Garcia-Pichel and Belnap, 1996). The so-called "cyanobacterial desert crusts" contribute significantly to the biogeochemistry and to the physical stability of arid soils. Other important terrestrial habitats of cyanobacteria are the surface or subsurfa ce of rocks: extensive endolithic cyanobacterial communities, usually dominated by members of the genus *Chroococcidiopsis*, have been described from tropical, desert and polar environments (Friedmann, 1982; Wessels and Büdel, 1995).

In the course of evolution, cyanobacteria have entered into symbiotic associations with a multitude of organisms. These have reached a wide range in the degree of interdependence between partners (see Symbiosis between Phototrophic Bacteria and Eukaryotes in this Chapter).

Principles and Prerequisites of Photosynthesis

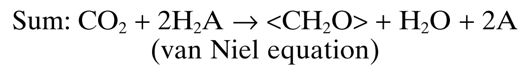
Bacterial photosynthesis can be divided into two different types of reactions 1) the light reaction, in which light energy is trapped and converted into ATP (via a proton-motive force ΔP) and a reduced redox carrier $R_{red}\cdot H^+$, and 2) the so-called dark reaction of biosynthetic carbon reduction.



$$\text{Light reaction: } 2H_2A + 2R_{ox} + \text{light} \rightarrow 2A + 2R_{red}\cdot H + \Delta P$$

$$ADP + P_I + \Delta P \rightarrow ATP + H_2O$$

$$\text{Dark reaction: } CO_2 + ATP + 2R_{red}\cdot H + H_2O \rightarrow \langle CH_2O \rangle + ADP + Pi + 2R_{ox}$$



$$\text{Sum: } CO_2 + 2H_2A \rightarrow \langle CH_2O \rangle + H_2O + 2A$$

(van Niel equation)

Microorganisms have found different ways to accomplish these two tasks.

Light Energy and the Spectral Distribution of Radiation

The present day solar irradiance at the average distance of Earth to the sun and outside the atmosphere (the so-called *solar constant*) is $1353\cdot W\ m^{-2}$ (Kirk, 1983). The spectral energy distribution of this solar radiation approximates that of a black body at 6000°K (the surface temperature of the sun). According to Wien's Law, a black body at this temperature has a maximum emission of electromagnetic energy at about 480 nm. The actual spectral energy distribution of solar radiation exhibits minima which reflect the absorption bands of hydrogen in the outer atmosphere of the sun (Fig. 7). The total light energy received by the Earth is $5.46\cdot 10^{24}\ J\cdot year^{-1}$, which would correspond to $339.4\ W\cdot m^{-2}$. The actual solar (time and space-averaged) irradiance reaching the surface of the Earth amounts only to $160\ W\cdot m^{-2}$ (Gates, 1962; Dietrich et al., 1975). This large reduction is due to Raleigh scattering by air molecules and dust particles, and of light absorption by water vapor, O_2, O_3 and CO_2 during the passage of radiation through the Earth's atmosphere. Concomitantly, the spectral distribution of solar irradiance is changed especially because water vapor absorbs infrared light (Fig. 7). At sea level, light of the wavelength regions 400–700 nm (PAR, photosynthetically available radiation) constitutes 50% of this irradiance (Kirk, 1983).

Based on estimates for global primary productivity, only 0.13% of the flux of solar energy reaching the surface of the Earth is converted into chemical energy by photosynthesis (Odum, 1983; see Introduction in this Chapter). Under natural conditions, photosynthesis of the various groups of phototrophic prokaryotes is limited by different environmental factors including light, reduced sulfur compounds, organic carbon substrates, oxygen, and temperature. The physical

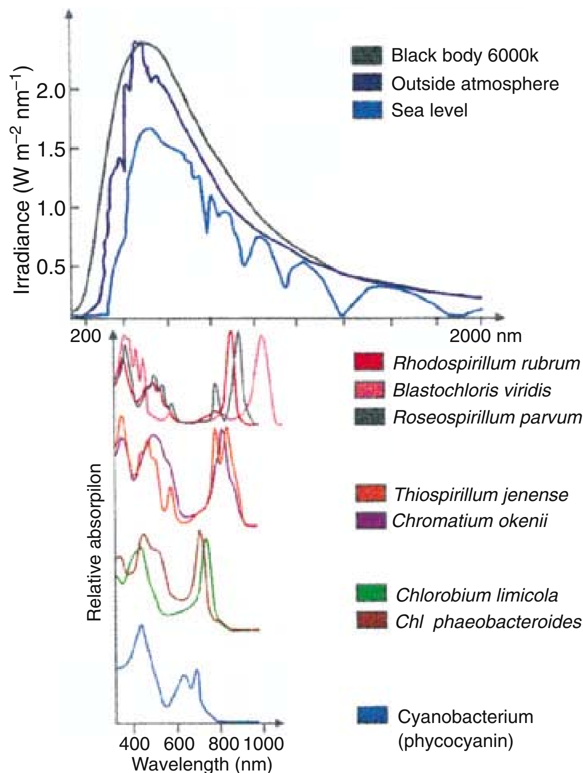


Fig. 7. Spectral energy distribution of solar radiation outside the atmosphere and at sea level as compared to the absorption spectra of various phototrophic bacteria. Absorption spectra of the purple nonsulfur bacterium *Rhodospirillum rubrum* (containing BChl *a*, spirilloxanthin), *Blastochloris viridis* (BChl *b*, 1,2-dihydroneurosporene), and *Roseospirillum parvum* (BChl *a*, spirilloxanthin, lycopenal), of the Chromatiaceae species *Thiospirillum jenense* (BChl *a*,lycopene, rhodopin) and *Chromatium okenii* (BChl *a*, okenone), of the Chlorobiaceae species *Chlorobium limicola* (BChl *c*, chlorobactene) and *Chlorobium phaeobacteroides* (BChl *e*, i sorenieratene) and of a cyanobacterium (Chl *a*, phycocyanin) are depicted.

characteristics of the medium have, through processes of absorption and scattering, a large influence on the available radiation (see Competition for Light in this Chapter). As a second major limiting factor, the availability of nutrients limits the growth of phototrophic bacteria and as a consequence, photosynthetic energy conversion.

Surface environments exposed to sky radiation (as in strong shades) may be enriched in blue and UV radiation (Fig. 6). Water is the major light-absorbing component only in very clear open ocean and inland lakes. It strongly absorbs light of the ultraviolet, red and especially infrared (wavelengths around 745 and 960 nm). As a consequence, tens of meters below the surface of clear waters the spectrum is enriched in blue wavelengths. Several meters below coastal or most lacustrine water surfaces, the spectrum is enriched towards the green wavelengths, and deep(several millimeters) in the photic zones of sediments and soils infrared wavelengths dominate. Yellow substance in lakes is mostly of terrestrial origin and particularly absorbs light of the ultraviolet and blue portion of the spectrum (Kirk, 1983). In dystrophic lakes in which high concentrations of humic compounds are the major light-absorbing components, light of the red wavelength range prevails such that green-colored species of green sulfur bacteria have a selective advantage over their brown-colored counterparts or purple sulfur bacteria (Parkin and Brock, 1980a).

In benthic and soil ecosystems, light quality differs fundamentally from that in the pelagic environment. In the visible wavelength range, radiation is strongly attenuated by mineral and biogenic particles. In sandy sediments light attenuation occurs preferentially in the wavelength range of blue light due to the reflection by sand grains (Jørgensen and Des Marais, 1986; Kühl and Jørgensen, 1992). The presence of iron minerals results in an enhanced attenuation of UV and blue wavelengths (Garcia-Pichel and Belnap, 1996). In contrast, absorption of infrared light by sediment particles is low and absorption by water is negligible due to the short optical pathlength. As a consequence of the optical properties of the sediment particulates, the red and infrared portion of the spectrum penetrate to the deepest levels. Multiple scattering causes the light fields to become rapidly diffuse, so that bacteria thriving within these environments receive light from all directions. The parameter measuring light received at a point in space from all directions is called scalar irradiance (E_0, or photon fluence rate). A third important, but counterintuitive, phenomenon is the presence of maximum irradiance values close to the surface, which are even larger than the incident scalar irradiance (Fig. 6). Below this surficial zone where the E_0 maximum occurs, E_0 attenuates exponentially (Jørgensen and Des Marais, 1986; Jørgensen and Des Marais, 1988; Kühl and Jørgensen, 1992; Lassen et al., 1992). For visible light, the measured photic depths (depths where E_0 is attenuated to 1% of the incident) varied between 3.1 mm for quartz sand and 0.45 mm for silty muds (Garcia-Pichel and Bebout, 1996b). In the ultraviolet (UV) at 310 nm, the corresponding depths were only 1.25 and 0.23 mm.

Light Absorption and Light Energy Transfer in Prokaryotes

Principle

The chlorophyll-based photosystems of bacteria convert electromagnetic energy into a redox gradient. The redox reactions are initiated by

absorption of electromagnetic energy, leading to a transition of specific molecules into an excited electronic state. An increase in the electronic energy of a molecule requires more energy than changes in vibrational or rotational states. Since the energy of light quanta is inversely related to their wavelength (Planck's Law), molecules absorb electromagnetic radiation of short wavelengths (ultraviolet and visible light) during changes in electronic energy, and longer wavelengths during changes in vibrational (near infrared radiation) and rotational energy (far infrared radiation and microwaves). Changes in the electronic state of molecules, and thus photochemically driven redox reactions by light absorption, can only occur by absorption of quanta of wavelengths <1240 nm (i.e., an energy larger than 1 eV per electron). This fact obviously limits the wavelength range that is usable for photochemical reactions. The major fraction of solar energy is present in the wavelength range between 400 and 750 nm. These wavelengths can only be harvested by organic molecules containing delocalized π-electrons in conjugated double bonds (Fig. 7).

Pigments and Light-Harvesting Complexes

To capture light for photosynthesis, phototrophic organisms employ three classes of pigment molecules: magnesium porphyrins (chlorophylls and bacteriochlorophylls, also called chlorins), open-chain tetrapyrrole bilin pigments (phycobilins), and carotenoids. However, other types of chromophores may be used in non-photosynthetic light-harvesting, as is the case of the flavins and pterines of DNA-photolyase (Tanada et al., 1997) and in specific regulatory photoreceptors (Halobacteriaceae, bacteriorhodopsin). Until recently it appeared that only the magnesium-containing chlorin molecules were employed as the major photosynthetic pigment. The aerobic photosynthetic bacterium *Acidiphilium rubrum* is the first photosynthetic organism known to employ zinc-containing bacteriochlorophyll *a* as the photochemically active pigment (Wakao et al., 1996).

Free molecules remain in the excited singlet state for as little as 10^{-8} to 10^{-9} sec and rapidly return to the ground state (fluorescence). Through the multiplicity of vibrational and rotational states associated with each electronic energy level, two different electronic energy states may overlap. In such molecules the lowermost electronic energy level (the lowest excited singlet state) is reached in a rapid series of radiationless transitions with a concomitant small decrease in free energy. The wavelengths emitted during the subsequent return of the electron to the ground state therefore is longer than those wavelengths that were absorbed (Stokes shift). Chlorophylls and bacteriochlorophylls exhibit two major absorption bands (Table 2) and, when excited in the dissolved state, a corresponding red (685 nm for chlorophyll a) or infrared (786 nm for bacteriochlorophyll *a*) fluorescence. In photosynthetically active c ells, however, only about 1% of the absorbed light energy is lost by fluorescence. It is a characteristic of the photosynthetic apparatus of living organisms, that fluorescence (hence loss of already absorbed energy) is minimized. Instead, most of the energy absorbed by the antenna pigments is channeled by vectorial and radiationless inductive dipole resonance toward the reaction centers, where it drives the photochemical redox reactions. The specific coordination of pigment molecules in photosynthetic organisms favors inductive resonance and photochemical reactions over fluorescence. Within the photosynthetic antenna, a fine modulation of the

Table 2. Major absorption maxima of chlorins in whole cells and in the dissolved state, and fluorescence maxima of whole cells of phototrophic prokaryotes.

	Absorption maxima (nm)	Fluorescence maxima (nm)	
Chlorin	Whole cells	Acetone extracts	Whole cells
Chl *a*	670–675	435, 663	680–685
Chl *b*	n.d.	455, 645	(in acetone 652)
Chl *d*	714–718	400, 697	(in acetone 745)
BChl *a*	375, 590, 805, 830–911	358, 579, 771	907–915
BChl *b*	400, 605, 835–850, 986–1035	368, 407, 582, 795	1040nm
BChl *c*	457–460, 745–755	433, 663	775
BChl *d*	450, 715–745	425, 654	763
BChl *e*	460–462, 710–725	459, 648	738
BChl *g*[a]	375, 419, 575, 788	365, 405, 566, 762	n.d.

[a]Bacteriochlorophyll *g* of the Heliobacteriaceae shows structural relationships to chlorophyll *a* because it contains a vinyl group on tetrapyrrole ring I. Like in bacteriochlorophylls *a* and *b*, pyrrole ring II is reduced, however, and the esterifying alcohol is famesol as in bacteriochlorophylls of green sulfur bacteria. As for bacteriochlorophyll *a* or *b*, the reduced state of ring II in bacteriochlorophyll *g* causes an additional though smaller absorption maximum, the Q_x band at about 567nm.
n.d., not determined.

absorption properties of the pigments occurs because of differences in their binding to the antenna proteins, so that the vectorial excitation cascade is thermodynamically favored (i.e., in a sequence involving pigments with progressively longer absorption maxima). The resulting small differences in the energy level of antenna pigments directs the transfer of excitation energy more or less to the reaction center.

A second consequence of the interactions between pigment molecules and proteins is the shift of the absorption peaks of the former towards longer wavelengths. In the case of chlorophyll *a*, the shift is comparatively small while it is larger in bacteriochlorophyll-protein complexes (up to 650 nm in bacteriochlorophyll *b*-containing phototrophic bacteria; Table 2). The shift for most carotenoids in association with proteins is as small as for chlorophyll *a*. In intact cells, carotenoids absorb mainly in the 420–550 nm wavelength region. In contrast, binding of one type of porphyrin pigment (bacteriochlorophyll *a*) by different apoproteins has led to a considerable diversification of the long-wavelength absorption maxima in purple sulfur and nonsulfur bacteria (Fig. 7). Obviously the role of proteins in pigment-protein-complexes is not confined to the proper coordination of pigment molecules but als o can represent a means to exploit wavelength regions not utilized by other phototrophic organisms. Especially in intertidal microbial mats, variations in the fine structure of the pigment-protein complexes is a means of ecological niche separation (see Competition between Phototrophic Bacteria in this Chapter). The absorption spectra of whole cells of phototrophic bacteria seem to have evolved in such a way that almost the entire electromagnetic spectrum suitable for electrochemical reactions can be exploited (Fig. 7).

The first step of porphyrin synthesis is the formation of 5-amino levulinic acid (δ-ALA). In *Chloroflexus aurantiacus*, β- and γ-Proteobacteria, *cyanobacteria*, *Heliobacteriaceae*, and green sulfur bacteria, δ-ALA is synthesized from glutamate (C5-pathway), which therefore appears to represent the more ancestral pathway. In contrast, α-Proteobacteria as well as yeasts, fungi, and animals form δ-ALA by the ALA synthase-mediated condensation of glycine with succinyl-CoA (Beale, 1995; Oh-Hama, 1989; Oh-Hama et al., 1991).

All (bacterio)chlorophylls exhibit two major absorption bands (Table 2), leaving a considerably wide gap in the absorption spectrum. The latter is partially complemented by the absorption spectrum of carotenoids found in all phototrophic bacteria or by a range of phycobiliproteins in most cyanobacteria. Owing to the presence of up to 15 conjugated double bonds, carotenoids absorb light at the short wavelength end of the visible range.

The light-harvesting antenna complexes of green sulfur bacteria and *Chloroflexus* are extramembranous ovoid organelles, so-called chlorosomes, which are attached to the inner surface of the cytoplasmic membrane and contain bacteriochlorophylls *c*, *d*, or *e*. Chlorosomes are exceptional in that proteins do not seem to be involved as ligands for most of the antenna bacteriochlorophyll molecules. Instead, interactions between the bacteriochlorophylls themselves govern the absorptive properties of the photosynthetic antenna in green sulfur bacteria (Blankenship et al., 1995; Fig. 3A). In all other phototrophic prokaryotes studied, chlorins and carotenoid molecules occur in complexes with proteins.

Chlorins in pigment-protein complexes are noncovalently bound by histidine imidazole residues, which ligate the central magnesium atom of the porphyrin (Drews and Golecki, 1995). In some cases (e.g., heliobacterial reaction center protein; Vermaas, 1994) the histidine residues are replaced by asparagine, glutamine or arginine, which may function as ligands. Noncovalent binding of carotenoids seems to be mediated largely by hydrophobic interactions. In the purple nonsulfur bacteria, the *Chromatiaceae*, and *Ectothiorhodospiraceae*, all antenna complexes (and reaction centers) are located within intracytoplasmic membranes that are differentiated from, but contiguous to, the cytoplasmic membrane of the cell. In purple nonsulfur bacteria, *Chromatiaceae*, and *Ectothiorhodospiraceae*, intracellular membranes occur as vesicles, stacks, lamellae, or tubules (Figs. 2 and 3B). Most photosynthetic species of the α-Proteobacteria (*Rhodocyclus purpureus*, *Rhodocyclus tenuis*, *Rubrivivax gelatinosus*) do not form extensive intracellular membrane systems. The photochemical apparatus of purple nonsulfur bacteria is confined to the intracellular membrane system, whereas the enzyme complexes of the respiratory chain and transport systems are located in the cytoplasmic membrane (Bowyer et al., 1985). This functional differentiation does not seem to exist in purple sulfur bacteria (*Allochromatium vinosum*, *Ectothiorhodospira mobilis*; Drews and Golecki, 1995). With one known exception, the photosynthetic apparatus in *cyanobacteria* is located on specialized intracellular membranes (thylakoids). Thylakoids may be either single or stacked, a nd are distributed concentrically (parallel to the cytoplasmatic membrane), radially, or randomly (Fig. 2). Like in chloroplasts, lateral heterogeneity (spatial separation of photosystem I in stroma lamellae and of photosystem II in grana stacks) has been found in "Prochlorophytes."

In *Heliothrix*, the *Heliobacteriaceae*, some purple nonsulfur bacteria (e.g., *Rhodocyclus tenuis*; Wakim and Oelze, 1980) and one cyanobacterium (*Gloeobacter violaceus*), the photosynthetic apparatus is located in the cytoplasmic membrane.

The light-harvesting antenna complexes of purple nonsulfur and purple sulfur bacteria are composed of two small, membrane-spanning α- and β-polypeptides to which bacteriochlorophyll *a* or *b*, and carotenoids are noncovalently bound. The polypeptide monomers aggregate within the membrane to form ring structures of 16 (LHI) or 9 (LHII) subunits, respectively (McDermott et al., 1995; Fig. 3B). According to the current structural model, the ring of 16 LHI-subunits surrounds one reaction center. Several LHII-aggregates transfer energy to this supercomplex.

In *Cyanobacteria*, light-harvesting chlorophyll *a* is present in two different types of protein complexes. The CP43 and CP47 core-antenna complexes are tightly associated with photosystem II (Barry et al., 1994). In photosystem I, however, antenna chlorophylls are an integral part of the reaction center itself (Golbeck, 1994; Fig. 3C).

A third class of light-harvesting complexes are phycobilisomes. They occur in the division *Cyanobacteria* (and in the plastids of red algae and some other groups of eukaryotic algae), and in most species are the main light-harvesting antenna structures of these bacteria. Under the electron microscope, phycobilisomes appear as hemidiscoidal to cylindrical particles attached to the cytoplasmic side of the thylacoids. In *Gloeobacter violaceus*, the cytoplasmic membrane is underlain by a continuous subcortical layer containing the phycobilisomes. Light energy absorbed by phycobilisomes is transferred preferentially to photosystem II, with chlorophyll *a* serving as antenna for photosystem I. However, short-term or partial spillover may occur, as the phycobilisomes are quite mobile (van Thor, J.J., et al., 1998). While the blue and red wavelength range is absorbed mainly by chlorophyll; the phycobilisomes harvest the blue-green, yellow, and orange regions (450–655 nm) of the light spectrum, thereby extending the spectral range of photosynthetic light-harvesting considerably (Fig. 7). The capacity of forming phycobilisomes is of selective advantage for the colonization of low light aquatic habitats (see Competition between Phototrophic Bacteria in this Chapter). Most (80%) of the phycobilisome mass is water-soluble phycobiliproteins, which contain open-chain tetrapyrrole chromophores (the phycobilins). Four types of phycobilins are known, the blue-colored phycocyanobilin (PCB), red-colored phycoerythrobilin (PEB), yellow-colored phycourobilin (PUB), and purple-colored phycobiliviolin (PXB, also sometimes abbreviated CV). They are found in various molar ratios, and form part of four recognized types of phycobiliproteins: allophycocyanin (APC), phycocyanin (PC), phycoerythrocyanin (PEC), and phycoerythr in (PE). In contrast to (bacterio)chlorophylls, the chromophores are covalently bound by thioether linkages to cysteine residues of the apoproteins. Up to three chromophores may be bound to a single α- or β-polypeptide. The phycobiliproteins are heteromonomers forming $(\alpha\beta)_3$ trimeric disks. Together with chromophore-free linker polypeptides, these disks are assembled in aggregates, the phycobilisomes, which are attached to the cytoplasmic side of photosystem II (Fig. 3C). Peripheral rod elements consisting of phycoerythrin (which harbors PEB, and sometimes also PUB) or phycoerythrocyanin (with PCB and PXB), and phycocyanin (with PCB, and in some cases small amounts of PEB) are arranged in a hemidiscoidal fashion around a core substructure consisting largely of allophycocyanin (with PCB). The different absorption properties of the phycobilins are the result of differences in the number of conjugated double-bonds (the conjugated π-electron system is shorter for PEB and PUB), in the side chains of the tetrapyrrole prosthetic groups, including also chemically distinct chromophore-protein linkages, and in the protein environments of the chromophores (Sidler, 1994). Light energy is absorbed mainly by the peripheral rods, and transferred rapidly by radiation-less downhill energy transfer from phycoerythrin (absorption maximum 495– 575 nm) or phycoerythrocyanin (575 nm) to phycocyanin (615–640 nm). Finally, allophycocyanin (650–655 nm) transfers the energy to photosystem II.

Not all cyanobacteria possess all of these different phycobiliproteins. Those synthesizing exclusively APC and PC appear blue-green. Many heterocystous cyanobacteria also produce PEC in addition to APC and PC (Bryant et al., 1982); these strains never produce PE. Dark-colored strains of many benthic genera contain large amounts of PC and PE. Red cyanobacteria, typical for deep lacustrine and marine waters produce large amounts of PE, and only small amounts of PC. Marine open ocean cyanobacteria (*Synechoccus*, *Trichodesmium*) contain large amounts of a PUB-rich PE, with absorbance maxima around 495–500 nm.

In Chl *b*-producing cyanobacteria (the former “Prochlorophytes”), the photosynthetic antennae are intrinsic to the membrane, and in *Prochlorothrix hollandica*, they contain chlorophyll *a* and β-carotene (PSI; photosystem I), or chlorophylls a and b, and zeaxanthin (PSII; photosystem II). In contrast to the other two known

species, *Prochlorococcus marinus* contains divinyl-chlorophyll *a* and divinyl-chlorophyll *b*. The presence of chlorophyll *b* and zeaxanthin and their functional connection to the reaction center of PSII enables these bacteria to absorb light in the wavelength range of 460–500 nm, and is of selective advantage under light conditions present in the lower euphotic zone of oligotrophic oceans (see Competition for Light in this Chapter). However, chlorophyll *b* represents only a minor fraction of the photosynthetic pigments. In *Prochloron*, the ratio of chlorophyll *a*/chlorophyll *b* is between 2.6 and 12.0 (Thorne et al., 1977); this ratio is even higher in *Prochlorothrix* (10–18), in which the ratio of PSI to PSII is > 3 : 1. In *Prochlorothrix hollandica*, cells grown at low light intensities exhibit the lowest chlorophyll *a*/chlorophyll *b* ratios (Matthijs et al., 1994).

A very interesting variation is exemplified by *Acaryochloris marina*, where Chl *d* is the major antenna chlorin (2% of the dry weight, whereas Chl *a* is only 0.1%) harvesting light for both photosystems (Schiller et al., 1997). *A. marina* also contains traces of a Chl *c*-like pigment in addition to more typically cyanobacterial carotenoids (α-carotene—found also in *Prochlororococcus*—and zeaxanthine—found in many cyanobacteria) and phycobiliproteins (APC and PC; Miyachi et al., 1997).

In purple bacteria, the size of the photosynthetic antenna is in the range of 20–200 bacteriochlorophyll *a* per reaction center (Zuber and Cogdell, 1995). The specific bacteriochlorophyll *a* content of aerobic bacteriochlorophyll-containing bacteria reaches only 5–10% of that of anoxygenic phototrophic bacteria (Yurkov and Beatty, 1998). At least in one strain (*Rhizobium* BTAi1), the size of the photosynthetic unit is similar to that of anoxygenic phototrophic bacteria (Evans et al., 1990), indicating that the low pigment content is due to a low number of reaction centers. In PSII of cyanobacteria, the antenna comprises 300–800 phycobilin chromophores and 47 chlorophyll *a* molecules (Sidler, 1994; Matthijs et al., 1994), whereas the reaction center protein PsaA of PSI binds 110 chlorophyll *a* molecules (Golbeck, 1994). The photosynthetic antenna of green sulfur bacteria is significantly larger than that of other anoxygenic phototrophs and comprises about 1000 bacteriochlorophyll molecules connected to one reaction center (see The Family Chlorobiaceae, Physiology section in Volume 7). This appears to be one major reason for the competitive success of green sulfur bacteria in low-light environments (see Competition for Light in this Chapter). Antenna size is smaller in *Chloroflexus* (Olsen, 1998). About 35 molecules of bacteriochlorophyll g are associated with one reaction center in *Heliobacteriaceae* (Amesz, 1995).

Efficiency of Light Harvesting

The light absorption capabilities of photosynthetic prokaryotes can be judged best by calculating which fraction *f* of the light impinging on a single cell is actually absorbed. This fraction is considerable for purple sulfur and other bacteria. The highest bacteriochlorophyll-specific attenuation coefficient k_B has been determined for a population of *Amoebobacter purpureus* (0.050 $m^2 \cdot (mg\ BChl\ a)^{-1}$; Overmann et al., 1991a). For comparison *Prochlorococcus* has a chlorophyll-specific attenuation coefficient of 0.0147–0.0232 $m^2 \cdot$(mg Chl a^{-1} (Moore et al., 1998). For *Amoebobacter*, *f* is 0.36, or 36%, as calculated from Beer's Law and using the value of k_B, the intracellular c oncentration of light-harvesting pigments C (10.3×10^6 mg $BChl \cdot m^{-3}$, calculated from a content of 85 μg BChl·(mg protein)$^{-1}$; van Gemerden and Mas, 1995; Watson et al., 1977) and the average optical path-length d of a cell (2 μm):

$$f = 100 \times \exp(-k_B \times C \times d)$$

Of the photosynthetic pigments that absorb this high fraction of incident light, the majority (typically >97%) serves in light-harvesting and transfers excitation energy to the photochemical reaction centers. The combination of antenna complexes with one reaction center constitutes the photosynthetic unit. The efficiency of energy transfer within the photosynthetic unit and its size determine the fraction of the quantum flux that is harvested.

Large concentrations of pigments result in self-shading and thus a reduced efficiency of light absorption per mole of pigment. At the cell size and intracellular pigment concentrations typical of most prokaryotic phototrophs, this decrease in efficiency is not very important (Garcia-Pichel, 1994a), but it might be significant in some extremely low-light adapted anoxygenic phototrophs like the green sulfur bacterial strain isolated from the Black Sea chemocline (Overmann et al., 1991a).

Close proximity of photosynthetic pigments enables an efficient transfer of excitation energy but at the same time also causes a so-called "package effect" (Kirk, 1983) by which self-shading of the pigment molecules exceeds that predicted by the Lambert-Beer law. The package effect is seen clearly in a flattening of absorption peaks, commonly observed when recording absorption spectra of whole cells (see The Family Chlorobiaceae, Identification section in Volume 7). Because the energy requirement for biosynthesis of additional antenna structures is rather constant, the net energy gain for a photosynthetic cell must decrease at higher intracellular pigment concentrations, which restricts the

amount of light-harvesting structures a photosynthetic cell can synthesize. Polypeptides of the photosynthetic machinery (a significant fraction of the total cell protein) amount to 20% in purple nonsulfur bacteria and >50% in phycobiliprotein-containing cyanobacteria. Interestingly, the total protein content of cyanobacterial cells is comparable to other phototrophic bacteria. Possibly, cyanobacteria contain reduced levels of proteins involved in nonphotosynthetic processes to compensate for the high energy and nitrogen expenditure of the antenna proteins.

The biosynthesis of proteins requires a major fraction of the energy expenditure of the bacterial cell (Gottschalk, 1986). In chlorosomes, the mass ratio of protein:bacteriochlorophyll is significantly lower than in other light-harvesting complexes (Table 3). Probably this is one major reason for the larger antenna size and the lower light energy requirements of green sulfur bacteria as compared to their purple and cyanobacterial counterparts (see Competition between Phototrophic Bacteria in this Chapter), and might help explain the competitive advantage gained by *Prochlorocococcus* over their close relatives *Synechococcus* in the open oceans.

Conversion of Light into Chemical Energy

PRINCIPLE The unifying principle of bacterial and archaeal photosynthesis is the light-driven generation of a proton-motive force (PMF). The PMF is subsequently used by ATP synthase to form ATP, or for active transport and motility.

In chlorophyll-based photosynthesis, redox reactions and charge separation precede the establishment of the PMF. In addition, reducing power (NAD(P)H + H^+) is generated as a primary product of the light reaction in *Cyanobacteria*. In the photochemical reaction, only the energy of the lowest excited singlet state (see Light Absorption and Light Energy Transfer in Prokaryotes in this Chapter) of the chlorophylls is used. Consequently, all absorbed light quanta have the same effect irrespective of their original energy (wavelength). When comparing the light energy available in different habitats, or the light adaptation of different phototrophic bacteria, it is therefore more meaningful to express irradiances in units of mol quanta$\cdot m^{-2} \cdot s^{-1}$ rather than $W \cdot m^{-2}$ (see Competition for Light in this Chapter).

The standard free energy for the reduction of CO_2 depends on the redox potential of the photosynthetic electron donor employed (Table 4, Fig. 8). If this energy requirement for electron transfer is compared with the energy available after absorption of photons of different wavelengths, it becomes clear that oxygenic photosynthesis is not feasible in photosystems containing the known types of chlorin pigments, and requires the absorption of two photons per electron (Fig. 8).

The biological conversion of light into chemical energy has been found to be remarkably efficient: the number of charge separation events per absorbed photon is 1.0 (Kok, 1973; Wraight and Clayton, 1973) and the efficiency of the entire photoconversion process of a red photon to chemical energy by oxygenic photosynthetic organisms is 43% (Golbeck, 1994). Whereas the efficiency of energy transfer between antenna bacteriochlorophyll and the reaction center in most cases is close to 100% (Amesz, 1995), the transfer between antenna carotenoids and the reaction center can be significantly lower, 70% in *Heliobacteriaceae* (Amesz, 1995) and even

Table 3. Pigment:protein ratio in different photosynthetic antenna complexes.

	Protein:pigment	
Antenna complex type	Mass ratio	Per pigment molecule (in Da)
Chlorosomes	0.5–2.2	420–1,840
B806-866 complex[a]	3.9–5.8	3,550–5,290

[a]*Chloroflexus aurantiacus*.

Data from Olson, 1998 or calculated from Sidler, 1994, Loach and Parkes-Loach, 1995, Zuber and Cogdell, 1995. Carotenoids have been neglected in these calculations because of their lower numbers as compared to bacteriochlorophylls (B800-850 LHII), their absence in phycobilisomes, and the controversy concerning their functional significance in light-harvesting (chlorosomes). Only antenna complexes which are separate entities from reaction centers were considered. Photosystem I does not contain a distinct antenna structure; the PsaA protein of the reaction center binds 110 chlorophyll *a* molecules.

Electron acceptor	**E_o^{-}[mV]**
CO_2/<CH_2O>	−434

[a]Taken from Brune, 1989; Widdel et al., 1993; Thauer et al., 1977; Zehnder and Stumm, 1988.

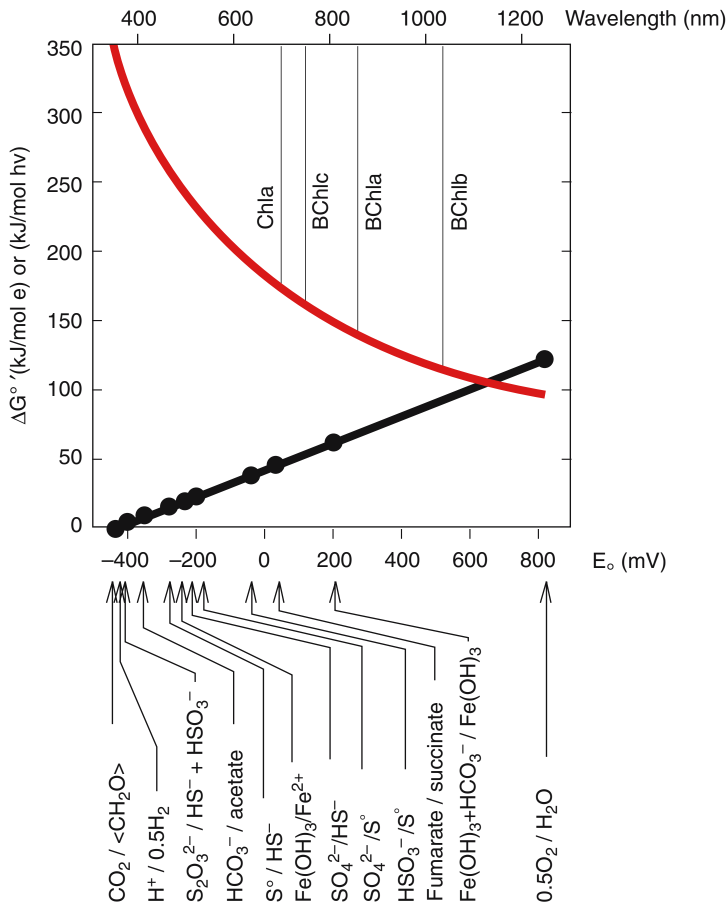

Fig. 8. Free energy of one mol quanta calculated from Planck's constant h (6.63×10^{-34} J·s), the speed of light c (2.99×10^{8} m·s^{-1}), the wavelengths of light λ, and the Avogadro constant $N_A = 6.023 \times 10^{23}$ mol^{-1} according to $\Delta G^{0\prime}_{h\nu}$; = $N_A \cdot h \cdot c \cdot \lambda^{-1}$. Free energy required for the transfer of 1 mole of electrons from an electron donor with standard redox potential $E^{0\prime}_{d}$ (see Table 4) to CO_2 calculated according to $\Delta G^{0\prime}_{el} = -F \cdot (-470 - E^{0\prime}_{d})$ using the Faraday constant F (96.5 kJ·V^{-1}·mol^{-1}). Dotted vertical lines indicate the energy that is available after absorption of light by the long wavelength Q_y absorption bands of different photosynthetic pigments.

20% in a purple nonsulfur bacterium (Angerhofer et al., 1986). When carotenoids serve as the only light-harvesting pigments, 2.5 times higher irradiances are required by *Rhodopseudomonas acidophila* to attain the same growth rates as compared to light-absorption by bacteriochlorophyll (Göbel, 1978). In aerobic phototrophic bacteria, most of the highly diverse carotenoids do not function as light-harvesting molecules but might serve in quenching of toxic oxygen radicals (Noguchi et al., 1992; Yurkov et al., 1994). The same has been proposed recently for the carotenoid isorenieratene/β-isorenieratene in brown-colored green sulfur bacteria (J. B. Arellano, J. Psencik, C. M. Borrego, R. Guyoneaud, C. A. Abella, L. J. Garcia-Gil, T. Gillbro, personal communication).

One prerequisite for the photoconversion process is the presence of a membrane that is impermeable to protons and separates two different cell compartments. Three integral membrane multisubunit protein complexes participate in the generation of ATP in all phototrophic bacteria: the photosynthetic reaction center, a cytochrome complex, and an ATP synthase. All three are highly conserved within the bacterial radiation. Reaction centers have a dimeric core and consist of two closely associated integral membrane polypeptides plus additional proteins (Fig. 3). The special protein environment of the reaction center stabilizes the excited state and prevents back reaction after charge separation by enforcing ultrafast electron transfer to other electron acceptors nearby. The transfer of excitation energy from the antenna complexes to the reaction center initiates a charge separation at a special bacteriochlorophyll dimer (special pair), which is located on the periplasmic (or lumen) side of the photosynthetic mem brane. It is this endergonic process of charge separation that is ultimately driven by light energy; all the following redox reactions are exergonic. An electric potential is established across the membrane (inside negative). In its excited state, the special pair becomes a powerful reductant and ultimately reduces a quinone (in pheophytin-type reaction centers) or ferredoxin (in FeS-type reaction centers) on the cytoplasmic side of the photosynthetic membrane. The quinol or reduced ferredoxin leaves the reaction center complex and in turn donates electrons to a membrane-bound cytochrome complex or NADH dehydrogenase. A series of redox reactions results in the establishment of a proton-motive force across the photosynthetic membrane. Finally, the PMF is converted to ATP by ATPase.

In contrast to the (bacterio)chlorophyll-based systems of bacteria, light energy conversion of Halobacteria does not involve redox reactions and is limited to a vectorial transport of protons by bacteriorhodopsin. Upon excitation by light, the prosthetic retinal undergoes a series of reversible photochemical transformations (an isomerization from the all-*trans* to the 13-*cis* form) and releases a proton into the extracellular space. The PMF thus generated is used for ATP synthesis by ATPase. Due to its low solubility, O_2 in the concentrated salt solution is present in significantly lower amount than in freshwater. Rhodopsin-mediated formation of ATP may become the sole source of energy for growth under anaerobic conditions in the light (Oesterhelt and Krippahl, 1983) and has therefore been viewed as an adaptation to the natural brine habitat of Halobacteria. Because of its distinct mechanism, archaeal "photosynthesis" is not discussed in further detail in the present section. Additional information can be found in chapters titled Introduction to the Classification of Archaea and The Family Halobacteriaceae.

Molecular Architecture of the Reaction Center

All bacteria which perform anoxygenic photosynthesis possess—or (in the case of cyanobacteria which are capable of using sulfide as electron donor) employ—only a single photosystem. The decrease in redox potential that a single photosystem can undergo upon excitation appears to be limited (Blankenship, 1992, compare Fig. 8). A combination of two different photosystems is required for the thermodynamically unfavorable utilization of water as an electron donor for photosynthesis (Fig. 3C). With the relatively simple architecture of their photosystems, all anoxygenic phototrophic bacteria depend on electron donors that exhibit standard redox potentials more negative than water (e.g., H_2S, H_2, acetate; Table 4). This molecular feature is one major reason for the narrow ecological niche of anoxygenic phototrophic bacteria in extant ecosystems (see Habitats of Phototrophic Prokaryotes in this Chapter).

Two different types of reaction centers occur in photosynthetic bacteria. Based on the chemical nature of the early electron acceptors, a pheophytin/quinone-type reaction center and a FeS-type reaction center are distinguished (Blankenship, 1992; Fig. 3A,B). The first type is found in green gliding *Chloroflexus* species, phototrophic members of the α- and β-Proteobacteria, *Chromatiaceae*, *Ectothiorhodospiraceae*, and in PSII of *Cyanobacteria*. The reaction center of *Proteobacteria* consists of three protein subunits (L, M, H) which bind four bacteriochlorophylls, two bacteriopheophytins, two quinones and one high-spin nonheme Fe^{2+} (Lancaster and Michel, 1996; Fig. 3B). Many species (e.g., *Chloroflexus aurantiacus*, *Blastochloris viridis* and *Allochromatium vinosum*) contain an additional tetraheme cytochrome c polypeptide attached to the periplasmic side of the reaction center.

Following the transfer of the electrons by ubiquinol or plastoquinol, the redox reactions at the cytochrome bc_1 (or b_6f) complex drive proton transport across the cytoplasmic membrane. Protons are translocated either into the extracellular space (anoxygenic phototrophic bacteria) or the intrathylacoidal space (cyanobacteria). The ratio of protons translocated to electrons transferred (H^+/e^- ratio) is 2. The reaction center and cytochrome bc_1 in pheophytin-type reaction centers of *Proteobacteria* and *Chloroflexus* are functionally linked by two diffusible electron carriers, ubiquinone in the hydrophobic domain of the membrane and cytochrome c_2 or auracyanin (Meyer and Donohue, 1995) in the periplasmic space. The liberated electron is transferred back to the special pair via quinone, the cytochrome bc_1 complex and soluble periplasmic soluble electron carrie r (often cytochrome c_2). Owing to this cyclic electron transport, the only primary product of photosynthesis is the proton-motive force, and the reduced pyridine nucleotide required for photosynthetic CO_2 fixation is generated by energy-dependent reverse electron flow (Fig. 3).

In oxygenic phototrophic bacteria, plastoquinone is the electron acceptor of PSII and donates electrons to the cytochrome b_6f-complex. The special pair is reduced by the manganese-containing water-splitting system located at the lumenal side of the transmembrane PSII complex (Fig. 3C).

In the pheophytin-type reaction centers of aerobic phototrophic bacteria, photoinduced charge separation occurs only in the presence of O_2 (Okamura et al., 1985). It has been proposed (Yurkov and Beatty, 1998) that oxic conditions are required for photochemical activity because the primary acceptor ubiquinone has a significantly higher midpoint redox potential than in anoxygenic photosynthetic bacteria (65 to 120 mV more positive). The primary acceptor therefore may stay in its oxidized, electron-accepting state only in the presence of O_2.

The second type of reaction center contains iron-sulfur clusters as early electron acceptors and occurs in green sulfur bacteria (Fig. 3A), *Heliobacteriaceae*, and in the photosystem I of *Cyanobacteria*. Functionally, the reaction centers of green sulfur bacteria, *Heliobacteriaceae*, and PSI of cyanobacteria are therefore similar. However, the former two are homodimeric and only

one reaction center gene has been detected, whereas the reaction center of PSI of cyanobacteria and green plants contains two nonidentical, but similar, subunits (PS I-A and PS I-B; Vermaas, 1994). In FeS-type reaction centers, the redox potential of the special pair in its reduced state (P*) is sufficiently low to permit a transfer of electrons to ferredoxin. Until recently, it has therefore been assumed that noncyclic electron flow can directly reduce $NAD(P)^+$ and does not require further energy expenditure not only in cyanobacteria but also in green sulfur bacteria. However, the sequencing of the whole genome of *Chlorobium tepidum* has not provided any indications for the presence of a ferredoxin-NADP+ oxidoreductase (D. A. Bryant, personal communication).

Electron Donors

Anoxygenic phototrophic bacteria of the α- and β-Proteobacteria use a wide variety of reduced organic carbon compounds as electron-donating substrates (see Carbon Metabolism in this Chapter; Table 4; Fig. 8). Most phototrophic sulfur bacteria are capable of using sulfide as photosynthetic electron donor. Other inorganic electron donors utilized include H_2, polysulfides, elemental sulfur, thiosulfate, sulfite, and iron (Widdel et al., 1993). Sulfide is oxidized to zero-valent sulfur, which in *Chromatiaceae* appears to be deposited as polysulfides or polythionates rather than in the form of S_8 rings (Steudel, 1989; Steudel et al., 1990). In addition, thiosulfate is formed as an oxidation product by some species (see The Family Chlorobiaceae in Volume 7; Steudel et al., 1990). The photosynthetic sulfide oxidation rates of purple sulfur bacteria are higher than required for growth and remains constant at all growth rates. As a result, storage of sulfur is at maximum at low growth rates (van Gemerden and Mas, 1995). Zero-valent sulfur is further oxidized to sulfate. In microbial mats, polysulfides and organic sulfur compounds may be significant as photosynthetic electron donor. Polysulfide oxidation has been reported for *Chlorobium limicola* f.sp. *thiosulfatophilum*, *Allochromatium vinosum*, *Thiocapsa roseopersicina*, while dimethylsulfide is utilized and oxidized to dimethylsulfoxide by the two purple sulfur bacteria *Thiocystis* sp. and *Thiocapsa roseopersicina* (van Gemerden and Mas, 1995). In addition to reduced sulfur compounds, hydrogen serves as electron donor in the majority of green sulfur bacteria, and in the metabolically more versatile species of purple sulfur bacteria (such as *Allochromatium vinosum*, *Thiocapsa roseopersicina*). In green sulfur bacteria which lack assimilatory sulfate reduction, a reduced sulfur source is required during growth with molecular hydrogen. Finally, a few species of purple nonsulfur bacteria, of *Chromatiaceae*, and of the green sulfur bacteria have been found to utilize ferrous iron as photosynthetic electron donor (Widdel et al., 1993; Heising et al., 1999).

Sulfide acts as a strong poison of PSII activity in many algae and cyanobacteria. The ability of some *Cyanobacteria* to conduct anoxygenic photosynthesis with sulfide as an electron donor to PSI (Cohen et al., 1975; Padan, 1979; Padan and Cohen, 1982), or to continue oxygenic photosynthesis in the presence of sulfide (Cohen et al., 1986), may be one of the key traits that extend the habitat of sulfide-utilizing cyanobacteria into the temporarily anoxic, sulfide-containing, layers of hot springs (Castenholz and Utkilen, 1984), marine microbial mats (De Wit and van Gemerden, 1987a; De Wit et al., 1988), and the chemoclines of meromictic lakes (Jørgensen et al., 1979; Camacho et al., 1996). Sulfide is an inhibitor of PSII and induces the synthesis of a sulfide-oxidizing enzyme system. In contrast to phototrophic sulfur bacteria, cyanobacteria oxidize sulfide to elemental sulfur or thiosulfate but do not form sulfate (De Wit and van Gemerden, 1987b). However, the use of sulfide by cyanobacteria in anoxygenic photosynthesis must be regarded as a detoxification mechanism, since their low affinity for sulfide (De Wit and van Gemerden, 1987b; Garcia-Pichel and Castenholz, 1990) renders them unable to compete with purple or green sulfur bacteria for sulfide as an electron donor.

In the natural habitat, growth of phototrophic sulfur bacteria is limited mainly by light and sulfide. Sulfide often becomes the growth-limiting factor at the top of the phototrophic sulfur bacterial layers where light intensities are highest, while sulfide has to diffuse through the remainder of the community. The affinity for sulfide during photolithotrophic growth varies between the different groups of anoxygenic phototrophs (including cyanobacteria growing with sulfide) and has been shown to be of selective value during competition experiments. Green sulfur bacteria and *Ectothiorhodospiraceae* exhibit 5 to 7 times higher affinities for sulfide than *Chromatiaceae* (van Gemerden and Mas, 1995). On the contrary, affinities for polysulfides are comparable between green sulfur bacteria and *Chromatiaceae*.

Efficiency of Growth and Maintenance Energy Requirements

For any photochemical reaction, the quantum yield is defined as the number of molecules converted per light quantum absorbed. The quantum efficiency is the ratio of energy stored in a com-

pound, to the radiant energy absorbed for its formation. The quantum requirement is the reciprocal of the quantum yield. For CO_2 fixation of purple sulfur bacteria, a quantum requirement of 8 and 10.5 mol quanta· (mol CO_2)$^{-1}$ is theoretically expected (Brune, 1989), considering that reverse electron transport is necessary. Experimentally, a quantum requirement of 12 ± 1.5 and 11.7 mol quanta·(mol CO_2^{-1} was determined, which corresponds to a quantum yield of 0.083 (Wassink et al., 1942 in Brune, 1989; Göbel, 1978).

In contrast, calculated values for the quantum requirements of green sulfur bacteria lie between 3.5 and 4.5 mol quanta·(mol CO_2)$^{-1}$, if noncyclic electron transport is assumed. However, earlier measurements had yielded much higher values (9–10; Brune, 1989). This discrepancy may be explained by the very recent finding that a gene for ferredoxin-NADP$^+$ oxidoreductase does not seem to be present in the genome of *Chlorobium tepidum* (D. A. Bryant, personal communication), which makes noncyclic electron transport rather unlikely also for green sulfur bacteria.

The quantum yield for CO_2-fixation determined for *Prochlorococcus* isolates incubated in daylight spectrum fluorescent light was between 0.086 and 0.128 mol C·(mol quanta)$^{-1}$ (Moore et al., 1998), thus reaching Emerson's theoretical maximum for O_2 evolution in oxygenic photosynthesis. In cyanobacteria, typically thriving in oxic environments where only oxidized sources of nitrogen and sulfur are available, a large proportion of the reducing power generated in the light reactions must be diverted to assimilatory nitrate or sulfate reduction, or to nitrogen fixation, so that the quantum requirement for CO_2 fixation can be substantially lower than that for oxygen evolution.

In a careful study of *Rhodobacter capsulatus* and *Rba. acidophilus* grown with lactate as electron donor in a light chemostat, a value for the maintenance light energy requirement of m_q = 0.012 mol quanta·(g dry weight·h)$^{-1}$ was determined (Göbel, 1978). The maintenance energy requirements of green sulfur bacteria are significantly lower compared to their purple conterparts (van Gemerden and Mas, 1995). This may be explained by the fact that protein turnover is highly energy demanding and that the protein content of the green sulfur bacterial antenna is much lower than in purple sulfur bacteria (Table 3).

Response to Changes in Light Intensity and Quality

Phototrophic bacteria acclimate to changes in light intensity and quality by diverse mechanisms. Anoxygenic phototrophic bacteria as well as cyanobacteria respond to a step-down in irradiance by increasing the specific pigment content and vice versa (references compiled in Sánchez et al., 1998). These changes can be accomplished either by varying the number of photosynthetic units per cell, the size of the individual photosynthetic unit, or both (see Long-term Adaptations to Changes in Light Intensity in this Chapter). Besides long-term biochemical changes in the composition and the amount of light-harvesting complexes, short-term redistribution of antenna capabilities (see State Transitions in this Chapter) occur in oxygenic phototrophs.

Many species use vertical migration, mediated by tactic responses (see Movement by Flagella in this Chapter) and formation of gas vesicles to regulate their vertical position and exposure to light. Especially in the stably stratified pelagic habitats of phototrophic sulfur bacteria, the difference in buoyant density from the surrounding water would cause a sedimentation of bacterial cells out of the photic zone and towards the lake bottom. The minimum buoyant density, which has been determined for phototrophic cells devoid of gas vesicles, was 1010 kg·m^{-3} (Overmann et al., 1991b). Actively growing cells, which contain storage carbohydrate and—in the case of *Chromatiaceae*—elemental sulfur, can easily attain much higher buoyant densities (up to 1046 kg·m^{-3}; Overmann and Pfennig, 1992). By comparison, freshwater has a considerably lower density (e.g., 996 kg·m^{-3}; Overmann et al., 1999c). As a consequence, sedimentation losses are significant for natural populations of several species of phototrophic sulfur bacteria (Mas et al., 1990). Phototrophic bacteria have developed two ways to adjust their vertical position along gradients of light intensity and spectral composition. For purple sulfur bacteria, motility in response to changes in irradiance is known to be of ecological significance in both planktonic and benthic situations. In benthic and terrestrial cyanobacteria, vertical locomotion by gliding is common. Planktonic cyanobacteria inhabiting stratified waters perform vertical migrations by changing their cellular gas vesicle content and ballast mass (intracellular carbohydrates and protein) and hence their buoyant density. Planktonic anoxygenic phototrophic bacteria do not seem to perform vertical migrations mediated by changes in gas vesicle content but rather use these cell organelles t o maintain their position within the chemocline (Overmann et al., 1991b; Overmann et al., 1994; Parkin and Brock, 1981).

Long-Term Adaptations to Changes in Light Intensity

In those photosynthetic bacteria in which the entire photosynthetic apparatus is confined to

the membrane, light absorption often is increased by formation of intracellular membrane systems (Fig. 2). In *Rhodobacter capsulatus*, the number of intracellular membrane vesicles increases by a factor of 6.3 when the cells are shifted from high to low light intensities. As a result, the area of intracellular membranes under these conditions is 2.7-fold larger than the area of the whole cytoplasmic membrane. Photosynthetic species of the β-Proteobacteria which do not form extensive intracellular membrane systems (*Rhodocyclus purpureus*, *Rhodocyclus tenuis*, *Rubrivivax gelatinosus*) increase the density of photosynthetic units in their cytoplasmic membrane (Drews and Golecki, 1995). Intracellular membranes appear to be absent in *Heliobacteriaceae* and *Heliothrix*, where pigments are confined to the cytoplasmic membrane (Fig. 2). In *Chloroflexus aurantiacus*, the increase in cellular concentrations of bacteriochlorophylls a and c is mediated by an increase in the number and volume of chlorosomes, and the percentage of cell membrane surface covered by chlorosomes (Golecki and Oelze, 1987). In a similar manner, green sulfur bacteria adapt to low light intensities by increasing the size and the cellular number of chlorosomes (see The Family Chlorobiaceae, Physiology section in Volume 7).

During induction of the photosynthesis apparatus in *Proteobacteria*, invaginations of the cytoplasmic membrane, increases in the number and size of the photosynthetic units, and bacteriochlorophyll synthesis occur simultaneously. Under anoxic conditions, the amount of pigment synthesized by anoxygenic phototrophic bacteria is inversely related to the available light intensity and varies by a factor of up to 6.6 (Göbel, 1978). After a shift to low light intensity, the ratio of light-harvesting complex I per reaction center remains constant (at about 30 bacteriochlorophylls per reaction center), whereas the relative amount of the peripheral light-harvesting complex II increases. As a result, the size of the photosynthetic unit changes by a factor of two to five. Conversely, the specific NADH dehydrogenase activity decreases as does the amount of cytochrome and ubiquinone per reaction center. In *Rba. capsulatus* and *Rba. spheroides* these changes take about 2–3 generations and the growth rate is lowered during adaptation due to energy limitation. In the purple sulfur bacterium *Allochromatium vinosum*, low-light adaptation is also accomplished by increasing the size of the photosynthetic unit (Sánchez et al., 1998). Species like *Rhodospirillum rubrum* and *Blastochloris viridis*, which harbor only one type of light-harvesting complex, increase the number of photosynthetic units (Drews and Golecki, 1995).

Similar to anoxygenic phototrophic bacteria, changes in both the number and the size of the photosynthetic unit have also been decribed for cyanobacteria. In marine *Synechococcus* strains, the cellular content of the light-harvesting phycoerythrin can be varied by a factor of 20 and decreases with increasing light intensity. In marine benthic *Microcoleus chthonoplastes*, an increase in the content of total phycobilines and a change in the ratio of PEC to PC occurs with decreasing light intensity. The latter increase the ratio of phycocyanin to chlorophyll *a* during low-light adaptation (Foy and Gibson, 1982; Post et al., 1985). Acclimation to very low light intensities usually involves an increase in the size of the photosynthetic unit, such as in metalimnetic *Oscillatoria (Leptolyngbya) redekei* and *Oscillatoria agha rdii*. Changes in both the number and the size of the photosynthetic units seem to occur in *Microcystis* (Zevenboom and Mur, 1984).

Adaptations to Low Light Intensities

The capability to adapt to low light intensities represents a competitive advantage for phototrophic organisms. An estimate of the minimum irradiance I_{min} required for survival of phototrophic cells in the environment can be calculated from a few physiological parameters, namely the pigment content of the cells, P (in mg bacteriochlorophyll·g C^{-1}); the maintenance energy requirement, m_q (in mol quanta·g $C^{-1}·s^{-1}$); the (bacterio)chlorophyll-specific attenuation coefficient, k (in m^2·mg BChl a^{-1}); the cellular dry weight content, D (in g C·m^{-3}); and the mean optical pathlength of one cell d:

$$I_{min} = m_q \cdot D \cdot d / [1 - \exp(-k \cdot D \cdot P \cdot d)]$$

Employing the appropiate values for m_q (see Efficiency of growth and maintenance energy requirements), k and P (see Light Energy and the Spectral Distribution of Radiation in this Chapter), D ($1.21·10^5$ g C·m^{-3}; Watson et al., 1977) and d (0.5 m for the smaller anoxygenic phototrophs), this yields a minimum irradiance (I_{min}) of 2 μmol quanta·$m^{-2}·s^{-1}$. In many natural habitats of anoxygenic phototrophic bacteria, irradiances of this order of magnitude or lower have been measured. *Prochlorococcus* has been found at deep water layers down to 300 m. However, these bacteria do not grow at light intensities below 3.5 mol quanta·$m^{-2}·s^{-1}$ (Moore et al., 1998) and thus appear to be less low-light adapted than the green sulfur bacterial strain MN1 isolated from the Black Sea which grows a t light intensities as low as 0.25 μmol quanta·$m^{-2}·s^{-1}$ (Overmann et al., 1991a). Lower irradiances could be used by phototrophic prokaryotes after a decrease of m_q or an increase of P or both. Both adaptations are present in strain MN1 (Overmann et al., 1991a).

Adaptations to High Light Intensities

Sessile cyanobacteria living on the surface of benthic microbial mats are typically adapted to very high light conditions and contain large amounts of sunscreen pigments. For oxygenic phototrophs, special adaptations to oxygen-dependent photoinhibition of photosynthesis are of particular relevance. The protein D1 of PSII, coded by the *psbA* gene, has been identified as the central target of photoinhibition at high light intensities. In *Synechococcus* PCC 7942, *psbA* contains actually a multigene family coding for three different forms of the protein D1, which are differentially expressed according to the light conditions. Analysis of mutants showed that the isoforms expressed under high light conditions allow for optimal performance of PSII under photoinhibitory conditions (Golden, 1994). In addition, carotenoids probably play a central role in avoiding oxygen-mediated pho tosensitized bleaching of photosynthetic pigments and photooxidation of fatty acids under high light conditions.They function as antioxidant quenchers of excited molecules (such as triplet state chlorins and singlet oxygen) in many organisms and perhaps also as inhibitors of free-radical reactions (Britton, 1995). The photoprotective xanthophyll cycle typical of green algae and higher plants is not present in cyanobacteria, but judging from its increased specific content at high light intensity, zeaxanthin seems to play an important photoprotective role in some strains (Kana et al., 1988; Masamoto and Furukawa, 1997; Millie et al., 1990). Glycosylated myxoxanthophylls seem to attain the same role in others (Nonnengießer et al., 1996; Garcia-Pichel et al., 1998; Ehling-Schulz et al., 1997). Because there is a considerable photooxidation of carotenoids themselves at high light intensities, the maintenance of high carotenoid contents requires an increased expression of their biosynthetic genes.

Chromatic Adaptation

Several species of cyanobacteria are capable of changing the amount of peripheral phycoerythrin in response to changes in the spectral composition of light. During growth in white or green light, red-pigmented PE hexamers are added to the peripheral rods whereas additional blue-pigmented PC is added under red light (Sidler, 1994). This complementary chromatic adaptation is found only in strains capable of forming PE, but not in those forming PEC. The complementary change in antenna pigment composition optimizes the light-harvesting capabilities of populations of *Oscillatoria* spp., which thrive in deeper layers of stratified lakes where light is predominantly in the blue-green to green wavelength range (Utkilen et al., 1985; Fig. 6).

Genetic Regulation in Response to Light

The synthesis of the photosystem is especially energy consuming because of the high amount of light-harvesting and reaction center protein present in phototrophically grown cells of phototrophic *Proteobacteria* (20% in purple nonsulfur bacteria). The maintenance energy requirements seem to be increased in low-light adapted cells (Sánchez et al., 1998). An effective regulation of photosynthesis gene expression therefore would prevent futile synthesis of cellular proteins. The synthesis of the photosystem in anoxygenic phototrophic bacteria is under the control of a complex regulatory network (Bauer and Bird, 1996).

The expression of light-harvesting complex I and reaction center genes is controlled 1) by the linkage of genes in superoperons, 2) at the level of transcription initiation, and 3) posttranscriptionally by the decay rate of mRNA (Bauer, 1995).

In *Rhodobacter capsulatus*, the genes coding the structural, biosynthetic and regulatory proteins for light-harvesting I and reaction center complexes are found assembled in a 46 kb-long photosynthetic gene cluster (Alberti et al., 1995). The arrangement of the genes within the cluster seems to be conserved among different phototrophic species of the α-Proteobacteria, like *Rhodobacter sphaeroides*, *Rhodocista centenaria* and *Rhodospirillum rubrum* (Bauer et al., 1993). Only the *pucBA* operon which codes for structural α- and β-polypeptides of light-harvesting complex II is found in a distant location on the bacterial chromosome (about 18 kb of the *puhA* in *Rhodobacter capsulatus*; Suwanto and Kaplan, 1989).

In anoxygenic phototrophic bacteria, transcription of the photosynthesis genes occurs only under anoxic conditions. Different photosynthesis genes exhibit varying levels of expression and degrees of regulation (Bauer and Bird, 1996). The *pufA,B,L,M* genes (coding for the α- and β-polypeptide of the light-harvesting complex I and the reaction center L and M structural polypeptides) as well as *puhA* (coding for the structural polypeptide subunit H) are tightly coregulated, transcribed at a high rate under anoxic conditions and strongly regulated (15- to 30-fold). An inverted repeat sequence located between *pufA* and *pufL* affects the longevity of the respective mRNA primary transcript. A reduction of light leads to an activation of *puf* and *puh* gene expression by the *hvrA* gene product, which probably directly interacts with the two promoter regions. Light of 450 nm exhibits

the most severe repressing effect, indicating that a flavin-binding protein (possibly HvrA itself) is the photoreceptor. Notably in aerobic phototrophic bacteria, a blue light sensitive system seems to regulate biosynthesis of bacteriochlorophyll *a* (Shimada, 1995).

The intracellular bacteriochlorophyll concentrations appear to affect *puf* and *puc* gene expression not only at the transcriptional but also the posttranscriptional level in *Rhodobacter capsulatus* (Rödig et al., 1999). The polycistronic organization allows the coordinate expression of the structural polypeptides of light-harvesting complex I and the two integral membrane-proteins of the reaction center. Since, however, many light-harvesting I complexes are required per reaction center in *Proteobacteria*, additional regulatory mechanisms must exist. Differential degradation of various portions of the polycistronic mRNA are one means to regulate the stoichiometry of different components of the photosynthetic apparatus. The synthesis of different amounts of gene products is achieved by posttranscriptional regulation (Rödig J. et al., 1999). Because of a h ighly stable secondary terminator structure at its 3´-end and the absence of specific recognition sites for endonucleolytic cleavage, the mRNA coding the two light-harvesting polypeptides has much higher stability than that of the entire *puf* gene transcript. The degradation of the downstream *pufLM* section of the mRNA is mediated by an endonuclease. A similar regulation mechanism may exist for the polycistronic mRNA of bacteriochlorophyll synthesis genes (*bchFNBHLM-F1696*) and the *puhA*, and operate in regulation of light-harvesting complex II expression.

A shift to low light intensities results in an increase especially of light-harvesting complex II. The corresponding *pucBA* operon is highly expressed but only moderately regulated (4-fold). In the purple nonsulfur bacterium *Rhodobacter capsulatus*, four-fold less *puc* mRNA but at the same time four times as many light-harvesting II complexes were detected after a shift from high to low-light conditions (Zucconi and Beatty, 1988). Therefore regulation by light most likely involves posttranscriptional regulation. A posttranscriptional regulation appears to occur (Bauer, 1995).

Bacteriochlorophyll and carotenoid biosynthesis genes are only weakly expressed and moderately (2 to 4-fold) regulated. Light intensity may control the rate of bacteriochlorophyll degradation (by oxidative degradation of bacteriochlorophyll; Biel, 1986) rather than the rate of synthesis (Biel, 1995). This is another distinct difference from the regulation by oxygen, where inhibition of δ-aminolevulinate synthase by molecular oxygen appears to occur (see Chemotrophic Growth with O_2 in this Chapter). Bacteriochlorophyll may be stabilized by insertion in pigment-protein complexes, however. The promotor of the bacteriochlorophyll synthesis gene *bchC* is of the sigma-70 type and leads to one large superoperon (Yurkov and Beatty, 1998). In contrast, an alternative sigma factor appears to recognize the strongly regulated structural *puf* and *puh* genes (Bauer, 1995). These differences explain the independent and different levels of regulation observed for the two classes of genes.

Recently the promoter for the carotenoid biosynthesis genes *crtB* and *crtP* were identified in *Synechocystis* PCC 6803, and shown to be light regulated (Fernández-González et al., 1998).

State Transitions

In cyanobacteria, state transitions involve redirecting the pathways of excitation energy transfer from light-harvesting complexes to both photosystems, and can be recognized by fluorescence analysis. Cyanobacteria can reach two energetically different states, in which one of the photosystems is preferentially excited. This is achieved with fast changes in the coupling between the light-harvesting complexes and the reaction center (van Thor et al., 1999). Evidence is accumulating that at least in the chlorophyll *b*-containing phototrophic bacteria ("Prochlorophytes"), the short-term regulation occurs by a mechanism similar to that in green chloroplasts (Matthijs et al., 1994). In the latter, polypeptides of the PSII antenna (LHCII) are rapidly phosphorylated during overexcitation of this photosystem, and as a consequence detach from PSII and migrate to the stromal thylakoids. This mechanisms ensures a bala nced energy distribution between PSII and PSI. The net result of state transitions is the balanced function of both photosystems and an optimization of the quantum yield for photosynthesis during short-term changes, such as those that planktonic cells might experience during vertical transport by water currents.

Movement by Flagella

Phototrophic *Proteobacteria* swim by means of flagella, whereas one species of the green sulfur bacteria (*Chloroherpeton thalassium*), members of *Chloroflexus* subgroup and cyanobacteria move by gliding. Of the α-Proteobacteria, most phototrophic species are motile. Peritrichous or lateral flagella are only found in *Rhodomicrobium vannielii* and the swarming phase of *Rhodocista centenaria*. About two thirds of the known *Chromatiaceae* species are motile. Larger forms (*Chromatium okenii*, *Chr. weissei*, *Chr. warmingii*, *Chr. buderi*, *Thiospirillum jenense*)

are motile by means of bipolar multitrichous tufts of flagella. *Thiospirillum jenense* is bipolarly flagellated. Forms with smaller cells are monotrichously flagel lated (small *Chromatium* species, *Lamprocystis*, *Thiocystis*, *Thiorhodococcus*, *Thiorhodovibrio*). All *Ectothiorhodospiraceae* are flagellated. A new mode of motility has been described for a unicellular cyanobacterium which moves in a similar fashion to flagellated bacteria but apparently lacks a flagellum (Waterbury et al., 1985).

True phototaxis is the ability to move towards or away from the direction of light. Cyanobacteria are the only prokaryotes displaying true phototaxis (Garcia-Pichel and Castenholz, 1999). Phototaxis may not be of competitive value for microorganisms adapted to live at low light intensities in the subsurface of sediments, soils and mats because the light fields may be close to diffuse deep below the surface. However, directed movements can still be of much use in microorganisms dwelling at or close to the sediment surface, where the light fields contain a significant downward directionality. Photophobic responses are changes in the direction of movement in reaction to abrupt changes in light intensity (Castenholz, 1982; Häder, 1987). In the step-up photophobic response, organisms will reverse direction when sensing an increase in light intensit y, which results in a net accumulation of organisms at lower light intensities. In a step-down photophobic (or scotophobic) response, the organisms will tend to accumulate in the region of higher light intensity. Photophobic responses are the basis of photomovement in all flagellated bacteria (Armitage, 1997), and in most gliding cyanobacteria (Castenholz, 1982).

In swimming cells of phototrophic *Proteobacteria*, a decrease in light intensity triggers a reversal of flagellar rotation (*Rhodospirillum rubrum*, *Chromatium* spp.) or an increase in stopping frequency (*Rhodobacter sphaeroides*). Owing to a memory effect, cells of the latter species retain a higher stopping frequency for up to 2 min, which prevents the cells from being trapped in the dark but instead permits reorientation of the cells and a return to higher light intensities (Armitage et al., 1995). As a result of this scotophobic response, the cells accumulate in the light and at wavelengths corresponding to the absorption maxima of photosynthetic pigments. A change in light intensity of as little as 2% can be sensed (Armitage et al., 1995). Active electron transport is required for the scotophobic response.

The formation of flagella in *Chromatium* species is induced by low sulfide concentrations and low light intensities. These two environmental variables are mutually dependent: the lower the light intensity, the higher the sulfide concentration at which a given strain can persist in its motile stage (Pfennig and Trüper, 1989). In the natural environment of purple sulfur bacteria, gradients of light and sulfide are opposed to each other. The control of motility by the two interdependent environmental variables (instead of only one) enables *Chromatium* cells to return either from low sulfide/high light environment above the chemocline or from the high sulfide/low light environment below the chemocline back to their habitat.

In its pelagic habitat, *Chromatium okenii* may display diurnal migrations with a vertical amplitude of about 2 m (Sorokin, 1970). In other lakes, vertical migrations of *Chromatium minus* extended over a distance of 30–35 cm (Lindholm et al., 1985; Pedrós-Alió and Sala, 1990). Vertical migration of nonthermophilic *Chromatium*, and of *Chromatium tepidum* also has been observed in ponds and in intertidal or hot spring microbial mats (Castenholz and Pierson, 1995; Jørgensen, 1982; Pfennig, 1978). In the latter environments, *Chromatium* cells migrate upwards to the surface of the mat and enter the overlaying water as a result of positive aerotaxis during the night. The cells contain high amounts of intracellular sulfur globules, which are formed during incomplete sulfide oxidation by anoxygenic photosynthesis during daytime. It is assumed that migration into microoxic layers enables the cells to grow chemoautotrophically by oxidation of sulfide or intracellular sulfur with molecular oxygen (Jørgensen, 1982; Castenholz and Pierson, 1995).

If phototrophic sulfur bacteria would solely follow the light gradient, their scotophobic response would ultimately lead them into oxic water layers. Both the scotophobic behavior and aerotaxis respond to the rate of intracellular electron flow (presumably sensed as changes in the redox state of an intermediate). Because the two tactic reponses interact through a common signal, a combination of light and molecular oxygen elicits a differential response. *Rhodobacter sphaeroides* exhibits pronounced aerotaxis when precultivated aerobically, but negative aerotaxis when grown anaerobically in the light. Conversely, cells only swim towards higher light intensities in anoxic medium. A pulse of oxygen in the light causes a transient fall in the membrane potential which probably represents the primary tactic signal. As a result, the bacteria move towards environments where electron transport rate is increased (Armitage et al., 1995).

Rhodocista centenaria exhibits a characteristic swarming behavior. In liquid media, cells move with a single polar flagellum. Upon contact with solid agar media, formation of a large number of lateral flagella is induced. Lateral flagella allow whole colonies to swarm towards or away from the light (Ragatz et al., 1994). The supposedly

true phototaxis of these swarming colonies (Ragatz et al., 1995) has later been proven to actually be aerotaxis following microgradients within the colonies (Sackett et al., 1997). The light sensing system in this species appears to be more complex, since infrared light leads to positive, and visible light to negative phototaxis. In microbial mats, infrared light penetrates to much greater depths than light of the visible wavelength range (see Competition for Light in this Chapter). It has been suggested that the ratio of visible to in frared light may be used to maintain an optimum position in such environments (Armitage et al., 1995; Ragatz et al., 1995).

Cyanobacteria are the only prokaryotes displaying true phototaxis (Garcia-Pichel and Castenholz, 1999). Surface dwelling cyanobacteria such as *Lyngbya* spp. from hot springs mats and intertidal sediments and the motile phases (hormogonia) of terrestrial *Nostoc* spp. from desert soils exhibit this type of movement. The bundle-forming *Microcoleus chthonoplastes* also is able to display a "populational phototaxis" in that bundles of trichomes of this cyanobacterium are able to steer in the direction of the incoming light, whereas single trichomes are apparently not able to do so (Prufert-Bebout and Garcia-Pichel, 1994). True phototaxis is a mechanism for the orientation of cells at or close to the sediment surface, where the light field contains a significant downward directionality. In contrast, phototaxis does not provide a selective advantage for bacteria thriving in the subsurface of sediments, soils and mats because of the diffuse light field. In natural microbial mats photophobic responses to changes in light intensity are probably involved in the migrations of gliding bacteria (Nelson and Castenholz, 1982; Pentecost, 1984). In microbial mats, some strains of cyanobacteria are able to migrate vertically following their optimal light intensity over the diel cycle (Garcia-Pichel et al., 1996). The upward migrations of cyanobacteria in mats is preferentially prevented by short wavelengths, especially by UV radiation (Garcia-Pichel and Castenholz, 1994b; Bebout and Garcia-Pichel, 1995; Kruschel and Castenholz, 1988) and not by red nor green light.

Phototrophic consortia are structural associations between a colorless central bacterium and several surrounding cells of pigmented epibionts (see Interactions between Phototrophic Bacteria and Chemotrophic Bacteria in this Chapter; The Family Chlorobiaceae in Volume 7; Fig. 5). Intact consortia of the type "Chlorochromatium aggregatum" exhibit a scotophobic response and accumulate in a spot of white light. In phototrophic consortia, only the central colorless bacterium carries a flagellum (J. Glaeser and J. Overmann, unpublished observation). The action spectrum of scotophobic accumulation corresponds to the absorption spectrum of the green sulfur bacterial epibionts, however. It has to be concluded that a rapid signal transfer exists between the light-sensing but immotile epibionts and the colorless motile rod (Fröstl and Overmann, 1998).

Gas Vesicles

Buoyancy-conferring gas vesicles are common in green sulfur bacteria, *Chromatiaceae*, and cyanobacteria. Gas vesicles are cylindrical structures with conical ends; their length and width are variable and species-specific. The sheath of gas vesicles are composed of proteins (Walsby, 1994). The gas mixture within the gas vesicles is the same as in the surrounding medium and is at the same partial pressures. Gas vesicles occur in a third of the species of *Chromatiaceae* (belonging to the genera *Amoebobacter*, *Lamprobacter*, *Lamprocystis*, *Thiodictyon*, *Thiopedia*, *Thiolamprovum*) and some green sulfur bacteria (genera *Ancalochloris*, *Pelodictyon*, *Chloroherpeton*). Of the *Ectothiorhodospiraceae*, only *Ectothiorhodospira vacuolata* forms gas vesicles during stationary phase. This reflects the distribution of both families of purple sulfur bacteria in nature, where *Chromatiaceae* typically colonize low-light stratified aquatic environments, whereas *Ectothiorhodospiraceae* typically inhabit more shallow saline ponds and sediments. Gas vesicles also are present in *Prochlorothrix hollandica*. In planktonic habitats, cells of cyanobacteria and phototrophic sulfur bacteria often contain gas vesicles, which indicates a selective advantage of this cellular property.

Gas vesicle formation in the green sulfur bacterium *Pelodictyon phaeoclathratiforme* is induced exclusively at light intensities <5 mol quanta·m^{-2}·s^{-1} (Overmann et al., 1991b). This appears to be the reason for the rare observation of gas vesicles in pure cultures of green sulfur bacteria which routinely are incubated at much higher light intensities. A transfer of *Amoebobacter purpureus* strain ML1 to the dark results in an increase of the gas vesicle volume by a factor of nine (Overmann and Pfennig, 1992). Ambient temperature controls gas vesicle formation in *Thiocapsa pendens* (Eichler and Pfennig, 1986).

The buoyancy of many species of *Cyanobacteria* is regulated by the formation of gas vesicles. Highly buoyant cells may float towards the surface of stagnant water bodies. When the turgor pressure within the surrounding cytoplasm rises, such as by accumulation of low molecular weight photosynthates during periods of intense photosynthesis, the critical pressure may be exceeded and the gas vesicles collapse. New vesicles are formed by de novo synthesis rather than by re-inflation of collapsed vesicles. Short-term regula-

tion of cell buoyant density occurs in cyanobacterial species thriving in stratified lakes, like *Aphanizomenon flos-aquae*, *Anabaena flos-aquae*, and green-colored *Oscillatoria* spp. (Konopka et al., 1978; Oliver and Walsby, 1984; Utkilen et al., 1985). In these species, the proteinaceous gas v esicle sheaths are weak enough to permit a collapse at high intracellular turgor pressures as they are reached during periods of intense photosynthesis. By this mechanism, cells lose buoyancy within 30 minutes and thus can sink out of surface layers of stratified lakes. After de novo synthesis of gas vesicles in lower water layers, utilization of photosynthates, and a decrease of turgor pressure, cells rise back to the surface during the night. Rapid, turgor-mediated reduction of buoyancy together with gas vesicle formation thus represents an adaptation to the pronounced diurnal variations in light intensity and the limitation of growth by inorganic nutrients as they occur during summer stratification in the surface layer of eutrophic lakes. In some instances (e.g., *Microcystis aeruginosa*) diurnal migrations are mediated by an increase of carbohydrate ballast alone and gas vesicles do not collapse even at maximum turgor pressure (Kromkamp and Mur, 1984; Thomas and Walsby, 1985).

In contrast, gas vesicles of red-colored *Oscillatoria aghardii* and of phototrophic sulfur bacteria are mechanically stronger and do not collapse even at maximum cell turgor pressure. A decrease in the cellular gas vesicle content is therefore the result of their dilution during growth and division of the cells, and thus proceeds rather slowly (Overmann et al., 1991b; Overmann and Pfennig, 1992). Bacteria of this category mostly colonize the low-light environments shortly above or within the chemocline of stratified lakes where photosynthetic rates typically are strongly limited by light and hydrostatic pressure is high. Gas vesicles in green sulfur bacteria are rigid enough to persist at hydrostatic pressures down to depths of 38 m (Overmann et al., 1991b). The cyanobacterium *Trichodesmium* contains extremely stable gas vesicles (mean crit ical collapse pressures up to 3.7 MPa, corresponding to a depth of 370 m; Walsby, 1978). The differences in strength of gas vesicles formed by different species is related to their shape (especially the diameter) and the primary structure of the GvpC protein of their sheath (Walsby, 1994).

In addition to the formation of gas vesicles, a new type of buoyant density regulation was detected in *Pelodictyon phaeoclathratiforme*. Cells of this species form large extracellular slime layers during the stationary phase which leads to an increase of the cellular volume by a factor of three (Overmann et al., 1991b).

Advantages of the Vertical Movement by Flagella and by Gas Vesicles

Theoretically, motility based on flagellar movement and vertical migration by means of gas vesicle formation have different advantages under natural conditions. Movement by flagella requires a permanent, (albeit sometimes low) fraction of metabolic energy (proton-motive force), whereas gas vesicle synthesis represents an initial one-time investment of a higher amount of metabolic energy. Once formed, gas vesicles keep bacterial cells in their habitat without any further demand for energy. The purple sulfur bacterium *Lamprobacter modestohalophilus* is capable of both flagella and gas vesicle formation. Motile cells are usually devoid of gas vacuoles and initially dominate during growth in fresh media. Later, cells become immotile and form gas vesicles and slime capsules (Gorlenko et al., 1979). In a very similar manner, cells of *Ectothiorhodospira vacuolata* are flagellated at low sulfide concentrations and light inte nsities, and become immotile and form gas vesicles in stationary phase (Imhoff et al., 1981). This supports the view that flagellar movement of purple sulfur and purple nonsulfur bacteria is favored under conditions of continuous energy supply, while gas vesicle formation represents an adaptation to conditions of starvation. Within one lake ecosystem, vertical migration of a flagellated species (*Chromatium minus*) was observed while the gas-vacuolated *Amoebobacter* did not change its vertical position (Pedrós-Alió and Sala, 1990).

A minimum quantum requirement of flagellar motility can be estimated from data in the literature. A vertical migration over a distance of 2 m (the maximum amplitude of vertical migration observed in nature) during 6 hours corresponds to a swimming speed of 93 $\mu m \cdot s^{-1}$. At a similar speed of 100 $\mu m \cdot s^{-1}$ the frequency of flagellar rotation is >100 s^{-1} in *Rhodobacter sphaeroides* and requires between 200 and 1000 H^+ per rotation (Armitage et al., 1995). This yields a proton translocation rate of $\sim 6 \times 10^4$ $H^+ \cdot s^{-1}$ at a swimming velocity of 100 $m \cdot s^{-1}$. Based on an absorbing cross sectional area of the cell of 1 m^2, an absorption of 36% of the incident light (see Efficiency of Light Harvesting in this Chapter), a ratio of protons translocated to electrons transferred (H^+/e^- ratio) of 2 (see Conversion of Light into Chemical Energy in this Chapter), and assuming that each photon absorbed leads to transport of an electron, the proton translocation rate of 6×10^4 $H^+ \cdot s^{-1}$ would be reached at an underwater irradiance of 0.2 mol quanta$\cdot m^{-2} \cdot s^{-1}$. However, all available quanta would be required just for motility at this irradiance and no vertical migration would be possible during the night. Therefore motility by flagella will be of compet-

itive advantage only at significantly higher irradiances. In many lakes, underwater irradiances in layers of phototrophic sulfur bacteria are ≤1 mol quanta$\cdot m^{-2} \cdot s^{-1}$ (Overmann and Tilzer, 1989a; Overmann et al., 1999a). Under these conditions, purple sulfur bacteria harboring gas vesicles dominate over flagellated forms in the chemocline community (Fig. 4). At least in some lakes, gas vesicles appear to be of selective advantage also at higher underwater irradiances (Overmann et al., 1991b; Overmann and Pfennig, 1992).

Interestingly, the extremely low-light adapted *Chlorobium phaeobacteroides* strain MN1 isolated from the chemocline of the Black Sea was not capable of gas vesicle formation. The green sulfur bacterial layer is located at an 80-m depth and with respect to light intensity represents the lower limit for growth of a phototrophic organism (see The Family Chlorobiaceae in Volume 7). The isolated strain exhibits an extremely low maintenance energy requirement. It therefore appears that gas vesicle formation is too energy demanding at the very low light intensities available at an 80-m depth in the Black Sea.

Carbon Metabolism of Phototrophic Prokaryotes

In the natural environment, the principal carbon source of phototrophic bacteria in many instances is CO_2 (Madigan et al., 1989; Sinninghe Damsté et al., 1993; Takahashi et al., 1990). In *Cyanobacteria*, *Chromatiaceae*, *Ectothiorhodospiraceae* and purple nonsulfur bacteria, CO_2 is assimilated by the reductive pentose phosphate or Calvin cycle. Employing this cycle, the formation of one molecule of glyceraldehyde-3-phosphate requires 6 $NAD(P)H+H^+$ and 9 ATP. By comparison, the reductive tricarboxylic acid cycle used for CO_2-assimilation by green sulfur bacteria requires 4 $NADH+H^+$, 2 reduced ferredoxins, and only 5 ATP. As two of the reactions of the reductive tricarboxylic acid cycle (the α-oxoglutarate synthase and pyruvate synthase rea ctions) require reduced ferredoxin as electron donor, this pathway of CO_2 fixation can only proceed under strongly reducing conditions. Furthermore, reduced ferredoxin is a primary product of the light reaction only in FeS-type reaction centers. Ultimately, the lower demand for ATP is possible because of the adapatation of green sulfur bacteria to the strongly reducing conditions of their natural environment. CO_2-fixation by the hydroxypropionate cycle in *Chloroflexus aurantiacus* requires 8 ATP per glyceraldehyde-3-phosphate and therefore is energetically less favorable than in green sulfur bacteria.

Organic carbon as it is present in canonical microbial biomass ($<C_4H_8O_2N>$; Harder and van Dijken, 1976) is considerably more reduced than CO_2. Given the high energy demand of autotrophic growth, the capability for assimilation of organic carbon compounds is of selective advantage especially if natural populations are limited by light or by low concentrations of electron-donating substrates, as is typically the case for phototrophic sulfur bacteria. At limiting concentrations of sulfide or thiosulfate, the cell yield of green sulfur bacteria is increased three times if acetate is available as an additional carbon source (Overmann and Pfennig, 1989b). Acetate represents one of the most important intermediates of anaerobic degradation of organic matter (Wu et al., 1997). That almost all anoxygenic phototrophic bacteria (with the exception of *Rhodopila globiformis*; Imhoff and Trüper, 1989) are capable of acetate assimilation is therefore not surprising. In most phototrophic *Proteobacteria*, acetate is assimilated by acetyl-CoA synthetase and the enzymes of the glyoxylate cycle. In green sulfur bacteria, the ferredoxin-dependent pyruvate synthetase, PEP synthetase, and reactions of the reductive tricarboxylic acid cycle serve this purpose. The capacity for organotrophic growth seems to correlate with the presence of α-oxoglutarate dehydrogenase. The latter is a key enzyme for the complete oxidation of the carbon substrates in the tricarboxylic acid cycle (Kondratieva, 1979), whereas a complete cycle is not needed for the photoassimilation during the presence of inorganic electron donors. The range of carbon substrates utilized and the capacity for photoorganotrophy or chemoorganotrophy varies considerably among the different groups of phototrophic pr okaryotes (Pfennig and Trüper, 1989).

Organic carbon compounds not only are assimilated but also can serve as photosynthetic electron donors in purple nonsulfur bacteria, some *Chromatiaceae* and *Ectothiorhodospiraceae*, all *Heliobacteriaceae*, and members of the *Chloroflexus* subdivision.

Green sulfur bacteria are the least versatile of all phototrophic prokaryotes. All known species are obligately photolithotrophic and assimilate only very few simple organic carbon compounds (acetate, propionate, pyruvate). Few strains have been shown to assimilate fructose or glutamate. Whereas green sulfur bacteria have a higher growth affinity for sulfide than purple sulfur bacteria, acetate seems to be used by purple sulfur bacteria at an affinity 30 times higher than in green sulfur bacteria (Veldhuis and van Gemerden, 1986). In addition, uptake of acetate in *Chlorobium phaeobacteroides* is inhibited by light (Hofman et al., 1985).

Based on their metabolic flexibility, two groups can be distinguished among the *Chromatiaceae*. Several species (*Chromatium okenii*, *Chr. weissii*, *Chr. warmingii*, *Chr. buderi*, *Chr. tepidum*, *Thiospirillum jenense*, *Lamprocystis roseopersicina*, *Thiodictyon elegans*, *Thiodictyon bacillosum*, *Thiocapsa pfennigii*, *Thiopedia rosea*) are obligately phototrophic, strictly anaerobic and photoassimilate acetate and pyruvate only in the presence of CO_2 and sulfide. Assimilatory sulfate reduction is absent in these species (Pfennig and Trüper, 1989). However, particularly those species with limited metabolic flexibility form dense blooms under natural conditions (see Coexistence of Phototrophic Sulfur Bacteria in this Chapter). The second physiological group within the *Chromatiaceae* comprises the small *Chromatium* species (*Chr. gracile*, *Chr. minus*, *Chr. minutissimum*), *Allochromatium vinosum*, *Lamprobacter modestohalophilus*, as well as *Thiocystis* spp., *Thiocapsa*. Most of these species use thiosulfate as electron donor and a wide range of organic carbon compounds including glucose, fructose, glycerol, fumarate, malate, succinate, formate, propionate, and butyrate for photoassimilation, and often are capable of assimilatory sulfate reduction. In some species (especially *Allochromatium vinosum*), these organic carbon substrates also serve as electron-donor for phototrophic or chemotrophic growth.

Most *Ectothiorhodospiraceae* species are capable of photoorganotrophic growth, with *Ectothiorhodospira halophila* and *Ectothiorhodospira halochloris* being the exceptions. The spectrum of electron-donating carbon substrates for photoorganotrophic growth resembles that found in the versatile *Chromatium* species (Pfennig and Trüper, 1989). Assimilation of acetate and propionate proceeds by carboxylation and therefore depends on the presence of CO_2.

Chloroflexus aurantiacus grows preferably by photoorganoheterotrophy (Pierson and Castenholz, 1995). The carbon substrates utilized comprise acetate, pyruvate, lactate, butyrate, C_4-dicarboxylic acids, some alcohols, sugars and amino acids (glutamate, aspartate). This versatility has been seen as the major cause for the profuse growth of *Chloroflexus* in microbial mats where accompanying microorganisms, especially cyanobacteria, may provide the required carbon substrates (Sirevåg, 1995). However, high rates of formation of low-molecular-weight organic carbon substrates by the anaerobic food chain have also been observed in other stratified systems, where the dominating anoxygenic phototrophs could utilize only a narrow range of carbon substrates (Overmann, 1997; Overmann et al., 1996). The refore, the presence of low-molecular-weight organic carbon substrates is not necessarily the most selective factor in the natural environment.

Slow photolithoautotrophic growth with H_2S or H_2 as electron-donating substrates has been shown in laboratory cultures of *Chloroflexus aurantiacus* and in hot spring populations (Pierson and Castenholz, 1995). Carbon fixation proceeds by carboxylation of acetyl-CoA and via hydroxypropionyl-CoA as an intermediate and yields glyoxylate as the net product (hydroxypropionate cycle; Holo, 1989; Strauß and Fuchs, 1993; Eisenreich et al., 1993). So far this cycle has not been found in any other member of the Bacteria. Glyoxylate is further assimilated into cell material with tartronate semialdehyde and 3-phosphoglycerate as intermediates (Menendez et al., 1999).

The highest metabolic versatility is found in phototrophic α- and β-Proteobacteria (purple nonsulfur bacteria). All representatives grow photoorganoheterotrophically and (with the exception of *Blastochloris viridis*) photolithoautotrophically with H_2 in the light. In addition to the substrates used by versatile purple sulfur bacteria, the spectrum of substrates that can serve as electron donors comprise long-chain fatty acids (like pelargonate), amino acids (aspartate, arginine, glutamate), sugar alcohols (sorbitol, mannitol), or aromatic compounds (benzoate; Imhoff and Trüper, 1989). With the exception of *Rubrivivax gelatinosus*, none of the purple nonsulfur bacteria is capable of degradation of polymers and therefore depends on the anaerobic food chain for the supply of electron-donating substrates required for growth. This dependence and the competition with chemotrophs for the carbon substr ates might be the major reason why dense blooms of purple nonsulfur bacteria do not occur under natural conditions (see Habitats of Phototrophic Prokaryotes in this Chapter). Some species are capable of also using reduced sulfur compounds as electron donors. However, most species oxidize sulfide to elemental sulfur only (Hansen and van Gemerden, 1972).

In *Heliobacteriaceae*, only a limited number of carbon substrates can serve as photosynthetic electron donor including pyruvate, ethanol, lactate, acetate, and butyrate. High levels of sulfide are inhibitory (Madigan, 1992; Madigan and Ormerod, 1995).

Cyanobacteria are obligate autotrophs par excellence; however, small molecular weight organic compounds such as acetate, sugars and amino acids are assimilated. In the case of amino acids, the presence of various efficient uptake systems has been interpreted as a means of recovery of leaked organic nitrogen, rather than a true chemotrophic capability (Montesinos et al., 1997). Certain strains of cyanobacteria can grow facultatively as chemoheterotrophs in the

dark (Rippka et al., 1979), but even under these conditions all of the photosynthetic machinery is synthesized. This lack of regulation implies that chemotrophy has played no significant evolutionary role in these organisms.

Chemotrophic Growth with O_2

Ecophysiology of Chemotrophic Growth

In lakes, purple sulfur and green sulfur bacteria are confined to environments where light reaches sulfide-containing water layers. The physiological properties restrict the distribution of these bacteria in the pelagic habitat (Pfennig, 1978). Dense accumulations of anoxygenic phototrophic bacteria, which apparently are growing chemotrophically, are only known for *Chloroflexus* (see Habitats of Phototrophic Prokaryotes in this Chapter). Although populations of other anoxygenic phototrophic bacteria do not seem to grow permanently by chemotrophy, the ability of many strains to shift to an aerobic chemotrophic mode of growth is of selective advantage in environments like intertidal sediments.

Green sulfur bacteria and *Heliobacteriaceae* are obligate anaerobes. Under oxic conditions, the reaction of reduced ferredoxin of the type I reaction center with molecular oxygen would create superoxide and other activated oxygen species. *Heliobacteriaceae* are rapidly damaged by exposure to molecular oxygen. This has been attributed not only to the formation of toxic oxygen radicals but also the destruction of the unsaturated fatty acids present in the cell membrane by activated oxygen species (Madigan and Ormerod, 1995). In green sulfur bacteria, it has been observed that the energy transfer from light-harvesting bacteriochlorophylls c/d/e to bacteriochlorophyll *a* drops by a factor of 10 after an increase in redox potential due to the quenching by chlorobium quinone. This mechanism may protect the cells during brief anoxic/oxic transitions. (see The Family Chlorobiaceae, Physiology section in Volume 7).

All other groups of phototrophic prokaryotes comprise species that not only generate metabolic energy by photosynthesis but are also capable of chemosynthesis with O_2.

Chloroflexus aurantiacus is capable of growth as an aerobic heterotroph. During phototrophic growth, β-carotene, γ-carotene, and hydroxy-γ-carotene-glucoside are the major carotenoids, whereas echinenone and myxobactone predominate in aerobically grown cells (Pierson and Castenholz, 1995). Unlike in purple nonsulfur or purple sulfur bacteria, synthesis of some carotenoids by *C. aurantiacus* is greatly enhanced under aerobic conditions (Pierson and Castenholz, 1974). The expression of the chlorosome CsmA protein is transcriptionally or posttranscriptionally regulated by oxygen (Theroux et al., 1990).

Almost all known species of phototrophic α- and β-Proteobacteria (purple nonsulfur bacteria) are capable of microaerophilic or aerobic chemoorganoheterotrophic growth with oxygen as terminal electron acceptor. Of the purple sulfur bacteria, *Ectothiorhodospira* species, and eight small-celled species of the *Chromatiaceae* (*Thiocapsa rosea*; *Chromatium gracile*; *Chr. minus*; *Allochromatium vinosum*; *Thiocystis violascens*; *Thiocapsa roseopersicina*; *Thiocystis violacea*; *Thiorhodovibrio winogradskyi*) can grow by chemolithotrophy, oxidizing sulfide or thiosulfate with molecular oxygen (De Wit and van Gemerden, 1987b; Kämpf and Pfennig, 1980; Overmann and Pfennig, 1992). Only few species grow also chemoorganotrophically with organic carbon substrates as electron donor of respiration. The group of facultatively chemotrophic *Chromatiaceae* includes typical inhabitants of benthic microbial mats like *Thiocapsa roseopersicina* and *Thiorhodovibrio winogradskyi*. This is not surprising considering the pronounced oxic/anoxic fluctuations in this type of habitat. The cells of purple sulfur bacteria in benthic systems are often immotile and form aggregates together with sand grains, apparently as an adaptation to the hydrodynamic instability of the habitat (van den Ende et al., 1996). At the same time, however, immotile cells are exposed to strong diurnal variations in oxygen concentrations. The growth affinities for sulfide are lower for chemotrophically growing *Thiocapsa roseopersicina* than for colorless sulfur bacteria, which may explain that no natural populations of purple sulfur bacteria are known that grow permanently by chemotrophy (see Interactions between Phototrophic Sulfur Bacteria and Chemotrophic Bacteria in this Chapter).

When grown anaerobically in the light, facultatively chemotrophic species of the purple nonsulfur and purple sulfur bacteria contain a potentially active repiratory system and exhibit ≥50% of the respiratory activity of chemotrophically growing cells (De Wit and van Gemerden, 1987a; Kämpf and Pfennig, 1980; Overmann and Pfennig, 1992; Pfennig, 1978). In cells that still contain bacteriochlorophyll, respiration is inhibited by light. This indicates that respiration and photosynthesis are coupled (e.g., by the membrane potential or common redox carriers; Richaud et al., 1986). An example is the soluble cytochrome c_2 which has a dual function in *Rhodobacter sphaeroides* where it is needed for electron transfer from the cytochrome bc_1 complex to the reaction center during ph otosynthesis, and to the cytochrome c oxidase during

respiration with molecular oxygen. During photosynthetic growth, expression of cytochrome c_2 is increased. At limiting concentrations of electron donating substrate, photosynthesis is preferred over respiration as long as the intracellular bacteriochlorophyll content is maintained at a sufficiently high level (4–7 g bacteriochlorophyll a·mg protein$_{-1}$ in *Thiocapsa roseopersicina* at light saturation; De Wit and van Gemerden, 1990a).

Growth continues after a shift to microoxic or aerobic conditions. Under oxic conditions the synthesis of pigments and of pigment-binding proteins of the photosynthetic apparatus ceases. The number of intracellular membrane vesicles is reduced dramatically and the composition of membrane lipids is altered. The pigment content in purple sulfur bacteria is inversely related to the ambient oxygen concentration (Kämpf and Pfennig, 1986). At 25% air saturation (52 M) of oxygen, pigment synthesis in *Thiocapsa roseopersicina* is completely repressed and cells become colorless (De Wit and van Gemerden, 1987b). In continuous cultures of purple sulfur bacteria, active degradation has not been observed and intracellular bacteriochlorophyll concentrations follow the washout curve. Thus bacteriochlorophyll does not seem to be actively degraded but is diluted out by cell division (De Wit and van Gemerden, 1987b). Concomitantly, the activities of respiratory enzymes (NADH dehydrogenase, cytochrome c oxidases) are increased in chemotrophically grown cells. When the cells of *Thiocapsa roseopersicina* become colorless, they use only one third of the electron donor for reduction of CO_2. The remaining two thirds are used for energy generation and respired. Correspondingly, the protein yield reaches one third of that of phototrophically grown cells (De Wit and van Gemerden, 1987b; De Wit and van Gemerden, 1990b).

In aerobic phototrophic bacteria, aerobic growth is stimulated by light that is absorbed by bacteriochlorophyll *a*. This stimulation is only transient, however, since bacteriochlorophyll synthesis is repressed even by low light intensities (Yurkov and van Gemerden, 1993) thus leading to a loss of the photosynthetic apparatus under continuous illumination.

Respiration in *cyanobacteria* involves a full respiratory chain including a cytochrome aa_3 terminal oxidase. Monomeric sugars are degraded using the oxidative pentose phosphate cycle. A complete tricarboxylic acid cycle has never been shown for any cyanobacterium. The NADPH formed in sugar catabolism is fed to the membrane-bound electron transport chain at the level of plastoquinone. This is in contrast to green chloroplasts, in which plastoquinol is autoxidized (Peltier and Schmidt, 1991). The respiratory electron transport chain of cyanobacteria is located in both the plasma and the thylakoidal membrane, and it shares many functional components with photosynthetic electron transport. The role of exogenous respiration of organic substrates is probably minor under natural conditions. Under anoxia, the known electron acceptor alternatives to oxygen for cyanobacterial chemoorganotrophy are some organic compounds and elemental sulfur. Fermentation seems to be a relatively widespread ability in benthic and bloom-forming cyanobacteria, but it is not universal (Moezelaar and Stal, 1994).

Genetic Regulation by O_2

A shift from anoxic to oxic growth conditions requires the expression of new proteins and cofactors. On the genetic level the formation of the photosynthetic apparatus and the intracytoplasmic membrane system is regulated by two main environmental variables, light intensity (see Response to Changes in Light Intensity and Quality in this Chapter) and molecular oxygen. The two factors act independently of one another and are involved in different mechanism of regulation of bacteriochlorophyll synthesis (Arnheim and Oelze, 1983). Compared to light, molecular oxygen acts as a stronger repressor, however. Although oxygen is a major factor controlling the formation of the photosynthetic apparatus in most of the facultatively phototrophic *Proteobacteria*, *Rhodovulum sulfidophilum* and *Rhodocista centenaria* are exceptional in that these species form the photosynthetic apparatus under both aerobic and anaerobic conditions (Hansen and Veldkamp, 1973; Nickens et al., 1996). Photopigment synthesis is not repressed by O_2 in *Rhodocista centenaria*.

The regulation of bacteriochlorophyll synthesis in purple nonsulfur bacteria is complex. The cells synthesize very little bacteriochlorophyll, probably because of the inhibition of bacteriochlorophyll biosynthesis enzymes (the δ–aminolevulinic acid synthesis and enzymes for the conversion of coproporphyrin; Oelze, 1992) by O_2. Oxygen does not seem to exert an effective transcriptional control. Under oxic conditions the transcription of bacteriochlorophyll synthesis genes decreases 2-fold, while that of light-harvesting I and reaction-center genes decreases by a factor of 30–100 (Bauer, 1995). The tetrapyrrole synthesis pathway has four different branches (leading to heme, bacteriochlorophyll, siroheme and vitamin B_{12}). While the bacteriochlorophyll content is drastically reduced in the presence of oxygen (Arnheim and Oelze, 1983), heme synthesis remains unaffect ed (Lascelles, 1978). The intracellular activity of δ-aminolevulinic acid synthase, the key enzyme of tetrapy-

rrol synthesis in α-Proteobacteria, is reduced in the presence of oxygen. Regulation by oxygen may occur also during some later steps of tetrapyrrole synthesis. It appears that oxygen inhibits magnesium chelatase, thereby increasing the protoporphyrin IX pool, which in turn leads to increased formation of heme. Feedback inhibition of δ-aminolevulinate synthase by heme would then slow down the synthesis of intermediates but still guarantee the amount needed for heme biosynthesis (Beale, 1995; Biel, 1995; Rebeiz and Lascelles, 1982).

After return to anoxic conditions the synthesis of the photosynthetic apparatus and intracellular membranes occurs in a light-independent manner. Anoxygenic photosynthetic bacteria contain a distinct light-independent protochlorophyllide reductase, composed of probably three subunits (BchN, BchB, and BchL). In angiosperms, the reduction of the fourth ring of the Mg-tetrapyrrole intermediate by NADPH-protochlorophyllide oxidoreductase is a light-dependent step in the chlorophyll biosynthetic pathway. This protein represents one of the only two enzymatic transformations known to require light (Suzuki and Bauer, 1995). Cyanobacteria, green algae and gymnosperms contain both, the light-dependent and light-independent protochlorophyllide reductase. The capacity to synthesize (bacterio)chlorophyll in the dark is of significance for the competitive success of *Chromatiaceae* in intertidal microbial mats. During anoxic conditions in the dark, *Thiocapsa roseopersicina* can synthesize bacteriochlorophyll *a* at maximum rate. Under the fluctuating conditions as they are observed in benthic microbial mats (oxic light, anoxic dark phase), purple sulfur bacteria therefore can maintain a photosynthetic mode of growth as long as bacteriochlorophyll synthesis during the night compensates for the wash out of pigments during the day (De Wit and van Gemerden, 1990b).

A multicomponent regulatory cascade controls the coordinate expression of the light-harvesting and reaction center *puf*, *puh*, and *puc* genes and involve various transcription factors (Bauer, 1995; Bauer and Bird, 1996). In *Rhodobacter capsulatus*, a redox-sensitive repressor (CrtJ) binds under oxic conditions to a conserved palindrome sequence in promotors of bacteriochlorophyll, carotenoid, and light-harvesting complex II genes. A second system for the regulation of the *puf*, *puh*, and *puc* operons probably consists of three components, a membrane-spanning sensor kinase (RegB), a soluble response regulator (RegA), and a hypothetical activator of the nonspecific alternative sigma factor σ^P (RegX). A decrease in oxygen tension causes autophos phorylation of the membrane-spanning sensor kinase RegB, which then phosphorylates the cytoplasmic response regulator RegA. The latter acts as intermediate and probably transfers its phosphate to a putative third DNA-binding component that activates gene expression. The RegA-RegB system also is involved in regulation of the expression of cytochrome c_2 and the Calvin cycle CO_2 fixation genes and therefore is of general significance for the regulation of cellular metabolism.

The transcripts of the photosynthetic gene cluster exceed 10 kb and extend from pigment biosynthesis genes across promoter regions and into the genes for light-harvesting complex I and reaction center proteins. In *Rhodobacter capsulatus*, transcription of the genes coding structural polypeptides of the reaction center and light-harvesting complex I are not the only peptides initiated at their respective promotors. The transcripts of the bacteriochlorophyll biosynthesis *bchCA* operon extends through the promoter and coding sequences of the downstream *puf BALM* operon, and the transcript of the carotenoid biosynthesis *crtEF* operon extends through both (Wellington et al., 1992). Similarly, the *bchFBKHLM-F1696* and *puhA* operons are transcriptionally linked. The linkage of operons of different components of the phot osynthetic apparatus in such superoperons also has been detected in other species of purple nonsulfur bacteria and may play a significant role in the adaptation of cells to changes in environmental oxygen tension. According to a model (Wellington et al., 1992), the presence of superoperons ensures a rapid physiological response to a decrease in oxygen tension. In the presence of oxygen, a basal level of light-harvesting I and reaction center polypeptides is constantly formed and incorporated into the membrane, but these polypeptides disappear again in the absence of bacteriochlorophyll (Dierstein, 1984; Drews and Golecki, 1995) due to degradation. After a shift from oxic to anoxic conditions, the presence of a basal level of structural polypeptides considerably shortens the lag time for the change from aerobic respiratory to anaerobic photosynthetic growth. During this lag ph ase, the cellular amount of structural polypeptides of the photosynthetic apparatus is further increased by increasing the transcription rate of the *puf* and *puh* genes.

Oxygen does not only regulate the transcription of photosynthesis genes but also later steps in gene expression. Posttranscriptional regulation involves mRNA processing (mRNA degradation) and possibly some later steps (Rödig J. et al., 1999).

In most bacteria, the formation of multiple sigma factors is a prerequisite for the coordination of the regulation of a large number of genes in response to changes in environmental condi-

tions. Sigma factors are dissociable subunits that confer promoter specificity on eubacterial core RNA polymerase and are required for transcription initiation. In phototrophic bacteria, the diversity of sigma factors of the σ^{70} family as they are present in the different phylogenetic groups appears to be correlated with their metabolic flexibility. In the unicellular cyanobacteria *Synechococcus* sp. and *Synechocystis* sp., nine different sigma factors (one member of group 1, four members of group 2, and four members of group 3) have been found, whereas one group 1 and three group 2 sigma factors have been found in *Chloroflexus* spp. In contrast to most other bacteria, the green sulfur bacterium *Chlorobium tepidum* contains only one group 1, but no alternative group 2 sigma factor (Gruber and Bryant, 1998). In *Chloroflexus*, one group 2 σ^{70} factor (SigB) is transcribed at fourfold higher levels during aerobic growth and therefore appears to be involved in the shift in metabolism. It has been proposed that SigB is involved in regulation of pigment synthesis (Gruber and Bryant, 1998).

Significance of Anoxygenic Photosynthesis for the Pelagic Carbon and Sulfur Cycles

The carbon fixation of phototrophic sulfur bacteria has been determined in a wide range of habitats, mostly inland lakes (Overmann, 1997; van Gemerden and Mas, 1995). The theoretical maximum of primary production by phototrophic sulfur bacteria has been estimated to be 10,000 mg $C{\cdot}m^{-2}{\cdot}d_{-1}$. Purple and green sulfur bacteria can contribute up to 83% of total primary productivity in these environments. This high number notwithstanding, anoxygenic primary production only represents a net input of organic carbon to the food web if 1) the anaerobic food chain is fueled by additional allochthonous carbon from outside and 2) aerobic grazers have access to the biomass of phototrophic sulfur bacteria. Based on recent experimental evidence, these conditions are met at least in some aquatic ecosystems (Overmann, 1997).

With the exception of geothermal springs, the sulfide required by phototrophic sulfur bacteria for CO_2-assimilation originates from sulfate or sulfur reduction during the terminal degradation of organic matter. This organic matter cannot be provided solely by anoxygenic phototrophic bacteria, since growth (hence accumulation of reduced carbon) constantly diverts electrons from their cycling between anoxygenic phototrophic bacteria and sulfate-reducing bacteria. At least part of the sulfide formation is therefore fueled by carbon that has already been fixed by oxygenic photosynthetic organisms within or outside the ecosystem. Consequently anoxygenic photosynthesis represents not new, but secondary primary production. A complete degradation of the carbon fixed by phototrophic sulfur bacteria in the anaerobic food chain (and thus an efficient recycling of electrons) in an anoxygenic primary production has been estimated to exceed oxygenic photosynthesis by as much as ten times (Overmann, 1997). In reality, anoxygenic photosynthesis surpasses that of phytoplankton mostly in oligotrophic lakes. In many oligotrophic lakes, the input of allochthonous carbon derived from terrestrial sources in the watershed is significant (Rau, 1980; Sorokin, 1970). In an oligotrophic saline meromictic lake (Mahoney Lake, B.C., Canada), purple sulfur bacteria together with the anaerobic food chain efficiently converted allochthonous organic carbon into easily degradable bacterial biomass (Overmann, 1997). It appears likely that phototrophic sulfur bacteria have this ecological function also in other aquatic ecosystems.

The presence of hydrogen sulfide in layers of phototrophic sulfur bacteria may prevent their biomass from entering the grazing food chain. This has been substantiated by stable carbon and sulfur isotope data, which indicated that phototrophic sulfur bacteria are not consumed to a significant extent by higher organisms (Fry, 1986). In addition, a quantitative analysis of loss processes conducted in a few lakes indicates that predation must be of minor significance (Mas et al., 1990; van Gemerden and Mas, 1995). In contrast, recent investigations have revealed that at least in one lake ecosystem, a major fraction of purple sulfur bacterial biomass enters the aerobic food chain via rotifers and calanoid copepods (Overmann et al., 1999b; Overmann et al., 1999c). The key environmental factors that caused this efficient link between anoxic and oxic water layers were the autumnal upwelling of phototrophic bacteria into oxic water layers by mixing currents, and the formation of gas vesicles and large cell aggregates by the dominant species, *Amoebobacter purpureus*.

Sulfide formation by sulfate- and sulfur-reducing bacteria and sulfide oxidation back to sulfur and sulfate occur at comparable rates in several lakes (Overmann et al., 1996; Parkin and Brock, 1981). This leads to a closed sulfur cycle and a detoxification of sulfide without concomitant depletion of oxygen (Pfennig, 1978).

The significance of phototrophic sulfur bacteria for the oxidation of sulfide in stratified environments is critically dependent on their cell density rather than the absolute biomass per surface area of the ecosystem (Jørgensen, 1982). Dense populations in laminated microbial mats can account for 100% of the total sulfide oxidation in those systems, whereas some dilute pelagic populations oxidize only very small amounts (e.g., 4% in the Black Sea) of the sulfide

diffusing from below into the chemocline (Overmann et al., 1991a; Overmann et al., 1996).

No information on the ecological significance of aerobic phototrophic bacteria is available to date.

Interactions with Other Microorganisms

Competition for Light Blue light prevails in very clear open oceans (Fig. 6) where marine *Synechococcus* cells thrive under conditions of low photon flux (~10 mol quanta·m^{-2}·s^{-1}; Carr and Mann, 1994). Two ecotypes of the marine *Synechococcus* exist which differ in the intracellular ratio of phycourobilin to phycoerythrobilin (Waterbury et al., 1986). Two subpopulations are distinguished according to the predominant chromophore associated with the phycoerythrin. Phycourobilin-rich strains are characteristic of the open oceans whereas strains with a lower PUB content predominate in shelf waters (Olson et al., 1990a). Compared to PEB-containing antennae (absorption maximum, ~550 nm), incorporation of PUB (absorption maximum, ~495 nm) increases the efficiency of light absorption significantly in deeper water lay ers of oligotrophic oceans.

Similarly, coexisting and phylogenetically closely related but genetically distinct populations of *Prochlorococcus* are adapted for growth at different light intensities, which results in their broad depth distribution (Moore et al., 1998). The low-light-adapted ecotype has a higher intracellular content of chlorophylls a and b, a higher chlorophyll b/a ratio, and exhibits a higher maximum quantum yield reaching the theoretical maximum of 0.125 mol C·(mol quanta)$^{-1}$. Its properties enable this ecotype to colonize very low water layers. It has been suggested that the distribution of different ecotypes in the same water column would result in greater integrated production than could be achieved by a single ecotype (Moore et al., 1998).

Based on the specific physiological properties of oxygenic and anoxygenic phototrophic bacteria, multilayered microbial communities frequently develop in stratified pelagic and in benthic (Fig. 5A,B) habitats. Cyanobacteria, eukaryotic algae and even plants (Lemna) form the topmost layers overlying populations of *Chromatiaceae* and green sulfur bacteria (Dubinina and Gorlenko, 1975; Caldwell and Tiedje, 1975; Pfennig, 1978; Camacho et al., 1996; Pierson et al., 1990; Pierson et al., 1990).

Phototrophic sulfur bacteria require the simultaneous presence of light and sulfide, which usually restricts their occurrence to layers well below the surface of lakes and sediments. As a consequence of the absorption of light in the overlying water, the light energy available to phototrophic sulfur bacteria in most pelagic environments is rather low (0.02–10% of surface light intensity; van Gemerden and Mas, 1995; Parkin and Brock, 1980b; Camacho et al., 1996). Similar values have been determined for purple layers in benthic microbial mats (Kühl and Jørgensen, 1992; Pierson et al., 1990; Garcia-Pichel et al., 1994c). A tight correlation between anoxygenic photosynthesis and the amount of light reaching phototrophic sulfur bacteria strongly suggests that light i s the main environmental variable controlling the anoxygenic photosynthesis (van Gemerden and Mas, 1995). Therefore, a selective pressure for efficient light harvesting and maximum quantum yield exists in anoxygenic phototrophs. The same holds true for a few niche-specialized, deep-dwelling cyanobacteria.

The ecological niches of green sulfur bacteria and *Chromatiaceae* show considerable overlap because both groups grow preferably or exclusively by photolithotrophic metabolism, using ambient sulfide as electron-donating substrate. Different species of the same group should be even more competitive. Besides differences in maintenance energy demand, in adaptation to low light intensities and metabolic flexibility, another important factor determining the species composition of phototrophic sulfur bacteria in their natural habitats is the spectral composition of underwater light. In the overlying layers, light is absorbed by water itself, dissolved yellow substance (gilvin), phytoplankton and inanimate particulates. The limited wavelength range available at great depth selects for species of anoxygenic phototrophic bacteria with complementary absorption spectra. In many lacustrine habitats, light absorption by phytoplankton exceeds that of gilvin or water itself (Kirk, 1983), and light of the blue green to green wavelength range reaches layers of phototrophic sulfur bacteria. Those *Chromatiaceae* which contain the carotenoid okenone (Fig. 7) dominated in 63% of the natural communities studied (van Gemerden and Mas, 1995). It was proposed that energy transfer from carotenoid antenna pigments to the reaction center is more efficient in okenone-forming strains than in other purple sulfur bacteria (Guerrero et al., 1986). In addition, the capability of gas vesicle formation, and the different kinetics of sulfide oxidation (see Coexistence of Phototrophic Sulfur Bacteria in this Chapter) appear to be of selective value for the colonization of pelagic habitats. Below accumulations of purple sulfur bacteria, the green-colored forms of the green sulfur bacteria dominate because of their superior capability to harvest the light reaching them, which has its spectrum shifted to a maximum intensity at 420–450 nm (Table 2) (Montesinos et al., 1997). In contrast, the brown-colored forms of the green sulfur bacteria dominate in lakes

where the chemocline is located at depths greater than 9 m and in eutrophic lakes with a pronounced light absorption in the oxic zone.

A similar niche separation occurs in the phototrophic consortia (see The Family Chlorobiaceae in Volume 7), which encompass green-colored or brown-colored epibionts (Overmann et al., 1999b). The ecological niche of the brown-colored green sulfur bacteria may be attributed to their use of significantly lower light intensities than purple sulfur bacteria for phototrophic growth and to their lower maintenance energy requirements (see Light Absorption and Light Energy Transfer in Prokaryotes in this Chapter; The Family Chlorobiaceae in Volume 7). An extremely low-light adapted strain of the green sulfur bacterium *Chlorobium phaeobacteroides* has been isolated from the chemocline of the Black Sea located at an 80-m depth (Overmann et al., 1991a). This isolate (strain MN1) could grow at light intensities as low as 0.25 μmol quanta·m^{-2}·s^{-1}.

In sedimentary environments with their particular optical properties (Fig. 6), the irradiance reaching anoxygenic phototrophic bacteria may be reduced to ←1% of the surface value for light in the visible region, while >10% of the near infrared light is still available (Kühl and Jørgensen, 1992; see Light energy and the spectral distribution of radiation). As a consequence, the long wavelength Q_y bands of bacteriochlorophylls are significant for light-harvesting in sediments, whereas light absorption of anoxygenic phototrophic bacteria in lakes is mediated by carotenoids and the Soret bands of bacteriochlorophylls. In microbial mats, the spectral quality of the scalar irradiance is strongly modified as it penetrates. The presence of populations of phototrophic microorganisms impose strong absorption signatures on the spectrum of the scalar irradiance (Jørgensen and Des Marais, 1988; Pierson et al., 1987). As a result of vertical niche separation, benthic microbial mats can consist of up to five distinctly colored layers that are formed (from the top) by diatoms and cyanobacteria, cyanobacteria alone, purple sulfur bacteria with bacteriochlorophyll a, purple sulfur bacteria with bacteriochlorophyll b, and green sulfur bacteria (Nicholson et al., 1987). In this vertical sequence different wavelength bands of red and infrared light (compare Table 2, Fig. 7) are successively absorbed by the different microbial layers (Pierson et al., 1990). Distinct blooms of bacteriochlorophyll *b*-containing anoxygenic phototrophic bacteria have been observed only in benthic habitats. Employing this pigment, the phototrophic Proteobacteria *Blastochloris viridis*, *Blastochloris sulfoviridis*, *Thiocapsa pfennigii*, *Halorhodospira halochloris*, *Halorhodospira abdelmalekii* harvest light of a wavelength range (1020–1035 nm), which cannot be exploited by any other photosynthetic organism.

Until recently, no strain of anoxygenic photosynthetic bacteria was known that could absorb light in the wavelength range between 900 and 1020 nm. Because of the prevalence of infrared radiation in the anoxic layers of microbial mats and the strong competition for this wavelength region, bacteria containing other types of photosynthetic antenna complexes would have a high selective advantage. Recently, the α-Proteobacterium *Rhodospira trueperi* was isolated, which contains bacteriochlorophyll *b* in a light-harvesting complex with a maximum absorption at 986 nm (Pfennig et al., 1997). Employing a selective enrichment strategy, the α-Proteobacterium *Roseospirillum parvum* could be isolated which harbors another new type of photosynthetic antenna complex. Here, bacteriochlorophyll *a* is the light-harvesting pigment and in vivo exhibits an absorption maximum at 911 nm (Glaeser and Overmann, 1999, Fig. 7). Both isolates originate from benthic microbial mats, indicating that the diversity of pigment-protein complexes in *Proteobacteria* is higher than previously assumed. The variation in the in vivo absorption spectra of the same pigment must be the result of differences in binding to light-harvesting proteins. In contrast, changes in the absorption spectra of the light-harvesting complex of green sulfur bacteria are the result of chemical alterations (e.g., methylation) of the pigment molecules (Bobe et al., 1990) because pigment-pigment interactions dominate in the chlorosomes (see Light Absorption and Light Energy Transfer in Prokaryotes in this Chapter).

Because methanogenesis is the predominant pathway of terminal degradation in rice fields, *Heliobacteriaceae* probably compete with the photoheterotrophic purple nonsulfur bacteria in their natural environment (Madigan and Ormerod, 1995). Owing to the presence of bacteriochlorophyll g, *Heliobacteriaceae* take advantage of a wavelength region of the electromagnetic spectrum, which is not absorbed by other phototrophic bacteria. As a result of the small and fixed size of the photosynthetic antenna (see Light Absorption and Light Energy Transfer in Prokaryotes in this Chapter), these bacteria are adapted to higher light intensities than other anoxygenic phototrophic bacteria (≈1,000 mol quanta·m^{-2}·s^{-1}).

In addition to the capacity of absorbing light in the long wavelength range, metabolic flexibility is of highly selective value for the colonization of benthic habitats with their high fluctuations in oxygen and sulfide concentrations (see Chemotrophic growth with O_2).

However, the composition of communities of phototrophic sulfur bacteria is not solely deter-

mined by competition. The simultanous presence of green sulfur bacteria and *Chromatiaceae* possibly is also based on syntrophic interactions (see Coexistence of Phototrophic Sulfur Bacteria in this Chapter).

Coexistence of Phototrophic Bacteria Within the *Chromatiacea* the small-celled genus *Chromatium* species exhibit a considerably greater metabolic flexibility than the large-celled species (see Carbon Metabolism and Chemotrophic Growth with O_2 in this Chapter). In addition, small-celled species like *Allochromatium vinosum* have a higher growth affinity for sulfide. Based on these pure culture data, it is therefore unexpected that large-celled forms in fact dominate in natural ecosystems. The large-celled *Chromatium weissei* oxidizes sulfide twice as fast as the small-celled *Allochromatium vinosum*. Whereas the former preferentially oxidizes sulfide to zero-valent sulfur, the latter oxidizes a larger fraction directly to sulfate. Under fluctuating conditions as they occur in the chemocline of lakes, *Chromatium weissei* is capable of rapidly oxidizing sulfide at the onset of illumination, thereby accumulating zero-valent sulfur. During the remaining light period and because of its higher affinity for sulfide, *Allochromatium vinosum* utilizes most of the sulfide. Continuous cocultures of both species have thus been established by illumination in light-dark cycles (van Gemerden, 1974).

Furthermore, stable coexistence of two organisms is feasible in the presence of two substrates for which the two competitors have complementary affinities. Stable syntrophic interactions can be established in laboratory cocultures of purple sulfur (*Allochromatium vinosum*) and green sulfur bacteria (*Chlorobium limicola* f.sp. thiosulfatophilum; van Gemerden and Mas, 1995). Because of its higher affinity, the green sulfur bacterium oxidizes sulfide to zero-valent sulfur. The extracellular sulfur is mobilized as polysulfide, which can be used instantaneously as electron donor of the purple sulfur bacterium. The presence of sulfide inhibits the green sulfur bacterium from using polysulfide (see The Family Chlorobiaceae in Volume 7). Sulfide and polysulfide thus are the mutual substrates for the two different phototrophic sulfur bacteria.

Purple and green sulfur bacteria also have complementary affinities for sulfide and acetate (see Carbon metabolism). Accordingly, stable continuous cocultures of *Chlorobium phaeobacteroides* and *Thiocapsa roseopersicina* can be established (Veldhuis and van Gemerden, 1986).

Interactions Between Phototrophic Sulfur Bacteria and Chemotrophic Bacteria A considerable number of strains of *Chromatiacae* is capable of switching to a chemolithotrophic growth mode after prolonged incubation in the presence of molecular oxygen (see Chemotrophic Growth with O_2 in this Chapter). Under these conditions, purple sulfur bacteria compete with colorless sulfur bacteria like *Thiobacillus* spp. Compared to thiobacilli, the purple sulfur bacterium *Thiocapsa roseopersicina* attains a higher growth yield under chemolithotrophic conditions (De Wit and van Gemerden, 1987a). However, the growth affinity for sulfide of the colorless sulfur bacteria is up to 47 times higher than that of *Chromatiacae* (De Wit and van Gemerden, 1987b; van Gemerden and Mas, 1995). Therefore *Chromatiacae* growing exclusively by chemolithotrophy would be rapidly outcompeted by colorless sulfur bacteria.

Culture experiments indicate that *Thiocapsa roseopersicina*, a typical inhabitant of laminated microbial mats in temperate environments, can replenish its photosynthetic pigments during anoxic periods in the dark, thereby maintaining a phototrophic growth mode also during the subsequent oxic light period (De Wit and van Gemerden, 1990b). Based on microelectrode measurements, purple sulfur bacteria in marine microbial mats of the North Sea barrier islands are exposed to oxygen during most of the day, whereas anoxic conditions prevail during the night (De Wit et al., 1989). Thus, the anoxygenic phototrophs cannot grow during the night and face competition for sulfide by colorless sulfur bacteria during the day. Because of their higher affinity for sulfide, the latter would be expected to outcompete phototrophically growing purple sulfur bacteria. In cocultures of *Thiocapsa roseopersicina* and *Thiobacillus thioparus*, sulfide is indeed entirely used by the colorless sulfur bacterium in the presence of oxygen. If oxygen concentrations are limiting, however, sulfide is oxidized incompletely by the chemolithotroph and soluble zero-valent sulfur formed (either as polysulfide or polythionates) that in turn is used by the purple sulfur bacterium for phototrophic growth (van den Ende et al., 1996). Both diurnal fluctuations between oxic light and anoxic dark periods and syntrophism based on sulfur compounds may permit a stable coexistence of these groups and explain their simultaneous presence in natural microbial mats.

Stable associations can be established between green sulfur bacteria and sulfur- or sulfate-reducing bacteria (see The Family Chlorobiaceae in Volume 7; Interactions with Chemotrophic Bacteria in this Chapter). These associations are based on a cycling of sulfur compounds but not carbon (see Significance of Anoxygenic Photosynthesis for the Pelagic Carbon and Sulfur Cycles in this Chapter). The simultaneous growth of both types of bacteria is fueled by the

oxidation of organic carbon substrates and light. In a similar manner, cocultures of *Chromatiaceae* with sulfate-reducing bacteria have been established in the laboratory (van Gemerden, 1967).

The most spectacular type of association involving phototrophic bacteria is represented by the phototrophic consortia. These consortia consist of green sulfur bacterial epibionts that are arranged in a regular fashion around a central chemotrophic bacterium. A rapid signal transfer exists between the two partners and permits phototrophic consortia to scotophobotactically accumulate at preferred light intensities and wavelengths. In this association, the immotile green sulfur bacteria attain motility like purple sulfur bacteria. The high numbers of phototrophic consortia found in many lakes indicate that this strategy must be of high competitive value under certain environmental conditions.

A commensal relationship may exist between coccoid epibiotic bacteria and the purple sulfur bacterium *Chromatium weissei* (Clarke et al., 1993). This unidentified epibionts attaches to healthy cells but does not form lytic plaques on lawns of host cells like the morphologically similar parasite *Vampirococcus* (see Significance of Bacteriophages and Parasitic Bacteria in this Chapter). Possibly, the epibiont grows chemotrophically on carbon compounds excreted by the purple sulfur bacterium.

A syntrophic interaction between cyanobacteria and sulfate-reducing bacteria appears to exist in microbial mats where both types of microorganisms occur in close spatial proximity, if not intermixed with each other. In these ecosystems, the excretion of organic carbon substrates by cyanobacteria may provide the electron-donating substrates for sulfate-reducing bacteria (Jørgensen and Cohen, 1977; Skyring and Bauld, 1990; Fründ and Cohen, 1992). The glycolate produced by photorespiration (Fründ and Cohen, 1992), as well as the formate, acetate and ethanol produced by glycogen fermentation (Moezelaar and Stal, 1994) most likely are the substrates excreted by cyanobacteria.

Despite a pronounced limitation of sulfate reduction by carbon substrates (Overmann et al., 1996; Overmann, 1997), no close syntrophic relationship was found between purple sulfur and sulfate-reducing bacteria in a meromictic lake. In this specific environment degradation of biomass by the entire anaerobic food chain rather than excretion of small carbon molecules and their direct utilization by sulfate-reducing bacteria provides the electron-donating substrates for sulfate-reducing and sulfur-reducing bacteria.

Symbioses Between Phototrophic Bacteria and Eukaryotes Only one example is known for an intracellular symbiosis of anoxygenic phototrophic bacteria with an eukaryotic organism. The ciliate *Strombidium purpureum* inhabits the photic zone of sulfide-containing marine sands and harbors 200–700 purple endosymbionts. Symbionts are arranged along the periphery of the host cell and contain intracellular tubular or vesicular membranes, bacteriochlorophyll *a* and spirilloxanthin (Fenchel and Bernard, 1993a; Fenchel and Bernard, 1993b). The ciliate shows a photosensory behavior, accumulating at wavelength that corresponds to the absorption maxima of the endosymbionts. It has been suggested that the intracytoplasmic purple bacteria increase the efficiency of the fermentative host by using its end products for anoxygenic photosynthesis. Furthermore, respiration of the bacteria may protect the host against oxygen toxicity.

In the course of evolution, *Cyanobacteria* have entered into symbiotic associations with a multitude of organisms (Schenk, 1992). Besides all eukaryotic phototrophs, from microalgae to *Sequoia sempervirens*, which have intracellular cyanobacterial symbioses, the most common extracellular symbioses of nonheterocystous cyanobacteria are in the form of cyanolichens and involve the unicellular genera *Chroococcidiopsis*, *Gloeocapsa*, "*Chroococcus*," and *Gloeothece*, as well as members of the genera *Nostoc*, *Calothrix*, *Scytonema*, *Stigonema*, and *Fischerella* as photobionts. Heterocystous cyanobacteria in the genus *Nostoc* form extracellular symbioses with liverworts and hig her plants (Cycads, duckweed). *Anabaena* enters in symbiosis with water ferns of the genus *Azolla*. *Prochloron* strains, large-celled *Synechocystis* and small-celled *Acaryochloris marina* are known from extracellular symbioses with ascidians in tropical or subtropical marine waters; *Prochloron* is found as ectosymbiont on the marine didemnid ascidian *Lissoclinum patella* (Lewin and Withers, 1975). Extracellular symbioses of the *Pseudanabaena*-like "*Konvophoron*" occur in Mediterranean invertebrates. Finally, intracellular symbioses of nonheterocystous cyanobacteria are known with tropical sponges ("*Aphanocapsa*", *Oscillatoria*, *Synechocystis*, *Proc hloron*), with green algae (*Phormidium*) and dinoflagellates (unidentified). Heterocystous cyanobacteria occur intracellularly in oceanic diatoms of the genera *Hemiaulus* and *Rhizosolenia* (and the cyanobacterium *Richelia intracellularis*). The cyanobacterial symbiont consists of a short cell filament with a terminal heterocyst (Mague et al., 1977). The numbers of filaments varies with host species. *Nostoc* thrives intracellularly in *Trifolium* (clover) and also in the terrestrial non-lichenic fungus *Geosiphon pyriforme*. With the notable exception of lichenic photobionts, many symbiotic cyanobacteria have resisted cultivation in spite of continued efforts.

Significance of Bacteriophages and Parasitic Bacteria In addition to grazing, light and nutrient limitation, cyanophage infection of cyanobacteria may be a significant factor limiting primary productivity in the marine environment. However, because of inactivation by solar radiation and resistence of the host cells, the role of cyanophages has remained unclear (Bergh et al., 1989; Proctor and Fuhrman, 1990; Suttle et al., 1990; Suttle et al., 1993; Waterbury and Valois, 1993).

Several bacteria have been discovered that attack phototrophic bacteria (Guerrero et al., 1986; Nogales et al., 1997). *Vampirococcus* attaches to the cell surface of *Chromatium* spp. where it divides, forming chains of up to three cells. Concomitantly, the cytoplasm of the host cell appears to be degraded. *Daptobacter* penetrates the cell envelope and divides intracellularly by binary fission. In contrast to *Vampirococcus*, *Daptobacter* has been cultivated in the absence of the host and grows by fermentative metabolism. *Bdellovibrio* has a broad host range, and under laboratory conditions attacks also purple sulfur bacteria. *Bdellovibrio* forms daughter cells by multiple division in the periplasmic space of the host cell. The Gram-negative chemotrophic bacterium *Stenotrophomonas maltophilia* is a non-obligatory parasite of green sulfur bacteria, which causes cell lysis and ghost formation (Nogales et al., 1997). Its host range is not limited to green sulfur bacteria. The presence of parasitic bacteria in water samples becomes evident by the formation of lytic plaques on lawns of host bacteria (Esteve et al., 1992; Nogales et al., 1997). Up to 94% of the cells of phototrophic sulfur bacteria may be infected by parasitic bacteria in natural samples. Since infection is largely limited to nongrowing cells, the impact of parasitism on populations of phototrophic sulfur bacteria appears to be limited (van Gemerden and Mas, 1995).

Evolutionary Considerations

Porphyrins are found in all organisms from archaebacteria through plants to animals, and are indispensable as prosthetic groups for energy conservation. In contrast, the partially reduced derivates of porphyrins, the (bacterio)chlorophylls, are synthesized by members of only a few bacterial divisions (Fig. 1). This indicates that the capability for synthesis of porphyrins is a very ancient trait, whereas only a few prokaryotes acquired the capability to form photosynthetic pigments. Photosynthesis requires the presence of various complex protein structures and cofactors, and thus the expression of a large number of different genes (see Photosynthetic Gene Cluster in this Chapter). Previously, it had therefore appeared justified to consider all phototrophic prokaryotes as a monophyletic group only distantly related to nonphototrophic bacteria (Pfennig and Trüper, 1974; Trüper and Pfennig, 1978). Two lines of evidence have been used to recon struct the evolution of photosynthesis.

Fossil Evidence The oldest fossils of microorganisms have been dated back to the early Archaean (3.8 billion years ago) and may represent remains of cyanobacteria (Awramik, 1992). They consist of chemical fossils and stromatolites that have been detected especially in sedimentary rocks of the Pilbara region, Western Australia, and the Barberton Mountain Land, South Africa. Stromatolites are laminated convex domes and columns of cm to dm size and have been found in 3.5 to 0.8 billion year old rocks. Although scarce in biosynthetic molecular skeletons, the insoluble, high-molecular-weight organic matter (kerogen) contains isotopic evidence for autotrophic carbon fixation. The ratio of stable carbon isotopes ($\delta^{13}C$ values) are in the range of –35.4 to –30.8°/oo, which is typical for CO_2-carbon fixed by the ribulose-1,5-bisphosphate cycle (Hayes et al., 1983). In addition, the se ancient sediments contain laminated domes and columns of cm to dm size, which in analogy to extant stromatolites have been interpreted as organosedimentary structures produced by the trapping, binding, and precipitation activity of filamentous microorganisms, most likely cyanobacteria.

Alternatively, it has been proposed that anoxygenic photosynthetic bacteria and not the oxygenic cyanobacteria formed the oldest stromatolites. Based on the phylogenetic analysis of the 16S rRNA gene sequence (Oyaizu et al., 1987) and the ecophysiology (Ward et al., 1989) of the filamentous green photosynthetic bacterium *Chloroflexus aurantiacus*, similar anoxygenic phototrophic bacteria may be the more likely candidate microorganisms that built the most ancient stromatolites. However, according to analyses of the nucleotide sequences of its reaction center polypeptides and primary sigma factor (see Molecular Evidence in this Chapter), *Chloroflexus aurantiacus* does not represent a deep branch of bacterial evolution. Gypsum layers within the supposed stromatolites have been interpreted as indicators of sulfide oxidation by either anoxygenic phototrophs or colorless sulfur-oxidizing bacteria (Awramik, 1992). However, similar structures have been discovered in lacustrine, and thus sulfur-depleted, settings with little input of allochthonous organic carbon (Buick, 1992). Therefore, at least some 2.7 billion year-old stromatolites are more likely to have harbored oxygenic cyanobacteria. Taken together with the fossil evidence, this would indi-

cate that diversification of the major groups of phototrophic microorganisms did occur during the early Archaean (Awramik, 1992).

Because of the indefinite character of the fossil evidence, 16S rRNA sequences and components of the photosynthetic apparatus of the different photosynthetic prokaryotes have been used to gain additional insight into the evolution of photosynthesis.

Molecular Evidence Chlorophyll-based photosystems are only found in the Bacteria and chloroplasts, suggesting that this type of energy conversion originated in the bacterial lineage after the divergence of Archaea and Eukarya. So far, photosynthetic species have not been discovered in the very early lineages of the bacterial radiation (e.g., the thermophilic oxygen reducers and *Thermotogales*; Fig. 1). Because most species of these lineages are chemolithotrophic, it has been proposed that chemolithoautotrophy preceded phototrophy during the evolution of the Bacteria (Pace, 1997). This conclusion is supported by the fact that in phylogenetic trees based on protein sequences of elongation factor EF-Tu and the β-subunit of ATP synthase, only the *Aquificales* and *Thermotogales* branch deeper than the majority of the bacterial divisions, while the *Chloroflexus* subdivision does not (Stackebrandt et al., 1996), thus indicating that *Chloroflexus* does not represent the descendant of a more ancient ancestor than other phototrophic bacteria.

At present, five of the known bacterial lineages comprise phototrophic species (Fig. 1, see Taxonomy of Phototrophy among Prokaryotes in this Chapter). Based on 16S rRNA sequences, extant phototrophic species of different lineages are only very distantly related to each other. Furthermore, one lineage, the *Chloroflexus* subgroup, represents an early branch in the evolution of the Bacteria. Given the complexity of the photosynthetic apparatus, it is unlikely that photosynthesis has evolved more than once during the evolution of the domain Bacteria (Woese, 1987). The phylogenetic analysis indicates that either an early ancestor of most known bacteria had acquired the capacity for photosynthetic growth (Stackebrandt et al., 1988) or, alternatively, that the genes coding the photosynthetic apparatus were transferred laterally between phylogenetically distant bacteria. The evidence for the various scenarios of the evolution of bacterial photosynthesis is discussed in the present section.

Originally, it had been proposed (Oparin, 1938; Gest and Schopf, 1983a) that anaerobic, heterotrophic prokaryotes capable of fermenting hexose sugars were among the earliest life forms and that electron transport and photosynthesis evolved as a response to the depletion of organic nutrients from the primordial soup. Based on one hypothesis (the Granick hypothesis; Granick, 1965), the biosynthetic pathway of photosynthesis pigment molecules may be taken as a recapitulation of evolution such that compounds with shorter biosynthetic pathways reflect the more ancestral state. The synthesis of bacteriochlorophyll requires one additional enzymatic reduction than that of chlorophyll. Because chlorophyll precedes bacteriochlorophyll in the biosynthetic pathway, the former should have existed earlier in nature. It has been proposed (Pierson and Olson, 1989) that a non-oxygenic photosynthetic ancestor containing chlorophyll *a* and the two types of reaction centers evolved prior to the major radiation event of the Bacteria. During the subsequent radiation, oxygen evolution appeared in one line of descent whereas either the quinone or the FeS-type photosystem was lost in other lineages, concomitant with the emergence of the different bacteriochlorophylls. Besides avoiding an a priori lateral gene transfer of the complete photosynthetic gene cluster, this Pierson-Olson hypothesis takes into account the ecological conditions of the early biosphere in which the absence of oxygen and ozone caused a predominance of radiation in the blue and UV wavelength range, which in turn would render the red-shifted absorption maxima of bacteriochlorophylls of little selective advantage (Boxer, 1992).

As an argument against the Granick and Pierson-Olson hypotheses, several types of phototrophic bacteria that would be expected are apparently missing in nature. As an example, anoxygenic chlorophyll-containing forms have never been found, although it has been argued that the 8-hydroxychlorophyll-containing *Heliobacteriaceae* represents this type inasmuch as bacteriochlorophyll g is easily converted to chlorophyll *a* by oxidation. Bacteriochlorophylls occur in both types of reaction centers, the pheophytin-type (*Proteobacteria*, *Chloroflexus*) and the FeS-type. This could indicate that the presence of bacteriochlorophyll represents a primitive trait. The chlorophyll-first hypothesis postulates that bacteriochlorophyll has replaced chlorophyll independently in at least three different bacterial lineages. Chlorophyll, however, is presently only found in oxygen-evolving organisms of the phylum *Cyanobacteria* whic h, based on 16S rRNA sequence comparison, represents the most recently evolved group of phototrophic bacteria (Woese, 1987, Fig. 1). *Cyanobacteria* contain two different photosystems and thus have the most complex photosynthetic apparatus. In addition, the much higher complexity of the oxygen-evolving PSII of oxygenic phototrophic organisms may imply that it

appeared later than the other photosystems during evolution.

As another argument against the Pierson-Olson hypothesis, chlorophyll itself should have been of little selective advantage in Earth's early biosphere and it has been proposed that quinone-iron complexes represented the first photosynthetic unit (Boxer, 1992). In contrast to the complex porphyrin pigments, quinones can form spontaneously from acetyl thioesters (Hartmann, 1992). Furthermore, the discrepancy between the presence of chlorophyll exclusively in the most highly evolved bacteria and its shorter biosynthetic pathway may be explained by the finding that the chlorin reductase, which catalyzes the additional step of the biosynthetic pathway for bacteriochlorophyll, is phylogenetically older than the enzyme (protochlorophyllide reductase) that catalyzes the preceeding step. This enzyme is present in both the chlorophyll- and bacteriochlorophyll-containing bacteria (Burke et al., 1993). An ancien t reductase may have been able to perform both, the reduction of protochlorophyllide and of chlorin, such that bacteriochlorophyll was the photochemically active pigment in the last common ancestor of all extant phototrophic bacteria.

An analysis of the distribution of the different types of reaction centers among the different bacterial phyla and the amino acid sequences of reaction center proteins (Blankenship, 1992) provides an alternative hypothesis for the evolution of photosynthesis, namely the possibility of lateral transfer of photosynthesis genes. Both the pheophytin/quinone and the FeS-type reaction centers are found in phylogenetically distant groups (e.g., a pheophytin/quinone reaction center in *Chloroflexus* and phototrophic members of the α-Proteobacteria). Even more significantly, a phylogenetic analysis of the amino acid sequences of pheophytin-type reaction center polypeptides from the three different bacterial lineages *Chloroflexaceae*, *cyanobacteria* and α-Proteobacteria indicated that the reaction center of *Chloroflexus aurantiacus* is more closely related to that of phototrophic members of the α-Proteobacteria than to the PSII reaction center of cyanobacteria (Blankenship, 1992). Thus the reaction center of *Chloroflexus* must have evolved after (and not prior to) the divergence of the D1/D2 branch from the L/M line of descent. Another essential component of the photosynthetic apparatus of *Chloroflexus* and green sulfur bacteria are the light-harvesting chlorosomes. Based on amino acid sequence comparison of protein constituents, chlorosomes of both groups have a common evolutionary origin (Wagner-Huber et al., 1988). Similarly, a comparison of the amino acid sequences of the group 1 σ^{70} primary sigma factor also has demonstrated a close relationship to the green sulfur bacteria with respect to this component of the central housekeeping function (Gruber and Bryant, 1998). Other features of *Chloroflexus aurantiacus* appear to be unique (like the lipid and carotenoid composition), or ancient (like the hydroxypropionate pathway of CO_2-fixation). Recently, the activity of the key enzymes of this pathway have been reported for some archaea (Menendez et al., 1999) such that *Chloroflexus aurantiacus* seems to represent a "chimeric" organism.

Based on the most parsimonious assumption that homodimeric reaction centers are ancestral to homodimeric ones, the reaction centers of green sulfur bacteria and *Heliobacteriaceae* would resemble most the reaction center of the ancestor of all extant bacteria. It has been hypothesized (Gruber and Bryant, 1998) that the reaction center of *Chloroflexus aurantiacus* was acquired by a recent lateral gene transfer event that may have replaced a type I reaction center with a type II (FeS) reaction center, whereas other features like primary sigma factor or chlorosomes still reflect the common descent of *Chloroflexus* and the green sulfur bacteria. Alternatively, it has been suggested that transfer of the genetic information of the relatively simple chlorosomes occurred after the evolution of the two classes of reaction centers and that the green sulfur bacteria represent a relatively modern evolutionary invention (Stackebrandt et al., 1996).

The presence of two homologous polypeptides in all known reaction centers would suggest a single gene duplication event in an early ancestor of all phototrophic bacteria. As an additional result of the phylogenetic analysis of the amino acid sequences of pheophytin-type reaction center polypeptides from the three different bacterial lineages (*Chloroflexaceae*, *cyanobacteria* and α-Proteobacteria; Blankenship, 1992), the most likely occurrence of two independent gene duplications is suggested—one leading to the reaction center of PSII in cyanobacteria and green plants (polypeptides D1 and D2) and another to the reaction center of *Chloroflexus* and purple nonsulfur bacteria (polypeptides L and M). Another, third, independent gene duplication has to be assumed during the evolution of the FeS-type reaction center. The reason for the paraphyletic development of the three lineages may be a functional advan tage of dimeric reaction centers over monomeric ones.

Yet another evolutionary scenario for photosynthetic reaction centers (Vermaas, 1994) has been based on the finding that the sixth membrane-spanning region of the heliobacterial (FeS- or PSI-type) reaction center shows a great similarity to the sixth membrane-spanning

region of the CP47 antenna polypeptide of (the quinone-type) PSII, and the preceeding N-terminal five hydrophobic regions still show significantly greater similarity to CP47 (and to another PSII antenna protein, CP43) than to the respective portion of PSI. According to this model, an ancestral homodimeric antenna/reaction center complex comprised 11 putative transmembrane regions and contained two quinones and an F_x-type Fe_4S_4 iron-sulfur center. Relatively few modifications may have led to the homodimeric complex of green sulfur bacteria and *Heliobacteriaceae*, whereas a gene duplication event and divergent evolution led to the heterodimeric PSI. As a para llel line of descent, splitting of the ancestral reaction center complex into a reaction center and a separate antenna protein may have occurred. Operon duplication, loss of the FeS, and divergent evolution are assumed to have resulted in two separate lineages. By association with an additional water-splitting enzyme system, PSII was formed. In contrast, the separate antenna polypeptide was lost and replaced by a modified antenna complex (light-harvesting I) during evolution of the reaction center of Proteobacteria and *Chloroflexus*. Significantly, however, this theory does not explain the occurrence of the quinone-type reaction center in these latter two groups, which are phylogenetically very distant. In addition, the combination of a reaction center typical for *Proteobacteria* with an antenna structure characteristic for green sulfur bacteria would still need to be explained by lateral gene transfer of either of the two components.

Based on the obvious discrepancy between the phylogeny of ribosomal RNA and reaction center proteins, the hypothesis of lateral transfer of photosynthesis genes between distantly related groups of bacteria has been put forward. Lateral gene transfer as yet seems to provide the simplest explanation for the distribution pattern of photosynthesis genes within the bacterial radiation (Blankenship, 1992; Nagashima et al., 1993; Nagashima et al., 1997). Such a lateral gene transfer would encompass reaction center structural genes, genes coding for other electron transfer proteins, and genes needed for the biosynthesis of pigments and cofactors. In purple nonsulfur bacteria the majority of these genes indeed form a single cluster of 46 kb (which does not encompass the genes for the light-harvesting II complex, however; Bauer and Bird, 1996; Wellington et al., 1992; Yildiz et al., 1992). The genetic organization may be taken as evidence for lateral gene transfer as the cluster represents only ~1.3% of the total genome size. It should be mentioned, however, that clustering of most photosynthesis genes may also be due to structural or regulatory constraints. Supporting the latter argument (Yildiz et al., 1992), photosynthesis genes in α-Proteobacteria are transcriptionally coupled in superoperons involving overlapping transcripts. The particular genetic organization is the prerequisite for adaptation of the cells to changing light intensity (see Genetic Regulation in Response to Light in this Chapter) and oxygen tension (see Genetic Regulation by O_2 in this Chapter). Therefore a selective pressure may exist to retain the linkage order and would make the genetic organization of the photosynthesis genes less suitable for phylogenetic inference. Furthe rmore, the high correlation between the phylogenetic trees for 16S rRNA and cytochrome c in phototrophic members of the α-Proteobacteria has been taken as evidence that a lateral transfer of photosynthesis genes did not occur at least within this phylogenetic group (Woese et al., 1980). Thus, the presence of reaction centers in aerobic bacteriochlorophyll-containing α-Proteobacteria may represent an atavistic trait, and the genes coding the reaction center might have been lost frequently during the evolution of aerobic representatives in this group (Stackebrandt et al., 1996).

Because the pigment composition of the oxygenic photosynthetic "Prochlorophytes" is very similar to that of green plant chloroplasts, and like the latter "Prochlorophytes" have appressed thylakoid membranes, it has been proposed that the chloroplasts of green plants evolved from an endosymbiotic "prochlorophyte" (van Valen and Maiorana, 1980; Lewin, 1981). In contrast to the other oxygenic phototrophs, *Prochlorococcus* contains divinyl isomers of chlorophylls a and b, and α- instead of β-carotene (Chrisholm et al., 1992; Goericke and Repeta, 1992). However, based on sequence comparison of 16S rRNA (Urbach et al., 1992) and the *rpoC1* (Palenik and Haselkorn, 1992) genes, the three known prochlorophyte lineages (*Prochloron*, *Prochlorothrix*, and *Prochlorococcus*) are no direct ancestors of chloroplasts. In addition, these analyses revealed that "Prochlorophytes" most likely are of polyphyletic origin and that the use of chlorophyll *b* as additional light-harvesting pigments must have developed at least four times during evolution. In this case, too, a horizontal transfer of the respective biosynthesis genes could be invoked to explain the distribution pattern of chlorophyll *b* among the different members of the cyanobacterial division (Palenik and Haselkorn, 1992). Immunological studies and differences in the chlorophyll a/chlorophyll *b* ratio of the antennae isolated from different "Prochlorophytes" indicate that the capacity to bind chlorophyll *b* arose several times and independently from the cyanobacterial ancestors, and thus confirm the results of s equence comparisons of the *16S rRNA* and *rpoC1* genes.

CHAPTER 1.4

The Anaerobic Way of Life

RUTH A. SCHMITZ, ROLF DANIEL, UWE DEPPENMEIER AND GERHARD GOTTSCHALK

Introduction

Molecular oxygen in appreciable amounts is found only in those areas on earth that are in direct contact with air or are inhabited by organisms carrying out oxygenic photosynthesis. The solubility of oxygen in water is low. In equilibrium with air at 1.013 bar and at 20°C, pure water will contain approximately 9 mg/liter of dissolved oxygen. In aqueous systems, aerobic organisms rapidly consume dissolved oxygen, so that deeper layers of many waters and soils (especially if they are rich in organic compounds), as well as mud and sludge, are practically anaerobic. Nevertheless, these areas are inhabited by numerous organisms that fulfill the important ecological role of converting insoluble organic material to soluble compounds and gases that can circulate back into aerobic regions. Other important anaerobic habitats are the rumen, the intestinal tract, and man-made anaerobic digestors of sewage treatment plants.

Anaerobic prokaryotes that can live in the above-mentioned environments are either phototrophs, which, of course, can only flourish if light is available, or chemotrophs. With respect to their relationship to aerobic metabolism, three groups of organisms capable of growth in an anaerobic environment can be identified:

1. Organisms that are aerobes but can use alternate electron acceptors such as nitrate or nitrite when exposed to an anaerobic environment. The electron transport from NADH to these acceptors is coupled to the phosphorylation of ADP, as is the electron transport to oxygen.
2. Organisms that are facultative aerobes. The enterobacteria are the most prominent representatives of this group. These organisms grow as typical aerobes in the presence of oxygen; in its absence, they carry out fermentations.
3. Obligately anaerobic bacteria that are characterized by the inability to synthesize a respiratory chain with oxygen as terminal electron acceptor. They are restricted to life without oxygen.

The diversity of microorganisms able to thrive under anaerobic conditions is overwhelming. Up to now more than 200 genera of obligate anaerobic microorganisms have been described. Obligate anaerobes are found in all three domains. The eukaryotes are represented by anaerobic fungi, ciliates and flagellates, the archaea by the methanogens, which comprise 23 genera, and by the most hyperthermophilic genera *Pyrolobus*, *Pyrodictium* and *Pyrococcus*. Most genera of the obligate anaerobes belong to the bacteria. Especially prominent are the 32 genera characterized by their ability of dissimilatory reduction of sulfate, sulfite or sulfur. Spore formers are well represented, e.g., by the genera *Clostridium*, *Sporomusa*, *Desulfotomaculum*, *Moorella* and *Thermoanaerobacterium*. There are halophiles such as the genera *Haloanaerobacter* and *Sporohalobacter* and alkaliphiles like *Anaerobranca*. A few genera comprise more than a dozen species: *Bacteroides*, *Bifidobacterium* and *Clostridium* (the genus which by far contains the most species), *Desulfotomaculum*, *Desulfovibrio*, *Eubacterium* and *Thermococcus*. Quite a few genera are represented just by one species, e.g., *Acetitomaculum*, *Acetonema*, *Chrysiogenes*, *Desulfobacula*, *Hippea*, *Stetteria* and *Succinispira*. Autotrophic CO_2-fixation is widespread among the acetogenic anaerobes such as *Acetobacterium woodii*, *Clostridium aceticum* and *Moorella thermoautotrophica* and especially among the methanogens of which only a few representatives are unable to grow with CO_2 plus H_2, e.g., *Methanosaeta concilii*, *Methanosarcina acetivorans* and the *Methanosphaera* species. A few sulfate-reducing bacteria utilize CO_2, such as *Desulfobacterium autotrophicum* and *Desulfosarcina variabilis*. The ability to fix molecular nitrogen is probably more common among anaerobes than known at the moment. Several clostridia are able to do so, with *Clostridium pasteurianum* being the first species demonstrated to have nitrogenase activity. Methanogens express active nitrogenase under nitrogen-limited growth conditions as has been demonstrated for *Methanosarcina barkeri*, *Methanosarcina mazei* and *Methanococ-*

Table 1. Reactions yielding ATP by substrate-level phosphorylation in anaerobes.

Reaction	Enzyme	ΔG_{abs}^0 (kJ/mole)
1,3-Bisphosphoglycerate + ADP ⇔ 3-phosphoglycerate + ATP	Phosphoglycerate kinase	–24.1
Phosphoenolpyruvate + ADP ⇔ pyruvate + ATP	Pyruvate kinase	–23.7
Acetyl phosphate + ADP ⇔ acetate + ATP	Acetate kinase	–12.9
Butyryl phosphate + ADP ⇔ butyrate + ATP	Butyrate kinase	–12.9
Carbamoyl phosphate + ADP ⇔ carbamate + ATP	Carbamate kinase	–7.5
N^{10}-Formyl FH_4[a] + ADP + P_i ⇔ formate + FH_4 + ATP	Formyl-FH_4 synthetase	+8.32
Glycine + 2H + ADP + P_i ⇔ acetate + NH_3 + ATP	Glycine reductase	about –46.0

[a]FH_4, tetrahydrofolic acid.

cus maripaludis. Many more anaerobes can be expected to do so.

So obligate anaerobes are known now for all-important anaerobic habitats on earth. Because of their inability to utilize oxygen, they had to develop their strategies to conserve energy in the form of ATP, to metabolize substrates and to cope with some of their own products such as ethanol, lactate, butyrate or acetate. Some of the characteristic features of the anaerobes will be outlined.

Novel Ion Translocation Reactions Involved in Energy Conservation

It is a fact that several anaerobic microorganisms produce ATP only by substrate-level phosphorylation. Growth on sugars or on amino acids coupled to the formation of ethanol, lactate, butyrate or acetate very often indicates that substrate-level phosphorylation is involved (Thauer et al., 1977). This holds true for lactic acid bacteria and also for many clostridia. Some of the reactions employed for ATP synthesis by these bacteria and by other anaerobes are listed in Table 1. It can be seen that the reactions 1 to 4 listed in Table 1 are part of the glycolytic pathway of acetate and butyrate formation. Carbamoyl phosphate is formed in the conversion of arginine to ornithine, and thereby becomes available for ATP synthesis. The conversion of N^{10}-formyl FH_4 (N^{10}-formyl tetrahydrofolic acid; an intermediate of methyl group oxidation) to formate, and FH_4 gives rise to ATP synthesis. Glycine reductase is involved in the reductive part of the Stickland reaction, the pairwise fermentation of amino acids. This interesting reaction will be discussed in detail below.

There are fermentations in which at first sight reactions giving rise to ATP synthesis cannot be identified. Such processes are for instance hydrogen-dependent fermentations; some are summarized in Table 2. Here it has been assumed for quite some time that electron transport processes might be coupled to ion translocation and that the ion-motive force generated might support ATP synthesis. Experimental proof for this assumption has been provided in recent years.

Wolinella succinogenes grows on fumarate and H_2 according to the equation given in Table 2. Clearly, this organism must gain ATP by electron transport phosphorylation. The electron transport chain that catalyzes this reaction (Fig. 1B) consists of hydrogenase, menaquinone and fumarate reductase (Lancaster and Kröger, 2000). Using vesicles and reconstituted liposomal systems the generation of a proton-motive force could be demonstrated in the course of H_2-dependent menaquione reduction as catalyzed by the hydrogenase (Gross et al., 1998). A number of other bacteria also can take advantage of ion-translocating electron transport system using fumarate as a terminal electron acceptor (Kröger et al., 1992). Formate, NADH or H_2 are typical electron donors, and succinate or propionate are formed as catabolic end products.

The pathway (as employed by the methanogens) for CO_2-reduction to methane by H_2 is depicted in Fig. 2. It has been demonstrated in recent years that one reaction, the methyl group transfer from methyltetrahydromethanopterin to coenzyme M, is coupled to the translocation of sodium ions (Deppenmeier et al., 1996). This

Table 2. H_2-dependent fermentations.

Reaction			Change of free energy
Fumarate + H_2	→	succinate	$\Delta G^{o\prime} = -86$ kJ/mol
$CO_2 + 4\ H_2$	→	$CH_4 + 2\ H_2O$	$\Delta G^{o\prime} = -131$ kJ/mol
$2\ CO_2 + 4\ H_2$	→	$CH_3{\cdot}COO^- + H^+ + 2\ H_2O$	$\Delta G^{o\prime} = -95$ kJ/mol
$SO_4^{2-} + 4\ H_2 + H^+$	→	$HS^- + 4\ H_2O$	$\Delta G^{o\prime} = -152$ kJ/mol
2 FeOOH + H_2 + 4 H^+	→	2 Fe^{2+} + 4 H_2O	$\Delta G^{o\prime} = -110$ kJ/mol

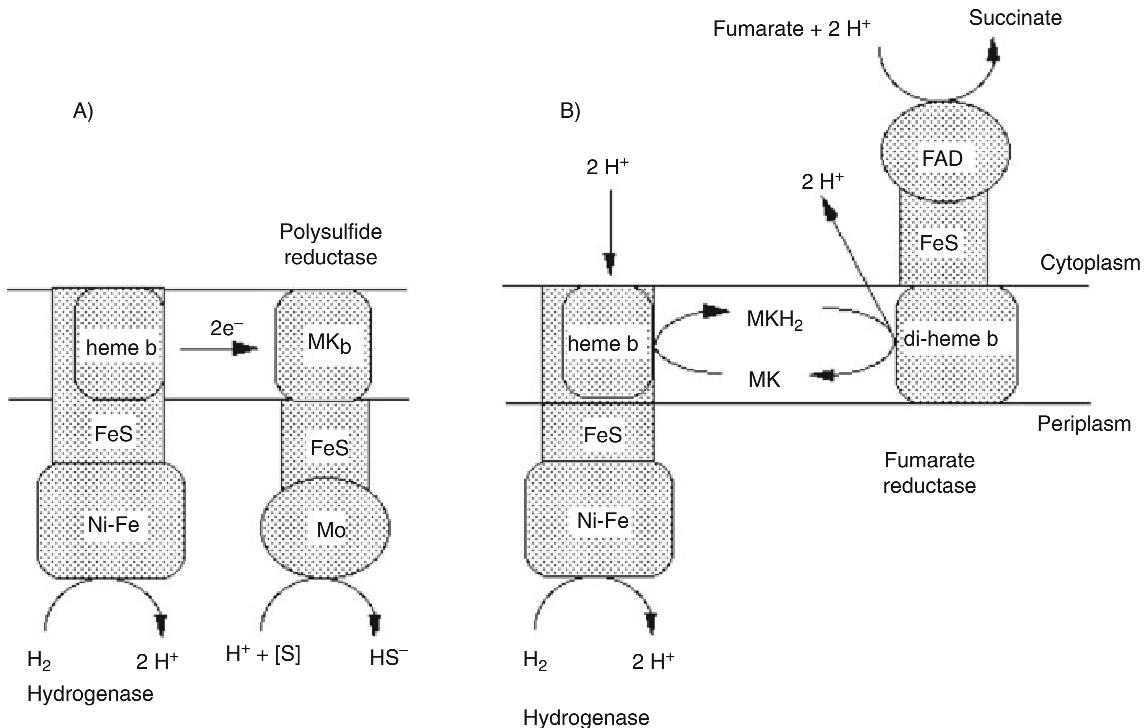

Fig. 1. Anaerobic respiration in *Wolinella succinogenes*. A) Polysulfide reduction: The membrane-bound hydrogenase is composed of three subunits (HydABC) and contains heme *b*, iron-sulfur clusters (FeS) and the nickel/iron center (Ni-Fe) for hydrogen oxidation. The gene products PsrA, B and C form the polysulfide reductase which contains a molybdopterin guanine dinucleotide (Mo), iron sulfur clusters (FeS). A menaquinone (Mkb) is tightly bound to the protein. Electron transfer is probably mediated by diffusion and collision of the enzymes. B) Fumarate reduction: The hydrogenase is identical to the one shown in Fig. 1A. The fumarate reductase consists of three subunits (*frdCAB*). A diheme cytochrome *b* anchors the enzyme in the membrane (di-heme *b*). The catalytic subunit carries a covalently bound FAD. These subunits are connected by an iron-sulfur protein (FeS). Electron transfer from the hydrogenase to the fumarate reductase is mediated by menaquinone.

system represents a novel type of sodium ion pump, which will be discussed below in connection with other sodium ion pumps. Some methanogens (e.g., *Methanosarcina* spp.) employ two novel membrane-bound electron transport systems generating an electrochemical proton gradient. The systems are composed of the heterodisulfide reductase and either a membrane-bound hydrogenase or an $F_{420}H_2$ dehydrogenase (Bäumer et al., 2000), which is functionally homologous to the proton-translocating NADH dehydrogenase (complex I of the respiratory chain). It has been shown that all of these enzymes are involved in proton translocation. Interestingly, the electron transport systems of these organisms contain electron carriers (such as cytochromes and the novel redox carrier methanophenazine), not found in methanogens utilizing only H_2 + CO_2 (Deppenmeier et al., 1999).

A number of archaea as well as of bacteria reduce elemental sulfur with H_2 to H_2S (Hedderich et al., 1999). Examples are *Pyrodictium occultum*, *Stetteria hydrogenophila* and *Desulfurobacterium thermolithotrophum*, but also the already mentioned *Wolinella succinogenes* in which a H_2:polysulfide reductase was characterized consisting of a nickel-iron hydrogenase, menaquinone and a molybdenum iron sulfide-containing polysulfide reductase (Fig. 1A). Because the solubility of elemental sulfur in water is extremely low, it is believed that polysulfide is the actual electron acceptor (Hedderich et al., 1999). It is formed in an H_2S environment according to:

$$nS^0 + HS^- \rightarrow S^{2-}{}_{n+1} + H^+ \qquad (1)$$

Proton gradients are also established in the process of dissimilatory sulfate reduction. Here, the electron transfer from H_2 to sulfite is coupled to ATP synthesis via a chemiosmotic mechanism (Badziong and Thauer, 1980). Shewanella putrefaciens (not an obligate anaerobe) can grow with Fe^{3+} and H_2. The mode of energy conservation is not known as yet.

Diffusion gradients may also be exploited for the generation of a proton-motive force. As long as the intercellular lactate concentration is high

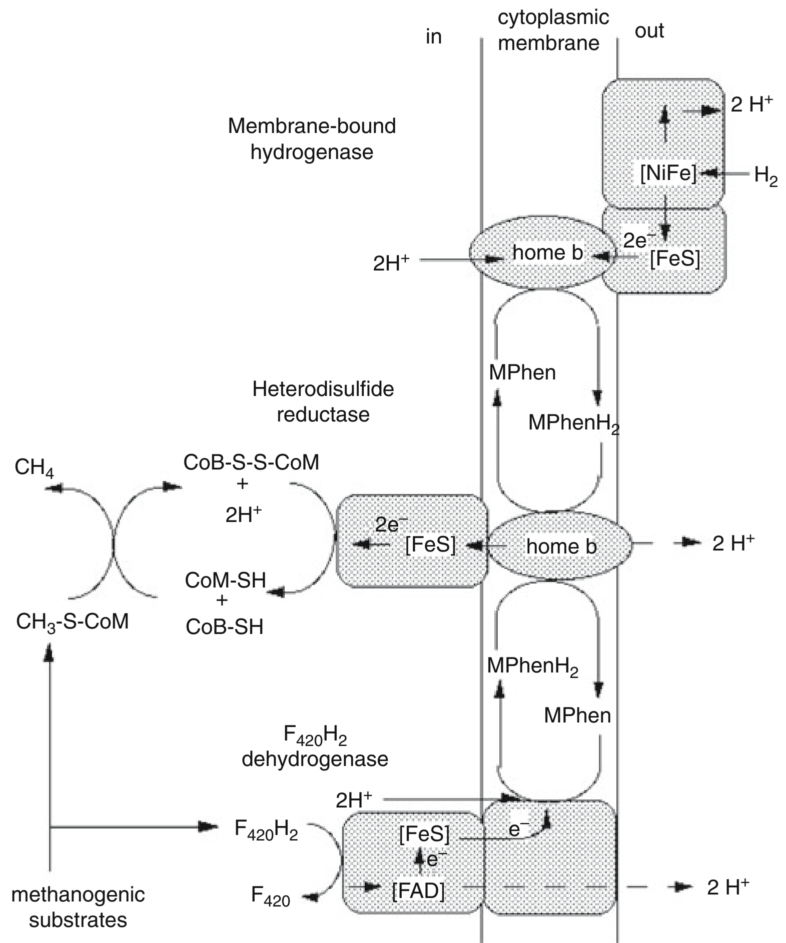

Fig. 2. Membrane-bound electron transport chain in *Methanosarcina mazei*. In the course of methanogenesis, methyl-coenzyme M (CH3-S-CoM) is formed and is reductively cleaved by the methyl-CoM reductase which uses coenzyme B (HS-CoB) as electron donor. The reaction results in the formation of methane and a heterodisulfide (CoB-S-S-CoM) from HS-CoM and HS-CoB. The disulfide functions as electron acceptor of the anaerobic respiratory chain. Molecular hydrogen or reduced coenzyme F_{420} ($F_{420}H_2$) serves as electron donors. The $F_{420}H_2$ dehydrogenase contains FAD and FeS clusters and is responsible for the oxidation of $F_{420}H_2$. Electrons are transferred to methanophenazine (MPhen). The reduced form of this novel cofactor is the electron donor of the heterodisulfide reductase. This enzyme contains heme b and iron-sulfur clusters. It catalyzes the reduction of CoM-S-S-CoB. The H_2-dependent electron transport system is composed of a membrane-bound hydrogenase which is very similar to the corresponding enzyme from *Wolinella* (Fig. 1). Methanophenazine functions as mediator of electron transport to the heterodisulfide reductase.

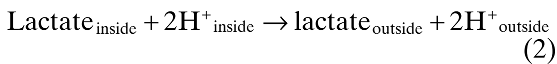
as compared to the extracellular one, it can be exported accompanied by two protons:



$$\text{Lactate}_{\text{inside}} + 2\text{H}^+{}_{\text{inside}} \rightarrow \text{lactate}_{\text{outside}} + 2\text{H}^+{}_{\text{outside}} \quad (2)$$

Thus, the proton/product symport helps lactate acid bacteria to increase their ATP yield (Konings et al., 1997).

Sodium Ion Pumps

Cells have the tendency to expel sodium ions from the interior. Usually expulsion is catalyzed by sodium-proton antiporters, but a number of obligately anaerobic microorganisms have primary sodium ion pumps at their disposal. In these organisms certain exergonic reactions are coupled with Na^+-translocation across the cytoplasmic membrane. One example was given already: the methyltetramethanopterin:coenzyme M methyltransferase reaction which is present in all methanogens and which is responsible for the Na^+-dependence of growth and methane formation of this group of archaea. This enzyme system is an extremely complex one consisting of eight different subunits and containing B_{12} as cofactor (Gottschalk and Thauer, 2001). A related enzyme system may occur in *Acetobacterium woodii* and related organisms that are Na^+-dependent and generate a sodium ion-motive force during acetogenesis (Heise et al., 1989). This, however, is not true for all acetogens. Organisms such as *Clostridium aceticum* and *Moorella thermoautotrophica* are not Na^+ dependent; they contain cytochromes and apparently generate a proton gradient instead of a sodium ion gradient (Hugenholtz and Ljungdahl, 1990).

Certain decarboxylases have been found to function as primary Na^+ pumps. They are membrane bound and they contain biotin. These enzymes occur in organisms such as *Propionigenium modestum*, *Acidaminococcus fermentans* or *Klebsiella pneumoniae*, and the acids are decarboxylated with Na^+ extrusion are oxaloacetate, methylmalonyl-CoA, glutaconyl-CoA or malonyl-acyl carrier protein (malonyl-ACP; Dimroth, 1997; Dimroth and Schink, 1998). A scheme is depicted in Fig. 3.

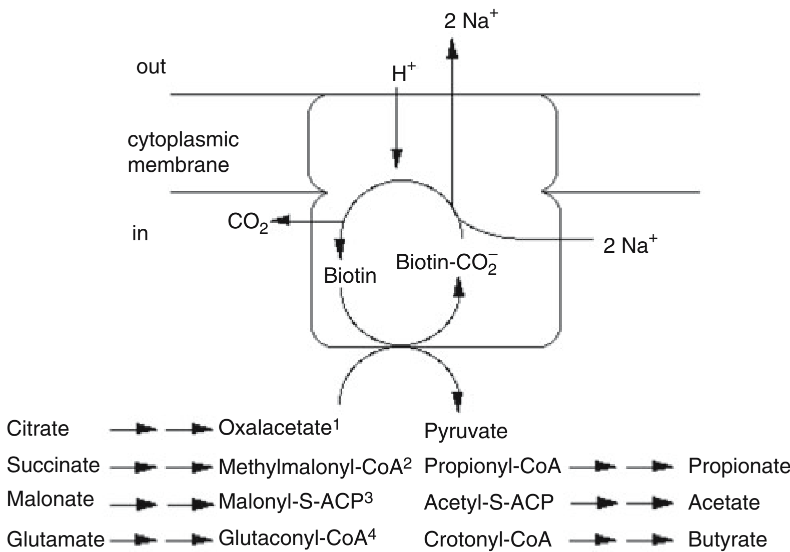


Fig. 3. Decarboxylation reactions coupled to sodium ion translocation: 1) Oxaloacetate decarboxylase (e.g., is used by *Klebsiella pneumoniae* to ferment citrate); 2) Methylmalonyl-coenzyme A (CoA) decarboxylase (e.g., is used by *Propionigenium modestum* for succinate metabolism); 3) Malonyl-S-acyl carrier protein (ACP) decarboxylase (e.g., is used by *Malonomonas rubra* growing on malonate); and 4) Glutaconyl-CoA decarboxylase (e.g., is used by *Acidaminococcus fermentans* to ferment glutamate).

Degradative Pathways

With respect to the degradation of substrates, the anaerobes have disadvantages and advantages. One difficulty is that in the absence of an external electron acceptor anaerobes must balance their oxidation and reduction reactions. The electron donors and acceptors are derived from organic molecules of medium redox states such as sugars, organic acids, heterocyclic compounds and amino acids. Often more reduced (e.g., ethanol) and more oxidized (e.g., CO_2) products are formed. In a few fermentations, the redox state of the substrate and the product is the same, e.g., the fermentation of hexoses to two lactates or three acetates. Highly oxidized or reduced compounds such as carbon dioxide or hydrocarbons, respectively, are only suitable for fermentation together with inorganic electron donors or acceptors.

Another disadvantage of anaerobes is, of course, that oxygen cannot be employed for the initial attack of certain substrates such as hydrocarbons. On the other hand, there are a number of advantages. Oxygen-sensitive systems can be taken advantage of radical reactions or even of radical enzymes. So under the dictate of balanced redox reactions and with the involvement of unique enzymes and reactions, a fascinating array of unusual fermentations has evolved; some will be discussed now.

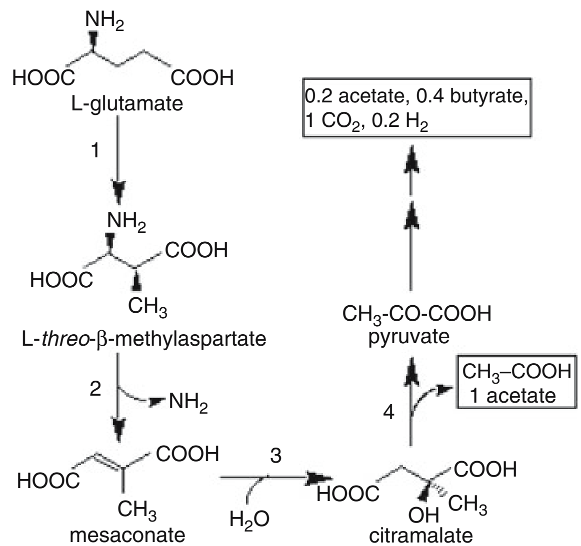

Fig. 4. Pathway of L-glutamate fermentation by *Clostridium tetanomorphum*: 1) Glutamate mutase (coenzyme B_{12}-dependent); 2) β-Methylaspartase; 3) Citramalate dehydratase; and 4) Citramalate lyase.

Coenzyme B_{12}-Dependent Pathways

When *Clostridium tetanomorphum* or *Clostridium cochlearium* grows on L-glutamate, the substrate is prepared for a cleavage into a two-carbon and a three-carbon compound in an interesting way. Under the catalysis of glutamate mutase (a B_{12}-containing enzyme), L-glutamate is converted to L-*threo*-β-methylaspartate (Buckel and Golding, 1996b). This carbon-skeleton rearrangement facilitates the elimination of ammonia and formation of mesaconate by β-methylaspartase. Subsequently, mesaconate is hydrated to citramalate, which then is cleaved into acetate and pyruvate (Buckel, 1980; Fig. 4). Oxidative decarboxylation of pyruvate results in

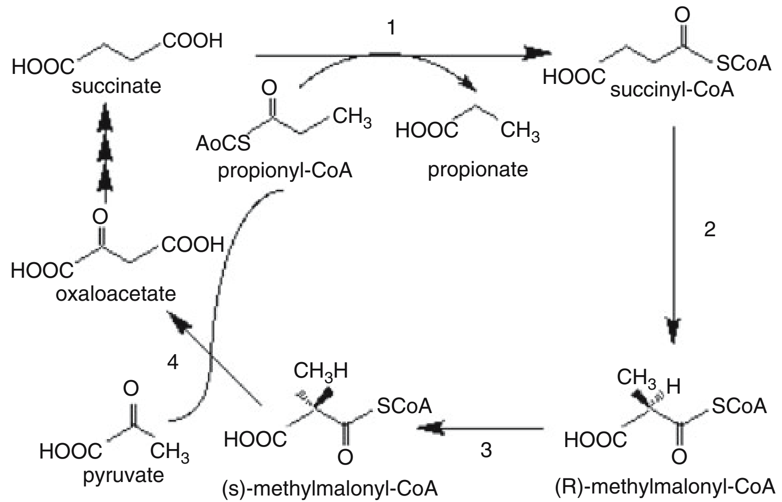

Fig. 5. Interconversion of succinate and propionate by methylmalonyl-CoA mutase: 1) Propionate CoA-transferase; 2) Methylmalonyl-CoA mutase (coenzyme B_{12}-dependent); 3) Methylmalonyl-CoA epimerase; and 4) Transcarboxylase (biotin-containing).

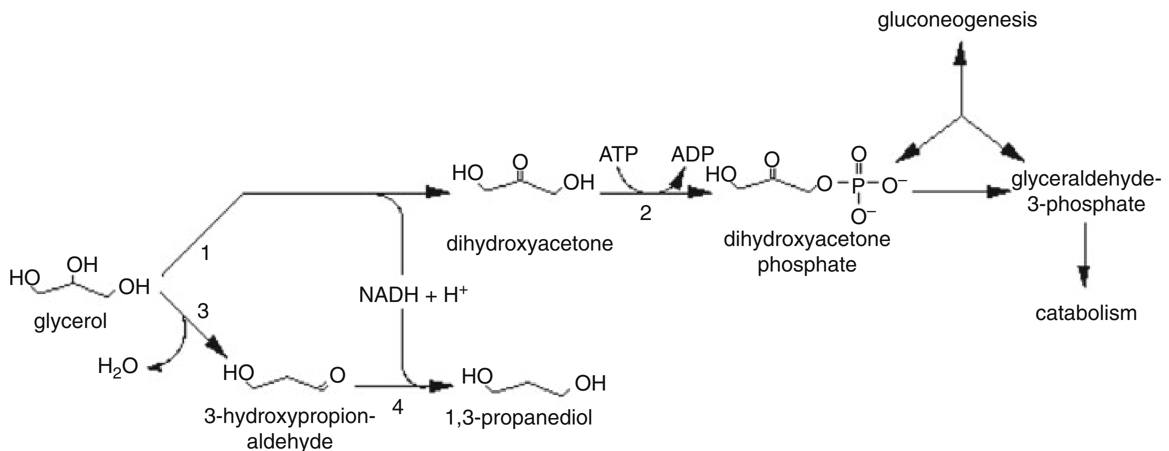

Fig. 6. Pathway of glycerol fermentation by *Citrobacter freundii*: 1) Glycerol dehydrogenase; 2) Dihydroxyacetone kinase; 3) Glycerol dehydratase (coenzyme B_{12}-dependent); and 4) 1,3-Propanediol dehydrogenase.

the formation of acetyl-CoA and reduced ferredoxin, which is reoxidized during the synthesis of butyryl-CoA from two moles of acetyl-CoA. Then, ATP is synthesized in the acetate and butyrate kinase reactions (Barker, 1981). By this pathway, a degradation of glutamate via the tricarboxylic acid cycle is circumvented; the latter would not be feasible because of an unbalanced generation of reducing equivalents in the form of NADH and $FADH_2$.

Coenzyme $B1_2$-dependent rearrangements like the glutamate mutase reaction proceed via radical intermediates; they are per se oxygen sensitive although another reaction of this type, the methylmalonyl-CoA mutase reaction, proceeds in higher eukaryotes such as man. This reaction is also of key importance in propionic acid bacteria and many other anaerobes because it allows the interconversion of succinate and propionate (Fig. 5).

A fermentation that involves a coenzyme B_{12}-dependent reaction and proceeds only under anaerobic conditions is the glycerol conversion to 1,3-propanediol. This fermentation was discovered in enteric bacteria such as *Citrobacter freundii* and *Klebsiella pneumoniae*; it proceeds as depicted in Fig. 6. Glycerol is oxidized to dihydroxyacetone, which is converted further to dihydroxyacetone phosphate. To balance the fermentation, a portion of glycerol is dehydrated to 3-hydroxypropionaldehyde in a coenzyme B_{12}-dependent reaction. Subsequently, the aldehyde is reduced to the major fermentation product 1,3-propanediol, which is of great biotechnological interest. The bottleneck of the pathway is the coenzyme B_{12}-dependent glycerol dehydratase

that is rapidly inactivated during glycerol dehydration (Daniel et al., 1998).

Degradation of Amino Acids and α-Hydroxy Carboxylic Acids

Novel reactions occur in a number of anaerobes for the utilization of α-amino acids and α-hydroxy carboxylic acids. If redox balance allows, these acids can be oxidized, of course, to the corresponding α-keto acids and then very easily metabolized further. So lactate or alanine can be oxidized to pyruvate and further to acetyl-CoA. This often is not possible because an acceptor for the electrons generated is not available. A commonly used pathway involves the reduction of the α-keto acids generated by deamination of amino acids to the corresponding hydroxy carboxylic acids, followed by activation to the CoA ester and dehydration to an enoyl-CoA (Fig. 7). A simple dehydration of α-hydroxy carboxylic acids is not feasible because it would have to proceed against the rule of Markovnikov (Jones, 1961). A well-studied example is the dehydration of α-hydroxyglutaryl-CoA to glutaconyl-CoA carried out by *Acidaminococcus fermentans*. The enzyme, α-hydroxyglutaryl-CoA dehydratase, is extremely oxygen sensitive and contains [Fe-S] clusters, reduced riboflavin, and $FMNH_2$. The activation of the dehydratase is catalyzed by an activator protein and requires a reducing agent and catalytic amounts of ATP and Mg^{2+}. A novel mechanism involving thiol ester-derived radical anions (ketyls) has been postulated for these dehydrations (Buckel, 1996a).

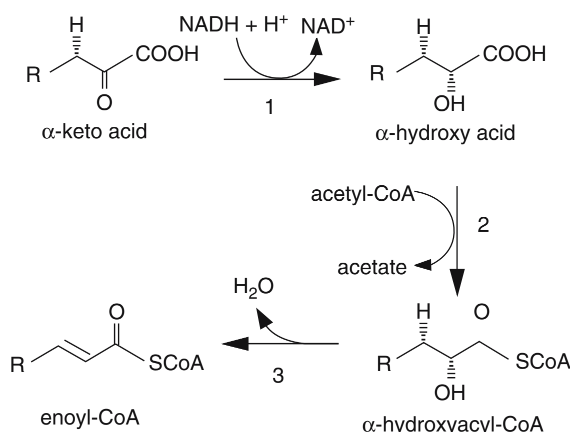

Fig. 7. α-Hydroxy acid pathway: 1) α-Hydroxy acid dehydrogenase; 2) CoA transferase; and 3) α-Hydroxyacyl-CoA dehydratase.

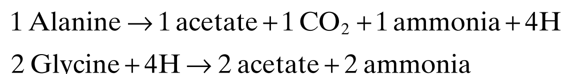
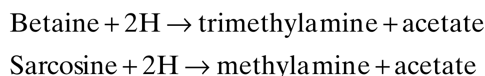
Another way to deal with certain α-amino acids is reductive deamination. Such deaminations are part of the Stickland reaction in which amino acids are fermented pairwise. Alanine, for instance, is oxidized and the reducing equivalents generated are transferred to glycine:



$$1\ \text{Alanine} \rightarrow 1\ \text{acetate} + 1\ CO_2 + 1\ \text{ammonia} + 4H$$
$$2\ \text{Glycine} + 4H \rightarrow 2\ \text{acetate} + 2\ \text{ammonia}$$

The structurally related compounds betaine and sarcosine can also serve as hydrogen acceptors (Naumann et al., 1983; Hormann and Andreesen, 1989), methylamines being formed instead of ammonia:



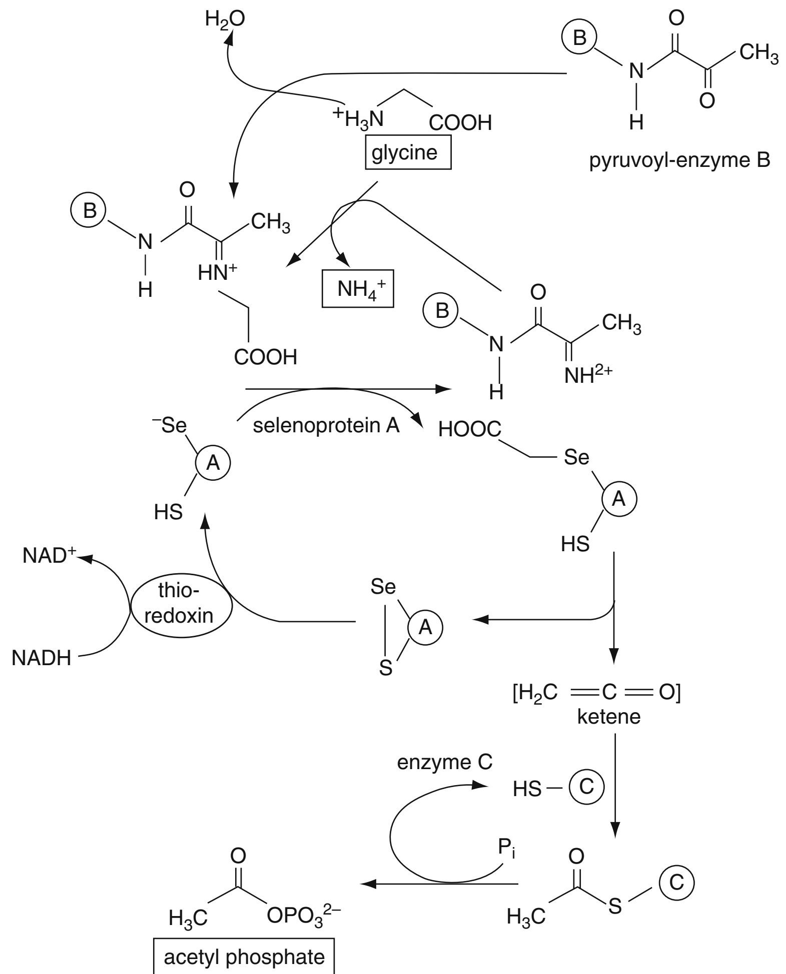
$$\text{Betaine} + 2H \rightarrow \text{trimethylamine} + \text{acetate}$$
$$\text{Sarcosine} + 2H \rightarrow \text{methylamine} + \text{acetate}$$

Acetate formation from glycine proceeds via acetyl phosphate, and the last step of acetate formation is catalyzed by acetate kinase giving rise to ATP synthesis by substrate-level phosphorylation. The key enzyme of glycine fermentation (glycine reductase) was well studied in *Eubacterium acidaminophilum* (Andreesen, 1994). The enzyme consists of four proteins including one selenoprotein (enzyme A), a pyruvoyl-protein (enzyme B), enzyme C, and thioredoxin. The reaction mechanism is depicted in Fig. 8. The pyruvoyl residue of enzyme B forms a Schiff-base with glycine, which then reacts with the Se^--anion of protein A to yield a carboxymethylselenocysteine residue linked to protein A and the iminopyruvoyl protein. Subsequently, ammonia is released by hydrolysis or in the next turnover. Elimination of ketene yields the oxidized protein A-Se-S intermediate, which is reduced by thioredoxin. Reduction of thioredoxin is catalyzed by thioredoxin reductase with NADH or another electron donor. The hypothetical ketene intermediate adds to the cysteine residue of protein C. An acetylcysteine is formed, which is cleaved by phosphate (P_i) to form acetyl phosphate. Again, this is a complex reaction, which only can be visualized to occur in anaerobes.

Degradation of Aromatic Compounds and Hydrocarbons

Most of the aromatic compounds studied to date are first transformed to benzoyl-CoA, the central intermediate of the best-studied pathway for anaerobic degradation of aromatic compounds (Harwood et al., 1999). Benzoyl-CoA then

Fig. 8. Mechanism of glycine reductase.



undergoes a reductive attack (Schink et al., 2000). The key enzyme for this attack is the benzoyl-CoA reductase, which was purified from the denitrifying bacterium *Thauera aromatica* and characterized as a FAD- and iron-sulfur cluster-containing enzyme complex (Boll and Fuchs, 1995). Under hydrolysis of ATP, one electron is added to the thiol ester carbonyl of benzoyl-CoA and the resulting radical intermediate is reduced further to cyclohexa-1,5-dienecarboxyl-CoA (Buckel and Golding, 1999; Fig. 9). This reaction may be of general importance for the anaerobic degradation of aromatic compounds. Recently, it was shown that the reductive strategy for destabilization of the ring is not the only one used in anaerobic degradation of aromatic compounds. Anaerobic degradation of 3,5-dihydroxybenzoate by *Thauera aromatica* (Philipp and Schink, 2000) and 1,3-dihydroxybenzene by *Azoarcus anaerobius* (Philipp and Schink, 1998) proceeds by a novel mechanism. Phenolic compounds with their hydroxyl groups in *meta* position to each other are hydroxylated by membrane-bound enzymes yielding hydroxyhydroquinone, which is later dehydrogenated to the nonaromatic compound hydroxybenzoquinone. Thus, oxidation rather than reduction is used to overcome the stability of the aromatic ring.

Radical Enzymes

Glycyl radical enzymes are involved in a number of anaerobic reactions. Well-studied examples are the pyruvate formate lyase (Knappe et al., 1984), the anaerobic ribonucleotide reductase (Licht et al., 1996), and the benzyl succinate synthase (Leuthner et al., 1998). The latter initiates the breakdown of toluene under anaerobic conditions. These glycyl radical enzymes are formed from their precursor enzyme in a reaction, which requires S-adenosyl methionine. The pyruvate formate lyase of *Escherichia coli* is synthesized

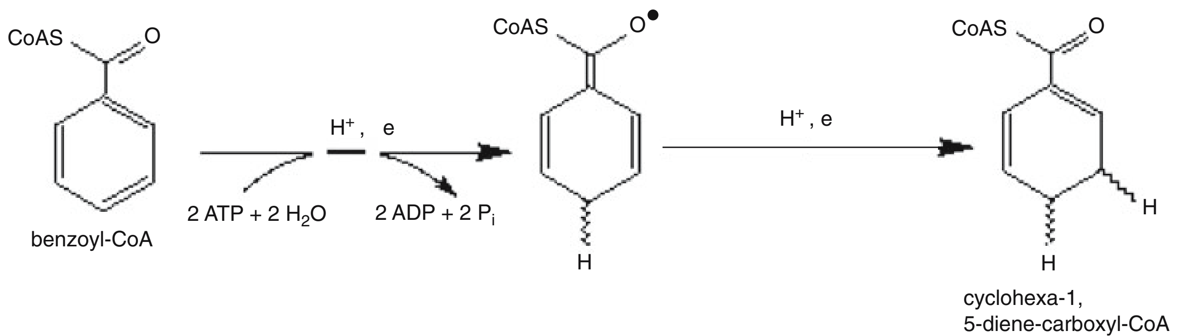


Fig. 9. Mechanism of benzoyl-CoA reductase.

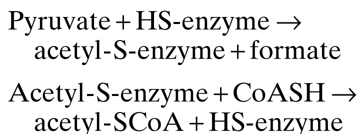
as an inactive and coenzyme-free protein. The enzyme is posttranslationally modified by S-adenosyl methionine and a reduced flavodoxin in a reaction catalyzed by an activase. A hydrogen atom is abstracted from a specific glycine residue, yielding methionine and 5′-deoxyadenosine from S-adenosyl methionine. The formed free radical (HS-enzyme) is involved in a two-step reaction:



$$\text{Pyruvate} + \text{HS-enzyme} \rightarrow \text{acetyl-S-enzyme} + \text{formate}$$

$$\text{Acetyl-S-enzyme} + \text{CoASH} \rightarrow \text{acetyl-SCoA} + \text{HS-enzyme}$$

Pyruvate formate lyase, like the other glycyl radical enzymes, is rapidly inactivated by oxygen.

Anaerobic alkane-degrading bacteria have also been isolated recently. Alkanes are used as substrates by several species of sulfate-reducing microorganisms (Aeckersberg et al., 1998). Another group of anaerobic hydrocarbon-degrading bacteria is dependent on syntrophic associations with methanogens. The biochemistry of the process is still poorly understood but it can be speculated that again radicals are generated to initiate this breakdown (Zengler et al., 1999).

A number of potentially hazardous compounds in our environment are halogenated (e.g., pentachlorophenol or perchloroethene). These compounds can be partially or completely degraded under anaerobic conditions. This degradation occurs by reductive dehalogenations. Organisms such as *Desfulfitobacterium dehalogenans*, *Dehalobacter restrictus* or *Dehalospirillum multivorans* contain corrinoid-proteins, which exhibit dehalogenase activities (Holliger et al., 1999). There is evidence that these H_2-dependent fermentations are also coupled with the generation of a proton-motive force.

Anaerobic Food Chains

The anaerobic degradation of complex organic matter depends on the cooperation of various trophic groups of anaerobic bacteria and archaea. Two possible schemes for anaerobic food chains, as they occur in nature in the absence or in the presence of sulfate, are presented in Fig. 10. Polymers such as polysaccharides, proteins and nucleic acids are initially converted to oligomers and monomers and subsequently fermented by the "classical" primary fermentative bacteria. In the absence of sulfate, the products acetate, methanol, methylamines, CO_2 and H_2 can be used directly by methanogenic bacteria to convert them to methane and carbon dioxide. Alcohols longer than one carbon atom, fatty acids longer than two carbon atoms and branched or aromatic fatty acids are degraded by the secondary fermenters to acetate, C1-compounds and H_2, which are subsequently used by the methanogens. Because the reactions catalyzed by the secondary fermentative bacteria are mostly endergonic under standard conditions, they depend on a very efficient cooperation with the subsequent partners. Such cooperations are called syntrophic relationships, in which the pool size of shuffling intermediate has to be kept small to allow efficient degradation. In sulfate-rich anaerobic habitats, such as marine sediments, sulfate-reducing bacteria further degrade the primary fermentation products. As many sulfate reducers are metabolically more versatile than methanogenic bacteria, they can use and oxidize all classical fermentation products to carbon dioxide, simultaneously reducing sulfate to sulfide (Hansen, 1994; Jansen and Hansen, 1998; Zengler et al., 1999; Fig. 10B). In addition to the primary fermentations that have already been mentioned, three important points should be briefly discussed here: the fate of acetate under anaerobic conditions, production of H_2, and the syntrophic relationships.

Acetate is the end product of a number of fermentations starting from substrates with two (e.g., ethanol) or more carbon atoms (e.g., glucose), but it is also produced by acetogenic organisms from one-carbon compounds (e.g.,

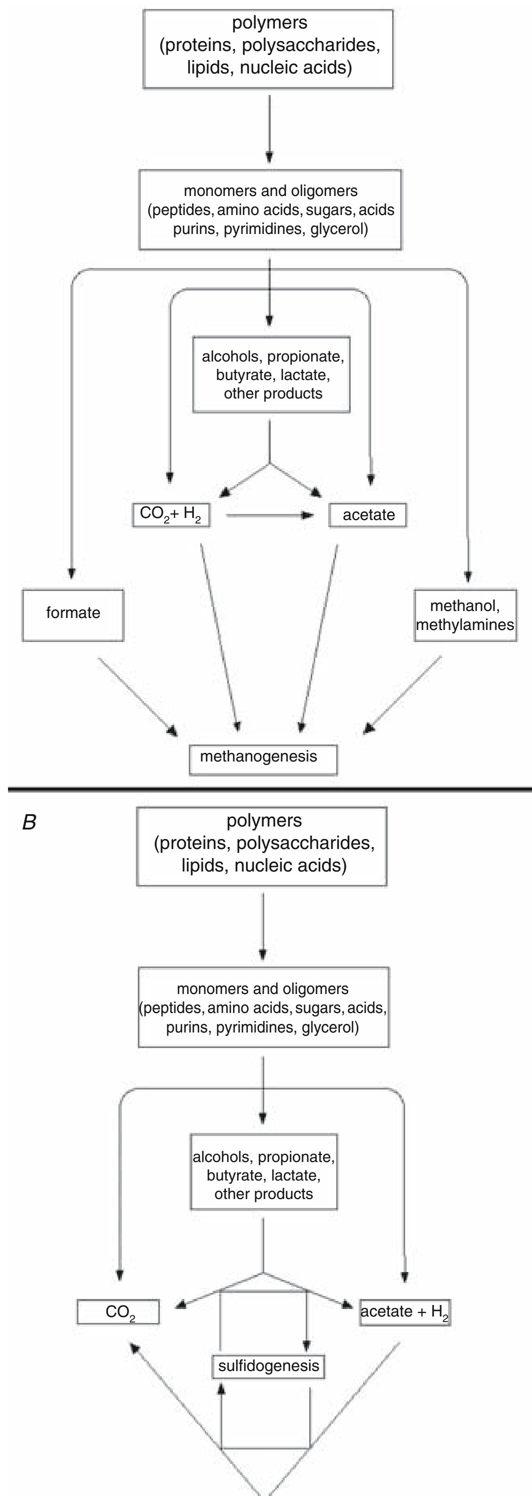


Fig. 10. Anaerobic food chains. (A) Methanogenesis. As a terminal process, all organic material is metabolized to methane via a few methanogenic substrates: CO_2 + H_2, acetate, formate, methanol and methylamines. (B) Sulfidogenesis. As a terminal process, incomplete oxidizers convert various products to CO_2 and acetate, and the complete oxidizers couple sulfate reduction with acetate oxidation to CO_2. In addition, H_2 can be used for sulfate reduction.

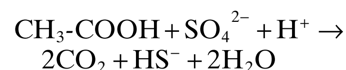
methanol) and from $H_2 + CO_2$. Because so many pathways lead to the formation of acetate under anaerobic conditions, the further degradation of acetate is of great importance for carbon flow under anaerobic conditions. Among the methanogenic archaea, only species of the genera *Methanosarcina*, *Methanosaeta* and *Methanothrix* are able to utilize and degrade acetate to methane and carbon dioxide (e.g., *Methanosarcina barkeri*, *Methanothrix thermophila* and *Methanosaeta concilii*). The degradation occurs according to the following equation (Thauer et al., 1989):

$$CH_3\text{-}COOH \rightarrow CH_4 + CO_2 \Delta G^{0\prime} = -36\,kJ/mol$$

Initially acetate is activated to acetyl-CoA by acetate kinase and phosphotransacetylase or directly by acetyl-CoA synthetase (*Methanosaeta*). Acetyl-CoA is subsequently bound to the carbon monoxide (CO) dehydrogenase complex, at which it is decarbonylated by cleavage of the carbon-carbon bond. The methyl-group is subsequently transferred via tetrahydromethanopterin (THMP) to coenzyme M, and CO is oxidized to CO_2, providing the reducing equivalents for the reduction of the methyl-coenzyme M to methane by the pathway shown in Fig. 11 (Thauer, 1998; Ferry, 1997; Ferry, 1999). It is interesting that the CO dehydrogenase complex, which catalyzes the decarbonylation of acetyl-CoA to methyl-THMP and CO and the oxidation of CO, also catalyzes the reactions mentioned in a reversible manner. In methanogens utilizing acetate, the direction of decarbonylation predominates; when, however, organisms such as *Methanobacterium thermoautotrophicum* grow with $H_2 + CO_2$, they use this enzyme system to synthesize acetyl-CoA from methyl-coenzyme M and CO for autotrophic growth (Zeikus, 1983; Fuchs, 1986; Shieh and Whitman, 1988; Huber and Wachtershäuser, 1997). Similarly, acetogenic bacteria such as *Acetobacterium woodii* and *Moorella thermoacetica* produce acetyl-CoA from methyl-tetrahydrofolate and CO (Wood et al., 1986; Ljungdahl, 1986; Shanmugasundaram et al., 1988; Menon and Ragsdale, 1999).

A number of sulfate-reducing bacteria are also able to oxidize acetate completely to CO_2 under anaerobic conditions:



$$CH_3\text{-}COOH + SO_4^{2-} + H^+ \rightarrow 2CO_2 + HS^- + 2H_2O$$

Most of them also take advantage of the described C1-pathway with the CO dehydrogenase complex for decarbonylating acetyl-CoA. The pathway is investigated in more detail in *Desulfotomaculum acetoxidans*, *Desulfobacterium autotrophicum* and in the archaeon *Archaeoglobus fulgidus* (Spormann and Thauer,

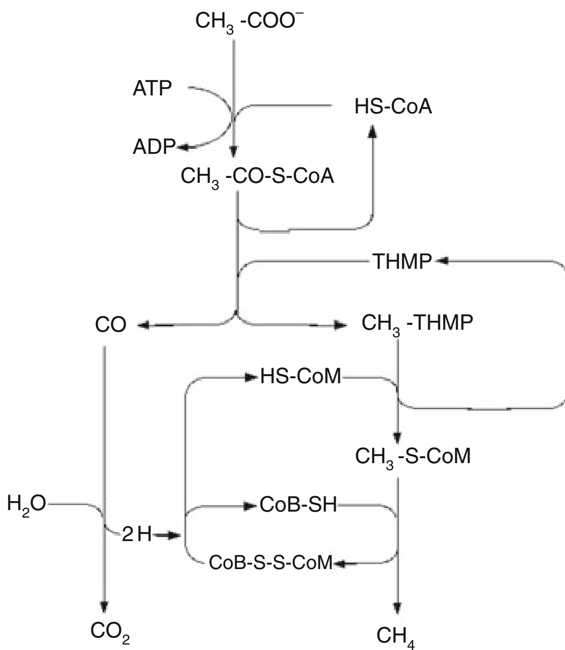


Fig. 11. Conversion of acetyl-CoA to methane and carbon dioxide. THMP, tetrahydromethanopterin; HS-CoM, coenzyme M.

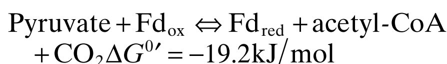
1988; Hansen, 1994; Möller-Zinkhahn et al., 1989; Brüggemann et al., 2000). Only a small number of acetate oxidizing, sulfate reducers (e.g., *Desulfobacter postgatei*) use the tricarboxylic acid cycle to carry out acetyl-CoA oxidation (Brandis-Heep, 1983; Möller et al., 1987; Thauer, 1988; Thauer et al., 1989). Activation of acetate in *D. postgatei* occurs by a succinyl-CoA:acetate CoA-transferase; acetate kinase and phosphotransacetylase are lacking.

Many fermentation reactions are associated with the evolution of molecular hydrogen, H_2. This allows a shift from producing alcohols and lactate to acetate and butyrate, a shift beneficial to the organisms because the ATP yield is increased. Important precursors of H_2 are formate and reduced ferredoxin, and H_2 formation is catalyzed by formate hydrogenlyase and hydrogenase, respectively. There are two important reactions coupled to ferredoxin reduction and ultimately to H_2 formation:

1) The pyruvate-ferredoxin oxidoreductase reaction:



$$\text{Pyruvate} + \text{Fd}_{ox} \Leftrightarrow \text{Fd}_{red} + \text{acetyl-CoA} + \text{CO}_2 \Delta G^{0\prime} = -19.2 \text{kJ/mol}$$

The reaction is exergonic so that it can drive H_2 formation even at a hydrogen partial pressure (PH_2) of 1.013 kPa. The enzyme was first purified from *Clostridium acidiurici* (Uyeda and Rabinowitz, 1971; Charon et al., 1999).

2) The NADH-ferredoxin oxidoreductase:

$$\text{NADH} + \text{Fd}_{ox} \Leftrightarrow \text{Fd}_{red} + \text{NAD}^+ + \text{H}^+ \Delta G^{0\prime} = +18.8 \text{kJ/mol}$$

This reaction was discovered in *C. kluyveri* (Jungermann et al., 1969; Gottschalk and Chowdhury, 1969); it is endergonic and will only proceed at a largely reduced P_{H2}. In anaerobic habitats, the P_{H2} is kept as low as 10 Pa by H_2-consuming organisms such as the methanogenic archaea, and acetogenic and sulfidogenic bacteria. Hydrogen consumption by these microorganisms results in the phenomenon of interspecies hydrogen transfer, which has two consequences. First, the product patterns of saccharolytic fermentations as carried out by many clostridia are changed; for example, glucose can be fermented to acetate and CO_2. The second consequence of the generation of a low P_{H2} by the hydrogen-consuming bacteria is that it opens up an ecological niche for a fascinating group of anaerobes, the obligate proton-reducing bacteria. These organisms, were first described in 1967, when a culture called "*Methanobacillus omelianskii*" was found to consist of two different organisms carrying out two different fermentations (Bryant et al., 1967):

1) The "S" organism carries out ethanol oxidation:

$$CH_3\text{-}CH_2\text{-}OH + H_2O \rightarrow CH_3\text{-}COOH + 2H_2$$

2) A methanogenic archaeon consumes molecular hydrogen for methane production:

$$2H_2 + 1/2\,CO_2 \rightarrow 1/2\,CH_4 + H_2O$$

Cocultures of this type were termed "syntrophic" cultures, because the organisms involved mutually depend on one another. Molecular H_2 evolution allows fermentative growth of the "S" organism, but only if the PH_2 is kept low enough by the methanogenic bacterium. The term "interspecies hydrogen transfer" was coined for this kind of connection between H_2 evolution and H_2 consumption. Other examples for syntrophically ethanol-oxidizing bacteria known today are *Thermoanaerobacterium brockii* (Ben-Bassat et al., 1981), Pelobacter species (Schink, 1984; Schink, 1985), and in the absence of sulfate, *Desulfovibrio vulgaris* (Bryant et al., 1977). Not only alcohols but also organic acids can be oxidized to acetate and H_2 this way, such as propionate by *Syntrophobacter pfennigii* (Wallrabenstein et al., 1995) and butyrate by *Syntrophomonas* species (Roy et al., 1986; McInerney et al., 1981). As these oxidations are more endergonic than alcohol oxidations, PH_2 has to be decreased to significantly lower values (<10 Pa) than for example for ethanol (<100 Pa). Synthrophic degradation of aromatic compounds, amino acids and glycolate also

has been discovered (Mountfort and Bryant, 1982; Friedrich et al., 1991; Feigel and Knackmus, 1993). In addition to methanogens, H_2 consumption can also occur by sulfur- and sulfate reducers, homoacetogenic fumarate- or glycine-reducing bacteria (Schink, 1997). In this respect one species is of special interest, the homoacetogenic strain, named "acetate-oxidizing rod-shaped eubacterium" (AOR), which can either oxidize or synthesize acetate depending on the PH_2 (Lee and Zinder, 1988a; Lee and Zinder, 1988b; Zinder and Koch, 1984). Based on interspecies hydrogen transfers, metabolically different bacteria are connected in syntrophic relationships, which are a speciality of obligate anaerobes, and are the basis for the formation of consortia and aggregates in which the various types of microorganisms are in close physical contact (Schink and Thauer, 1987; Stams, 1994; Schink, 1997). One recent example is a marine consortium consisting of archaea and sulfate-reducing bacteria, which apparently mediate the anaerobic oxidation of methane (Boetius et al., 2000). However the elusive microorganisms responsible for this conversion have not yet been isolated and the pathway of anaerobic oxidation of methane is not characterized yet.

Anaerobes and Molecular Oxygen: Oxygen Sensitivity and Sensing

Oxygen Sensitivity

Metabolic reduction of oxygen results in the production of highly toxic and reactive oxygen species ("ROS"), such as superoxide anion ($O_2^{-\cdot}$) hydrogen peroxide (H_2O_2) and the hydroxyl radical ($\cdot OH$) (Fridovich, 1995; Cannio et al., 2000b). The latter is most likely responsible for the toxic effects of molecular oxygen. Its production can occur nonenzymatically, when superoxide reacts with hydrogen peroxide in the presence of transition metals (Haber-Weiss reaction [Eq. 4]; Haber and Weiss, 1934). The most probable sites involved in the production of superoxide and hydrogen peroxide at the level of the electron transport chain are cytochrome b_{566} and ubiquinone (Eqs. 1 and 2). In addition superoxide can be generated from O_2 by nonspecific oxidations of reduced flavines, catecholamines and tetrahydrofolates, or chemically.

$$O_2 + 1e^- \rightarrow O_2^{-\cdot} \quad (1)$$

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \quad (2)$$

$$O_2^{-\cdot} + e^- + 2H^+ \rightarrow H_2O_2 \quad (3)$$

$$O_2^{-\cdot} + H_2O_2 \rightarrow OH^- + \cdot OH + \cdot O_2 \quad (4)$$

Most aerobes have developed appropriate protective mechanisms to overcome the toxic effects of hydrogen peroxide and the superoxide anion. Non-enzymic detoxification is effected by glutathione, which is present in high concentration in many bacteria. The main detoxification, however, involves the enzymes superoxide dismutase (Eq. 5), catalase (Eq. 6) and nonspecific peroxidases (Eq. 7) (Fridovich, 1995; Niimura et al., 2000).

$$O_2^{-\cdot} + O_2^{-\cdot} + 2H^+ \xrightarrow{\text{superoxide dismutase}} H_2O_2 \quad (5)$$

$$2H_2O_2 \xrightarrow{\text{catalase}} 2H_2O + O_2 \quad (6)$$

$$H_2O_2 + RH_2 \xrightarrow{\text{peroxidase}} 2H_2O + R \quad (7)$$

Four classes of superoxide dismutases have been identified based on the metal cofactor, which can be either dinuclear Cu/Zn or monomeric Fe, Mn or Ni (Whittaker and Whittaker, 1998). Most bacteria contain only one superoxide dismutase with either Fe or Mn as cofactor. However, *E. coli* contains both types, the Mn-type only induced during aerobiosis and the Fe-type under both conditions, in the presence and absence of oxygen (Kargalioglu and Imlay, 1994). The novel type of superoxide dismutase with Ni as a cofactor has been recently discovered in several *Streptomyces* species (Youn et al., 1996a; Youn et al., 1996b). Interestingly, a few examples for extracellular superoxide dismutases are known, e.g., in *Sulfolobus solfataricus* (Cannio et al., 2000a) and *Streptococcus pyogenes* (Gerlach et al., 1998). Catalases are generally present in aerobic and facultative anaerobic bacteria.

Among the obligate anaerobic bacteria, organisms are found that are more or less aerotolerant. Many of these organisms (e.g., a number of lactic acid bacteria) have been shown to contain superoxide dismutase and lack catalase (Morris, 1976; Archibald and Fridovich, 1981). A number of obligate anaerobes, however, are extremely oxygen sensitive. Most noteworthy in this respect are the methanogenic archaea, clostridial species and sulfate-reducing bacteria. Cultivation of those anaerobes in the laboratory requires special precautions (Hungate, 1969). Simple exclusion of molecular oxygen is not sufficient to provide good conditions of growth. In addition, they require a low redox potential in their environment and growth media supplemented with compounds such as ascorbate, hydrogen sulfide, sodium thioglycolate or cysteine. Curiously, despite their catalytic capacity for producing molecular oxygen, Fe-containing superoxide dismutases have been discovered in the methanogenic archaea *Methanobacterium bryantii* (Kirby et al., 1981), *Methanobacterium thermoautotrophicum* (Takao et al., 1991; Meile et al., 1995) and *Methanosarcina mazei* Gö1 (G. Gottschalk, unpublished observation). Further

examples of Fe-containing superoxide dismutases in strict anaerobes have been reported for sulfate-reducing bacteria, e.g., *Desulfovibrio desulfuricans* (Hatchikian and Henry, 1971) and *Desulfoarculus boarsii* (Pianzzola et al., 1996). Interestingly, a superoxide reductase from the hyperthermophilic anaerobic *Pyrococcus furiosus* has been discovered, which reduces superoxide without the production of oxygen and therefore confers a selective advantage for anaerobes (Jenney et al., 1999). The physiological role of superoxide dismutases and superoxide reductases in anaerobes that supposedly evolved in ecosystems lacking oxygen, however, has to be elucidated.

Oxygen Sensing

Adaptation of facultative anaerobic microorganisms to anaerobic growth conditions is accompanied by dramatic changes in metabolic gene expression. To make these adaptations, those microorganisms have to be able to sense changes in the environmental oxygen availability. Various sensory and regulatory systems control the expression of aerobic and anaerobic metabolism in response to oxygen. Most of the oxygen sensor proteins known today contain heme, iron sulfur clusters or iron as cofactors, e.g., FixL from *Sinorhizobium meliloti* (Gilles-Gonzalez et al., 1995), the fumarate nitrate regulator (Fnr) and SoxR from *E. coli* (Hidalgo et al., 1995) and rhizobial NifA-proteins (Fischer, 1994; Fischer, 1996), respectively. The Fnr from *E. coli*, which is one of the prominent examples for oxygen sensing and redox control of gene expression in prokaryotes, will be briefly discussed here.

The global regulator Fnr controls transcription of genes, whose functions facilitate adaptation to growth under oxygen limitation (Spiro, 1994; Bauer et al., 1999). Under anaerobic conditions, it contains a [4Fe4S]-cluster, which is required for the oxygen-sensing function. Recent data suggest, that this [4Fe4S]-cluster is sufficiently unstable towards oxygen and apparently mediates the sensitivity of the transcriptional activator to oxygen (Khoroshilova et al., 1997; Kiley and Beinert, 1998; Beinert and Kiley, 1999). The presence of the [4Fe4S]-cluster favors dimerization of Fnr, which is correlated with increased site-specific DNA binding of the transcriptional activator Fnr. Upon the presence of oxygen, the [4Fe4S]-cluster is disrupted, resulting in the conversion of transcriptionally active Fnr-dimers into inactive monomers (Lazazzera et al., 1996; Melville and Gunsalus, 1996; Beinert and Kiley, 1999). Homologues of Fnr have been identified in several facultative anaerobic bacteria, some of which differ with respect to the cysteine residues and the coordination of the iron-sulfur clusters (reviewed in Spiro, 1994; Cruz Ramos et al., 1995; Saunders et al., 1999; Vollack et al., 1999).

CHAPTER 1.5

Bacterial Behavior

JUDITH ARMITAGE

Introduction

It is apparent that the majority of prokaryotic species move around their environment, either actively swimming using flagella, or gliding over surfaces. Although a lot less is understood about gliding, we know that swimming uses the most complex organelle identified in prokaryotes. The flagellum is the product of the controlled expression of up to 50 genes, producing an organelle which has components in the cytoplasm, the cytoplasmic membrane, the outer membrane and externally. This flagellar structure can rotate at speeds of up to 350 Hz to move a bacterium at well over 20 μm/sec through its environment. Incredibly, if driven by sodium rather than protons the flagellum can rotate at over 1,300 Hz, moving cells at speeds as great as 150 μm/sec. Unlike gliding, which may have evolved independently several times during evolution, flagellar driven motility may have only evolved once, as all bacteria and archaea seem to have flagella built along similar patterns, although the archaeal flagellum has some differences that may become more significant as more is discovered about motility in that kingdom. Interestingly, control of both flagella- and gliding-based motility is common to all prokaryotes, again suggesting development early in bacterial evolution.

The synthesis and control of motility can be metabolically expensive, therefore if a species is motile, it is because motility provides it with a survival advantage. This chapter will deal with the mechanisms involved in the synthesis and operation of flagella, and to a more limited extent, gliding and twitching. The control of responses by environmental gradients and the possible role of chemotaxis in reaching sites for symbiotic or pathogenic growth, or maintaining positions in natural environments will also be discussed. It has recently become apparent that motility and tactic responses may be important in physiological phenomena such as biofilm formation and social behavior and the possible role of motility in these will be described.

Reynold's Number and Brownian Motion

The environment in which a bacterium lives is very different from that experienced by larger organisms. At the very small size of a bacterium, the dominant physical force is due to viscosity, with almost no measurable force of inertia. A bacterium therefore does not move by displacing liquid, as a larger organism does, and does not glide or coast when the flagellum stops rotating; indeed, a bacterium will stop within the diameter of a proton when its motor stops rotating (Berg, 1983). The equation linking the physical environment to cell size is $R = Lv\rho/\eta$, where R is the Reynolds number, L the length of the organism, v the velocity of the organism, ρ the density, and η the viscosity of the liquid. While a large organism, such as man, may have a Reynolds number of over 100, a bacterium has one of about 10^{-6}. At these low Reynolds numbers, fluid flow is smooth and streamlining unnecessary; bacteria do not displace liquid, but carry a shell of medium with them.

In addition to the problems involved in swimming through a highly viscous environment, bacteria also have to cope with the buffeting that comes from the movement of the molecules in the water, i.e., Brownian motion. Nonmotile cells observed with a microscope are seen to be constantly moving. Swimming bacteria are subject to the same forces and therefore cannot swim in a straight line or stay on course for more than a few seconds. This combined with a gentle curve which results from the rotation of the cell body means that a sensory system has evolved to frequently reset the swimming direction and allow movement in a positive direction despite the constant bombardment.

The majority of bacterial species are also too small to sense a stimulus gradient along their body length. This means that unlike eukaryotic microbes, which can have a head and a tail and swim directly towards the source of an attractant, prokaryotes cannot sense spatially, but must make temporal comparisons (Berg and Brown,

1972; Berg and Turner, 1995). They compare the strength of a stimulus now with that a few seconds before. This means that their patterns of swimming must be different from eukaryotes: rather than steering towards an attractant, prokaryotes must change direction regularly to "check" whether they are going in a positive direction. (See Patterns of Swimming in this Chapter)

Flagella

The structure of the flagellum was thought to be generally conserved amongst all swimming prokaryotes, but recently it has become apparent that the motor structures of bacteria and archaea may be somewhat different, leading to the suggestion of two separate evolutionary events or distant divergence. However, both swim by rotating semi-rigid helical flagella filaments using the electrochemical ion gradient (usually the proton motive force, but in some species, a sodium motive force) across the cytoplasmic membrane to drive that rotation.

Patterns of Flagellation

An early method of classification relied on whether the bacteria swam, and if they did, the pattern of flagellation. We now know that whether a bacterium swims may depend on the medium in which it is grown, and many only swim under limited growth conditions or at certain phases of the growth cycle. The pattern of flagellation along with cell size and shape can still be a reasonable start in identification, however. Some species have single flagella, which may be polar as in *Pseudomonas aeruginosa* or subpolar as in *Rhodobacter sphaeroides*. Many species have flagella arising from apparently random sites all over the cell surface. These peritrichous flagella tend to come together in bundles to cause the cells (such as *Escherichia coli* or *Sinorhizobium meliloti*) to swim. Bundles of flagella are also found at the poles of some species, and these might be at both poles (as in *Rhodospirillum rubrum*, *Helicobacter pylori* or *Halobacterium salinarium*) or at one pole (as in *Chromatium vinosum*). Some species even have internalized filaments, a characteristic of the spirochetes. Interestingly, several species alter patterns of flagellation, dependent on their physical environment. *Vibrio alginolyticus* swims using a single flagellum when in an aquatic environment, but when it reaches a surface, a new set of flagella are synthesized and the hyperflagellate cells are now able to move over the surface (Atsumi et al., 1992; McCarter et al., 1988). This is not an uncommon phenomenon, having been known for many years as a characteristic of *Proteus* species and now recognized in *Bacillus*, *Salmonella*, *Rhodospirillum* and many other species (Harshey, 1994a). What makes the *V. alginolyticus* particularly interesting is the switch between sodium and proton motors that occurs when cells switch from free-swimming to surface movement (see below).

Patterns of Swimming

All flagella appear to be passive helices, rotated at their base by a transmembrane motor which is driven by either the electrochemical proton or sodium gradient. The different patterns of swimming seen in different species arise because of different patterns of motor switching. The best studied swimming pattern is that of the peritrichously flagellate bacteria. The individual flagellar motors can rotate either clockwise (CW) or counterclockwise (CCW) and switch between the two states (Khan and Macnab, 1980; Macnab, 1976; Macnab, 1977). When the majority of flagella are rotating CCW, the helical filaments come together as a bundle, rotate together and push the cell forward. Periodically a number of motors switch to CW rotation, causing a polymorphic transition in the flagellar helix such that the handedness and wavelength changes. The bundle of flagella is forced apart and the cell "tumbles" on the spot. The bundle reforms when the majority of motors return to CCW rotation and the cell resumes swimming, usually in a new direction (Berg and Anderson, 1973; Turner et al., 2000). This pattern of periods of smooth swimming interspersed every few seconds with a short tumble results in a three-dimensional random pattern of swimming. Other species achieve the 3D swimming pattern by different motor behavior. *Rhodobacter sphaeroides* has a single flagellum which only rotates CW. Every few seconds the flagellar motor stops rotating and the flagellar filament changes conformation to a large amplitude, short wavelength coil against the cell body. The cell is reoriented partly by Brownian motion and partly by the slow rotation of this coiled form, and when a functional helix reforms, the cell is usually pointing in a new direction (Armitage et al., 1999b; Armitage and Macnab, 1987). Other species with a single flagellum, such as *Ps. aeruginosa* change direction by briefly switching to CW rotation, the flagellum then pulls rather than pushes the cell for a brief period. Recent studies into the efficiency of using brief reversals rather than tumbles as a mechanism for moving through different media suggested that while tumbling is efficient in liquid, brief reversals worked better at moving bacteria through particulate media.

Sinorhizobium meliloti swims using a bundle of flagella. Rather than stopping or switching

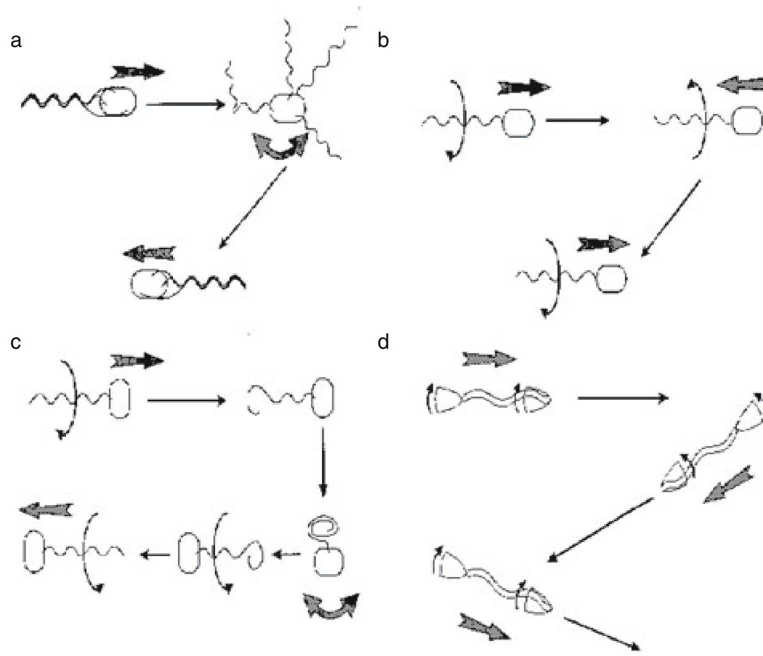

Fig. 1. This cartoon shows four different patterns of flagellation and the corresponding mechanisms of direction changing. a) *Escherichia coli* swims by rotating a bundle of flagella counterclockwise. Periodically, a number of motors switch to clockwise rotation, and the bundle flies apart and the cell tumbles. When the majority of filaments return to counterclockwise rotation and the bundle reforms, the cell is usually pointing in a new direction. b) *Pseudomonas aeruginosa* swims by rotating its single polar flagellum pushing the cell forwards. Periodically, the motor reverses and pulls the cell. During this time, Brownian motion tends to reorient the cell. The motor again reverses and pushes the cell, usually in a new direction. c) *Rhodobacter sphaeroides* has a single flagellum that rotates clockwise, pushing the cell. Periodically, the motor stops and the flagellum relaxes into a short wavelength large-amplitude filament. This is rotated slowly, reorienting the cell. The motor resumes normal rotation and the functional filament reforms to push the cell in a new direction. d) *Rhodospirillum rubrum* has two polar tufts of flagella that rotate to move the spiral-shaped cells through the medium. The bundles switch rotational direction synchronously to change swimming direction.

rotational direction, a number of flagella slow their rotational speed. This results in disruption of the bundle, and the cell changes direction without either stopping or tumbling (Sourjik and Schmitt, 1998a). This again results in a random swimming pattern. Spiral-shaped species such as *Rhodospirillum rubrum* have polar tufts of flagella that rotate in opposite directions, spiralling the cells through the medium. Periodically both bundles simultaneously switch rotational direction and the cell changes direction. In spirochetes these polar bundles of flagella are internalized, but they still rotate. Evidence indicates that the rotation of the filament lying between the outer cell wall and the cell body causes one to rotate against the other, and the spiral-shaped cell body to move through the viscous environment (Berg, 1976; Charon et al., 1992). These species all move far more efficiently through viscous media, and as many are pathogens, this is thought to aid their invasion of, for example, mucous membranes (Kaiser and Doetsch, 1975). Periodic direction changing occurs when the flagella at the two poles first stop rotating in the opposite direction and begin rotating in the same direction, and the cell body then flexes, causing the cell to change orientation.

Few archaea have been investigated in detail, but *Halobacterium salinarium* has polar bundles of filaments. When these change direction of rotation, the bundle does not separate but rotates smoothly in either CCW or CW directions, suggesting a slightly different flagellar structure (Alam and Oesterhelt, 1984; Marwan et al., 1991).

Some species swim differently under different growth conditions. Species from a wide range of genera have been shown to differentiate into highly flagellate swarmer cells when inoculated onto surfaces. In most cases it is thought that the expression of the genes involved in flagella synthesis is increased in response to some surface stimulus, either cell density or increased viscous drag (Alberti and Harshey, 1990; Givskov et al., 1998; Harshey and Matsuyama, 1994b; Kohler et al., 2000; McCarter et al., 1988).

Many members of the γ subgroup of Proteobacteria can be induced to swarm, including

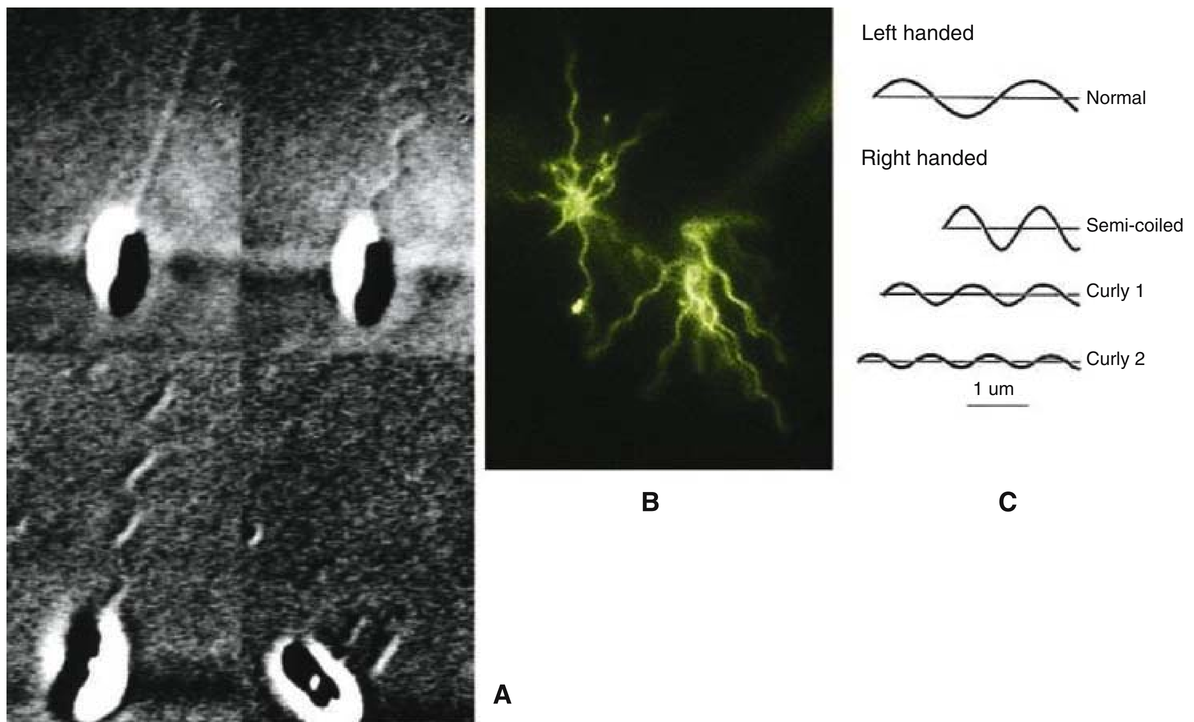

Fig. 2. Changes in shape and motion of flagella during swimming, tumbling and reversal of motor rotation. a) Still differential interference contrast (DIC) microscope images taken from a video film of swimming *Rhodobacter sphaeroides* showing a polymorphic transformation of the flagellar filament. The functional filament can switch to a longer wavelength (apparently straight form) or change to a coiled large amplitude (short wavelength form) when rotation stops. From Armitage et al. (1999b)) Still image taken from a video of tumbling *Escherichia coli* with filaments labelled with fluorescent dye. From Turner et al. (2000). c) Polymorphic shapes taken on by flagella during changes in the direction of motor rotation. (Figures 2a and 2b are courtesy of H.C. Berg and L. Turner using the Rowland Institute DIC microscope.)

E. coli, *Salmonella typhimurium*, *Serratia marscesens* and *Yersinia* species. The best studied are the swarmer cells of the marine vibrio, *Vibrio parahaemolyticus* and *Vibrio alginolyticus* and the enteric *Proteus* species, *P. mirabilis* and *P. vulgaris*. *Proteus* species swim in liquid medium in much the same way as *E. coli*. However, when inoculated onto agar plates, the cells differentiate into long filamentous cells with a several fold increase in flagella numbers per unit cell surface. The highly flagellate filamentous cells move together as rafts over the surface, the increase in cell surface allowing them to overcome the surface tension. The marine vibrios, *V. haemolyticus* or *V. alginolyticus* actually synthesize completely new flagella motors when grown on surfaces, switching from the fast, sodium-driven motors (controlling polar flagella when free swimming) to large numbers of slower proton-driven motors when grown on surfaces (Atsumi et al., 1992). Another species which increases lateral flagella synthesis on surfaces is *Rhodospirillum centenum* (Ragatz et al., 1995). In this case, rather than some of the hyperflagellate cells moving away as rafts from the colony, the whole colony of photosynthetic bacteria moves over the agar surface towards red light. *Agrobacterium tumefaciens*, another α-subgroup bacterium can also become hyperflagellate on surfaces.

Swarming is not confined to Gram-negative genera, as both *Bacillus* and *Clostridium* species have been shown to swarm. The increased viscous drag on the polar motor appears to trigger the expression of the peritrichous proton-driven motor genes in *V. alginolyticus*, but this does not appear to be the signal for all switches to peritrichous expression, as the artificial increase in external viscosity only causes peritrichous expression in some species. Obviously, the increased expenditure of energy required to synthesize large numbers of flagella indicates that moving over a surface must provide a survival advantage for these species. There have been suggestions that motility may increase infectivity of *Proteus* spp. (Allison et al., 1992; Gygi et al., 1995; Mobley and Belas, 1995) and may help marine *Vibrios* maintain themselves on nutrient-rich surfaces, but evidence is still limited. Interestingly, many bacterial species found in biofilms move. Depending on the species, this

may be by twitching, gliding, or multiflagellate swarming, each of which can move a cell through a highly viscous environment and presumably provide survival advantages. Detailed analyses of gliding and twitching are starting to suggest that these may use common mechanisms (Semmler, 1999; Watnick and Kolter, 2000). A free-swimming *Synechococcus* cyanobacterial species has been isolated which swims without any obvious means of propulsion (Brahamsha, 1996; Pitta et al., 1997; Waterbury et al., 1985). Dark field and differential interference contrast (DIC) microscopy, and attempts at flagella isolation using classical techniques such as pH reduction or shearing, have all failed to identify any extracellular means of propulsion. Jet propulsion has been ruled out and the current hypotheses suggest Ca^{2+} is involved in movement along with very short, fine cilia-type structures, but the mechanism remains unclear.

Flagella Structure: Flagellin

Bacteria The majority of species investigated have flagellar filaments made from a single protein, flagellin. Flagellins vary in size from species to species, but all have a conserved C- and N-terminal domain, which allows the flagellum to polymerize into a helical structure (Fedorov et al., 1984; Macnab and DeRosier, 1988; Mimori-Kiyosue et al., 1997; Vonderviszt et al., 1991). Unusual amino acids are often found in flagellin proteins and many flagellins are glycosylated, but the significance of this has not been identified. The C- and N-terminal domains are on the inside of the hollow filament structure and allow the individual subunits to interact as protofilaments along the axis of the filament, with 11 protofilaments making up the complete structure of many thousand flagellin subunits (Morgan et al., 1995; Namba and Vonderviszt, 1997; Namba et al., 1989; Trachtenberg and DeRosier, 1987a; Trachtenberg and DeRosier, 1991). The flagellin subunits can interact with the neighboring subunits in two defined ways, which allows the protofilaments to be long or short. The association of short with long protofilaments creates the twist in the cylinder and hence the helical shape, and the relative numbers of short to long protofilaments defines the wavelength and handedness of the structure. The protein regions involved in the bi-stable switching have recently been putatively identified in the crystal structure of a flagellin fragment (Namba, 2001; Samatey et al., 2000; Yamashita et al., 1998). The change in helical shape results from the torque imposed on the filament by the rotating motor being transmitted through a junction protein connecting the flagellar filament to the hook (Fahrner et al., 1994). The helical filament can be several times longer than the cell body, for example filaments as long as 7 μm have been seen on *R. sphaeroides*, which is only 2 μm long. The filament itself is between 15 and 20 nm in diameter, but the wavelength is constant for the whole length of the filament. Analysis of cells tethered to glass slides by antibody bound to either the cell filaments or hook region, which connects the filament to the cell, suggests that the filament is one of the most rigid proteins in biology, certainly more rigid than actin (Block et al., 1989).

The central domain of the flagellin protein is highly variable and it is this region that is exposed on the outside of the flagellar filament. This provides the highly antigenic domain, the H-Ag, used for many years to type, for example, *Salmonella* strains. This region is not required for assembly, and mutants can be created lacking most of the central domain, but still capable of functional flagella assembly. *Salmonella* is known to "phase shift" flagellin expression, and by inverting genes, to express different flagellins under different conditions. It has been suggested this phenomenon may help the bacterium overcome the immune system of the host, although little research has been carried out to identify whether this is indeed the case (Iino and Kutsukake, 1983). This phase variation was used to show that flagella assemble from the distal end of the growing flagellum, not the base (Iino, 1969).

Some species have flagella made up of more than one flagellin, for example *S. meliloti*, *Treponema pallidum* and *Caulobacter crescentus*, have flagellar filaments composed of several related flagellins. The reason for this is unclear, although *S. meliloti* filament is more rigid (known as complex flagella) than other flagellar filaments, and these filaments are thought not to undergo polymorphic transitions (Trachtenberg et al., 1987b). The flagellins are expressed and incorporated sequentially rather than randomly mixed in the structure, and though mutants in the individual flagellin genes tend to still assemble functional filaments, these are often not as efficient as wild-type filaments.

Archaea The flagellins that have either been sequenced or identified from genome sequences of the archaea suggest slightly different flagellins than those of the bacteria. Unlike most bacterial flagellin, the archaeal flagellins appear to be glycosylated. The bundle of flagella rotate CCW and CW without disruption of the flagellar bundle, and it is thought the glycosylation may allow the filaments to slide past each other during the change in rotational direction, without getting tangled (Alam and Oesterhelt, 1984).

Motor Structure

Bacteria The semirigid helical flagellum is connected to the cell body via a short region, the hook, with a protein structure similar to the filament, but composed of a different protein (Uedaira et al., 1999; Wagenknecht et al., 1982). The role of the hook is not certain, but it is less rigid than the filament and may be involved in allowing the filaments to come together as a bundle and/or it may be involved in transmitting the changes in torque from the motor to the filament, allowing the polymorphic transformation needed for direction changing (Block et al., 1991). There are two proteins between the hook and the filament, known as hook-associated proteins (HAPs). Mutations in the gene coding for HAP3 of *E. coli* result in a filament that changes conformation far more frequently that the wild type. The HAP3 protein may hold the protofilaments in specific conformations and only allow changes when the torque transmitted through the hook from the motor changes significantly (Fahrner et al., 1994).

The hook then connects to the rotor via a rod that passes through the layers of the bacterial membrane. In Gram-negative species, the rod passes through a pair of rings in the outer membrane, the L and P rings, which probably act as a grommet to allow rotation of the rod without disrupting the outer membrane. In Gram-positive species, the rings are replaced by a collar-like structure. The motor consists of a rotor and a stator. The rod is connected to the rotor, which itself is a series of rings located in the cytoplasmic membrane and cytoplasm of the cell (Fig. 3). Early work suggested that the actively rotating region was the MS-ring in the cytoplasmic membrane, but that is now known to be a passive structure made of the protein product of a single gene (Ueno et al., 1994). On the cytoplasmic face of the MS ring is the active part of the rotor. It is estimated that about 26–30 copies of the FliG, M and N proteins form the C-ring (Mathews et al., 1998; Sockett et al., 1992; Thomas et al., 1999; Toker and Macnab, 1997; Zhao et al., 1996a; Zhao et al., 1996b). The movement of protons through the membrane cause FliG to rotate, rotating the rod and the helix (Blair and Berg, 1990; Blair and Berg, 1991). The FliM and FliN proteins are thought to interact with the cytoplasmic sensory signalling pathway to cause the motor to switch the direction of rotation (Bren and Eisenbach, 1998; Sockett et al., 1992; Sourjik and Berg, 2000; Zhao et al., 1996b). To allow rotation, there must be not only a rotor, but also a stator. The stator consists of a ring of about eight complexes of MotA and MotB proteins. The MotB protein has a single transmembrane domain and a large periplasmic region, which has a terminal peptidoglycan-binding domain (Muramoto and Macnab, 1998). This is thought to anchor the proteins to the cell wall. In addition, MotB is linked to MotA, which has four transmembrane domains and is the proton channel through the membrane (Zhou et al., 1998b; Zhou and Blair, 1997a). Protons, about 1000 per revolution, pass through MotA and interact with FliG, and this flow causes rotation to occur at about 300 Hz (Meister et al., 1987). Each of the Mot complexes is an independent force-generating unit (Block and Berg, 1984; Ryu et al., 2000). Crystal structures of MotA fragments and second-site suppressor mutations indicate a number of essential amino acids on FliG and MotA are essential for torque generation (Braun et al., 1999; Lloyd et al., 1999; Mathews et al., 1998; Zhou et al., 1998b). All bacterial motors investigated have homologues of the motor proteins, suggesting that the mechanism of driving rotation is common. Sodium motors, which work much faster, also have MotA and MotB homologues, but also have additional proteins (PomA, PomB, MotX and MotY; Asai et al., 1997; McCarter, 1994a; McCarter, 1994b). The role of these is still not understood, but chi-

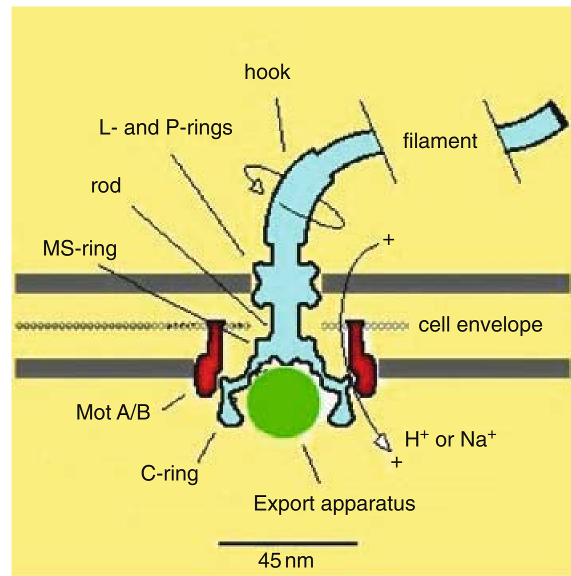

Fig. 3. Structure of the flagellar motor. Cartoon of the flagellar motor shows the L- and P rings (which act as a grommet through the outer membrane of Gram-negative bacteria), MS ring, (which provides the scaffold for the C-ring [the rotor part of the motor]). The C-ring is comprised of FliG, which interacts with the stator (MotA/B) and the electron chemical ion gradient, and FliM/N, which form the switch component and interact with the chemosensory pathway. A ring of 8–12 MotA/B proteins make up the stator, anchored in the membrane by MotB. Binding to the peptidoglycan, the ions move through MotA to interact with FliG on the C-ring to drive rotation. From Berry and Armitage (1999).

meric motors have been made with MotB from a proton-driven motor and MotA from sodium motors, which function as sodium motors.

Also, on the cytoplasmic side of the membrane and associated with the C-ring is the export apparatus. Recent studies on the toxin-exporting type III secretion pathway of species such as *Yersinia pestis* and *Shigella* has identified structures remarkably similar to the central flagellar motor and components which are remarkably similar to the flagellar-specific export pathway, suggesting a common evolutionary origin (Kubori et al., 1998; Macnab, 1999; Minamino and Macnab, 1999). While the proteins that make up the outer membrane L and P rings have classical signal sequences, the rod, hook and flagellin proteins lack these sequences and are exported through the 30 Å central channel of the forming flagellum, before polymerization at the distal end of the growing structure (Minamino and Macnab, 1999; Suzuki et al., 1998). It is assumed that the proteins are exported in an unfolded form and must therefore be held in an unfolded form before export. Export depends on FliI, a protein with significant sequence similarity to the B-subunit of ATP synthase, and thought to be a flagellar-specific export protein (Dreyfus et al., 1993; Vogler et al., 1991). Many of the other proteins involved in the export process have homologues in the Type III secretion system. For the components of the flagellar filament to be assembled across the inner cytoplasmic and outer membranes of a bacterium, the rod protein must pass through the peptidoglycan layer. A component of the flagella regulon, FlgJ has been found to digest a hole through the peptidoglycan to allow assembly of the motor components (Nambu et al., 1999).

Motor activity needs to be controlled by environmental signals for swimming to have any environmental advantage, controlling either the switching of rotational direction or causing the motor to transiently stop. As with the mechanism involved in rotation, that involved in switching is unclear. However, a cytoplasmic signalling protein, CheY is known to interact, when phosphorylated, with the FliM component of the C-ring via a sensory signalling pathway. The interaction of CheY-P with FliM is thought to cause conformational changes in the FliG proteins, such that the direction of rotation is reversed, even though ion flow remains inward (Welch et al., 1994).

ARCHAEA Much less is known about the motor proteins of the archaea, but the classical membrane ring structure of the bacterial motor is not evident in electron micrographs. A large cytoplasmic structure is however evident, but the composition of this is still very uncertain (Kupper et al., 1994).

Interestingly, large disk-like structures have been found associated with the eubacterium *Wolinella succinogenes*, and their role is uncertain, but structurally the whorl-like structures formed are very different from those seen in the archaea (Engelhardt et al., 1993; Kupper et al., 1989; Schuster and Baeuerlein, 1992; Stahlberg et al., 1995).

Gene Expression and Assembly

It takes about 40–50 genes to construct a functional flagellum, and as components are located in the cytoplasm, across both membranes and extracellularly, it is extremely important that flagellar assembly is highly ordered (Macnab, 1992; Macnab, 1996). There are only a specific number of flagella per cell, and therefore expression of the flagellar genes must be regulated by the growth rate (except when some species are induced to become hyperflagellate). In *E. coli*, a master operon, encoding FlhC and FlhD, under the control of the catabolite repression system, initiates expression of a series of operons in a highly coordinated manner. There is a flagellar specific sigma factor, σF or σ28, which controls expression of later proteins, whereas any assembly errors feedback and inhibit further operon expression. An anti-σ factor, FlgM, binds to σF until exported from the cell, which happens after rotor assembly. This is the signal that the motor has been correctly assembled, and the flagellin proteins can now be expressed and exported (Brown and Hughes, 1995; Iyoda and Kutsukake, 1995; Kutsukake and Iino, 1994). Although the majority of research has been on *E. coli* and *S. typhimurium*, other motile species studied in detail appear to have highly organized expression of the flagellar genes, and usually a σ28 homologue. Some species may have σ-54-dependent control of the initial operons rather than σ70, suggesting environmental regulation of motility.

Control of gene expression is more complex in species such as *C. crescentus*, which is only motile during certain stages of its life cycle. A sessile, stalked cell divides to produce a motile swarmer cell, which is unable to grow or divide but swims to a new location to settle and produce a stalk for attachment at a surface. In this case, the timing of flagellar gene expression is critical. In this species a response regulator protein, CtrA, controls both methylation of DNA and flagella synthesis. Phosphorylated CtrA inhibits cell division and DNA replication, and activates DNA methylation and flagella synthesis. Localized proteolysis of the protein in stalked cells appears to allow the cell cycle to continue in stalked cells while inhibiting division in swarmer

cells (Brun et al., 1994; Newton and Ohta, 1990; Reisenauer et al., 1999; Wheeler et al., 1998; Wu et al., 1995).

Gliding

Gliding is considered to be movement over surfaces that is produced without obvious motility organelles. It seems possible that there is more than one mechanism involved in gliding because the patterns of movement vary far more than flagellate motility. Gliding is the most common form of motility amongst cyanobacteria. In some genera, all the cells are motile, whereas in others, only differentiated structures such as hormogonia glide, probably helping dispersal. Interestingly, many species also have gas vacuoles, but these allow dispersal over large distances in species living in open water and allow diurnal movement in response to light and nutrient levels. Genera as distantly related as *Flavobacteria*, *Myxobacteria* and *Mycoplasma* also glide on surfaces.

Rates and patterns of gliding vary dramatically from species to species. *Flavobacterium johnsoniae* (*Cytophaga*) can move across surfaces at rates of 10 μm/sec, almost as fast a free-swimming bacterium, periodically changing direction by dramatically up-ending on the pole of the cell and then falling to point in a new direction (Beatson and Marshall, 1994; Gorski et al., 1993; Pitta et al., 1993). *Myxococcus xanthus*, on the other hand, moves at a maximum of 5 μm/min, very slowly gliding over surfaces and changing direction by simply reversing gliding direction (Hartzell and Youderian, 1995; Ward and Zusman, 1997). Extracellular polysaccharide has been implicated in gliding motility, supported by genetic evidence from *F. johnsoniae* (Agarwal et al., 1997; Gorski et al., 1993).

The best studied system of gliding is that shown by *Myxococcus xanthus*. This species undergoes a complex life cycle in which colonies of bacteria glide over surfaces, releasing antibiotics to kill other bacterial species, which then provides the cells with their nutrient source. Under nutrient limiting conditions, large numbers of cells (up to 100,000) aggregate to form fruiting bodies in which spores are formed. A complex system of cell-cell signalling controls this process, which depends on the ability of the cells to glide (Hartzell and Youderian, 1995). Two patterns of gliding have been characterized in *M. xanthus*: "adventurous" motility in which single cells move away from the central colony and "social" motility in which the colony moves as a unit. Little is known about the mechanisms involved in "adventurous" gliding, but "social" gliding requires cell-cell contact and trail formation (Rodriguez and Spormann, 1999). Cell-cell contact appears to occur at the poles of the gliding cells and requires type IV pili or fimbriae (Kaiser, 2000). Extracellular, peritrichous filaments known as "fibrils" have also been shown to be required for social motility (Dworkin, 1999).

Although the mechanisms involved in movement are unknown, it has been suggested that twitching motility, which also requires type IV pili and is important in biofilm formation, and gliding may be closely related, if not in fact the same phenomenon (Sager and Kaiser, 1994; Spormann, 1999; Wall and Kaiser, 1999; Ward et al., 1998a).

The wall-less pathogenic genus, *Mycoplasma*, also glides. Unlike all other prokaryotic species studied so far, these bacteria have a true polarized morphology, with a "head" and a "tail," which appears to help in attachment. *Mycoplasma mobilis* glides at speeds of up to 4 μm/sec and always leads with the head, which has a smaller diameter than the rest of the cell. Direction changing results from the cells turning. In the case of this gliding species, it has been suggested that there are adhesion proteins which flow along the cell surface, moving the cell forward, to be recycled to the front of the cell when they reach the rear (Neimark, 1983).

Twitching

Twitching has become the focus of increasing attention. Type IV pili turn out to be essential for twitching motility, for surface attachment and biofilm formation (O'Toole and Kolter, 1998). As Type IV pili are also essential for social gliding in *M. xanthus*, it suggests that twitching and at least some forms of gliding may in fact all be the result of Type IV pili. The role of motility, adhesion and biofilms in surface colonization makes this of particular interest to both medical and environmental research. Twitching motility has been identified in a wide range of bacterial species, but is best studied in *Ps. aeruginosa* where it can result in speeds of up to 5 μm/sec (Darzins and Russell, 1997). Twitching was defined as the intermittent twitching movement of cells, which can occur singly or as groups, although it seems likely that some contact is required with neighboring cells for movement to occur. Twitching results in a thin-spreading zone from a bacterial colony, which can occur between the Petri dish and agar surface or over the surface of solid agar.

Type IV pili are about 6 nm in diameter, therefore less than half the diameter of flagella, but can be several μm in length. They are made of pilin, which form helical strands along a

hollow tube. Pilin has a conserved N-terminal region which appears to be involved in assembly and is located on the inner surface of the pili, whereas a more variable C-terminal domain forms the outer surface and is thought to be involved in adhesion. Type IV pili are found at the poles of the cells, and over 30 genes are involved in their synthesis and assembly (Alm and Mattick, 1997). Recent data suggest that they may only be expressed in the cells at the actively moving bacterial front. Unlike flagellar assembly, pili assemble from the cell body outward. A family of proteins involved in protein secretion, DNA transfer, and the morphogenesis of filamentous bacteriophage are related to pilin and are all initially synthesized with a short, positively charged characteristic leader sequence. Prepilin is processed by a cognate prepilin peptidase to produce pilin, with an unusual first amino acid residue, *N*-methyl phenylalanine. Assembly occurs from the cytoplasmic membrane outwards and three additional proteins have been identified, PilC and PilB, in the cytoplasmic membrane and PilQ in the outer membrane. Their role in pilin assembly or function is currently unknown. Twitching direction appears to be controlled, and homologues of the chemosensory system which control flagellar activity have been identified (Alm and Mattick, 1997; Darzins and Russell, 1997; Watson et al., 1996). It is to be expected, therefore, that a number of cytoplasmic proteins remain to be identified which control the activity of the pili.

The mechanisms involved in twitching are still a mystery. Early research suggested that movement was the result of the pili retracting and extending. Extension and retraction have also been suggested as a mechanism for cell-cell interaction during social gliding. The helical nature of the fibrillar strands in the pili has lead to the suggestion that rotational forces coupled to retraction may be important in twitching. Recent studies using laser tweezers to measure the force of retraction of pili showed that the forces of retraction could exceed 80 pico-Newton (pN), moving cells at about 1 μm/s (Kaiser, 2000; Merz et al., 2000b). As protein synthesis and the *pilT* gene are both required, it is thought that Type IV pili attach cells to surfaces or to other cells, and then retract the pili pulling the cell forward. The subsequent resynthesis and reattachment of the pili allows cells to pull themselves along surfaces as the result of pilin retraction. Electron micrographs of *Neisseria gonorhoeae* twitching colonies show extensive pili interconnecting cells in the colonies, suggesting that these pili may be involved in colony movement (Merz and So, 2000a).

Intracellular Movement by Mobilizing Actin Filaments

Several pathogenic bacterial species (including *Salmonella* and *E. coli*) have developed mechanisms for usurping and exploiting the eukaryotic cells' own actin-based cytoskeleton machinery to aid invasion (Frischknecht and Way, 2001; Goosney et al., 1999; Zhou et al., 1999). Several species have taken this ability further and have evolved mechanisms for taking over the eukaryotic cytoskeleton both for the process of invasion and for cell-to-cell spreading. Species such as *Shigella flexneri*, *Listeria monocytogenes* and *Rickettsia rickettsii* produce toxins that cause actin polymerization and cell ruffling close to the bacterium, inducing uptake into the eukaryotic cell. Once inside the cell, the bacteria produce a number of toxins allowing release of the bacteria from the phagocytic vacuole. They also produce surface proteins which act as nucleation centers for polymerization of the eukaryotic actin. The polar expression of these proteins results in the formation of actin "comet"-tails capable of exerting considerable mechanical force—proteins which, by polymerization, depolymerization and association with a number of actin-associated proteins (such as profilin and small GTPases), push the cells through the cytoplasm at speeds of about 12 μm/min and cause spreading of the bacteria both across the epithelium and from cell to cell (Cossart and Bierne, 2001; Dramsi and Cossart, 1998; Frischknecht and Way, 2001; Gerbal et al., 2000; Heinzen et al., 1999; Kuo and McGrath, 2000; Nhieu and Sansonetti, 1999; Rathman et al., 2000; Tran-Van et al., 1999; Tran-Van et al., 2000).

Behavioral Control

Motility can be divided into at least three types: free-swimming, swarming over surfaces using flagella, and gliding or twitching. In all cases, expression of the locomotory organelle requires a large number of genes, and expression is energetically expensive. In addition, while running, a proton motor may take less that 1% of the proton-motive force of a bacterium growing under rich conditions, it may take several percent under growth-limiting conditions. The observation that many species stop swimming in rich growth conditions and only start under limiting conditions, strongly suggests that motility provides a major advantage under most naturally occuring conditions. To help a bacterium reach or maintain itself in its optimum environment for growth, motility must be under the control of environmental sensing systems. In general, bac-

teria are far too small to be able to sense a gradient along their length. They therefore sample their environment in time, comparing the concentration or strength of a stimulus at one time with that a few seconds earlier (Berg, 1983). All bacteria tend to move in a random pattern, whether three dimensionally, as with free-swimming cells, or two dimensionally on surfaces. This random pattern is biased in a favorable direction by the cell changing direction more often when moving away from a positive stimulus and changing direction less often when moving in a positive direction (Berg and Brown, 1972; Block et al., 1982). Prokaryotes can sense a very wide range of stimuli, including light, oxygen and other terminal electron acceptors, extracellular chemicals, intracellular metabolic state, pH, osmolarity and even, in some cases, the Earth's magnetic field. All of these signals must be sensed and balanced to produce an overall response. Of course, different species will respond to different stimuli, and many will be repelled by the dominant attractants of other species. Over the past few years, it has become apparent that the rather straightforward chemosensory pathway identified in *E. coli*, while being the core of chemosensing in other species, is a much simpler system than that used by many bacteria outside of the γ subgroup.

To allow any kind of behavioral response, a number of sensory steps are required: 1) the stimulus must be sensed; 2) the signal must be relayed to the motor apparatus; 3) the signal must be rapidly terminated; and 4) the receptor must be reset to allow future changes to be sensed. The mechanisms involved in these stages is best understood in *E. coli* (Armitage, 1999a; Armitage and Schmitt, 1997c; Falke et al., 1997).

Chemotaxis in *E. coli*

The best understood chemosensory system is that of *E. coli* and the closely related, *Salmonella*. Transport and metabolism are not required for chemotaxis by *E. coli*. Transport mutants are still chemotactic, whereas specific chemotaxis mutants can still metabolize the chemoattractant (Adler, 1969). In addition, nonmetabolizable analogues are still attractants. Four chemoreceptors, Tsr (for serine), Tar (for aspartate and maltose), Trg (for ribose and galactose), and Tap (for dipeptides), have been identified (Stock and Surette, 1996). The Tap receptor is found in *E. coli*, but not *Salmonella* (Manson et al., 1986). *Salmonella* has a receptor, Tcp, for citrate, which is not a metabolite for *E. coli* (Yamamoto and Imae, 1993). This illustrates that even the pathways of two very closely related species have adapted to the metabolic requirements of that species. In addition, a related protein has been identified, Aer, which is involved in oxygen sensing (see Aerotaxis in this Chapter).

S-Adenosyl methionine is required for resetting the signalling state of the receptors, i.e., adaptation (Aswad and Koshland, 1975; Kort et al., 1972). Mutants lacking S-adenosyl methionine behave like mutants with deficiencies in the proteins of the adaptation pathway, and tumble constantly. Receptor methylation, the extent of which depends on whether an attractant is added or removed, resets the receptor protein into a nonsignalling state and allows gradient sensing. In *E. coli*, therefore, one of a limited number of attractants binds to transmembrane receptors, and as a result, a signal is generated which results in a change in swimming pattern, biasing the random swimming pattern in a favorable direction. Modification of the receptors stops signal generation, and if the concentration of stimulus remains unchanged, allows gradient sensing. Five genes responsible for encoding the proteins for general chemosensory signal transduction were identified in motile but non-chemosensing mutants of *E. coli*. These (*cheB*, *cheR*, *cheA*, *cheY* and *cheZ*) form the intracellular signalling sequence to the flagellar motor. Related schemes have been found in almost all other motile species, but in the majority of nonenteric species, the sensory pathways are more complex (see section on Chemotaxis in Nonenteric Species in this Chapter).

Chemoreceptors

The chemoreceptors of *E. coli* are all built on the same basic design (Falke et al., 1997; Mowbray, 1999; Mowbray and Sandgren, 1998). Sequencing of the chemoreceptors of a wide range of species from archaea through to bacteria has identified a common domain in all receptors necessary for sensory transduction. The conservation of the core of the chemosensory pathway between species has allowed identification of the likely chemosensory genes in many species whose genomes have recently been identified. One of the major surprises (along with the number of apparently parallel signalling pathways in many species, see later) has been the number of chemoreceptor genes, which can be over 25 in species such as *Pseudomonas palustris* and *Vibrio cholerae*, and seems to average 10–15 in other species. This suggests that bacteria faced with complex environments have receptors to sense a wide range of chemical stimuli, while others, such as *E. coli* use a pared down system suited to a world with limited changes.

The four *E. coli* chemoreceptors (533–553 amino acids in length) have two membrane-spanning domains (a large periplasmic domain and a large cytoplasmic N-terminal domain).

Recent crystal and nuclear magnetic resonance (NMR) structures of the periplasmic and the cytoplasmic domain suggest that the chemoreceptors are one of the longest proteins found in a bacterial cell, extending a distance of 40 nm from the chemoeffector binding domain to signalling domain (Djordjevic and Stock, 1998; McEvoy et al., 1998). There is very little homology between the periplasmic domains on a sequence level, nor is there obvious similarity between the transmembrane domains, however, the cytoplasmic domain is very highly conserved between transducers. It is this highly conserved cytoplasmic domain that is common to chemosensory transducers across the bacterial and archaeal world.

These chemosensory receptors are called "methyl-accepting chemotaxis proteins" or MCPs and form stable dimers in the cell's membrane. The periplasmic domains of the different MCPs "sense" different chemoeffector molecules. Interestingly, some receptors, for example Tar, can sense two completely different stimuli, in this case the amino acid aspartate and the sugar maltose, bound to its periplasmic binding protein (PBP; Gardina et al., 1992; Gardina et al., 1997; Gardina et al., 1998). This has interesting implications for the sensing of the two chemoeffectors acting through Tar. The Tar receptor itself is expressed as part of the flagellar and chemosensory regulon, and as aspartate interacts directly with Tar, interaction will be directly related to the extracellular concentration of the amino acid. Expression of the maltose PBP, on the other hand, is under the control of the maltose transport system, and the response will depend on the level of its expression. The size of the response to a given aspartate stimulus will always be the same, while that to the maltose stimulus will depend on the level of induction of the PBP. Sugars also can be sensed through the phosphotransferase transport system (see section on Phosphotransferase Sugar Sensing in this Chapter). As this is also an inducible system, it means that *E. coli* responds constitutively to amino acids, but its responses to sugars depend on growth conditions. The biological implications of this for *E. coli* have not been investigated.

Because Tar is able to respond to binding of both a small amino acid, aspartate, and a large protein (the maltose PBP), the mechanisms involved have been extensively investigated. The effector interaction appears to occur at the interface of the two MCP monomers, with steric hindrance preventing the binding of two MBPs at once and only one aspartate-binding site being accessible to solvent at any one time. Although both attractants bind at different sites, there is steric hindrance between the sites, and saturated concentrations of one attractant will inhibit responses to the second; although if both are added simultaneously, the response is partially additive (Gardina et al., 1992).

Transmembrane Signalling

Once the ligand has bound, this binding has to be signalled across the membrane to the cytoplasmic domain of the MCP. The MCPs form stable dimers, resulting in four transmembrane α-helices, two from each monomer (Milligan and Koshland, 1988). Extensive studies have been carried out on the possible mechanisms involved in signalling across the membrane, involving nuclear magnetic resonance (NMR) spectroscopy of isolated periplasmic domains and membrane-bound receptors, large-scale cysteine substitution to crosslink different regions of the α-helices, tryptophan fluorescence, and revertant and second site suppressor studies of signalling mutants to identify the interface of the transmembrane (TM) helices (Chervitz and Falke, 1995; Danielson et al., 1994; Falke and Hazelbauer, 2001; Falke and Koshland, 1987; Lee et al., 1995a; Lee et al., 1995b; Ottemann et al., 1999). The occurrence of crystal structures of the periplasmic domains that signal through to the TM α-helices suggests that there is a small vertical movement of the TM2 helix in the membrane and a slight tilt (Milburn et al., 1991; Scott et al., 1993). Binding of an attractant is therefore thought to signal through to the cytoplasmic domain by the movement of one of the TM2 transmembrane helices with respect to the relatively fixed central axis of the TM1s. However, these changes may be one component of signal transduction, as recent evidence suggests that effector binding may also bring together numbers of receptors in clusters, allowing the cytoplasmic domains to interact.

Cytoplasmic Domain

The change in receptor binding has to change the cytoplasmic domain of the chemoreceptor in such a way that the cytoplasmic signalling sequence as well as eventual adaptation of the receptor is set in train. The cytoplasmic domain of the MCPs is very highly conserved, particularly the central signalling region. Several hundred MCPs from different bacterial species (all eubacterial subgroups and from archaea) have now been sequenced, and all show extensive conservation of the cytoplasmic signalling domain. The diversity of species with this conserved signalling domain suggests that chemotaxis as well as motility has a very early evolutionary origin. The conservation of this domain in transducers (which are not only transmembrane, but may be cytoplasmic, as in *R. sphaeroides* and *H. salinarium*, or may sense oxygen via bound redox

groups) may argue that this domain is the early central component of the signalling pathway, and the sensing domains have been added according to the niche of the species.

The cytoplasmic domain is made up of 10 α-helices (5 from each monomer), which have been divided into domains on the strength of mutational and crosslinking studies (Ames and Parkinson, 1994; Bass and Falke, 1999; Borkovich et al., 1992; Spiro et al., 1997). There is a region called the "methylation domain," which contains the glutamate and glutamine residues methylated by the *S*-adenosylmethionine-dependent methyl transferase, CheR, during receptor adaptation (Kehry and Dahlquist, 1982a; Kehry et al., 1983; Kehry et al., 1985). Between these two regions is the highly conserved signalling domain.

The signalling domain is the site of interaction with CheW and CheA, the proteins involved in initiating cytoplasmic signalling to the motor, and is the region highly conserved across species (Liu and Parkinson, 1989; Morrison and Parkinson, 1997). Genetic studies show that mutations within this domain can result in cells that are either predominantly smooth swimming or predominantly tumbly, suggesting that this region controls the activity of the histidine protein kinase, CheA.

Cytoplasmic Signalling

A small protein, the 18-kDa CheW, links the signalling domain of the MCP to the histidine protein kinase, CheA (Conley et al., 1989; Gegner et al., 1992; Liu and Parkinson, 1989; Sanders et al., 1989b; Schuster et al., 1993). It has no known catalytic activity, but without it, signalling stops. Although it is thought to be a simple scaffolding protein, transmitting the conformational changes in the signalling domain to the kinase, its structure is fairly well conserved between species. The MCP-binding region of CheW has been identified by mutagenesis, but the region binding to CheA is less certain.

CheA is a soluble histidine protein kinase (HPK) homodimer. It belongs to the extensive family of HPKs identified in a wide range of bacterial species. Functioning as a dimer, CheA binds ATP to a conserved domain, which allows the protein to phosphorylate a conserved histidine, His-48, on the other monomer of the dimer, located near the N-terminus of the protein. The region containing His-48, known as P1, also has a structure conserved with other HPKs. Purified P1 has no enzymatic activity, but can be phosphorylated by another kinase, after which it can function alone to transfer phosphate to its substrates, CheY and CheB (Zhou and Dahlquist, 1997b; Zhou et al., 1995). The phosphoramidate bond of phospho-His is very unstable compared to, for example, phospho-Ser, inasmuch as the standard free energy of phosphotransfer from ATP to His is positive (Bilwes et al., 1999; McNally and Matsumura, 1991; Tawa and Stewart, 1994; Zhou et al., 1995). In vitro, phospho-CheA can phosphorylate ADP to ATP. It is assumed that in vivo, the high intracellular concentration of ATP and the rapid transfer of the phosphate to the substrate proteins keeps a high rate of CheA autophosphorylation operating with little back reaction (Bilwes et al., 1999). Between the conserved histidine and the domain involved in ATP binding is a domain, P2, which binds CheY and CheB, the eventual substrates of CheA (Shukla and Matsumura, 1995). The CheY-binding domain is flanked by two flexible regions not found in other HPKs. This domain may move rapidly and independently of the rest of the CheA molecule allowing fast inter-domain phosphotransfer, possibly resulting in an amplified signal.

CheA phosphorylates conserve aspartate residues on two competing response regulators. One is the small 14-kDa protein, CheY, which is the prototypical response regulator, having only the aspartate receiver domain of response regulators and no other domains (Stock et al., 2000). Mutants with *cheY* deleted or mutated are smooth swimming, i.e., they cannot switch the direction of flagella rotation. The CheY protein binds to the P2 domain of CheA, and phosphate is removed from His-48 in a reversible reaction to generate phospho-CheY (Welch et al., 1998). This is released from P2 and diffuses through the cell to the motor, binding to FliM of the flagellar switch and increasing the probability of the motor switching to CW, probably by reducing the energy barrier between CCW and CW rotation (Barak and Eisenbach, 1992a; Ravid et al., 1986).

CheY, being only 14 kDa, has been crystallized and also studied by solution NMR spectroscopy under a range of conditions, including recently in a phosphorylated conformation. The structure of CheY is probably common to the phosphorylation domains of all response regulators. It has 5 α-helices surrounding a 5-stranded parallel β-sheet structure, with the phosphorylation site on aspartate 57. In addition, there is another group of conserved acidic, usually aspartate, residues that are located close to the active site forming an acidic pocket (Bourret et al., 1990; Cho et al., 2000; Sanders et al., 1989a; Stock et al., 1989; Volz and Matsumura, 1991; Zhu et al., 1997a). Phosphorylation depends on Mg^{2+} and involves CheY itself acting as a phosphotransferase. Indeed, Che Y can take phosphate from several metabolic phosphodonors such as carbamoyl phosphate or acetyl phosphate, although whether this has a role under natural conditions

is unknown. The presence of Mg^{2+} probably serves to stabilize the transition state. Dephosphorylation of CheY-P occurs autocatalytically with a half time of under 10 s. This is in contrast to many other response regulators that remain phosphorylated for many tens of minutes, and reflects the need for a fast signal and signal termination in chemotaxis. The majority of HPK and response regulator systems identified are involved in controlling transcription, and therefore rapid signal termination is not required. The natural rate of autodephosphorylation of *E. coli* CheY-P is still not fast enough for signal termination in chemotaxis, and a second protein (CheZ) increases the rate in enteric species. Not well characterized, CheZ has been isolated as a dimer, as well as a high order oligomer in the presence of phospho-CheY, but not of CheY. Also, CheZ appears to compete with FliM for CheY-P, but not for CheY (Blat et al., 1998; Blat and Eisenbach, 1994; Kuo and Koshland, 1987; McEvoy et al., 1999; Stock and Stock, 1987; Zhu et al., 1997b). The oligomer is thought to increase the rate of hydrolysis.

CheZ homologues have not been found in species outside the γ-subgroup. Bacteria from other subgroups do, however, usually have two copies of CheY, one often fused to CheA. It seems possible that signal termination occurs through the activities of these two CheYs, with both CheY homologues being phosphorylated, but only one able to bind the flagellar motor. As CheY-P can phosphotransfer to CheA, the second non-FliM binding CheY-P could operate as a phosphate sink, particulalry if the two CheYs had different phosphotransfer kinetics (Armitage and Schmitt, 1997c; Sourjik and Schmitt, 1998a).

Adaptation

CheA not only transfers phosphate to CheY, it can also phosphorylate another response regulator, CheB. Another unusual response regulator, CheB has a catalytic methyl esterase domain, in addition to the regulatory domain of a standard response regulator (Lupas and Stock, 1989; Stewart and Dahlquist, 1988). The activity of the methyl esterase is controlled by whether the aspartate-containing domain is phosphorylated, and the phosphorylation increasing methyl esterase activity by an order of magnitude. Adaptation is an essential part of chemotaxis. If the receptor were not reset after encountering a change in receptor occupancy, the receptor would continue to generate a signal and the cell would be unable to respond to future changes. In fact, mutants in the adaptation mechanism are either smooth swimming, CheR mutants, or constantly tumbling, CheB mutants. Therefore, although the signalling pathway is intact, without the ability to reset the receptor, a gradient cannot be sensed.

The cytoplasmic domains of most MCPs have two regions which have conserved glutamate residues that serve as substrates for the two enzymes involved in receptor adaptation (CheR, the methyl transferase and CheB, the methyl esterase). In *E. coli*, there are three methylation sites on one domain and one on the C-terminal domain (Kehry and Dahlquist, 1982b). The glutamates may be transcribed as glutamines, but CheB can posttranslationally deamidate the amino acid to form glutamate. It appears that newly translated MCPs have glutamines as well as glutamates to prevent inappropriate signalling. Mutants deleted for CheR cannot methylate the receptors and constantly swim, whereas CheB mutants have overmethylated receptors and tumble constantly. The decrease in attractant bound to a receptor changes the conformation of the cytoplasmic domain of the receptor and increases the autophosphorylation rate of CheA. In addition, CheY and CheB compete for binding to P2, and phospho-CheB becomes an active methyl esterase (West et al., 1995). This can then remove methyls from the conserved glutamates of the relevant MCP. The methyl groups are released generally as methanol (Kehry et al., 1985). The change in methylation probably alters the packing of the methylation helices and reduces the signal through the signalling domain to CheA. The four methylation sites can be methylated independently to alter the helical configuration, allowing adaptation over a range of stimulus strengths. This process of posttranslational reversible carboxymethylation of glutamates appears unique to bacterial chemotaxis (Shapiro et al., 1995; Springer et al., 1982).

The methyl groups are added to the glutamates by a specific methyl transferase, CheR, which has been crystallized and the structure elucidated (Djordjevic and Stock, 1997). There is a specific CheR docking motif on the C-terminal end of some, but not all, MCPs (Barnakov et al., 1998). In *E. coli* and *Salmonella*, the chemoreceptors Tsr, Tar and Tcp have a CheR-binding domain but Trg and Tap do not; nevertheless, they are still methylated in response to attractant binding. However, Trg is not methylated if Tsr or Tar are not present in the membrane, suggesting that the CheR bound to Tsr or Tar can methylate the glutamate residues of Trg, and indicating that they must be physically close in the membrane (Feng et al., 1999).

Localization of MCPs

Early studies of MCPs suggested that they were randomly located around the cell. However, immunogold electron microscopy using antibody

raised to the highly conserved domain of MCPs showed that MCPs are in fact localized at the poles of *C. crescentus*, *E. coli* and *R. sphaeroides* (Alley et al., 1992; Harrison et al., 1999; Maddock and Shapiro, 1993). In addition, they are also found in a cytoplasmic cluster in this latter species. Green fluorescent protein (GFP) fusion of a membrane-spanning MCP (McpG) and a cytoplasmic MCP (TlpC) expressed from genomic constructs has identified specific chemoreceptors at the poles and in the cytoplasm of *R. sphaeroides* (Wadhams et al., 2000). Detailed measurement of the numbers found at the poles of *E. coli* and the fluorescence at the poles and cytoplasm of *R. sphaeroides* suggest that the MCPs are targeted after cell division, as one pole always has significantly larger numbers than the other, but during cell growth, the number appears to increase. If mutants lack either CheW or CheA, the MCPs are found dispersed over the surface of the cells, but deletion of CheR and/or CheB does not affect localization. The cytoplasmic proteins CheA and CheW are therefore essential for localization of MCPs. Figure 4 illustrates the localization of an MCP in *R. spheroides*.

There are several reasons why MCPs might be located at the poles. 1) Bacteria may in fact have a "nose," and clustering receptors may help in gradient measurement. This is very unlikely as almost all bacteria are too small to sense a gradient along their length, and there is no evidence (with the possible exception of gliding mycoplasmas) that they swim with a particular pole forward (Berg and Turner, 1995). Indeed *R. sphaeroides* has a flagellum which is subpolar, causing the cell to swim with the long side of the cell forward, but the MCPs are still at the two poles, and it has been shown that *E. coli* swims with either pole forward. 2) This is simply the default location. Many proteins appear to default to the previous septation site, and the several thousand MCPs, not required for transport or energy producing processes, may localize there. 3) Localization may allow methylation of Trg or Tap by CheR-bound Tsr or Tar (Beel and Hazelbauer, 2001). 4) Changes in the binding of a chemoeffector to the periplasmic domain of an MCP may alter the packing of the MCPs in the membrane, bringing together the cytoplasmic domains in a conformation that allows signalling (Duke and Bray, 1999; Levit et al., 1998; Stock, 1999). Thus, a repellent would alter packing such that CheA would become active, whereas the addition of an attractant would hold CheA in an inhibited conformation. The glutamate residues involved in adaptation would therefore cause signalling because of electrostatic repulsion between cytoplasmic domains. When methylated, the charges would be masked and the conformation become active. On the other hand, when demethylated, the glutamate charges would result in repulsion, conformational change and signalling. Higher order interaction between receptor dimers would be essential for signalling in this model, hence the polar clusters. A model based on signalling through the formation of receptor clustering has been proposed in which the dynamic range of sensitivity seen in bacterial chemosensing depends on controlling the sizes of the receptor clusters (the extent of lateral packing controlling the signal), allowing a bacterial cell to respond to a change of a few molecules over background concentrations of several orders of magnitude (Bray et al., 1998; Shimizu et al., 2000). The evidence that receptor clustering is required for this level of sensitivity is currently limited, but modelling and crystal structures of the cytoplasmic domain indicate that the chemoeffector dimers may pack as trimers of dimers, and it is possible to develop higher order packing models based on these dimer-trimers.

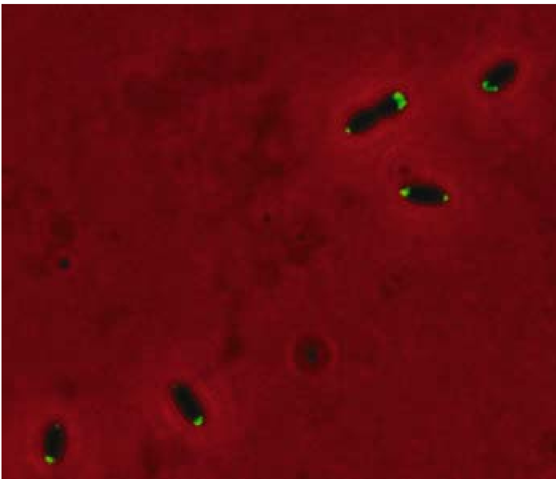

Fig. 4. Localization of a methyl-accepting chemotaxis protein (MCP) in *Rhodobacter sphaeroides*. The gene encoding McpG in *R. sphaeroides* was replaced behind its native promoter by a gene encoding McpG-GFP. The MCP was found to form clusters at the poles of the cells. These clusters depend not on the MCP itself but on the chemosensory proteins CheA and CheW. From Wadhams et al. (2000).

Phosphotransferase Sugars

Escherichia coli not only responds to the binding of sugar-binding proteins to MCPs, but also to sugars transported through the phosphoenolpyruvate-dependent phosphotransferase system (PTS) independently of the MCPs. *Escherichia coli* has at least 15 PTS systems (Nikaido and Saier, 1992). Membrane-bound substrate-specific transport proteins, enzymes II

or EII, accept phosphate from a nonspecific donor enzyme, enzyme I or EI, and phosphorylates the sugar as it is transported. Enzyme EI, a phosphoenol pyruvate (PEP)-dependent histidine kinase and a phosphohistidine carrier protein (HPr) are the phosphorelay to the EIIs. Although metabolism of the sugar is not required for a chemotactic response, the sugar must be transported to cause a signal. Methylation is not required for signalling to occur, but CheA and CheY are necessary. Enzyme EI of the PTS has been shown to interact directly with CheA, suggesting that EI when actively involved in transporting sugars suppresses CheA phosphorylation, resulting in smooth swimming (Lengeler and Jahreis, 1996; Lux et al., 1999; Pecher et al., 1983). Interestingly, fructose is transported via a rather different PTS system, where phosphorylation relies on FPr, a fusion between an HPr-like protein and EI. This protein does not cause a chemotaxis signal, and *E. coli* transporting through this pathway is not chemotactic to fructose. *Rhodobacter sphaeroides* has only an FPr PTS, and its chemotactic response to fructose depends not on PTS transport, but on metabolism of the sugar (Jeziore et al., 1998).

Thermotaxis

Escherichia coli not only responds to changes in chemical concentration, it also responds to changes in temperature (Maeda et al., 1976). Cells swim towards their growth temperature, biasing their swimming pattern from either a lower or higher temperature. Mutants in the serine receptor, Tsr, no longer respond to temperature and neither do cells incubated in saturating levels of serine. Temperature probably alters the conformation of the cytoplasmic signalling domain of Tsr and causes a sensory signal, which is inhibited if the receptor is fully occupied and a conformational change cannot be induced (Imae, 1985). Although Tsr seems to be the major thermosensory receptor, the other receptor proteins, particularly Trg and Tar, have also been shown to respond to temperature changes. Thus, Tsr, Tar and Trg appear to be "warm" sensors, while Tap acts as a "cold" sensor. However, though unmethylated Tar receptor acts as a "warm" receptor, when completely methylated, it will function as a "cold" receptor. Mutations in the adaptation sites or of the adaptation proteins alters the responses. Thermosensing may be caused by the temperature-dependent equilibrium between methylation and demethylation of the receptors, temperature-dependent alterations in this would result in a sensory signal to the motor (Nishiyama et al., 1997; Nishiyama et al., 1999).

Repellent Sensing

Chemotaxis studies on *E. coli* tend to use the removal of an attractant or addition of a repellent as the signal. Addition of a repellent results in a change in receptor methylation similar to the removal of the attractant, but the characteristics of the response have never been as clear cut. *Escherichia coli* shows repellent responses to heavy metals (such as Ni and Co), to changes in pH and amino acids (such as leucine and organic acids). The latter two can be growth substrates, indeed *E. coli* grows very well on acetate. Why *E. coli* should be repelled by good metabolites is not understood, and may indicate a more nonspecific mechanism involved in repellent responses than in the sensing of attractants (Kihara and Macnab, 1981; Repaske and Adler, 1981).

Tsr again appears to be a major receptor for repellents, although the other receptors may be involved, and changes in methylation may affect all receptors. The responses to organic acids and pH may all involve changes to the cytoplasmic signalling domain of the MCPs in a similar manner to temperature stimuli. Recently studies into the involvement of fumarate in receptor-independent control of flagellar switching suggested that several repellents may act by altering the activity of the fumarase enzyme, and any increase in cytoplasmic fumarate might cause motor switching directly, independently of the chemosensory pathway (Barak and Eisenbach, 1992b; Marwan et al., 1990; Montrone et al., 1998; Prasad et al., 1998).

The simultaneous release of "caged" positive and negative chemoeffectors by a flash of ultraviolet light, and the use of time-resolved motion analysis, suggested that while single receptors time-averaged different ligands, when effectors using two different receptors were used, a non-integrated response could result, with the cells initially tumbling and then smooth swimming (Jasuja et al., 1999; Khan et al., 1993). This suggests that the processing time for the signals through different receptors may not be identical and the signals may not be of the same strength ("caged" compounds are chemoeffectors chemically bound to a large molecule which can be released by photolysis to produce a step-up in effector concentration within a very short and measurable time frame).

Osmotaxis was one of the early responses measured by Pfeffer, with bacterial cells being shown to respond to their osmotic environment. The relationship between osmotaxis and chemotaxis is not really understood. *Escherichia coli* is attracted to its optimum concentration of an osmotic agent such as sucrose or ribitol and repelled by higher or lower concentrations.

These responses appear to be independent of the MCP receptors (Adler et al., 1988; Li et al., 1988; Qi and Adler, 1989).

Pattern Formation in Enteric Species

One of the earliest observations of *E. coli* chemotaxis involved the formation of moving rings of bacteria through soft nutrient agar. When the soft agar contained a number of metabolizable attractants, several moving rings of cells were seen, but if a mutant lacking a specific chemoreceptor was used, fewer rings would be present. This led to the realization that populations of bacteria were following gradients of nutrients, the gradients caused by their own metabolism. One ring was the population following, for example serines, while the second ring might be the population following the gradient of maltose. Several years later, much more elaborate patterns were seen in soft agar, with *E. coli* aggregating to form regular, complex but stable patterns on some substrates, particularly succinate. The complex patterns formed from the circular swarm rings described above, with of the formation of focal aggregates within the rings responding to secreted attractants, usually aspartate, to produce highly symmetrical complex geometric patterns (Brenner et al., 1998; Budrene and Berg, 1995; Emerson, 1999).

Chemotaxis in Nonenteric Species

While the majority of research has been carried out on *E. coli* and *S. typhimurium*, there is an increasing body of literature on a wide range of other species. This combined with the increasing number of complete genome sequences suggests that chemotaxis in the majority of other species is much more complex. Other species often have multiple copies of the chemosensory genes, and expression of the different genes may be controlled by the environment in which the cells are grown, that is they can fine-tune their chemosensory response to current growth conditions. In addition, many species have chemoreceptors that are only expressed under certain growth conditions, and some of these receptors are cytoplasmic and probably sense the metabolic state of the cell. Thus, unlike *E. coli* which uses only four constitutive receptors to sample the environment, and has no choice but to respond if there is a gradient of a specific chemoeffector, other species may only respond if they are currently limited for that nutrient. The Department of Energy (DOE) and the Intsitute of Genomic Research (TIGR) bacterial genome databases (http://www. jgi.doe.gov/JGI_home.html) suggest that these complex chemosensing systems may be common in bacterial species living in complex environments with flexible metabolic capabilities.

Alpha-Subgroup of Proteobacteria *Rhodobacter sphaeroides*, *Sinorhizobium meliloti*, *Rhodopseudomonas palustris* and *Caulobacter crescentus* are all members of the α-subgroup of Proteobacteria, and all now have sequenced genomes. This particular subgroup includes a very large number of free-living and symbiotic soil and water microorganisms. Analysis of their chemosensory system illustrates well the common themes that are being identified outside of the much studied γ sub-group. They also illustrate that chemosensing relies on a common central signalling pathway, related to that identified in the *E. coli*, but it has either become more elaborate in the α subgroup, or that of *E. coli* represents a pared-down system.

Rhodobacter sphaeroides has great metabolic flexibility. It is able to grow anaerobically as a photoheterotroph or using anaerobic respiration as an aerobic heterotroph. It also has a quorum-sensing system and may form biofilms (Puskas et al., 1997). It can fix nitrogen and carbon dioxide and can also ferment. *Sinorhinozobium meliloti* is an obligate aerobe, but it can fix nitrogen when maintained anaerobically in a symbiotic relationship with leguminous plants. *Caulobacter crescentus*, on the other hand, appears to have a restrictive metabolic lifestyle, living as a strictly aerobic organism in oligotrophic environments. However, it does go through a differentiation cycle with stalked cells dividing to release motile swarmer cells that cannot grow or divide but swim to new locations to settle down and differentiate into stalked cells and start the cycle again (Brun et al., 1994). The genomes of *S. meliloti*, *C. crescentus*, *Rps. palustris* and *R. sphaeroides*, while not all fully assembled, have provided details of the motility and chemosensory pathways.

A combination of the molecular genetic studies on the different species plus the genome sequencing of these species suggests they may have similar chemosensory pathways, much more complex than those of *E. coli* and *Salmonella*. They appear to have a large numbers of MCPs, between 12 and 28 (G.H. Wadhams and J.P.Armitage, unpublished observation; DOE Joint Genome Institute Sequence Database) (http://www.jgi.doe.gov/JGI_home.html). Deletion of these putative receptor genes does not result in the complete loss of chemosensory responses to a specific attractant, but usually only results in a reduction in a response, sometimes to a group of compounds. Not all of the genes

code for membrane-spanning proteins, but some code for cytoplasmic proteins. These still have the highly conserved signalling domains of MCPs, but no obvious transmembrane regions. These probably sense metabolites inside the cell, not in the extracellular environment. The chemosensory responses of *R. sphaeroides* are not identical under all growth conditions, and this species will respond to some carbon and nitrogen sources only when they are limiting for growth (Poole and Armitage, 1989). A large number of studies have shown that transport and metabolism are required for some responses to compounds as diverse as ammonia, sugars and amino acids, again suggesting a link to growth conditions.

The expression of the chemosensory systems and MCPs in *R. sphaeroides* has been found to be environmentally regulated. Immunogold electron microscopy and Western blot analysis using an antibody against the conserved region of MCPs showed a 17-fold increase in MCP levels under aerobic conditions compared to anaerobic conditions (Harrison et al., 1999). Under aerobic conditions, large clusters of MCPs are seen at both poles of the cell, and there are also clusters within the cytoplasm. But under anaerobic conditions, the polar clusters are greatly reduced in number. This supports the hypothesis that the cytoplasmic receptors may sense metabolic state and only respond if limiting for that particular metabolite. A GFP fusion to one specific *R. sphaeroides* MCP, McpG, shows that this receptor is expressed under both aerobic and anaerobic conditions, as is the cytoplasmic receptor TlpC (Wadhams et al., 2000). However, TlpC is expressed at a much lower level under all conditions, and segregation just before cell division suggests copy number is important for proper chemosensory behavior.

Genetic analysis and gene sequencing has shown that *R. sphaeroides* and *Rps. palustris* have three and *C. crescentus* and *S. meliloti* have two chemosensory operons coding for multiple homologues of the *E. coli* chemosensory genes. Interestingly, in all species, it seems that one operon may be dominant under laboratory conditions, mutations producing measurable phenotypes, and the roles of the other operons is less clear. This may indicate that these dominate under different growth conditions, e.g., in biofilms. All these species, and indeed every species studied outside of the γ-subgroup, lack a CheZ homologue, but instead have two or more CheY homologues, in the case of *R. sphaeroides*, seven *cheY* genes have been identified. Rapid signal termination is an essential component of chemotaxis, and CheZ is thought to increase the rate of CheY-P dephosphorylation in *E. coli*. In vitro studies examining the phosphorylation and dephosphorylation kinetics of the purified CheA and two of the CheY homologues of *S. meliloti* suggest that one of the CheY homologues function as a phosphate sink to terminate the chemosensory signal (Sourjik and Schmitt, 1998a). One CheY may be able to bind the flagellar motor when phosphorylated, and the other not. The motor-binding CheY may rephosphorylate CheA, the second (non-motor binding) CheY then acts as a phosphate sink and causes rapid signal termination (Shah et al., 2000a). However, *H. salinarium* and *B. subtilis* also have two copies of CheY, and experimental data on these species suggest an interaction of CheY-P with the MCP via another chemosensory protein (CheD) not found in the γ group, and this helps in receptor adaptation rather than signal termination (Kirby et al., 1999; Rosario and Ordal, 1996). As *S. meliloti* and *R. sphaeroides* also have copies of *cheD*, the role of the multiple CheYs remains somewhat uncertain. The role of the CheY homologues in *R. sphaeroides* might be even more complex as there are at least seven. Mutagenesis suggests that only two have a major motor-binding function, and the reason for the other five is unknown, although mutation alters the chemosensory phenotype by increasing response duration (Shah et al., 2000b). In vitro dephosphorylation studies of the *R. sphaeroides* CheYs suggests a much faster inherent dephosphorylation rate than *E. coli* CheY, perhaps indicating an alternative role for the multiple homologues in these species.

The role of the different chemosensory protein homologues has yet to be elucidated. Few major mutational studies have been undertaken in *C. crescentus*, while in *R. sphaeroides* deletion of one operon with two *cheY*, one *cheA*, one *cheW* and one *cheR* homologue(s) results in only minor changes under some growth conditions. Deletion of the second operon, which has a third *cheY*, second *cheA*, two more *cheW*, a second *cheR* and a *cheB* gene results in the loss of chemosensory and photosensory responses under all conditions (Romagnoli and Armitage, 1999). All the genes when expressed in *E. coli* interfere with *E. coli* chemotaxis, while not altering growth, suggesting a role in chemotaxis (Hamblin et al., 1997; Shah et al., 2000a). Only CheB and CheR from *R. sphaeroides* fully complement *E. coli* mutants, but the *R. sphaeroides* CheY and CheW proteins restore normal swimming. The role of the products of the third operon remains to be identified.

Two of the operons are expressed differently under different growth conditions, with the highest levels of expression under aerobic conditions, suggesting that the different cytoplasmic sensory-transducing proteins may be connected to different sensory receptors. Interestingly, expres-

sion of the *R. sphaeroides* Che operon 2 is under the control of the Prr (Reg) histidine protein kinase system, which also controls expression of the photosynthetic genes, CO_2 and N_2 fixation genes in response to changes in electron flow through the terminal cytochrome cbb_3 oxidase, indicating a tight interconnection between metabolic capability and chemosensory behavior under these conditions (Dubbs et al., 2000; Eraso and Kaplan, 2000; Oh and Kaplan, 2000). Many more species have now been found to have multiple copies of the chemosensory genes, and hopefully research on other species will identify whether the sensory pathways operate under different growth conditions or are linked to different sensory receptors.

Obviously, to be of any advantage to the survival of a species, bacteria must respond to metabolites that they have evolved to use. Chemosensory receptors have almost certainly evolved in parallel with the metabolic pathways of the species. For example, while amino acids are the dominant attractants for *E. coli*, they are minor attractants for *R. sphaeroides*, which shows the strongest responses to organic acids, their favored carbon source. *Pseudomonas putida* will grow on and has an MCP-like chemoreceptor for naphthalene. The conserved cytoplasmic signalling domain compared with those of *E. coli*, but the major differences in the periplasmic sensing domain is a good illustration of how the conserved chemosensory pathway has been adapted to the lifestyle of specific species (Grimm and Harwood, 1999).

There is evidence that some transport proteins may be able to cause signalling independently of MCP. A good example of this is in *Pseudomonas putida*, which grows on the aromatic acid, 4-hydroxybenzoate and shows chemotaxis towards this compound. The permease for 4-hydroxybenzoate (4HB), PcaK, has been found to be not only a member of the major-facilitator-super family of transporters, but also required for the chemotactic response to 4HB and several other aromatic acids (Harwood et al., 1994). The permease PcaK does not resemble any MCPs, but is a classical transport protein with 12 membrane-spanning helices. Mutations in PcaK result in the loss of taxis to the aromatic acids, even at pHs where the aromatic acids are able to diffuse into the cell and allow normal growth, suggesting a real signalling role for the transport proteins in chemotaxis (Ditty and Harwood, 1999; Parales et al., 2000). This is probably a very different process from the PTS signalling process in *E. coli*. Analysis of sequenced genomes indicates that several more species may have transporters that may also be involved in sensory signalling.

BACILLUS SUBTILIS Few species have had the same attention lavished on them as *E. coli*, and therefore the sensory pathway in other species is much less well understood. *Bacillus subtilis* has, however, been studied in some detail, and also has a complete genome sequence. While *B. subtilis* may not have multiple homologues of many Che genes, as seen in the α-subgroup, it does appear to have copies of all the proteins identified as being involved in chemotaxis across all species, and as such, has been suggested to represent the most complete chemosensory system of species investigated to date. *Bacillus subtilis* responds to a very wide range of amino acids and sugars, and a large and diverse number of repellents have been identified. As with many nonenteric species, *B. subtilis* has all the central components of the *E. coli* signalling pathway, except CheZ. It does not, however, have two free copies of CheY, but rather a fusion between CheW and CheY called "CheV." Whether this fusion is involved in signal termination as suggested for the CheA-CheY fusions is not known, but there are suggestions it may have a role in receptor adaptation rather than signal termination. The number of receptors is small, as in *E. coli*, but the large number of amino acids sensed suggests that the amino acids probably do not interact with the receptors directly, but may use binding proteins. These have not yet been identified. The responses to sugars may involve the PTS transport system and E-I, as in *E. coli*, but in the case of *B. subtilis*, MCPs are also required for a normal response (Garrity et al., 1998). It is possible, however, that the requirement for MCPs in PTS signalling is indirect rather than direct, with the MCPs providing the scaffold for the CheW/CheA proteins. A major difference from the *E. coli* sensing paradigm is that an increase in CheY-P concentration appears to be the response to an increase rather than decrease in attractant. An increase in CheA phosphorylation activity results in smooth swimming in *B. subtilis* rather that tumbling (Rosario et al., 1995; Rosario and Ordal, 1996). Two proteins CheD and CheC seem to be involved in both CheB/CheR-dependent adaptation and signal termination. The MCPs of *B. subtilis* seem fairly similar to those of *E. coli* in that deletion causes the loss of responses to amino acids. However, although the MCPs have the glutamate residues required for methylation during receptor adaptation, the extent of their methylation shows little change after stimulation. What does change is the rate of turnover of methyl groups on all receptors, with methyl groups apparently moving from one MCP to another (Kirby et al., 1999; Zimmer et al., 2000). Also, CheC inhibits CheR-dependent methylation of MCPs with mutations in *cheC* resulting in smooth swimming and increased

methylation. Mutations in the other unusual gene, *cheD*, cause tumbly phenotypes and low levels of MCP methylation. This has led to the hypothesis that CheD binding to MCP is required for CheR to bind and methylate the MCP, and the binding of CheD is negatively controlled by CheC. The addition of an attractant would thus produce high levels of CheY-P, which would allow CheD and CheC to interact, and this would reduce their binding to the MCP and thus reduce CheA activity and the subsequent level of CheY-P.

In *E. coli*, methyl groups released from MCPs following demethylation are released as methanol only after the addition of a repellent or removal of an attractant. In both *B. subtilis* and the archaeon *H. salinarium*, methanol is released when either attractants or repellents are added, rather than when attractant is removed or repellent added. The methanol is not, however, released immediately, as in *E. coli*, but after several cycles of stimulation. There are data suggesting that methanol is not released from the MCPs directly, but from a protein to which the methyl groups are transferred, probably via CheB. The CheB protein does not seem to cause the release of the methyl groups as methanol as in *E. coli*, but to transfer the methyls to a carrier (Kirby et al., 1999).

The pattern of methylation and methanol release is very similar to that seen in the archaea, suggesting an early origin for this mechanism. Interestingly, sequence analysis of chemotaxis operons of *S. meliloti* and *R. sphaeroides* suggests that a *cheD* homologue is present in these Gram-negative eubacteria. Mutations in this gene result in abnormal behavior, with a change in the pattern of methanol release, but its role has not been fully characterized (Rosario and Ordal, 1996; Sourjik et al., 1998b). It may be relevant that patterns and the extent of methanol release in *S. meliloti* and *R. sphaeroides* are not as simple as in either *E. coli* or *B. subtilis*.

MYXOCOCCUS XANTHUS *Myxococcus xanthus* is a Gram-negative, social, gliding bacterium that moves very slowly in two dimensions over the leaf litter, preying on other soil bacteria. Over 100 genes control its gliding behavior, and these have been divided into two subsets, "social" motility and "adventurous," or single-celled, motility. Chemotaxis is involved in aggregation into multicellular spore-forming bodies, but there is disagreement about its role in other aspects of movement. There has been some controversy about whether slow gliding species, moving at 1–5 μm min^{-1}, can show chemotaxis using temporal gradients. However, there are genes in *M. xanthus* that are very similar to those coding for the chemosensory proteins of *E. coli* and mutations within these genes results in altered patterns of gliding, causing either smooth or reversing phenotypes. The *frz* genes code for proteins involved in controlling reversal frequency (Blackhart and Zusman, 1985; Blackhart and Zusman, 1986). An MCP homologue, *frzCD*, has the highly conserved signalling domain, but the putative protein sequence does not contain any transmembrane domains. The FrzA protein is the CheW homologue, and FrzG and FrzF, the CheB and CheR, respectively. The *frzE* gene encodes a CheA-CheY fusion, while *frzZ* encodes a CheY-CheY fusion. A CheA-CheY fusion has been identified in several other species, both Gram positive and Gram negative, and would fit with a model where one CheY was signalling and the other involved in signal termination. In *E. coli*, FrzB and FrzZ have no obvious homologues. What are the roles for these in the complex behavioral life of *M. xanthus*?

Myxococcus xanthus has a complex lifecycle, with all stages dependent on motility and influenced by the *frz* genes. The bacterium forms vegetative "swarms" when nutrients are plentiful, with the moving colonies of bacteria excreting complex mixtures of proteases, nucleases and lipases to digest macronutrients and other bacteria in their surroundings (Hartzell and Youderian, 1995). When nutrients become scarce, the cells form tighter aggregates and these become fruiting bodies with spores. "A" or adventurous motility, allows individual cells to move away from a group, and "S" or social motility requires cell-cell interaction, and the bacteria move as a group. This "S" gliding appears to involve a system closely related to the Type 4 pili-dependent system involved in twitching and discussed earlier (Sager and Kaiser, 1994; Spormann, 1999; Wall and Kaiser, 1999; Yang et al., 1998). Social motility also requires the presence of the extracellular organelles known as "fibrils" (Dworkin,1999). There are data implicating chemotaxis in at least two areas of these complex behaviors, but often in combination with a second independent sensory system which measures cell-cell contact or cell density. The MCP homologue, FrzCD has been found to methylate in response to increased nutrient levels, conditions under which reversals were also reduced (McBride et al., 1992). Also, FrzCD is cytoplasmic and this suggests that gliding cells can sense a change in an intracellular nutrient via FrzCD, and this signals, via FrzA (the CheW equivalent) and FrzE (the CheA-Y fusion), to control reversal frequency. Interestingly, only groups of cells respond; individual cells isolated from a group that showed a response, no longer respond to changes in nutrient level. This suggests that some form of cell-cell signalling is

involved in controlling movement of well-fed cells; the swarm would therefore be sensing not only the nutrient gradient, but also cell density (Shi et al., 1996; Ward et al., 1998b). Isolated single cells can, however, respond to repellents through this pathway and, while single cells do not respond to nutrient gradients (including extracts of *E. coli*), if a single cell comes into physical contact with a colony of *E. coli*, its prey, it enters the colony and stops gliding until the colony has been digested. Again, cell contact must be important in stopping the cell movement. Also, *frz* mutants do not show this stop response, again suggesting a connection between gliding behavior and cell-cell contact. While *M. xanthus* may not be attracted to *E. coli*, *E. coli* is attracted to *M. xanthus*. In limiting conditions, *M. xanthus* excretes what is probably an amino acid and this "lures" bacteria, presumably via their chemosensory systems, to their death (McBride and Zusman, 1996).

The Frz system therefore appears to be involved in both the scavenging behavior of *M. xanthus* swarms, and in development. Experiments in which the movements of tetrazolium-stained single cells were followed during fruiting body formation showed that large rafts of cells formed and reversed very infrequently, and this behavior required S-motility, *frz* genes and a cell-density dependent signal. The cell-density signal, C-signal, is sensed through the Frz chemosensory pathway as a type of "autoattractant." The reversal frequency, and thus the movement of cells within a developing fruiting body would therefore be controlled by the aggregation signal being sensed by the chemosensory pathway. For a general review of motility and development in *M. xanthus*, see Ward and Zusman (2000).

A great deal more remains to be understood about the sensory pathway, about the role of methylation, the uncharacterized proteins, the response regulator fusions and the significance of responses to nutrient gradients in well-fed cells, and the switch to cell aggregation and differentiation during starvation. *Myxococcus xanthus* also illustrates the interconnection of the chemosensory pathway with the other sensory systems in bacteria. It seems probable that this is not the only case in which chemosensing and "quorum" sensing operate together to control bacterial behavior, and it should be remembered that for species in natural environments, the final response of a cell is probably the result of several chemosensory inputs balancing with other sensory pathways.

ARCHAEA The photoresponses of the archaea have been well studied, but the chemosensory responses less so. The majority of research has centered on *H. salinarium*, which has homologues for all the chemosensory proteins found in *E. coli*, except CheZ, and again has some additional proteins. At least 13 *mcp* homologues have been identified encoding classical transmembrane receptors, cytoplasmic receptors, receptors with many transmembrane helices and one apparently linked to a heme-containing protein and thought to be involved in oxygen sensing (Hou et al., 2000). The major attractants are amino acids and the sensory signals are transduced through the chemosensory pathway to the flagellar motor. This is the first species in which a chemoattractant, arginine, has been shown to be sensed not by transmembrane MCPs, but by a cytoplasmic receptor (Storch et al., 1999). An additional sensory molecule, fumarate, has been identified in *H. salinarium*, which may also play a role in other sensory systems (Montrone et al., 1993; Montrone et al., 1996; Montrone et al., 1998).

Fumarate was identified as a signalling molecule that causes switching of flagellar rotation independently of the chemosensory transduction pathway. It is thought to be released from membrane-bound sites during stimulus responses in *H. salinarium*. Investigations using motile sphaeroplasts of *E. coli* suggest it may also have a role in chemosensory transduction in this species. Mutants in the Krebs cycle with altered fumarase activity show altered responses to some stimuli, particularly repellents, leading to the suggestion that repellent signalling may involve fumarate release (Prasad et al., 1998).

Several complete genome sequences are now available for thermophilic archaea. The genome sequences show that while the flagellar genes are all present, no chemosensory genes have been identified in *Methanococcus jannaschii* (Andrade et al., 1997). In all cases studied to date, motile prokaryotes have been found to be able to sense some sort of environmental gradient, the expense of synthesizing and operating flagella would make it difficult to contemplate a bacterium in which swimming is not used to reach an optimum environment (Kostyukova et al., 1992). The mechanisms controlling the behavior of this species is unknown, but it has been suggested that thermosensing may be the most important sensory pathway in these species, maintaining the bacteria at the optimum temperature between the superheated waters of the hydrothermal vents and the cold water of the ocean bottom; a thermosensory signal may directly control the motor. As fumarate has been found to directly control motor activity in bacteria, possibly the archaeal motor is controlled directly by metabolic signals. There is certainly some evidence for chemosensing in some related species and obviously more research

needs to be conducted to identify the transduction pathway in the archaea.

Phototaxis

Most motile bacterial species respond to the electron acceptors required for generation of an electrochemical proton gradient, and many that are capable of photosynthetic growth also respond to light. Light sensing in most other species is linked to photosynthetic electron transfer. Nonphotosynthetic bacteria will, however, respond to a flash of blue light by tumbling, and prolonged exposure can lead to a complete loss of motility. This is almost certainly the result of the photo-oxidation of porphyrins, which then act as repellent, signalling through the classical MCP system.

Some photosynthetic eubacteria, for example, *Ectothiorhodospira halophila*, *Chromatium salexigens* and some strains of *R. sphaeroides*, have been found to contain a 4-hydroxycinnamic-acid-dependent soluble protein, the photoactive yellow protein (PYP), which undergoes a photocycle in blue light, and many of these species do respond to flashes of bright blue light by stopping or reversing (Hellingwerf et al., 1998; Hoff et al., 1999; Sprenger et al., 1993). However, the role of this protein in these responses is uncertain. For example, in *Rhodospirillum centenum*, PYP appears to be involved in transcriptional control, and though the absorption spectrum of PYP fits the response spectrum of *R. sphaeroides*, deletion of the gene does not result in the loss of the blue-light response (Jiang et al., 1999).

Most photosynthetic bacteria respond to light by reversing when swimming over a light/dark boundary. In fact, reversing or stopping seems to be the most common mechanism for direction changing in photosynthetic species; few have been described that tumble like *E. coli*. Observations suggest swimming pattern changes little when photosynthetic bacteria swim over a dark boundary into light (Armitage, 1997a; Pfennig, 1968). They therefore appear to sense and respond primarily to a reduction in light intensity, rather than an increase. However, if *R. sphaeroides* is tethered by its flagellum and given subsaturating increases and decreases in light, the cells respond both to an increase and a decrease (Armitage, 1998; Romagnoli and Armitage, 1999). They respond to a decrease by stopping and then adapting to the change. and to an increase by reducing the stopping frequency and then adapting. The response to the increase is less obvious than to the decrease, because the natural bias (stopping frequency) of the motor is 0.8, which means that it is swimming more than it is stopped (that of *E. coli* is closer to 0.5), making the response when moving up a gradient stronger than that seen in *R. sphaeroides* (Berry and Armitage, 2000). The motor biases of other species has not been measured, but it would be interesting to identify whether a high bias is linked to a specific environment or way of changing direction.

Whether bacteria can respond to a gradient of light is arguable and may depend on their environment and the type of gradient formed in that environment. Free-swimming cells are unlikely to be able to move far enough in a given time to experience the 1% drop in light intensity required to cause a step-down response, and experiments with free-swimming cells support this. However, in environments where intensities fall rapidly, such a microbial mats or dense colonies, the response could be different. Indeed, a bacterium *Rhodospirillum centenum* has been shown to respond as a moving colony to a light gradient, the whole colony moving across an agar plate towards infra-red light and away from white light. If presented with light from two directions, the colony will move along the averaged path (Jiang et al., 1997; Jiang et al., 1998; Ragatz et al., 1995). When cells from a moving colony were resuspended in liquid medium, they did not respond to light gradients, suggesting the response is dependent on the cell density within the colony (Sackett et al., 1997). Oxygen electrode measurements showed a large oxygen gradient within the colony (Romagnoli et al., 1997). It is therefore possible that the colony movement is directed by a combination of negative-oxygen and positive-light sensing.

In all cases of positive responses to light by photosynthetic eubacteria, photosynthetic electron transport has been shown to be essential. Inhibitors of photosynthetic electron transport inhibit photoresponses, as do mutations within the reaction centers which leave pigments intact (Grishanin et al., 1997; Packer et al., 1996). The sensory signal is probably a change in electron transport rate rather than a change in Δp, as low concentrations of uncouplers which cause a step-down in Δp do not alter responses. However, electron transport inhibitors which alter the rate of electron flow but not the size of Δp do cause a response. The sensory-receptor protein signalling the change in electron transfer has not been identified, but mutants deleted for the cbb_3 oxidase-sensing protein, PrrB, involved in controlling both expression of Che operon 2 and aerotaxis in *R. sphaeroides*, still respond to changes in light level, indicating another light-sensing system (J. P. Armitage, unpublished observation). The signal from the unknown sensor is transmitted through the cytoplasmic chemosensory signal transduction pathway in both *R. sphaeroides* and *R. centenum*. Mutants in the *che* genes of *R. centenum* lost the ability to

swarm towards red light (Jiang et al., 1997). In *R. sphaeroides*, the situation is more complex as there are two chemosensory operons. Deletion of operon 1 has no effect on photoresponses, but deletion of operon 2 leads to the loss of photoresponses. The response requires both $CheA_2$ and $CheW_2$. As the only known role of CheW is to link MCPs to CheA, this indicates the involvement of an MCP-like protein in signalling (Romagnoli and Armitage, 1999). This is supported by the measurement of methanol release after the reduction in light intensity, indicating adaptation requires changes in receptor methylation, just as in *E. coli* chemotaxis. Photosensing in eubacteria therefore probably involves a redox sensor linked to an MCP-like receptor signalling through $CheW_2$ to $CheA_2$ and thus to the flagellar motor, with adaptation requiring methylation of the receptor to reset the structure.

The mechanisms involved in responding to light by the archaeon *H. salinarium* is probably the best understood system. It combines the mechanisms used for proton translocation by bacteriorhodopsin (BR) with the conserved signalling domain of an MCP. *Halobacterium salinarium* grows in saturating salt concentrations and when the oxygen levels are low, it induces BR, a retinal-based light-driven proton pump. In addition to BR, it has three other retinal based light-absorbing pigments: one halorhodopsin (HR) uses light to drive a chloride pump, but the other two are sensory rhodopsins (Hoff et al., 1997; Spudich, 1998). A constitutive retinal-containing sensory protein, SRII, absorbs blue light and undergoes a fast photocycle that generates a signal to control the flagella bundle, and increasing blue light causes the cells to reverse and keeps the cells out of damaging blue light. Under anaerobic conditions when BR is induced, an additional sensory rhodopsin (SRI) is also induced. SRI acts to produce both a positive signal to orange light and a negative repellent signal to blue light. The photopigment undergoes a fast transformation to a blue-absorbing form in orange light. If blue light is present. there is a fast transformation back to the orange-absorbing form, but if blue light is not present the transformation is slow. Therefore in orange light, which is useful for BR activity, the SRI is in the blue form and sends a positive signal, but when blue light is present the orange form predominates and this sends a negative signal. Each SR protein has an accompanying sensory protein, HtrI and HtrII (Bogomolni et al., 1994; Krah et al., 1994; Spudich, 1994). These proteins have cytoplasmic domains homologous to those of the highly conserved domains of MCPs. If the Htrs are deleted from *H. halobium*, the SR proteins are able to pump protons (Sasaki and Spudich, 1999). Absorption of the appropriate wavelength of light probably leads to a conformational change in the retinal and a charge change. The latter is transmitted to the Htr proteins through the transmembrane helices and alters the conformation of the signalling domain, and in turn the activity of CheA and CheY.

Aerotaxis and Electron Acceptor Taxis

As would be expected, the responses to oxygen vary from species to species, and these are some of the earliest responses seen in bacteria (Armitage, 1997b; Engelmann, 1881). Obligate aerobes will swim towards oxygen, while obligate anaerobes are repelled. Microaerophiles respond positively to low concentrations, but are repelled by atmospheric levels. In some cases, the responses are different under different growth conditions. *Rhodobacter sphaeroides* is attracted to oxygen when growing as a heterotroph, but repelled when growing as a photoheterotroph. *Escherichia coli* responds to oxygen concentrations that correspond to the Km values of the cytochrome oxidases. and as with the photoresponses, inhibition of electron transport caused a loss of response (Laszlo et al., 1984; Laszlo and Taylor, 1981). This suggests that again there may be a redox sensor responding to changes in the rate of respiratory electron flow. This type of behavior has been called "energy taxis" (Stock, 1997; Zhulin et al., 1997).

A redox sensor has been identified in *E. coli*. A flavin adenine dinucleotide (FAD)-binding protein, Aer has a cytoplasmic domain homologous to the highly conserved domain of an MCP (Bibikov et al., 1997; Bibikov et al., 2000; Rebbapragada et al., 1997). It is thought to sense the change in the rate of electron flow through the quinone region of the respiratory electron transport chain, rather than oxygen itself, and the change in redox state of the FAD is thought to signal to the conserved signalling domain through a redox sensing PAS domain, which has been identified in a wide range of sensory proteins, including those of higher eukaryotes (Repik et al., 2000). This change is then transmitted to CheA and CheY and thus to the motor. Mutants in Aer do not accumulate around air bubbles, but overexpression of Aer results in an increased sensitivity to oxygen. Mutants in Aer, however, still show some response to changes in oxygen level and there is some evidence that the MCP, Tsr, may be able to sense changes in Δp (electrochemical proton gradient) directly, but again the mechanism is not understood. It has been suggested that a balancing between signals from electron transport and responses to changes in Δp could account for both positive

responses to optimum oxygen concentrations and the repellent responses shown to potentially toxic high concentrations. Whether this would have a role under physiological conditions is not known.

There seem to have been several independent mechanisms evolved for sensing oxygen levels. Two of the 13 MCPs identified in *H. salinarium* appear to be oxygen sensors, but in this case it uses a cytochrome oxidase attached to the highly conserved domain of an MCP or myoglobin-like receptors (Hou et al., 2000; Zhang et al., 1996). This suggests that *H. salinarium* can sense molecular oxygen directly. *Desulfovibrio vulgaris*, a strict anaerobe, on the other hand, has a sensory protein, DcrA, with a *c*-type heme attached to a domain with homology to the highly conserved cytoplasmic signalling domain of an MCP (Dolla et al., 1992; Fu et al., 1994). The ecology of a strict anaerobe is obviously different from the facultative bacteria in which aerotaxis has been studied. Thus, DcrA could sense either oxygen or redox potential, as the heme irons of *D. vulgaris* have been shown to be directly oxidized by oxygen. Under anaerobic conditions, DcrA would be reduced and oxygen would lead to either the direct oxidation of bound heme or allow heme to bind to the signalling domain; this would alter the conformation and signalling through the highly conserved domain. Unlike Aer, which does not apparently have glutamate residues that could be methylated to allow adaptation, DcrA has been shown to be methylated in response to changing oxygen concentrations.

All the different sensory modules identified to sense changes in oxygen levels are linked to the highly conserved signalling domain of MCPs, suggesting that the highly conserved signalling domain was an early component in the evolution of chemosensing, and different sensory domains have been grafted on by different species to serve their specific niche.

Electron transfer is involved in both light and oxygen sensing, and in many species, electron transfer components are shared between the different pathways, which could result in competition between the sensory signals. This appears to be the case. Most bacteria that grow using respiratory electron transfer can also use other electron acceptors when oxygen is absent (anaerobic respiration), inducing expression of specific acceptors if an electron acceptor is in the environment. Thus *E. coli* will grow on nitrate in the absence of oxygen, and under these conditions, will show tactic responses to nitrate. *Rhodobacter sphaeroides* will grow on dimethyl sulfoxide (DMSO) in the absence of oxygen and again shows taxis towards DMSO (Gauden and Armitage, 1995). In both cases, if the responding cells are now exposed to oxygen, the response to nitrate or DMSO is reduced or lost and the cells now respond to oxygen. Electron transfer under these conditions is diverted from the alternative acceptor to oxygen. In *R. sphaeroides*, light inhibits or reduces responses to either DMSO or oxygen and oxygen reduces the size of the photoresponse in photosynthetically growing cells. Under all of these conditions, electron transfer components are shared and photosynthetic electron transfer has been shown to be faster than respiratory electron transfer, whereas electron flow to a terminal cytochrome oxidase will be dominant over flow to DMSO reductase (Grishanin et al., 1997). All of these data suggest that these bacterial species are not responding to light or oxygen or nitrate under these conditions, but responding to the change in electron flow through a common receptor which then signals through the chemosensory pathway. As suggested with Aer and Tsr for oxygen sensing, there may, however, be more than one receptor. In *R. sphaeroides*, deletion of $CheA_2$ results in a reduction in responses to oxygen. In addition, deletion of PrrB, the redox sensor of electron flow through the terminal cytochrome cbb_3 oxidase results in a loss of aerotaxis (J. P. Armitage, unpublished observation). This suggests that the histidine protein kinase, PrrB, not only controls the activity of the transcriptional activator, PrrA, but can directly control the chemosensory pathway, perhaps interacting with $CheA_2$ by a mechanism related to EI-CheA interactions in PTS chemotaxis. Little research has yet been carried out into competition between electron transport-dependent signals and the chemosensory signals.

The Role of Taxis in Natural Environments

Only *E. coli* and *Salmonella* have had their chemosensory pathways analyzed in any great detail, but the role of taxis in their natural environment has not been examined. Indeed there have been very few detailed studies on the effect of chemotaxis in natural gradients. There have been some attempts to model behavior, but few of these have used experimental data. Several models have been produced that develop patterns similar to those produced by bacteria in gradients, but because few are linked to experimental measurement, it is hard to estimate their true significance.

There have been a number of individual studies of the possible role of motility and chemotaxis to the natural history of a wide range of species, from environmentally important species to pathogens. The depth of investigation varies enormously, but it suggests that chemotaxis plays an essential part in the survival of a very wide range of species and in allowing surfaces to be

reached for colonization, making chemotaxis an important virulence factor for some pathogens and important in symbiotic interactions. It may also be important for the initial colonization of surfaces for biofilm formation. Some species thought to be nonmotile when originally isolated are now suggested to be motile in some environments. Many bacterial species lose motility when cultured, particularly in rich conditions. *Shigella* was considered a nonmotile species, until examined directly from the gut flora, where it appeared to be actively motile. It is therefore dangerous to define a species as nonmotile unless the species is cultured under a number of conditions and preferably examined directly in its natural environment. This emphasizes the problems of defining motility when growing bacteria only in rich media, which may repress flagellar synthesis. For example, when examined in situ, the majority of marine bacteria are actively motile, but motility is rapidly lost on cultivation. The only way to be sure a bacterium is nonmotile under all conditions is by gene sequencing.

Very little work has been undertaken to examine the role of taxis in situ. One of the situations where behavioral responses almost certainly play an important role in the natural ecology of bacteria is in magnetotaxis.

Magnetotaxis

A large number of bacterial species appear to be magnetotactic, although few have been isolated in pure culture. There are coccoid, spiral and rod-shaped species, but what they all have in common is intracellular membrane-bound magnetosomes, flagellate motility and negative aerotaxis. Magnetotactic species are usually found in estuarine or salt marsh mud, where they grow microaerophilically. The turbulent environment can result in the bacteria being displaced by tidal movement into the aerobic upper layers of the water. The chains of magnetosomes contain single domain magnetite, which orient the cells along the local magnetic field lines (Blakemore, 1982; Blakemore and Frankel, 1981; Mann et al., 1984; Stolz et al., 1986). This orientation combined with a strong negative aerotactic response results in a two- rather than three-dimensional swimming pattern, moving the cells back into the microaerophilic mud (Frankel et al., 1997).

Viscotaxis

There has been some limited research suggesting viscotaxis may help in the invasion of some spiral-shaped pathogens (Kaiser and Doetsch, 1975). The spirochetes all have a flexible spiral cell body. The helix of the spiral changes wavelength when moving into increasingly viscous environments, such as mucous membranes (Berg and Turner, 1979). The shorter wavelength causes increased swimming speed when moving into a viscous environment, and decreased speed when moving out. This would in effect help the bacterium to invade (Greenberg and Canale-Parola, 1977). The same physical enhancement of tactic ability has been suggested for the wall-less spiroplasmas when invading plant tissues (Daniels and Longland, 1984).

Biofilms

In natural environments, many bacteria are not found free living, as in the laboratory, but as biofilms, which may involve single or multiple species. Biofilms can be very stable and the bacteria within them are often metabolically very different from the same species growing individually in suspension (planktonic; Costerton et al., 1994; Costerton, 1995; Nickel et al., 1994). Biofilm formation by *Ps. aeruginosa* requires type IV pili possibly for attachment. Type IV pili are also the organelles required for twitching motility, but the role of twitching in biofilm formation has not been identified (Davies et al., 1998; O'Toole and Kolter, 1998; Wall and Kaiser, 1999). Biofilms cost oil and shipping industries large amounts of money, and the formation of biofilms on medical implants is a major problem for the medical profession. Biofilms on plant roots, on the other hand, are thought to protect plants from infection by pathogens and may be involved in nonsymbiotic nitrogen fixation (Davies et al., 1998; Kolter and Losick, 1998; Shapiro et al., 1993). It is likely that the interplay of at least two environmental responses is essential for biofilm formation, motility and quorum sensing, leading to the eventual process of extracellular matrix synthesis (O'Toole et al., 2000). Biofilm formation is a strategy not only for keeping a bacterial species in a particular location, but also for reducing overcrowding, nutrient limitation and toxin production by packing them at low density in a protective polysaccharide matrix. Secreted homoserine lactones, the bacterial cells' mechanism for sensing population density, is necessary for biofilm formation, but several studies have shown that motility is also essential for the very early stages of biofilm formation and perhaps for movement within the biofilm, which can project many tens of μm from the surface (Pratt and Kolter, 1999; Watnick and Kolter, 1999). Although the requirement for chemotaxis has not been shown conclusively, it may be required to direct the bacteria to surfaces on which they then form a biofilm. The local

charge and nutrient concentration tends to be higher at surfaces than in surrounding environments, and if it is a plant or animal tissue surface, there are probably local gradients of excreted compounds. Biofilms also slough off individual cells, and it is probable that this leads to population and biofilm spreading. This requires motility. *Rhodobacter sphaeroides* produces an *N*-acyl-homoserine lactone (HSL), but a mutant unable to produce it, forms large amounts of extracellular matrix and large flocculant colonies (Puskas et al., 1997). The addition of the *N*-acyl-HSL to a flocculant colony results in breakdown of the polysaccharide and an increase in swimming speed of the released cells. In this case, the interplay of motility, nutrient levels and quorum sensing may determine whether the cells are free swimming, planktonic, or form a protective biofilm-like matrix.

Symbiosis

There have been a number of studies on the role of chemotaxis in the colonization of legume roots, because of the economic and ecological importance of nitrogen fixation by both free-living and symbiotic species. Again there is no unequivocal data that a particular rhizobial species is attracted to its specific plant root hair as a result of any species-specific exudates, but rhizobia are highly motile and chemotactic and are attracted by root exudates (Ames and Bergman, 1981; Caetano-Anolles et al., 1988; Kurdish et al., 2001). Bacteria would therefore be attracted up the exudate gradient towards the root hairs, but the response may not be specific for the host. It seems probable that, as with most colonizations, the attachment to roots is a complex process with motility and chemotaxis taking bacteria to the surface, followed by adhesion and colonization, processes which combine quorum sensing and complex intracellular signaling pathways. Plants secrete *nod*-inducing flavonoids into the rhizosphere and these can be degraded by rhizobial species. It has been suggested that the degradative products of flavonoids in the rhizosphere could act as chemoattractants. While many rhizobial species have been shown to exhibit chemotaxis towards root exudates in general, the most most convincing evidence that chemotaxis is involved in colonization comes from studies on the free-living nitrogen-fixing bacterium, *Azospirillum brasilense* (Zhulin and Armitage, 1992). In in vivo studies, a number of mutants have been identified in this species that are nonmotile or nonchemotactic and are unable to colonize wheat roots (Vande et al., 1998). Polysaccharide production was found not to be important in primary colonization, but in later stages. Some studies have implicated flagella in the initial process of adhesion. Interestingly, the recent genome sequence of *Sinorhizobium meliloti* shows that this species has two complete sets of chemosensory genes, one organized on an operon located in the *sym* plasmid, which also encodes the genes essential for symbiotic development.

Bacillus megaterium is a root-colonizing bacterium, which has been shown to protect roots against fungal attack. This species shows a highly sensitive chemotactic response to soybean root exudates, particularly amino acids, over a wide range of temperatures and pHs (Zheng and Sinclair, 1996). This has led to the suggestion that chemotaxis leads to the successful colonization by the bacterium of plant roots, which serves to protect the roots from potential fungal pathogens.

Plant Pathogens

The role of motility and chemotaxis in plant wound infection is unclear. There are reports that wound secretions act as attractants for the pathogen *Agrobacterium tumefaciens*, causing behavioral responses at lower concentrations than required to induce the expression of pathogenic genes, suggesting that the bacterium can sense a wounded plant, swim towards it and then cause disease (Ashby et al., 1988; Hawes and Smith, 1989; Parke et al., 1987; Shaw et al., 1988). Wounded plants secrete specific inducers of virulence genes, acetosyringones, and sugars. A periplasmic protein, ChvE, is involved in both chemotaxis towards monosaccharides and virulence gene induction. *Erwinia*, *Pseudomonas* and *Xanthomonas* species are all motile, but whether that motility has a direct role in their pathogenicity has not been investigated. Mixed inocula of motile and nonmotile transposon mutants of *Pseudomonas fluorescens* did show that only the motile wild type could effectively colonize the rhizosphere around spinach roots, although when directly inoculated, there was no significant difference in the ability to colonize the roots (Dekkers et al., 1998). This finding suggests that motility may be an essential trait in reaching the roots for colonization, but plays no part in the actual process of invasion.

Animal Pathogens

A great deal more research has been carried out on the role of motility and taxis in pathogenic interaction by animal pathogens. As many virulence factors, quorum sensing, specific pilin development and toxin secretion pathways are similar in plants and animals, it seems likely that motility will have a role in moving plant as well as animal pathogens to their site of adhesion

and/or invasion. In animal pathogens, flagellar synthesis and virulence factors are often coregulated. Nonmotile or nonchemotactic mutants usually remain pathogenic if inoculated directly onto an invasion site, but if incubated with the host rather than inoculated onto the site of potential infection, infection is lost (e.g., a nonchemotactic *Vibrio anguillarum* will not infect trout when added to its water, although pathogenicity has not been lost; O'Toole et al., 1996). A mutation in the methyl transferase gene, *cheR*, resulted in a smooth-swimming phenotype, and although the mutants remained fully pathogenic when added to the fish directly, these could not cause infections when added to the fish tanks. This and a related fish pathogen, *V. alginolyticus*, have been shown to exhibit strong chemotactic responses to mucus from sea bream (Bordas et al., 1998). Mucus was isolated from different parts of the fish, and the pathogens were found to respond to and adhere to mucus from the skin and gills (the usual sites of infection) but showed little response to mucus from the intestine.

There have been many studies on the role of motility in human infection. *Vibrio cholera* is highly motile, and there is research suggesting that motility and expression of virulence factors are intimately linked: the correct environmental signals for pathogenicity switching off motility and switching on virulence genes. However, the initial role of motility in invasion has not been fully characterized (Klose et al., 1998; Postnova et al., 1996). Interestingly, flagellar mutants were not only inefficient at colonizing mouse intestine, they also had an altered colony morphology and biofilm structure, emphasizing the interconnection between this range of physiological phenomena, geared to optimizing survival under different growth conditions (Watnick et al., 2001). More detailed studies have been carried out on wound infection, urinary tract infections and intestinal mucus invasion. Research has concentrated on infections by *Campylobacter jejuni* and *Helicobacter pylori*, given their involvement in serious outbreaks of gasteroenteritis and in stomach ulcers and gastric cancer, respectively. Early studies of *C. jejuni* showed, surprisingly, that in vivo, this organism did not appear attached to the gut lining, but freely swimming in mucus filled pits of the large intestine (Grant et al., 1993; Lee et al., 1988; Nachamkin et al., 1993). *Campylobacter jejuni* is highly motile in viscous media that inhibit most flagellate species, suggesting that motility has evolved to enable this organism to operate efficiently in its niche in the intestine. There is some evidence that chemotaxis is essential for colonization, as nonchemotactic but motile mutants showed a limited ability to colonize intestines in animal models, whereas nonmotile mutants were unable to colonize birds or rabbits (Szymanski et al., 1995; Wassenaar et al., 1993; Yao et al., 1997). Also, CheY mutants failed to colonize mice. Similarily, flagellar mutants of *H. pylori* were less able to colonize gnotobiotic piglets. *Helicobacter pylori* has been found to respond chemotactically to urea and bicarbonate and negatively to oxygen (Eaton et al., 1992). The gastric epithelial cells secrete urea and bicarbonate, and hydrolysis of urea by urease is essential for colonization of the gastric mucosa (Foynes et al., 2000; Nakamura et al., 1998; Yoshiyama et al., 1998). The positive responses to these compounds strongly suggests that chemotaxis plays an essential role in colonization of the stomach by *H. pylori* and helps to maintain it in that niche.

Proteus mirabilis is a major cause of urinary tract infections. It is one of an increasing number of bacterial species that (when in liuide medium) have been found to swim using a small number of flagella; however, when growing on surfaces, the increased viscosity apparently induces increased flagella synthesis and the cells become hyperflagellate, and often elongated, allowing them to move as large rafts of cells over surfaces. In the case of *P. mirabilis*, it has been suggested that the hyperflagellate, swarming cells may be better able to colonize the urethra, bladder and kidneys (Allison et al., 1992; Mobley and Belas, 1995). Indeed, swarmer cells have been shown to increase expression of a large number of identified virulence factors, and mutations that cause the loss of motility and swarming also inhibit expression of virulence factors. In animal models, only swarmer cells were isolated from infected kidneys, even though the initial inoculum had only contained free-swimming non-swarmer cells, suggesting that swarmer differentiation does occur in vivo (Liaw et al., 2000; Mobley et al., 1996). Experiments designed to investigate the role of flagella in infection have however been equivocal, with one study showing a reduction in infection by nonmotile cells and the other showing no effect (Legnani-Fajardo et al., 1996). These results suggest that the link between motility and virulence may be very complex, and more sophisticated studies may be needed before we can be sure whether *P. mirabilis* swarms up the human urethra to reach sites of infection. *Clostridium septicum* is another pathogenic species with small free-swimming cells that differentiate into swarmers on surfaces. Adhesion to and invasion of cultured human epithelial cells was greatest if the short motile form was used rather than swarmers, suggesting that differentiation may play different roles in different species (Wilson and Macfarlane, 1996). A connection between swarming motility and quorum sensing has been identified in the occasional

human pathogen, *Serratia liquifaciens*, where the development of swarmers has been shown to require genes controlling not only flagella synthesis, but also the synthesis of the quorum sensing molecule, homoserine lactone. Again, this finding indicates that motility is just one of several environmental sensing systems determining the development and behavior of the cell (Eberl et al., 1996; Givskov et al., 1998; O'Rear et al., 1992).

It may be interesting that the so called "Type III secretion system," used by a range of important pathogens such as *Yersinia*, *Shigella*, *Salmonella* and *Bordetella* to secrete toxins, is very similar to the flagellar motor in structure (see earlier). This system is required for the direct release of toxic proteins without a classical signal sequence. For example, the Yops from *Yersinia* "inject" toxins directly into the eukaryotic cytoplasm after cell-cell contact, and there are suggestions of a common evolutionary origin for the export apparatus for flagellar proteins and Type III toxins. The majority of Type III-secreting pathogens are also motile. In several of these, including *Bordetella*, a link between motility and pathogenicity has been suggested (Akerley et al., 1995). The cells are flagellate and motile when not in a suitable colonization site, and one of the effects of the expression of virulence factors in response to extracellular signals is to switch off flagella synthesis. Mutants unable to switch off flagella synthesis showed a reduced ability to infect, even when the mutation was combined with one allowing expression of virulence factors. The antigenic ability of flagellin may be one reason, but it seems likely that in the case of this species, control of motility and colonization is essentially negatively connected. In these species, it has been suggested that the motile phase may be important for transmission rather than colonization.

Chemotaxis also may play a part in the survival of pathogens. *Escherichia coli* is repelled by concentrations of hydrogen peroxide, hypochlorite and *N*-chlorotaurine lower than the toxic concentrations (Benov and Fridovich, 1996). As these compounds are part of the "respiratory burst" produced by phagocytes in response to bacterial invasion, the ability of bacteria to use chemotaxis to evade the leukocytes could help in survival.

Aquatic Environments

In general, studies of the behavior of bacteria in aquatic environments have centered on the behavior of photosynthetic species in microbial mats and in stratified lakes. Often these species have gas vacuoles, which move bacteria over large distances. In mats, swimming motility may be important in local movements during the natural day-night cycle. Several species have been identified with both gas vacuoles and flagella (for example, *H. salinarium*), but few studies have been undertaken into the relative roles of the two systems under natural conditions. Indeed, the gas vacuoles proved a nuisance during phototactic studies in *H. salinarium*, therefore all the phototactic research is conducted in gas-vacuole-minus mutants.

There is some evidence that gliding motility is important in maintaining the vertical distribution of both the sulfur bacterium *Thioploca*, and cyanobacteria within sediments, and recent studies on the behavior of a mixed population of sulfate-reducing bacteria within a cyanobacterial mat showed extensive diurnal migration by the bacteria (Huettel et al., 1996). It has been suggested that diurnal oxygen stress and the balancing of chemotaxis towards oxygen, carbon and sulfate may maintain the different species, (whether facultative, microaerophilic or anaerobic) in their optimum environment. In experiments where microcores of natural microbial mats were replaced with small glass beads, highly motile species were found to concentrate and position themselves within a very distinct band within three days of regrowth. The sensory signal for maintaining the bacteria within the band was not identified, inasmuch as classical chemoattractants had no effect on positioning of the band; however, since the species were not identified, the dominant effectors may not have been identified, and oxygen could have played a major role.

Measurement of bacteriochlorophyll fluorescence of photosynthetic bacteria in a stratified lake in situ showed that they moved several centimeters during the day (Joss et al., 1994). The movement might be the result of a combination of photoresponses and responses to the changing sulfide and oxygen concentrations. In the day, the photosynthetic bacteria need to be in high light and sulfide, but low oxygen and balancing the signals may be the cause of the cyclic movement.

Clouds of highly motile bacteria are found close to surfaces in marine environments. These unclassified bacteria show strong aerotactic and chemotactic behavior, which may maintain them close to surfaces where nutrient levels are higher than in the open waters (Mitchell et al., 1995). Marine algae also have been found to secrete high levels of demethylsulfoniopropionate (DMSP), and there is evidence that marine bacteria may be chemotactic to DMSP, using it as a metabolite, and responsible for its turnover in natural environments. *Alcaligenes* M3A was found to be attracted to 10^{-6} M DMSP, which is similar the concentration measured close to phytoplankton (Steinbüchel and Schubert,

1989). Dimethylsulfide (DMS) gas is the major source of biogenic sulfur emissions from the oceans and is involved in climate regulation. This is therefore a situation where chemotaxis could be directly involved in the rate of DMS production and sulfur cycling between seawater and atmosphere.

Several marine isolates move differently when free living rather than on surface. Free-living *Vibrio alginolyticus* swims using a single sodium-driven flagellum, but on surfaces, the increased viscosity is sensed through the flagellar motor and induces the synthesis of large numbers of proton-driven lateral flagella, which allow the cells to move over surfaces (Liu et al., 1990). This type of transformation, from single or few flagella on free-swimming cells to large numbers of lateral filaments when the cells are on surfaces is now being found in all sorts of species of Gram-positive bacilli, suggesting that this is a common solution to the problem of small bacteria moving over surfaces. They tend to move as large rafts, and this multicellular movement probably helps to overcome the excessive viscous drag and tension of the surface.

An interesting behavioral response is shown by stable consortia of bacteria. Several phototrophic consortia have been identified in eutrophic fresh water, "*Chlorochromatium aggregatum*" and "*Pelochromatium roseum*" being two whose behavior have been investigated (Frostl and Overmann, 1998; Overmann et al., 1998). They are both consortia formed between a large central, motile but pigmentless bacterium and pigmented nonmotile cells that surround it (some have been described with several layers of cells around the motile central cell). These consortia are not rare and can make up as much as two-thirds of the biomass of the chemocline of a lake and may therefore be important in the general physiology of these ecosystems. Analysis of the vertical distribution of specific consortia shows that they are found at specific regions with maximum light intensity but very low oxygen levels. The behavioral response must balance the signals from oxygen, light, sulfide and iron to keep the consortia in these regions. The diurnal distribution also was found to change, with the consortia moving upwards at night. When the behavior of these bacteria were analyzed in the laboratory, it was found that although the motile member of the group was not photosynthetic, the consortia responded to changes in light intensity and accumulated in wavelengths that corresponded to bacteriochlorophyll *c* and *d*, the pigments found in the nonmotile members of the group. The nonmotile species therefore must signal the motile bacterium when the light intensity changes. The mechanism is unknown, but many motile species respond to changes in pH, and the change in extracellular pH that may accompany changes in photosynthetic activity could serve as a signal. In some cases, consortia only remain together when incubated photosynthetically and disperse in the dark. Given the predominance of these consortia in some freshwater lakes, it seems likely that this association and the phototactic and chemotactic behavior that goes with their formation is important for the colonization of these lakes.

Conclusion

It seems likely from the sequencing of bacterial genomes, that the majority of bacterial species move, either swimming or gliding to their optimum environment for growth. What has become apparent is that the motility and chemosensory pathways of the majority of bacterial species are built from the same basic skeleton as found in *E. coli*. However, different species have expanded and added to the basic system to tune it to their requirements. Therefore, different species not only sense different stimuli, but also the number of sensory signals varies greatly. Many species also seem to have several different chemosensory pathways, expressed under different conditions. The reason for this is unclear and may reflect the kinetic requirements of responses to different signals. What is really apparent, however, is that motility and chemotaxis do not stand alone as physiological traits, but are just part of a large, interconnected sensory network that makes a particular species robust for life in a current specific niche.

CHAPTER 1.6

Prokaryotic Life Cycles

MARTIN DWORKIN

Introduction

Modern prokaryotic biology has focused much of its attention on understanding the nature and regulation of bacterial growth. This reflects Francois Jacob's memorable rhetorical question, "A bacterium, an amoeba . . . what destiny can they dream of other than forming two bacteria, two amoebae . . .?" (Jacob, 1973). It has been an unstated assumption that the primary approach to fulfilling this destiny is to optimize growth, exemplified by the remarkable efficiency and adaptability of the growth of enteric bacteria, pseudomonads, and other prokaryotes. However, the ability of many bacteria to go through a life cycle is another way (more common than is recognized) that prokaryotes increase the likelihood that one bacterium will eventually become two. It is the goal of this chapter to describe some typical life cycles found among the bacteria.

Prokaryotic life cycles can be divided into three general groups: 1) there are simple life cycles, during which the cells alternate between two states, each of which is optimal for a different set of environmental conditions; for example, cells may alternate between growing and resting, between the motile and sessile state, or between infectious and reproductive stages. 2) There are complex cycles where more than two developmental stages are involved; an example is the cycle found in the myxobacteria where cells may not only alternate between vegetative and resting stages, but also undergo a colonial morphogenesis and form multicellular fruiting bodies. 3) Finally, there are life cycles leading to the formation of truly differentiated populations; for example, a culture of the cyanobacterium *Anabaena* may simultaneously contain vegetative cells, nitrogen-fixing heterocysts, and resistant akinetes.

This chapter will describe representatives of each of these groups, but for a more detailed description of those prokaryotes that have been used as experimental model systems for studies in development, the reader is directed to the recent excellent monograph on prokaryotic development edited by Brun and Shimkets (2000a).

Simple Life Cycles: Alternation Between Two States

Some bacteria have a relatively constant habitat (i.e., they are not subjected to constantly changing environmental conditions). For example, an organism that is an extracellular or intracellular parasite of a higher organism is likely to be the fortunate inhabitant of an environment that is relatively constant with regard to such physiological parameters as temperature, pH, ion concentration, and rate of supply of nutrients. Other bacteria, however, are likely to be subject to environmental conditions that frequently change. The physiological makeup of an organism that must alternate, on the one hand, between inhabiting the gut of a warm-blooded animal while attached to an epithelial cell, and on the other hand, floating suspended in a body of fresh water, must have considerable flexibility. An organism that inhabits the soil must be able to deal with changing temperature, nutrient level, moisture content, and light-dark cycles.

Bacteria have evolved a number of different adaptive strategies. An organism like *Escherichia coli* has evolved an extraordinarily sophisticated network of regulatory mechanisms that allows it to adapt quickly and effectively to different substrates, levels of nutrient, osmotic environments and temperatures. Its modus vivendi allows it to grow extremely rapidly when conditions are optimal, more slowly when they are not, and when growth is not possible, to remain dormant until growth conditions are again available. However, an alternative strategy is in fact available, namely the developmental alternation between two morphogenetic states, each of which is optimal for a different set of circumstances.

This strategy of functional specialization allows the organism to exist in narrowly optimized alternative states rather than in a single, broad optimal state. The advantage of this may

be that the limits of the conditions that can be dealt with by each differentiated state are substantially greater than the limits contained in the repertoire of the undifferentiated, but more broadly versatile cell. In its simplest states, the alternation may take four different forms. These are described below and examples of each alternation are given.

Alternation Between Vegetative Growth and a Resistant, Resting Stage

This developmental pattern is characteristic of many genera but three exemplary types are discussed here: *Bacillus* endospores, *Azotobacter* cysts, and methylotroph exospores. (Some other types of resting cells whose formation is part of a more complex life cycle will be dealt with in subsequent sections. Also, see in Breznak, 2001, the description of *Sporomusa*, a Gram-negative endospore-former.)

The Life Cycle of *Bacillus* The processes of sporulation and germination in *Bacillus* have been intensively studied for over 50 years, with the result that we now know more about the details of these developmental processes than about any other (Sonnenshein, 2000; Slepecky and Hemphill, 1992). A variety of other genera of bacteria also form endospores, e.g., *Clostridium* (Hippe et al., 1992), *Sporosarcina* (Claus et al., 1992; Zhang et al., 1997), *Sporolactobacillus* (Claus et al., 1992; Kitahara and Lai, 1967), *Thermoactinomyces* (Cross and Goodfellow, 1973), and *Desulfotomaculum* (Widdel, 1992; Campbell and Postgate, 1965), and as far as is known, the morphological events leading to endospore formation in these organisms seem relatively similar. While it is tacitly assumed that the developmental events in these organisms are fundamentally the same, evidence to make that statement with any confidence is insufficient. (For a brief discussion of the diversity of bacteria able to form endospores, see Slepecky and Leadbetter, 1983, and Slepecky and Hemphill, 1992.)

The endospore of *Bacillus* is a metabolically quiescent cell, resistant to extremes of temperature, desiccation, chemical agents, radiation, and physical disruption. The events leading to its formation are customarily divided into seven stages, diagramatically represented in Fig. 1. The definition of these stages is based on discernable morphological changes and the isolation of mutants that are blocked in any one of these stages. (For

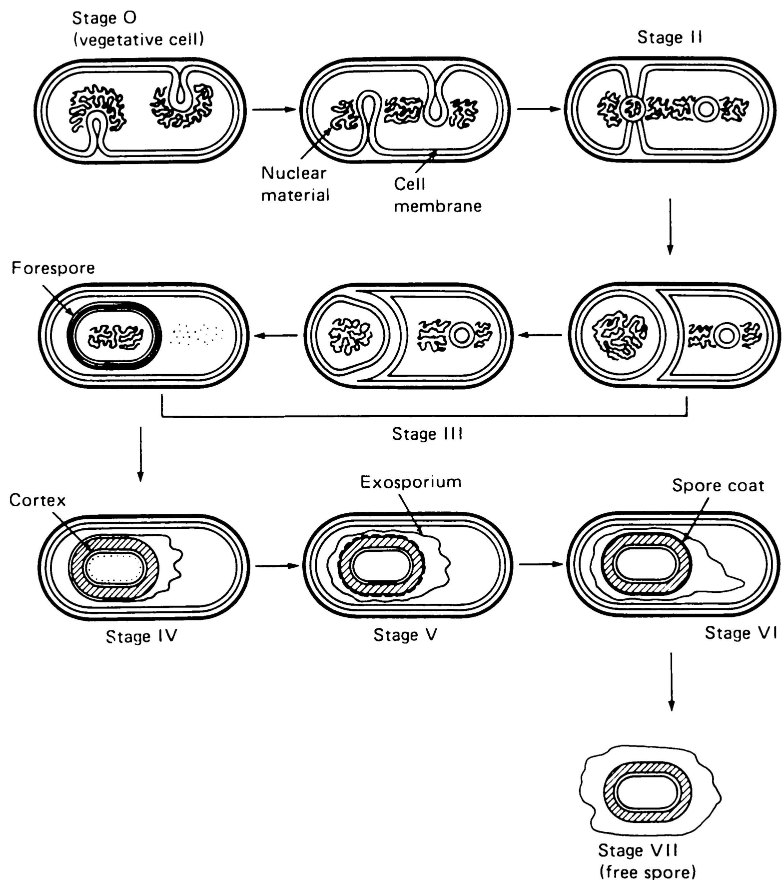

Fig. 1. The seven stages of sporulation in *Bacillus*. (From Dworkin, 1985a.)

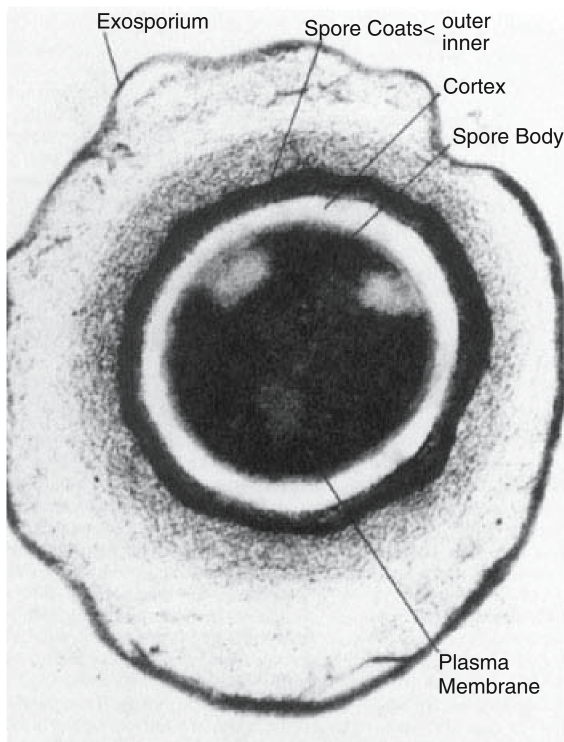

Fig. 2. Electron micrograph of a thin section of a spore of *Bacillus sphaericus*. (Courtesy of Dr. S. Holt.)

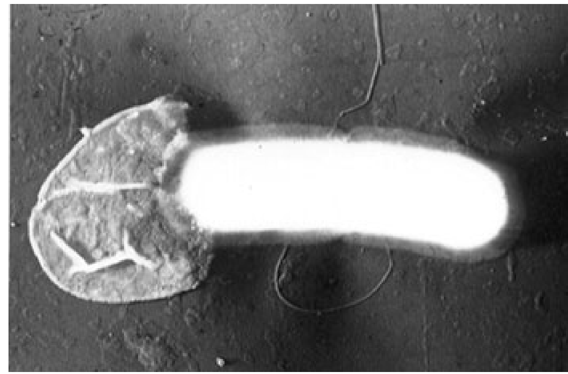

Fig. 3. Electron micrograph of a germinating cell of *Bacillus cereus*. (From Strange and Hunter, 1969.)

a detailed description of the genetic analysis of endospore formation in *Bacillus*, see Errington, 1993.)

When vegetatively growing cells of some species of *Bacillus* are subjected to a nutritional deficiency (shift-down), the nature of which has not been precisely defined, the cells cease the process of dividing by binary transverse fission and instead go through an asymmetrical division leading to the formation of a mother cell and a forespore (Fig. 1, stage III). It has been shown (Lencastre and Piggot, 1979; Losick and Stragier, 1992) that there is considerable biochemical and genetic cross-talk between these two cells, resulting finally in a mature spore (Fig. 2) and a mother cell that eventually lyses and dies.

Most of the emphasis on the mechanisms that control sporulation have focused on the transcriptional regulation of developmental gene expression (Stragier and Losick, 1996). Relatively little attention has been paid to that part of the process that completes the cycle-namely, spore germination (Fig. 3). Germination is perhaps an even more remarkable process than sporulation. The spore may exist for a considerable period of time (Dombrowski, 1963; Gest and Mandelstam, 1987; Cano and Borucki, 1995), in a state of metabolic quiescence, resistant to most external extremes, yet it is poised to return almost instantaneously to a state of metabolic competence and active vegetative growth. There is a considerable amount of information about the mechanisms of resistance of the *Bacillus* endospore and its DNA. The resistance of the endospore seems to be a result of the relative dehydration and mineralization of the spore coat (Marquis et al., 1994), whereas the resistance of the spore DNA is a result of the protective effect of a series of small, acid-soluble spore proteins (Setlow, 1995). Less insight is available regarding the mechanisms that allow the remarkable transformation of a resistant, resting cell to an actively growing one (Setlow, 1983).

THE LIFE CYCLE OF *AZOTOBACTER* *Azotobacter* is a large, Gram-negative, free-living, nitrogen-fixing rod that forms cysts as an alternative stage in its life cycle (Becking, 1992). Its life cycle is diagrammatically represented in Fig. 4. Figures 5 and 6 are electron micrographs of thin sections of a vegetative cell and a mature cyst of *Azotobacter vinelandii*, respectively. Unlike the endospore of a *Bacillus* species, the cyst is formed by the rounding up of the entire cell. *Azotobacter* cysts are not resistant to extremes of temperature, but are resistant to desiccation and to some deleterious chemical and physical agents (Socolowsky and Wyss, 1962). As is usually the case with sporulation or encystment, the developmental events are set in motion by a nutritional shift-down; encystment in *Azotobacter vinelandii* (the organism used for most of the developmental studies), is considerably accelerated by the addition of β-hydroxybutyric acid (Sadoff et al., 1971), which serves as a precursor of the electron-transparent poly-β-hydroxybutyrate granules that are characteristic of the cysts (Fig. 6). The cells shed their flagella, cease nitrogen fixation, gradually become rounded, and finally become optically refractile. The cyst is surrounded by a thickened, multilayered outer coat called "the exine," consisting

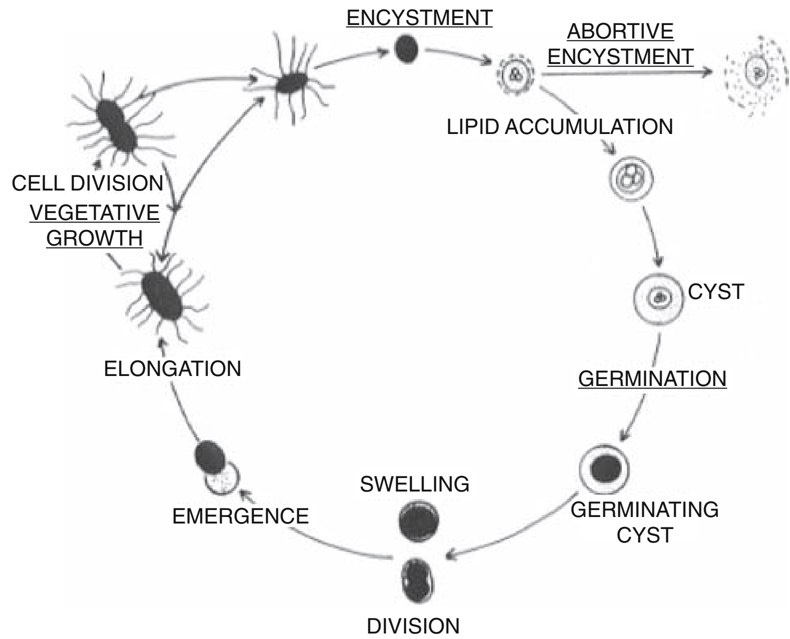

Fig. 4. A schematic of the life cycle of *Azotobacter vinelandii*. (From Sadoff, 1975.)

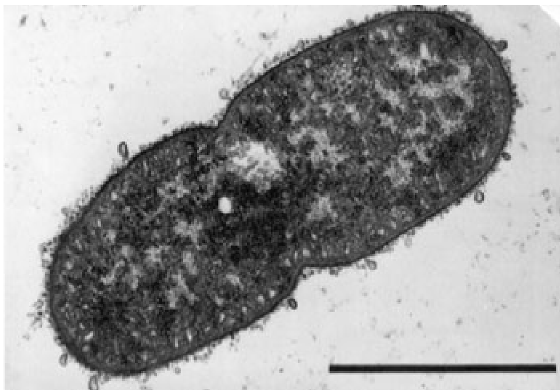

Fig. 5. Electron micrograph of a thin section of a dividing vegetative cell of *Azotobacter vinelandii*. Bar = 1 µm. (From Hitchins and Sadoff, 1970.)

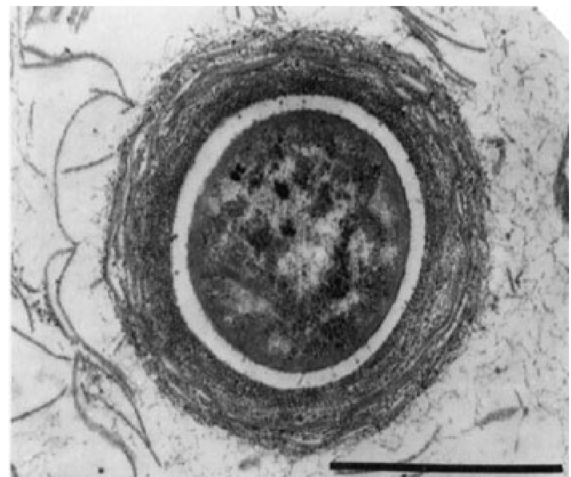

Fig. 6. Electron micrograph of a thin section of a mature cyst of *Azotobacter vinelandii*. Bar = 1 µm. (From Hitchins and Sadoff, 1970.)

of lipoprotein and lipopolysaccharide. A number of unique lipids have been shown to be synthesized and form part of the cyst structure (Reusch et al., 1981). Germination occurs when the cysts are placed in the presence of an exogenous carbon source such as glucose. This immediately induces respiration, macromolecular synthesis, and the conversion of the cyst to the vegetative cell.

THE LIFE CYCLE OF METHYLOTROPHS The methanotroph *Methylosinus trichosporium* (Bowman, 2000) forms an unusual type of resting cell called an "exospore" (Whittenbury et al., 1970). When cells of *M. trichosporium* reach the stationary phase of growth, a proportion of the cells elongate, become tapered, and bud off rounded bodies, which gradually acquire optical refractility. These events are illustrated in Fig. 7. The exospore is resistant to desiccation and to elevated temperatures of at least 78°C. Germination occurs slowly when the cells are placed once again under conditions conducive to growth. Figure 8 is an electron micrograph of a thin section of a mature spore of *M. trichosporium*, and Figs. 9 and 10 illustrate successive stages in the germination of an exospore. Relatively little is known about the biochemistry, physiology, regulation, and developmental biology of these unusual resting cells.

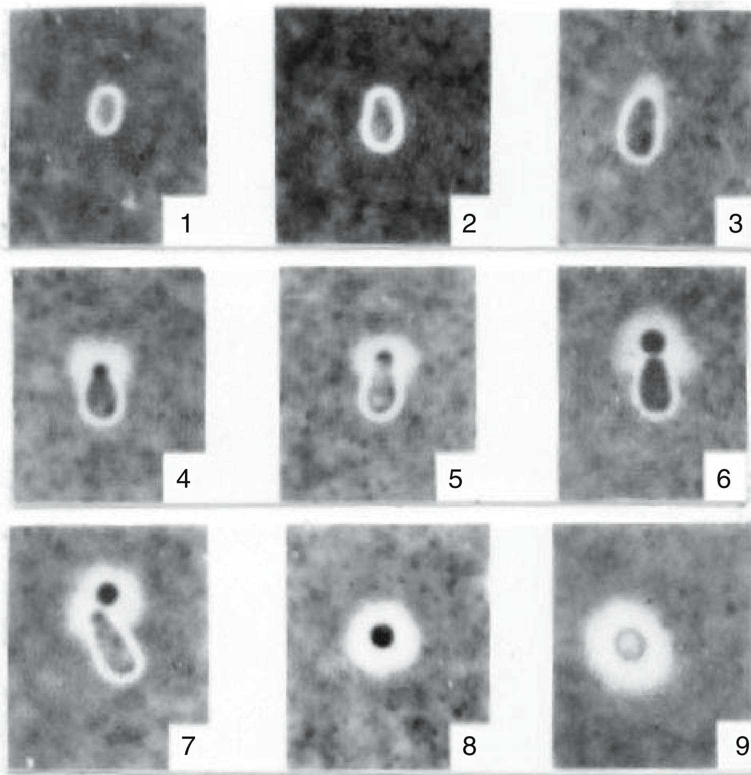

Fig. 7. Phase contrast photomicrographs of exospore formation by *Methylosinus trichosporium*. The capsulated, rod-shaped, vegetative cell becomes pear-shaped, and the tapered end buds off the cell that is eventually released as the refractile exospore. (From Whittenbury et al., 1970.)

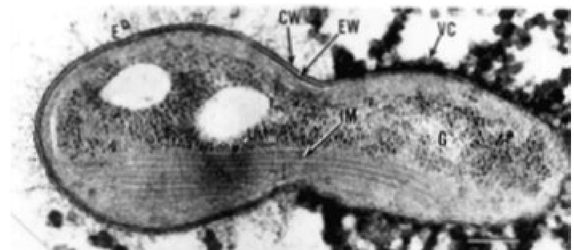

Fig. 10. The same as Fig. 9, but at a later stage. (From Reed et al., 1980.)

Alternation Between Sessile and Motile Stages

CAULOBACTER LIFE CYCLE; ALTERNATION BETWEEN STALKED AND SWARMER CELLS *Caulobacter crescentus* has been the subject of considerable attention on the part of prokaryotic developmental biologists (Brun and Janakiraman, 2000b; Gober and England, 2000; Ohta et al., 2000; Hung et al., 2000; also see the chapter on the Dimorphic Prosthecate Bacteria in Volume 5). This organism provides an excellent model system for asking two general types of developmental questions. The first question has a spatial quality and pertains to the cellular localization of the stalk and the flagellum; the second concerns the temporal aspects of development and is concerned with the regulatory relationship between the growth and the development of the cells. While neither of these may seem to bear any obvious relationship to the issue of sessile versus motile stages, the end result of the developmental events in *Caulobacter* is, in fact, an alternation between two states: the flagellated, free-swimming, nongrowing swarmer stage and the stalked, sessile, reproductive stage. Thus, *Caulobacter* exemplifies the temporo-spatial aspects of development and offers an almost unique opportunity to examine the epigenetic aspects of developmental regulation in the context of an extremely convenient and tractable experimental system.

The life cycle of *Caulobacter* is diagrammed in Fig. 11. Starting from the inexperienced stalk cell

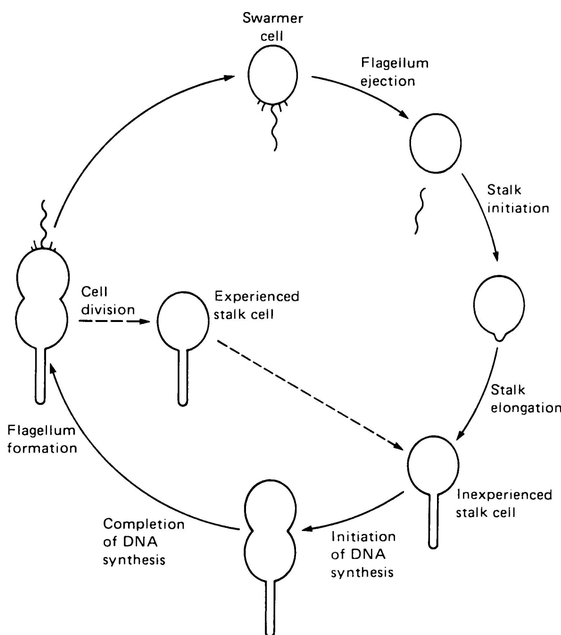

Fig. 11. Diagram of the life cycle of *Caulobacter crescentus*. (From Dworkin, 1985a.)

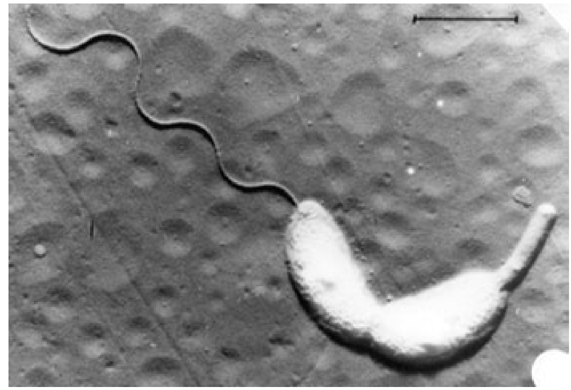

Fig. 12. Electron micrograph of a shadowed cell of *Caulobacter crescentus*. The stalked mother cell is in the process of dividing, leading to the formation of a flagellated swarmer cell. Bar = 1 μm. (From Poindexter, 1964.)

(i.e., a stalk cell that has not yet undergone a cell division) attached to a substrate, the cell will grow and produce a flagellated daughter cell (Fig. 12). This motile daughter cell apparently is involved in colony dispersal and will, at some point, attach to a surface via its holdfast, shed the flagellum, and in its place synthesize the characteristic *Caulobacter* stalk. At this point it again becomes a new, inexperienced stalk cell. The original stalk cell meanwhile continues to grow and produces new swarmer cells. In a sense, the stalk cell acts as an immortal stem cell; unlike the situation in conventionally dividing bacteria where one cannot distinguish between a mother and a daughter cell, in *Caulobacter*, the mother is theoretically immortal, continuing to bud off daughter swarm cells.

Figure 13 relates biochemical and developmental events to the cell cycle and further emphasizes the relationship between growth and development (Laub et al., 2000).

It is evident that, unlike those developmental cycles in which events (such as the formation of a resistant resting cell) is an alternative to growth of the cell, in *Caulobacter*, the two processes are intimately intertwined (Hung et al., 2000). The asymmetric localization of the stalk and subsequently the flagellum has been the model system for examining the process of spatial differentiation (Gober and England, 2000). What are the clues that determine the polar placement of the stalk and the flagellum? It appears that the spatial localization of polar structures in *Caulobacter* is a result both of cell pole-specific gene expression and protein targeting.

The questions of spatial morphogenesis in *Caulobacter* are essentially no different from the kinds of questions one can ask about the biosynthesis and placement of cellular structures in organisms that do not exhibit a developmental

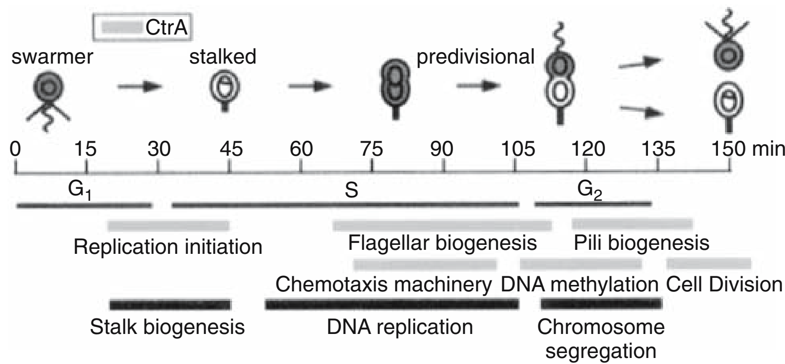

Fig. 13. A schematic illustrating various developmental and biosynthetic events as a function of the cell cycle of Caulobacter crescentus. Circles and "theta" structures in the cells represent quiescent and replicating chromosomes, respectively. A member of a two-component signal transduction family, CtrA, is present in the shaded cells, where it represses DNA replication and is cleared by proteolysis during the swarmer-stalked cell transition. (From Laub et al., 2000, with permission of the American Association for the Advancement of Science.)

life cycle, and it is an intriguing possibility that the answers may emerge from the investigations of *Caulobacter* rather than from work on these simpler systems. In fact, recent work with *Caulobacter* has taken the lead in examining development as an integrated regulatory system, and has shown that a single regulatory factor CtrA, a member of a two-component signal transduction family, is involved in the control of a quarter of all the cell-cycle associated genes (Laub et al., 2000).

THE LIFE CYCLE OF SPHAEROTILUS *Sphaerotilus*and the related genus *Leptothrix* (Mulder and Deinema, 1992) behave in a way that is analogous to *Caulobacter*. Both groups of organisms alternate between a motile and a sessile state. In the case of *Sphaerotilus*, however, the sessile state is represented by a filamentous sheath that encloses the rod-shaped cells (Fig. 14) and is attached by one end (the holdfast) to a surface (Fig. 15). As growth and division occur, the cells acquire polar flagellation (Figs. 14B and 16) and emerge from the sheath. Upon reaching an appropriate new site, the cells attach to a surface, shed the flagellum, and begin dividing within a new sheath. Neither the physiology nor the regulatory developmental events in *Sphaerotilus* have been extensively examined.

THE LIFE CYCLE OF THE ACTINOPLANETES The actinoplanetes are a group of nine genera within the actinomycetes (Kroppenstedt and Goodfellow, 1992) and represent another variation of a life cycle based on the theme of alternation between a sessile, feeding, and reproducing stage and a motile, nonreproductive one. In these organisms, the sessile stage is the vegetative mycelium, and the motile stage is represented by flagellated spores formed within a sporangium. (The actinomycetes will be further discussed later in this chapter as an example of a complex life cycle; at this point, only the alternation between the sessile and motile stages will be discussed.) Figure 17 is a diagram illustrating the characteristic sporangial morphology and the zoospores of various genera among the actinoplanetes. Figure 18 is an electron micrograph of a thin section of a sporangium of *Pilimelia* filled with spores.

Alternation Between an Extracellular, Infectious Stage and an Intracellular, Reproductive Stage

THE LIFE CYCLE OF BDELLOVIBRIO Bdellovibrio is a genus comprising three species of small, Gram-negative, predatory bacteria (Jurkevitch, 2000). They are obligate intracellular parasites of other Gram-negative bacteria such as the enteric bacteria, *Pseudomonas*, *Rhizobium*, *Spirillum*, *Photobacterium* and *Chromatium*. The cells alternate between a motile, polarly flagellated, nonreproducing, extracellular form and a nonmotile, reproductive form localized in the periplasmic space of the host cell. Figure 19 illustrates the morphology of the free-swimming, extracellular form. The anterior of the cell is differentiated into a distended tip that serves as a holdfast, with which the Bdellovibrio attaches to the surface of the host cell. The polar flagellum is unusual in that it is covered by a sheath, which is a continuation of the outer cell membrane (Fig. 20).

The encounters between the *Bdellovibrio* cell and its host appear to be random; no evidence for a chemotactic perception of host cells or their extracts has been found (Straley and Conti, 1977), despite the fact that *B. bacteriovorus* is chemotactic toward other compounds (Straley et al., 1979). There is an initial, reversible stage

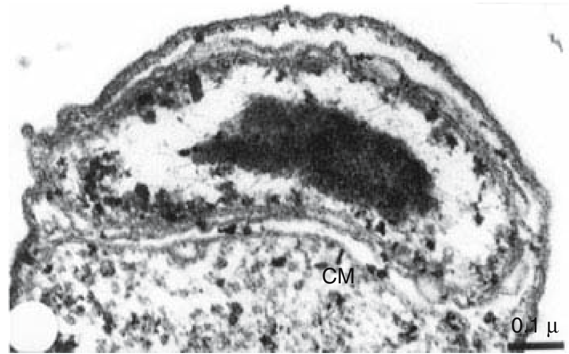

Fig. 22. Electron micrograph of the late stage of penetration of the host cell by *Bdellovibrio bacteriovorus*. The *Bdellovibrio* occupies the periplasm of the host cell. CM, cell membrane. (From Burnham et al., 1968.)

after contact, quickly followed by an irreversible stage (Fig. 21). The *Bdellovibrio* then penetrates the outer envelope by a mechanism that seems to involve its rapid rotation at speeds up to 100 rotations per second (Stolp, 1967). The parasite sheds its flagellum and enters the periplasm, between the inner cell membrane and the peptidoglycan layer (Fig. 22). It then grows into a septate filament, which, when growth ceases, fragments into flagellated, attack-phase progeny. These cells then lyse the host and swim off, ready for the next encounter with a susceptible host. These events are schematically illustrated in Fig. 23.

The attack-phase cells, which are free-living, are differentiated from the morphologically distinct intracellular reproductive cells by considerable physiological differences. The intracellular stage is able to carry out the biosynthesis of RNA, DNA and protein, in contrast to the free-living cells, which are biosynthetically inert. The cells have the unusual ability to transport ATP and phosphorylated nucleosides; however, the two cell types also differ in this trait. The attack-phase cells are characterized by a system with a high substrate affinity and a low V_{max}, whereas the transport system of their intracellular counterparts has just the reverse properties, i.e., a low affinity and high V_{max} (Ruby, 1985). The ability of *Bdellovibrio* to take up phosphorylated compounds is reflective of their general ability to utilize the high-molecular-weight components of the parasitized host cell directly for their own biosynthetic processes. This results in an unusually high level of growth efficiency; up to 65% of the host cell material is converted to *Bdellovibrio* (Rittenberg and Hespell, 1975).

It has been possible to obtain mutants of *Bdellovibrio* that are host independent, i.e., that can be grown axenically on conventional laboratory media (Seidler and Starr, 1969; Cotter and

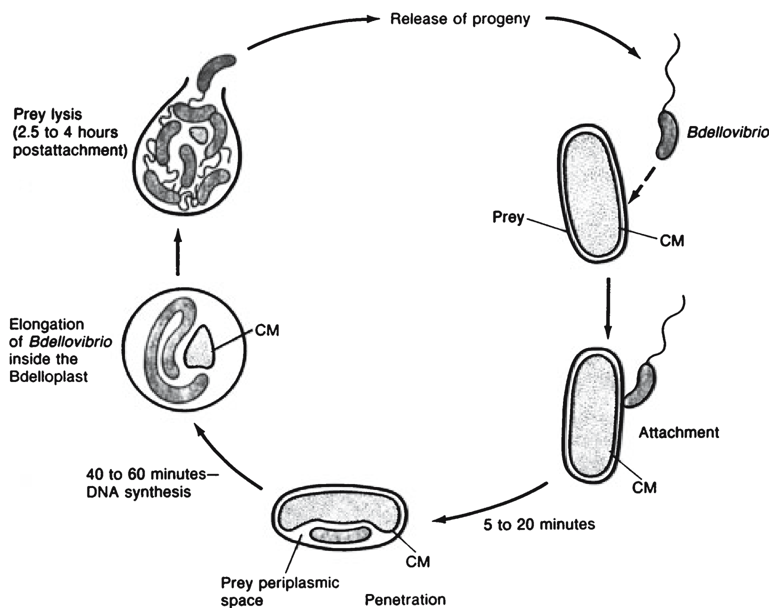

Fig. 23. Diagrammatic representation of the life cycle of *Bdellovibrio*. CM, cell membrane. (From Brock and Madigan, 1988, with permission of Prentice-Hall, Inc., Englewood Cliffs, NJ.)

Thomashow, 1992). However, more useful from an experimental point of view has been a technique that allows the release of intact, viable growth-phase cells, which can be induced to convert to the motile attack-phase cells (Ruby and Rittenberg, 1983). This has allowed a physiological and biochemical comparison of the two types of cells (Ruby, 1989).

There is relatively little information on the nature of the regulatory events that control the conversion from one cell type to the other. Gray and Ruby (1991) have proposed that there are likely to be at least two signals—one triggering the conversion of the attack phase cells into the growth phase cells, and the other initiating DNA replication in the growth phase cells.

The Life Cycle of Chlamydia *Chlamydia* is an obligate parasite that alternates between two states, extracellular and intracellular. Correspondingly, its life cycle consists of two alternating cell types, the elementary body and the reticulate body, each of which is specifically adapted to carry out one aspect of the organism's life cycle (Rockey and Matsumoto, 2000; Kalayoglu, 2001).

The elementary body is a resting cell, resistant to desiccation, unable to grow, and highly infectious. Its primary functions seem to be its resistance to adverse, extracellular conditions, and its infectivity. Its alternative state, the reticulate body is a larger cell, containing ribosomes and possessing the ability to use the biosynthetic capacities of the host cell for its own growth. Table 1 gives a comparison of the properties of the two cell types.

The life cycle of *Chlamydia* consists of the following series of events:

1. Infection of the host cell by the elementary body. It is likely that there are specific interactions between the chlamydial cell and that of its susceptible host, but that has not been demonstrated. The elementary body is immediately phagocytized by the host cell and engulfed in a phagosome, an organelle bounded by a membrane derived from the host membrane. Within the phagosome, the Chlamydia is protected from the normal lysosome-mediated destruction that would occur with other types of bacterial invaders.

2. Conversion of the elementary bodies to the reticulate bodies. Within 10–15 h, the chlamydial cells have synthesized ribosomes, reorganized

Table 1. Properties of the elementary body and the reticulate particle of the genus *Chlamydia*.

Property	Elementary body	Reticulate particle
Size (nm)	200–400	600–1,000
Rigid cell wall	+	–
Extracellular stability	+	–

their DNA, acquired a new and different cell wall, and begun to divide by binary fission.

3. Growth and replication proceed until the phagosome is filled with cells of *Chlamydia*.

4. The reticulate bodies convert once again to the elementary bodies, lyse the host cell, and either emerge to the outside environment or reinfect adjacent cells.

A phagosome filled with both types of cells and some intermediary forms is shown in Fig. 24.

The Life Cycle of *Flexibacter*

Flexibacter filiformis is one of a group of filamentous, gliding bacteria. It is distinguished from the others, however, by its ability to go through a cycle in which long, threadlike filaments alternate with short, fat, almost coccoid rods. Figure 25 illustrates the presence of both cell types in a heterogeneous population growing on an agar surface. This is probably a reflection of the fact that the conversion of the long, filamentous cells to the short cells occurs when the culture enters the stationary phase of growth (Simon and White, 1971). Poos et al. (1972) showed that the conversion also could be regulated by the growth temperature. When a culture of *Flexibacter* was grown at 30°C, the cells grew exponentially as long filaments and then divided in the middle; when the culture was shifted to 35°C, the cells fragmented into the shorter forms and continued to grow in that fashion. The authors suggested that the shift-up in temperature increased the rate of septum formation and induced cell separation, whereas the shift-down in temperature inhibited cross-wall formation but not growth.

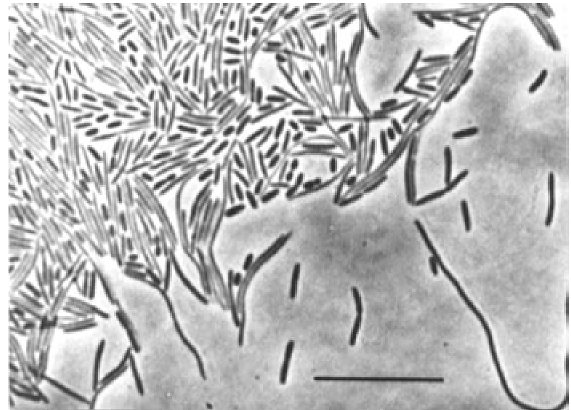

Fig. 25. Phase contrast photomicrograph of individual cells and long filaments of *Flexibacter filiformis*. (From Reichenbach, 1989.)

Complex Life Cycles: Multiple Alternative States

There are prokaryotes whose life cycles consist of multiple alternative states. These include alternations between growing and resting states, between sessile and motile states, and between unicellular and multicellular states. When the possibility of different modes of growth and the formation of structures such as fruiting bodies are added, the developmental tapestry becomes an even more intricately woven one.

The Life Cycle of *Myxobacteria*

The life style of the myxobacteria is at the interface between unicellularity and multicellularity. Their life cycle is characterized by pervasive cell-cell interactions during both growth and development. Their most distinguishing features are that they move by gliding over solid surfaces and their life cycle culminates in the formation of macroscopic, multicellular, often complex fruiting bodies (Dworkin, 2000; Reichenbach and Dworkin, 1992; see Figs. 29 and 30).

The myxobacteria share the property of gliding motility with a large, heterogeneous, essentially unrelated group of bacteria referred to as the gliding bacteria (Reichenbach and Dworkin, 1981; Spormann, 1999). While a number of theories have been proposed for the mechanism of gliding, none of these has emerged as a definitive explanation (Spormann, 1999).

The unique feature of the myxobacteria is their ability to go through a complex life cycle, during which the cells aggregate, form fruiting bodies, and within the fruiting bodies, convert to myxospores.

Most of the recent work on the myxobacteria has focused on two species, *Myxococcus xanthus* (Ward and Zusman, 2000; Kaiser, 2000; Shimkets, 2000) and *Stigmatella aurantiaca*

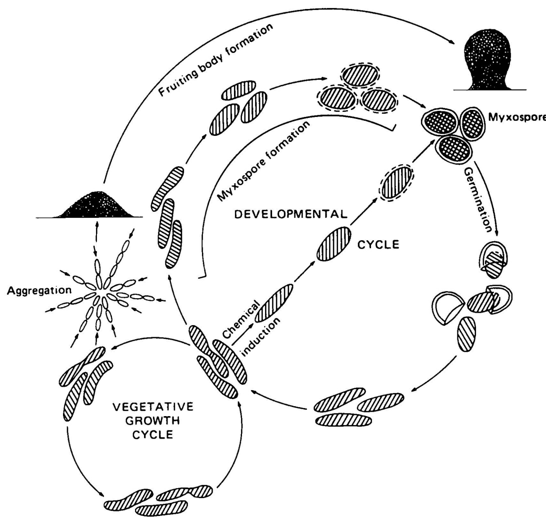

Fig. 26. Diagram of the life cycle of *Myxococcus xanthus*. The fruiting body is not drawn to scale, but it is a few hundredths of a mm in diameter, in contrast to the vegetative cells, which are about 5–7 × 0.7 μM. (From Dworkin, 1985a.)

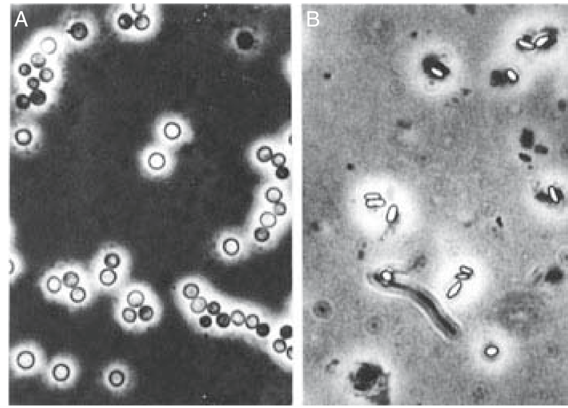

Fig. 28. Phase contrast photomicrographs of myxobacterial myxospores. (A) *Myxococcus xanthus*. (B) *Stigmatella aurantiaca*. (Courtesy of Dr. H. Reichenbach.)

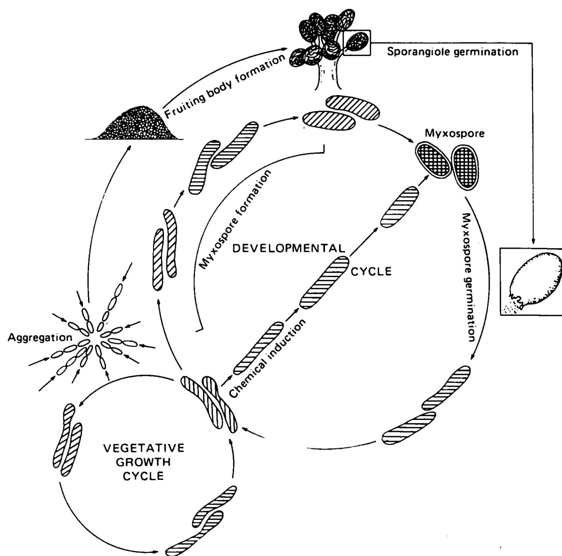

Fig. 27. Diagram of the life cycle of *Stigmatella aurantiaca*. (From Dworkin, 1985a.)

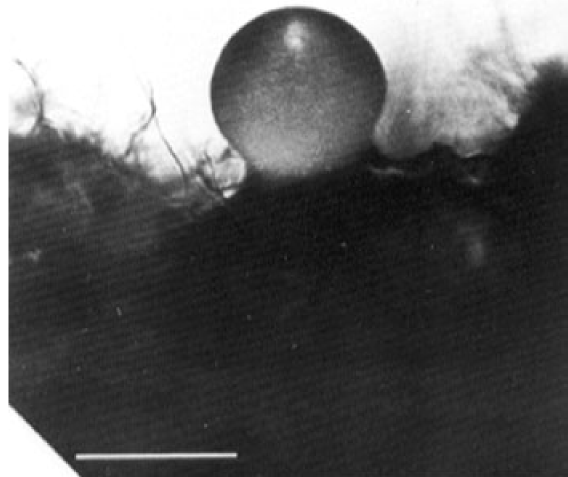

Fig. 29. Fruiting body of *Myxococcus fulvus*. Bar = 35 μm. (From Reichenbach, 1984.)

(White and Schairer, 2000). The life cycles of these organisms are illustrated in Figs. 26 and 27.

The myxospores of *M. xanthus* are optically refractile, resistant, resting cells (Fig. 28) that are able to germinate when placed under conditions that allow vegetative growth.

There are essentially two parts to the myxobacterial life cycle. *Myxococcus xanthus* uses proteins, peptides, or amino acids as its source of carbon, energy, and nitrogen (Shimkets, 1984), and under favorable conditions, the cells grow exponentially with a generation time of about 3.5 h. Three conditions must be satisfied for the cells to shift from the growth mode to the alternative developmental mode (Dworkin and Kaiser, 1985b): 1) The cells must experience a nutritional shift-down. 2) The cells must be on a solid surface. 3) The cells must be at a high cell density. If these three conditions are met, the cells cease growth and begin to aggregate into centers that eventually become the fruiting bodies. These fruiting bodies may be either more (Fig. 29) or less (Fig. 30) elaborate.

Myxobacteria feed by excreting a variety of powerful hydrolytic enzymes, which they use to degrade proteins, polysaccharides, lipids, and nucleic acids. They are thus at the mercy of the

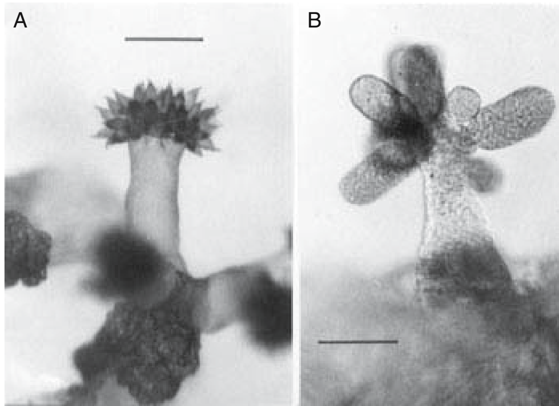

Fig. 30. (A) Fruiting body of *Chondromyces apiculatus*. Bar = 150 µm. (B) Fruiting body of *Stigmatella aurantiaca*. Bar = 40 µm. (Courtesy of Dr. H. Reichenbach.)

processes of diffusion—of the enzymes away from the cell and of the products of hydrolysis toward the cell. It has been shown that their feeding on macromolecules is a density-dependent process (Rosenberg et al., 1977), and it has been suggested that the function of the myxobacterial life cycle is to maximize feeding efficiency by maintaining a high cell density at all times; this has been referred to as a "microbial wolf-pack effect" (Dworkin, 1973).

A feature of the myxobacteria that is extremely unusual for prokaryotes, and that has been the central subject of many of the studies of their development, is the role of cell-cell interactions during growth, motility and development. These interactions involve both diffusible chemical signals exchanged between the cells (Kaiser, 2000) as well as contact-mediated signals (Dworkin, 1999).

The myxobacteria represent an unusual example of multicellularity among the prokaryotes, and as such, offer the opportunity to pursue questions about cell interactions and multicellular morphogenesis in the context of an experimentally tractable system.

The Life Cycle of *Streptomyces*

Streptomyces is one of the genera comprising the actinomycetes (Ensign, 1992), a group of Gram-positive soil bacteria, and is distinguished by a marked tendency toward mycelial growth. The life cycle of *Streptomyces* is characterized by the presence of two types of mycelium, aerial and substrate, by the alternation between vegetative cells and hyphal spores, and by the developmental autolysis of a substantial portion of the population (Champness, 2000). These stages are diagrammatically illustrated in Fig. 31.

The life cycle may be considered to begin with the germination of the hyphal spore, which

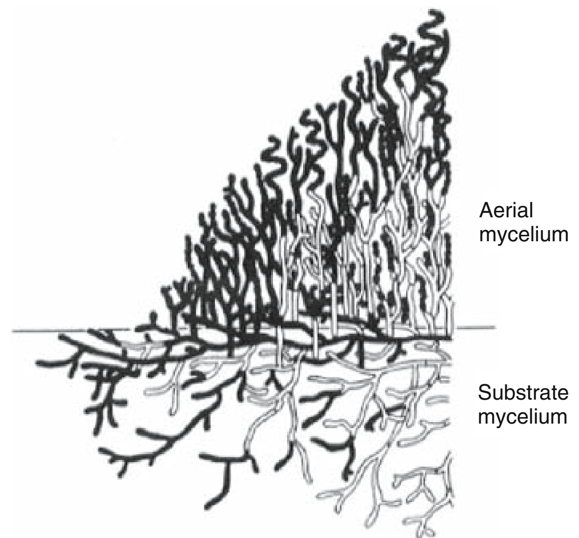

Fig. 31. Idealized diagram of a vertical section through the center of a sporulating colony of *Streptomyces coelicolor*. The black color indicates intact cells and the white color disintegrating or lysing cells. (From Dworkin, 1985a.)

occurs when the spore is placed in appropriate physical and nutritional conditions (Hirsch and Ensign, 1976). The germinated spore produces a structure morphologically analogous to a fungal germ tube; this gives rise to a radially spreading, branched mycelium that either penetrates into the substrate or travels along its surface. After a number of hours of substrate growth, the mycelia begin to develop vertically. These aerial mycelia are the forerunners of the hyphal spores and differ from the substrate mycelia physiologically as well as by being considerably more hydrophobic. (Their hydrophobic nature is possibly of value to a cell that must exist in the absence of water.) Presumably as a consequence of nutrient depletion, these aerial mycelia then begin to form spores. The formation of the spores and aerial mycelia give a colony of Streptomyces its characteristic fuzzy, powdery appearance. The process of sporulation is illustrated in Fig. 32. During this process of aerial mycelium and spore formation, the population undergoes massive autolysis (Fig. 31), the function of which is unknown. The spores are metabolically quiescent resting cells and are resistant to desiccation and to slightly elevated temperatures (i.e., 55°C). Their function is presumably to aid in dispersal of the organism and to allow the organism to withstand periods of nutrient depletion, desiccation, and the temperature extremes that might be encountered in the soil.

One of the most striking features of the *Streptomyces* is the ability of various species of the genus to produce antibiotics; over 8,000 have been discovered (Champness, 2000) and almost

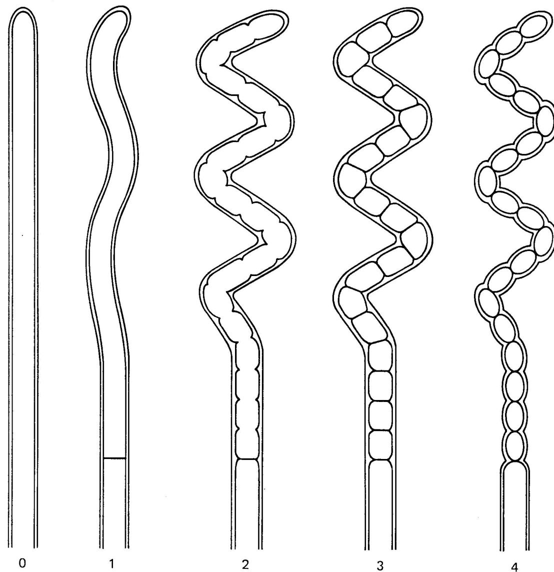

Fig. 32. Diagram of the four stages of sporulation in *Streptomyces coelicolor*. After a phase of vegetative growth, as shown in (0), the sporulating hyphae are divided into long cells by ordinary cross-walls, and the tips begin to coil (1). The apex is then partitioned into spore-sized compartments by sporulation septa (2). The cell walls thicken and constrictions appear between the young spores (3). As spores mature, they round off and separate (4). Some spores begin to germinate immediately after maturation. (From Dworkin, 1985a.)

2,000 have been characterized (Berdy, 1974). The function of an antibiotic for the producing organism is not clear. Historically, the two opposing arguments have been an ecological one and a developmental one. The ecological argument, originally suggested by Selman Waksman (Waksman, 1961), who discovered streptomycin, one of the first *Streptomyces* antibiotics, was that the ability of the organism to produce the antibiotic in the soil would reduce competition for nutrients and space. The developmental argument notes that the overwhelming majority of the organisms that produce antibiotics (e.g., fungi, actinomycetes, myxobacteria, and *Bacillus*) go through a life cycle during which spores are produced. It has thus been frequently suggested that antibiotics may be regulatory molecules that function to coordinate or regulate the developmental process or to maintain the dormancy of the spore. A combination of the ecological and developmental arguments has recently emerged; it suggests either that organisms with life cycles may be particularly vulnerable to predation at certain stages (e.g., during spore germination), or that massive lysis of portions of the population during development (e.g., aerial mycelial formation by *Streptomyces* or fruiting body formation by myxobacteria) may generate nutrient-rich areas, which other microbes could detect and enter chemotactically (Chater and Hopwood, 1989). The production of an antibiotic may thus enable the developing organism to ward off predation or reduce competition during a particularly vulnerable stage of its life cycle. For a recent review of the developmental genetics of *Streptomyces*, see Chater (2000).

The Life Cycle of *Rhodomicrobium vannielii*

Rhodomicrobium vannielii is a photoheterotrophic, budding bacterium. It combines in its life cycle the alternation of growing cells and resistant, resting cells characteristic of the sporeforming prokaryotes, and the alternation of sessile, reproductive cells and swarming, nongrowing cells characteristic of *Caulobacter*.

If one examines a batch culture of *R. vannielii*, one may find three types of cells simultaneously present. These are peritrichously flagellated rods, ovoid cells linked together by branched, mycelial connections, and heat-resistant, angular exospores. The understanding of the developmental relationship among these three types was facilitated by the finding that the swarmer cells and the budding, mycelial forms could be separated by passing the culture through a column containing glass wool. Thus, homogeneous populations of each cell type could be obtained and the sequence of developmental events connecting them determined (Whittenbury and Dow, 1977). Figures 33 and 34 illustrate the morphology of these three cell types. Whittenbury and Dow (1977) clarified the developmental relationship between these cell types, and this is illustrated in Fig. 35. The polarly flagellated swarmer

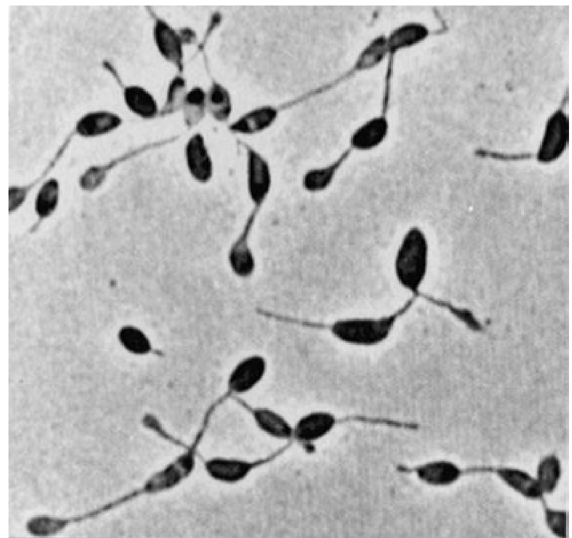

Fig. 33. Electron micrograph of cells of *Rhodomicrobium* in the growth phase. (Courtesy of Dr. P. Hirsch.)

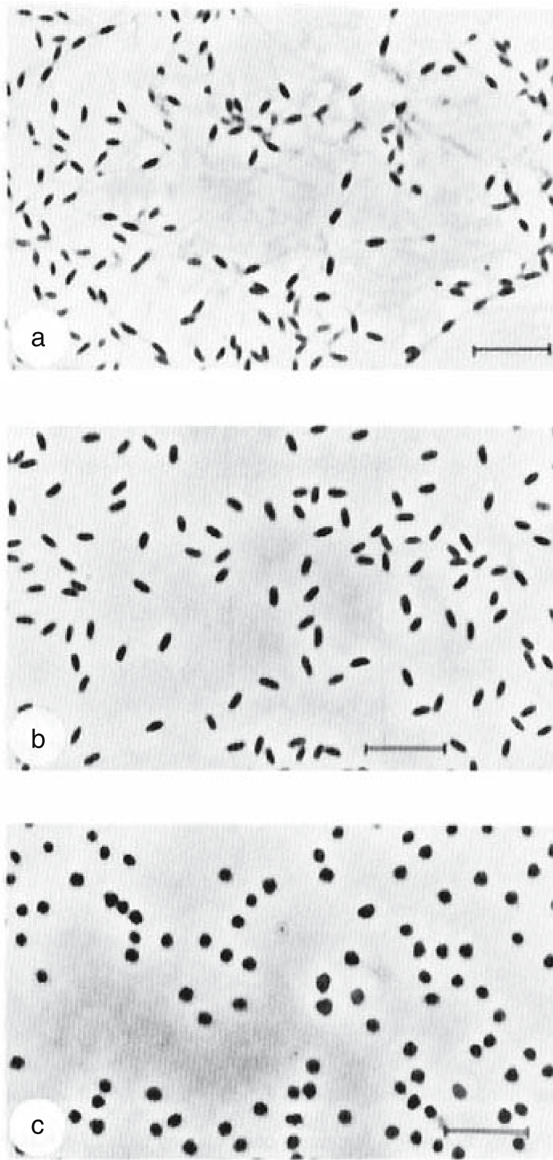

Fig. 34. Phase contrast micrographs of *Rhodomicrobium*. (a) Mycelial forms. (b) Homogeneous population of swarmer cells. (c) Exospores. Bar = 10 μm. (From Dow and Whittenbury, 1979.)

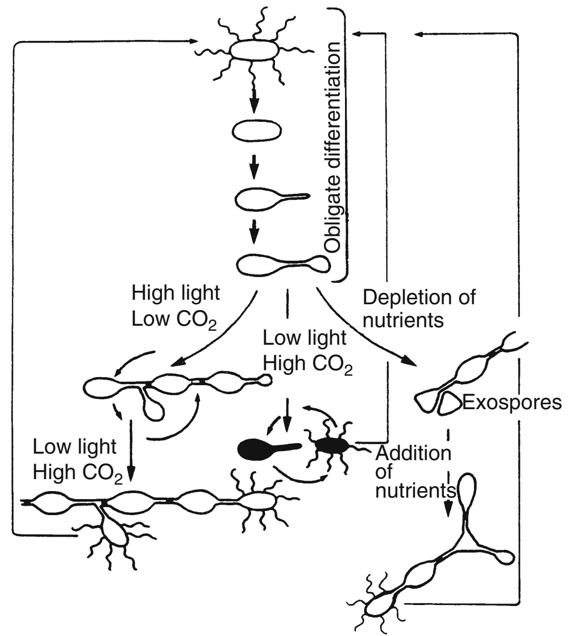

Fig. 35. Diagrammatic representation of the life cycle of *Rhodomicrobium* showing the developmental responses of the cells to environmental stimuli. (From Dow and Whittenbury, 1979.)

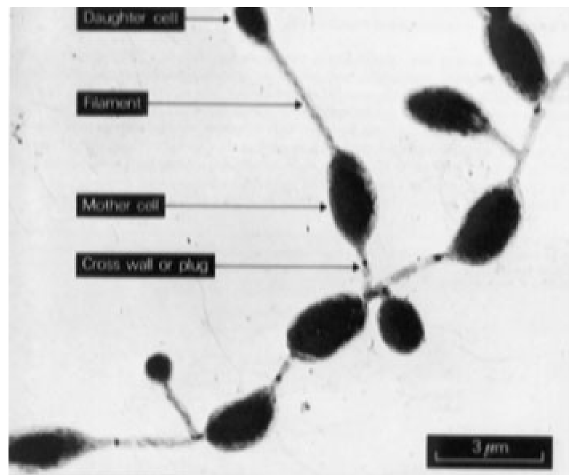

Fig. 36. Electron micrograph of shadowed cells of *Rhodomicrobium*. Bar = 2 μm. (From Dow and Whittenbury, 1979.)

cell is, like its swarmer cell counterpart in *Caulobacter*, a nongrowing cell, whose function seems to be to maximize dispersal. Its formation is induced by conditions of low light intensity and high levels of CO_2; both of these conditions would be generated by a high cell density—the low light intensity by shading of the cells and the high CO_2 by the respiratory activity of the cells. In the presence of optimal light intensity, the swarmer cells shed their flagella and begin to undergo the morphogenetic conversion to the budding, mycelial stage—the reproductive phase of the organism's life cycle. These budding cells then have three developmental options, depending on the circumstances of light intensity, nutrient concentration, and CO_2 partial pressure. Under conditions of high light intensity and low partial pressure of CO_2, the cells remain in the budding, mycelial mode (Fig. 36). As indicated earlier, when these conditions are reversed (i.e., low light intensity and high CO_2 partial pressure), the budding cells revert to the swarmer stage. Finally, when the nutrient level drops below a threshold, the budding cells begin to

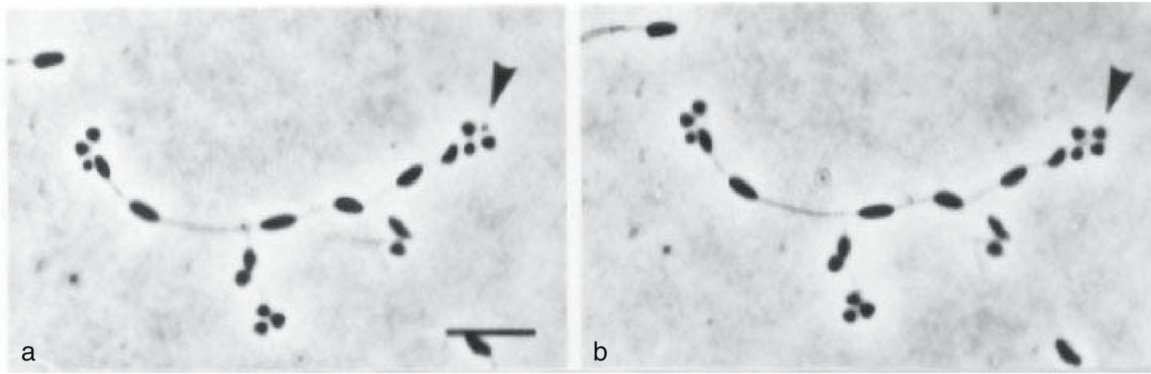

Fig. 37. Phase contrast micrographs of exospore formation in *Rhodomicrobium*. Figure 37b is at a later time than Fig. 37a. The exospores are formed terminally from the filament tip (arrowhead) and characteristically are arranged in clusters. Bar = 10 µm. (From Whittenbury and Dow, 1977.)

produce an unusual resting cell somewhat similar to the exospores formed by the methylotroph *Methylosinus trichosporium* (see "The Life Cycle of Methylotrophs" in this Chapter). The spores are budded off the mother cells and are formed at the tips of prosthecae. The process is illustrated in Figs. 37 and 38. Note that each prosthecal tip may give rise to multiple exospores. The exospores are bona fide resting cells and are resistant to desiccation and to elevated temperatures (e.g., 60°C). The exospores can germinate (presumably under conditions that are optimal for growth), and the sequence of events during their germination is depicted in Fig. 39.

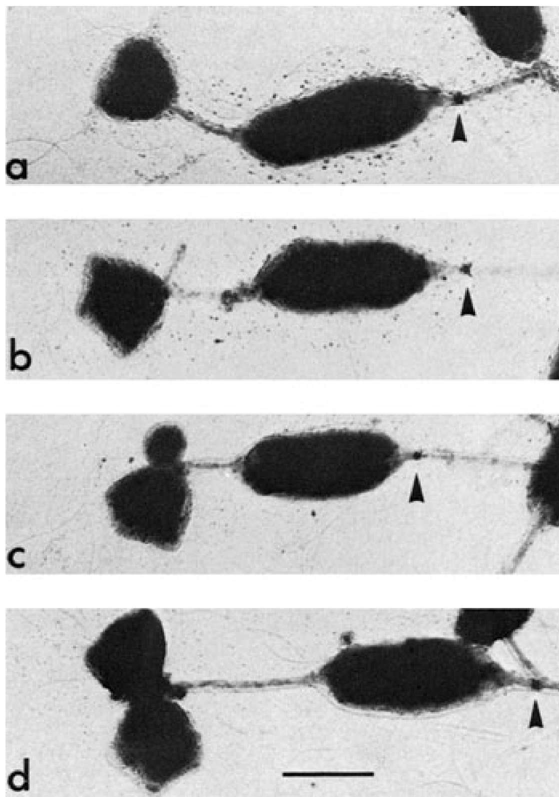

Fig. 38. Electron micrographs of shadowed, sporeforming cells of *Rhodomicrobium*. (a) First exospore formed. (b) Filament for second exospore is extended. (c) Beginning formation of second exospore. (d) Completion of second exospore. Arrowheads indicate filament plug separating the mother cell from the rest of the vegetative cells. Bar = 1 µm. (From Whittenbury and Dow, 1977.)

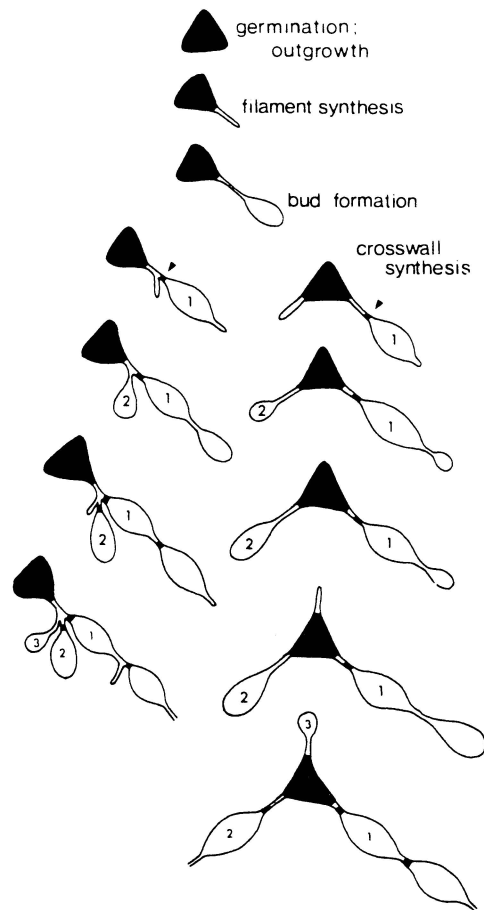

Fig. 39. Diagrammatic representation of exospore germination in *Rhodomicrobium*. The left and right sides show two different exospores. (From Whittenbury and Dow, 1977.)

As pointed out earlier, the strategy of alternating swarmer and stalked cells is strikingly similar to that manifested by *Caulobacter*. However, there is a considerable strategic difference. In *Caulobacter*, development is bifunctional whereas *Rhodomicrobium vannielii* is able to generate three developmental forms. Furthermore, in *Caulobacter*, swarmer cells and stalked cells must alternate with each other; a stalked cell cannot give rise to another stalked cell, but only to a swarmer cell. The sessile, reproducing cell of *R. vannielii*, on the other hand, has the option of either entering the dispersal mode, i.e., producing a swarmer cell, or it can continue to produce additional reproductive units. It can also generate a resistant, resting cell. In addition to this remarkable panoply of developmental options, it can metabolize either anaerobically as a phototroph or aerobically as a chemotroph, so it is clearly an extremely versatile organism.

Life Cycles Involving True Differentiation

The Cyanobacteria

In their classic review in 1971 on the Chroococcales, Stanier et al. (1971) pointed out that for the blue-green algae (as they were then called), the transition from natural history to biology required that the organisms be subjected to study in pure culture. That is what Stanier then proceeded to do for the Chroococcales (the unicellular cyanobacteria) (Stanier et al., 1971) and the Pleurocapsales (those cyanobacteria that reproduce by multiple fission; Waterbury and Stanier, 1978). Stanier's work also emphasized that the blue-green algae were indeed bacteria, and thus hastened the terminological conversion from "blue-green algae" to the present, generally accepted term, "cyanobacteria" (Stanier, 1982). The use of pure cultures has now led to an accurate portrayal of the life cycles of many of the cyanobacteria (Waterbury, 1992).

THE FILAMENTOUS CYANOBACTERIA *The Heterocyst* Among the filamentous cyanobacteria, Anabaena is the genus that has been subjected to the most scrutiny (Wolk, 2000). In addition to its photosynthetic properties, it is capable of fixing dinitrogen (as can many of the cyanobacteria), and it forms heterocysts, akinetes, and hormogonia. The heterocyst (Fig. 40) is Anabaena's solution to the problem of carrying out oxygen-sensitive dinitrogen fixation in an oxygenic phototroph. The heterocyst is the site of dinitrogen fixation; however, the absence of oxygen-generating photosystem II, and the presence of an outer coat that effectively insulates the cell from external oxygen, ensure that the oxygen-sensitive nitrogenase in the heterocyst will not be inactivated. The heterocyst exists in a syntrophic association with neighboring vegetative cells (Fig. 41), exchanging fixed nitrogen and reducing power (Fig. 42). This remarkable division of labor, resulting from the differentiation of the population into heterocysts and vegetative cells, was first suggested by Fay et al. (1968) and conclusively demonstrated by Wolk (1979).

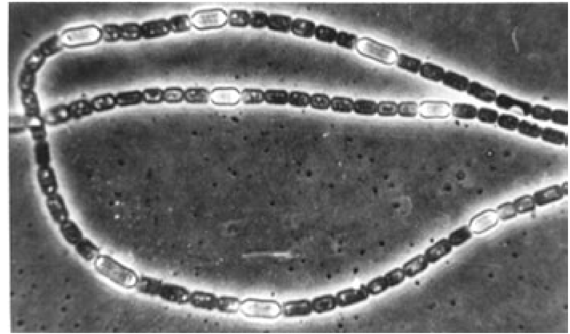

Fig. 40. Phase contrast photomicrograph of *Anabaena* filaments, showing the vegetative cells and the interspersed heterocysts. (From Wilcox et al., 1975.)

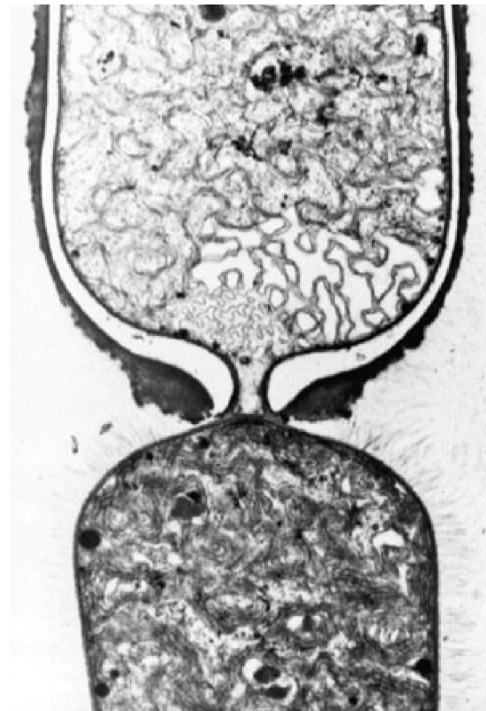

Fig. 41. Electron micrograph of a thin section of a heterocyst (top) and a vegetative cell (bottom) of *Anabaena*. (From Lang, 1968.)

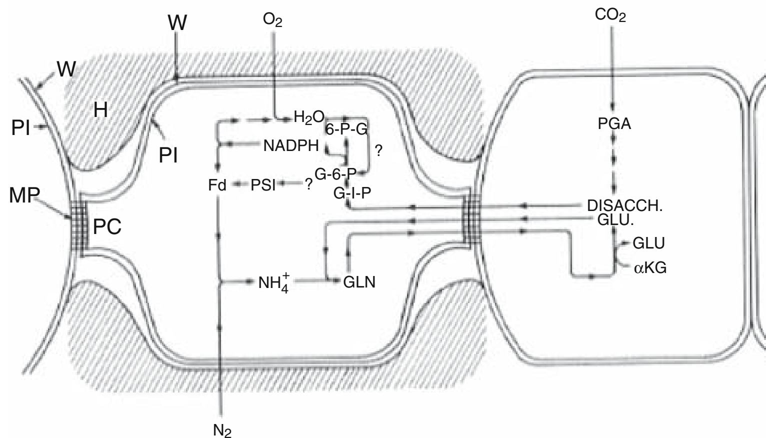

Fig. 42. Diagrammatic representation of the principal structural differences and metabolic interactions between a heterocyst (left) and a vegetative cell (right) of Anabaena. The wall (W) of the heterocyst is surrounded by a three-layered envelope consisting principally of a laminated glycolipid layer, a homogeneous polysaccharide layer (H) and an outermost fibrous layer. The plasma membranes (Pl) of the two cell types are joined by microplasmodesmata (MP) at the end of the pore channel (PC) of the heterocyst. A disaccharide formed by photosynthesis in the vegetative cells moves into the heterocysts and is then metabolized to glucose-6-phosphate and oxidized by the oxidative pentose phosphate pathway. Pyridine nucleotide reduced by this pathway (NADPH) can donate electrons to O_2 to maintain reducing conditions within the heterocysts, and can reduce ferredoxin (Fd). Ferredoxin can also be reduced by photosystem I (PSI). Reduced ferredoxin can donate electrons to nitrogenase, which reduces N_2 to NH_4^+. Glutamate (GLU) produced principally by vegetative cells reacts with the NH_4^+ to form glutamine. The glutamine moves into the vegetative cells, where it reacts with α-ketoglutarate and forms two molecules of glutamate. (Adapted from Wolk, 1979.)

Strictly speaking, the heterocyst is not part of a cycle; it is a dead-end cell (and as such, unusual in prokaryotes) that is not able to divide or germinate. It is formed in the absence of fixed nitrogen, i.e., fixed nitrogen in the medium will prevent heterocyst formation. The approximate timing of events is as follows: Four to five hours after a culture of *Anabaena* has depleted its supply of fixed nitrogen (NH_4^+) or has been transferred to a nitrogen-free medium, proheterocysts begin to appear along the filaments at regularly spaced intervals. After about 16 h, a maximum of 10% of the vegetative cells have been converted to proheterocysts, and after about 32 h, they have become mature heterocysts (Bradley and Carr, 1976).

The Akinete A number of cyanobacteria form cells that have some of the properties of resistance and metabolic quiescence characteristic of bacterial spores. These cells, called "akinetes," are usually larger and thicker-walled than the parent vegetative cells. In *Anabaena*, akinetes usually form immediately adjacent to a heterocyst (Fig. 43) and may form strings of such cells extending along the filament.

They are somewhat more resistant to desiccation and physical disruption than the corresponding vegetative cells, but the akinete's metabolic or resistance properties have not been the subject of a great deal of work. It is likewise not possible to make any easy generalizations as to the physical or nutritional conditions that induce their development. However, it has been shown that a culture of *Anabaena* strain CA, grown on a medium containing nitrate, will form filaments consisting entirely of vegetative cells; at the end of exponential growth, these become almost completely converted to akinetes (Fig. 44). Under optimal environmental conditions, the akinetes will germinate; the spore coat ruptures and the germling emerges and begins to grow and divide. When this happens to a chain of akinetes, it results in the pattern illustrated in Fig. 45. If germination takes place in the absence of fixed nitrogen, heterocysts appear at approximately every seventh cell (Fig. 45). Occasionally, germination will take place within the spore, without breaking the spore coat (Fig. 46). These

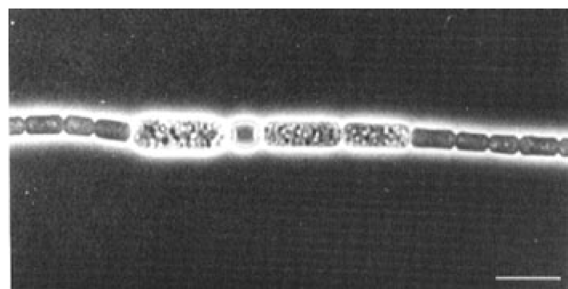

Fig. 43. Phase contrast photomicrograph of part of a filament of *Anabaena cylindrica*, showing a heterocyst with akinetes on either side. (From Nichols and Adams, 1982.)

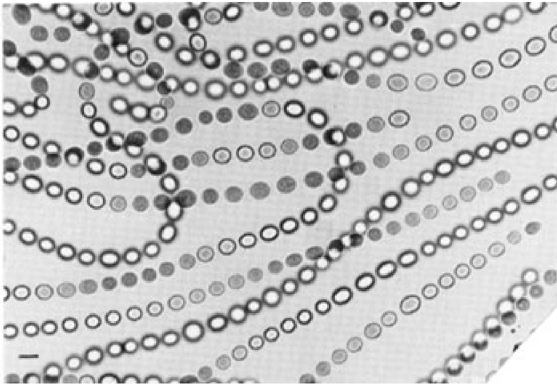

Fig. 44. Phase contrast photomicrograph of *Anabaena* grown in the presence of nitrate, showing filaments completely transformed into akinetes. (From Nichols and Adams, 1982.)

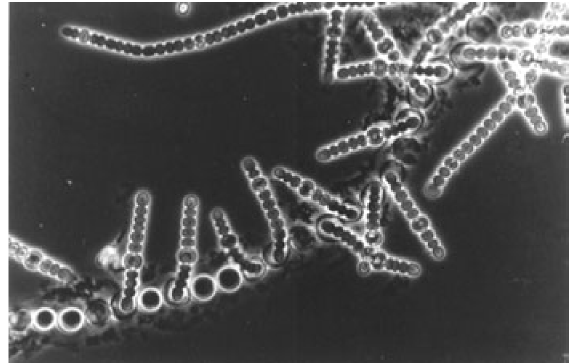

Fig. 45. Phase contrast photomicrograph of a filament of germinated akinetes of *Anabaena*. Short germlings, each containing a heterocyst, are emerging from many of these akinetes. Bar = 10 μm. (From Nichols and Adams, 1982.)

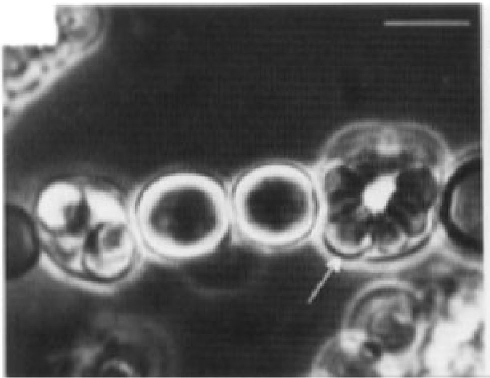

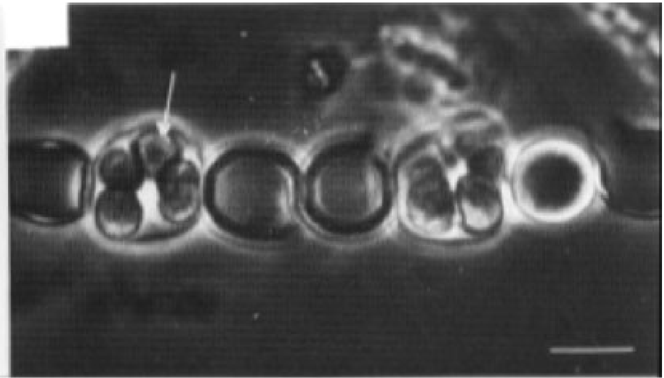

Fig. 46. Phase contrast photomicrographs of germinated akinetes of *Anabaena*. Here the strings of germlings, often containing heterocysts (arrows), have remained within the akinete coat. Bars = 10 μm. (From Nichols and Adams, 1982.)

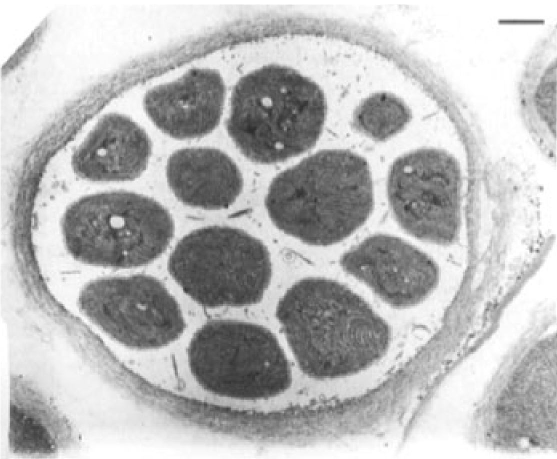

Fig. 47. Electron micrograph of a thin section of a *Dermocarpa* cell. The cell has undergone multiple fission and is filled with baeocytes, each of which is surrounded by layers of peptidoglycan and outer membrane. Bar = 1 μm. (From Waterbury and Stanier, 1978.)

too may contain periodic heterocysts (Fig. 46). Herdman (1987) has reviewed the properties of akinetes.

THE PLEUROCAPSALEAN *CYANOBACTERIA* The pleurocapsalean cyanobacteria characteristically reproduce by multiple fission. The initial cell, termed a "baeocyte," becomes covered by a thick, fibrous sheath and increases in size—in some species of *Dermocarpa* by as much as 1,000-fold. When the maximum size has been reached, the cell undergoes multiple fissions within the fibrous sheath (Fig. 47). The parental cell then ruptures, releasing the numerous small baeocytes. This is illustrated in Fig. 48, at 288 h. The baeocytes are phototactic and motile by gliding until the cells become covered by the fibrous sheath. At this point, they tend to become attached to a solid surface. Figure 49 is of a mass culture of *Dermocarpa*, showing the baeocytes and the parental cells either undivided or filled with baeocytes.

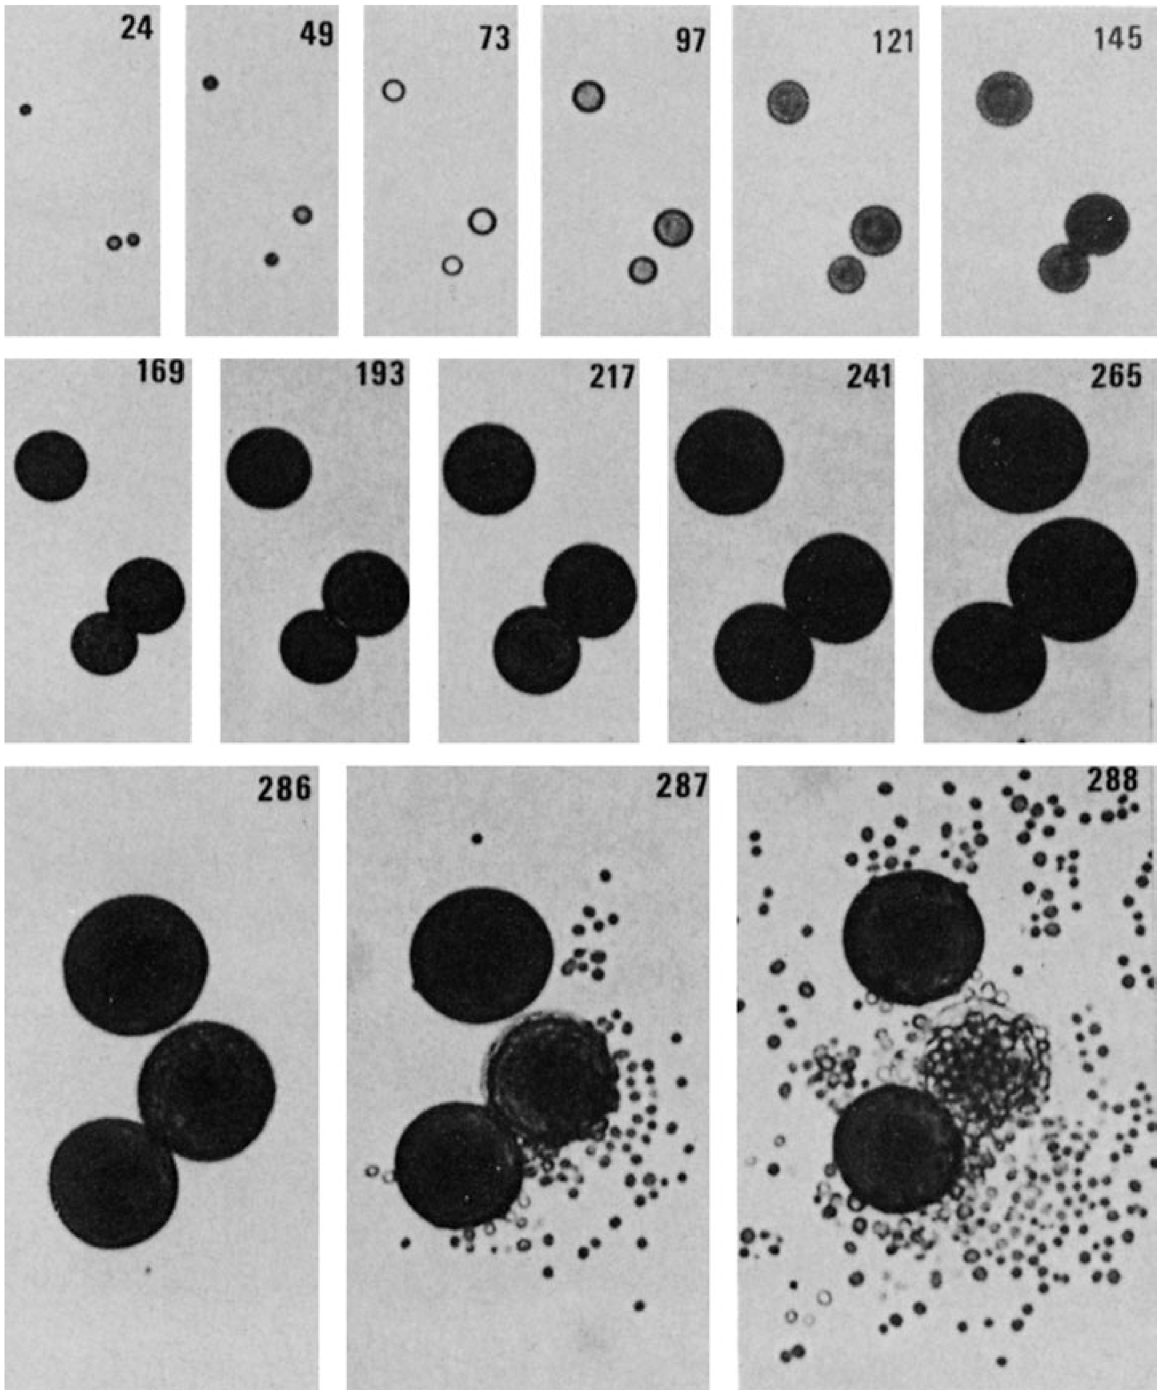

Fig. 48. Phase contrast photomicrographs illustrating the development of *Dermocarpa*. The number on each photo indicates the elapsed time in hours since the initial observation. (From Waterbury and Stanier, 1978.)

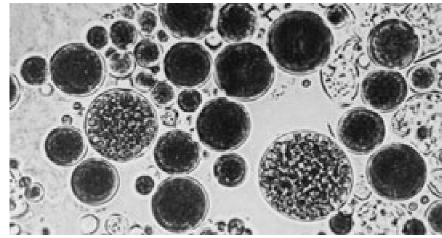

Fig. 49. Phase contrast photomicrograph of a mass culture of *Dermocarpa* illustrating the range of sizes of the spherical cells that either have not yet undergone fission or are filled with baeocytes. (From Waterbury and Stanier, 1978.)

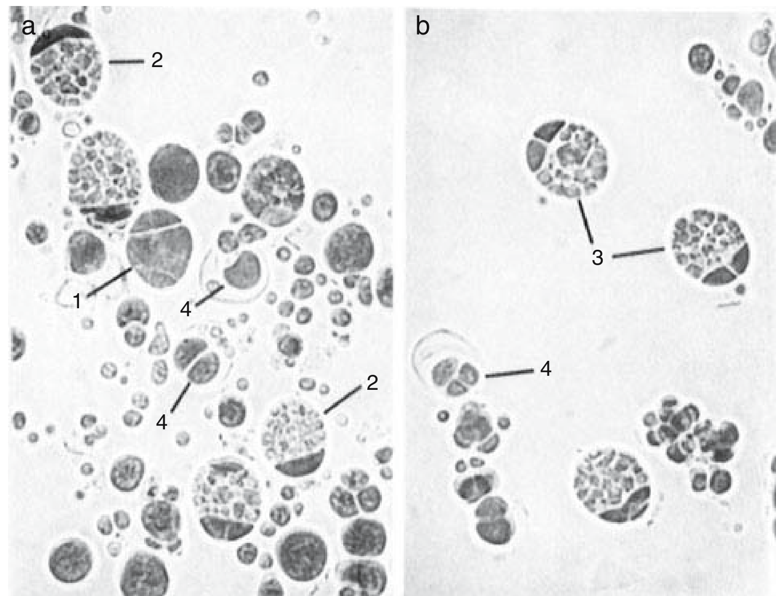

Fig. 50. Phase contrast photomicrographs a) and b) of *Dermocarpella* illustrating the various stages of division: 1) a cell that has just undergone transverse fission to form a small basal and a large apical cell; 2) individuals containing a single basal cell and an apical cell that has completed multiple fission; and 4) individuals in which baeocytes have been released from the apical cell, revealing the parental wall layer. (From Waterbury and Stanier, 1978.)

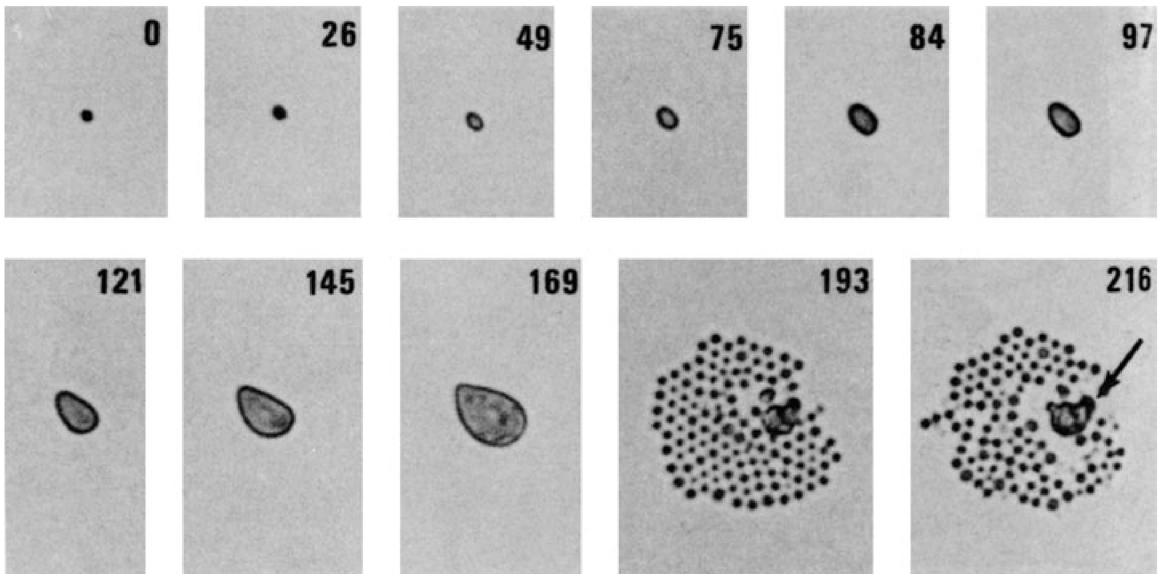

Fig. 51. Phase contrast photomicrograph of the growth pattern of *Dermocarpella*, beginning with a single baeocyte. The cell undergoes asymmetric enlargement, leading to a large ovoid cell, which goes through a binary fission, followed by multiple fissions. The arrow points to the basal cell remaining after baeocyte release. The numbers refer to the hours elapsed after the initial observation. (From Waterbury and Stanier, 1978.)

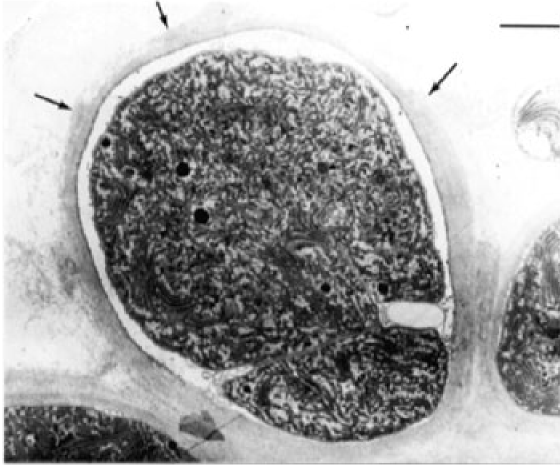

Fig. 52. Electron photomicrograph of a thin section of *Dermocarpella* at an early stage of fission. The cell has just completed binary fission, separating the apical cell (arrows) from the basal cell. Bar = 1 µm. (From Waterbury and Stanier, 1978.)

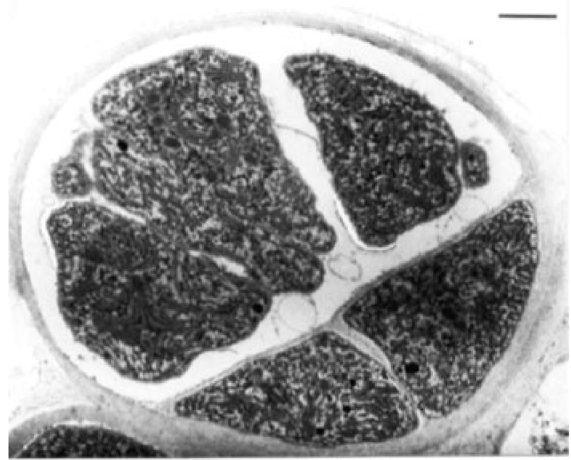

Fig. 53. Electron photomicrograph of a thin section of *Dermocarpella* at a later stage of fission. The basal cell has undergone a second binary fission, while the apical cell has begun its process of multiple fission. Note that the basal cells are beginning to be surrounded by the newly synthesized outer layer. Bar = 1 µm. (From Waterbury and Stanier, 1978.)

An interesting variation of this theme is manifested by the genus *Dermocarpella*. A mass culture of *Dermocarpella* is shown in Fig. 50. Figure 51 illustrates the sequence of events starting from a single baeocyte. The baeocyte enlarges, becomes ovoid and pyriform, and eventually releases its baeocytes; the structure that remains retains some of its cellular material. The series of electron photomicrographs in Figs. 52–54 illustrate the sequence of events as follows: The cell undergoes an asymmetric division, the larger daughter cell undergoing subsequent divisions to form the baeocytes and the smaller daughter becoming completely enclosed by the fibrous sheath. The larger portion of the cell ruptures, releasing the baeocytes, while the smaller portion presumably remains attached to its original site. This pattern is functionally similar to the life cycle of *Caulobacter*, with one of the asymmetric daughter cells remaining attached to its site and continuing to produce progeny, while the released, motile daughter cell(s) are free to seek a new site for attachment and growth. A schematic (Fig. 55) summarizes the life cycles of the pleurocapsalean cyanobacteria. This admirable work, begun in the laboratory of the late Roger Stanier, has been continued by John Waterbury at the Woods Hole Oceanographic Institute.

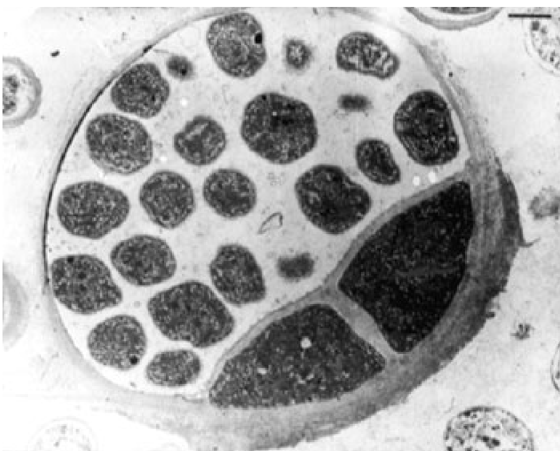

Fig. 54. Electron photomicrograph of a thin section of *Dermocarpella* at a terminal stage of fission. The cell is filled with baeocytes ready to be released. Bar = 1 µm. (From Waterbury and Stanier, 1978.)

Applications and Conclusion

The relationship between prokaryotic life cycles and the production of valuable secondary metabolites is well established, yet only a tiny fraction of these sorts of organisms have been explored for their ability to produce antibiotics. Furthermore, if we are truly serious in our attempts to determine the effects of our additions to or our manipulations of our environment, the effects on life cycles as well as on growth must be determined. Finally, and perhaps most importantly, one may justify an interest in prokaryotic life cycles solely on the ground that locked within them there is a vast array of undiscovered biological secrets. The developmental processes of differentiation and morphogenesis are far from being fully understood. And until we have a clearer picture of the nature and regulation of

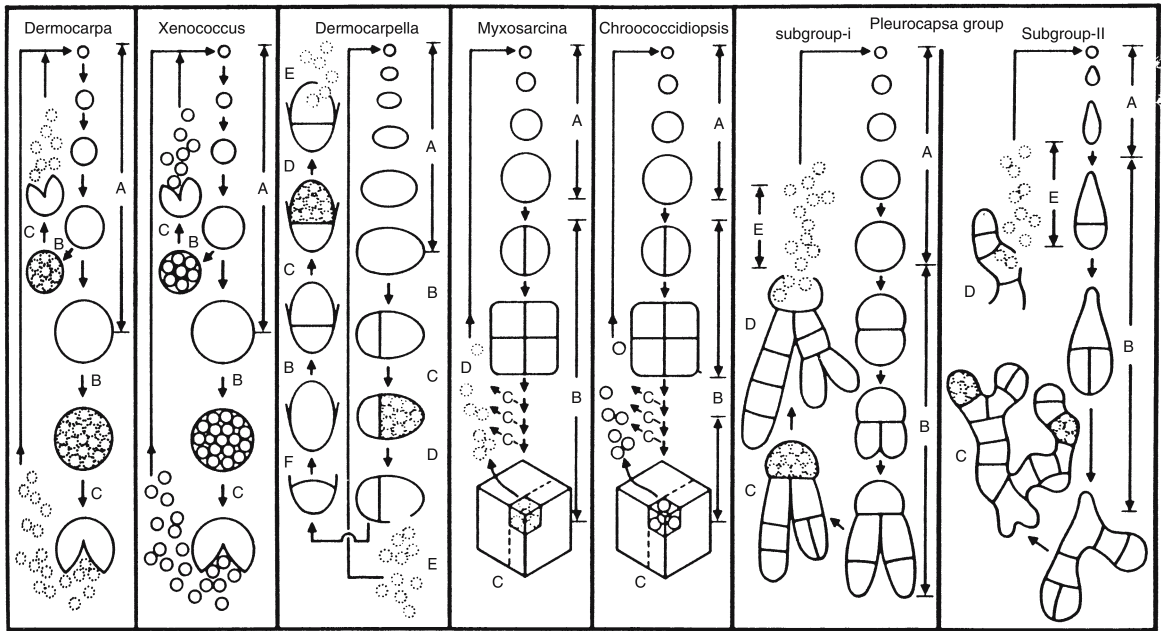

Fig. 55. Diagrammatic comparison of the pleurocapsalean life cycles. (From Waterbury and Stanier, 1978.)

life cycles, we will not fully understand the nature of the complex and delicate interactions between an organism and its environment.

CHAPTER 1.7

Life at High Temperatures

RAINER JAENICKE AND REINHARD STERNER

Introduction

In contrast to the simplistic definition of life as the quality that distinguishes a vital and functional being from a dead body, present-day biological sciences are mechanistically oriented, i.e., cells and their inventory are functionally determined by the nonvitalist principle that living matter is composed of chemical substances obeying the fundamental laws of physics. Any biological function, including ecological adaptation, differentiation and behavior, can be described in terms of the structures of those substances and the reactions that they undergo. However, one apparent difference between the life sciences on the one hand, and physics or chemistry on the other, deserves mentioning: Physics and chemistry study the unchanging properties of matter and energy, while the subject matter of biology (presently known organisms) is evolving, i.e., includes only a subset that has managed to produce descendents under the changing physical conditions of the biosphere.

Within the framework of biology and physical biochemistry, life refers to cellular organisms whose characteristics are 1) the capacity for metabolism (energy transformation), 2) growth, 3) response to stimuli, and 4) reproduction. Their constituent building blocks comprise a relatively small number of complex biomolecules (proteins, nucleic acids, carbohydrates and lipids), with the first two serving as substrates for the process of evolution. Evolution occurs because natural selection favors, among all the combinations available, those individuals whose characteristics increase their reproduction in a particular environment. At this point the physical or chemical conditions of the environment come into the play. As a consequence of the stochastic mechanism of "successful adaptation" to changing environmental conditions, all organisms are phylogenetically related to one another; in addition, they share most of the basic biochemical processes involved in replication, transcription, and translation, and in the basic reactions governing metabolic and energy-transfer pathways. Thus, fundamental biochemical and biophysical problems may be studied in whatever organism is practical or convenient. In the context of the present chapter, the specific properties of biomolecules from thermophilic microorganisms may provide us with a deeper understanding of general mechanisms underlying differences in the stability of proteins, nucleic acids and lipids, as well as in their metabolic turnover.

Dedicated to the memory of Professor John T. Edsall (3 November 1902–12 June 2002), one of the founders of physical biochemistry: scientist, teacher and mentor.

Adaptation to Extremes of Physical Conditions

Among the three alternative responses (avoidance, compensation or detoxification, and mutative adaptation) of microorganisms to extreme physical conditions, only mutative adaptation can cope with high temperature and high hydrostatic pressure, simply because cells in their natural aqueous environment are isothermic and isobaric (Jaenicke, 1981; Jaenicke, 1990). At this point, we include high pressure as a second variable because in many cases the term "environmental extremes" refers to a whole set of factors, e.g., high pressure and low or high temperature in deep sea hydrothermal vents (Somero, 1992; Kelley et al., 2001), or low pH and high temperature in acid solfataras (Brock, 1986; Stetter, 1996; Stetter, 1999). In addition, physicochemical parameters may have an indirect effect on an organism, e.g., temperature effects on the solubility of gases or on the viscosity and ionization of the aqueous medium. In such cases, in vitro experiments can easily compensate for such perturbations, this way eliminating indirect effects.

Considering mutative adaptation to extreme conditions, it is obvious that to grow and reproduce, the whole inventory of an extremophile needs to be adapted; fitness to survive in the

competitive situation of a given environment is defined by the least stable constituent of a species. In the context of thermophilic adaptation, the example of temperature-sensitive point mutants stresses this argument.

High temperature can be defined as the upper temperature range in which mesophilic organisms do not survive while specifically adapted hyperthermophilic organisms grow and multiply, not simply tolerating the high temperature but requiring it as their standard physiological condition. Commonly, species diversity in extreme environments is distinct from that in mesophilic environments, and therefore may be used as a criterion for extremophilism. In extreme environments (with low species diversity) often whole taxonomic groups are missing. For example, in saline and thermal lakes, as well as in hydrothermal vents, there are no vascular plants or vertebrates; in the most extreme high-temperature environments, only prokaryotic microorganisms have been discovered so far. Here, the low species diversity may sometimes be limited by extreme conditions to a few or even one species (Brock, 1978). In analyzing this phenomenon, we may ask how and at which level the extreme environment interferes with the normal growth of mesophilic organisms; in turn, to discover the essential characteristics of thermophiles, studying the adaptive mechanisms decelerating, or even inhibiting the growth of thermophiles at suboptimal temperature seems most promising. In the following, no strict distinction between thermophiles and hyperthermophiles will be made, because the limits are not well defined. Commonly, the temperature boundary of thermophiles is ca. 60°C, while hyperthermophiles show optimal growth temperatures of 80°C or above. Both estimates refer to growth, not survival. Needless to say, many bacteria, especially those capable of forming endospores, can tolerate temperatures much higher than those needed for optimal growth. However, it is the temperature range over which a microorganism is able to maintain growth and proliferation that is essential for evolution. The temperature range in the biosphere reaches from –80°C (in the Arctic [to approximately 65°N latitude] and in the Antarctic) to +350°C near white or black smokers in deep-sea vents. The upper temperature limit that still allows growth and proliferation of microorganisms is difficult to determine because of the extreme in situ turbulence in volcanic areas of the ocean. Evidently, "black smoker" bacteria alleged to grow at 250°C and 265 bar are in fact merely the subject of Jules Verne phantasy (Bernhardt et al., 1984).

Pyrolobus fumarii may serve as a well-established example for bacterial life at the upper temperature limit of viability. Its physiological characteristics are: growth between 90 and 113°C, with an optimum at 106°C (1 hr doubling time at $pH_{opt} = 5.5$ and $[NaCl]_{opt} = 1.7\%$), no growth at 85 and 115°C (Blöchl et al., 1997). The recent new world record, a Pyrodictium- and Pyrobaculum-related "Strain 121" with a temperature of maximal growth at 121°C and a survival half-life of ~6 min at 130°C draws a new line (Kashefi and Lovley, 2003). However, considering the rise of T_{max} during the last 40 years (Cowan, 2004), it is obvious that there is a sigmoidal time course that extrapolates to the expected upper temperature limit of viability around 140°C. The physical reasons are twofold: (i) crucial biomolecules undergo hydrothermal decomposition and (ii) the energetic costs of repair and resynthesis become unsustainable (Bernhardt et al., 1984; White, 1984; Stetter, 1998; Jaenicke and Böhm, 1998; Jaenicke, 2000a).

Since water in its liquid state is a necessary requirement for biological function in terms of the above criteria, the freezing temperature of homogeneous nucleation (–40°C) defines the lower limit at which life can exist. Chill conditions in the aqueous cytosol can persist down to this temperature and even below (Franks et al., 1990). Commonly, freezing damages cells irreversibly. In contrast, dehydration, e.g., in seeds and other dormant states of cells and tissues, allows various forms of cryptobiosis. Generally speaking, these limits are based on 1) the effect of low temperatures on the weak interactions between biomolecules (especially on the self-organization of proteins and lipids) and 2) metabolic and/or protective regulation mechanisms involving compatible solutes and other forms of stress response. For details regarding cold tolerance, resistance, acclimation, adaptation and cryptobiosis, see Crow and Clegg (1978); Finegold (1986); Laws and Franks (1990); Carpenter et al. (1993); Graumann and Marahiel (1996); Marshall (1997); Thieringer et al. (1998); Phadtare et al. (1999); Cavicchioli et al. (2000); Zachariassen and Kristiansen (2000), and Clegg (2001).

Over the whole biologically relevant temperature range, from psychrophiles up to hyperthermophiles, it is essentially impossible to predict how temperature changes may affect viability. Considering the complexity of metabolic pathways, the kinetics of each single step in any linear or cyclic reaction sequence may become rate limiting, either by its own high activation energy or by product inhibition. As evolution has produced efficient coupling mechanisms whereby products of reactions become the substrates for subsequent reactions, temperature perturbation will necessarily lead to a decrease in coupling efficiency. This holds because the relative reaction rates are determined not only by the specific dif-

ferences in the temperature coefficients of ligand binding and enzyme turnover, but also by the stability of the cellular microcompartmentation, e.g., in multienzyme complexes and by a wide variety of transport processes (Franks, 1985–1990; Jaenicke, 1990).

Water

General Properties

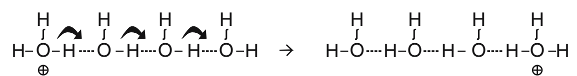
Because it is ubiquitous and the main component in the cell, water might be regarded as a mere space filler in living organisms. Actually, Thales of Miletus with more insight praised water as the basic element. As the various aspects of the physics, chemistry and biology of water have reached encyclopedic dimensions (Franks, 1975–1982; Franks, 1985–1990), this subject cannot be detailed to any great extent in this chapter. Instead, we will focus on liquid water and its significance in the context of the structure-function relation of biomolecules and their intrinsic and extrinsic stability.

Evidently, from a physico-chemical point of view, water is involved in biological processes as 1) medium in natural biotopes, 2) solvent within the cell, and 3) reactant or product in all biochemical and biophysical reactions. In the life cycle of the cell, this holds from the biosynthesis of proteins, nucleic acids, lipids, and carbohydrates to their degradation. Beyond this "housekeeping" part of life, water is of critical importance in the formation and maintenance of macromolecular and supermolecular structures; it determines not only the structure of the aforementioned biomolecules and their cellular compartmentation (e.g., in membranes), but also their function. For this reason, most cells have evolved mechanisms to control their water balance to avoid osmotic stress under extreme physical conditions (salt stress, desiccation, freezing, etc.; Hochachka and Somero, 1973).

When compared with other common solvents, liquid water exhibits unique properties (Table 1). Its anomalously high melting and boiling points, heat capacity, enthalpy of melting and vaporization, and its high surface tension, all indicate that the forces of attraction between molecules in the liquid state must be significant. As a consequence of this internal cohesion, the molecular mobility and fluidity of water remain unchanged, even if aqueous solutions are confined to subnanometer films or pores (Raviv et al., 2001). This property is attributable to the structure of the H_2O molecule itself (Fig. 1A): The O atom shares an electron pair with each of the two H atoms. Owing to the repulsion of the paired electrons by the unpaired ones, the H-O-H bond angle of 104.5° deviates from the tetrahedral arrangement (109.5°), which is a characteristic of ordinary hexagonal ice (Pauling and Hayward, 1964). As a consequence, the H_2O molecule possesses a high dipole moment (1.84 Debye) and a high dielectric constant, thus favoring dipole-dipole interactions involving hydrogen bonds (see below).

As shown in Fig. 1B and C, the water molecule has the ability to form four H-bonds, with two proton donor and two proton acceptor sites. The spatial disposition of these sites gives a clear visual conception of the geometry within each cluster.

To what extent does such ordered molecular arrangement persist in the liquid, bearing in mind that (compared to the covalent H-O-H bonds) the hydrogen bond is only a weak interaction? In this context, two observations are important: 1) As shown by the anomalously high conductivity of protons (= hydronium ions H_3O^+) in aqueous solution, the distinction between covalent and noncovalent bonds in a water cluster is blurred, since proton conductivity is "charge transfer without mass transport" according to



The reason is that in bulk water the transition of a bound proton to a neighboring free electron

Abbreviations: F_p, melting point; K_p, boiling point; ΔH_{vap}, specific enthalpy of vaporization; c_p, specific heat capacity; σ, surface tension at 25°C; ε, dielectric constant at 25°C; and η, viscosity. Data for σ, ε and η refer to 25°C, except for liquid NH_3, which was investigated at –34°C.

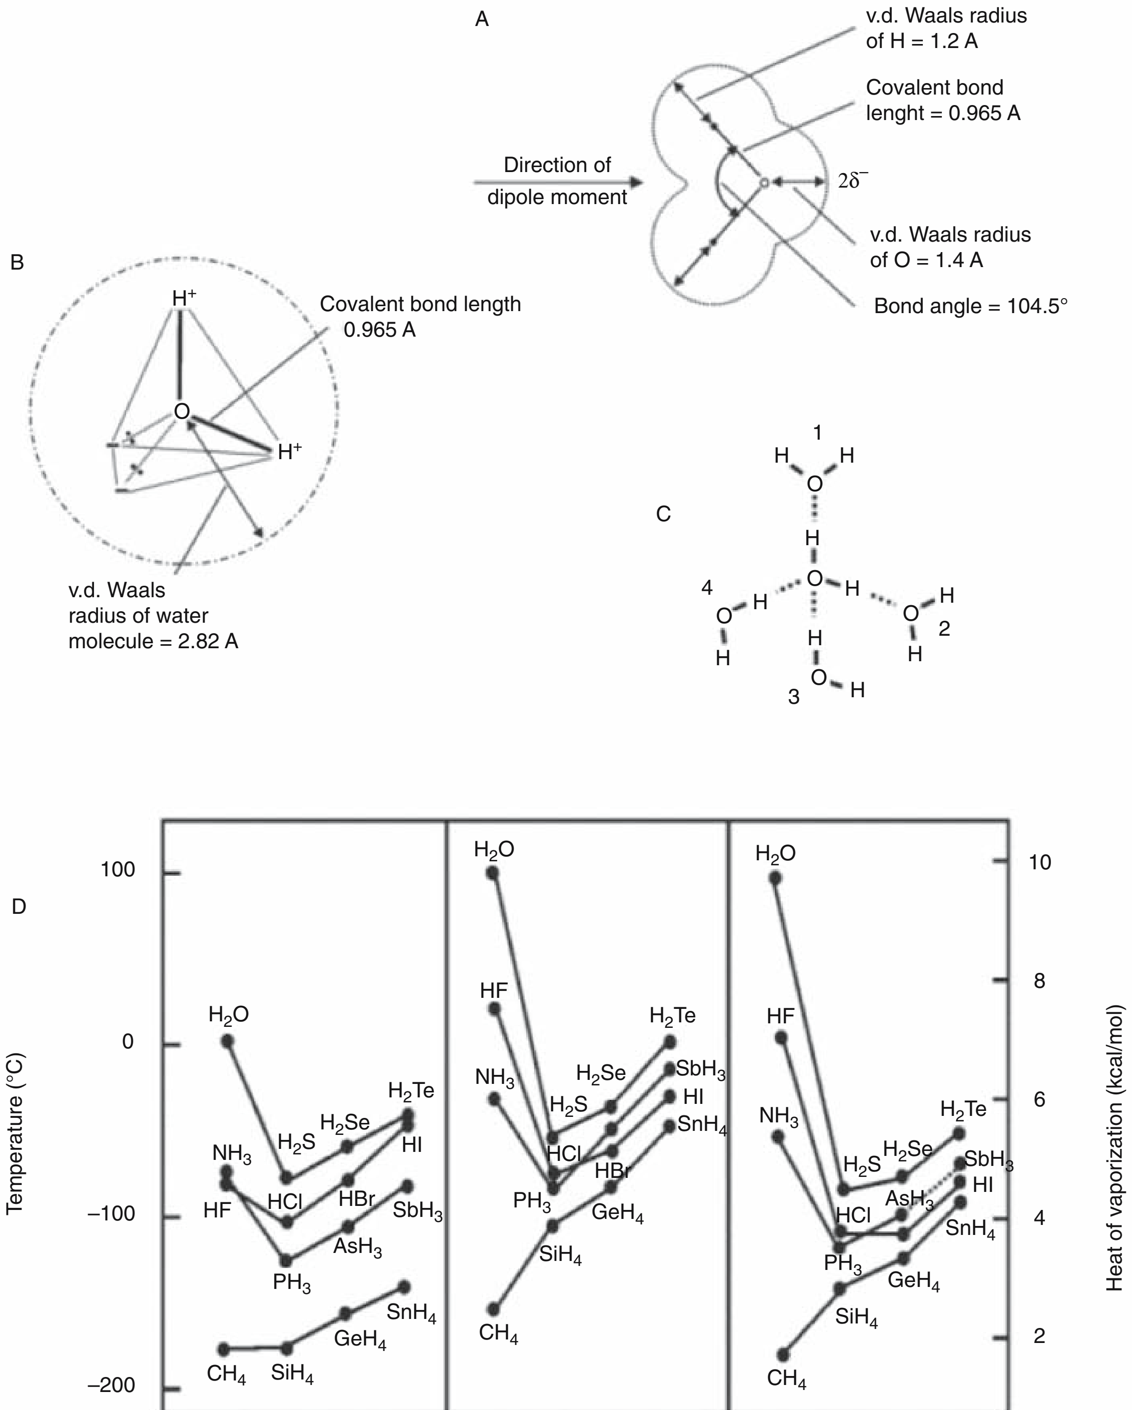

Fig. 1. The water molecule and its anomalies. A. Ball-and-stick crystallographic model giving the bond angles and lengths. B. Four-point-charge model with the oxygen atom placed in the center of a regular tetrahedron with vertices occupied by two positively charged hydrogen atoms and two negatively charged electron pairs. The distance of closest approach of two molecules (van der Waals radius) is 0.282 nm. C. Schematic view of the tetrahedral hydrogen bonding around a water molecule in ice; molecule (1) and (2) and the central H_2O molecule are in the plane of the paper, while (3) and (4) are above and behind it. D. Melting points (left), boiling points (middle) and heats of vaporization (right) of the isoelectronic sequences of hydrides in various rows of the periodic table. All three plots illustrate the effect of the anomalous interatomic forces between water molecules. Data from Pauling (1940), cf. Edsall and Wyman (1958).

pair in a hydrogen bond takes less than 10^{-12} second (<1 picosecond [ps]); thus, the lifetime of a given $(H_2O)_n$ arrangement is adequately described as a "flickering cluster." 2) The enthalpies of melting and vaporization of ice and water allow an estimate of H-bonding in liquid water to be given: close to the melting point, around 85% of the H-bonds in ice are still intact in the liquid state, whereas at the boiling point, single H_2O molecules prevail (Edsall and Wyman, 1958). Obviously, thermal energy opposes the structural forces so that physical parameters as well as solutes of various kinds are expected to easily perturb water structure. In turn, water is capable of modifying the intermolecular interactions between solute molecules as well as intramolecular interactions within each solute macromolecule. Thus, the biological significance of water stems from the intimate details of the compromise between water-water and water-solute interactions; the quantitative treatment of these interactions in terms of potential functions and activation profiles in the given multicomponent system is presently not feasible.

Temperature Dependence

As taken from its pressure/temperature (p/T) phase diagram over the whole biologically relevant range of hydrostatic pressure (<110 MPa, 1.1 kbar ~ 1100 atm), water either is in its liquid state or is hexagonal phase-I ice. Owing to its exceptionally low density, the latter shows a decrease of its freezing point with increasing pressure. Over the whole p/T range, there is no significant effect on the clustering of water molecules: evidently, pressure alone does not break H-bonds (Groß and Jaenicke, 1994). Focusing on isobaric conditions at atmospheric pressure, Table 2 summarizes the change of some important physical properties of water over the temperature range between –25 and 100°C, with +25°C representing the common seasonal temperature in the natural environment of mesophilic species. It is obvious that the temperature dependences are not linear but become more pronounced at low temperatures. In fact, many physical properties of water appear to diverge at –45°C (Franks, 1985; Franks et al., 1990).

Apart from the temperature effects on water structure in terms of cluster size and water-solute interactions, from the biochemical point of view, the most relevant change that takes place at varying temperature refers to the changed dissociation of water into H^+ and OH^-, described by the equilibrium constant K_w or its negative logarithm pK_w. In an aqueous environment, the solvent acts as conjugate acid or base, and any change in K_w or pK_w will produce changes in the respective dissociation constants K_d or pK-values of acids and bases that define ionization equilibria in solution. As both H^+ and OH^- are involved in most cellular processes (condensation, hydrolysis, reduction/oxidation, and membrane transport), it is likely that the large decrease in K_w with increasing temperature will affect equilibrium and kinetic processes. With increasing temperature, the dissociation of water increases, i.e., pK_w decreases. Most biopolymers are polyelectrolytes, but the pK values of their ionizable groups do not necessarily show the same temperature dependence observed for pK_w. Therefore, both their net charge and the state of ionization of crucial functional groups will change with temperature.

Table 2. Physical properties of liquid water at varying temperature.

	–25°C	+25°C	100°C
Density ($g{\cdot}cm^{-3}$)	0.987	0.996	0.958
Heat capacity C_p ($J{\cdot}[mol{\cdot}K]^{-1}$)	80	75	76
Isothermal compressibility ($10^6 MPa^{-1}$)	720	440	490
Hypersonic sound velocity ($m{\cdot}s^{-1}$)	1220	1480	1540
Dielectric constant	102	79	65
Self-diffusion coefficient ($10^5{\cdot}cm^2{\cdot}s^{-1}$)	0.32	2.2	8.4
Viscosity (mPa·s)	6.5	0.89	0.28
pKw[a]	17.3	14.0	12.3

[a]Refers to the changed dissociation of water into H^+ and OH^- at varying temperature.Data taken from the first volume of Franks (1975).

Thus, their conformational stabilities and biological activities may be affected in a complex way because any such influences would presumably be compounded by changes in the dielectric properties of the solvent, especially in structures with high charge density such as hyperthermophilic proteins, nucleotides and sulfated polysaccharides.

Hydration

The common knowledge that living cells and tissues contain around 70% water means that all cellular components interact with water; their native conformation results from the balance between intra- and intermolecular forces, on the one hand, and forces resulting from interactions with the aqueous solvent, on the other. Since all major biomolecules and water have the strongly polar hydroxyl group in common, it is obvious that what was called "clustering" is not restricted to H_2O, but also holds for proteins, nucleic acids, carbohydrates and fatty acids and their constituents. Here, from the energetic point of view, the stabilizing effect of H-bond formation within a biomolecule is expected to be marginal, because

most of the energy gained by forming the new "stabilizing bond" has to be paid by the breaking of a pre-existing solute-water bond. Evidently, multiple H-bonds in cooperative units such as α-helices or strands of nucleic acids, as well as additional contributions (e.g., from hydrophobic constituents) may accumulate to reach a high energy of stabilization, frequently referred to as "conformational energy" (Kauzmann, 1959; Franks, 1975–1982; Franks,1985–1990; Dill, 1990; Jaenicke, 1991b; Pace et al., 1996).

In the case of carbohydrates and fatty acids, the dominance of the polar hydroxyl and carboxyl groups is evident. They are responsible for the high solubility of sugars and other oligo- and polyhydroxy compounds as well as uronic acids, *N*-acetyl glucosamine, etc. (Suggett, 1975; Franks and Grigera, 1990). Conjugated with proteins, they allow the solubility and stability properties of their partner molecules to be modified (Kern et al., 1992; Kern et al., 1993). The net result of the aqueous environment for proteins is the protection of the nonpolar polypeptide core from the polar solvent. In nucleic acids, the situation is more complex: Here, secondary- and tertiary-structure formation is the result of an equilibrium between 1) electrostatic repulsion of the negatively charged phosphate groups along the linear polyelectrolyte, 2) stacking interactions and hydrogen bonding between the nucleotide bases, and 3) the conformational energy of the sugar-phosphate backbone. In its preferred conformation, the two polynucleotide strands in a duplex expose their deprotonated phosphates to the dielectric screening by the solvent, this way promoting the stacked arrangement of adjacent bases. As a result, a hydrophobic core is created in which H-bonds between the bases as well as additional sugar-base and sugar-sugar interactions are favored. The aqueous solvent contributes to the stability by 1) screening the charges of the phosphates, 2) hydrogen bonding to the polar exocyclic atoms of the bases, and 3) influencing the conformations of nucleotide constituents with methyl groups via nonpolar interactions (see below). Besides, because of the periodicity of the helical conformations, local binding sites of firmly bound structural water and linear arrangements of "bridges" of water molecules (involving nucleic acid polar atoms) can lead to favored structural arrangements with high conformational stability (Saenger, 1984; Westhof and Beveridge, 1990).

In spite of the well-established fact that the aqueous solvent is essential in accomplishing and maintaining the native state of biopolymers, so far theoretical treatments involving either distribution functions of the various intra- and intermolecular increments of stabilization, or energy functions aimed at structural parameters of hydration have been of limited success. On the other hand, a wealth of experimental data has been accumulated applying a wide variety of techniques: X-ray and neutron diffraction, hydrogen-deuterium exchange, Raman, infrared (IR) and nuclear magnetic resonance (NMR) spectroscopy, sorption/desorption of water vapor, calorimetry (including heat capacity calorimetry), dilatometry, sedimentation analysis, viscometry and other hydrodynamic methods. The reason why all of them "gave a better view of the experimenters' interests than of water structure" (G.A. Jeffrey) is that there is no clear definition of "hydration" (or "solvation" in general); in addition, the problem of how to separate the contributions of the solute from the background of the solvent and from potential conformational effects in a highly dynamic system is still unresolved.

Considering the various experimental approaches, the most detailed information is expected from high-resolution X-ray data and solution NMR (Westhof and Beveridge, 1990; Otting et al., 1991; Frey, 1993; Goodfellow et al., 1994). Comparing the results, it is important to note that in the crystalline state, lattice forces may affect the number and position of spatially well-defined water molecules, so that in different crystal forms not all binding sites are conserved (Zhang and Matthews, 1994). NMR measurements allow two qualitatively different types of hydration sites to be distinguished: 1) a small number of interior water molecules (with residence times of 10^{-2}–10^{-8} s and X-ray coordinates in the crystal) and 2) surface hydration (with residence times $<10^{-9}$ s, not necessarily fixed in the crystal structure; Otting et al., 1991). How the latter type of hydration compares to the hydrodynamically relevant bound water is still unresolved. Regarding hydration/dehydration at elevated temperature, phase separation and neutron scattering measurements have been applied mainly to quantify macromolecular interactions, especially in protein mixtures. Available data are rudimentary and far from being understood in quantitative terms (Benedek, 1997; Tardieu et al., 1999; Jaenicke and Slingsby, 2001). In qualitative terms, at this point, theoretical approaches are promising in interpreting available experimental data: Using the RNA duplex $r(CpG)_{12}$ as a structurally well-defined model (Conte et al., 1996; Gyi et al., 1998), molecular dynamics simulations at $5 \rightarrow 40°C$ gave evidence for a significant decrease in the residence time of water molecules and potassium ions bound in the first coordination sphere of the duplexes, indicating decreased order in the solvent around the solute with increasing temperature (Auffinger and Westhof, 2002; E. Westhof, personal communication). In general, unfolding and/or aggregation of

the solute upon melting lead to a drastic further release of water (Jaenicke, 1971; Lauffer, 1975; Jaenicke and Seckler, 1997).

The present knowledge of the role of water in connection with the stability and activity of biomolecules may be summarized as follows:

1) *Dielectric constant (ε)*. The formation and maintenance of cellular components occur in the presence of excess water; thus, the weak interactions responsible for their various functions are governed by the energetics of solvated partners in a strong dielectric, dielectric (~80), not by interactions in vacuo (= 1) (Dill, 1990).

2) *Temperature effects on biomolecules and water*. High temperatures alter the energetic properties (e.g., vibrational modes) of biomolecules in their aqueous solvent, which itself shows a strong temperature-dependence in its interaction parameters (cf. Table 2); both levels are intertwined in a complex way.

3) *Hofmeister effects*. In the case of high charge densities on the surface of polyelectrolytes, as well as in the presence of high salt concentrations (e.g., in halophiles), electrostatics are complicated by the clustering of water around the charged groups and by the competition of (counter-)ions for their own water of hydration (Jaenicke, 1991b). At this point, the fundamental laws of electrochemistry have to consider the specific effects of the size, charge and hydration of each individual electrolyte, which taken together determine the solubility of polyelectrolytes (salting-in and salting-out effects) and many other physicochemical and biological phenomena. The immediate cause of the "Hofmeister series of cations and anions" is the differences in hydration attributable to the intensities of the electrostatic field around each specific ion (von Hippel and Schleich, 1969). The "Hofmeister series" was first reported by Hofmeister (1888) for the coagulation of lyophilic colloids, and later for many other physical, chemical and biological phenomena (Edsall and Wyman, 1958). Ordering cations and anions according to their capacity to promote the solubility of neutral and alkaline proteins, the following two series are observed: $Li^+ < Na^+ < K^+ < NH_4^+ < Mg^{2+}$ and $SO_4^{2-} < PO_4^{3-} < CH_3COO^- < Citrate^{3-} < Cl^- < ClO_4^- < Br^- < I^- < SCN^-$. The solubilizing or precipitating effects can be explained in terms of the competition for water between a polyelectrolyte (here the protein) and excess electrolyte in the solvent (Collins and Washabaugh, 1985; Baldwin, 1996; Jaenicke and Seckler, 1997). One important Hofmeister effect is that guanidine denaturation depends on the anion. While guanidinium sulfate ($[Gdm]_2SO_4$) has no denaturing effects, GdmCl is a strong denaturant and GdmSCN is the strongest chaotropic agent.

4) *Volume effects of solutes*. Considering the "structure-making effects" of biomolecules in water, peripheral charges and nonpolar groups exposed to the aqueous solvent show an anomalous increase in solvent density (decrease in volume), "electrostriction" in the case of ions and "iceberg formation" in the case of exposed nonpolar groups (Kauzmann, 1959; Jaenicke, 1981; Groß and Jaenicke, 1994).

5) *"Hydration numbers."* Attempts to quantify both the hydrophobicity and hydration of amino acid residues can be summarized by the following series (with hydration estimated by the number of moles of H_2O per mole of amino acid residue in parenthesis): Phe (0); Cys, Gly, Ile, Leu, Met, and Val (1); Ala (1.5); Arg^+, Pro, and Tyr (3); His^+, hydroxyproline (4); Lys^+ (4.5); Asp^- (6); Glu^-, Tyr^- (7.5) (Kuntz, 1971; Kuntz and Kauzmann, 1974; Kyte and Doolittle, 1982).

6) *Types of "bound water."* In comparing tabulated hydration data from X-ray crystallography, NMR (see above), and thermodynamic and hydrodynamic measurements, it becomes clear that different experimental approaches "see different types of bound water molecules." Most of the respective terms are self-explanatory; since space does not permit a detailed discussion, key references may suffice: Structural hydration (the number and positions are determined from X-ray and NMR coordinates), hydrodynamic hydration (the amount of "hydration shell" migrating with the solute is determined in sedimentation/diffusion experiments and viscometry), low-temperature hydration (estimated, e.g., as "non-freezable water"), and preferential hydration (measured by thermodynamic methods in the presence of low-molecular weight additives competing with the macromolecular component for its hydration) (Tanford, 1961; Kuntz and Kauzmann, 1974; Franks, 1975–1982; Franks, 1985–1990; Franks and Eagland, 1975; Eisenberg, 1976; Timasheff, 1995; Timasheff and Arakawa, 1997).

In the case of proteins, quantitative data vary between 0.25 and 0.40 g of H_2O per g of protein. A rough estimate of the bound water surrounding the protein whose properties differ from those of the bulk water, can be obtained as the sum of the hydration numbers of the constituent amino acids (see 5 above); this holds despite the fact that part of the amino acid residues are buried in the protein interior and not accessible to the solvent.

7) *Dehydration causes denaturation*. If the structure-function relation of lysozyme is taken as a model, it becomes clear that dehydration below the limiting value of 0.25 g of H_2O per g of protein causes reversible deactivation paralleled by drastic changes of all available physical characteristics (Careri et al., 1980).

8) *Residual hydration of proteins*. Complete dehydration (e.g., by freeze-drying or high-temperature dry-weight determination) cannot be accomplished. Even dry biopolymers still contain residual water of the order of 5–10%; before the dry state is reached, chemical modification (such as deamidation) occurs.

9) *X-ray structures yield biologically relevant information*. Biopolymer crystals investigated by X-ray crystallography contain ca. 50% aqueous mother liquor filling the space between the single molecules; thus in the crystal, there is sufficient water available to guarantee complete hydration, i.e., native-like conditions. From this we may conclude that three-dimensional (3D) structures based on crystallographic data are biologically relevant.

10) *Structure determination at high temperature*. Regarding the structural analysis of macromolecular components from thermophiles and hyperthermophiles at elevated temperature, only sparse high resolution data have been reported. It would be desirable to develop the necessary methods to bridge this gap in order to gain insight into the correlation of stability and molecular flexibility up to the temperature limit of viability.

Stability of Biomolecules

Intrinsic vs. Extrinsic Stability

The physical limits of life at high temperature are defined by the temperature dependence of the interatomic forces involved in the covalent and noncovalent stabilization of the molecular inventory of the cell. Except for membranes, the lipids of which often are anomalous phytanyl-ethers instead of fatty acid esters (see below), the inventory of thermophilic and hyperthermophilic cells consists of the same building blocks as those found in mesophilic cells. The occurrence of covalent modifications such as methylation and glycosylation of biopolymers from hyperthermophiles has been frequently reported; whether they are biologically relevant molecular strategies of stabilization is still unclear (Vieille and Zeikus, 2001; see sections on Adaptive Stabilization Mechanisms of Nucleic Acids and Adaptive Stabilization Mechanisms of Lipids and Membranes in this Chapter).

Mutational Adaptation

Given the conventional set of canonical nucleic acid bases and amino acids, the general response to evolutionary stress is the selection for beneficial mutations on the genome level. In the case of thermophilic adaptation, these mutations lead to an enhancement of the intrinsic stability of the protein inventory.

At high temperature, the integrity of nucleic acids is threatened by strand separation and chemical damage to the nucleotide chains. Mechanisms providing intrinsic stabilization comprise an increase in G+C content of tRNAs and rRNAs and posttranscriptional modification. Extrinsic stabilization may be provided by specific salts or histone-like proteins, and by efficient repair systems (Grogan, 1998; di Ruggiero et al., 1999; for details, see section on Adaptive Stabilization Mechanisms of Nucleic Acids in this Chapter).

Considering proteins, the thermal stabilities of the orthologous homologs are found to be positively correlated with the maximal environmental temperature (see also Alexandrov, 1969; Hochachka and Somero, 1984, and Dahlhoff and Somero, 1993; Fig. 2).

Thus, the balance between stabilizing and destabilizing forces is adjusted during evolution such that homologous proteins from different species retain similar conformational stabilities at their respective physiological temperatures (Jaenicke, 1991b; Somero, 1995; Somero, 2000). Generally, both thermophilic and hyperthermophilic proteins exhibit high intrinsic stabilities and long denaturation half-lives of the order of hours close to the boiling point of water (Jaenicke et al., 1996; Daniel, 2000; Jaenicke and Böhm, 2001). Basically, the natural amino acids would allow the formation of proteins with sta-

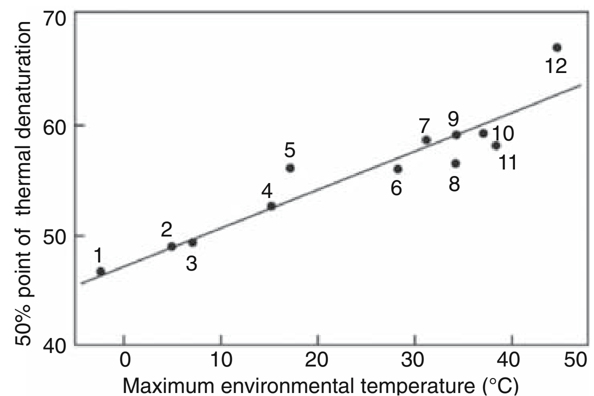

Fig. 2. The thermal stabilities of eye lens crystallins increase with the respective physiological temperatures of vertebrates. Coordinates refer to the 50% points of thermal denaturation and the adaptation temperatures of the following species: 1) *Pagothenia borchgrevinki* (Arctic fish); 2) *Coryphaenoides armatus* (deep-sea fish); 3) *Coryphaenoides rupestris* (deep-sea fish); 4) *Oncorhynchus mykiss* (rainbow trout); 5) *Cebidichthys violaceus* (tidepool fish); 6) *Rana muscosa* (frog); 7) *Alticus kirkii* (Red Sea fish); 8) *Rana erythraea* (frog); 9) *Gekko gekko* (lizard); 10) *Rattus norwegigus* (rat); 11) *Tropidurus hispidus* (reptile); and 12) *Dipssaurus dorsalis* (desert iguana). Data from McFall-Ngai and Horwith (1990).

bilities exceeding the magic upper temperature limit of ~115°C (de Grado, 1988; van den Burg et al., 1998). What constrains evolution for maximum thermal stability becomes obvious, keeping in mind that proteins are fundamentally multifunctional, combining the capacity to fold, serve a wide range of functions, and be degradable at the same time. As a consequence, protein evolution is a compromise between rigidity (stability) and flexibility (function, regulation, and turnover; Wetlaufer, 1980; Somero, 1995; Jaenicke, 2000a; Jaenicke, 2000b). At this point, it needs to be mentioned that the correlation between molecular flexibility and function (i.e., catalytic activity) is ambiguous and cannot be generalized because conformational stability is a global property, whereas the influence of flexibility on stability may be either global or local, as shown by kinetic unfolding experiments (Jaenicke, 1999; Bieri and Kiefhaber, 2000; Jaenicke and Lilie, 2000; Wright and Baldwin, 2000). The question of how local motions involved in the catalytic reaction are correlated with the fast anharmonic global dynamics, monitored spectroscopically or by X-ray analysis, is still open (Daniel et al., 1998, 1999). Comparing the Arrhenius activation energy and thermal stability of various enzymes, a new intrinsic thermal parameter, T_{eq}, was defined, that arises from the T-dependent equilibrium between the active and inactive enzyme at its true temperature optimum (Peterson et al., 2004). Beyond T_{opt}, the decrease in enzyme activity, induced by the T-dependent shift in the equilibrium, is up to two orders of magnitude greater than occurs through irreversible thermal denaturation. T_{eq} is central to the physiological adaptation of an enzyme to its environmental temperature, linking the molecular, physiological and environmental aspects of adaptation.

Disulfide Bonds

Disulfide bonds are known to be of utmost importance in stabilizing proteins such as hormones, plasma proteins or hydrolases and their inhibitors (Cecil and McPhie, 1959; Cecil, 1963; Friedman, 1973; Schulz and Schirmer, 1979; Fersht, 1998a; Branden and Tooze, 1999). Because the environment inside typical cells is reducing, cystine crosslinks are rarely found in intracellular proteins; in those exceptional cases where they are found, they usually exist transiently, playing roles in redox signaling or disulfide exchange, rather than serving to stabilize proteins, as they do outside the cell.

The suggestion that cystine might be essential in stabilizing cytosolic proteins in thermophiles was raised by a series of crystal structures of archaeal and bacterial proteins, e.g., elongation factor Ts from *Thermus thermophilus* (Jiang et al., 1996), TATA-box binding protein from Pyrococcus woesei (DeDecker et al., 1996), triosephosphate isomerase from *Thermotoga maritima* (Maes et al., 1999), adenylosuccinate lyase from *Pyrobaculum aerophilum* (Toth et al., 2000), ferric reductase from Archaeoglobus fulgidus (Chiu et al., 2001), and ferredoxin Fd1 from *Aquifex aeolicus* (Meyer et al., 2002). Based on this structural evidence, computational genomics and proteomics were applied to do a careful sequence-structure mapping study over the completely sequenced microbial genomes (Mallick et al., 2002). As a result it turned out that in the case of the intracellular proteins of certain hyperthermophilic archaea, especially the two crenarchaea *Pyrobaculum aerophilum* and *Aeropyrum pernix*, there is a clear preference for even numbers of cysteine residues that are mapped within disulfide bonding distance: More than 40% of the cysteine residues in *Pyrobaculum aerophilum* are predicted to be involved in disulfide bonds. Experimental findings support the computational results (T. O. Yeates, personal communication, 2002).

Stabilizing Additives and Molecular Chaperones

Apart from the intrinsic stabilization coming from contributions of intra- and intermolecular interactions within and between biomolecules, additional extrinsic stability increments may come from ligand binding, preferential solvation in the presence of high concentrations of compatible solutes, crowding and the action of molecular *chaperones*. Circumstantial evidence indicates that crowding effects within the living cell may extend the temperature range of stability significantly (Hochachka and Somero, 1973; Carpenter et al., 1993; Somero, 1995; Timasheff, 1995; Blöchl et al., 1997; Jaenicke, 2000a; Minton, 2000).

The discussion of intrinsic and extrinsic stability would be incomplete without mentioning molecular chaperones as accessory components involved in the stabilization of proteins at the borderline between self-organization and destruction. Functionally they are known to promote the long-term stability of proteins by regulating the kinetic partitioning of polypeptides between proper folding and association, on the one hand, and misfolding and subsequent aggregation or degradation, on the other (Jaenicke, 1987, 2004; Zettlmeissl et al., 1979; Goldberg et al., 1991; Kiefhaber et al., 1991; Jaenicke and Seckler, 1997). Using the primary meaning of the word, molecular chaperones avoid the "illegitimate interactions" between nascent or folding chains by keeping the level of aggregation-

competent polypeptide chains below a critical concentration, either by complex formation or by "iterative annealing," without becoming integral parts of the final native structure. The binding energy that drives the formation of the complex between the protein substrate and its chaperone may be used to rescue nascent or folding chains already on an off-pathway of proper folding (Beissinger and Buchner, 1998; Burston and Saibel, 1999; Jaenicke and Lilie, 2000; Leroux and Hartl, 2000; Walter and Buchner, 2002).

From their designation as "heat-shock proteins" (HSPs) (or "thermosomes" in the case of thermophilic archaea) one might expect that close to the limit of viability they would represent prototypes of proteins showing exorbitantly high intrinsic stability. However, as in the case of mesophiles, the term is a misnomer: heat-shock proteins are ubiquitous both in mesophiles and extremophiles, also under physiological conditions. Ubiquitous refers not only to the three phylogenetic domains, Eukarya, Bacteria and Archaea, but also to all the branches of the phylogenetic tree. In the case of (hyper-)thermophilic Archaea this means that all phyla, including the newly discovered nanoarchaeota (Huber et al., 2002) contain HSPs or thermosomes and other types of chaperones (Baross and Holden, 1996; Waters et al., 2003; Laksanalamai and Robb, 2004).

Considering the concise definition of molecular chaperones as "any protein that transiently interacts with and stabilizes an unstable conformer of another protein, facilitating its folding, assembly and interaction with other cellular components, as well as its intracellular transport or proteolytic degradation" (Leroux and Hartl, 2000), it is obvious that accessory proteins that assist protein folding, compartmentation and turnover, etc., must be of utmost importance in thermophiles. As a matter of fact, representatives of most chaperone families, Hsp100, Hsp90, Hsp70, Hsp60, Hsp40, GimC (prefoldin), and Hsp 16.5 (sHsp), have been isolated and studied in detail, in certain cases to the level of high-resolution 3D structures and systematic investigations of their structure-function relationship. From the physicochemical and functional point of view, they do not exhibit anomalous characteristics, except for differences in their quaternary structure and their ATP requirement. Space limits do not permit a detailed presentation of the rapidly growing field. Some aspects will be discussed in connection with the adaptive stabilization mechanisms of proteins. For reviews, see Fink and Goto (1997), Bukau (1999), Pain (2000), and Kiefhaber and Buchner (2004); and for special systems, Trent et al. (1991), Phipps et al. (1991), Trent (1996), Baross and Holden (1996), Trent et al. (1997), Andrä et al. (1998), Kim et al. (1998, 2003), Huber et al. (2002), and Laksanalamai and Robb (2004). At this point we focus our attention to only a few general observations that are connected with systematic, structural, cell biological and mechanistic aspects:

1. *Systematics*. The paradigm for chaperone-assisted protein folding has been the *group I* GroE system from *Escherichia coli*, which is generally found in bacteria and eukaryotic organelles of bacterial origin (Sigler et al., 1998; Hartl and Hayer-Hartl, 2002). The *group II* homologs in archaea (and the cytosol of eukaryotes) show a number of distinct features, as expected from the low sequence identity (<25%): Group I forms cages made up of seven-membered rings of Hsp60 subunits (as chaperone) and Hsp10 subunits (as co-chaperone), whereas *group II* consists of eight- or nine-membered hetero-oligomeric rings, with no general co-chaperone. The domain organization (equatorial ATPase domain, apical *recognition* domain and intermediate *connecting* domain) has been conserved between the two groups. However, in the "protrusion region" of the apical domain, significant differences have been discovered that allow the binding of the substrate protein without the help of the *group I* co-chaperone to be explained (Heller et al., 2004).

2. *Beyond systemaics: horizontal gene transfer*. As one would expect after the discovery of horizontal gene transfer, nature does not follow simple systematic rules. In the case of *group I* and *group II* chaperones, an archaeon has been found in which both types of HSPs, group I and group II, coexist. Inspecting the complete genomes of several species of the genus Methanocarcina, the first archaeal genomes were identified to contain both the GroEL/GroES (*group I*) and the thermosome/prefoldin (*group II*) genes. Both chaperones are coexpressed in the cytosol; under heat stress they are moderately induced. The GroE proteins show the structural features of their bacterial counterparts, whereas the thermosome contains three paralogous subunits (α, β and γ) which assemble at a molar ratio 2:1:1. As shown in vitro, the ATP- and ADP-dependent assembly reaction is regulated by the β subunit. The role of the two chaperones in one and the same cellular compartment with respect to substrate specificity and protein sorting from the ribosome to the proper chaperone machine is still enigmatic (Klunker et al., 2003; Figueiredo et al., 2004).

3. *Mechanism*. The functional significance of the structural flexibility ("plasticity") of proteins has been a well-established paradigm in the elucidation of enzyme mechanisms, self-assembly processes, molecular mechanics, etc. In the case of assisted protein folding, the molecular

machines nature has developed during evolution are absolutely unique: Binding a nascent or (re-)folding polypeptide chain via aggregation-competent hydrophobic core residues in a hydrophobic cage-like protein assembly, altering the hydrophobic surface of the cage into a hydrophilic one by closing the lid, and now allowing the secluded substrate polypeptide to find its energy minimum in the natural micro-environment sounds like a magician's trick, but that is what the thermosome manages to achieve (Gutsche et al., 1999; Bosch et al., 2000).

4. *Expression level*. The level of chaperone expression may vary over a wide range. In Pyrodictium occultum, a shift from 102 to 108°C has been reported to enhance the level of two bitoroidal hexadecameric ATPases of 56 and 59 kDa with optimal activity at 100°C to 80% of the total cytosolic protein concentration (Phipps et al., 1991; Baross and Holden, 1996). Similarly, electron micrographs of T-stressed *Sulfolobus shibatae* cells display a dense filamentous network of bitoroidal octodecamers, which suggests chaperone assemblies play a cytoscelet role in Archaea (Kagawa et al., 1995; Trent et al., 1997). On the other hand, the quantitative assessment of the role of the GroE system in protein folding in *Escherichia coli* suggested that there is sufficient GroEL to facilitate the folding of no more than 5% of all of cellular proteins within the cell (Lorimer, 1996); interestingly, overexpression of GroEL to high cellular levels in *Escherichia coli* does not inhibit cell growth (R. Rudolph, personal communication, 2004).

5. *Function of recombinant thermosomes*. The hyperthermophilic thermosomes from Pyrodictium occultum (*P.o.*) and Methanopyrus kandleri (M.k.) are members of the Hsp60 family. They form high-molecular-mass complexes, arranged in two rings of eight subunits each, stacked back to back, without Hsp10 as a co-chaperone. In *P.o.* two types of subunits (α and β) participate in the formation of the cage; they seem to alternate within each of the two rings. Overexpressing the two polypeptides separately and jointly in Escherichia coli yields authentic hexadecameric quaternary structures for all three-all-α, all-β and α+β. All three exhibit ATPase activity and bind denatured protein substrates, inhibiting their heat -aggregation. At temperatures up to 55°C, no release of renatured substrate was detectable. For technical reasons, experiments at physiological temperature were not feasible (Minuth et al., 1998). Switching to *M.k.* avoided the ambiguities caused by the hetero-polymeric quaternary structure of the *P.o.* thermosome. Strangely enough, its synthesis is not increased upon heat shock, and its ATPase activity depends on NH_4^+. The homo-hexadecameric recombinant protein is authentic and shows chaperone-like activity; again, no release of the substrate polypeptide chains is detectable at temperatures up to 60°C (Minuth et al., 1999).

6. *Structural studies at high temperature*. As taken from the thermosome example, collecting structural and functional data at the temperature limits of hyperthermophiles would be highly desirable. In this context, novel approaches have been developed. For example, in the case of the above mechanism of *group II* archaeal chaperones (see point 1) the functional details were deduced from differences between X-ray and solution-NMR data at varying temperature (Heller et al., 2004). Unfortunately, for both experimental approaches, presently data collection at temperatures close to or beyond the boiling point of water is impeded by crystallization problems and line broadening as well as signal overlap. In the case of NMR, using dipolar couplings allowed the loss of NOE information at high temperature to be compensated; on the other hand, assigning and separating single resonances of aromatic amino acids was facilitated by selective ^{19}F-labeling of Trp residues. Using the cold-shock protein (Csp) from *Thermotoga maritima* as a model, both methods were applied to extend structural studies into the physiological temperature regime. Taking the room-temperature structure as a reference, most significant alterations at high temperature occur in regions of the molecule that have been modeled as binding sites for single-stranded DNA, in agreement with the idea that *Tm*Csp plays a central role in the regulation of gene expression under cold-shock conditions (Jung et al., 2004). ^{19}F tryptophan labeling was used to study the folding of *Tm*Csp over a wide temperature range. In combination with stopped-flow experiments at lower temperatures, global line-shape analysis showed that the folding rate of *Tm*Csp closely resembles data collected for mesophilic Csps. However, the unfolding rate constant of *Tm*Csp is two orders of magnitude lower over the entire temperature range. Thus, stability differences are solely due to differences in the unfolding rates of the mesophilic and thermophilic proteins (Sterner and Liebl, 2001). A thermodynamic analysis points to an important role for entropic factors in the stabilization of *Tm*Csp relative to its mesophilic conterparts (Schuler et al., 2002).

7. *Small heat-shock proteins (sHSPs)*. sHSPs from thermophilic and hyperthermophilic organisms form multimeric complexes with (occasionally heterodisperse) molecular masses ranging from 200 kDa to more than 1 MDa. Although they show high diversity, the majority of acid sHSPs share amino acid sequence similarity with the vertebrate eye-lens α-crystallins; both groups are molecular chaperones (Jacob et al., 1993;

Jaenicke and Creighton, 1993). Presently available sparse structural data suggest that their monomeric structures share a common building-block structure (van Montfort et al., 1992). The mechanism of action seems to be defined by the individual quaternary structure; evidently, dissociation/association reactions play a role in the regulation of chaperone activity (Laksanalamai and Robb, 2004). In contrast to the acidic chaperones (IP~4.6), basic sHSPs (IP~9) are involved in nucleotide binding (Korber et al., 2000).

Measuring Thermodynamic Stability

The conventional introduction to the subject, with its emphasis on heat engines, is almost certain to convince the student that thermodynamics is sheer sophistry and unrelated to the real business of biochemistry. But an understanding of some of the ideas of thermodynamics is important to discover how molecules make organisms work (van Holde, 1985).

The thermodynamic stability, e.g., of nucleic acids or proteins, can be quantified by measuring the temperature- or denaturant-induced unfolding, excluding irreversible side-reactions such as chemical modifications or aggregation (Tanford, 1968; Tanford, 1970; Privalov, 1979; Jaenicke and Seckler, 1997). To illustrate the procedure, we assume an N U equilibrium transition of a monomeric globular protein from its native (N) to the denatured state (U). The free energy of conformational stability is the difference between the free energies of the unfolded and the folded states

$$\Delta G_{stab} = G_{unfolded} - G_{native} \quad (1)$$

as well as the Gibbs-Helmholtz equation

$$\Delta G_{stab} = \Delta H_{stab} - T\Delta S_{stab} \quad (2)$$

where T is the absolute temperature, and ΔH_{stab} and ΔS_{stab} are the enthalpy and entropy differences between the unfolded and the folded states

$$\Delta H_{stab} = H_{unfolded} - H_{native} \quad (3)$$

can be determined either directly from calorimetric experiments (ΔH_{cal}) or from a "van't Hoff plot," i.e., from the temperature dependence of the apparent equilibrium constant K of the transition

$$N \overset{K}{\Leftrightarrow} U \quad (4)$$

according to

$$\Delta H_{van't\ Hoff} = RT^2\, d(\ln K)/dT \quad (5)$$

where R is the gas constant. The "two-state assumption" underlying Eq. (4) can be tested by comparing the results of both approaches. If only N and U and no intermediates are populated in the N→U transition, ΔH_{cal} equals $\Delta H_{van't\ Hoff}$, otherwise $\Delta H_{cal}/\Delta H_{van't\ Hoff}$ is >1 (Privalov, 1979; Jaenicke, 1991b).

A further qualitative standard criterion to test the two-state assumption is to compare the denaturant-induced equilibrium transitions monitored by different spectral properties of a protein. If the unfolding profiles do not coincide, intermediates are present in significant amounts, and Eq (4) does not adequately describe the denaturation process (Pace and Scholtz, 1997). If Eq (4) is sufficient to describe the reaction, the thermodynamic stability of the protein can be calculated from the apparent equilibrium constant K according to

$$\Delta G_{stab} = -RT \ln K \quad (6)$$

Under physiological conditions, i.e., in water at constant pH, pressure and temperature (pH 7, 1 bar, 25°C), the change in Gibbs free energy as 1 mole of substrate is converted to 1 mole of product ([substrate] = [product] = 1 mole/liter) represents the standard Gibbs free energy change $\Delta G°'$. Given the high molecular mass of proteins and their relatively high partial volume, molar concentrations are experimentally inaccessible. In the case of simple first-order reactions such as Eq (4), this is irrelevant; in more complex reactions, to compare the stabilities of proteins, their free energies have to be normalized, e.g., to millimolar or micromolar concentrations (Dams and Jaenicke, 1999).

It is obvious that the above equilibrium constant K depends on the denaturation conditions, because in a given experiment different variables may be superimposed in the destabilization of a protein. For example, sometimes neither low pH nor chaotropic agents (urea or guanidinium chloride) alone are able to denature a protein. This holds especially for ultrastable proteins from hyperthermophiles, where most proteins only unfold beyond the boiling point of water; thus to shift the melting temperature (T_m) at which half of the protein is thermally unfolded down to a manageable range, low pH values or the addition of chaotropic agents are required. The measured ΔG_{stab} values at these nonphysiological solvent conditions have to be extrapolated to obtain ΔG_{stab} data at zero denaturant concentration; this allows the thermodynamic stabilities of different proteins, e.g., from mesophiles and hyperthermophiles, to be compared (Privalov, 1979; Pace, 1986; Pace and Scholtz, 1997; Pfeil, 1998).

Because of the significant temperature dependence of ΔH_{stab} and ΔS_{stab}, ΔG_{stab} versus T profiles observed for the thermal unfolding of proteins exhibit parabolic characteristics (Privalov, 1979; Schellman, 1997; Fig. 3A); their maxima cluster in a narrow range between 30 and 80 kJ/mol (7–20 kcal/mol; Fig. 3B); other modes of denaturation such as guanidinium chloride, urea

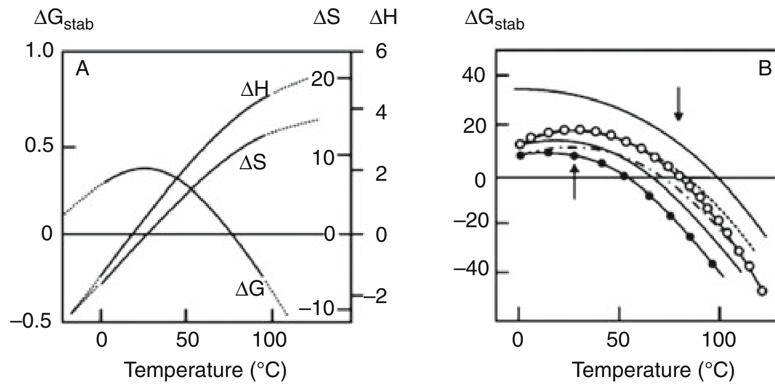

Fig. 3. Temperature dependence of ΔH, ΔS and ΔG_{stab} of proteins. A. Temperature-dependence of the enthalpy, entropy and free energy of stabilization (ΔG_{stab}) of sperm whale myoglobin, calculated per mole of amino acid residues (Privalov, 1979; Privalov and Gill, 1988). B. ΔG_{stab} versus T profiles of structurally related proteins from mesophiles and hyperthermophiles. The various profiles illustrate that enhanced thermal stability may be accomplished either by flattening the parabola, or by an upward shift (to a higher overall free energy), or by a shift to higher temperature; they belong to the β-barrel DNA-binding protein Sso7d from *Sulfolobus solfataricus* (—), all-β tyrosine kinases BtkSH3 (- - -) and Tec-SH3 (• – • –), α-spectrin (--), CspA from *Bacillus subtilis* (•) and Csp from *Thermotoga maritima* (o). The arrows at ~30 and 80°C refer to the physiological optimum temperatures of *B. subt*, and *T. maritima*, respectively. Taken from Jaenicke (2000a).

or pH give the same result, provided they are corrected to standard conditions (Makhatadze and Privalov, 1995; Pfeil, 1998). Thus, in spite of the large number of noncovalent contacts maintaining the native structure of proteins, ΔG_{stab} is only marginal, no more than the equivalent of a few weak intermolecular interactions, even in the case of extremophilic proteins. Representing the minute difference between the large contributions of attractive and repulsive forces, ΔG_{stab} determines the close packing of the polypeptide chain and the minimization of the hydrophobic surface area that are typical for globular proteins in aqueous solution. The balance of attraction and repulsion corresponds exactly to the abovementioned compromise between rigidity and flexibility.

In contrast to the two-state assumption, protein denaturation is rarely fully reversible, so that determining the thermodynamic stability in terms of ΔG_{stab} may be difficult or even impossible. In these cases, operational definitions of stability are used to characterize proteins, especially if homologs from different species or wildtype and mutant proteins are compared. To this end, most commonly apparent (nonequilibrium) T_m values or the denaturant concentration at which half of the protein is unfolded ($c_{1/2,urea}$ or $c_{1/2,GdmCl}$) are used. For multidomain and multisubunit proteins this approach has often been the only means to obtain at least a qualitative estimate of stability.

Thermodynamics vs Kinetics

Thermodynamics and kinetics are commonly considered as separate domains; the first, with emphasis on energy and mass action, ignores time as a physical parameter, while the second is focused on reaction coordinates and rates. However, describing chemical equilibrium as the situation defined by the balance of the formation and decay of the reaction product.

$$K = \frac{\vec{k}}{\overleftarrow{k}} \tag{7}$$

with K as the equilibrium constant, and and as rate constants of the forward and backward reactions, kinetics and thermodynamics are obviously connected. Combining equations (6) and (7), evidently, kinetics can be used to define and measure stability: Higher ΔG_{stab} values, e.g., of thermophilic proteins compared to homologous mesophilic proteins, could be due to an increase in the rate of folding or a decrease in the rate of unfolding, or a combination of the two. The rate of the unfolding reaction is limited by the highest activation barrier upon the N→U transition. Thus, protein stability may be governed, in terms of kinetic stabilization, by a high free energy of activation ($\Delta G_{N\rightarrow U}$) that separates N from the transition state. In a number of cases the rate of unfolding of hyperthermophilic proteins has been shown to be drastically decelerated compared to their mesophilic counterparts, supporting the view that the increase in $\Delta G_{N\rightarrow U}$ is responsible for the enhanced ΔG_{stab} (Sterner and Liebl, 2001). To give an example, the cold-shock proteins from *Bacillus subtilis* (equilibrium unfolding at $T_m = 52°C$), *Bacillus caldolyticus* ($T_m = 72°C$) and *Thermotoga maritima* ($T_m = 90°C$) show a dramatic decrease in their unfolding rates with increasing T_m, whereas folding occurs at

closely similar high rates ($\tau = 1.0 \pm 0.2$ ms; Perl et al., 1998; Perl et al., 2000; Perl and Schmid, 2001). Evidently, from the ecological point of view, a high $\Delta G_{N\rightarrow U}$ may provide a significant advantage for the hyperthermophilic organism, because, owing to the turbulence in hydrothermal vents, exposure times to a lethal temperature range may be short compared to the half-time of the N→U unfolding transition; on the other hand, the fast folding reaction allows the rapid formation of the compact native structure, this way protecting the nascent protein during the folding process against irreversible damage by covalent modification or aggregation (Hensel et al., 1992; Jaenicke and Böhm, 1998; Plaza del Pino et al., 2000).

Forces and General Mechanisms in Protein Stabilization

The observation that the Gibbs free energy of stabilization represents a minute difference between strong attractive and repulsive potentials means that proteins exist close to the borderline of denaturation. Comparing tabulated ΔG_{stab} values with the bond energies of the relevant weak interactions (Bernal, 1939; Bernal, 1958; Kauzmann, 1959; Stillinger, 1977; Pfeil, 1998), it becomes clear that a few hydrogen bonds, or a hydrophobic patch, or just one ion pair may suffice to shift the optimum stability of proteins from the mesophilic to the thermophilic temperature regime (Fig. 3B). Evidently, evolution can choose between an astronomical number of ways to adapt to extreme conditions; therefore, no general rules of protein stabilization are to be expected. The following brief survey of the interatomic forces that contribute to macromolecular stability may provide some understanding of the many reasons why certain amino acid substitutions are essential for protein stability, while others are neutral.

Basically, the spatial structure of proteins is determined by electrostatic forces between polar and ionized groups and by hydrophobic interactions involving nonpolar residues (Dill, 1990; Jaenicke, 1991a; Jaenicke and Böhm, 2001a; Petsko, 2001; Spyracopoulos and Sykes, 2001). The electrostatic forces include ion pairs, hydrogen bonds and van der Waals forces.

Single surface-exposed ion pairs have often been considered of secondary importance because they are normally present in small numbers and not highly conserved in proteins; thermodynamic data and evidence from protonation/deprotonation experiments seemed to confirm this assumption (Kauzmann, 1959; Dill, 1990). The relatively small contribution to the thermal stability of no more than ~4 kJ/mol could be easily explained because the gain in the free energy is practically compensated by the entropic cost of dehydration plus the reduction of the conformational freedom when the protein goes from the denatured to the native state (Jaenicke, 1991b; Matthews, 1996; Fersht, 1998b). One would predict that at high temperature this effect becomes even more important. However, again referring to the above cold-shock proteins, about half of the difference in $\Delta G_{stab,70°C}$ between the mesophilic *B. caldolyticus* and the thermophilic *B. stearothermophilus* protein is due to electrostatic interactions between two exposed amino acid residues (Pace, 2000; Perl et al., 2000; Mueller et al., 2000; Perl and Schmid, 2001). Along these lines, an increase in the number of electrostatic interactions, which are often organized in clusters of ion pairs between charged amino acid side chains, has been frequently found in hyperthermophilic proteins compared to their mesophilic counterparts (Jaenicke and Böhm, 1998; Szilágyi and Závodszky, 2000; Sterner and Liebl, 2001). These networks can increase protein stability by a number of mechanisms: 1) Each extra ion pair added to the network requires the desolvation and localization of only a single residue; 2) networks of charged groups are often located in cavities and at interfaces where their conformational freedom is restricted; as a consequence, part of the entropic cost has already been provided during the folding of the polypeptide chain; 3) hydration effects play a minor role at high temperature (Elcock, 1998); and 4) the dielectric constant (in the denominator of the Coulomb equation) decreases with temperature, resulting in an increase in electrostatic energy upon ion-pair formation. Perutz's early hypothesis on the significance of ion pairs for the stability of thermophilic proteins may be rationalized on the basis of given arguments (Perutz and Raidt, 1975).

In summarizing our present understanding of the contribution to ΔG_{stab} attributable to electrostatic potentials between charged groups, one important conclusion is that the key stabilizing feature is not so much the type and the number of groups, but their structural context and optimum placement. The ion-pair network in the glutamate dehydrogenase family illustrates this conclusion: The comparison of the crystal structures of the mesophilic, moderately thermophilic and hyperthermophilic enzymes and homology modeling clearly indicate that the decrease in T_m correlates with the reduction ("fragmentation") of ion-pair networks (Yip et al., 1995; Yip et al., 1998).

The significance of hydrogen bonds as the dominant stabilizing force in protein folding and stability has been controversial for more than 60 years (Mirsky and Pauling, 1936; Bernal, 1939;

Bernal, 1958; Kauzmann, 1959; Fersht, 1987; Dill, 1990; Jaenicke, 1991a; Jaenicke, 1991b; Makhatadze and Privalov, 1995; Pace, 1996; Schellman, 1997; Petsko, 2001). Attempts to quantify their bond energy resulted in a range between 12 and 38 kJ/mol (3–9 kcal/mol), including 21 kJ/mol (5 kcal/mol) for the amide-amide NH···O bond (Fersht, 1998b). Mutant studies focusing on the energy increment inherent to an intrachain H-bond relative to the H-bond with the aqueous solvent yielded 1.2 ± 0.6 kcal/mol (Fersht, 1987; Matthews, 1995; Matthews, 1996; Pace et al., 1996; Jaenicke, 1999). Using standard proteins such as ribonuclease T1 or phage T4 lysozyme, a large amount of experimental data corroborated this estimate. For the contribution of the H-bond to the stability of nucleic acids, also 1 kcal/mol was suggested by Crothers and Zimm (1965); their prediction was confirmed using polynucleotides as models (Freier et al., 1986).

Commonly, forming an H-bond, e.g., in a helix or a β-strand, requires the transfer of polar groups from the periphery into the interior of the protein. This unfavorable process has been hypothesized to reduce the above H-bond energy to a value close to the thermal energy (kT); however, given the large number of H-bonds involved in secondary structure formation, it was assumed that even a marginal increase in the free energy of stabilization ΔG_{stab} value will accumulate to a significant net stabilization (Pace et al., 1996). Recent studies, comparing Asn→Ala, Leu→Ala and Ile→Val mutants, have shown that the burial of an amide group contributes more to protein stability than the burial of an equivalent volume of $-CH_2-$ groups. Obviously, this is in contrast to the above hypothesis because it clearly indicates that the desolvation penalty for peptide groups is much smaller than assumed so far; at the same time, it allows the conclusion that the hydrogen bonding and van der Waals interactions of peptide groups in the tightly packed interior of the folded protein are more favorable than similar interactions with water in the unfolded polypeptide chain (Pace, 2001).

In summarizing the present state of theory and experiment regarding the role of hydrogen bonds in the stabilization of globular proteins and other biopolymers in aqueous solution, it is now well-established that H-bonds exhibit a significant stabilizing effect over the whole biologically relevant temperature range.

The hydrophobic effect is a way of describing the tendency of nonpolar compounds such as hydrocarbons to transfer from water to an organic solvent. Its physical nature was previously considered to be entropic, attributable to the reorganization of the normal hydrogen-bonding network in water (called "iceberg formation") by the presence of a hydrophobic compound or nonpolar groups. In forming a hydrophobic interaction, the release of the icebergs from nonpolar groups or surfaces into the bulk phase of the aqueous solvent leads to an increase in entropy which exceeds the free energy terms due to losses of rotational or translational degrees of freedom (Kauzmann, 1959; Tanford, 1962; Tanford, 1980; Lauffer, 1975; Privalov, 1979; Dill, 1990; Privalov and Gill, 1988). According to Eq (2), the entropic nature of hydrophobic interactions would suggest that their contribution to ΔG_{stab} increases with temperature. As a logical consequence, it has been claimed that the increased stability of proteins from thermophiles compared to mesophiles is attributable to an increase in hydrophobicity. A critical analysis proved the differences to be statistically insignificant (Böhm and Jaenicke, 1994); this result has been recently confirmed for the much larger data base gained from the complete genomes of mesophilic, thermophilic and hyperthermophilic bacteria and archaea (Jaenicke and Böhm, 1998; Sterner and Liebl, 2001). The results do not allow the conclusion that hydrophobic interactions do not contribute to ΔG_{stab}, for various reasons: 1) The result of determining the probabilities with which polar and nonpolar amino acids are localized in the core or in the exterior confirm the relative solubilities of all amino acids in water or other less polar solvents (Nozaki and Tanford, 1971). However, detailed normalized distributions of the solvent accessibilities of all 20 amino acids, calculated from known 3D structures clearly show that in the folding process, there are roughly equivalent decreases in the accessibility of both the polar and nonpolar groups (Richards, 1977; Rose et al., 1985). Obviously, the relevant forces and the final structure of proteins require more careful definition than is implied by the common assumption that inside equals nonpolar and outside equals polar. 2) Using the relative solubilities, i.e., the transfer of nonpolar substances into water, as a model reaction to quantify hydrophobic interactions, the temperature dependence is characterized by parabolic profiles (Fig. 4). At the minimum, the hydrophobic effect shows its maximum, $\Delta H_{transfer}$ equals zero, and $\Delta G_{transfer}$ is fully determined by $T\Delta S_{transfer}$ (Privalov, 1988a; Pace, 1992).

At higher temperatures, the hydrophobic effect decreases and finally vanishes at ~120–140°C (Sturtevant, 1977; Baldwin, 1986; Privalov and Gill, 1988; Dill, 1990; Makhatadze and Privalov, 1995). Evidently, the hydrophobic effect is a highly complex phenomenon. 3) Recent thermodynamic data have shown that there is a significant enthalpic contribution to the hydrophobic effect, which can be attributed

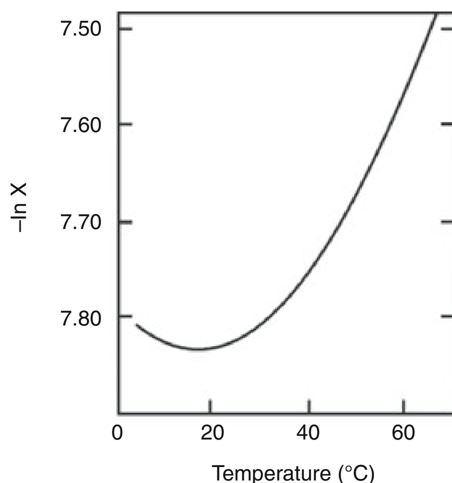

Fig. 4. The temperature dependence of the solubility (x) of benzene in water reflects hydrophobic interactions. Data taken from Franks et al. (1963). The corresponding thermodynamic data for the transfer of benzene and ethylbenzene from the pure liquid phase to water at 25°C are:

	Surface area (Å^2)	Solubility (mole fraction)	$\Delta H_{transfer}$ (kJ/mol)	$\Delta S_{transfer}$ (J/K·mol)	$\Delta G_{transfer}$ (kJ/mol)	ΔC_p (J/K·mol)
Benzene	240	4.01×10^{-4}	2.08	−58	19.4	225
Ethylbenzene	302	0.258×10^{-4}	2.02	−81	26.2	318

ΔC_p, the change in heat capacity, may be gained from a ΔH versus T plot according to the Kirchhoff equation $\Delta C_p = \partial(\Delta H)/\partial T$ (cf. Privalov and Gill, 1988; Dill, 1990; and textbooks of physical chemistry).

to van der Waals interactions (P.L. Privalov, personal communication, 1998). A sound thermodynamic treatment of the correlation of temperature, stability and the hydrophobic interaction has been put forward by Schellman (1997).

In summarizing the forces and general mechanisms involved in the stabilization of proteins, it is important to note that, as a state function, the free energy of stabilization ΔG_{stab} is an additive quantity. According to the Gibbs-Helmholtz equation (Eq [2]), its increments are either enthalpic or entropic. Three major contributions are dominated by enthalpy: attractive forces between ion pairs, hydrogen bonds, and van der Waals interactions. Hydrophobic interactions have enthalpic and entropic increments. Apart from its significance in the hydrophobic effect, entropy clearly dominates three characteristics of thermophilic proteins: 1) the increase in proline or the decrease in glycine residues, 2) the reduced lengths of loops, and 3) anomalously high states of association. In the case of 1) and 2), stabilization comes from the destabilization of the denatured state, attributable to the decrease in the degrees of freedom of the unfolded polypeptide chain (Matthews et al., 1987; Suzuki et al., 1991; Watanabe et al., 1991; Watanabe et al., 1994; Watanabe et al., 1996; Watanabe et al., 1997). In the case of 3), both the burial of nonpolar sites in the inner core of the protein and the release of water (accompanying ion-pair formation), lead to an increase in entropy and a gain in free energy (Lauffer, 1975; Jaenicke, 1987; Jaenicke and Seckler, 1997; Schellman, 1997; Thompson and Eisenberg, 1999).

Temperature Effects on Ligand Binding and Enzyme Function

Concerning thermal effects on enzymatic catalysis and regulation, ligand binding is of crucial importance. At this point, binding-site geometry, active-site fitting of the ligands, and conformational changes upon binding, transformation and release of substrates, products and effectors are expected to be temperature dependent. However, binding of substrates and/or coenzymes often exhibits entropy-enthalpy compensation (Lumry and Rajender, 1970), so that the overall free energy of ligand binding seems to be more or less indifferent to temperature changes (Fig. 5A).

Michaelis-Menten constants (K_m) for homologous enzymes from mesophiles and thermophiles often cluster in a narrow range, when compared at optimum physiological temperatures (Fig. 5B). At a fixed temperature, enzymes from mesophiles show higher catalytic turnover numbers (k_{cat}) than their homologs from thermophiles; however, owing to the general enhancement of reaction rates with temperature, at

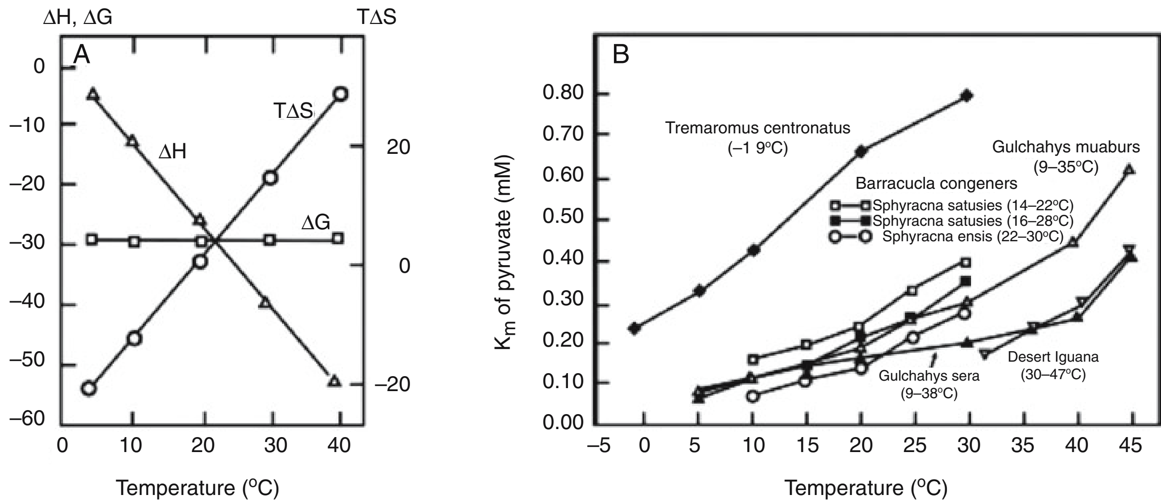

Fig. 5. Thermal adaptation and protein function. A. Data taken from Somero (1995).

physiological temperature k_{cat} also is conserved in accordance with the frequently observed unity in diversity observed in comparative physiology (Somero, 2000).

Biochemical Limitations at High Temperature

The high-temperature regime of life is limited not only by the above-mentioned temperature coefficients of the relevant interatomic interactions in biomolecules, but also by their hydrothermal decomposition (Dill, 1990; Jaenicke, 1991a; Jaenicke, 1991b; Blokzijl and Engberts, 1993; Elcock, 1998; Jaenicke and Böhm, 1998; Sterner and Liebl, 2001). In the cytosol's multicomponent system, amino acids, nucleic acid bases, carbohydrates and lipids are prone to a wide variety of covalent chemical modifications, especially under various extreme physical conditions. In the case of proteins at elevated temperature, these modifications comprise deamidation of the amide side chains of Asn and Gln residues, succinimide formation at Glu and Asp, β-elimination, oxidation of His, Met, Cys, Trp and Tyr, disulfide interchange, lanthionin formation, Maillard reactions, hydrolysis, ring cleavage, etc. (Zale and Klibanov, 1986; Ledl and Schleicher, 1990; Creighton, 1994; Table 3).

Since these reactions have high activation energies, they become increasingly important at high temperatures. On the other hand, their reaction rates have been shown to be higher for small peptides with high flexibility than for proteins, when comparing the same amino acid sequence (Wearne and Creighton, 1989). Similarly, enhanced rates were observed for unfolded proteins compared to the same proteins in their native state (Hensel et al., 1992). Thus, the typical high packing density of thermophilic proteins will have a protecting effect, to the extent that degradative reactions may be assumed to play no significant role as long as the native conformation of a given protein is intact (Daniel et al., 1996). For this reason, hyperthermophiles and thermophiles must either inhibit unfolding and subsequent degradation of proteins or compensate for both processes. Possible strategies are the accumulation of compatible solutes, or enhanced protein synthesis and repair. Little is known about the chemistry of thermal degradation or specific protection of proteins, and even less about repair. An exception is the L-*iso*aspartyl methyltransferase from *Thermotoga maritima*, a highly active repair enzyme that catalyzes the transfer of the methyl group from S-adenosylmethionine (SAM) to the α-carboxyl group of L-*iso*aspartyl residues, resulting from the deamidation of Asn and the isomerization of Asp (Ichikawa and Clarke, 1998). Interestingly, the k_{cat} of the enzyme at 80°C is ~20-fold higher than that of mesophilic homologs at 37°C, supporting the view that it is specifically adapted to the high need of protein repair close to the boiling point of water.

The thermal stability of the different canonical natural amino acids at neutral pH decreases in the following series: (Val, Leu) > Ile > Tyr > Lys > His > Met > Thr > Ser > Trp > (Asp, Glu, Arg).

Table 3. Degradative chemical reactions and isomerization reactions important to irreversible protein denaturation, especially at elevated temperature.

Reaction	Amino acids involved	Comments
Deamidation	Asn, Gln (especially in Asn-Gly and Asn-Ser sequences)	Independent of pH, product: *iso*-Asp as substrate of methyl transferase, leading to repair or clearance.
Racemization	Asp	
Isomerization	Pro (*cis-trans* isomerization)	Catalyzed by peptidyl prolyl-*cis-trans* isomerases.[a]
Glycation	Lys and other amino acids reacting with reducing sugars	Cross-linking by Maillard reactions, involved in in vivo degradation.[b]
Oxidation	Cys ⇔ sulfenic → cysteic acid (oxidation or SH/SS exchange via mixed disulfides) Met ⇔ sulfoxide → sulfone	Thiolate mechanism catalyzed by Cu^{2+} or Fe^{2+} or protein disulfide isomerases (PDI, DsbA/DsbB, etc.). Significant both in vivo and in vitro in the presence of oxygen radicals.
Proteolysis	Polypeptides → amino acids	Caused either by proteases or autolysis, or by H^+-catalyzed peptide cleavage; nonenzymatic, between Asp and Pro and Asp and (C-terminal) Asn.
Photodegradation	Trp → kynurenin → *N*-formyl kynurenin Tyr → DOPA, dityrosine Cystine → 2 Cys	Caused by nonionizing or ionizing radiation, depending on the local microenvironment of the amino acids.

Abbreviations: Asn, asparagine; Gln, glutamine; Ser, serine; Asp, aspartate; Lys, lysine; Pro, proline; Cys, cysteine; Met, methionine; PDI, protein disulfide isomerase; DsbA/DsbB, disulfide-bond forming proteins; and DOPA, dihydroxyphenylalanine.

Greenstein and Winitz (1961); Meister (1965); Cecil (1963); Gottschalk (1972); Freedman (1973); Barrett (1985); Stadtman (1990); Stadtman and Oliver (1991); Volkin et al. (1995); Berlett and Stadtman (1997); Jaenicke and Seckler (1997); Daniel and Cowan (2000); Jaenicke and Lilie (2000); Schiene-Fischer and Yu (2001); and Vieille and Zeikus (2001).

Cysteine exhibits low stability: Depending on temperature and pH, it undergoes either oxidation (to form cystine), or elimination of sulfur (lanthionin formation). The lower limit at which degradation in aqueous buffer solutions was detectable was ca. 110°C (Bernhardt et al., 1984). One may assume that up to this temperature range, biosynthesis can still balance the thermal decomposition. In the temperature regime of hydrothermal vents, e.g., at 250°C (265 bar), the half-lives of the amino acids, peptides and proteins undergoing degradation were found to be too short to be offset by biosynthesis of these molecules (White, 1984).

ATP and ADP hydrolysis become significant between 110 and 140°C (Leibrock et al., 1995). This upper temperature limit coincides with the temperature range at which the hydrophobic hydration of nonpolar residues in aqueous solution vanishes (Sturtevant, 1977; Privalov, 1979; Baldwin, 1986; Jaenicke, 1991b; Jaenicke, 2000a).

In summarizing the biochemical limitations of viability from the point of view of water-soluble proteins, temperatures beyond ca. 130–140°C are not tolerable, for two reasons: 1) natural amino acids are hydrothermally decomposed and 2) the solvent properties of water are altered, blurring the difference between polar and nonpolar residues, thus interfering with the "hydrophobic collapse" (as the initial step of protein folding) and the formation of the densely packed hydrophobic core (as the prerequisite of protein stability). For nucleoproteins and lipoproteins or membranes, the same holds true because of the temperature limits of the intermolecular interactions between the polar and nonpolar components in the respective complexes. For both classes of proteins, extrinsic factors and compatible solutes may enhance the stability as well as the limits of growth (see below). The given upper temperature limit of viability has been confirmed for cells of the most extreme hyperthermophiles *Pyrolobus fumarii*, and strain 121 with its temperature of maximal growth at 121°C (Blöchl et al., 1997; Kashefi and Lovley, 2003). Whether the protective action of compatible solutes and/or crowding induced by high levels of molecular chaperones contribute to this extreme thermotolerance, needs further investigation (cf. Carpenter et al., 1993; Zimmerman and Minton, 1993; Somero, 1995; Trent et al., 1997; Minton, 2000).

Clearly, the biochemical limit of viability depends not only on the intact organization of the cell's standard high-molecular weight components, but also on the low-molecular weight compounds such as coenzymes and metabolites. Again, in general, extremophiles make use of the common repertoire of compounds known from the metabolism of mesophiles. Keeping in mind the high catalytic rate of most enzymes under physiological conditions, the majority of meta-

bolites do not limit viability at temperatures close to 100°C. The reported half-lives of ATP and ADP range from ~1–6 hours at 100°C, depending on the pH and the presence of metal ions (Ramirez et al., 1980; Leibrock et al., 1995; Daniel et al., 1996). However, the oxidized nicotinamide adenine dinucleotide (NAD^+) has a half-life at 100°C of no more than 10 min. To cope with this instability, nature can make use of at least four strategies: 1) high catalytic turnover, or 2) channeling of labile intermediates, 3) local stabilization in enzyme-ligand complexes, and 4) usage of an alternate metabolic pathway or a different, more stable compound. In the case of 3), the high affinity of ligands for their respective enzymes has frequently been shown to cause mutual stabilization (Danson, 1988; Jaenicke et al., 1996; Dams and Jaenicke, 1999).

Adaptive Stabilization Mechanisms of Nucleic Acids

The integrity of nucleic acids is threatened at high temperatures, which can induce either strand separation and chemical damage of the nucleotide constituents or, at the extreme, breakage of backbone phosphodiester bonds (Grogan, 1998; Daniel and Cowan, 2000).

Mechanisms to Avoid Strand Separation

An increased G+C content is known to increase the temperature T_m at which melting, i.e., strand separation of DNA and RNA occurs. Thus, a possible adaptation mechanism of nucleic acids to thermophilic and even more to hyperthermophilic conditions would be an increase in G+C. Indeed, a systematic study revealed a strong positive correlation between the G+C content of tRNAs and rRNAs with the optimum growth temperatures of prokaryotes (Galtier and Lobry, 1997; Fig. 6A). The same study showed, however, that the G+C content of genomic DNA is not correlated with the growth temperature (Fig. 6B).

Quite the contrary, the DNA of some of the most hyperthermophilic archaea has a strikingly low G+C content, with values as low as 31 mol%, e.g., for *Acidianus fervidus* and *Methanococcus igneus* (T_{max} >90°C), and an average of ca. 45 mol% for all presently known hyperthermophilic archaea and bacteria (Stetter, 1996; Grogan, 1998). These data clearly suggest that in these organisms, the DNA double helix must be stabilized either by extrinsic factors such as ions and small metabolites or by proteins. It has been known for a long time that the addition of salts or polyamines leads to an increase in T_m. Actually some, but not all, hyperthermophiles accumulate high concentrations of putative ionic thermoprotectants such as potassium di-inositol-1′,1′-phosphate and tripotassium cyclic-2,3-diphosphoglycerate (Hensel and König, 1988; Scholz et al., 1992). However, there is no clear correlation between the level of polycationic polyamines and growth temperature (Kneifel et al., 1986). In a number of archaeal hyperthermophiles, two unrelated groups of highly basic proteins were identified, which bind to DNA without marked sequence preference. Both the members of the HMf histone family, which are homologs of the eukaryal core histones, and the histone-like proteins from *Sulfolobus* species, for which no eukaryal homologues are known, increase the T_m of the DNA double helix significantly (McAfee et al., 1996; Soares et al., 1998). Thus, there is clear evidence that hyperthermophiles make use of different strategies to prevent DNA strand separation at their extreme growth temperatures. Certainly, the physiological interpretation of in vitro T_m data gained from topologically open molecules has to be taken with a grain of salt because cellular DNA is in a topologically closed conformation, and denaturation will not result in two independent single-stranded molecules, but in a random-coil structure with intertwined strands (Marguet and Forterre, 2001). As a result, topologically closed DNA is undoubtedly more resistant to denaturation than open DNA. It was postulated that the introduction of positive supercoils into closed DNA, which is catalyzed by reverse gyrases from hyperthermophiles, specifically stabilizes the double helix and keeps it in a functional state at high temperature (Forterre et al., 1996; Lopez-Garcia and Forterre, 1997, 2000). However, the hyperthermophile *Thermotoga maritima* contains both "normal" and reverse gyrases and propagates negatively supercoiled plasmid DNA (Guipaud et al., 1997).

tRNA molecules are not permanently integrated into larger macromolecular complexes. Therefore, in adapting to high temperatures, they must have developed mechanisms for intrinsic stabilization. Part of the stabilization energy may originate from an increased G+C content. However, unfractionated tRNA from the hyperthermophiles *Pyrococcus furiosus* and *Pyrodictium occultum* showed T_m values around 100°C, too high to be attributable to the measured G+C content (Kowalak et al., 1994). An early investigation identified a broad variety of covalent posttranscriptional modifications in nucleosides from tRNA preparations of thermophiles and hyperthermophiles, six of which were structurally novel in showing alterations of their bases as well as methylation of their ribose moiety (Edmonds et al., 1991). Altogether, 23 modified nucleosides were identified in *Pyrococcus furiosus*; three of them (Fig. 7) not only

exhibited enhanced relative abundance with increasing growth temperature, but also higher stability, which they effected by 1) restricting the conformational flexibility of the ribose ring, 2) favoring the A-type helix, and 3) preventing phosphodiester-bond hydrolysis (Inoue et al., 1987; Kawai et al., 1992; Kowalak et al., 1994; Cummins et al., 1995).

Apparently, the protecting effect of posttranscriptional tRNA modification is not restricted to the archaea: both the level of 5-methyl-2-thiouridine and the T_m value of tRNA from the bacterium *Thermus thermophilus* show a significant increase with increasing growth temperature (Watanabe et al., 1976). The effect becomes even more compelling if tRNAs from psychrophiles are included in the comparison. While the abundance and the variety of posttranscriptional tRNA modifications are more pronounced in thermophiles and hyperthermophiles than in mesophiles, significantly less modifications are found in tRNAs from psychrophiles (Dalluge et al., 1997). The most abundant one is dihydrouridine, whose nonplanar base resists stacking, this way decreasing stability. In addition, dihydrouridine favors the C-2′-endo sugar conformation, which is less rigid than the C-3′-endo conformer (Yokoyama et al., 1981). Obviously, enhanced flexibility is essential for optimal functioning at low temperature, whereas high intrinsic stability has lower priority.

In the case of rRNAs, significant stabilization is provided by their conjugation with proteins within the ribosomal complex. In accordance with this argument, the levels of posttranscriptional modifications of rRNAs are much lower than in tRNAs, both in mesophiles and in thermophiles. Still, rRNA modifications are much more abundant in *Sulfolobus solfataricus* than in *Escherichia coli*, and the level of stabilizing ribose O-2′ methylations significantly increases with the culture temperature of the hyperthermophile (Noon et al., 1998).

Mechanisms to Avoid and Repair Chemical Damage of Nucleotides

Chemical damage of nucleic acids by hydrolytic attack close to the boiling point of water is an enormous potential threat for hyperthermophiles. The most common damages to DNA are 1) base deamination, 2) loss of bases from one strand with apurinic or apyrimidinic sites as final products, and 3) hydrolytic cleavage of phosphodiester bonds. It was suggested that, above 100°C, DNA would be subject to a ca. 3000-fold increase in the levels of deamination and depurination compared with DNA at 37°C (Lindahl, 1993). Furthermore, it was estimated from in vitro stability data that under the physiological conditions of *S. solfataricus* (intracellular pH 6, 80°C) two apurinic sites per gene per cell division would accumulate (Grogan, 1998). The most severe damage of nucleic acids is the hydrolytic cleavage of the backbone phosphodiester bond. For this reaction, it was postulated that the preceding depurination at an adjacent site is the rate-limiting step (Marguet and Forterre, 1998; Marguet and Forterre, 2001). In contrast, for RNA, hydrolytic strand breakage is not coupled to depurination; instead it occurs via the direct attack of the phosphodiester bond by the ribose 2′-OH oxygen. In vitro, at around 100°C, single-strand breaks occur at a high rate (Marguet and Forterre, 1994; Grogan, 1998). The corresponding lesions could lead to lethal double-strand breaks, if not prevented or repaired in vivo. Therefore, it was suggested that hyperthermophiles must have evolved highly efficient mechanisms to protect and/or repair their DNA (Grogan, 1998). In support of this hypothesis, when *Pyrococcus furiosus* cells are exposed to 100°C, their DNA is about 20 times more resistant to breakage than DNA from *Escherichia. coli* at the same temperature (Peak et al., 1995). Furthermore, passive protection of DNA might be provided by similar mechanisms as used to increase the T_m of the DNA double helix, i.e., high salt concentrations, and binding to proteins (see above). Indeed, it has been shown that the presence of Mg^{2+} and K^+ protect double-stranded DNA from depurination, probably by directly stabilizing the N-glycosidic bond between the deoxyribose and the base (Marguet and Forterre, 1998). With respect to the formation of nucleoprotein complexes, archaeal histones are known to protect plasmid DNA against radiation (Isabelle et al., 1993).

In spite of these well-established protection mechanisms, DNA in hyperthermophiles will almost certainly be damaged to a larger extent than DNA in mesophiles. A model organism for comparative research in this context is the radiation-resistant bacterium *Deinococcus radiodurans*. Both, γ-irradiation and heat have been shown to induce double-strand breakage of DNA, which can be repaired efficiently by *D. radiodurans*. This capacity derives from multiple copies of its chromosome providing intact copies for repair by a DNA recombinase (Minton and Daly, 1995). In analogy, the chromosome of the archaeon *Pyrococcus furiosus*, after irradiation-induced fragmentation, was reassembled by the cells upon incubation at 95°C (di Ruggiero et al., 1997). Open reading frames encoding homologues of RecA proteins involved in recombination repair in bacteria and eukarya were found in the archaeal genomes sequenced so far. Strong experimental evidence suggests that at least one of these homologs, FEN-1 from *P. furiosus*, is involved in double-strand breakage repair

(di Ruggiero et al., 1999). Other than double-strand breakage-repair, activities have been demonstrated in vitro for several other archaea. For example, *Methanobacterium thermoautotrophicum* is able to remove ultraviolet light-induced photoproducts, supposedly with a photolyase as catalyst (Kiener et al., 1989; Ögrünc et al., 1998). Furthermore, a T/G-selective DNA thymine N-glycosylase takes care of the mutagenic effect of hydrolytic 5-methylcytosine deamination (Horst and Fritz, 1996), while uracil-DNA glycosylases seem to be involved in the repair of cytosine deamination (Koulis et al., 1996); in addition, O_6-alkylguanine-DNA transferase activities were also found in hyperthermophiles (Skorvaga et al., 1998). On the other hand, MutL and MutS, which are used in all bacterial and eukaryal mismatch-repair systems, have not been found in any of the archaeal genomes so far.

In summary, the present knowledge of the specific mechanisms by which hyperthermophilic microorganisms preserve the integrity of their genetic material is still incomplete. More information is needed about the intracellular salt concentrations and the DNA-binding and DNA-protecting proteins, to establish in vitro test systems that come as close as possible to the in vivo situation. Moreover, homologs of known bacterial and eukaryal repair enzymes from hyperthermophiles need to be characterized to identify their catalytic properties under physiological conditions. The ongoing genome-sequencing projects will help identify the most promising candidates for this approach.

Adaptive Stabilization Mechanisms of Lipids and Membranes

Living cells have a cytoplasmic membrane serving as a barrier between the cytoplasm and the environment. It consists of lipid layers with embedded proteins that generate specific and vital solute concentration gradients across the membrane. Penetration of small solutes through the lipid component of the membrane is caused either by active transport or passive diffusion. Being directly proportional to the thermal energy (kT), passive diffusion is accelerated with increasing temperature (Einstein, 1905; Einstein, 1906; van de Vossenberg et al., 1998). In hyperthermophiles, extreme temperature may lead to the breakdown of solute gradients. Therefore, their membranes need to be extremely thermostable, but they also require specific adaptive mechanisms to limit the permeability of ions. This holds especially for protons because of the essential role of proton gradients in energy-requiring processes such as ATP synthesis, active transport of specific solutes across the membrane, flagellar rotation, and maintenance of the intracellular pH and turgor (Albers et al., 2000).

Chemical Composition of Membrane Lipids

At physiological temperatures, membrane lipids are in a liquid-crystalline state (Melchior, 1982), forming a suitable matrix for the attachment or integration of membrane proteins. The overall structure of the lipid membrane is conserved between eukarya, bacteria and archaea. The inner and outer hydrophilic surfaces, which are composed of polar headgroups, enclose the hydrophobic interior consisting of long hydrophobic hydrocarbon chains. At this point, the chemical composition of archaeal membranes has been found to be significantly different from the chemical composition of bacterial and eukaryal membranes. Both bacterial and eukaryal lipids have esters between glycerol and fatty acid chains (glycerol fatty acyl diesters), whereas the lipids of archaeal membranes are formed by ethers between glycerol (or another alcohol such as nonitol) and branched C_{20}-hydrocarbon side chains (Langworthy and Pond, 1986). The side chains consist of repeated saturated isoprenoid units containing a methyl side group at every fourth carbon atom in the backbone. These methyl side groups restrict the mobility of the chains, thereby stabilizing them and restricting ion permeability (see below). The two hydrocarbon chains can be ether-linked to either one glycerol unit (forming a C_{20}, C_{20}-isopranyl glycerol diether = diphytanylglycerol diether = archaeol), or two glycerol units (forming a dibiphytanylglycerol tetraether = caldarchaeol; Fig. 8A and B). The archaeols are found in all archaea, whereas the caldarchaeols (and nonitol-caldarchaeols) are only found in thermophilic archaea. The caldarchaeols can be further modified by cyclopentane rings in the biphytanyl side chains (Fig. 8C–E).

The caldarchaeols of thermophilic archaea are typically glycosylated at C_3 and C_6 of the glycerol and nonitol backbones, respectively. Probably, hydrogen bonds between the glycosyl headgroups stabilize the membrane structure by reducing lateral lipid mobility (van de Vossenberg et al., 1998; Daniel and Cowan, 2000).

An unsaturated diether lipid was found in the archaeon *Methanopyrus kandleri* (Hafenbradl et al., 1993). This lipid, 2,3-di-*O*-geranylgeranyl-*sn*-glycerol, resembles terpenoids, but the consequences for membrane function are still unknown. Another type of unsaturated lipid was discovered in the psychrophilic archaeon *Methanococcoides burtonii* (Nichols and Franzmann, 1992). This lipid contains a double bond that can distort the short-range order of the membrane, thus allowing the necessary fluidity of the mem-

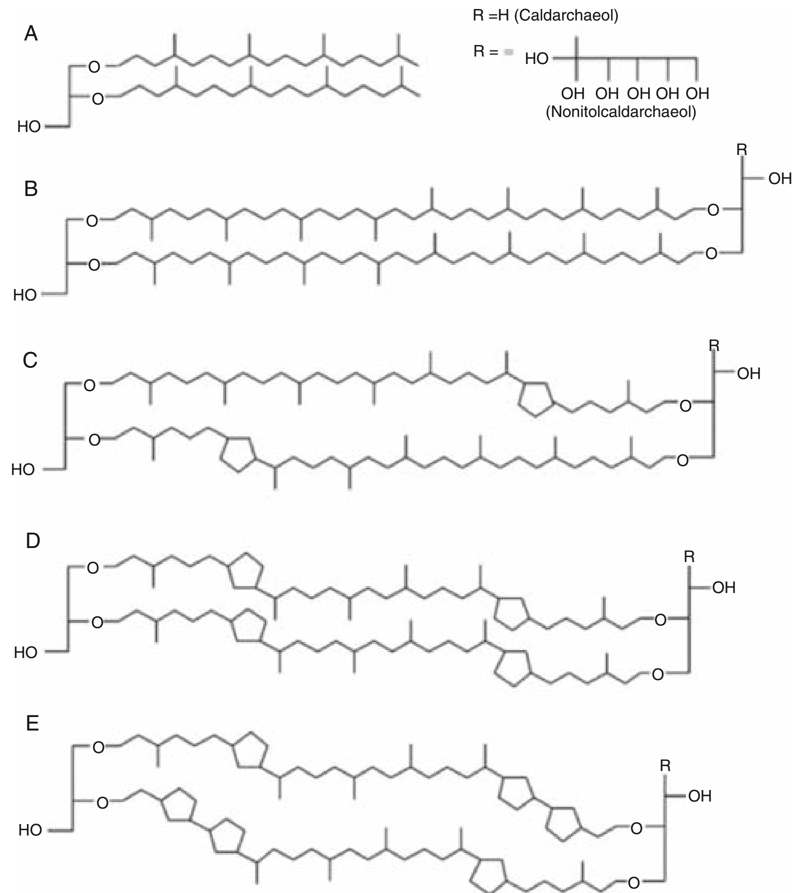

Fig. 8. Archaeal lipid architecture. (A) Diphytanyl glycerol diethers, (B) dibiphytanyl diglycerol tetraethers, and (C–E) internal cyclization in dibiphytanyl diglycerol tetraethers. From Daniel and Cowan (2000).

brane to be adapted to the physiological low temperature (Suutari and Laakso, 1992).

Topology, Stability and Permeability of Membranes

The glycerol-diester lipids of bacteria and eukarya form bilayer membranes. The same holds for the archaeol lipids of halobacteria and most other archaea growing under moderate conditions (Kates et al., 1993; Upasani et al., 1994; Kates, 1995). In contrast, the caldarchaeol lipids of the thermophilic and acidophilic archaea form monolayers spanning the entire membrane (de Rosa et al., 1991; Relini et al., 1996). In monolayers, two glycerol units are covalently linked by the phytanyl side chains, whereas in bilayers the glycerol units are noncovalently linked by hydrophobic interactions between the fatty acid side chains. As a consequence, monolayers have a diameter between 2.5 and 3.0 nm (Gliozzi et al., 1983), somewhat thinner than typical C_{18} glycerol-diester bilayers, but much more stable: Vesicles generated from *Thermoplasma acidophilum* ether lipids are more resistant to high temperature and surface-active agents than vesicles of bacterial dipalmitoyl phosphatidyl-choline (Ring et al., 1986). Moreover, liposomes prepared from tetraether lipids from a number of archaea were shown to be extremely stable toward high temperature, alkaline pH and enzymatic degradation by phospholipases (Chang, 1994; Choquet et al., 1994).

As has been mentioned, to guarantee energy production, membranes of all microorganisms, no matter whether they are psychro-, meso-, thermo- or hyperthermophilic, must provide an efficient barrier against the flux of protons. Liposomes prepared from lipids derived from a variety of organisms with different growth temperatures were compared for their proton permeabilities (van de Vossenberg et al., 1995). This study showed that, at the respective growth temperature, proton permeability was closely similar for the various liposomes (Fig. 9).

This “homeoproton permeability adaptation” is reminiscent of the “corresponding states” observed for homologous pairs of enzymes from mesophiles and thermophiles, most of which were shown to exhibit comparable stabilities, flexibilities and activities at their respective physiological temperatures (Jaenicke, 1991b; Somero, 1995; Jaenicke and Böhm, 1998). As a logical consequence, at a given fixed temperature, the proton permeability of membranes is decreased with increasing temperature of adaptation, fol-

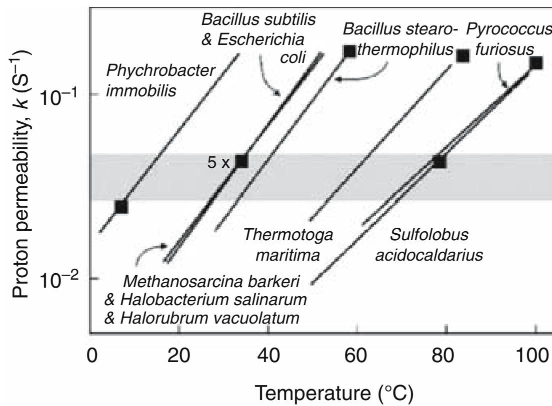

Fig. 9. The proton permeability of archaea and bacteria that live at different temperatures. At the respective growth temperatures, the proton permeability falls within a narrow range (gray bar). *Thermotoga maritima* and *Bacillus stearothermophilus* have higher permeabilities than those of other organisms. Both organisms overcome this problem differently. From Albers et al. (2000).

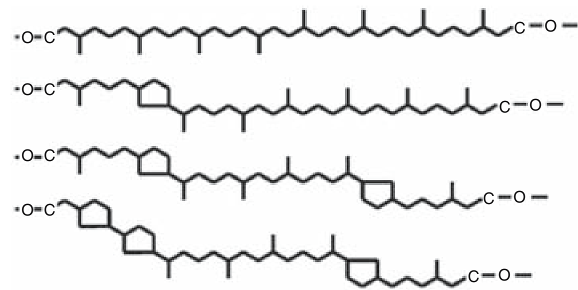

Fig. 10. Cyclization of the phytanyl chains of the *S. solfataricus* tetraether lipids. Only one of the phytanyl side chains is shown. The degree of cyclization increases from top to bottom. From Albers et al. (2000).

lowing the order: psychrophiles > mesophiles > thermophiles > hyperthermophiles. Various archaeol and caldarchaeol lipids were 6–120-fold less permeable to water, solutes, protons and ammonia than bacterial diphytanyl-phosphatidylcholine liposomes (Mathai et al., 2001). It was shown that the crucial factor ensuring low permeability are cyclopentane rings in the phytanyl side chains, which limit the mobility in the midplane hydrocarbon region. The substutitution of ether- for ester-bonds provides an additional barrier that specifically impairs the flux of protons.

Bacterial thermophiles have membrane lipids rich in saturated fatty acids, which make the membranes more rigid and stable at high temperatures because stronger hydrophobic interactions are formed between saturated fatty acids compared with unsaturated ones (Brock, 2000). Other differences between membranes from mesophilic and thermophilic bacteria include alterations in acyl chain length, branching, and/or cyclization (Tolner et al., 1998). Interestingly, the extremely thermophilic *Thermodesulfobacterium* contains lipids combining bacterial and archaeal properties; here, glycerol is ether-linked to a unique C_{17} hydrocarbon side chain along with some fatty acids instead of phytanyl side chains (Brock, 2000).

Adaptation of Membrane Structure and Function to Temperature Fluctuations

Bacteria and archaea can grow over a wide range of temperatures. When facing environmental temperature shifts, most of them adapt the structure of their membranes to ensure constant stability and permeability. In archaea, as well as in mesophilic and psychrophilic bacteria, this adaptation is achieved by adjusting the chemical composition of the lipids. Archaea adapt to low temperatures by decreasing the degree of saturation of their hydrocarbon side chains (Nichols and Franzmann, 1992), whereas they respond to high temperature by the cyclization of the side chains and by replacing diether to with tetraether lipids (de Rosa and Giambacorta, 1988; de Rosa et al., 1991; Yamauchi and Kinoshita, 1995): For *Sulfolobus solfataricus* and *Thermoplasma*, it was shown that the number of cyclopentane rings incorporated into the lipid diphytanyl side chains increase with growth temperature, this way rigidifying the membrane and limiting passive diffusion of small molecules (Mathai et al., 2001; Fig. 10).

In *Methanococcus jannaschii*, a different mechanism is observed: here, increasing temperatures induce the change from diether lipids to the more thermostable tetraether lipids (Sprott et al., 1991).

To investigate adaptive changes of membranes from bacteria, *Bacillus subtilis* was grown at the boundaries of its growth temperature (van de Vossenberg et al., 1999). The average lengths of lipid acyl side chains, the degree of saturation, and the ratio of *iso*- and *anteiso*-branched fatty acids increased with temperature. In accordance with the concept of homeoproton permeability adaptation, these modifications kept the proton permeability of the cytoplasmic membrane at a rather constant level. Likewise, in psychrophiles, the proton permeability is maintained at a constant level when the growth temperature is varied (van de Vossenberg et al., 1995). In contrast, in thermophilic bacteria such as *Bacillus stearothermophilus* and *Thermotoga maritima*, homeoproton permeability cannot be maintained, as their membranes become porous at high temperatures. Some moderately thermophilic bacteria can compensate for the high proton leakage by drastically increasing the respiration rate, and together with that, the rate of proton pumping (de Vrij et al.,

1988). A different strategy is found in the moderate thermophile *Caloramator fervidus*, which, instead of the proton, uses the less permeable sodium ion as the main coupling component for energy transduction (Speelmans et al., 1993a; Speelmans et al., 1993b).

In summary, a number of different mechanisms have been identified that keep membranes stable and functional at high temperatures. Archaea contain lipids with ether linkages between various alcohols and hydrocarbon side chains, in which cyclopentane rings are incorporated in a growth-temperature dependent manner. Thermophilic bacteria, which contain less stable ester lipids prone to proton leakage, evolved alternative strategies to maintain vital chemiosmotic gradients under physiological conditions. As the number of novel lipid structures constantly grows, more variations on these themes are to be expected.

Adaptive Stabilization Mechanisms of Proteins

To fulfil their diverse functions, proteins from hyperthermophiles need to be in their native, folded state at temperatures around 100°C. In contrast, most proteins from mesophiles are unfolded at ~50°C (Fig. 2), often followed by irreversible aggregation and/or chemical damage (Jaenicke and Seckler, 1997). What are the structural determinants that render proteins from hyperthermophiles much more thermostable than their homologs from mesophiles? As mentioned in the section on "Stability of Biomolecules," few additional favorable electrostatic or hydrophobic interactions suffice to shift ΔG_{stab} of a protein from the mesophilic to the thermophilic temperature regime (Jaenicke and Böhm, 2001; Fig. 3B). In addition, proteins from hyperthermophiles are not only stabilized intrinsically, but also by extrinsic factors such as compatible solutes or molecular chaperones. What follows briefly summarizes our current knowledge of the intrinsic and extrinsic stabilization of hyperthermophilic proteins. For further details see (Jaenicke and Böhm, 2001; Petsko, 2001; Sterner and Liebl, 2001; Vieille and Zeikus, 2001).

Intrinsic Stabilization: There Are No General Rules

In the section on "Stability of Biomolecules," the electrostatic and hydrophobic interactions that stabilize proteins were discussed. Moreover, the contributions of enthalpy and entropy to the free energy gain caused by these interactions was pointed out. Pairwise comparisons of amino acid sequences and X-ray structures of homologous proteins from mesophiles, thermophiles and hyperthermophiles showed that one or more of these stabilizing interactions were more frequent or more pronounced in the thermophilic and hyperthermophilic variants. These additional stabilizing interactions can in principle occur at all levels, from primary to the quaternary structure (Jaenicke and Böhm, 1998; Daniel and Cowan, 2000; Vieille and Zeikus, 2001; Sterner and Liebl, 2001; Yano and Poulos, 2003).

A large number of mutational studies have been performed to identify stabilizing interactions, which were frequently detected in hyperthermophilic proteins. To this end, selected amino acid residues were substituted by site-directed mutagenesis, and the resulting changes in stability were measured. Instructive examples are the enzymes phosphoribosylanthranilate isomerase (PRAI) and indoleglycerol phosphate synthase (IGPS), which catalyze two successive reactions within tryptophan biosynthesis and adopt the frequently encountered $(\beta\alpha)_8$-barrel fold (Höcker et al., 2001; Wierenga, 2001). PRAI is monomeric in most mesophiles but dimeric in *Thermotoga maritima* (Sterner et al., 1996). The two identical monomers of *Thermotoga maritima* PRAI are associated via intimate hydrophobic contacts at the N-terminal faces of their central β-barrels (Hennig et al., 1997). By replacing a Phe residue at the monomer-monomer interface of *T. maritima* PRAI by a Glu residue, the hydrophobic interactions are weakened. As a consequence, the enzyme becomes monomeric and thermolabile, without losing its catalytic activity (Thoma et al., 2000; Fig. 11).

The importance of increased association states for increased thermostability was also shown for ornithine carbamoyltransferase, which consists of four trimers in *Pyrococcus furiosus*, but only one in mesophiles. Gradual dissociation of dodecameric ornithine carbamoyltransferase from *Pyrococcus furiosus* into trimers, as induced by site-directed mutagenesis at subunit interfaces, led to a gradual decrease in thermal stability (Clantin et al., 2001). Indoleglycerol phosphate synthase is monomeric both in mesophiles and hyperthermophiles. However, IGPS from *Sulfolobus solfataricus* and *T. maritima* contain twice the number of potentially stabilizing ion pairs compared with *E. coli* (Hennig et al., 1995; Merz et al., 1999). Two *T. maritima* IGPS variants, which had one of these ion pairs disrupted by site-directed mutagenesis, showed significantly decreased thermostabilities (Merz et al., 1999). The stabilizing role of ion pairs was also proven by site-directed mutagenesis experiments performed with glyceralaldehyde-3-phosphate dehydrogenase (GAPDH) from *T. maritima*, glutamate dehydrogenases from both *Thermococcus litoralis* and *P. furiosus*,

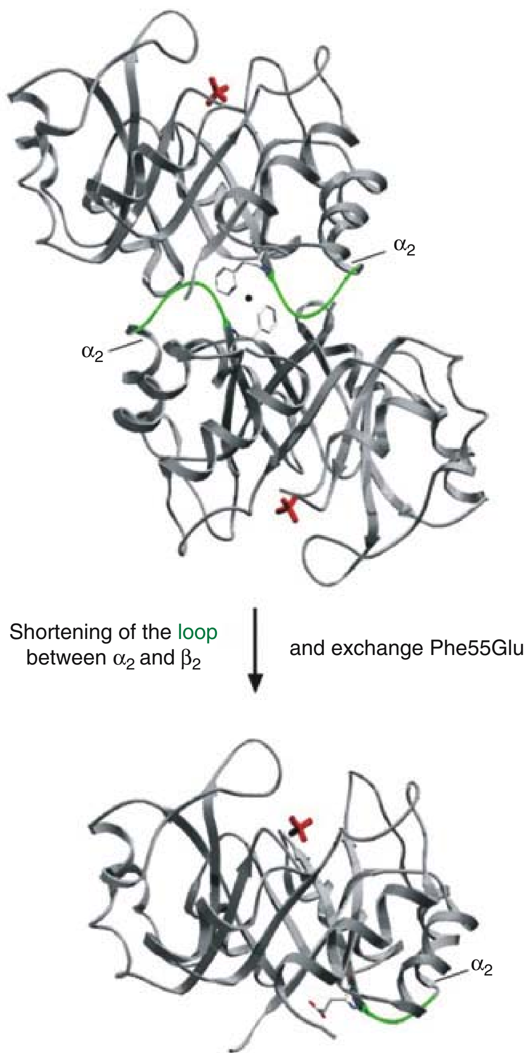

Fig. 11. Monomerization of the native homodimer of PRAI from *Thermotoga maritima* by rational design. Monomers were generated by shortening of the loops connecting helices α2 with strands β3 (in green), and by replacing the two Phe55 residues located close to the twofold symmetry axis (shown as a black dot) with glutamates (shown in stick format). The bound phosphate ions (red tetrahedrons) identify the active sites. The monomeric variants are catalytically as active as the dimer, but far more thermolabile. From Höcker et al. (2001), with permission.

3-isopropyl-malate dehydrogenase from *Thermus thermophilus*, rubredoxin from *P. furiosus*, and the archaeal histone from *Methanothermus fervidus*, and citrate synthase from psychrophiles to hyperthermophiles. The latter represents a good example for the whole spectrum of adaptive changes, including intersubunit ionic networks and varying states of association (Wrba et al., 1990; Tomschy et al., 1994; Pappenberger et al., 1997; Vetriani et al., 1998; Li et al., 2000; Nemeth et al., 2000; Strop and Mayo, 2000; Nordberg Karlsson et al., 2002, 2003; Bell et al., 2002, and references therein). The increased $\Delta G_{stab,70°C}$ of the hyperthermophilic cold shock protein from *T. maritima* compared to its mesophilic counterpart from *B. subtilis* was shown to be largely due to Arg3, whose positive charge improves the global electrostatic potential of the protein (Perl and Schmid, 2001; cf. the section on "Stability of Biomolecules"). This result suggests that the optimum placement of charged groups on the surface of a protein is crucial for its thermostability (Xiao and Honig, 1999), a hypothesis that is strengthened by a number of other experimental studies (Grimsley et al., 1999; Loladze et al., 1999; Spector et al., 2000).

In spite of these examples, in many cases the predicted stabilizing interactions (as deduced from pairwise mesophile-thermophile comparisons of sequences and structures) could not be verified experimentally. Therefore, it is still not possible to deduce general mechanisms that would lead to high protein thermostability. The reason for this shortcoming is the large number of neutral changes of amino acid residues and 3D structures that have accumulated during evolution without affecting protein stability (Böhm and Jaenicke, 1994; Arnold et al., 2001b). Based on this argument, large-scale structural comparisons of amino acid sequences and 3D structures, which reduce the large "phylogenetic noise," are likely to provide more significant results. Such systematic comparisons are now possible owing to the growing number of complete genome sequences from mesophiles and hyperthermophiles, and the fast rate with which new X-ray structures become available.

The amino acid compositions of a number of mesophiles and thermophiles were deduced from their genome sequences and compared in several systematic studies (Table 4).

These comparisons allow the following conclusions. Hyperthermophilic proteins 1) contain a decreased content of uncharged polar amino acids, this way avoiding deamidation of Gln and Asn catalyzed by Thr and Ser (Wright, 1991; Haney et al., 1999; cf. the section on "Biochemical Limitations at High Temperature"), 2) show an increased content of the charged amino acids Glu and Asp, a significant fraction of which may be involved in stabilizing ion pairs at the protein surface (see above; Haney et al., 1999; Cambillau and Claverie, 2000), and 3) are on avarage significantly smaller than their mesophilic homologs (Chakravarty and Varadarajan, 2000), presumably owing to shorter solvent-exposed surface loops (Thompson and Eisenberg, 1999) or extensions at the N- and/or C-terminal ends (Fig. 12).

Upon unfolding, small proteins show a smaller heat capacity change (ΔC_p) than large proteins (Murphy and Freire, 1992; Myers et al., 1995); a decrease in ΔC_p flattens the ΔG_{stab} versus T profile and leads to an increase in T_m (Fig. 3B).

The three-dimensional structures of proteins from mesophiles and thermophiles were compared in a number of comprehensive studies. From a non-redundant dataset of high-quality X-ray structures of protein subunits from mesophiles, thermophiles and hyperthermophiles, it revealed that the increase in intrinsic stability was paralleled by more ion pairs (apart from slight differences with respect to cavities), hydrogen bonds, secondary structure content and polarity of surfaces (Szilagyi and Závodszky, 2000; Table 5).

A similar study suggested that ion pairs and side chain-side chain hydrogen bonds are more frequent in thermophilic than in mesophilic proteins (Kumar et al., 2000a; 2000b). There was no evidence for significant differences with respect to compactness, hydrophobicity, polar and nonpolar surface area, protein size, and number of Pro residues in loops; however, thermophilic proteins appeared to have a higher fraction of residues in α-helices.

Two further investigations confirmed that the α-helices of thermophilic proteins show increased stability, mainly due to the higher intrinsic helical propensities of the amino acids involved (Petukhov et al., 1997; Facchiano et al., 1998). Two systematic comparisons of lactate dehydrogenases (LDH) and triosephosphate isomerases (TIM) from psychrophiles, mesophiles and hyperthermophiles revealed positive correlations between thermostability and the number of intra-subunit (LDH) and inter-subunit ion pairs (TIM), respectively (Auerbach et al., 1998; Maes et al., 1999).

Table 4. Change in amino acid composition going from proteins of mesophiles to proteins of thermophiles.

Amino acid	Gains	Losses	Ratio	Net change	Change, %
Ile	842	658	1.28	184	9.5

Abbreviations: Ile, isoleucine; Glu, glutamic acid; Arg, arginine; Lys, lysine; Pro, proline; Tyr, tyrosine; Ala, alanine; Trp, tryptophan; Leu, leucine; Cys, cysteine; Phe, phenylalanine; Asp, aspartic acid; Val, valine; His, histidine; Gly, glycine; Met, methionine; Gln, glutamine; Asn, asparagine; Ser, serine.
Data from Haney et al. (1999).

The results of the cited mutational studies, and those of the systematic and comprehensive comparisons between the amino acid sequences and 3D structures of psychrophilic, mesophilic and thermophilic proteins can be summarized as follows: Owing to the small differences between ΔG_{stab} of hyperthermophilic and mesophilic proteins (Matthews, 1993; Matthews, 1996; Jaenicke and Böhm, 1998), attempts to find a unifying set of rules of stabilization must fail. The structural features that characterize some of the known hyperthermophilic proteins are increased numbers of hydrogen bonds, higher packing densities and α-helical contents, improved hydrophobic interactions, optimized surface areas, decreased volumes, fewer cavities, and a shortening of the polypeptide chains. Attempts to define the relative significance of these many different factors by counting their frequency in comprehensive comparative studies led to four major contributions: 1) stabilized α-helices, 2) decreased entropy of the unfolded state by increased numbers of Pro and β-branched amino acid residues, 3) decreased content of chemically labile polar amino acid residues, and in particular, 4) increase in the number of optimized ionic interactions (Sanchez-Ruiz and Makhatadze, 2001). The latter finding is in accordance with theoretical work suggesting ion pairs are more stabilizing at high than at low temperatures and might therefore be crucial for the stability of hyperthermophilic proteins (Elcock and McCammon, 1997; Elcock, 1998; De Bakker et al., 1999). It is important to note that the stabilizing effect of a given ion pair depends on its structural context. Ion pairs that connect N- and C-termini in IGPS and GAPDH from *T. maritima* contribute significantly to thermostability, probably by preventing the fraying of the N- and C-termini, which might initiate thermal denaturation (Pappenberger et al., 1997; Merz et al., 1999). Also, for entropic reasons, clusters of ion pairs are likely to be more stabilizing than individual ion pairs (Yip et al., 1995; Yip et al., 1998).

Although our knowledge of the structural basis of high intrinsic protein thermostability is still incomplete, considerable operational progress has been achieved in the last years, especially in the first successful examples of rational or semi-empirical improvements of protein thermostability (Malakauskas and Mayo, 1998; van den Burg et al., 1998). An alternative approach to improve protein thermostability is "directed molecular evolution" (Wintrode and Arnold, 2000; Arnold et al., 2001b). It mimics the

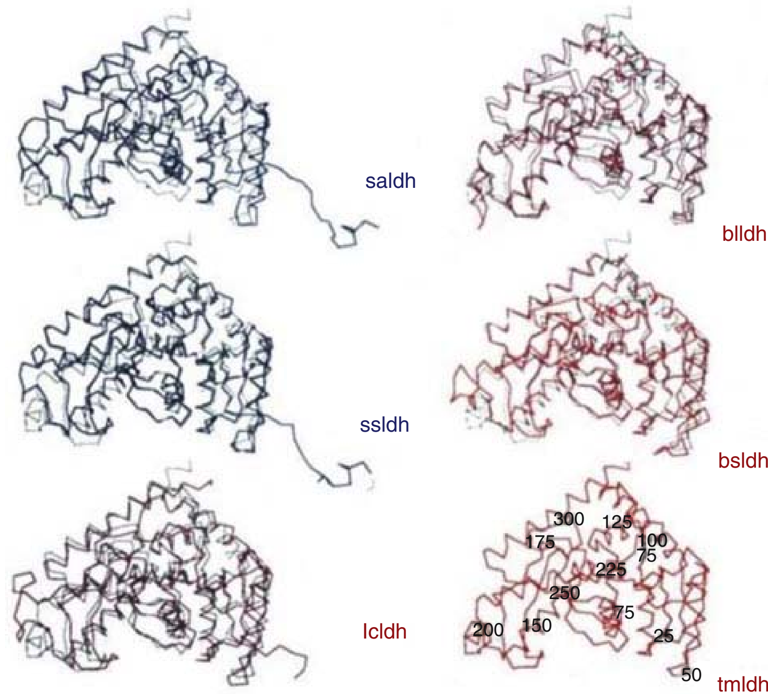

Fig. 12. The three-dimensional structures of lactate dehydrogenases (ldh) from hyperthermophiles, on the one hand, and mesophiles as well as a cold-blooded fish, on the other, are practically isomorphous, with root-mean-square (r.m.s.) differences below 2.4 Å. Comparisons of the 2–3 Å resolution crystal structures of the various homologs with the enzyme from *Thermotoga maritima* (as the reference; in gray) show that the increase in thermostability is parallelled 1) by a reduction in the length of the C-terminal extension, 2) by an increase in compactness of the tetrameric assembly, and 3) by the presence of an additional "thermohelix" (αT) in each of the subunits of the hyperthermophile enzyme. The shift from blue to red in the figure characterizes the temperature range of the organisms from which the various enzymes were isolated The corresponding abbreviations and physiological T_{opt}-values refer to: sa, *Squalus acanthias* (dogfish, ~10°C); ss, *Sus scrofa* (pig, 37°C); lc, *Lactobacillus casei* (~30°C); bl, *Bifidobacterium longum* (~40°C); bs, *Bacillus stearothermophilus* (~65°C) and tm, *Thermotoga maritima* (~80°C). For details, see Auerbach et al. (1998).

natural evolution process by applying iterative rounds of random mutagenesis and selection (or screening) of stabilized protein variants. Given an appropriate selection or screening system, this approach is generally applicable because it does not require specific knowledge of the structure of the protein to be stabilized. Moreover, directed evolution is instructive because it is unbiased and may provide stabilizing amino acid exchanges at positions in the protein that were

not anticipated. Moreover, because wildtype and stabilized proteins differ only in few amino acids, the analysis of the observed effects is considerably simplified, compared with the analysis of the much more diverse homologous mesophilic-thermophilic protein pairs. Recent successful examples of stabilizing proteins by directed evolution were summarized in Arnold (2001a) and Sterner and Liebl (2001).

Extrinsic Stabilization by Accessory Compounds

It has been known for some time that the intrinsic stability of some proteins from hyperthermophiles is too low to allow their function in vivo (Thomm et al., 1986; Fabry and Hensel, 1987). These observations suggested that these proteins are stabilized by extrinsic factors such as metabolites or proteins. Many organisms accumulate high concentrations of organic solutes in response to various stress conditions. These solutes are called "compatible solutes" because they do not compromise cellular functions (Carpenter et al., 1993; da Costa et al., 1998). Low-molecular mass solutes in the aqueous environment of proteins can have various effects on protein solubility and stability. At low concentrations, salts can increase protein solubility (i.e., have a salting-in effect), whereas at high concentrations they can lead to protein precipitation (i.e., a salting-out of protein; cf. the section on "Water," subsection "Hydration"). Also, some solutes (e.g., urea or guanidinium chloride) destabilize proteins, whereas others (e.g., glycerol) have a stabilizing effect (Timasheff, 1995; Timasheff and Arakawa, 1997). Two conclusions follow from the fact that in all these cases high concentrations (usually >1 M) of the additives are required: 1) the intermolecular interactions involved must be nonspecific and weak, and 2) water (i.e., hydration) must play an important role, since the effect of a particular compound depends on the differential affinities of the protein and the additive for water (Timasheff, 1995). The precipitating and stabilizing compounds are preferentially excluded from the surface of the protein, that is, the protein has a higher affinity for water than for these agents. As a consequence, proteins are preferentially hydrated, which favors the native state and makes unfolding more unfavorable. In contrast, destabilizing agents bind more strongly than water to proteins. Stabilizing compounds include sugars and polyols (sucrose, trehalose, glycerol, mannitol and sorbitol), amino acids (proline and glycine), methyl amines (sarcosine, trimethylamine-*N*-oxide, and glycine betaine), tetrahydropyrimidine derivatives (ectoins), and some salting-out salts (Timasheff, 1995; Knapp et al., 1999).

In recent years, a number of compatible solutes have been found specifically in thermophiles and hyperthermophiles (Fig. 13). Some of them are likely to be adaptations to life at high temperatures: they are overproduced upon up-shifting the growth temperature of a given microorganism, and significantly increase the stability of a number of its proteins in in vitro measurements. For example, cyclic 2,3-diphosphoglycerate (cDPG) was discovered in hyperthermophilic methanogens (Hensel and König, 1988; Martins et al., 1997), and increasing growth temperature was found to increase its concentration in *Methanothermus fervidus*. The addition of cDPG drastically increased the in vitro stability of GAPDH from *M. fervidus*, but not that of the homologous enzyme from rabbit (Hensel and König, 1988). Various derivatives of *myo*-inositol phosphate were found in hyperthermophilic archaea and bacteria; a correlation between solute accumulation and growth temperature was detected in some cases (Ciulla et al., 1994; Martins and Santos, 1995; Martins et al., 1996; Martins et al., 1997; Ramakrishnan et al., 1997; Lamosa et al., 1998). Di-*myo*-inositol phosphate was found to stabilize GAPDH from *Pyrococcus woesei*, but sodium citrate had a similar effect (Scholz et al., 1992). Clearly, more information is required about the stabilization of proteins by *myo*-inositol phosphate derivatives. It is remarkable that a number of hyperthermophiles with a low salt requirement, e.g., *Thermotoga thermarum*, *Fervidobacterium islandicum*, *Pyrobaculum islandicum* or *Thermococcus zilligii* AN1, do not produce significant amounts of compatible solutes, either at their optimum growth temperatures or after a temperature up-shift (Martins et al., 1996; Lamosa et al., 1998). It was therefore postulated that some compatible solutes, which are produced by slightly halophilic thermophiles, might act when osmotic and temperature stress occur simultaneously (Lamosa et al., 1998).

MOLECULAR CHAPERONES As mentioned earlier, molecular chaperones are ubiquitous in all living cells (cf. to the section "Stability of Biomolecules"). As heat-shock proteins (HSPs) they regulate the kinetic partitioning between folding→association and misfolding→aggregation of polypeptide chains at elevated temperature (Bukau, 1999; Jaenicke and Lilie, 2000). "Thermosomes" in thermophilic and hyperthermophilic Archaea are double-ring cages with eight- to ninefold symmetry consisting of HSP60-subunits (Archibald et al., 1999). As shown for *Pyrodictium occultum*, at the upper temperature limit of viability they may be expressed to protein levels up to 80% of the total cellular protein, indicating that the chaperone is essential for survival under stress conditions (Phipps et al., 1991).

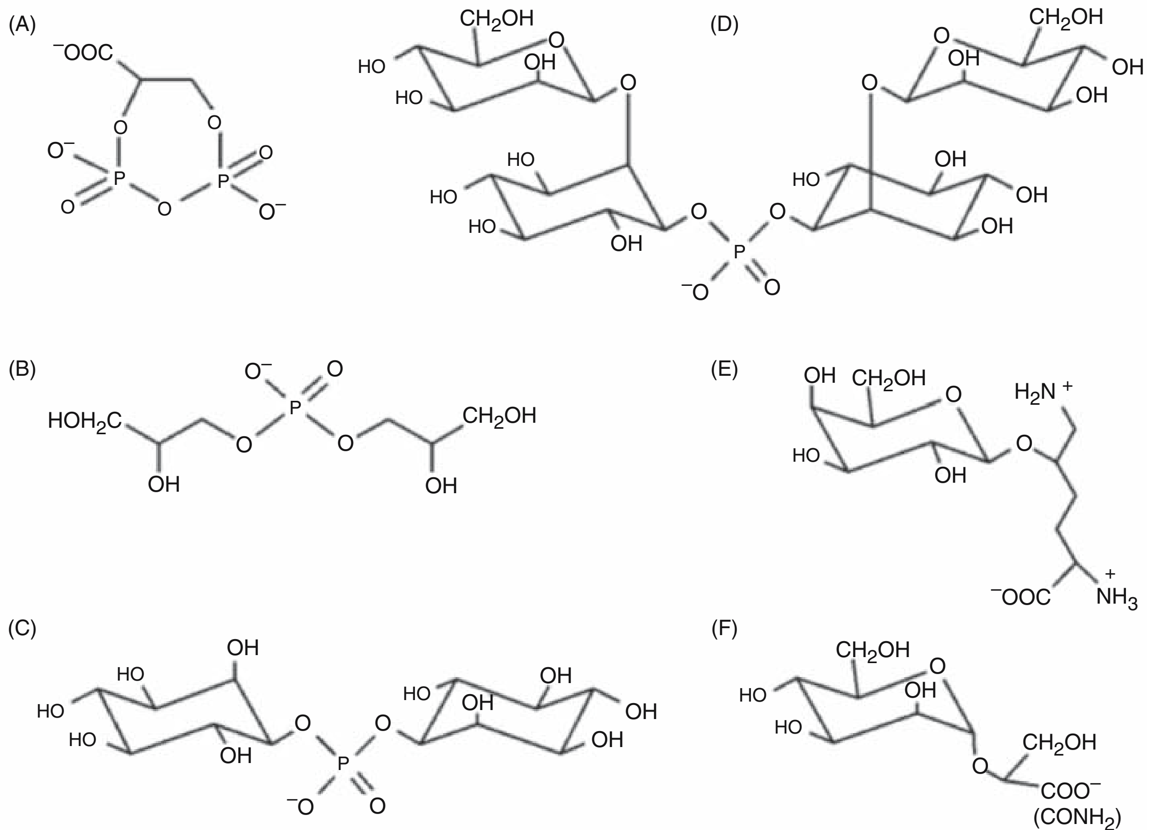

Fig. 13. Compatible solutes from hyperthermophiles. A) Cyclic 2,3-diphosphoglycerate, B) diglycerol phosphate, C) di-*myo*-inositol-1,1′-phosphate, D) di-2-*O*-β-mannosyl-di-*myo*-inositol-1,1′-phosphate, E) β-galactopyranosyl-5-hydroxylysine, and F) α-mannosylglycerate and α-mannosylglyceramide.

Similarly, the hyperthermophiles *Sulfolobus shibatae* and *Archaeoglobus fulgidus* display heat-induced synthesis of high chaperone levels (Kagawa et al., 1995; Emmerhoff et al., 1998). Apart from the correlation of heat stress and HSP expression, relatively little is known about the specific functions of thermosomes. In vitro experiments with the recombinant proteins clearly showed, that the thermosomes from *Pyrodictium occultum* and *Methanopyrus kandleri* display chaperone-like activities, but only dead-end complexes with non-native substrates bound to the reconstituted thermosomes were observed (Minuth et al., 1998, 1999). Because of the complexity of the systems, these experiments were performed with mesophilic substrate proteins below the optimum growth temperatures of the hyperthermophiles. To elucidate the in vivo function, further experiments under more physiological conditions are required.

Hsp70 (or DnaK) proteins have a multitude of functions; they are coupled to nucleotide binding and hydrolysis, and modulated by the co-chaperones Hsp40 (DnaJ) and GrpE (Bukau and Horwich, 1998). Some moderately thermophilic archaea such as *Methanobacterium thermoautotrophicum* possess Hsp70, while the most thermophilic ones have no *hsp*70-homolog encoding genes in their genomes (Gribaldo et al., 1999; Macario et al., 1999); it was therefore speculated that a structurally unrelated chaperone may take over its role in these archaea (Leroux et al., 1999; Siegert et al., 2000). In contrast, the hyperthermophilic bacteria belonging to the genera *Thermotoga* and *Aquifex* possess Hsp70 homologs (Macario et al., 1999).

An important function of chaperones, in addition to the inhibition of aggregation, is the unfolding of proteins, which either feeds misfolded proteins into the cellular degradation system, or offers aggregated protein molecules another chance for proper folding by "iterative annealing" (Horwich et al., 1999; Shtilerman et al., 1999; Weber-Ban et al., 1999; Chen et al., 2001; Grantcharova et al., 2001). Members of the Hsp100/Clp family display significant unfoldase activity of misfolded proteins in yeast and *E. coli*, cooperating with Hsp70 (DnaK) in the subsequent refolding process (Glover and Lindquist, 1998; Goloubinoff et al., 1999; Mogk et al., 1999; Weber-Ban et al., 1999). Protein aggregates are first bound by ClpB; an ATP-triggered structural change leads then to the presentation of hydrophobic regions of aggregated proteins, which are

subsequently solubilized by DnaK. The cooperation of ClpB and DnaK was also demonstrated for ClpB and DnaK from the extreme thermophile *Thermus thermophilus*. In vitro, the DnaK system (DnaK, DnaJ, GrpE and ATP) suppressed heat-induced aggregation of substrate proteins, and ClpB-induced efficient refolding (Motohashi et al., 1999). It is not clear whether similar DnaK-ClpB systems exist in other hyperthermophiles. While the genomes of the hyperthermophilic bacteria *T. maritima* and *Aquifex aeolicus* contain *dnaK* and *clpB* gene homologs, no such homologs have been detected in the archaea so far.

In summarizing, the extrinsic stabilization of proteins by compatible solutes and molecular chaperones appears to be crucial for many hyperthermophiles, especially when they grow close to their upper temperature limits. Further experiments under these extreme conditions promise insights into the cellular mechanisms that set the upper temperature limit at which life is possible.

Conclusions

This survey is based on the assumption that the upper temperature limit of life is dictated by molecular instability at the level of both cytosolic low-molecular weight compounds and biopolymers. As indicated by in vitro experiments, a number of metabolites, especially coenzymes, are unstable under optimum growth conditions of thermophiles and hyperthermophiles. Mechanisms to overcome this instability include 1) rapid catalytic turnover, 2) metabolic channelling and 3) local stabilization by weak intermolecular interactions. In the case of biopolymers, the canonical building blocks are sufficiently stable to allow structural and functional integrity at temperatures close to or even beyond the boiling point of water. Depending on the structural context, significantly higher stabilities can be accomplished, e.g., by evolutionary protein design or chemical modification. However, evolution in the biosphere optimizes for (multi-)functionality rather than stability. Basically, the free energy of stabilization is accumulated from small increments involving electrostatic and hydrophobic interactions. Covalent modifications or extrinsic factors such as salts, specific ligands and compatible solutes may significantly improve thermostability.

In the case of nucleic acids, chemical modification (e.g., RNA methylation) and binding of extrinsically stabilizing components (salts and histone-like basic proteins) are essential in maintaining replication, transcription and translation at temperatures close to or even beyond the melting temperature of DNA and RNA. Only for RNAs, enhanced base-pairing has been observed, whereas thermophile and hyperthermophile DNA shows unexpectedly low G+C contents, even for archaea with optimal growth temperatures above 100°C.

Considering the lipid constituents of mesophilic and thermophilic membranes, characteristic differences have been discovered: Thermophilic archaea contain highly caldarchaeol ether-lipids, which form stable monolayers that span the entire membrane (Fig. 8), whereas the ester-lipids of bacterial thermophiles are stabilized by a high content of saturated fatty acids. The necessary fluidity is regulated either by differences in the degree of saturation, or by adjusting the chemical composition of the fatty-acid hydrocarbon side chains.

In the case of proteins, enhanced intrinsic stability in thermophiles compared to their mesophilic counterparts is the cumulative effect of minute improvements of local interactions at the secondary-, tertiary- and quaternary structural level, e.g., higher packing efficiency, networks of ion pairs and/or hydrogen bonds, and reduction of conformational strain. Taken together, these increments suggest that thermostability corresponds to increased rigidity at low temperature and shifts to normal flexibility at physiological temperature; evidently, evolutionary adaptation to a physical parameter tends to maintain "corresponding states" with regard to conformational flexibility. At this point, it seems appropriate to stress that any generalization in considering the structure-function relationship of biopolymers, on the one hand, and their stability on the other, needs careful controls. In the present case, this may be illustrated by a number of contradicting observations: 1) There are hyperthermophilic enzymes with high intrinsic thermostability that are more active than their mesophilic counterparts, even at room temperature, thus combining high catalytic efficiency with high overall rigidity (Sterner et al., 1996; Ichikawa et al., 1998; Merz et al., 1999). 2) In stressing overall rigidity, it is important to notice that there is not necessarily a single measure of flexibility: a given 3D structure of a protein molecule may provide a rigid scaffold, e.g., a $(\beta\alpha)_8$-barrel, at the same time showing high catalytic efficiency due to the local flexibility of its active center (Shoichet et al., 1995). Along these lines, attempts have been reported to distinguish the "macro-" and "microstability" of proteins (Závodszky et al., 1998). 3) There is no fundamental reason for stability and rigidity to be strictly correlated because flexibility implies high conformational entropy of the folded state, which is favorable to thermodynamic stability. In addition, rigidity and flexibility may depend on the methods applied; one and the same protein

may be rigid on a nanosecond time scale, but flexible on a millisecond time scale (Lazarides et al., 1997; Daniel and Cowan, 2000). 4) Making use of the amide hydrogen-exchange rates in rubredoxin from *Pyrococcus furiosus* (the most thermostable protein presently known), it was shown that conformational opening processes occur within milliseconds for all amide positions along the polypeptide chain; the corresponding distribution of amide protection factors is indistinguishable from data reported for typical mesophilic homologs (Hernández et al., 2000; Jaenicke, 2000b). Obviously, these data are in contrast to the above generalization that enhanced conformational rigidity in the folded native state determines the increased thermal stability of thermophilic and hyperthermophilic proteins. At present, there is no way to resolve the apparent discrepancies; more experiments need to be done to combine the data to a new general view of protein stabilization.

Another open question refers to the phylogeny of microorganisms and their genes (cf. Doolittle, 1998; Koonin et al., 1998). Considering the protein repertoire of mesophiles and thermophiles, a wealth of experimental data proved that the average stabilities of thermophilic proteins exceeds the stabilities of the corresponding mesophilic proteins (Fig. 2). Roughly speaking, the mutative adaptation of a mesophile to a high-temperature environment requires the adaptation of the complete proteome to the higher temperature. For the reverse shift, a single temperature-sensitive mutation is sufficient. In spite of this simple argument, it is still unclear which of the two alternatives describes the direction of natural selection in the early evolution of the biosphere. The accumulation of extreme thermophiles close to the root of the (16S rRNA) phylogenetic tree (Fig. 14) favored the hypothesis that the prebiotic soup was hot, suggesting that ther-

mophiles preceded mesophiles in the early history of life (Woese et al., 1990).

However, the advent of complete genome sequences made it clear that the phylogenetic tree has more complex roots than expected from a single genetic marker molecule inasmuch as different genes may or may not agree with the tRNA tree. Even more perplexing, genomes may contain a mix of DNAs, some related to archaea, while others are close to bacteria, so that a given microorganism, depending on the marker gene, ends up at different phylogenetic placements. It looks as if each gene has its own history, possibly due to mechanisms such as horizontal gene transfer or "gene swapping" (Nelson et al., 1999; Ochman et al., 2000). Although the mechanism of gene swapping is still unknown, there seems to be no better explanation for the observation that 17 out of 34 families of eukaryotic proteins that date back to early cell evolution look as if they come from bacteria, while only 8 families show a greater similarity to archaea, the supposed ancestor of eukarya. In spite of these inconsistencies, presently available genome sequences still fit the three-kingdom hypothesis (Miller and Lazcano, 1995; Woese, 1998; Deckert et al., 1998; Doolittle, 1998; Daniel and Cowan, 2000). No thermophilic eukarya have been discovered so far (R. Rachel, personal communication, 2001); possible reasons for this observation have been mere speculation.

Concerning the geological time when hyperthermophilic microorganisms might have evolved, there are claims for the occurrence of a variety of early archaea around 4 billion years ago. Photosynthetic life (both anoxygenic and oxygenic) has been established as early as 3.5–3.7 billion years ago (Rosing, 1999), molecular fossil evidence allowed the existence of cyanobacteria to be traced back 2.7 billion years (Brocks et al., 1999), and in addition, chemotrophic archaea have been spotted in 3.2 billion year-old volcanogenic massive sulfide rocks (Rasmussen, 2000). The latter finding extends the realms of thermophilic archaeal life into the extreme of deep-sea hot springs, in addition to the open ocean, mid-ocean ridges, lake communities, costal sediments and coastal hydrothermal systems. It does not show that abyssal hydrothermal life came before photosynthesis; however, it may be taken to support the idea that steps in the early history of life took place around hydrothermal systems (Nisbet, 2000).

CHAPTER 1.8

Life at Low Temperatures

SIEGFRIED SCHERER AND KLAUS NEUHAUS

Introduction

Most habitats on our planet are permanently cold. By volume, 90% of the world's oceans have a temperature of 5°C or less, supporting both psychrophilic and psychrotolerant microorganisms. When terrestrial habitats are included, over 80% of the earth's biosphere is permanently cold (Russell, 1990a). Archaea contribute significantly to biomass in cold environments, although few have been isolated (Goodchild et al., 2004).

Microorganisms that are able to grow at low temperatures are termed "psychrophilic" (sometimes also "obligate psychrophiles") and "psychrotolerant" (or "facultative psychrophiles" or "psychrotrophs") or even "psychroactive" (Nozhevnikova et al., 2001b). We recommend here the use of only the designations "psychrophilic" and "psychrotolerant." (Morita, 1975) has defined psychrophiles "as organisms having an optimal temperature for growth at about 15°C or lower, a maximal temperature for growth at about 20°C, and a minimal temperature for growth at about 0°C or lower." This author summarized the confusing discussion started about 100 years ago concerning which definitions and terms are appropriate. The above-mentioned terms have no generally accepted definitions. However, this is not surprising since microorganisms are adapted to low temperature to very different degrees, and a continuum of evolutionary transitions exists in all genera that harbor cold-adapted strains. For instance, strains of typical psychrophiles or psychrotolerants within the same species may have quite different doubling times at the same low temperature. The terms "mesophile," "psychrotolerant," and "psychrophile" are therefore impossible to define exactly.

Table 1 suggests the use of three temperatures for defining principal types of cold adaptation. Because of the evolutionary variability of bacteria, many transitions between thermal types commonly exist; therefore, any such temperature ranges should be considered approximate guidelines only.

The first reported growth of a bacterium at low temperature was probably by (Forster (1887)) and about luminescent bacteria from salt water: ". . . they grow almost as well in the ice box as at the usual room temperature." For a review, see Morita (1975). However, within the last five years, the number of papers dealing with cold adaptation has increased sharply. This is true both for the analysis of the cold shock response (see the section on The Cold Shock Response and Cold Adaptation in this Chapter), as well as the description of new psychrophilic and psychrotolerant species, especially from permanently cold habitats. This sharp increase in interest (as reflected in the increased number of reviews written about bacterial life at low temperature in recent years) is certainly fueled by many emerging biotechnological uses of cold tolerant organisms (Margesin and Schinner, 1999).

Table 2 lists selected psychrotolerant and psychrophilic species described in the literature between 2000 and 2003. Generally, cold-adapted species are found throughout the entire taxonomic range of bacteria and archea as well as in many climates.

Some general reviews on the physiological adaptations of cold-adapted microorganisms have been published within the last decade by Russell (1998), (1990b); Gounot (1991), Margesin and Schinner (1999), and D'Amico et al., (2002a). The reader may consult these reviews for further references. Reviews on specific subjects within the area of cold adaptation are mentioned below (see Table 9). This article will mainly focus on data published within the last few years.

The Cold Shock Response and Cold Adaptation

Organisms respond to a cold shock by a specific pattern of transient gene expression (Yamanaka, 1999a); reviewed in Weber and Marahiel (2003). However, note that the "specific pattern" described in literature is based nearly exclusively on observations made in cultures growing exponentially in a liquid broth. Comparison of cold shocked gel-entrapped *Escherichia coli* cells to

Table 1. Definitions for typical cold-adapted and mesophilic microorganisms.

	Growth temperature[a]		
	Minimal	Optimal	Maximum
		(°C)	
Typical psychrophile (obligately psychrophilic)	<0	<15	<20
Typical psychrotolerant (facultatively psychrophilic, psychrotrophic)	<7	>20	>25
Typical mesophile	>10	>25	>35

[a]The temperatures given for a psychrophile are taken from Morita (1975). Taking into account the temperature variations for the growth of microorganisms in refrigerated food reported in the literature, the lower growth limit of psychrotolerants in Table 1 has been set to 7°C.

Table 2. Selection of psychrotolerant and psychrophilic species described between 2001 and beginning of 2005.

free floating cells revealed significant differences in the protein response (Perrot et al., 2001). What one would define as a specific cold shock stimulon is therefore dependent on the experimental procedures. To our knowledge, virtually no report deals with the cold shock response of stationary phase cells, though many bacteria spend most of their lifetime in stationary phase (Kjelleberg, 1993).

Although low temperature induces an adaptation of many cellular components, e.g., the membrane composition, the supercoiling of the DNA,

and the transcriptome (see the section Cold Shock and the Degradation in this Chapter), the most severe problem seems to be initiation and translation of bulk mRNA at low temperatures (Broeze et al., 1978; Jones and Inouye, 1994). Shifting a culture of *Escherichia coli* from 37°C to 8°C or below resulted in polysomal run-off and accumulation of free ribosomes (Broeze et al., 1978; Xia et al., 2002).

Other stresses, e.g., some antibiotics (VanBogelen and Neidhardt, 1990), dilution of a culture with fresh medium (Brandi et al., 1999a; Brandi et al., 1999b), an upshift in the concentration of nutrients (Yamanaka and Inouye, 2001a), diauxic lag (Novotna et al., 2003), oxidative stress (Smirnova et al., 2001b), hydrostatic pressure (Wemekamp-Kamphuis et al., 2002), or exposure to colicin E9 (Walker et al., 2004) can mimic a cold shock response or at least induce the cold shock stimulon to some extent (Wick and Egli, 2004). Therefore it could be hypothesized that every event stopping or stalling the ribosomes leads to an induction of the cold shock response (Walker et al., 2004). This is most obvious for the cold shock response itself (Gualerzi et al., 2003), the use of certain antibiotics affecting the translational speed (VanBogelen and Neidhardt, 1990), or after nutrient upshift (Brandi et al., 1999a) in which many new mRNAs are synthesized to adapt to the new nutrition provided.

Chilling of bacterial cells affects their viability. In *Bacillus subtilis* it was shown that death after cold shock is not only due to a passive event (a reaction velocity decrease and outrun of energy), but also to translocation of a DNase (YokF) from the periplasm into the cytoplasm attacking the DNA of the cell. This partly resembles apoptosis in eukaryotic cells (Sakamoto et al., 2001).

Most work on cold shock was done with the mesophiles *E. coli* and *B. subtilis*. This article, therefore, reports mainly on these two organisms. The reader may consult the detailed review by Weber and Marahiel (2003) about bacterial cold shock responses. Besides cold shock proteins, some cold adaptation proteins have been described. However, much less is known about the permanent response of bacteria towards low temperature. This work is summarized in the section Cold Adaptation.

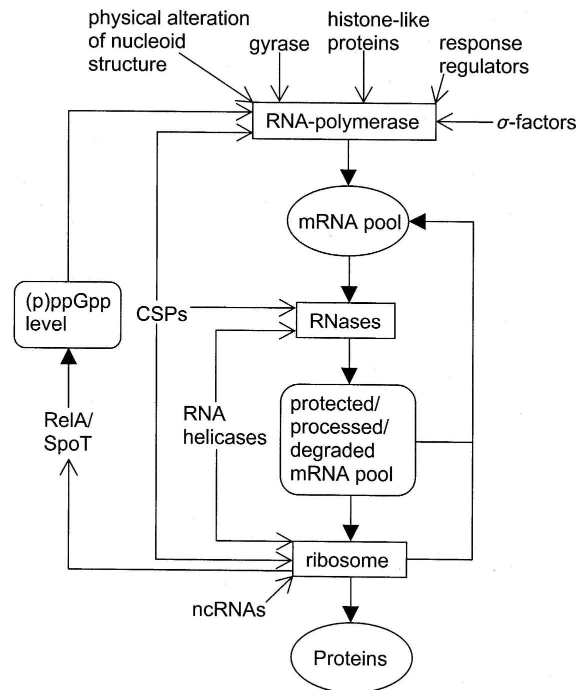

Fig. 1. Regulation of bacterial cold shock responses as a multiple filter model. The arrows indicate the flow of genetic information from DNA (via RNA polymerase, top) to protein (bottom), in turn affecting via a feedback circuit response (eventually conducted by effector molecules) this genetic flow. The T-arrows have to be read as "modulates activity of." The filter systems are boxed in square boxes. These filters are integration systems reacting directly or indirectly to temperature changes. Adapted from Weber and Marahiel (2003).

Major Cold Shock Proteins: CspA–CspI

In most free-living bacteria, a cold shock protein (Csp) family has been identified (Francis, 1997) and displays homology to CspA, first discovered in *E. coli* (Jones et al., 1987); reviewed in Ermolenko and Makhatadze (2002). Since CspA has the highest induction level, these proteins are often termed "major cold shock protein(s)" (MCSPs; Goldstein et al., 1990; Etchegaray and Inouye, 1999b; Lopez and Makhatadze, 2000). However, note that many parasitic or pathogenic bacteria do not contain such a protein family (e.g., *Chlamydia trachomatis*, *Helicobacter pylori*, *Mycoplasma* sp. and others (Yamanaka, 1999a) and some psychrotrophic bacteria, as *Aeromonas hydrophila*, may not respond with a "typical" cold shock response (Imbert and Gancel, 2004). After a downshift from 37°C to 10°C, the major cold shock proteins of *E. coli* (CspA, B, G and I) are induced. The Csps reach 13% of the total protein synthesis, and synthesis of CspA is increased 30-fold under certain circumstances (Jones et al., 1987; Goldstein et al., 1990; Lee et al., 1994; Thieringer et al., 1998; Etchegaray and Inouye, 1999b; Wang et al., 1999; Gualerzi et al., 2003). In the psychrotolerant *Yersinia enterocolitica*, a CspA tandem has been discovered which may lead to a higher rate of CspA synthesis (Neuhaus et al., 1999). A first hypothesis formulated on the basis of CspA's abundance after a cold shock was that this protein may function as an antifreeze protein.

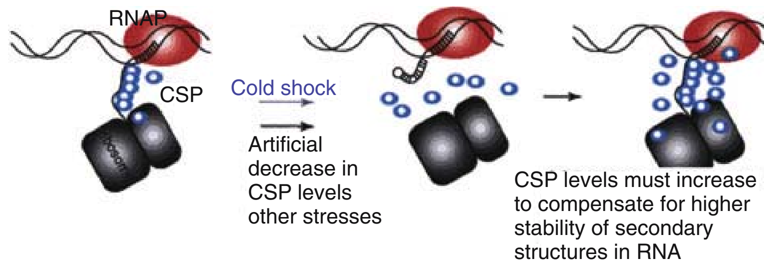

Fig. 2. Model for the function of cold-shock proteins (CSPs) as RNA-chaperones that couple transcription to translation of mRNA. During growth at 37°C, CSPs bind to mRNA as it protrudes from the RNA-polymerase complex (RNAP) and maintain the RNA in a linear form. The ribosome then displaces CSPs, which have only low affinity for RNA, and initiates translation. Accordingly, an artificial decrease in the CSP concentration would lead to the formation of secondary structure in RNA and prevent translation. After cold shock or other stresses (e.g., carbon starvation), an increase in the CSP concentration is needed to counterbalance the increased stability of RNA secondary structure. Redrawn after Graumann and Marahiel (1998).

Although a cold adaptation period preceding freezing enhances freezing tolerance (Thammavongs et al., 1996); Kim and Dunn, 1997; Kim et al., 1998), the role of MCSPs in that protection has not been demonstrated unequivocally (Wouters et al., 1999).

Apparently, CspA is-at least in part-an mRNA chaperone, opening the secondary structures of mRNAs at low temperature, an alteration which helps the ribosomes to function after a cold shock (Jiang et al., 1997); Fig. 2). Besides CspA, *E. coli* contains a family of highly similar Csps, containing eight other members: CspB consists of 71 amino acids (aa) and is 79% identical to CspA. Similarly, CspC contains 69 aa and has 70% identity to CspA; CspD (74 aa) has 45% identity; CspE (69 aa) has 70% identity; CspF (70 aa) has 44% identity; CspG (70 aa) has 73% identity; CspH (70 aa) has 47% identity; and CspI (70 aa) has 70% identity (Lee et al., 1994; Yamanaka et al., 1994; Yamanaka et al., 1998; Nakashima et al., 1996; Wang et al., 1999). Also, Bacillus cereus contains a family of MCSPs (Mayr et al., 1996). All these different CspA homologs are believed to be stress adaptation proteins for different tasks, but the cold-inducible Csps can replace each other to some extent (Graumann et al., 1997; Yamanaka et al., 1998; Gualerzi et al., 2003). CspA is induced after a cold shock from 30°C down to 10°C, CspB and CspG occur between 20°C and 10°C, and CspI occurs below 15°C (Wang et al., 1999). A quadruple deletion mutant missing CspA, CspB, CspE and CspG was cold sensitive and formed filamentous cells at 15°C. This phenotype was suppressed by overexpression of each member of the cold-shock protein family except CspD, which causes lethality (Phadtare and Inouye, 2004b; Xia et al., 2001b). A different function of CspA and CspD was supported by another line of evidence. Green fluorescent protein (GFP) fusions were found in the nucleoid in the case of CspD, and in a polar position of the cell in the case of CspA (Giangrossi et al., 2001a), however, in Pseudomonas Csp seems to be distributed evenly in the cytosol of the cell (Khan et al., 2003).

Most cold inducible MCSPs have an unusually long mRNA leader region of 156–256 bp upstream of the translational start. An exception is the mRNA leader region of the *cspH* gene from *Salmonella enterica*, which is only 55 bp long (Kim et al., 2001). Another exception was reported recently, the cold-inducible CspA-homolog CspV from *Vibrio cholerae*, which exhibits a leader of only 12 bp (Datta and Bhadra, 2003).

The CspA molecule is small (7.4 kDa and 70 aa), acidic (pI 5.92), and very hydrophilic (Goldstein et al., 1990). A remarkable feature is the high sequence similarity of the bacterial major cold shock proteins to eukaryotic Y-box factors, including human YB-1 (which is 44% identical with CspA) and frog FRG Y1/2 (Didier et al., 1988; Tafuri and Wolffe, 1990; Lee et al., 1994). These are domains of DNA or RNA-binding motifs which bind to a specific regulatory sequence called the “Y-box motif,” ATTGG/CCAAT (Wolffe, 1994), and are therefore designated “cold-shock domains” (CSDs; Karlson and Imai, 2003). Interestingly, a protein with a similar fold, initiation factor 1, can complement in a *B. subtilis cspB cspC* double mutant (Weber et al., 2001a). Figure 3 shows the three-dimensional (3D) structure of CspB from *B. subtilis* (Schindelin et al., 1992; Schindelin et al., 1993; Schindelin et al., 1994; Schnuchel et al., 1993), which is similar to that CspA from *E. coli* (Schindelin et al., 1994; Feng et al., 1998). It consists of five antiparallel β-sheets, which form a barrel. The RNP-1 motif KGFGFI (Landsman, 1992; Lee et al., 1994) and RNP-2 motif VHVHF

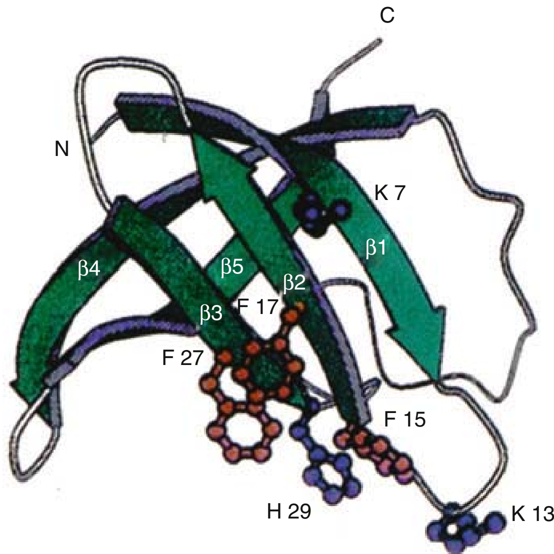

Fig. 3. Three-dimensional structure of CspB from *B. subtilis* features five antiparallel β-sheets, which form a barrel. From Graumann and Marahiel (1996a).

(Landsman, 1992; Schnuchel et al., 1993) contain most of the aromatic residues. They are exposed to the water phase and interact with single-stranded (ss) DNA (Schröder et al., 1993; Newkirk et al., 1994). If the aromatic residues in the RNP-1 or RNP-2 are replaced as a result of mutations, binding of ssDNA containing the Y-box motif is abolished (Schröder et al., 1995).

CspB is very similar to CspA, the time frame of its induction follows closely that of CspA (Etchegaray et al., 1996). The promoter regions of *cspA*, *cspB* and *cspG* display similar features with similar promoter sequences and the same unusually long leader region of about 156–256 bases (Nakashima et al., 1996; Datta and Bhadra, 2003). The function of CspH needs to be elucidated (Yamanaka et al., 1998); however, in *Salmonella enterica*, *cspH* was described as cold inducible (Kim et al., 2001).

Among the non-cold-inducible MCSPs, CspC is rather highly expressed at normal growth temperature (37°C) and its level remains unchanged after a cold shock (Lee et al., 1994). Also, CspC was found to be a multicopy repressor of the *mukB106* mutant (Yamanaka et al., 1994). This mutant has a defect in chromosomal partitioning (Niki et al., 1991). CspD is induced at the onset of the stationary phase and inversely dependent on growth rate or glucose starvation. Guanosine-3′-diphosphate-5′-(tri)diphosphate, collectively abbreviated (p)ppGpp, is a positive regulator for CspD (Yamanaka and Inouye, 1997; Yamanaka et al., 1998). Because overproduction of CspD is lethal, the presence of overproducing cells is indicated by a typical morphology, which is due to impaired DNA replication. CspD inhibits effectively both the initiation and the elongation of minichromosome replication in vitro (Yamanaka et al., 2001c), and it is switched off after cold shock (Lee et al., 1994). CspD has been found associated with the nucleoid in *E. coli* (Giangrossi et al., 2001a). The function of CspF is unknown and needs to be elucidated (Yamanaka et al., 1998).

CspE is abundantly produced at 37°C, but a *cspA* deletion mutant also has higher levels of CspE in the cold. Originally, CspE was found as a multicopy repressor of the *mukB106* mutant gene that codes for a protein, which, together with CspC, plays a role in chromosomal partitioning (Yamanaka et al., 1994). Later, CspE was found to interact with nascent RNA in transcription complexes, causing antitermination. The latter function is coupled to the nucleic acid melting abilities of this protein (Phadtare et al., 2002a; Phadtare et al., 2002b; Phadtare et al., 2004c). Furthermore, it binds to the Y-box motif and functions as a repressor for *cspA* at 37°C through an interaction with the transcription elongation complex (Bae et al., 1999). Recently, it was discovered that CspE binds to poly(A) tails of mRNAs (which is a decay signal) and subsequently impedes the 3′ to 5′ exonucleolytic decay by polynucleotide phosphorylase (PNPase). CspE also inhibits both internal cleavage and poly(A) tail removal by RNase E, thus stabilizing mRNA (Feng et al., 2001). CspE was also found to be important in radiation resistance of *E. coli* (Chattopadhyay, 2002; Mangoli et al., 2001). All evidences taken together imply that CspE is a regulator also important for translational fidelity of DNA in cold environments, and for DNA condensation and partitioning during growth (Mangoli et al., 2001; Sand et al., 2003).

The most prominent Gram-positive bacterium examined with respect to cold shock is the mesophile *B. subtilis* (Weber and Marahiel, 2002) extensively reviewed the cold shock response of this organism. Briefly, after a cold shock from 37°C to 15°C, protein synthesis resumed 2 h later. During the adaptation, CspB (which is a homolog to CspA of *E. coli*) is induced and remains at higher than pre-cold shock levels (Willimsky et al., 1992; Kunklova, 1995; Graumann et al., 1996b). A *cspB*::*lacZ* fusion showed a sevenfold induction after cold shock from 37°C to 10°C. In addition to CspB, CspC and CspD of *B. subtilis* are homologs; CspC is also cold inducible (Graumann et al., 1997) but differs slightly from CspB since the CspC increases more rapidly. Interesting genome-wide transcriptional profilings of the *B. subtilis* cold shock response were conducted by Kaan et al. (2002) and Beckering et al. (2002), the former

study describing genes not only induced but also repressed after cold shock in this organism.

In *B. subtilis*, CspB and CspC not only participate in the cold shock response, but also act as major stationary-phase induced proteins. This illustrates the broad functionality of these Csps in cellular physiology (Graumann and Marahiel, 1999a).

In Anabaena sp., no MCSP could be detected. However, an RNA helicase CrhC was found to be induced after cold shock (Chamot et al., 1999; Chamot and Owttrim, 2000). This helicase is completely membrane bound and mainly polar localized in this organism (El-Fahmawi and Owttrim, 2003). Interestingly, *E. coli* CspA has also been found in a polar position, but it remains in the cytoplasm (Giangrossi et al., 2001a). Even though the function of CrhC is not completely clear, the RNA unfolding abilities of both proteins, CrhC and CspA, seems to be needed in polar positions. In Synechococcus sp., a heat shock protein (Hsp)90 homolog, HtpG, was found to be heat and cold shock inducible (Hossain and Nakamoto, 2003).

Regulation of the Major Cold Shock Proteins

The regulation of CspA induction in *E. coli* after cold shock is rather complex and not yet fully understood. Transcriptional and posttranscriptional regulation of cold shock genes, including the MCSPs, was reviewed in detail by Gualerzi et al. (2003), and an overview of some aspects is given in Fig. 4. The cspA gene exhibits an unusually long leader sequence. The major transcription start +1 is located 159 bp upstream from the translational starting point. The promoter seems to be σ-70 dependent, since the –35 region (TTGCAT) and the –10 region (CTTAAT) are found to be similar to a σ-70 consensus sequence (TTGACA for the –35 and TATAAT for the –10 (Qoronfleh et al., 1992; Tanabe et al., 1992). Other regulatory elements in the gene sequence of cspA include the cold box (Fang et al., 1998; Jiang et al., 1996b), the upstream (UP) element, the downstream box (Mitta et al., 1997), the upstream box (Yamanaka et al., 1999c), and others (Yamanaka, 1999a). An overview of the features of the cspA gene sequence is given in Fig. 5.

The 5′ end of the *cspA* mRNA contains a regulatory sequence (cold box), which stabilizes the mRNA at low temperature, enabling cold shock induction (Xia et al., 2002). The consensus cold box sequence (5′ UGACGUACAGA) is found in *cspA*, *cspB* and *csdA* (Jiang et al., 1996b). However, if the 5′ end of *cspA* containing this cold box is overproduced, the expression of cold shock genes is no longer transient, and the synthesis of bulk proteins is impaired (Jiang et al., 1996b; Xia et al., 2002). Also, the cessation of regrowth after cold shock is prolonged. This fits

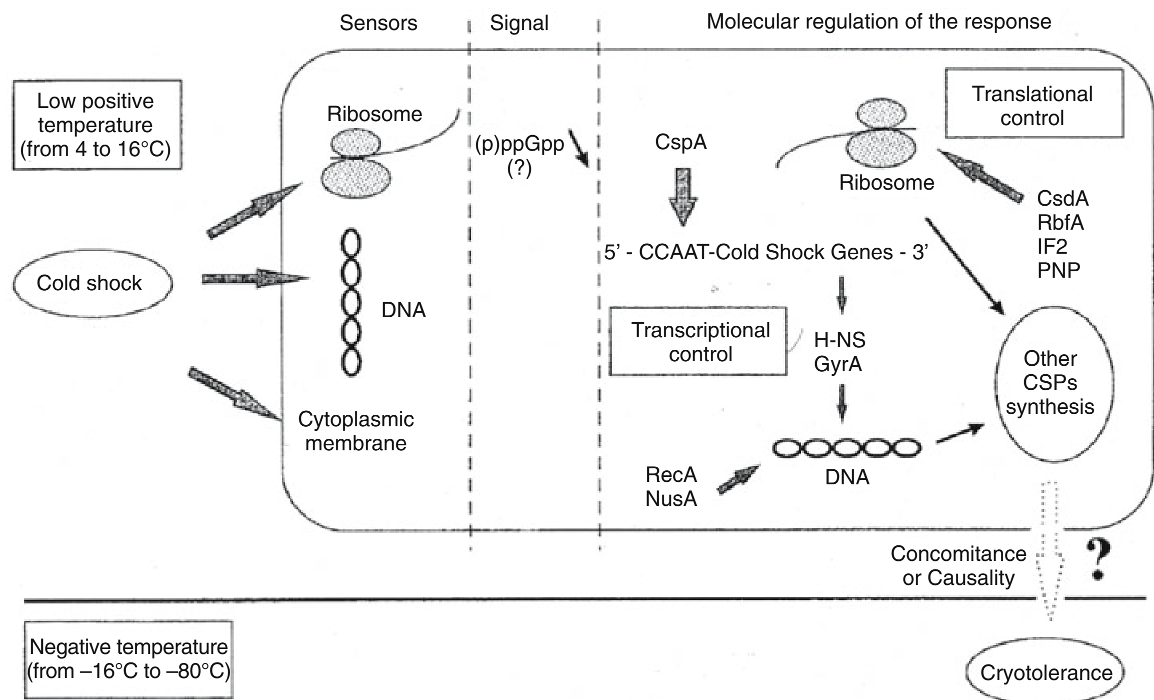

Fig. 4. Some aspects of the cold shock response. From Panoff et al. (1998).

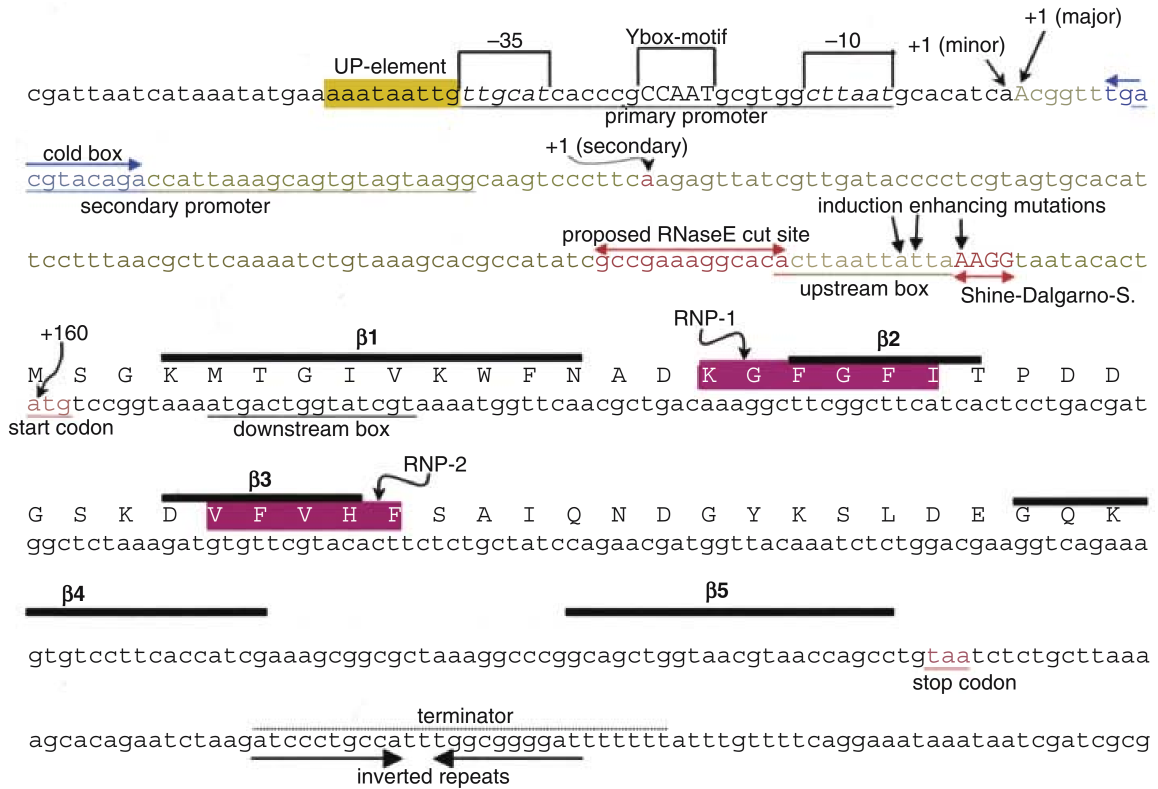

Fig. 5. Overview of the features of the *cspA* gene and the CspA protein.

nicely with the observation that *cspA* mRNA in excess is poisonous to the cell. The robust translatability of *cspA* mRNA depends on initiation, and the ribosome appears to be preadapted to translate *cspA* mRNA (Etchegaray and Inouye, 1999b; Xia et al., 2001a). Since overproduction of CspA together with the overproduction of the 5′-end restores the normal cold shock response, CspA itself probably interacts with the cold box (Jiang et al., 1996a). Furthermore, Giuliodori et al. (2004) could repeat the preferential translation of cold-shock mRNAs after cold shock in vitro. Apparently, cold-shock 70S ribosomes display some translational selectivity for MCSP mRNAs. The *trans*-acting factors involved are 1) CspA itself (increasing translatability of mRNA in the cold) and 2) the cold shock-induced stoichiometric imbalance between the initiation factors IF1, IF2 and IF3, on the one hand, and the ribosomes, on the other. Possible *cis*-acting elements discussed are the secondary or tertiary structures of the unusual long 5′ leader sequences of MCSP mRNAs.

Furthermore, in addition to CspA-mediated autoregulation, a repressor for *cspA* was found, which turned out to be CspE. CspE is abundantly produced at 37°C, and in a *cspE* mutant, *cspA* is derepressed (Fang et al., 1998). In vitro, CspE and CspA cause transcriptional pausing just behind the cold box of *cspA*, and CspA production is inhibited by addition of CspE to the translating ribosomes (Bae et al., 1999; Phadtare and Inouye, 1999).

Mutational analysis of the 5′-untranslated leader of *cspA* showed another element to be involved in regulation of CspA. A deletion of a few bases upstream from the Shine-Dalgarno sequence (SDS) decreased the CspA amount more than 10-fold. It turned out that a 13-bp sequence located 11 bp upstream of the SDS is conserved in the cold-inducible genes *cspA*, *cspB*, *cspG* and *cspI*. This element was designated the "upstream box," and it is speculated that this region may form different secondary structures at different temperatures, leading to an efficient translation at low temperatures or nearly zero translation at higher temperatures (Yamanaka et al., 1999c).

Another element in CspA induction is the so-called "downstream box" (DB; Mitta et al., 1997). This element is found downstream of the ATG start codon of some cold shock genes and, according to its proponents, should be able to anneal to a complementary anti-downstream box at the 16S rRNA, thereby enhancing translation initiation. The existence of the downstream box

has been disputed. Sprengart et al. (1996), Etchegaray and Inouye (1999a), Etchegaray and Inouye (1999c), Etchegaray and Inouye (1999d), Mironova et al. (1999), and Xia et al. (2001a) are in favor, while O'Connor et al. (1999), Resch et al. (1996), Bläsi et al. (1999), La Teana et al. (2000), and Rocha et al. (2000) are against. Apparently, Moll et al. (2001) finally rejected the concept of the downstream box.

Cold Shock and the Degradosome

Recently, the mRNA-decay machinery of bacteria came into focus. In general, adaptation to low temperature after cold shock includes the establishment of a new equilibrium of the transcriptome following changes in transcription and mRNA decay rates, both of which are important for gene regulation in bacteria. The mRNA content of the cell is therefore not only regulated by cold shock induction or repression of certain genes, but also by stabilization or destabilization (depending on the specific mRNA and on the usage of different subsets of RNases; Mohanty and Kushner, 2003; Polissi et al., 2003). The subsets include PNPase and RNase H, which are cold shock induced, and RNase II or RNase E, which are not (Cairrão et al., 2003).

The induction of CspA is mainly due to an increase in mRNA stability. Its half-life is 12 s at 37°C, but between 15 min and 30 min at 15°C in *E. coli* (Tanabe et al., 1992; Jiang et al., 1993; Fang et al., 1997; Gualerzi et al., 2003). If the coding region of *cspA* is fused to the constitutive promoter *lpp*, it is still cold inducible. This observation is explained by a strong vulnerability of the transcript to RNase E degradation at 37°C. Even if the *cspA* promoter is turned on constitutively, CspA can only be synthesized if the transcript is stabilized, perhaps by CspE (Fang et al., 1997; Feng et al., 2001). As in *E. coli*, the transcripts of *cspB* and *cspC* in *B. subtilis* are also dramatically stabilized, having a half-life of 1 min at 37°C and more than 30 min at 15°C (Kaan et al., 1999). A similar observation was made in *Rhodobacter capsulatus* with a *cspA* transcript half-life of around 4 min at 32°C and 47 min at 10°C (Jäger et al., 2004).

Downregulation of MCSP mRNA is an important step, at least in enterobacteria, before growth can resume. This phenomenon is mainly due to the exceptionally strong ability of MCSP mRNAs to initiate at the ribosome. Therefore MCSP mRNA outcompetes bulk mRNA and thus prevents growth (Neuhaus et al., 2000b; Xia et al., 2001a; Yamanaka and Inouye, 2001b). In the above-mentioned PNPase-deficient strains, the decay of *cspA* mRNA is delayed, subsequently preventing re-growth (Neuhaus et al., 2000b). In *Yersinia enterocolitica*, the *cspA* tandem mRNA is cleaved at multiple specific cut sites, with an AGUAAA consensus (termed "cold shock cut box") to downregulate the MCSP mRNA. After these initial cleaving steps, the fragments are removed rapidly and growth can resume (Neuhaus et al., 2003). Cleavage of the *cspA* transcript within the coding sequence and subsequent rapid removal of the fragments was also found in *Rhodobacter capsulatus* (a member of the alpha-proteobacteria), but no consensus cut sequence could be detected (Jäger et al., 2004). CspE was found to interfere with both the PNPase and RNase E of the degradosome machinery, inhibiting internal cleavage and removal of the poly(A) tails from mRNAs, thus stabilizing particular mRNAs (Feng et al., 2001).

Bacteria without PNPase, which is a secondary cold shock protein, are cold sensitive (Clarke and Dowds, 1994; Goverde et al., 1998; Bae et al., 2000; Zangrossi et al., 2000). Curiously, this appears not to be true for *Pseudomonas putida*, indicating surprising differences between some species (Favaro and Deho, 2003). The cold-temperature induction of PNPase in *E. coli* occurs by reversal of its autoregulation. At 37°C, ribonuclease III cleaves the leader of the pnp mRNA, whereupon PNPase represses its own translation via unknown mechanisms. This latter step is inhibited after cold shock (Beran and Simons, 2001; Mathy et al., 2001).

RNase H was recently found to be a cold shock protein, too. This protein, posttranscriptionally regulated by mRNA stabilization due to PNPase activity, subsequently regulates maturation of other mRNAs (especially small stable RNAs) by its exonuclease abilities. An RNase H mutant produces smaller colonies when grown at lower temperatures (Cairrão et al., 2003).

Other Cold-Inducible Proteins

CspA induces and is part of the cold stimulon, directly or indirectly regulating 30 proteins, such as H-NS or GyrA (Madan Babu and Teichmann, 2003; Martinez-Antonio and Collado-Vides, 2003). H-NS is a histone-like nucleoid protein acting on DNA bending (La Teana et al., 1991; Brandi et al., 1994; Giangrossi et al., 2001b) and GyrA is part of topoisomerase II (Maxwell and Howells, 1999). Those promoters of secondary cold shock proteins contain one or more of the so-called "Y-box motif" CCAAT. Recognized by CspA, this Y-box motif subsequently activates transcription of the protein (Qoronfleh et al., 1992). This is true at least for H-NS, GyrA, and possibly other proteins (La Teana et al., 1991; Jones et al., 1992b). The enhanced level of GyrA together with H-NS, and HUβ increases the negative supercoiling of plasmids and chromosomal DNA (Goldstein and Drlica, 1984; Giangrossi

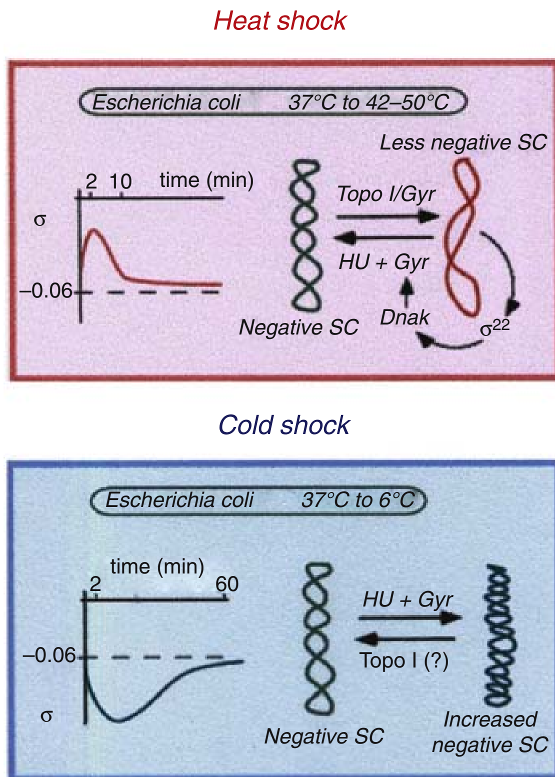

Fig. 6. Effects of heat shock and cold shock on plasmid DNA. The left side of each panel shows the variation in the plasmid-specific linking difference (σ = δLk/Lko), dependent on the time of exposure to the shock temperature. SC, supercoiling; Topo, topoisomerase; Gyr, gyrase; and HU, a small, basic, heat-stable DNA-binding protein. From Lopez-Garcia and Forterre (1999).

et al., 2002). Why GyrB is not induced is unclear, but the induction of GyrA seems to be sufficient to increase the DNA twisting after cold shock. The DNA twisting itself regulates at least the induction of recA, the gene of another cold shock protein found in *E. coli* (Hulton et al., 1990; La Teana et al., 1991; Wang and Syvanen, 1992; Brandi et al., 1996; Hurme and Rhen, 1998). However, the increase in negative supercoiling was found to be transient after cold shock (Fig. 6). This shows that the open complex formation of transcription turned cold-insensitive after the adaptation of the entire system to low temperature (Krispin and Allmansberger, 1995; Lopez-Garcia and Forterre, 1999). In addition, most promoters of the –10/–35 type "close" in vitro below 15°C, which in turn may prevent protein synthesis for vital proteins below a certain threshold temperature (Minakhin and Severinov, 2003; Severinov and Darst, 1997). (Actually, the lowest temperature reported for growth in *E. coli* is 7°C; Kawamoto et al., 1989). Also, replication (Atlung and Hansen, 1999; Nyborg et al., 2000), protein folding (Seaton and Vickery, 1994; Kandror and Goldberg, 1997; Vickery et al., 1997), and antitermination (Bae et al., 2000) are cold-regulated. A list of cold-inducible proteins from *E. coli* is shown in Table 3. The list of cold shock induced genes has been extended recently by a genome-wide transcriptional analysis of cold shocked *E. coli* cells. New genes found by this study include transport or metabolism of diverse sugars and molecular chaperones (mopA, mopB, htpG, and ppiA). However, not all cold shock genes are displayed in this study (e.g. genes of the nusA-pnp operon), since some mRNA's might be to unstable to be detected by this method (Phadtare and Inouye, 2004b).

Some cold-inducible proteins from *B. subtilis* indicate that very different physiological processes such as chemotaxis (CheY), sugar uptake (Hpr), translation (ribosomal proteins S6, L7 and L12), protein folding (PPiB), and general metabolism (CysK, HvC, Gap and triosephosphate isomerase) are temperature regulated (Graumann et al., 1996b). A list of cold-stress induced proteins in *B. subtilis* described has been published by Graumann and Marahiel (1999b), and transcriptional profiling of the cold shock response in this organism was conducted by Beckering et al. (2002) and Kaan et al. (2002).

Antitermination, which is mediated by CspA and other cold-shock induced Csps, was proposed to induce the genes of secondary cold-induced proteins (such as NusA, InfB, RbfA and Pnp) located in the region of the *metY-rpsO* operon. These Csps probably prevent secondary structure formation in the nascent RNA, which causes antitermination in ρ-independent terminator regions. The read-through produces a higher transcript level, which, in turn, increases the translation of such proteins (Bae et al., 2000; Zangrossi et al., 2000). *nusA* is an essential gene and NusA protein governs transcriptional elongation, pausing, termination and antitermination. The core RNA polymerase associates with the sigma factor (*sigA*) to form the holoenzyme that is capable of promoter recognition. As the polymerase complex enters the transcriptional elongation phase, NusA replaces SigA in the complex (Gopal et al., 2001). RbfA associates with the 30S subunit of the ribosome, enabling 16S rRNA maturation and interaction with mRNA (Xia et al., 2003).

Another ribosome associated cold shock protein was discovered recently. Yfia is associated with the ribosomes in *E. coli* (as long as the growth is arrested) and disappears afterwards (Agafonov et al., 2001; Rak et al., 2002).

A random observation of a cold-sensitive laboratory strain of *E. coli* led to the discovery of BipA. BipA was originally described as a protein induced after exposure to permeability-inducing

Table 3. *Escherichia coli* cold-inducible genes and their gene products.

protein produced by neutrophils. The function of BipA at low temperature is not known (Pfennig and Flower, 2001).

Another recent finding is the *ves* gene in *E. coli*, which is clearly cold inducible and shares some homology to *cspH*. But a mutant of this gene showed no phenotype at high or low temperature (Yamada et al., 2002).

Organisms other than *E. coli* or *B. subtilis* may exhibit an "untypical" cold shock response. For example, in *Listeria monocytogenes*, a ferritin homolog was found under cold shock conditions and, similarly in *Streptococcus thermophilus*, an iron-binding protein being a member of the Dps family (Nicodeme, 2004 #2525; Hébraud, 2000 #2662). In *Aeromonas hydrophila* no CspA-like protein was found after cold shock, but only to transiently and weakly expressed 11 kDa proteins (Imbert and Gancel, 2004).

The cold shock response is, as shown above, not a single event or a circumscribed response. Normally, cross-protection against other stresses is imprinted on the cells. A few recent reports on this finding include the induction of. barotolerance in Lactobacillus sanfranciscensis after cold stress (Scheyhing et al., 2004), NaCl tolerance in Shewanella putrefaciens (Leblanc et al., 2003), in Listeria monocytogenes sigB induction enhances freezing survival (Wemekamp-Kamphuis et al., 2004b), and survival of Vibrio parahaemolyticus after crystal violet challenge is higher after cold shock (Lin et al., 2004).

Cold Acclimation

The term "cold acclimation" is used for cells that have adapted to low temperature after cold shock and have reached logarithmic growth with a new, now longer doubling time. In cold acclimated cells the internal processes have reached new equilibria, as could be shown for the protein content in *Listeria monocytogenes* (Liu et al., 2002), or the transcriptome in *E. coli* (Polissi et al., 2003). An interesting phenomenon related to cold acclimation is filamentation as exemplified by *Salmonella*, *Escherichia* or *Pseudomonas* strains kept at low temperature (Khan et al., 2003; Mattick et al., 2003a; Mattick et al., 2003b). This is also observed in *Bacillus cereus* and *B. weihenstephanensis* (K. Neuhaus and S. Scherer, personal observation). Whether filamentation of

bacteria grown under various stresses is a response to or just an aftereffect of the stress is not clear. However, a quadruple deletion of the cold inducible MCSP in *E. coli* shows filamentation already at 15°C (Xia et al., 2001b).

Cold Acclimation Proteins

In contrast to cold shock protein (Csp) expression, cold acclimation protein (Cap) expression is at a higher level when the cold shock response has been downregulated (Hébraud and Potier, 1999). Not many reports deal with real Caps. However, both groups of cold-inducible proteins (Cips) are overlapping, since some cold-shock induced proteins have a transient maximum expression level but still show a higher level at low-temperature growth compared to growth at ambient temperatures. Our impression is, however, that the classifications given in the literature are not stringent. For instance, CspB is referred to as a cold shock protein in *B. subtilis*, but its expression is still higher at low than at ambient temperature (Weber and Marahiel, 2002; P. Graumann, personal communication; see the discussion section in Weber and Marahiel, 2002). According to Berger et al. (1997), CspB would be classified as a Cap. Therefore, the classification appears to be inconsistent and depends on the view of the particular researcher (Hébraud et al., 1994; Bayles et al., 1996; Michel et al., 1997; Mitta et al., 1997; Thieringer et al., 1998). Our simplified classification (Fig. 7) is based on Mitta et al. (1997) and Graumann and Marahiel (1999b) and the proposition that Cips are cold-induced proteins, irrespective of the kinetics of their regulation. Cips can be divided into Csps with a transient peak of induction, regardless of the levels attained in comparison to pre-shock levels. The Csps may be divided into class I Csps (with an induction more than 10-fold) and class II Csps (with an induction less than 10-fold). Cold acclimation proteins (Caps) are not strongly cold shock induced (no clear peak), but levels steadily increase after a temperature downshift and remain higher (during the period of low-temperature cellular growth) than levels at ambient temperatures.

In *E. coli* genes showing a higher transcriptional level 5 h after a cold shock to 15°C include genes encoding flagellar proteins, as well as the spermidine acetyltransferase *speG* (Phadtare and Inouye, 2004b). For *Pseudomonas fragi*, many different groups of Cips have been presented, but only four of them have been identified, and these belong to the CspA homology group. Two of them are designated "CapA" and "CapB," and the other two (also heat shock induced) are designated "TapA" and "TapB" (temperature adaptation proteins; Hébraud et al., 1994; Michel, 1996). A further study dealing explicitly with cold-acclimation proteins names the CspA-homolog from *Arthrobacter globiformis* "CapA." The protein level increases after cold shock and remains high for 24 h (Berger et al., 1997). In our opinion, the time period tested may be too short to determine whether this protein is a Csp or a Cap in this organism. When the cells were cold shocked from 25°C to 4°C, they had a subsequent lag phase of 14 h. For comparison, *Yersinia enterocolitica*, which can grow at –5°C like *A. globiformis* (Bergann et al., 1995), was cold shocked from 30°C to 10°C and had a lag of approximately 80 min. The level of the major Csps

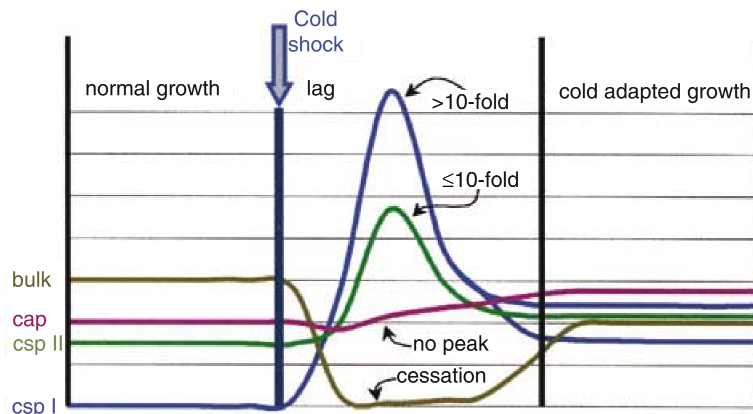

Fig. 7. Qualitative differences between different groups of cold induced proteins (Cips). Bulk proteins (brown) are also designated "housekeeping proteins." After a cold shock, they decrease. Cold shock proteins (Csps) of group I (blue) have low concentrations at ambient temperature but are highly induced (>10-fold) after cold shock. They can remain on a higher or lower level during cold-adapted growth, as indicated by a split of the blue line. Csps of group II (green) are present at normal growth and are induced less than 10-fold. Cold acclimation proteins (Caps, pink) are induced at low temperature, but have no peak after a cold shock. Modified according to Thieringer et al. (1998).

remains stable up to 3 h after cold shock. That means that the proteins are detectable at high level for more than twice as long as the lag phase (Neuhaus, 2000a). If this standard is applied to *A. globiformis*, the relatively large amounts of CspA should be detectable for 28 h, or even longer, before CspA finally disappears. A relatively recent list of cold-inducible proteins of *B. subtilis* and their classification is given by Graumann and Marahiel (1999b). They suggest several different proteins are Caps (e.g., L7/L12, L10, EFTs, EFTu, EF-G, Tig, GlnA, LeuC, ThrC, AroF and GuaB), which play different physiological roles in translation, protein-folding, and general metabolism. Recent studies suggest that in *B. subtilis* the transcription factor SigB, which is induced by cold shock, is important for continuous growth and sporulation at low temperature. Growth of a corresponding mutant is severely impaired at 15°C, but the mutant is rescued by addition of glycine betaine (Brigulla et al., 2003; Mendez et al., 2004). In *Pantoea agglomerans*, a 60-kDa protein was found to be a cryoprotective Cap; however, the nature of this protein is not known (Koda et al., 2001). A recent study with the psychrotolerant *Listeria monocytogenes* lists several genes as necessary for growth at 10°C. Most genes found were already known to participate in other stress responses, e.g., cold-adaptation (*flaA* and *flp*), regulatory adaptive responses (*rpoN*, *lhkA*, *yycJ*, *bglG*, *adaB* and *psr*), general stress (*groEL*, *clpP*, *clpB*, *flp* and *trxB*), amino acid metabolism (*hisJ*, *trpG*, *cysS* and *aroA*), cell surface alterations (*fbp*, *psr* and *flaA*), and degradative metabolism (*eutB*, *celD* and *mleA*). Four further proteins with unknown function, only present in *Listeria*, were found, too (Liu et al., 2002). As can be seen from the diversity of the listed proteins found to be enhanced during growth at low temperature, many different aspects of the cell metabolism are affected to varying degrees. Interestingly, no (classical) MCSP was found, except the well-known cold inducible *flaA* and *flp* genes (Bayles et al., 1996).

For the identification of cold acclimation genes in *Yersinia enterocolitica* during prolonged growth in the cold, a genome-wide expression analysis was performed by creating random transcriptional fusions to the *luxCDABE*-reporter. This approach allowed the direct comparison of promoter activities (by comparing cell growth rates) of various genes at normal and low temperature. Out of 5700 investigated lux-transposon mutants, approximately 100 genes were detected with enhanced promoter activity at low temperature (compared to promoter activity under optimal growth temperature). Most of these genes could be placed into functional groups like motility proteins, transport proteins, and regulatory proteins (Bresolin et al., 2004).

In any case, knowledge concerning cold acclimation proteins (which enable bacteria to grow constantly at low temperature) is limited, and further research in this area is needed. It would be especially interesting to examine psychrotolerant or psychrophilic organisms in contrast to their mesophilic counterparts. Such a comparison could be fruitful in genera containing psychrophile, mesophile, and thermophile species, such as Bacillus and others.

Compatible Solutes

An emerging result from cold shock studies is that compatible solutes (such as glycine betaine, L-proline, and similar compounds) play also an important role in adaptation to the low temperature. However, how compatible solutes protect the cells against low temperature remains unclear. Several, possibly overlapping, scenarios are conceivable according to (Kandror et al., 2002): 1) compatible solutes may act as "chemical chaperones" against low temperature denaturation or aggregation. 2) Cold stress may cause oxidative stress, too. Some compatible solutes, e.g., trehalose, act as free radical scavengers. 3) Compatible solutes protect the membrane or 4) compatible solutes are induced in expectance of a possible drop below freezing.

Listeria monocytogenes has at least two compatible solute transporters for glycine betaine: porter I is a Na/glycine betaine symporter and porter II is an ATP dependent transporter. Cold activated uptake of glycine betaine was most rapid between 7°C and 12°C (Mendum and Smith, 2002). Another compatible solute transporter is encoded by the *opuC* gene of *Listeria*, encoding for a carnitine transporter. This porter is also induced after chilling, and carnitine is also accumulated after osmotic or low temperature stress (Angelidis et al., 2002a), similar to observations made in *B. subtilis* by Brigulla et al. (2003). However, if the glycine betaine porter II is blocked, the increased carnitine uptake cannot completely restore the cryoprotective effect (Angelidis et al., 2002b). If all three compatible solute transporters are deleted, *L. monocytogenes* is severely impaired in growth at low temperature, but growth is not completely abolished (Wemekamp-Kamphuis et al., 2004a). In *E. coli*, the trehalose synthesis genes *otsAB* and the cryptic promoter (P1) of the *proU* transporter (important for mediating cytoplasmic accumulation of compatible solutes) are induced during low-temperature growth. Therefore, the cellular trehalose content increases up to eightfold after cold shock (Kandror et al., 2002; Rajkumari and

Gowrishankar, 2001). If compatible solutes are added to the medium, *L. monocytogenes* and *E. coli* survive better in cold (Dykes and Moorhead, 2001; Shahjee et al., 2002). However, the situation might be different in psychrophilic bacteria, since (Mindock et al., 2001) have found no compatible solute accumulation in such *Arthrobacter* species at 4°C.

Bacterial Cold Sensors

The reaction of bacteria towards cold stress should be as fast as possible. Currently, several processes that use a temperature signal to induce cellular processes have been suggested (for reviews, see Browse and Xin (2001) and Eriksson et al. (2002). Temperature is a factor that affects the whole bacterial cell immediately. Different mechanisms are used simultaneously to sense low temperature and these mechanisms might overlap as in the case of H-NS (see below). Note, furthermore, that many virulent bacteria have specially adapted temperature sensing mechanisms that determine whether they are inside or outside a host (for reviews, see DiRita et al., 2000; Eriksson et al., 2002; Gophna and Ron, 2003). A common threshold temperature for induction of virulence genes is around 30°C. Here, only the mechanisms involved in the cold shock or cold adaptation response (adaptation to temperature much lower than 30°C) will be discussed (see the section Pathogens in this Chapter).

DNA

In bacteria, the degree of superhelicity of the DNA varies in response to changes in the ambient temperatures. In many examples, the expression of genes is dependent on DNA conformation (Eriksson et al., 2002). Supercoiling is mainly regulated in *E. coli* by topoisomerases I and II (Drlica, 1992; Hurme and Rhen, 1998; Tse-Dinh et al., 1997). But the conformation is fine tuned by proteins such as H-NS. H-NS appears to bind curved regions of DNA and is responsible for the cold repression of bacterial genes, possibly by denying open promoter complex formation necessary for transcription (Eriksson et al., 2002; Williams and Rimsky, 1997). Similarly, the promoter of the cold inducible histone-like protein HUβ is possibly affected by temperatures that stop transcription from the promoter sites P1 to P3, but not by temperatures that allow transcription from P4. The HUβ protein affects DNA structure, fine tuning transcription of many genes at low temperature (Giangrossi et al., 2002). A further analysis of the cold shock response on the DNA level is given by Golovlev (2003).

An interesting facet is the involvement of the GATC methylation by the DNA methyltransferase Dam and its possible involvement in the cold shock response. According to this hypothesis, Dam is limited in fast growing cells (e.g. inside a host), leading to a hemi-methylated DNA which is more stable and displays a higher melting point. After shedding of *E. coli* into the environment, the cells experience a cold shock and the transcription of genes containing a GATC cluster will cease due to the high stability of hemi-methylated DNA. This effect might explain the decrease in transcription of some (many?) downregulated genes. However, this conclusions are only hypothetical so far (Riva et al., 2004).

Messenger RNA

As has been discussed in the section The Cold Shock Response, in this Chapter, the mRNA of CspA is degraded rapidly at high temperature but is stabilized at low temperature. The cold sensor, therefore, is the folding characteristics and associated resistance to degradation of the mRNA. This reaction upon temperature downshift occurs rapidly, since the folding involves the mRNA that is already synthesized. Another example is the mRNA of σ^{32}. At lower temperature, this mRNA is folded and therefore cannot be translated. At higher temperature, it is unfolded, becomes accessible to the ribosome, and the translated σ factor then switches on the heat shock response (Morita et al., 1999a; Morita et al., 1999b). A similar mechanism was described for σ^S, a stationary phase sigma factor. The transcription of *rpoS*, the gene for σ^S depends on *dsrA*, a small regulatory RNA which probably stabilizes the *rpoS* mRNA. The half life of *dsrA* is prolonged at 25°C compared to its half life at 37°C (Repoila and Gottesman, 2001). A similar system in which the mRNA acts as thermometer for thermal induction of a gene, is described by Chowdhury (2003) #2661.

Ribosome

That the ribosome may act as a sensor for both heat and cold shock has been proposed (Fig. 8). After heat shock, the A-site of the ribosome is empty; at cold shock, the A-site is blocked owing to a stop in the initiation and translation of misfolded mRNA. Both situations lead to an increase or decrease, respectively, of the stringent response regulator, guanosine 5′-triphosphate-3′-diphosphate and guanosine 5′-diphosphate-3′-diphosphate (collectively abbreviated [p]ppGpp). A decrease could be the signal for a cold shock response (VanBogelen and Neidhardt, 1990). For example, after a nutri-

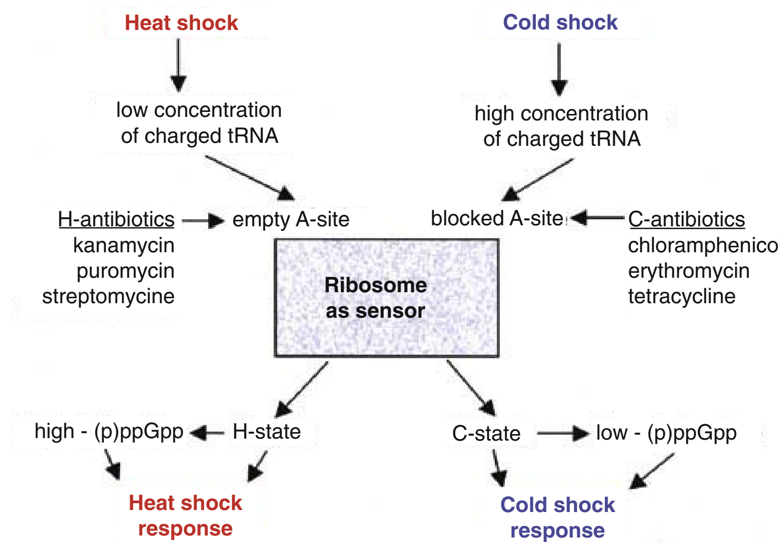

Fig. 8. Model of the ribosome as a sensor of temperature in bacteria. After a heat shock, translation proceeds faster than charged tRNA can be supplied, which may result in an empty A-site that is also affected by H-antibiotics. This could signal the ribosomal induction of the heat shock response (H-state) and increase of the guanosine 5′-triphosphate-3′-diphosphate and guanosine 5′-diphosphate-3′-diphosphate ([p]ppGpp) concentration. In contrast, cold shock leads to a reduced translational capacity of the cell and thereby a block of the A-site (as is also achieved by C-antibiotics) owing to a high concentration of charged tRNA. As a consequence, the cold shock response may be induced and the levels of (p)ppGpp are lowered, which in turn has been shown to increase the induction of cold-inducible proteins (Cips) after a cold shock. Redrawn from Graumann et al. (1996b).

tional downshift, the level of (p)ppGpp is increased and this leads to induction of DnaK and GroEL (both heat shock proteins; Schnier, 1987). Conversely, a nutritional upshift is coupled with a decrease in (p)ppGpp and leads to induction of CspA (Brandi et al., 1999a; Yamanaka and Inouye, 2001a). Additionally, a mutant lacking RelA ([p]ppGpp synthetase) and SpoT ([p]ppGpp hydrolase) is unable to produce (p)ppGpp and has a higher induction of cold shock proteins after a cold shock. This mutant phenotype seems to be preadapted to low temperature (Jones et al., 1992a).

Protein

Changes in protein conformation, namely denaturation, are more pronounced after an increase in temperature. Such misfolded proteins are bound by chaperones, subsequently inducing a heat shock response (Arsene et al., 1999; Eriksson et al., 2002). However, conformational changes in proteins because of low temperature are also used for cold adaptation in some instances.

An intriguing example of low temperature sensing by protein interaction is the aspartate chemotaxis of *E. coli*. The relevant thermosensors are transmembrane chemoreceptors or methyl-accepting chemotaxis proteins, one of them (Tap) being a cold sensor (Nara et al., 1991). During adaptation, receptor methylation (catalyzed by the methyltransferase CheR) and demethylation (catalyzed by the methylesterase CheB) regulate the histidine kinase activity of the sensors. Thermosensing may be due to the specific temperature dependency of the methylation-demethylation equilibrium (Nara et al., 1996; Nishiyama et al., 1997; Nishiyama et al., 1999a; Nishiyama et al., 1999b).

The action of H-NS (see the above section DNA) by influencing the conformation of DNA is itself to some extent dependent on the conformation of this protein. H-NS function is associated with oligomerization by means of a coiled-coil structure. This flexible structure stiffens at lower temperatures allowing better oligomerization and subsequent DNA binding of H-NS (Dorman et al., 1999; Smyth et al., 2000).

The Cytoplasmic Membrane

Another mechanism of cold-temperature sensing involves the physical state of the membrane (for reviews, see Vigh et al., 1998; Sakamoto and Murata, 2002). For instance, it has been proposed that the thylakoid membrane acts as a cellular thermometer where thermal stress is sensed and transduced into a cellular signal leading to

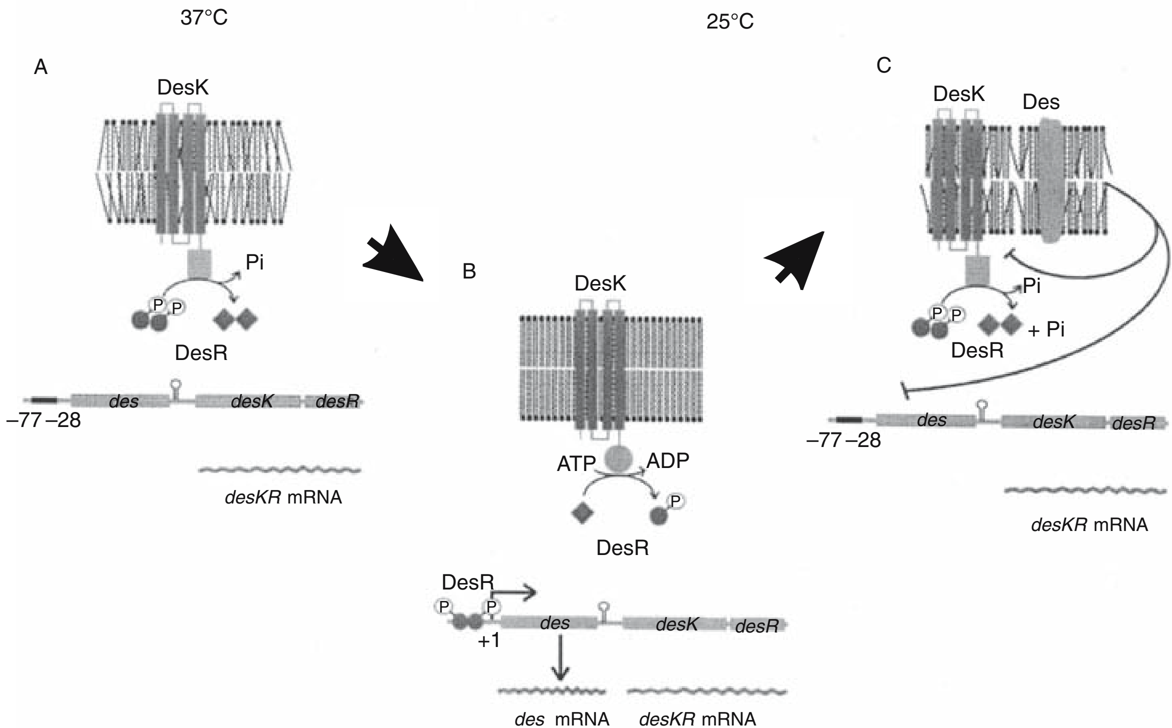

Fig. 9. Model of *des* transcriptional control by two-component temperature signal transduction proteins. It is proposed that DesK assumes different signaling states in response to a temperature-induced change in membrane fluidity. This is accomplished by regulating the ratio of kinase to phosphatase activity such that a phosphatase-dominant state is present at 37°C, when membrane lipids are disordered (A), whereas a kinase-dominant state predominates upon an increase in the proportion of ordered membrane lipids after a temperature downshift to 25°C (B). DesK-mediated phosphorylation of DesR results in transcriptional activation of *des* (B) leading to synthesis of Des, which desaturates the acyl chains of membrane phospholipids (C). These newly synthesized unsaturated fatty acids inhibit *des* transcription either by favoring DesK dephosphorylation of DesR-P or by causing dissociation of DesR-P from its binding site (C). Adapted from Aguilar et al. (2001) and Cybulski et al. (2004).

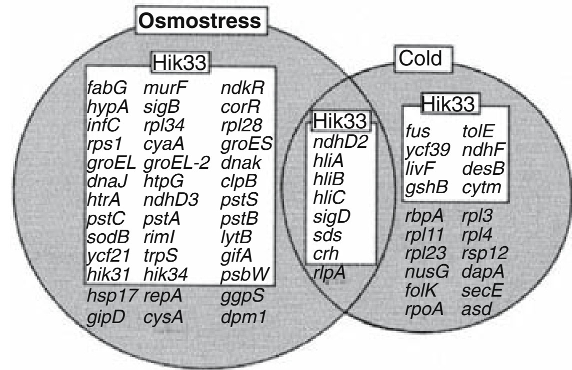
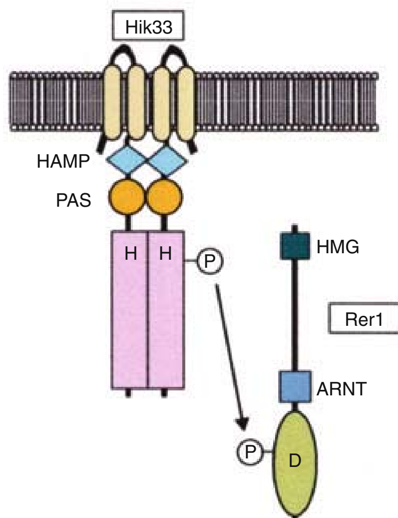
the activation of heat shock (HS) genes (Horvath et al., 1998).

In *B. subtilis*, a two-component signal transduction system was found involving a sensor kinase (DesK) and a response regulator (DesR). This system regulates the cold induction of the *des* gene coding for the D5-lipid desaturase. Unsaturated fatty acids (UFAs), which are the product of Des, act as negative signaling molecules of *des* transcription (Aguilar et al., 2001). Apparently, the physical state of the cytoplasmic membrane regulates the two-component system: DesK phosphorylates a DesR dimer after temperature downshift (which equals to ordered lipids in a more rigid membrane. The phosporylated DesR is able to bind to the promoter of *des*, inducing it thereby. After re-installing the fluid state of the membrane, DesK dephosphorylates DesR to inactivate it (Cybulski et al., 2004). The regulatory loop of DesK, DesR, Des and unsaturated fatty acids is shown in Fig. 9.

In the cyanobacterium *Synechocystis*, two histidine kinases and a response regulator have been identified which regulate several genes at cold temperature (Suzuki et al., 2000a; Suzuki et al., 2000b). Apparently, more than one cold-responding histidine kinase and probably several response regulators should be present in a cyanobacterial cell (Suzuki et al., 2001). Interestingly, the membrane bound histidine kinase senses not only cold but also osmotic stress with some overlap in the induced genes (Mikami et al., 2002). If the membranes are artificially rigidified by gene-engineering, some cold inducible genes are expressed at higher levels in this organism. However, some cold inducible genes do not respond to this intervention, suggesting that another cold sensor remains to be identified (Inaba et al., 2003). A similar two-component system is involved in upregulating phytopathogenic factors in *Pseudomonas syringae*. This system consists of the membrane-bound histidine protein kinase CorS and two transcriptional regulators, CorR and CorP, which induce virulence factors (Smirnova et al., 2002). Figure 11 summarizes the two-component sensor system from *Synechocystis* and *B. subtilis*.

Fig. 10. Osmostress-inducible and cold-inducible genes that were regulated by the sensor histidine kinase Hik33 in wild-type *Synechocystis* cells. Large and small circles enclose genes whose expression was induced by osmotic stress and cold stress, respectively. Rectangles in these circles enclose genes whose expression was regulated to a greater or lesser extent by Hik33 in cells under hyperosmotic stress and under cold stress. Genes outside rectangles appeared to be insensitive to the mutation in Hik33 in terms of their responses to the respective stresses. The rectangle in the overlapping region of the two circles encloses genes whose Hik33-regulated expression was observed under both kinds of stress. From Mikami et al. (2002).





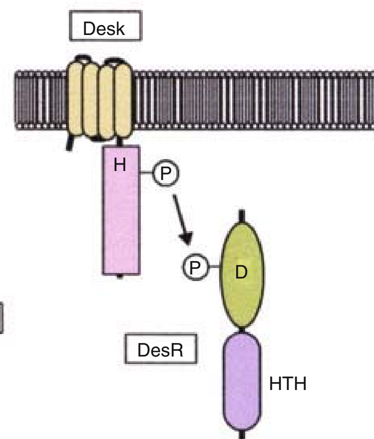


Fig. 11. Schematic representation of the predicted structures of cold-sensing histidine kinases and signal-transducing response regulators involved in the regulation of expression of fatty acid desaturases in *Synechocystis* and *B. subtilis*. (a) Hik33 and Rer1 are the histidine kinase and response regulator, respectively, in *Synechocystis* sp. PCC 6803. In Hik33, the histidine kinase domain is indicated by pink rectangles, and the histidine residue possibly involved in the phosphorylation relay reaction is indicated by "H." The HAMP (histidine-kinase-adenylyl-cyclase-methyl-binding protein phosphatase) domain and the PAS (PER-ARNT-SIM) domain (which is named after the period clock protein [PER] of *Drosophila*, the vertebrate aryl hydrocarbon receptor nuclear translocator [ARNT], and the single-minded protein [Whitby et al.] of *Drosophila*) are indicated by a blue diamond and a yellow circle, respectively. The PAS domain contributes to protein–protein interactions and, thus, Hik33 is likely to form a dimer, as shown in the figure. In Rer1, the receiver domain with a phosphorylatable aspartate residue is indicated by a green ellipse labeled "D." The amino-terminal region is assumed to form a DNA-binding domain, which contains an HMG (high-mobility-group) box and the transcriptional activation domain of the aryl hydrocarbon receptor nuclear translocator (ARNT; (Suzuki et al., 2000a). (b) DesK and DesR are the histidine kinase and the response regulator, respectively, in *B. subtilis*. The DNA-binding domain is indicated by the HTH (helix-turn-helix) motif in the carboxy-terminal region that binds to the 5'upstream region of the *des* gene (Aguilar et al., 2001). In both systems, the cold-induced phosphorylation of histidine residues and the relay of phosphorylation to aspartate residues (indicated by arrows) have not yet been demonstrated. From Sakamoto and Murata (2002).

Cold Adaptation: General Remarks

Mechanisms of cold adaptation in psychrotolerant and psychrotrophic bacteria remain poorly defined. Recent studies suggest multiple strategies to cope with low temperatures. A general conclusion drawn from such strategies is to allow more flexibility in any structures including membranes, proteins or RNAs (Dalluge et al., 1996; Dalluge et al., 1997; Saunders et al., 2003). In membranes, unsaturated fatty acids are introduced to maintain ambient membrane fluidity. Proteins from psychrophilic bacteria are less rigid in structure owing to amino acid exchange (Gerday et al., 1997), or tend to dissociate easier into nonfunctional monomers because of a

weakening in hydrophobic bonds (Jahns and Kaltwasser, 1993; Ramstein et al., 2003).

Cold Adaptation of the Cytoplasmic Membrane

General Strategies of Fatty Acid Alteration

Membrane adaptation to different growth temperatures has been a target of research for a long time (de Mendoza and Cronan, 1983). There is now a large body of data dealing with the effect of temperature on the membrane composition of many species (for reviews, see Russell, 1997; Sakamoto and Murata, 2002). The lipid composition of the cytoplasmic membrane is of great importance for many cellular processes such as nutrient uptake, electron flow in respiration or photosynthesis, ATP synthesis, and others. A biological membrane is a highly complex and dynamic structure that can switch between different physical states. If bacteria are subjected to rapid chilling or freezing, a variety of damages can occur, like damage and release of lipopolysaccharides and altering the permeability of the membrane (Boziaris and Adams, 2001; Kempler and Ray, 1978; Ray and Speck, 1973; Riva et al., 2004). Besides having such mechanical effects, temperature influences the fluidity of the membrane. The lipid composition of the membrane, in combination with the temperature, controls the phase transition from the fluid phase to the semicrystalline or solid phase (Jones et al., 2002; for a review, see, e.g., Dowhan, 1997). To grow at low temperature, cells must have cytoplasmic membranes that retain sufficient fluidity to maintain a physical state supportive of the multiple functions of the membrane-a concept that has been termed "homoviscous adaptation" (Sinensky, 1974; Suutari and Laakso, 1994).

Psychrophilic and mesophilic bacteria, as well as archaea, adjust the lipid composition of their membranes so that the proton permeability of their membranes remains within a narrow range. This phenomenon is termed "homeoproton permeability adaptation" (see Van de Vossenberg et al., 1995). The growth temperature-dependent alterations in fatty acyl chain composition are thus mainly aimed at maintaining the proton permeability of the cytoplasmic membrane at a rather constant level (Albers et al., 2000). For cold-adapted bacteria such as *Psychrobacter immobilis*, this means that a decrease of the temperature would lead to a low proton permeability, which must be counteracted by an appropriate adaptation of the membrane lipids (Fig. 12).

In general, several fatty acid changes are known to increase or decrease membrane fluidity in bacteria (for reviews, see Russell [1997] and Gounot and Russell [1999]). Most important for cold adaptation appears to be both unsaturation and chain shortening, but there are other adaptations (Table 4) which have been demonstrated experimentally. For instance, *lpxP* encodes a palmitoleoyl transferase. Palmitoleate is not present in *E. coli* grown at 30°C but comprises 11% of the fatty acid content in cells grown at 12°C. The *lpxP* gene was found to be 30-fold cold-inducible after 2 h. Thereafter, the activity gradually declines but does not disappear (Carty et al., 1999). A possible advantage suggested is that the palmitoleate content of the outer membrane provides a more effective barrier to harmful chemicals at low temperature (Vorachek-Warren et al., 2002).

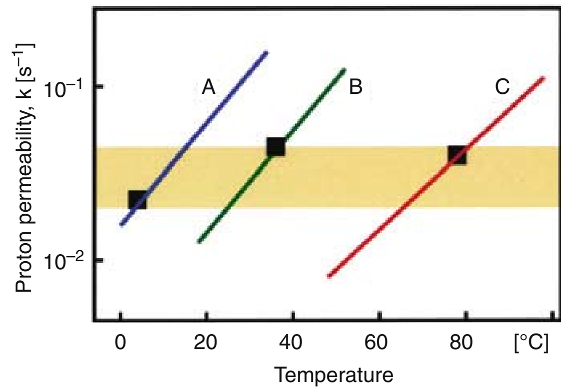

Fig. 12. Graphic representation of the proton permeability of the psychrophilic bacterium *Psychrobacter immobilis* (line A), five mesophilic species represented by line B (*Bacillus subtilis*, *Escherichia coli*, *Methanosarcina barkeri*, *Halobacterium salinarum* and *Halorubrum vacuolatum*), and the hyperthermophilic *Sulfolobus acidocaldarius*, line C. The black squares represent measured proton permeabilities and the yellow area indicates the rather narrow range within which proton permeability is maintained and growth is possible. Note that some thermophilic and hyperthermophilic bacteria have higher proton permeability. See Albers et al. (2000), which is also the source of this figure.

Table 4. Fatty acid changes influencing membrane fluidity in bacteria.

Increase of fluidity		Decrease of fluidity

Membranes in Psychrotolerants and Psychrophiles

Recently, rather few reports have dealt with the membrane adaptation of psychrotolerant or psy-

chrophilic bacteria (Jones et al., 1997; Nichols et al., 1997; Whyte et al., 1999; Allen and Bartlett, 2000; Allen and Bartlett, 2002; Drouin et al., 2000; Edgcomb et al., 2000; Kumar et al., 2002). The psychrotolerant *Listeria monocytogenes* is a foodborne pathogen that can grow well at refrigeration temperature. Probably because of the medical importance of *Listeria monocytogenes*, some studies have been performed recently. When grown in continuous culture at 10°C in contrast to 30°C, this bacterium has a lower proportion of *anteiso*-$C_{17:0}$ and a higher proportion of *anteiso*-$C_{15:0}$ and short chain fatty acids (Jones et al., 1997). Similarly, Mastronicolis et al. (1998) found that cold shocked *L. monocytogenes* displayed increased *anteiso*-$C_{15:0}$ in all lipid classes. Studies of fatty acid profiles of wildtype and cold-sensitive, branched-chain fatty acid-deficient mutants of *L. monocytogenes* suggest that the fatty acid 12-methyltetradecanoic acid (*anteiso*-$C_{15:0}$) plays a critical role in low-temperature growth of *L. monocytogenes*, presumably by maintaining membrane fluidity. The fluidity of isolated cytoplasmic membranes of the wildtype, and a cold-sensitive mutant of *L. monocytogenes*, grown with and without the supplementation of 2-methylbutyric acid, has been studied (Annous et al., 1997; Edgcomb et al., 2000). These authors concluded that the fatty acid *anteiso*-$C_{15:0}$ imparts an essential fluidity to the *L. monocytogenes* membrane and that this fluidity permits growth at refrigeration temperatures. However, even between closely related bacteria, differences in the membrane adaptation to low temperature can be found. The *L. monocytogenes* strains Scott A and CNL 895897 show differences in their pattern of branched fatty acids in response to low temperatures. The CNL strain uses, in addition to odd-numbered branched fatty acids found in both strains, substantial amounts of even-numbered branched fatty acids, too (Chihib et al., 2003). A similar example was reported from *Sphingomonas*, where one strain used unsaturated fatty acids and the other strain shifted from even-chain to odd-chain fatty acids (Männistö and Puhakka, 2001a).

The production of increased proportions of membrane unsaturated fatty acids correlates with bacterial growth at low temperature or high pressure (Allen and Bartlett, 2002). Allen et al. (1999) characterized the fatty acids produced by

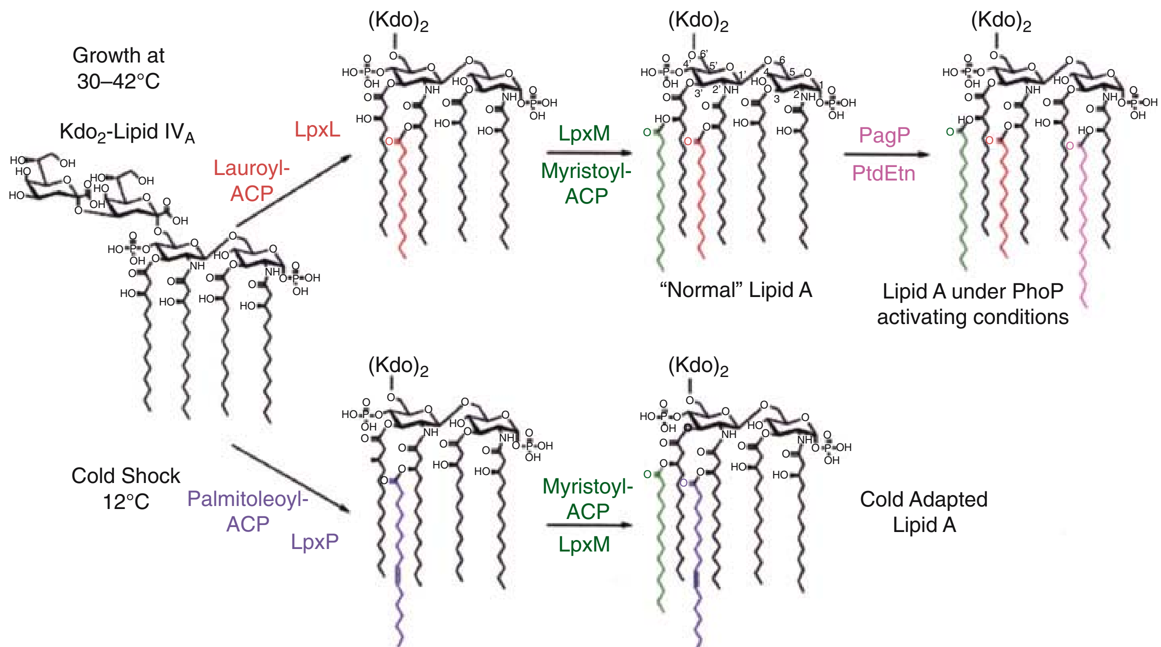

Fig. 13. Biosynthesis of Kdo2 -lipid A during cold shock. In cells grown at 30°C or above, the key precursor Kdo2 -lipid IVA is utilized solely by the lauroyltransferase LpxL (Clementz et al., 1996). However, in cold-shocked cells, an additional acyltransferase, designated "LpxP" (Carty et al., 1999), is induced, which is proposed to incorporate palmitoleate at the same site normally reserved for laurate. In wildtype cells, the action of LpxL and LpxP is followed rapidly by the myristoyltransferase, LpxM, generating hexa-acylated lipid A (Brozek and Raetz, 1990; Clementz et al., 1997). About two-thirds of the hexa-acylated lipid A isolated from cells grown overnight at 12°C contains palmitoleate, and the remainder contains laurate. When the PhoP/PhoQ system is activated or when cells are grown on ammonium metavanadate, a portion of the lipid A molecules contain a palmitate residue at position 2, which is incorporated by the outer membrane enzyme PagP using glycerophospholipids as palmitate donors (Bishop et al., 2000). From Vorachek-Warren et al. (2002).

the deep-sea bacterium *Photobacterium profundum* grown at various temperatures and pressures. In addition, oleic acid-auxotrophic mutants were isolated. One of these mutants, strain EA3, was deficient in the production of monounsaturated fatty acids and was both low-temperature sensitive and high-pressure sensitive in the absence of exogenous 18:1 fatty acid. The authors conclude that monounsaturated but not polyunsaturated fatty acids are required for growth of *P. profundum* both at high pressure and low temperature.

Note, however, that the fatty acid content does not always change dramatically in response to temperature. Könneke and Widdel (2003) examined a range of sulfate-reducing bacteria in their response of the fatty acid content (unsaturated vs. saturated). The highest levels of *cis*-unsaturated fatty acids was measured in the psychrophilic species, but a substantial response in increasing amounts of unsaturated fatty acids at low temperature was only found in the genus *Desulfobacter*. All other genera (*Desulfofaba*, *Desulfofrigus*, *Desulfotalea*, *Desulforhopalus*, *Desulfococcus*, *Desulfosarcina* and *Desulfovibrio*) responded only with slight changes (Könneke and Widdel, 2003). A similar result was formerly reported about psychrotrophic *Pseudomonas* species (Bhakoo and Herbert, 1980).

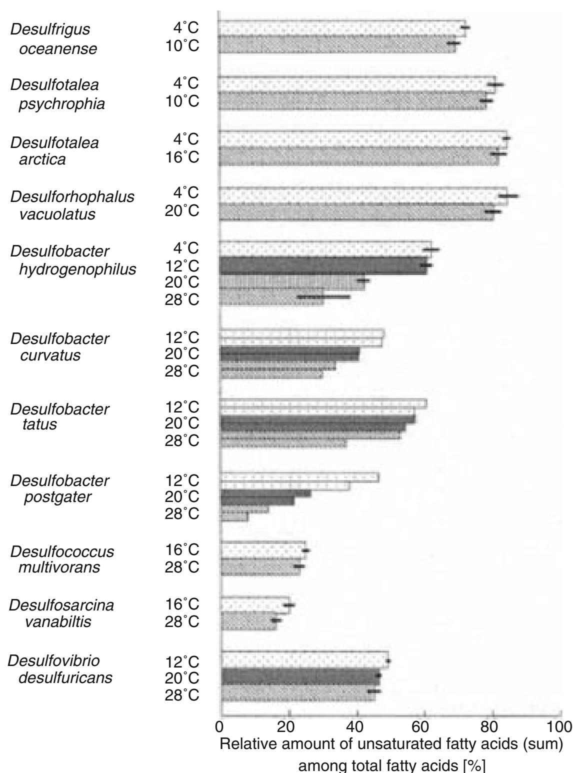

Fig. 14. Proportions of unsaturated fatty acids among total fatty acids in psychrophilic and mesophilic species of sulfate-reducing bacteria grown at different temperatures. Analyses were carried out when cells were still growing and had reached three-quarters of the maximum (final) optical density. Note that only in *Desulfobacter* species a substantial increase in unsaturated fatty acids is visible. In all other species examined virtually no increase in unsaturated fatty acids can be found. Adapted from Könneke and Widdel (2003).

Differences Between Closely Related Mesophilic and Psychrotolerant Strains

Randomly selected strains of a bacterial collection of marine sea-ice bacteria from Antarctica were analyzed to obtain a profile of the membrane fatty acids. Results showed that short-chain saturated and unsaturated fatty acids were more common in the psychrotolerants when compared to psychrophiles. In contrast, branched-chain fatty acids were more abundant in the psychrophiles (Rotert et al., 1993). Such observations raise the question of whether differences in the capability of membrane adaptation to low temperature between closely related psychrotolerant and mesophilic strains (i.e., belonging to the same species) are responsible for the thermal type.

Some species commonly harbor psychrotolerant as well as mesophilic strains. One example is *Rhizobium leguminosarum*, which is known as a mesophilic species growing poorly at temperatures under 10°C (Graham, 1992). However, psychrotolerant strains have been isolated from the Arctic legumes *Astragalus* and *Oxytropis*, and nitrogenase activity in Arctic nodules was detectable down to 0°C. The minimal and maximal growth temperature of isolates was 0°C and 27–30°C, respectively (for a review on Arctic rhizobia, see Prévost et al., 1999). Psychrotolerant and mesophilic strains have also been isolated from the legume species *Lathyus japonicus* and *L. pratensis* (Drouin et al., 2000). These authors have determined the fatty acid profiles after growth at 25°C, at 5°C, and after cold shock from 25°C to 5°C. Interestingly, the degree of psychrotolerance of the strains did not correlate with their fatty acid composition.

There is a vast body of literature concerning mesophilic and psychrotolerant isolates of the *Bacillus cereus*, which is a toxin producer (Granum and Lund, 1997; Dietrich et al., 1999; Prüß et al., 1999) in food (Mayr, 1999), and in soil (Von Stetten et al., 1999). All species of the *Bacillus cereus* group are so similar that they should be within the same species (Helgason et al., 2000). However, because members of the *Bacillus cereus* group are more or less medically important, placing them in a single taxon appears not to be sensible. Therefore, psychrotolerant

isolates have been described as the new species *Bacillus weihenstephanensis* (Lechner et al., 1998). The difference in growth rate of the mesophilic and psychrotolerant strains is shown in Fig. 15. Very little is known about the physiological and genetic basis of cold adaptation of psychrotolerant strains of the *Bacillus cereus* group relative to mesophilic strains. We therefore analyzed the fatty acid composition (among other parameters) of a mesophilic *Bacillus cereus* and a very closely related psychrotolerant *B. weihenstephanensis*. *Bacillus* is known to have a branched-chain fatty acid profile (Table 5). *Iso*- and *anteiso*-branched fatty acids are predominant, which is a characteristic observed in all species of *Bacillus* studied so far (e.g., Kämpfer, 1994). In both strains, *iso*-branched fatty acids increased about 6–7% at 12°C (in comparison to their amounts at 25°C) because of an increase of *i*-13:0 and *i*-16:0. A further increase of *i*-16:0 in the psychrotolerant strain at 7°C increased the level of branched *iso* fatty acids to nearly 50% of the total fatty acids. Upon lowering the temperature, straight-chain fatty acid and monounsaturated fatty acid levels decreased in response to changes in C16 fatty acid levels. These data confirm the hypothesis that bacilli adapt to decreasing environmental temperature by replacing the saturated straight-chain acids with the lower melting point branched-chain acids, or by changing to fatty acid branching instead of fatty acid unsaturation (Suutari and Laakso, 1992). Kaneda (1991) reported that mainly 12- and 13-methyltetradecanoic acids (= *a*-15:0 and *i*-15:0) controlled the fluidity of membranes with branched-chain fatty acids. Indeed, these fatty acids constituted the major fraction in our study at 25°C but decreased at 12°C. At this latter temperature, an increase of *i*-13:0 was observed, which may also play a role in the control of membrane fluidity. In addition, we found some unidentified fatty acids in both strains. Especially, two fatty acids with retention times of 27 and 29 min increased in both strains to high levels upon lowering the temperature.

We did not observe a correlation of the minimum growth temperature with the fatty acid composition. The nearly identical fatty acid pattern of the mesophilic and psychrotolerant *B. cereus* indicate that differences in lipid-dependent membrane architecture may not be responsible for the substantially different growth rates of these strains at 12°C.

Carotenoids in Membranes

Evidence is emerging that carotenoids in the cytoplasmic membrane also play a role in cold adaptation of some species (Jagannadham et al., 1996; Chattopadhyay et al., 1997). In vitro studies with synthetic membranes of phosphatidylcholine demonstrated that the major pigments zeaxanthin, β-cryptoxanthin and β-carotene were bound to these membranes and decreased their fluidity (Jagannadham et al., 2000). In this respect it is interesting that Gram-positive bacteria collected from the Antarctic region show a predominance of pigmented isolates. In *Arthrobacter agilis*, collected from the Antarctic sea ice, pigmentation is due to a C-50 carotenoid induced at low temperature. Hypothetically, such carotenoids stabilize the membrane, since such C-50 carotenoids are only reported from other extremophiles and archea, coping with salt, cold and radiation stress (Fong et al. [2001] and references therein). This speculation fits the observation reported by Varkonyi et al. (2002) that some carotenoids are only low-temperature induced in the thylakoid membranes of the cyanobacterium *Cylondrospermopsis raciborskii*, possibly protecting them from reactive radicals. However, carotenoid-mediated stabilization of membranes and decrease in membrane fluidity seems to offset the increase in membrane fluidity accompanying fatty acid changes in low temperature habitats. Further research is needed to elucidate the interplay between carotenoids and fatty acids at low temperature and the exact role of the former.

Differences Between Thermotypes of Archaea as an Example

A comparison of different thermotypes of microorganisms is possible by comparing single features, e.g., complete genomes or the MCSPs of different *Bacillus* species (Morra et al., 2003; Zeeb and Balbach, 2003a; Zeeb et al., 2003b; Zhou and Dong, 2003). Such an approach was chosen by Saunders et al. (2003), with interesting results for some Archaea: Comparative genomics between the two cold-adapted *Methanogenium frigidum* and *Methanococcoides burtonii* and other mesophile or (hyper-)thermophile Archaea revealed trends in amino acid and tRNA composition and structural features of proteins, which are to some extent applicable to eubacteria. Proteins from the cold-adapted Archaea are characterized by a higher content of noncharged polar amino acids, particularly Gln and Thr, and a lower content of hydrophobic amino acids, particularly Leu. Sequence data from nine methanogen genomes (optimal growth temperature 15–98°C) were used to generate 1111 modeled protein structures. Analysis of the models from the cold-adapted Archaea showed a strong tendency in the solvent-accessible area for more Gln, Thr, and hydrophobic residues and fewer charged residues. A cold shock domain (CSD) protein (CspA homolog) in *M. frigidum*,

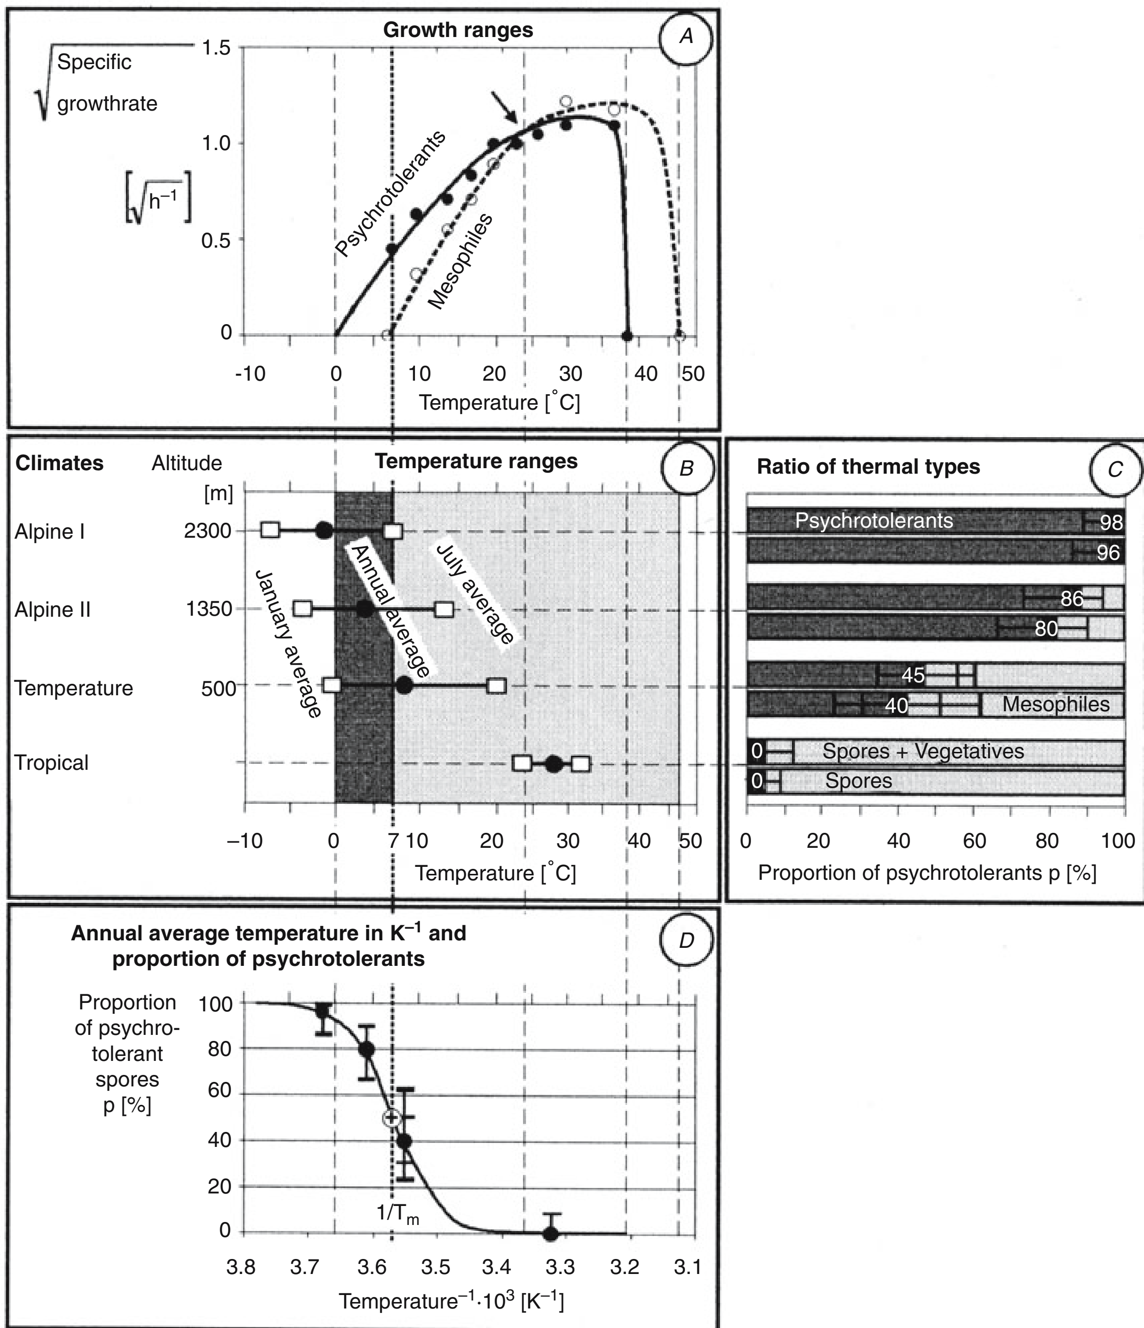

Fig. 15. Difference in growth rate of a mesophilic *Bacillus cereus* and a psychrotolerant *Bacillus weihenstephanensis* strain, and influence of different climates on the ratio of mesophilic and psychrotolerant *cspA* genotypes. To obtain a holistic view, the diagrams have common axes. (B) and (C) share the climate axis, and (A), (B) and (D) share the temperature axes. Temperatures are displayed as both °C and K-1. A) Comparison between the growth ranges of psychrotolerant and mesophilic strains. B) Temperature ranges of a tropical climate, and a climatic sequence, consisting of one temperate climate at 500 m altitude and two temperate high-mountain climates at 1350 m and 2300 m altitude designated as alpine II and alpine I. January and July average temperatures (□) and annual average temperatures (●) are indicated. The white area indicates temperatures below 0°C, where no substantial growth occurs; the darker area marks the range between 0°C and 7°C, where only psychrotolerant strains grow well, and the brighter area highlights the growth range of the mesophilic strains. C) The ratios (in %) of psychrotolerant (dark bar) to mesophilic (bright bar) *cspA* genotypes are displayed for each climate. The upper bar of each pair gives this ratio for the total population, consisting of spores and vegetative cells; the lower bar shows the ratio for spores only. The 95% confidence intervals of the individual assays are indicated by error bars. The bold outer error bars of the temperate sample indicate the estimated intraclimatic mean variation. D) Proportion of psychrotolerant spores over the annual average temperature. This relation can be described by a tangens hyperbolicus function, with its point of inflection () shifted to 7°C. From Von Stetten et al. (1999).

Table 5. Major fatty acids of a mesophilic *Bacillus cereus* WSBC 10030 and a psychrotolerant *Bacillus weihenstephanensis* WSBC 10226 grown at different temperatures in percent.

		Mesophilic strain grown at		Psychrotolerant strain grown at		
RT[b,c]	Fatty acid	12°C	25°C	7°C	12°C	25°C

[b]Small peaks, representing less than 1% of total fatty acids are not listed.

[c]See Byun et al. (2003).

two hypothetical proteins with CSD-folds in *M. burtonii*, and a unique winged helix DNA-binding domain protein in *M. burtonii* were identified. This suggests that these types of nucleic acid binding proteins play a critical role in cold-adapted Archaea. Structural analysis of tRNA sequences from the Archaea indicated that G+C content is the major factor influencing tRNA stability in hyperthermophiles but not in the psychrophiles, mesophiles or moderate thermo-philes. Below an optimal growth temperature of 60°C, the G+C content in tRNA was largely unchanged, indicating that any requirement for flexibility of tRNA in psychrophiles is mediated by other means.

Recently, a proteomic determination of the cold adaptation in the Antartic archaeon, *Methanococcoides burtonii* has been undertaken. By this approach many proteins necessary for growth at low temperature were described, however, the function and interplay of these proteins are still mostly unknown (Goodchild et al., 2004).

Response of Desaturases to Low Temperature

Both anaerobic and aerobic mechanisms are responsible for the synthesis of unsaturated fatty acids (UFA) in bacteria. The anaerobic pathway, elucidated in detail for *E. coli*, produces *cis*-UFA by a specific 2,3-dehydrase acting at the C-10 level (for a review, see Cronan and Rock, 1996). A second mechanism is the introduction of double bonds into the fatty acids. The reaction is catalyzed by oxygen-dependent desaturation of the full-length fatty acid chain, either as an acyl-thioester or as a phospholipid fatty acid moiety, and requires a specific electron transport chain (see references in Aguilar et al., 1998).

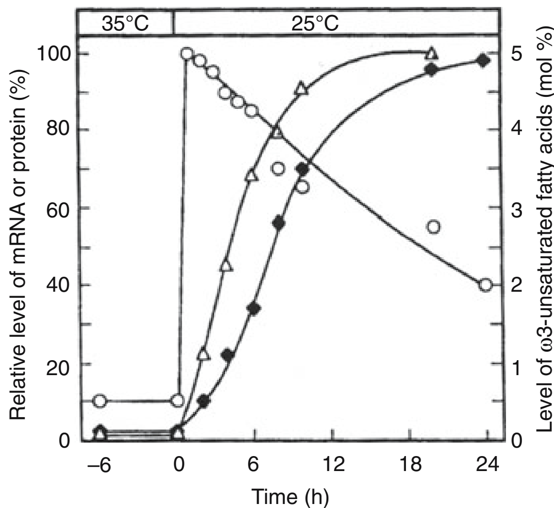

Fig. 16. Changes of levels of *desB* mRNA (open circles), the encoded 3-desaturase (open triangles) and ω3-unsaturated fatty acids (closed diamonds) in *Synechocystis* after a temperature downshift from 35°C to 25°C. From Los and Murata (1999).

The molecular basis of the response of fatty acid adaptation to cold shock has been studied in some detail in unicellular cyanobacteria (Los et al., 1997; Sakamoto and Bryant, 1997a; Sakamoto et al., 1997b; Los and Murata, 1999). In cyanobacteria, four desaturase genes (*desA–desD*) have been reported; *desA*, *B* and *D* have been demonstrated to be cold-inducible in *Synechocystis* (cf. Fig. 16). In addition, *desC* mRNA has been reported to be upregulated within 15 min upon cold shock in *Synechococcus*. This upregulation appears to be due to an increased stability of *des* mRNA at low temperature. A series of mutants was generated by targeted mutagenesis of individual desaturases (Tasaka et al., 1996). Inactivation of *desA* plus *desD* in *Synechocystis* lead to a cold-sensitive phenotype that prevented this mutant from propagating at 20°C. Clearly, the desaturation of membrane lipids is an important factor in acclimation to low temperature.

In contrast to cyanobacteria, *B. subtilis* has only a single desaturase gene, which was described mainly by two groups (Aguilar et al., 1998; Aguilar et al., 1999; Weber et al., 2001b). Cold shock induction of *des* occurs within 30 min and is almost exclusively controlled at the level of transcription, but unlike the situation in cyanobacteria, the stability of mRNA is not increased. Apparently, the *des* gene product is the only component of the *B. subtilis* desaturation system that is regulated by growth temperature. It is a typical transient cold shock induction, which would imply that desaturation does not occur through de novo synthesis of fatty acids.

Surprisingly, a *des* null mutant of *B. subtilis* has no phenotype even when cells are cold-shocked. However, this depends on the presence of isoleucine. In the absence of isoleucine, these mutants were cold sensitive. These data have been interpreted to mean that exogenous isoleucine triggers the switch from *iso*- to *anteiso*-branched saturated fatty acids, providing the organism with a second means to adapt membrane fluidity to low temperature (Klein et al., 1999; Fig. 17).

Adaptation of Protein Synthesis to Low Temperature

Protein Synthesis and the Cold Shock Response

The discovery by Broeze et al. (1978) that the initiation of mRNA transcription is impaired at low temperature indicated that the ribosome is a target of cold shock (Hurme and Rhen, 1998; Perrot et al., 2000). Acting as an RNA chaperone, CspA facilitates initiation and elongation of translation after cold shock (Jiang et al., 1997). Also, a ribosomal protein S21 homolog, which is encoded by *rpsU*, is cold induced in *Sinorhizobium meliloti* (O'Connell and Thomashow, 2000a) as well as in the cyanobacterium *Anabaena variabilis* (Sato, 1994; Sato et al., 1997). This protein may facilitate the binding of mRNA to the ribosome. Interestingly, *rpsU* is located downstream of *cspA* in *S. meliloti*. It may thus help the ribosome to function at low temperatures in the same way as other cold shock proteins (such as RbfA; Jones and Inouye, 1996; Huang et al., 2003). Possibly, small cold shock proteins (e.g., CspA), which appear to be synthesized continuously in some organisms (Graumann et al., 1997; Yamanaka et al., 1999b), may help render the ribosomes able to participate in translation at cold temperatures (i.e., transform them into cold-insensitive ribosomes), but this has not been demonstrated experimentally until now. In any case, by tagging CspB in *B. subtilis* with the green fluorescent protein, and ribosomal protein L1 with the blue fluorescent protein, CspB and ribosomes were seen to colocalize in the cell (Mascarenhas et al., 2001; Weber et al., 2001c).

The level of inactive ribosomes determines the extent of the expression of the cold shock response. Once a balanced translational capacity is achieved, the cold shock response is repressed. At least four proteins (RbfA, initiation factor [IF] 2, CsdA/DeaD, and pY/Yfia) have been proposed as mediators the ribosome's transformation into a cold-insensitive state (Jones and

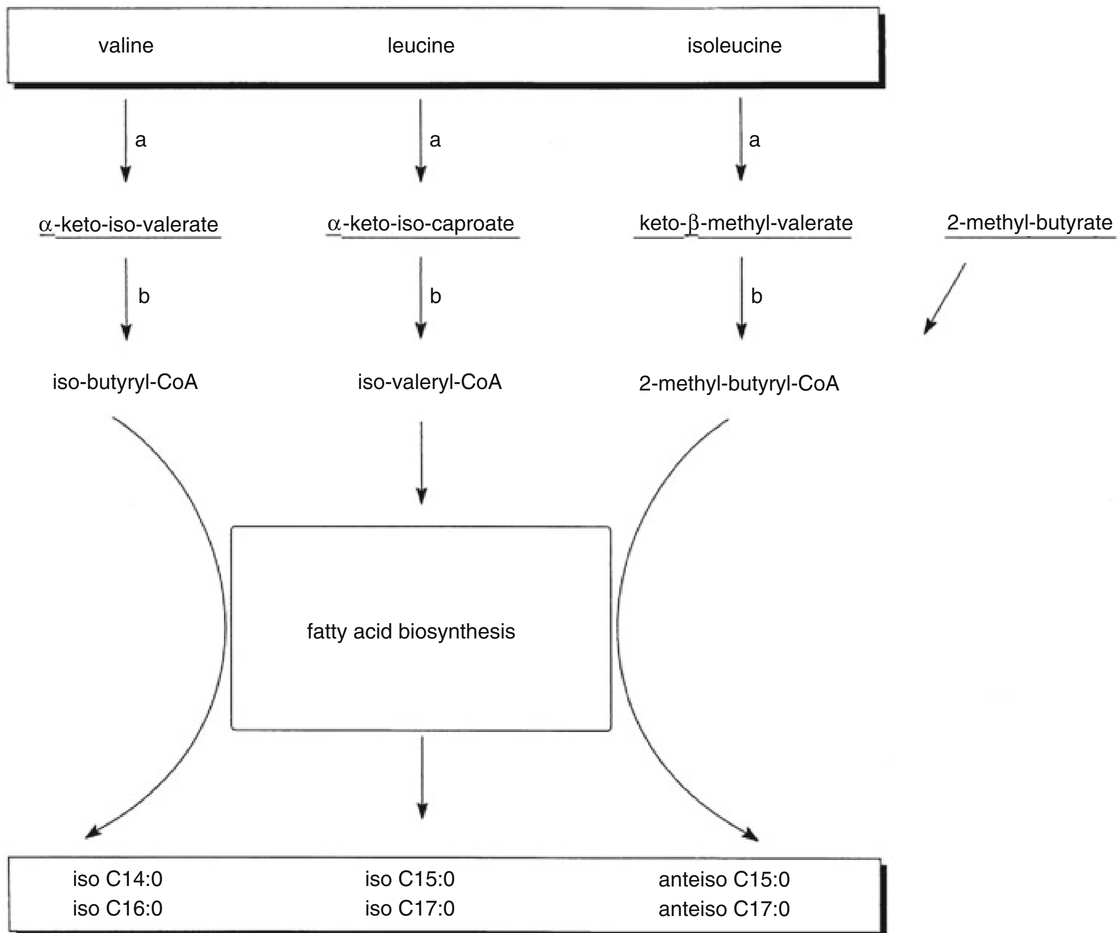

Fig. 17. Schematic representing branched chain fatty acid biosynthesis in *Bacillus subtilis* and its dependence on external supply of valine, leucine and isoleucine. The isoleucine-based pathway offers one possible avenue for membrane adaptation to low temperatures. From Klein et al. (1999).

Inouye, 1996). The ribosomal binding factor A (RbfA) was found to be a suppressor of a cold-sensitive mutation in the 16S rRNA. Cells lacking RbfA exhibit a cold-sensitive phenotype (Dammel and Noller, 1993; Dammel and Noller, 1995), perhaps because the 16S RNA is not processed properly (Bylund et al., 1998). CsdA was found in a 2D-gel analysis of 70S ribosomes from cold-shocked *E. coli* and designated "cold shock DEAD-box protein A." This protein is a homolog of the DEAD-box helicases and possesses RNA unwinding activity. Again, a CsdA mutant is impaired in growth at low temperatures and has the cold-sensitive phenotype of elongated cells (Jones et al., 1996). Recently, it was reported that CsdA is involved in biogenesis of 50S ribosomal subunits. Presumably the RNA helicase activity of CsdA permits a structural rearrangement during 50S biogenesis at low temperature (Charollais et al., 2004). Finally, IF2 is needed for initiation of mRNA translation at the ribosome (Moreno et al., 2000). New data about a ribosome modification after cold shock were published by Agafonov et al. (2001). Ribosomes of cold shocked *E. coli* are shown to be associated with a protein called "PY" or "Yfia" (Rak et al., 2002). However, this protein apparently disappears when the growth arrest is resolved (Kalinin et al., 2002). PY blocks the P as well as the A site of the ribosome, inhibiting translation initiation during cold shock but not under normal growth conditions. Only cold shock genes such as *cspA* may be able to override PY inhibition. By blocking the translation of all but cold shock proteins, the cell diverts all translation factors to the synthesis of cold shock proteins, thus ensuring its survival in the cold (Vila-Sanjurjo et al., 2004). This finding might explain the initiation inhibition after cold shock, originally observed by (Broeze et al., 1978).

O'Connell et al. (2000b) screened cold-shock gene loci in *Sinorhizobium meliloti* by using a

luxAB reporter transposon. Unexpectedly, they found that the transposon of many cold-inducible mutants was inserted in the 16S and 23S rRNA genes. Subsequent experiments confirmed that transcription of all three *rrn* operons of this bacterium is induced by cold shock. Since the number of ribosomes is usually positively correlated with growth rate, one would expect ribosome synthesis inhibition when growth at low temperature is downregulated. However, the cell may upregulate ribosome synthesis because protein synthesis is severely inhibited at low temperature but is needed for survival.

Cold Adaptation of the Ribosome

As has been described above, protein synthesis of mesophilic bacteria is a target of the cold shock response. For protein synthesis, a proper function of tRNA is essential. Many posttranscriptional modifications of tRNA are known. The study of three psychrophilic bacteria from the genera *Moritella* and *Vibrio* revealed that, among other posttranslational modifications, these organisms contained 40–70% more dihydrouridine than did mesophilic bacteria (Dalluge et al., 1997). Nuclear magnetic resonance studies showed that dihydrouridine leads to a higher local flexibility of RNA molecules (Dalluge et al., 1996). Apparently, therefore, the role of the elevated content of this modified nucleoside is to increase local conformational flexibility of tRNA under low temperature conditions where thermal motions and intermolecular interactions of biomolecules are compromised. Interestingly, downstream of the cold inducible *rbfA* gene, a pseudouridine tRNA synthase gene (*trueB*) is located in *E. coli* (S. Scherer and K. Neuhaus, unpublished observations).

In 1969, ribosomes prepared by Nash and Grant (1969) from a psychrophilic *Candida gelida* were inactivated rapidly at 40°C, whereas the ribosomes from a mesophilic *Candida utilis* were unaffected by a similar treatment. Ribosomes prepared by Szer (1970) from a psychrophilic *Pseudomonas* were functional at 0°C and contained a factor which could be washed off, leaving the ribosomes functional at 25–37°C but not at lower temperature. The ribosomes of the mesophile *E. coli* became activated at low temperature upon addition of this factor. Both authors thus concluded that the ribosomes of cold-adapted microorganisms should be structurally different from mesophilic ones, but the identity of the proteins involved is still unknown.

Cold-adapted microorganisms may therefore have structurally different ribosomes when compared to mesophilic bacteria. The comparison of mesophilic and psychrotolerant isolates from the *B. cereus* group showed a systematic difference in the structure of 16S rRNA (Lechner et al., 1998; Von Stetten et al., 1998). Interestingly, both signatures systematically contain A or T in psychrotolerant strains, and G or C in mesophilic strains. One may therefore speculate that the flexibility of the ribosome at low temperature may be increased in some parts of the molecule in the psychrotolerant isolates. However, the occurrence of specific sequence motifs in psychrotolerant strains is not necessarily due to a positive selection pressure associated with this ribosome's function but could be a consequence of neutral drift processes. Therefore, further analysis of the genomic DNA from a wide range of isolates was undertaken (Prüß et al., 1999). This analysis showed that *B. cereus* group strains have between 6 and 10 copies of 16S rDNA. Moreover, a number of these environmental strains have both rDNA operons with psychrotolerant signatures and rDNA operons with mesophilic signatures. The ability of these isolates to grow at low temperatures correlates with the prevalence of rDNA operons having psychrotolerant signatures, indicating specific nucleotides within the 16S rRNA play a role in psychrotolerance (Fig. 18). In vivo measurement of protein synthesis in a psychrotolerant *B. weihenstephanensis* and a mesophilic *B. cereus* clearly showed that ^{35}S-methionine incorporation at low temperature occurs faster by a factor of four (T. Kaplan et al., unpublished data).

Protein Structure and Enzyme Activity

In general, the temperature optima of enzymes from cold-adapted bacteria have been reported to be well above the growth optimum (e.g., Reichhardt, 1998), but those of extracellular enzymes from Arctic and sea ice bacteria have been reported to be as low as 15–20°C (Huston et al., 2000). Usually, the enzyme activity at low temperature is comparatively high (Sun et al., 1998) and the thermostability of cold adapted enzymes is reduced significantly. An example of temperature-dependent activity of the same enzyme isolated from a psychrophilic, mesophilic and thermophilic bacterium is shown in Fig. 19. However, investigation of the molecular basis of cold-active enzymes from psychrophiles has only recently received increased research attention owing to novel opportunities for biotechnological exploitation (Russell, 1998). The application of these enzymes offers considerable potential to the biotechnology industry, for example, in the detergent and food industries, for the production of fine chemicals, and in bioremediation processes (Gerday et al., 2000).

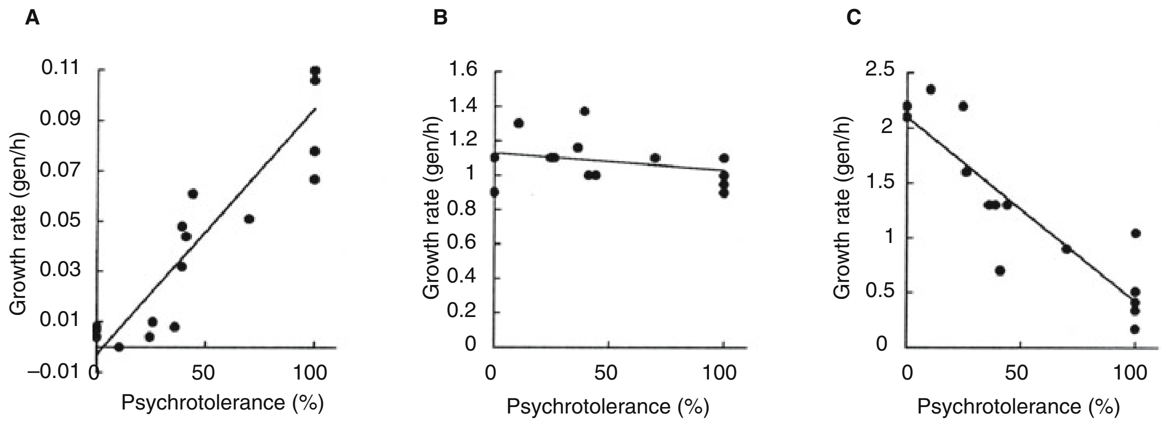

Fig. 18. Comparison of growth rates and psychrotolerance indices. Cultures were grown at 10°C (A), 28°C (B), and 42°C (C). The growth rates are plotted against the percentage of psychrotolerant signatures. A psychrotolerance index of 50% means that one half of the operons of this strain carries the psychrotolerant signature and the other half carries the mesophilic signature. The experiment was done two to six times, and the mean of the populations were determined. Data are from Prüß et al. (1999).

Chemical reactions are characterized by a strong dependency of the reaction velocity on the reaction temperature. The decrease of the rate constant can be described by the Svante Arrhenius equation

$$K = A\ e^{-Ea/RT}$$

where R and T represent the molar gas constant and absolute temperature, respectively, and A is the frequency factor. Typically, a decrease of the reaction temperature by 10°C will lead to a decrease of the reaction rate by a factor of 1.5–4 (Q_{10} value). Notably, the greater the activation energy E_a, the stronger is the temperature dependency of the reaction rate (the reaction rate constant is K). Reactions with low activation energies will only slightly depend on the reaction temperature.

The influence of the reaction temperature on the reaction rate is more complicated when enzyme-catalyzed reactions are considered (for reviews, see Gerday et al., 1999; Lonhienne et al., 2000; Feller, 2003a; Lonhienne et al., 2000). In this case, substrate concentration, enzyme concentration as well as the enzyme-substrate interaction play an important role. At nonsaturating substrate concentration, the reaction velocity depends also on the K_m, which is influenced by the nature of the interaction of the enzyme with the substrate. An electrostatic interaction will be weakened by an increase in temperature, while the hydrophobic interactions tend to be stabilized. Therefore, the reaction velocity of enzymes will be differentially influenced by temperature because of the relative contribution of electrostatic versus hydrophobic forces. Such factors

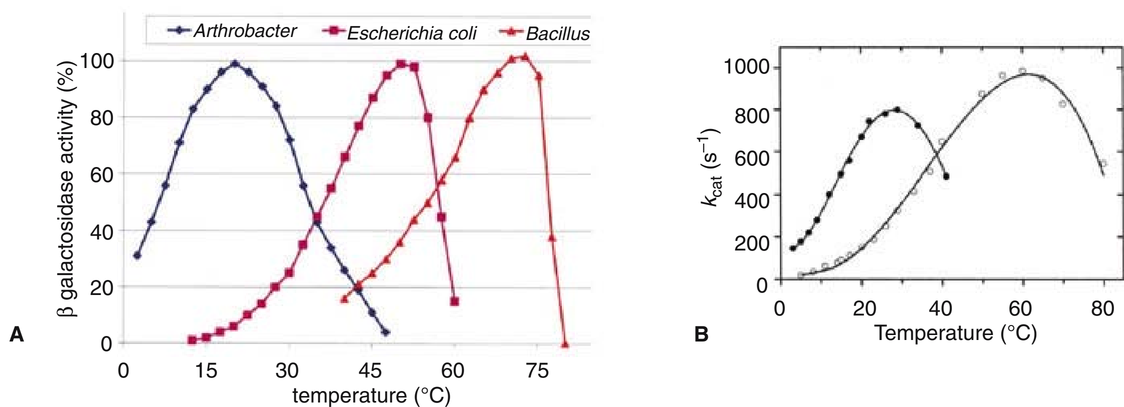

Fig. 19. Graphic comparison of the thermodependence of enzymes. A) β-Galactosidase from the psychrophile *Arthrobacter* D2 (blue), the mesophile *Escherichia coli* (violet) and a thermophilic *Bacillus* (red). Adapted from Brenchley (1996). B) α-Amylase from a psychrophilic (●) and a mesophilic (○) organism.

have to be considered to understand the cold adaptation of enzymes.

Generally, one would assume that enzyme stability, flexibility, and activity have to be properly adjusted to the low temperature. Another aspect of proteins from psychrotrophic organisms is not only the increased thermolability of the protein itself, but also the increased dissociation of monomers or heterodimers. As examples the H-NS-like protein from the psychrophilic *Psychrobacter* should be mentioned. The α-helical domain of this protein displays weaker intermolecular interactions, which may account for the low thermal stability at 37°C (Tendeng et al., 2003). In *E. coli*, H-NS has two isoforms, HUα and the cold-inducible isoform HUβ. HUβ-homodimers show weaker intermolecular interactions (Ramstein et al., 2003).

Recently, many cold active enzymes have been purified and characterized, both at the biochemical and structural level. This section does not cover the biochemical and biophysical aspects; instead, the reader is referred to recent reviews (Gerday et al., 2000; Russell, 2000; Lonhienne et al., 2000; D'Amico et al., 2002a; Feller, 2003a; Feller and Gerday, 2003b) or to Table 6, which lists recent studies of psychrotrophic enzymes. In summary, several adaptations to low temperature are found in different enzymes from psychrophilic bacteria (Table 7). Notably, in no case have all of these adaptations been realized in one protein; each protein has a couple of such changes which is sufficient to render the enzyme cold active. The rules governing their adaptation to cold appear to be relatively diverse, and they are only beginning to be understood.

Due to the widespread occurrence in all thermal types and the relative small size, CspB from *Bacillus* species is a favored model protein for examining thermostabilization, folding and similar structural effects. The findings obtained on CspB might be generalized on other protein families occuring in different thermal types of bacteria, but are beyond the scope of this review. The

Metabolic Activity and Growth

Bacteria experiencing a cold shock normally adapt by induction of the cold shock response and cold shock acclimation proteins. If they are kept at temperatures below the minimal growth temperature, cells tend to die over time. Estuarine and marine *Vibrio* species seem to disappear under low temperature conditions (e.g., below 15°C) from their habitat but reappear with increasing temperatures. Such organisms enter a so called viable but not culturable (VBNC) state. During this VBNC state, the cells become coccoid, whereas normally they are rod shaped and their metabolic activity is maintained. A resuscitation is possible by shifting the culture to higher temperature (e.g., to 37°C for 24 h) before plating (Carroll et al., 2001; Datta and Bhadra, 2003; Johnston and Brown, 2002). Other organisms are also known to enter a VBNC state after exposure to low temperature, as e.g., *Aeromonas hydrophila* (Mary et al., 2002). The latter strain was reported not to have a Csp similar to CspA of *E. coli*, which might contribute to the entering of a VBNC state (Imbert and Gancel, 2004). The VBNC condition might allow such organisms to become resistant and dormant below temperatures permissive for their growth and survive with a minimal metabolic rate. The lowest temperatures at which metabolically active bacterial communities exist has been reported to be –12°C to –17°C (Carpenter et al., 2000).

Motility

In any environment, bacteria use motility to either find nutrients or associate with a surface. Whether bacteria move in subzero environments, such as sea ice, is unclear since the lowest temperature tested for motility or chemotaxis is 5°C. Though *Colwellia psychrerythraea* was shown to be motile at –10°C, the minimum temperature for its growth is reported as –5°C. The swimming speed dropped to 28 μm/s before ceasing (Junge et al., 2003).

Nutrient Uptake

Nutrient uptake is a basic prerequisite for growth. Algae as well as bacteria have a reduced affinity for nitrate at low temperature (Nedwell and Rutter, 1994), and on the basis of the different nitrate uptake and ammonium uptake responses to temperature, dependency on ammonium as an inorganic nitrogen source is suggested to increase at low temperatures (Ray et al., 1999). Apparently, mesophilic bacteria have an enhanced substrate requirement at minimal growth temperatures (Wiebe et al., 1992). Therefore, one would expect that high activity of transport systems at low temperatures is a prime target of cold adaptation of psychrophilic bacteria (Russell, 1990a). Some reports state that sugar transport is largely independent of temperature in psychrophilic yeast and psychrotolerant bacteria (for a review, see Herbert, 1986). To our knowledge, only one transport system from a psychrophilic bacterium has been studied so far. The $^{14}CH_3NH_3^+$ uptake activity of a psychrophilic marine bacterium *Vibrio* sp. was markedly higher at 0–15°C, and the apparent K_m value for the uptake of $^{14}CH_3NH_3^+$ did not change significantly over the temperature range 0–25°C. Thus, the NH_4^+ transport system of this bacterium was highly active at low temperatures (Chou et al., 1999). Assessment of the temperature dependency of this system (Fig. 20) demonstrated its unusual psychrophilic properties.

Carbon Metabolism and Electron Flow

Carbon metabolism and electron flow is also affected by temperature. In chilling-sensitive cold-stressed plants, a decrease in temperature inhibits respiration, but not much is known about this response in bacteria. Cold stress seems to induce changes in the carbon flow of a given organism, either by increasing cold sensitive key enzymes necessary for certain metabolic pathways or by switching to alternative pathways or cold adapted isoenzymes.

Cold stress induces a change from respiratory metabolism to anaerobic lactate formation in psychrotrophic *Rhizobium* strains (Sardesai and Babu, 2000). Analysis of specific activities of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase of the pentose phosphate pathway showed the upward regulation of alternate pathways of carbohydrate metabolism under cold stress, resulting in rapidly

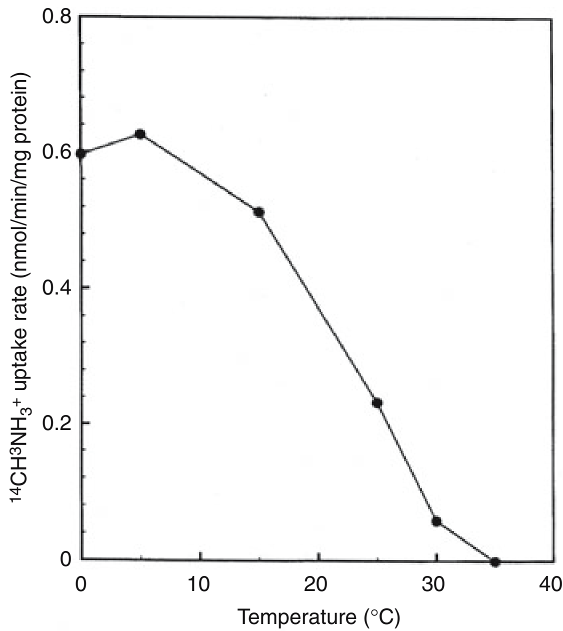

Fig. 20. Temperature dependence of the cold-adapted ammonium uptake system of the psychrophilic marine bacterium *Vibrio* sp. strain ABE-1. From Chou et al. (1999).

generated energy to overcome the stress. The glycolytic activity was also markedly stimulated by a factor of 2.5 in *Lactococcus lactis* upon cold shock from 30°C to 10°C (Wouters et al., 2000a). Upward regulation of malate dehydrogenase suggests that it is a critical input for cold tolerance (Sardesai and Babu, 2001). The cold-stress mediated decrease in the poly-β-hydroxybutyrate (PHB) in a psychrotolerant *Rhizobium* was due to an inhibition of PHB synthesis rather than an increase in its breakdown (Sardesai and Babu, 2001). A downshift in temperature had marked effects on carbon and electron flow in a methanogenic archaeal community in rice field soil, leading to a dominance of psychrotolerant homoacetogenesis (Fey and Conrad, 2000).

Glucose oxidation was also found to be temperature-regulated. At low growth temperature, *Pseudomonas fluorescens* accumulated 2-ketogluconate in the medium as the major oxidation product of glucose. At 30°C, no 2-ketogluconate was excreted at any time (Lynch et al., 1975a; Lynch et al., 1975b). Also, a marked effect of temperature on diauxic growth with glucose and organic acids was observed in this bacterium. Organic acids were preferentially used at 30°C during the first growth phase, and glucose utilization was delayed until onset of the second growth phase. At 5°C, glucose utilization was not repressed during the first growth phase (Lynch and Franklin, 1978). Another psychrotrophic member of this genus, *Pseudomonas syringae*, upregulates urocanase for histidine utilization upon a temperature downshift (Janiyani and Ray, 2002). To cope with cold, psychrophilic *Colwellia maris* expresses a thermolabile isocitrate lyase. This isocitrate lyase is able to utilize its substrate at lower temperatures because of a lower temperature optimum. The same organism has two isocitrate dehydrogenase isoenzymes: one with mesophilic (IDH-I) and the other with psychrophilic characteristics (Ochiai et al., 1979). Accordingly, both the tricarboxylic acid and glyoxylate cycles are important for growth in cold (Watanabe et al., 2002).

A lipase produced by a psychrotrophic *Pseudomonas* strain was found to have the lowest temperature optimum of 35°C in vitro, to have higher activity at low temperature, and to be thermolable compared to other lipases from the same enzyme subfamily (Rashid et al., 2001). The authors conclude that this lipase has adapted to function within the growth range of its host (i.e., –5°C to 35°C).

The psychrotrophic *Acinetobacter* sp. HH1-1 undergoes several metabolic changes in adaptation of its carbon metabolism if exposed to low temperature: 1) Isocitrate lyase is mainly found in the culture supernatant at low temperature. Whether this is due to leakage, as the authors of the study suggested, or to active transport is not clear. 2) The cell associated esterase activity increases and seems to be important for growth at low temperature. 3) Extracellular lipolytic enzymes and production of extracellular polysaccharide are negatively affected at lower temperatures (Barbaro et al., 2001).

Growth Rates

Many more physiological processes are adapted to low temperature in psychrophilic microorganisms. Examples are histidine utilization (Kannan et al., 1998), sulfate reduction (Knoblauch and Jørgensen, 1999a; Knoblauch et al., 1999b), transcription (Ray et al., 1999; Uma et al., 1999), adaptation of the outer membrane of Gram-negative bacteria (Ray et al., 1994; De et al., 1997), reduction of the polar polysaccharide capsular layer (Mindock et al., 2001), carotenoid synthesis (Chattopadhyay et al., 1997), or exoenzyme secretion. The latter is even maximal at –2°C to +4°C in four psychrophilic Antarctic bacterial strains (Feller et al., 1994).

In toto, numerous cold-adapted physiological reactions contribute to, and determine, the growth rate of cold-adapted bacteria (see also the section The Cold Shock Response and Cold Adaptation in this Chapter). As a result, at low temperature, growth rate is higher than in mesophiles, and the lower limit is lower. In principle, the lower growth limit is determined by the

freezing temperature of the cytosol. Most cells remain unfrozen at –10°C to –15°C because of the physical properties of the aqueous solvent systems inside and outside the cells (see Russell, 1990a). These physical boundaries thus determine the absolute lower growth temperature limit in general. The deepest temperature of metabolic activity in bacteria has been reported as –17°C (Carpenter et al., 2000).

The maximal specific growth rate of a psychrotolerant *Pseudomonas fluorescens* with respect to temperature was studied, yielding an Arrhenius plot with a drastic change in slope at 17°C (Fig. 21). Over the cold domain (0–17°C), the temperature characteristic was twofold higher than over the suboptimal domain (17–30°C; Guillou and Guespin-Michel, 1996). The protein content was also measured over the entire temperature range and the authors suggest that, below 17°C, protein degradation is inhibited. This influence of low temperature on protein turnover has also been reported for a psychrotolerant *Arthobacter globiformis* (Potier, 1990) and could be an explanation for the higher temperature characteristic of the Arrhenius plot in the low-temperature range. A biphasic behavior of the growth rate Arrhenius plot was also reported for a *Pseudomonas putida* strain (Chablain et al., 1997). It is, however, too early to suggest that this may be a general feature of cold-adapted strains.

Brenchley (1996) noted that only a few studies have been reported on growth rates at low temperatures. Table 8 lists some doubling times at low temperatures that have been compiled from

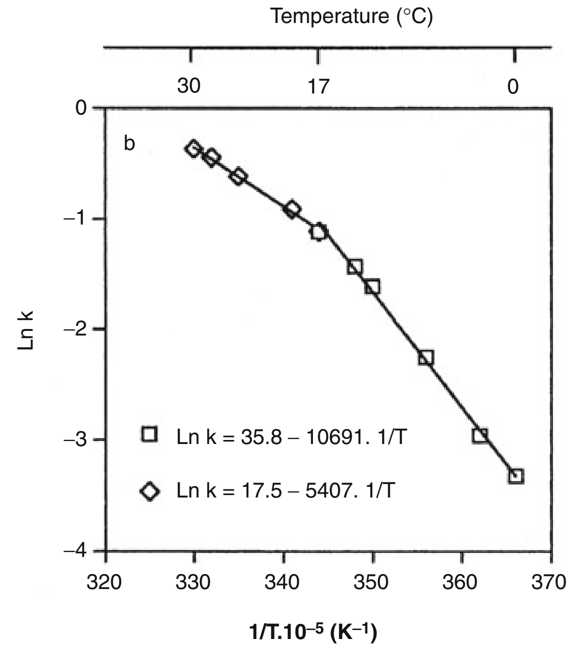

Fig. 21. Biphasic Arrhenius plot of the growth rate of *Pseudomonas fluorescens*. From Guillou and Guespin-Michel (1996).

this and other literature. This list gives a rough idea only, and is not a systematic survey. Three plots of growth rate versus temperature are shown in Fig. 22 for psychrotolerant and psychrophilic strains. The kind of mathematical equation that will describe these functions (and why this would be the case) has been discussed widely, but no firm conclusion could be reached (for a review, see, e.g., Berry and Foegeding [1997] and Gounot [1991]). Please note the very different ranges of growth rates shown in Fig. 22. Note also that the terms psychrophilic and psychrotolerant are defined by the growth ranges and by no means reflect growth rates. For instance, a psychrotolerant *Pseudomonas* has a doubling time of 3 h at 10°C, while a psychrophilic *Desulfotalea* species grows with a doubling time of 27 h at the same temperature. The growth rate depends on the substrate used in the experiment, among other factors. More important, some bacteria such as *Methanogenium* or *Desulfofrigus* are notoriously slow-growing organisms, irrespective of the growth temperature.

Cell Wall

A possibly overlooked phenomenon in response to low temperature might be an increase in cell wall thickness. This has been reported for a cold resistant *Pseudomonas fluorescens*, which showed a 2-fold increase in cell wall thickness, compared to its parent strain, not cold adapted (Khan et al., 2003). Our own observations during RNA extraction from cold shocked and non-cold shocked *Bacillus* strains also pointed in such a direction. Cold shocked cells give significantly reduced yields of RNA, with the same protocol. However, similar yields are obtained by elongated bead beating or sonification (pers. observations).

Environment and Applied Aspects

The rising interest in cold-adapted microorganisms is fueled by a diverse range of aims connected to their explorations. The answers to the following questions will increase understanding of geo-microbiological processes: Which organisms are found in which environment? And, how does low temperature (Stougaard et al., 2002) and climate (Bidle et al., 2002) influence microbial communities? Other questions deal with treatment of contaminated soil or water, usage of cold-adapted enzymes in technical applications (reviewed by Cavicchioli et al., 2002b), influence of temperature on pathogens (often in relation to food), and finally, usage of cold induced promoters for protein production.

A general remark about the occurrence of microbes in the environment was made by Martinus Beijerinck (1851–1931): "Everything is everywhere; the environment selects." This statement applies to microbial thermotypes.

Wherever a cold environment is found, e.g., a cold spring (Rudolph et al., 2001), some alpine meadows (Von Stetten et al., 1999), or a refrigerator somewhere in a jungle village, one can be sure that psychroactive microorganisms can be isolated (M. Neuhaus, personal communication). Conversely, hyperthermophilic organisms have been found in soils worldwide, including permafrost regions (Marchant et al., 2002), and some researchers would extend the search area for extremophile microorganisms into extraterrestrial space (Cavicchioli, 2002a; Mitrofanov et al., 2003). The following sections summarize or mention only recent publications in connection with the aims stated above, and one should be aware that each field overlaps.

Environmental Aspects

Investigating the ecology of bacteria and archaea is vital to understanding the functioning of the global biochemical cycles. Sulfate reducing bacteria and methanogenic archaea are important terminal oxidizers in the anaerobic mineralization of organic matter and can be seen as ecological equivalents, mineralizing organic matter to CO_2 or to CO_2 and CH_4 in, respectively, high- and low-sulfate environments (Purdy et al., 2003). Methanogenesis is also important as a possible climate influence. Methane has a high "green house" effect on the atmosphere. This may explain the great interest in the methanogenesis that occurs in low–temperature environments, which include the sea, the permafrost regions, and deep lakes (Simankova et al., 2003). In low temperature sediments in the Antarctic, *Desulfotalea-Desulforhopalus fulforhopalus* versus *Methanosaeta* appear to be the most abundant species of those groups (Purdy et al., 2003). Ecophysiological processes may change in anaerobic systems under extreme conditions (e.g., freezing). In low-sulfate sediments, H_2-driven methanogenesis was found to be mediated by sulfate reduction. After freezing, both methanogenesis and sulfate reduction decreased. In high-sulfate sediments, sulfate reduction was a major process in frozen and unfrozen samples (Mountfort et al., 2003). In deep lake sediments, a community of psychrophilic methanogens was found, with maximal rates of methane production occurring at 6°C (Nozhevnikova et al., 2003). However, permafrost sediments and other cold environments could also be a sink for methane, since methanotrophic (methane consuming) bacteria have been found in permafrost sediments of Siberia (Khmelenina et al., 2002) and elsewhere (for a review, see Trotsenko and Khmelenina, 2002). In the same environment, anabiotic (dormant) cyst-like bacteria were found in sediment samples drawn from a depth of 50–80 m (Dmitriev et al., 2001), and a variety of psychroactive bacteria have been found at a depth of 11–24 m. Interestingly, few Gram-negative isolates could grow at –10°C (the permanent temperature of the sampling site), but all of these isolates grew optimally at around 25–30°C. Therefore, they have to be classified as psychrotolerant (Bakermans et al., 2003).

Removal of soil contamination is an important issue, especially at low temperature. Petroleum hydrocarbons are the most widespread contaminants in the environment. Cold adapted bacteria able to biodegrade such hydrocarbons are already present in pristine soils but increase as a result of the contamination (Margesin et al., 2003). Similarly, psychrotrophic bacteria from the genera *Shewanella* and *Arthrobacter* have been isolated from oil-reservoir water and have potential for use in bioremediation (Kato et al., 2001). Obviously, microorganisms exist which are able to degrade the hydrocarbons and other organic wastes under such conditions (Männistö et al., 2001b; Männistö et al., 2001c; Baraniecki et al., 2002; Eriksson et al., 2001; Eriksson et al., 2003; Soares et al., 2003; Thomassin-Lacroix et al., 2001; Thomassin-Lacroix et al., 2002).

The poles of the earth (including habitats like sea ice, deep lakes, and similar places) have come into focus. Many scientists are excited by the finding of the big reservoir of liquid water beneath the Antarctic ice shield known as Lake Vostok (Fig. 23). To date, the biological resource of this lake remains untapped, since procedures to remove samples without introducing contamination are still under discussion (Gavaghan, 2002). However, other habitats of Antarctica were examined, and in a permanently frozen

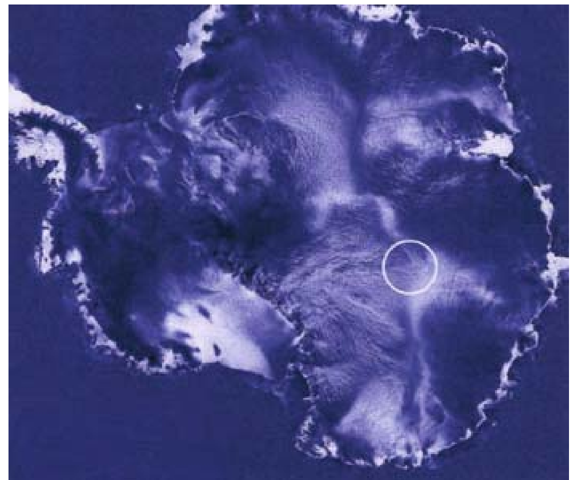

Fig. 23. Lake Vostok (ringed) has lain undisturbed below the ice sheets of Antarctica for many years. From Gavaghan (2002).

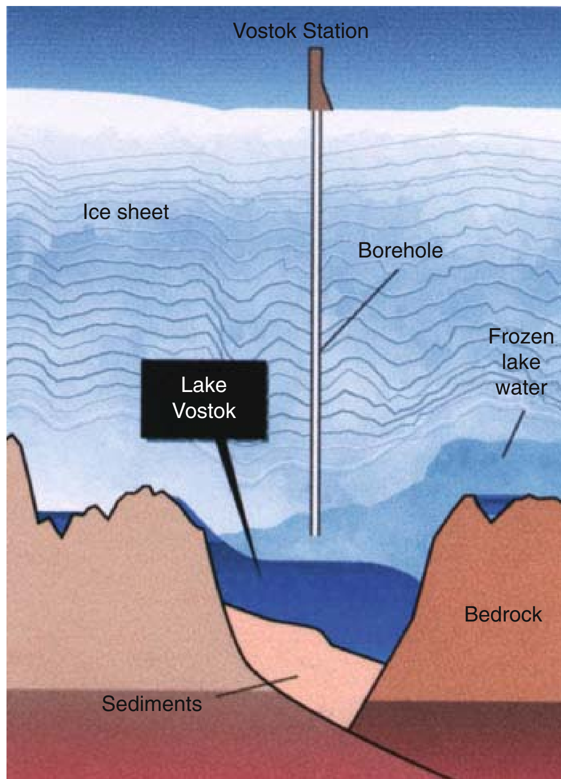

Fig. 24. Schematic view of the borehole to Lake Vostok. It extends beneath Vostok station into areas of frozen lake water but does not reach the lake. From Gavaghan (2002).

Antarctic Lake, a diverse range of phototrophic purple bacteria was found (Karr et al., 2003). This finding is surprising because organisms in Antarctic habitats commonly face continuous low temperatures, as well as poor light conditions and nutrient limitations, making Antarctica appear deserted. But many adapted organisms are thriving below the snow, playing a most fundamental role in the polar ecosystem (for reviews, see Laybourn-Parry [2002]; Thomas and Dieckmann [2002b], and Rossi et al. [2003]).

Technical Uses

An important step in wastewater treatments is the removal of water pollutants by microorganisms. But even in a moderate climate, wastewater temperature may drop to 10°C or 15°C in winter, eventually inhibiting growth of the microbial flora. Under certain conditions low temperature might be beneficial (e.g., low temperature reduces the number of bacteria introduced into the sea by Antarctic research stations; Hughes and Blenkharn, 2003), but mainly it poses a challenge to modern wastewater treatment facilities. Different technical solutions have been proposed to treat wastewater successfully at 13°C (for a review, see Lettinga et al., 2001). Another problem is the huge amount of solids entering sewage treatment facilities. Anaerobic digestion might decrease the amount, but this leads to fouling and biogas (including significant amounts of methane) emission (Nozhevnikova et al., 2001a). Conversely, psychrotolerant nitrifying bacteria may pose a threat to drinking water quality in cold climates (Lipponen et al., 2002).

For extraction of artificially expressed proteins, either for the laboratory (Moran et al., 2001) or for technical uses (Tutino et al., 2001), cold adapted organisms or promoters activated at low temperatures might have certain advantages for the production of thermolabile, toxic, or proteolytically sensitive proteins, for increasing proper folding, increased solubility, or stability (Gonzalez et al., 2003; Mujacic et al., 1999; Takeuchi et al., 2003; Tutino et al., 2001). For more information about the usage of cold inducible promoters in *E. coli*, the reader is referred to the review by Baneyx (1999) or the methodological papers by Baneyx and Mujacic (2003), Qing et al. (2004), and Duilio et al. (2004).

Food Production and Protection

Psychrophilic and psychrotolerant microorganisms are of great importance to the food industry. These organisms are used for direct production, e.g., of dairy products, on the one hand, and may spoil cold stored food or be pathogenic on the other (Russell, 2002).

Lactic acid bacteria (LAB) are traditionally used to produce fermented food, but this heterogeneous group is also used for other purposes, e.g., as probiotics and bioprotectives. Because of the importance and amount of food processed with LAB, a huge body of literature has accumulated that is focused on the cold shock response and cold survival. Different methods are applied to enhance survival of LAB after cold shock or freezing of starter cultures. Exopolysaccharides, overproduction of MCSPs, and employment of other stressful conditions enhances survival of LAB after chilling or freezing (Derzelle et al., 2003; Hong and Marshall, 2001; Maus and Ingham, 2003; Serror et al., 2003a). The discovery of new thermosensitive replicons and two transposons by Serror et al. (2003b) added to the toolbox for manipulating *Lactobacillus* species. For a review of the stress responses in LAB, including cold shock, see Van de Guchte et al. (2002) and the extensive literature survey provided by Carr et al. (2002).

Several studies have been published on the occurrence of psychrotrophic and psychrophilic

bacteria in food matrices. The publications can be divided into those dealing with spoiling organisms and those dealing with survival of certain pathogens under different low temperature conditions. A few recent publications in this field of low temperature research will be briefly mentioned. The smoky odor in chocolate milk stored at 4–9°C is due to guaicol produced by the spoiling organism *Rahnella aquatilis*. This is the first identification of an organism responsible for this type of spoilage (Jensen et al., 2001). Psychrotolerant LAB have been identified as causative agents for spoilage in cooked meat products (Hamasaki et al., 2003). The main flora of cold stored pork meat was found to be *Pseudomonas*, *Aeromonas* and *Acinetobacter* species (Olsson et al., 2003). Neither cold nor carbon dioxide induce a viable but nonculturable state in *Listeria monocytogenes* (Li et al., 2003). However, reduction in the number of this organism is achieved by using essential oils and freezing (Cressy et al., 2003). *Bacillus cereus* can be controlled in chilled dairy products by adding variacin, a lantibiotic produced by *Kocuria varians* (O'Mahony et al., 2001). However, the resistance of *Salmonella* and *E. coli* OH157:H7 (EHEC) to other stresses was increased by subjecting cells to cold temperature beforehand (Bollman et al., 2001; Gawande and Bhagwat, 2002). This increased resistance can be used to advantage in that more viable counts can be obtained by classical plating methods, thereby increasing the sensitivity of pathogen detection (Sol et al., 2002). Other organisms of particular concern able to grow at low temperature include *Clostridium perfringens*, *Campylobacter jejuni*, *Staphylococcus aureus*, *Yersinia enterocolitica*, etc. (Chan et al., 2001; Guentert and Linton, 2003; Harrison et al., 2000; Kalinowski et al., 2003; Steele and Wright, 2001; Zhao et al., 2003). Interestingly, the source of psychrophilic clostridia spoiling vacuum packed chilled meat products is most likely soil particles and fecal material introduced at the abattoir (Boerema et al., 2003).

Reduction or elimination of pathogenic psychrotolerant bacteria is a major aim of food processing. However, the ecology of the pathogen growing in the food matrix is often poorly understood. An elegant in situ method for monitoring a pathogenic *Yersinia enterocolitica* in cheese samples was reported by (Maoz et al., 2002). A full-length *luxCDABE* operon was introduced in the genome of this organism, which carried a constitutive promoter. The emitted light, corresponding to colony forming unit (cfu) counts, was monitored with a sensitive, charge coupled device (CCD) camera. This system does not need the addition of any further substance like antibiotics (to maintain a plasmid) or substrate for the light producing LuxAB enzymes. The influence of, e.g., bioprotective cultures and other means to control the pathogen, can be monitored in situ without laborious cfu plate countings. This technique can be used to monitor other pathogenic organisms (Francis et al., 2000).

Pathogens

Low temperature in connection with pathogens again includes many different facets. Survival of psychrotolerant pathogenic organisms in food has been mentioned in the section above. In this section, some recent findings about the connection between low temperature and pathogens and virulence are highlighted. Temperature regulation of virulence factors has been reviewed by DiRita et al. (2000) and Konkel and Tilly (2000).

Many pathogens regulate virulence genes via temperature sensing mechanisms (see the section Bacterial Cold Sensors in this Chapter). *Yersinia enterocolitica* contains a virulence plasmid, which carries multiple regions of intrinsic curvature. These bends are detectable at 30°C but melt at 37°C, the temperature at which the cells undergo phenotypic switching (Rohde et al., 1999). Other examples of such a behavior can be found in *Vibrio salmonicida*. Disease of Atlantic salmon occurs only if the water temperature is below 10°C. An important virulence factor of this species might be iron siderophores and other iron uptake systems expressed only at the low temperature (Colquhoun and Sorum, 2001). E.g. the main cold shock protein in *L. monocytogenes* seems to be a ferritin-like protein. A similar finding has been reported from *Streptococcus thermophilus*, also expressing an iron binding protein after cold shock (Hébraud, 2000 #2662; Nicodeme, 2004 #2525). In *L. monocytogenes*, the transcriptional activator PrfA controls many virulence genes. The mRNA of this activator acts as thermometer. The 5′ untranslated region renders the ribosome binding site inaccessible at lower temperature (e.g., 30°C) and then switches to an accessible form at higher temperature (e.g., 37°C; Johansson et al., 2002). However, findings showed virulence gene expression at 30°C and below in artificially infected *Drosophila melagonaster* (Mansfield et al., 2003).

Phytopathogens (e.g., *Pseudomonas syringae*) were also found to regulate virulence factors in response to temperature. The phytotoxin coronatine mimics the plant hormone jasmonate. The biosynthesis cluster is regulated by a two-component system, probably sensing membrane fluidity (Smirnova et al., 2002). Thermoregulated expression of virulence factors in plant-associated bacteria has been reviewed by Smirnova et al. (2001a). Conversely, a distinct

group of psychrotrophic *Pseudomonas* species can protect plants by disease-suppression or growth promotion (Johansson and Wright, 2003; Katiyar and Goel, 2003; Mishra and Goel, 1999). One could speculate that this increased plant resistance is due to CspA, which was shown to be a highly active elicitor of tobacco defense responses (Felix and Boller, 2003).

Recently, the general involvement of cold shock genes in virulence has been suggested. Cold-inducible RNases (PNPase and RNase H) were found to be important for full virulence of *Shigella* and enteroinvasive *E. coli* (see Cairrão et al. [2003] and references therein). The PerR regulon of Streptococcus pyogenes is needed for full virulence and contains a Csp (Brenot et al., 2005). Two studies showed a connection between susceptibility to certain antimicrobial substances and the cold shock proteins in *Staphylococcus aureus*: Methicillin resistant *S. aureus* can be treated with the detergent Triton X-100, which reduces the methicillin-resistance. The more resistant a particular strain was before treatment the more its resistance decreased. Comparative proteomics revealed that the MCSPs CspABC of such methicillin-resistant strains (unlike methicillin-sensitive strains) were highly induced (Cordwell et al., 2002). Insertion of a transposon in the *cspA* gene increases the resistance to an antimicrobial peptide of human cathepsin G in the same bacterium (Katzif et al., 2003). Possibly, increased MCSP levels increase the susceptibility to antibacterial substances in *S. aureus*, but more evidence is needed to define the role that CspA plays in such substance resistance. This finding is for some reason contrary to the cross-resistance to other various stresses, which normally increases after induction of the cold shock response and vice versa.

Concluding Remarks

The large number of proteins synthesized upon cold shock as well as in cold acclimation of psychrotolerant microorganisms (see the references in the sections The Cold Shock Response and Cold Acclimation in this Chapter) is clear evidence that many cellular processes contribute to a bacterium's capacity for growth at low temperature. Also obvious is that adaptations at the structural level of rRNA and proteins as well as transient adaptations in the pattern of gene expression are involved in cold adaptation. In toto, a variety of processes thus affect the fitness of cold-adapted bacteria, which, in turn, are important to understand the role of these organisms in their habitat. However, our understanding of the molecular structure of cold adaptation is still in its initial stage. Consequently, our understanding of the evolution of cold tolerance is also quite sketchy. The frequent presence of cold tolerant and mesophilic strains in the same genus or even in the same species suggests that the evolution of psychrotolerance is most probably a multiple step process, which may have occurred many times in parallel.

Even though this review tries to cover many aspects of bacterial life at low temperature, not every area can be covered in detail. Many specialized reviews have been written in recent years. Most of these reviews were cited in the appropriate section above, but to simplify the search for a specific topic, the following table lists reviews or similar articles with a broader scope (Table 9).

CHAPTER 1.9

Life at High Salt Concentrations

AHARON OREN

Introduction

A great variety of prokaryotes, Bacteria as well as Archaea, can be found in saline and hypersaline environments. These microorganisms are adapted to life at high salt concentrations and to the high osmotic pressure of their environment resulting from the high salinity. This chapter presents a general overview of the hypersaline environments as biotopes for prokaryotic life, the types of organisms encountered in them, and the mechanisms the different groups of prokaryotes have developed to cope with the special requirements of life in the presence of molar concentrations of salt. More detailed information on the variety of halophilic organisms can be found in the specific chapters that deal with the different taxonomic groups.

Saline and Hypersaline Habitats

The greatest part of the biosphere is saline. The waters of the oceans and seas that cover most of the earth's surface contain around 35 g dissolved salts per liter. Higher salt concentrations are often encountered in near-shore environments such as salt marshes, sabkhas and lagoons, under conditions in which evaporation is rapid and water exchange with the open sea is slow. Still higher concentrations of salts, up to saturation of NaCl and beyond, exist in natural inland salt lakes such as the Dead Sea on the border between Israel and Jordan (with total dissolved salts of about 340 g/liter), the Great Salt Lake in Utah (up to 333 g/liter in 1975, although values have decreased since 1975 due to the positive water balance of the lake), and many others. Gradients of increasing salt concentrations are found in the man-made evaporation ponds and crystallizer basins of multi-pond solar saltern systems near tropical and subtropical shores worldwide. All these environments, from seawater salinity to NaCl-saturated brines, are potential habitats for prokaryotic life (Brock, 1979; Rodriguez-Valera, 1988, 1993). Additional hypersaline environments inhabited by salt-tolerating (halotolerant) and salt-loving (halophilic) microorganisms are salted food products such as salted fish, animal hides treated with salt for their preservation, saline soils, and subterranean brines that are often associated with oil fields.

The properties of hypersaline environments as habitats for halophilic and halotolerant prokaryotes are primarily defined according to the total salt concentration. However, also the ionic composition is a key factor determining the properties of the environment as a biotope. Brines that originated by evaporation of seawater (so-called thalassohaline brines) reflect the ionic composition of the sea, at least during the first stages of evaporation (Fig. 1). The ionic composition starts to change significantly when evaporation proceeds to the stage at which the solubility limit of $CaSO_4$ is reached and gypsum precipitates (at a total salt concentration above 100–120 g/liter). The brines that enter saltern crystallizer ponds in multi-pond salterns are thus depleted in calcium and to a minor extent in sulfate. During the subsequent precipitation of NaCl as halite, the ionic composition changes again, and the relative concentrations of K^+ and Mg^{2+} increase. The Great Salt Lake, Utah, though since long detached from the world ocean, still reflects in its ionic composition the seawater that contributed its salt, and therefore its waters can still be classified as thalassohaline. Thalassohaline brines are characterized by neutral or slightly alkaline pH values (7–8).

In other hypersaline environments, the ionic composition may greatly differ from that of seawater ("athalassohaline environments"). The Dead Sea is a prime example of an athalassohaline lake. Here divalent cations dominate, with concentrations of Mg^{2+} (1.89 M) and Ca^{2+} (0.45 M) exceeding those of Na^+ (1.56 M) and K^+ (0.20 M) (1998 values). As a result of the high Ca^{2+} concentration the solubility of sulfate is low, and monovalent anions (Cl^- and Br^-) make up more than 99.9% of the anion sum (Fig. 1). The pH of the Dead Sea brine is relatively low, around 5.8–6.0.

Alkaline athalassohaline brines are relatively abundant. Alkaline "soda lakes" are present in

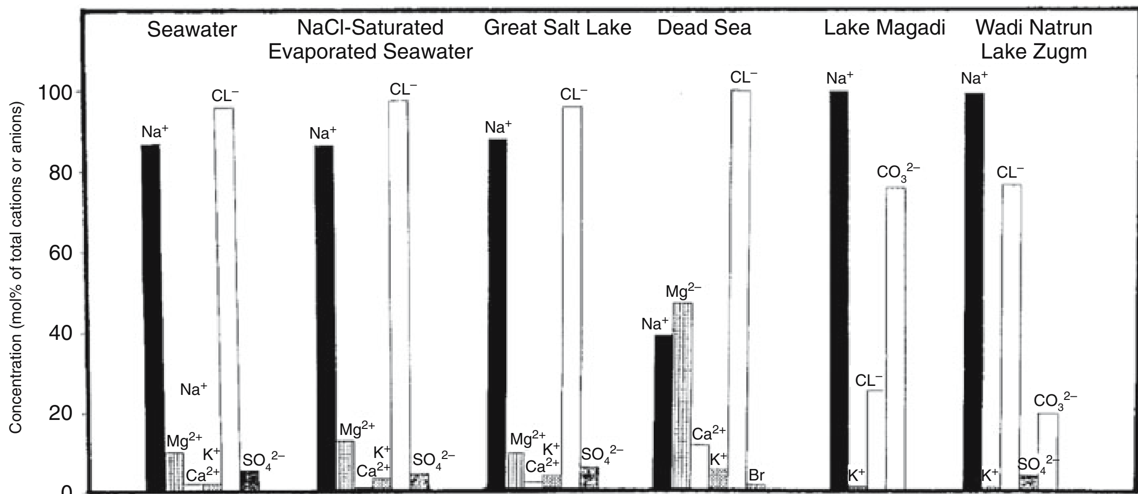

Fig. 1. The ionic composition of seawater and selected hypersaline environments. The bars represent the mol fraction of different cations and anions in the brines. Data for seawater, saltern brines and Great Salt Lake were derived from Javor (1989), and data on Lake Magadi (analyses for 1976) and on Lake Zugm, Wadi Natrun, Egypt, were from Grant and Tindall (1986) and from Grant et al. (1998a), respectively. Dead Sea data (deep water, 1998) were obtained from Michael Beyth (the Israel Ministry of National Infrastructures, personal communication).

diverse geographic locations such as in East Africa (Lake Magadi and other lakes in Kenya and Tanganyika), in the Wadi Natrun in Egypt, and in California, Nevada, India, Tibet, China, and elsewhere. Here the salt composition is dominated by monovalent cations. Because of the high pH (up to 10–11 and higher) the solubility of the divalent cations Mg^{2+} and Ca^{2+} is very low, and the concentrations of these ions may be below the detection limit. Carbonate and bicarbonate ions contribute a significant part of the anion sum in such lakes, in addition to chloride and sulfate.

Classification and Phylogeny of Prokaryotes Living at High Salt Concentrations

Microorganisms adapted to life at high salt concentrations are widespread, both within the bacterial and the archaeal domain. As a result, highly diverse prokaryote communities can be found at all salt concentrations from seawater up to about 340–350 g/liter (brines saturated with NaCl) in both thalassohaline and athalassohaline environments. A few microorganisms can adapt to life over the whole salt concentration range from near fresh water to halite saturation. *Halomonas elongata* is a well-known example of such a bacterium (Vreeland et al., 1980). In most cases, however, each organism has a relatively restricted salt concentration range enabling growth. Some bacteria are adapted to life in saturated and near-saturated brines, being unable to grow and even survive at NaCl concentrations below 15–20%. Most representatives of the halophilic Archaea of the order Halobacteriales show such a behavior. Others thrive at an intermediate salt concentration range. Salt requirement and tolerance may be temperature-dependent, and many cases have been described in which both salt tolerance and requirement are enhanced at increased temperatures (see e.g., Mullakhanbhai and Larsen, 1975).

Different classification schemes have been designed to define the salt relationships of microorganisms. All such schemes are artificial to some extent. Because of the continuum of properties found within the prokaryote world there will always be organisms that cannot unequivocally be classified within any of the groups defined. The most widely accepted classification according to salt dependence and salt tolerance is that of Kushner (1978, 1985), given in a slightly modified form in Table 1. This scheme recognizes different degrees of salt dependence (slightly, moderately, and extremely halophilic). In addition, halotolerant microorganisms exist that, while not requiring high salt concentrations for growth, are able to grow at high concentrations of NaCl and of other salts. *Staphylococcus* species present a good example for this category, as they grow well both in the absence of salt and at NaCl concentrations as high as 10–15% and even higher, a property often exploited in the design of selective and diagnostic growth media. It should be noted that classification should be based not only on

Table 1. Classification of microorganisms according to their response to salt.

Category	Properties	Examples
Non-halophilic	Grows best in media containing less than 0.2M salt	Most freshwater bacteria
Slight halophile	Grows best in media containing 0.2–0.5M salt	Most marine bacteria
Moderate halophile	Grows best in media containing 0.5–2.5M salt	*Salinivibrio costicola*
Borderline extreme halophile	Grows best in media containing 1.5–4.0M salt	*Halorhodospira halophila*
Extreme halophile	Grows best in media containing 2.5–5.2M salt	*Halobacterium salinarum*
Halotolerant	Non-halophile which can tolerate salt; if the growth range extends above 2.5M salt, it may be considered extremely halotolerant	*Staphylococcus aureus*

the behavior toward NaCl but to other ions as well, especially for organisms adapted to life in athalassohaline environments (Edgerton and Brimblecombe, 1981).

The table is based on classification schemes proposed by Kushner (1978, 1985).

Halophilic behavior is found all over the phylogenetic tree of the prokaryotes, both within the Archaea and the Bacteria. Within the archaeal domain, growth at salt concentrations above 15–20% has been documented not only in the Halobacteriales but also in the methanogenic genus *Methanohalophilus* (family Methanosarcinaceae). Most halophilic Bacteria characterized belong to the γ-subdivision of the Proteobacteria, but moderate halophiles can also be found in other subgroups of the Proteobacteria, the low G+C and the high G+C Gram-positive Bacteria, the cyanobacterial branch, the *Flavobacterium* branch, and the Spirochetes (Fig. 2) (Ventosa et al., 1998).

The archaeal order of the Halobacteriales contains the extreme halophiles par excellence. These are highly specialized microorganisms, most of which will not grow at total salt concentrations below 2.5–3 M. When suspended in solutions containing less than 1–2 M salt, cells are irreversibly damaged, and many species will lyse. Some of the early studies on this unique group of prokaryotes were summarized in Larsen's classic essay on "the halobacteria's confusion to biology" (Larsen, 1973), and a full account of their properties can be found elsewhere (e.g., Kushner, 1985; Oren, 1994; Tindall and Trüper, 1986).

The presence of dense communities of members of the Halobacteriales in hypersaline environments often can be observed with the unaided eye thanks to the bright red, orange, or purple coloration of most representatives of the group and to the extremely high community densities at which these Archaea may develop. The occurrence of red hues has been documented for the north arm of the Great Salt Lake (Post, 1977), the Dead Sea (Oren, 1988a), and hypersaline alkaline lakes such as Lake Magadi, Kenya (Grant and Tindall, 1986). Red colored brines also are present typically during the final stages of the evaporation of seawater in solar saltern crystallizer ponds (Borowitzka, 1981; Javor, 1989; Oren, 1993, 1994) (Figs. 3–6). Sometimes other types of microorganisms may also contribute to the color of the brine, such as the β-carotene-rich, green halophilic alga *Dunaliella salina* in saltern ponds (Fig. 6), or photosynthetic purple bacteria of the genus *Ectothiorhodospira*

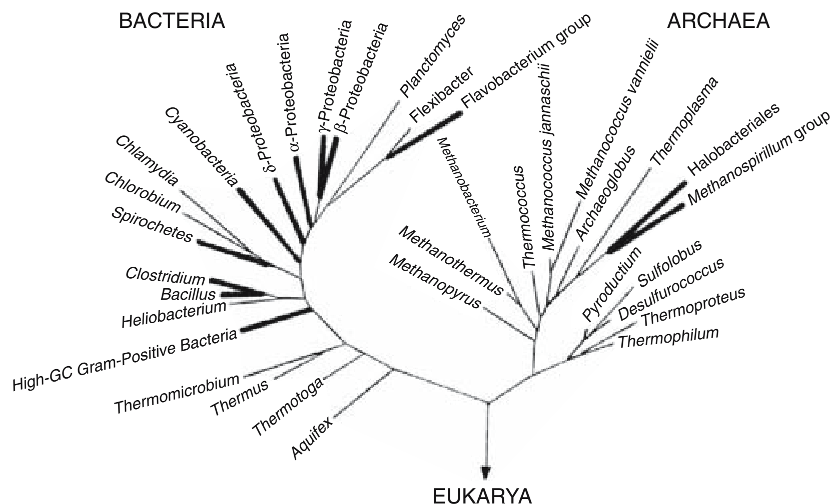

Fig. 2. Phylogenetic tree of the Bacteria and the Archaea, based on 16S rRNA sequence comparisons, indicating the distribution of halophilism. Bold lines indicate branches containing representatives able to grow at or near optimal rates at NaCl concentrations exceeding 15%.

Fig. 3. Saltern crystallizer pond of the Israel Salt Company at the Red Sea coast near Eilat at a total dissolved salt concentration of about 340 g/liter, colored red by halophilic Archaea.

Fig. 5. Saltern ponds of the Cargill Solar Salt Works (Newark, CA), showing a crystallizer pond colored brightly red by halophilic Archaea (courtesy of Carol D. Litchfield, George Mason University, Fairfax, VA).

or *Halorhodospira*, which may contribute at least part of the red coloration of the brines in the alkaline lakes of the Wadi Natrun, Egypt (Jannasch, 1957).

Halophilic Archaea may survive for prolonged periods within halite crystals. This property has aroused considerable interest in recent years, following the isolation of viable halophilic Archaea from salt collected from salt mines dating from the Triassic (195–225 million years B.P.) and Permian (225–270 million years B.P.) periods (Norton et al., 1993). A variety of halophilic Archaea was recently isolated from the Permian Salado salt formation near Carlsbad, New Mexico, including many unknown types (Vreeland et al., 1998). Controversy still exists over whether these bacteria were trapped within the crystals, where they retained their viability, or whether these cells may have entered the salt more recently, during disturbances of the salt layer that were caused by natural phenomena or human activity. Vreeland and Powers (1999) give a critical discussion of the intriguing findings of viable prokaryotic cells within ancient salt deposits. Recently, the heterogeneous 16S rRNA genes in *Haloarcula* isolates from ancient salt deposits have been compared with those of modern strains in the expectation that there are fewer differences between the genes of truly ancient *Haloarcula* than in modern strains if the gene multiplicity originated by duplication. No indications were found that the genes from present-day strains are more divergent than the ancient ones (Grant et al., 1998b).

Fig. 4. Saltern crystallizer pond of the Israel Salt Company at the Mediterranean coast near Atlit at a total dissolved salt concentration of about 340 g/liter, colored red by halophilic Archaea.

Fig. 6. Brines in crystallizer pond of the Cargill Solar Salt Works (Newark, CA), colored in part red due to dense communities of halophilic Archaea (foreground) and in part showing a more orange color imparted by the β-carotene-rich unicellular green alga *Dunaliella salina*. The total dissolved salt at the time (February 1997, following a period of heavy rains) was about 250 g/liter.

Other taxonomically coherent groups consisting solely or mainly of halophilic microorganisms are the order Haloanaerobiales and the family Halomonadaceae. The Haloanaerobiales form an order of moderately halophilic anaerobic bacteria within the low G+C branch of the Gram-positive Bacteria (Rainey et al., 1995). As discussed below and elsewhere (Oren, 1992), this group is of special interest because the mechanism of salt adaptation used by its members resembles that of the aerobic halophilic Archaea rather than that of the other halophilic or halotolerant Bacteria. The family of the Halomonadaceae (γ-subgroup of the Proteobacteria) contains some of the most versatile prokaryotes with respect to their adaptability to a wide range of salt concentrations. The adaptations of some of its representatives to salt have been studied extensively (Franzmann et al., 1988b; Ventosa et al., 1998).

Thermophilic, Psychrophilic, and Alkaliphilic Halophiles

Among the halophilic prokaryotes some are adapted to other forms of environmental stress in addition to salt stress. Thus, thermophilic, psychrophilic, and alkaliphilic halophiles are known. No acidophilic halophiles have been described as yet. The Dead Sea with a pH of about 6.0 is probably the most acidic environment in which mass development of halophilic Archaea has been reported (Oren, 1988a).

Most aerobic halophilic Archaea of the order Halobacteriales have rather high temperature optima, in the range between 35 and 50°C and sometimes even higher. Growth at high temperatures may be an adaptation to the often relatively high temperatures of salt lakes in tropical areas.

Within the anaerobic Bacteria of the order Haloanaerobiales several moderately thermophilic representatives were described. *Halothermothrix orenii*, the first truly thermophilic halophile discovered, was isolated from Chott El Guettar, a warm saline lake in Tunisia. It grows optimally at 60°C and up to 68°C at salt concentrations as high as 200 g/liter (Cayol et al., 1994). *Acetohalobium arabaticum* strain Z-7492 has a temperature optimum of 55°C (Kevbrin et al., 1995).

Cold-adapted halophiles also occur. The halophilic Archaeon *Halorubrum lacusprofundi* was isolated from Deep Lake, Antarctica, a hypersaline lake in which the water temperature varies according to the season between below zero to +11.5°C. The isolate grows optimally at 31–37°C, but slow growth does occur down to temperatures of 4°C (Franzmann et al., 1988a). In addition, a variety of halophilic and halotolerant Bacteria was isolated from different salt lakes in Antarctica (Dobson et al., 1991; Franzmann, 1991; McMeekin and Franzmann, 1988; McMeekin et al., 1993).

Halophilic Archaea of the order Halobacteriales are abundant in hypersaline soda lakes such as Lake Magadi (Kenya) (Grant and Tindall, 1986; Tindall and Trüper, 1986; Tindall et al., 1980, 1984), the Wadi Natrun lakes (Egypt) (Imhoff et al., 1978, 1979; Soliman and Trüper, 1982), and soda lakes in China (Wang and Tang, 1989) and India (Upasani and Desai, 1990). They may impart a red color to such lakes. These environments are characterized by salinity at or close to halite saturation and contain, in addition, high concentrations of carbonates. The pH values are around 10–11 (Grant and Tindall, 1986). Also anaerobic halophilic alkaliphiles occur in such environments. Lake Magadi was shown to harbor a varied anaerobic community, including cellulolytic, proteolytic, saccharolytic, and homoacetogenic bacteria (Shiba and Horikoshi, 1988; Zhilina and Zavarzin, 1994; Zhilina et al., 1996). The homoacetogen *Natroniella acetigena* was isolated from this environment. Its pH optimum is 9.8–10.0, and it can grow up to pH 10.7 (Zhilina et al., 1996). Anaerobes were also isolated from the alkaline saline Big Soda Lake, Nevada (Shiba and Horikoshi, 1988; Shiba et al., 1989).

Metabolic Diversity of Halophilic Microorganisms

A survey of the halophilic microorganisms for metabolic diversity shows that many, but not all types of dissimilatory metabolism known within the prokaryotic world, can function in hypersaline environments as well. Figure 7 presents an overview of the functional diversity of halophilic prokaryotes, based both on laboratory experiments with isolated cultures and on measurements of the processes as they occur in nature.

Oxygenic photosynthesis by cyanobacteria can occur almost up to NaCl saturation. Though the main planktonic primary producers in most hypersaline environments are eukaryotic algae of the genus *Dunaliella* (Javor, 1989; Oren, 1988a, 1994; Post, 1977), cyanobacteria such as *Aphanothece halophytica* [*Cyanothece*; for a discussion of the problems in the taxonomy of the "Halothece" group see Garcia-Pichel et al. (1998)] are often found abundantly in benthic microbial mats that cover the shallow sediments of salt lakes and saltern ponds, especially in the salinity range between 150–250 g/liter (Oren,

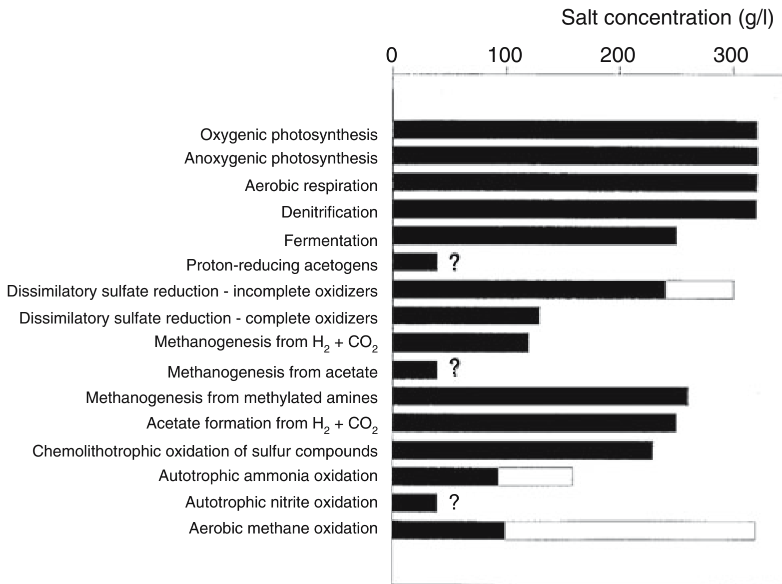

Fig. 7. Approximate upper salt concentration limits for the occurrence of selected microbial processes. Values presented are based in part on laboratory studies of pure cultures (black bars) and on activity measurements of natural microbial communities in hypersaline environments (white bars). Data were derived in part from Brandt and Ingvorsen (1998) , Ollivier et al. (1998), Oremland and King (1989), Oren (1988b, 1999), Sokolov and Trotsenko (1995), Zhilina and Zavarzin (1990), and many additional sources.

Fig. 8. A crust of gypsum densely populated with cyanobacteria (*Aphanothece halophytica* [*Cyanothece*; see Garcia-Pichel et al., 1998] and others) in a saltern evaporation pond of the Israel Salt Company at the Red Sea coast near Eilat at a total dissolved salt concentration of 286 g/liter. The author is sampling the carotenoid-rich upper unicellular cyanobacterial layer and the green layer of filamentous and unicellular cyanobacteria below.

1999). Figure 8 shows an example of a dense benthic community of unicellular cyanobacteria living within a gypsum crust of a saltern pond at a salt concentration of 286 g/liter.

Anoxygenic photosynthetic prokaryotes also abound up to the highest salt concentrations. Examples are representatives of the genus *Halorhodospira*, which contains species such as *Halorhodospira halochloris* and *Halorhodospira halophila* that can be classified as borderline extreme halophiles (see Table 1). *Halorhodospira* cells were documented to impart a bright red color to the alkaline hypersaline lakes of Wadi Natrun, Egypt (Jannasch, 1957). Additional halophilic purple bacteria have been characterized, such as *Halochromatium* and *Thiohalocapsa* (Caumette et al., 1991, 1997; Imhoff et al., 1998). There is also a report that green sulfur bacteria (*Chlorobium* or a relative) may occur at high salt concentrations (Anderson, 1958), but details are lacking.

Most halophilic prokaryotes that have been isolated and studied are aerobic chemoorganotrophs. Aerobic breakdown of organic compounds is possible at salinities up to NaCl saturation. Both halophilic Archaea of the order Halobacteriales and different types of Bacteria may be involved in the breakdown of organic compounds in hypersaline environments. In addition to simple compounds such as sugars, amino acids, etc., also a number of unusual substrates can be degraded at high salt concentrations. Aliphatic and aromatic hydrocarbons, including even- and odd-carbon-number saturated hydrocarbons; saturated isoprenoid alkanes (pristane); different aromatic compounds, including benzoate, cinnamate, and phenylpropionate; and long-chain fatty acids, such as palmitic acid, have been shown to serve as sole carbon and energy sources for certain isolates of halophilic Archaea (Bertrand et al., 1990; Emerson et al., 1994; Kulichevskaya et al., 1991). Degradation of hexadecane was shown in the Great Salt Lake up to a salinity of 172 g/liter (Ward and Brock, 1978). Other unusual compounds shown to be degraded or transformed at high salt concentrations are formaldehyde (Azachi et al., 1995) and organophosphorus compounds (DeFrank and Cheng, 1991). Oren et al. (1992) presented an overview of the potential for breakdown of unusual compounds, including industrial pollutants, at high salt concentrations.

Oxygen is poorly soluble in concentrated brines, and therefore it is not surprising to find a considerable variety of anaerobic halophilic heterotrophs. Many representatives of the aerobic halophilic Archaea of the order Halobacteriales can grow anaerobically by using nitrate as electron acceptor (Mancinelli and Hochstein, 1986). Other potential electron acceptors used by many species are dimethylsulfoxide, trimethylamine N-oxide (Oren and Trüper, 1990) and fumarate (Oren, 1991).

Halobacterium salinarum, but none of the many other aerobic halophilic Archaea tested (Oren and Litchfield, 1999), is able to grow fermentatively on L-arginine (Hartmann et al., 1980). However, the group of halophilic microorganisms that have specialized in anaerobic fermentative growth is that of the Haloanaerobiales (low G+C branch of the Gram-positive Bacteria) (Oren, 1992). Different sugars and in some cases also amino acids are fermented to products such as acetate, ethanol, butyrate, hydrogen, and carbon dioxide (Lowe et al., 1993; Mermelstein and Zeikus, 1998; Oren, 1992; Rainey et al., 1995).

In low-salt anaerobic environments breakdown of organic compounds is completed by the cooperative action of a variety of microbial processes, including fermentation, dissimilatory sulfate reduction, methanogenesis, and possibly also activity of proton-reducing acetogens that degrade compounds such as ethanol, butyrate, and others to hydrogen and acetate. Not all these processes have been identified as yet in anaerobic hypersaline environments (Oren, 1988b). For example, no reports on the occurrence and activity of proton-reducing acetogens in hypersaline environments have been published as yet. This lack of information may be due to the difficulty in handling these intriguing bacteria, which are being studied by a very small number of microbiologists only. Thus any claim that such halophilic organisms do not occur in nature may be premature.

Dissimilatory sulfate reduction occurs up to quite high salt concentrations. Black, sulfide-containing sediments are often found on the bottom of salt lakes and saltern ponds almost up to NaCl saturation. A number of halophilic sulfate reducers have been isolated in recent years. The most salt-tolerant isolate thus far is *Desulfohalobium retbaense*, isolated from Lake Retba in Senegal, which was documented to grow at NaCl concentrations of up to 24% (Ollivier et al., 1991). Other halophilic isolates such as *Desulfovibrio halophilus* and *Desulfovibrio oxyclinae* tolerate NaCl concentrations of up to 18–22.5% only (Caumette, 1993; Caumette et al., 1991; Krekeler et al., 1997; Ollivier et al., 1994). Most halophilic and halotolerant sulfate reducers isolated are incomplete oxidizers that grow on lactate and produce acetate. Only very recently was the first halophilic acetate-oxidizing sulfate-reducing bacterium isolated: *Desulfobacter halotolerans* was obtained from the bottom sediments of the Great Salt Lake (Brandt and Ingvorsen, 1997). This organism has a rather restricted salt range, being unable to grow above 13% NaCl. Possibly, bioenergetic constraints define the upper salinity limit at which the different dissimilatory processes can occur (Oren, unpublished data). The sulfate reducers are Proteobacteria that use organic compatible solutes to provide osmotic balance, a strategy that is energetically much more expensive than the use of inorganic ions for that purpose (see below). Accumulation of trehalose and glycine betaine was documented in *Desulfovibriohalophilus* (Welsh et al., 1996). Dissimilatory sulfate reduction provides relatively little energy, and therefore the need to spend a substantial part of the available energy for the production of organic osmotic solutes may set the upper limit to the salt concentration at which these bacteria can grow. The oxidation of lactate to acetate and CO_2 yields much more energy (2 $Lactate^-$ + SO_4^{2-} $\rightarrow$ 2 $Acetate^-$ + $2HCO_3^-$ + HS^- + H^+ ; $\Delta G^{o\prime} = -160.1$ kJ) than the oxidation of acetate with sulfate as electron acceptor ($Acetate^-$ + SO_4^{2-} $\rightarrow$ $2HCO_3^-$ + HS^-; $\Delta G^{o\prime} = -47.7$ kJ). This difference may possibly explain the apparent lack of complete oxidizers at the highest salt concentration range.

The main methanogenic processes in freshwater environments are the reduction of CO_2 with hydrogen and the aceticlastic split. Neither of these reactions has been shown to occur at high salt concentrations. Solar Lake (Sinai) sediments (70–74 g/liter salt) did not show any methanogenesis from acetate or from $H_2 + CO_2$ (Giani et al., 1984). The highest salt concentration at which methanogenesis from $H_2 + CO_2$ was demonstrated in nature was 88 g/liter (Mono Lake, CA) (Oremland and King, 1989). The most halotolerant isolate that grows on $H_2 + CO_2$ is *Methanocalculus halotolerans* obtained from an oil well. This organism grows up to 12% NaCl with an optimum at 5% (Ollivier et al., 1998). The upper salinity boundary for the use of acetate as methanogenic substrate is probably even lower, but available data are few. To my knowledge, no cultures of aceticlastic methanogens are extant that grow above 4–5% NaCl.

Energetic constraints may explain the apparent lack of truly halophilic methanogens that grow on $H_2 + CO_2$ or on acetate. In contrast to the aerobic halophilic Archaea of the order Halobacteriales which contain inorganic ions for osmotic stabilization, the methanogens use the energetically more expensive option of synthesizing organic osmotic solutes (see Table 5). The aceticlastic split yields very little energy

($\Delta G^{o\prime}$ = –31.1 kJ per mol acetate). The free energy yield during growth on hydrogen is –34 kJ per mol of hydrogen, not much higher than that on acetate.

Methanogenesis does occur, however, at much higher salt concentrations. The most salt-tolerant methanogens known in culture are *Methanohalobium evestigatum* and *Methanohalophilus portucalensis*, which grow in up to 25–26% NaCl (Boone et al., 1993; Lai and Gunsalus, 1992; Zhilina and Zavarzin, 1987). Additional moderately halophilic methanogens have been isolated, growing optimally at 4–12% salt (e.g., *Methanohalophilus mahii*, *Methanohalophilus halophilus*, *Methanohalophilus portocalensis*, and *Methanohalophilus zhilinae*). The energy sources used by these methanogens are methylated amines, methanol, and dimethylsulfide (Oremland and King, 1989; Zhilina and Zavarzin, 1987, 1990; see also the review paper by Ollivier et al., 1994). The substrates, such as trimethylamine and dimethylsulfide, used by these bacteria in their natural environment are largely derived from microbial degradation of methylated compounds that serve as organic osmotic solutes in many halophilic microorganisms (Oremland and King, 1989; Zhilina and Zavarzin, 1990; see also Table 5). Thermodynamic calculations show that the energy yield on methylated amines is relatively large (between –92 and –191 kJ per mol of substrate transformed), and this may explain, at least in part, why growth of methanogenic Archaea on methylated amines may occur up to high salt concentrations.

While, as discussed above, methanogens growing on $H_2 + CO_2$ appear to be absent in hypersaline environments, halophilic homoacetogenic bacteria that use the same substrates for the production of acetate have been isolated (Zavarzin et al., 1994; Zhilina and Zavarzin, 1990; Zhilina et al., 1996). *Acetohalobium arabaticum* is able to grow between 10–25% NaCl with an optimum at 15–18% (Zhilina and Zavarzin, 1990). At first sight, reaction thermodynamics do not explain why halophilic homoacetogenic bacteria do occur when CO_2-reducing methanogens do not, as the acetogenic reaction yields even less energy than the methanogenic reaction (–26.1 kJ and –31.1 kJ per hydrogen oxidized, respectively). However, the halophilic homoacetogens belong to the order Haloanaerobiales (Rainey et al., 1995; Zhilina et al., 1996), a group that uses the energetically cheaper option of accumulating inorganic ions to establish osmotic balance (Oren, 1986; Oren et al., 1997; Rengpipat et al., 1988).

Halophilic aerobic chemoautotrophic bacteria that obtain their energy from the oxidation of reduced sulfur compounds are known. *Thiobacillus halophilus*, isolated from a hypersaline lake in Western Australia, grows in as much as 24% NaCl (Wood and Kelly, 1991). However, autotrophic oxidation of NH_4^+ to NO_2^- was never demonstrated above 150 g/liter salt, and the salt limit for the oxidation of NO_2^- to NO_3^- may be even lower (Rubentschik, 1929). To my knowledge no halophilic or halotolerant ammonia- or nitrite-oxidizing bacteria are extant in culture that are able to grow at salinities significantly exceeding those of seawater. *Nitrosococcus halophilus*, with an optimum at 4% NaCl and a maximum at 9.4% may be the most halophilic strain isolated to date (Koops et al., 1996). An attempt to demonstrate nitrification in a microcosm simulation of the microbiology of the Great Salt Lake at a total salt concentration above 30% yielded negative results (Post and Stube, 1988). Lack of energy source is probably not the main reason: ammonia, and not nitrate, is the dominant inorganic nitrogen species in most or all hypersaline water bodies, and it generally occurs in quite high concentrations, in the Dead Sea even in the millimolar range. Energetic constraints may be the cause for the apparent lack of halophilic nitrifying bacteria in nature, as only very small amounts of energy are gained from the oxidation of ammonia and of nitrite.

Thermodynamic constraints cannot explain the apparent lack of aerobic methane oxidation in hypersaline environments. Methane oxidation is a highly exergonic process ($CH_4 + 2O_2 \rightarrow HCO_3^- + H^+ + H_2O$; $\Delta G^{o\prime}$ = –813.1 kJ). However, even in an environment with a relatively low salinity such as the epilimnion of Solar Lake, Sinai, during winter stratification (about 9% salt), no methane oxidation could be measured in spite of the availability of both methane and oxygen (Conrad et al., 1995). Recent reports on the occurrence of methane oxidation in sediments of hypersaline reservoirs in Ukraina and Tuva (up to 330 g/liter total dissolved salts) and on the isolation of halophilic methanotrophs from these environments (Kalyuzhnaya et al., 1998; Khmelenina et al., 1996, 1997; Sokolov and Trotsenko 1995) indicate that the existence of halophilic methane oxidizers is at least thermodynamically feasible, and that the earlier reported lack of methane oxidation in other hypersaline environments (Conrad et al., 1995; Slobodkin and Zavarzin, 1992) should have other reasons.

Physiological and Biochemical Properties of Halophilic Prokaryotes

As biological membranes are permeable to water, any microorganism living at high salt concentrations has to maintain its intracellular environment at least isoosmotic with the salt concentration in its environment, and even

hyperosmotic when a turgor pressure has to be maintained (Brown, 1976, 1990; Csonka, 1989; Vreeland, 1987). Two fundamentally different strategies exist that enable halophilic and halotolerant prokaryotes to cope with the osmotic stress exerted by the high ionic strength of their hypersaline environment. The first option, used by the aerobic Archaea of the order Halobacteriales and by the anaerobic Bacteria of the order Haloanaerobiales, is based on the accumulation of high concentrations of inorganic ions in the cytoplasm. In most cases, K^+ rather than Na^+ is the dominant intracellular cation, and Cl^- is the dominant anion. Presence of molar concentrations of inorganic ions requires special adaptations of the entire intracellular enzymatic machinery. The "salt-in" strategy permits little flexibility and adaptability to changing conditions, as many salt-adapted enzymes and structural proteins require the continuous presence of high salt for activity and stability. The adaptive evolution of proteins and salinity-mediated selection of their properties has recently been reviewed (Dennis and Shimmin, 1997).

The second strategy is to prevent high salt concentrations from reaching the cytoplasm, and maintaining "conventional" enzymes and other proteins, not specifically designed to function at high ionic strength. Low intracellular ionic concentrations are maintained by active pumping of ions out of the cells. Osmotic equilibrium is provided by organic solutes that are either produced by the cells or accumulated from the medium (Kempf and Bremer, 1998). Such "compatible" solutes are low-molecular-weight organic compounds, soluble in water at high concentrations, and not inhibitory to enzymatic activities even in the molar concentration range. The intracellular concentrations of the organic solutes are regulated according to the salinity of the external medium. Thus, the use of organic osmotic solutes provides a great deal of flexibility and adaptability to an often, wide range of salt concentrations, with the possibility of rapid adaptation to changes in the salinity of the medium. The strategy of maintaining isoosmotic concentrations of organic osmotic solutes is used by most halophilic and halotolerant Bacteria (with the exception of the Haloanaerobiales, as stated above) and by the halophilic methanogenic Archaea. Halophilic eukaryotic microorganisms also use organic compatible solutes for osmotic stabilization. Under certain conditions, the alkaliphilic members of the Halobacteriales also make use of an organic osmoticum (2-sulfotrehalose) to aid in the achievement of osmotic equilibrium with the environment (Desmarais et al., 1997).

The "Salt-In" Strategy

Analyses of intracellular ionic concentrations in different aerobic halophilic Archaea show that these microorganisms maintain extremely high salt concentrations inside their cells. Moreover, the ionic composition of their intracellular milieu differs greatly from that of the outside medium, with K^+ being the main intracellular cation (Table 2).

The representatives of the order Haloanaerobiales (low G+C Gram-positive branch of the Bacteria) display a number of physiological and biochemical properties that are characteristic for the halophilic aerobic Archaea, rather than for the moderately halophilic aerobic Bacteria which use the organic solute strategy. No organic osmotic solutes have been found as yet in this group of anaerobic halophilic fermentative Bacteria (Mermelstein and Zeikus, 1998; Oren, 1986; Oren et al., 1997; Rengpipat et al., 1988). High concentrations of Na^+, K^+ and Cl^- were measured inside the cells of *Haloanaerobium praevalens*, *Haloanaerobium acetoethylicum*, and *Halobacteroides halobius*, high enough to be at least isotonic with the medium (Table 3). In exponen-

Table 2. Estimates of intracellular ionic concentrations in aerobic halophilic Archaea of the order Halobacteriales.

	Medium concentration				Intracellular concentration			
Species	Na^+	K^+	Mg^{2+}	Cl^-	Na^+	K^+	Mg^{2+}	Cl^-
Halobacterium salinarum	4.0	0.032			1.37	4.57		3.61
Halobacterium salinarum[a]	3.7	0.013	0.1		1.63	2.94

[a]Data obtained by X-ray microanalysis in the electron microscope. Values probably underestimate the true values.
Data were derived from Oren (1986), Oren et al. (1997), and Rengpipat et al. (1988).

tially growing cells, K^+ was the major cation. Stationary phase cells showed a high variability among individual cells, part of the cells containing high concentrations of NaCl rather than of KCl (Oren et al., 1997).

The huge potassium concentration gradient over the cytoplasmic membrane (often up to three orders of magnitude) and also the generally large sodium gradient present can be created and maintained only at the expense of energy. Also the chloride ion is far from thermodynamic equilibrium, as the presence of an inside negative membrane potential would tend to expel Cl^- from the cell. The peculiar ionic composition of the cells' cytoplasm and the concentration gradients over the cell membrane are the result of the cooperative action of different ion pumps, antiporters, and other transport proteins. The most important ones are summarized in Fig. 9, and the numbers in square brackets in the explanation below refer to the different parts of that figure.

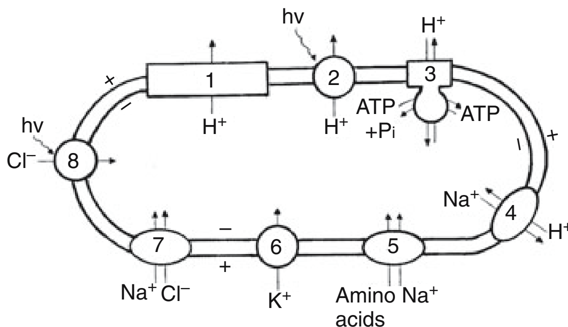

Fig. 9. Ion movements in the aerobic halophilic Archaea (order Halobacteriales): [1] proton extrusion via respiratory electron transport; [2] light-driven proton extrusion mediated by bacteriorhodopsin; [3] ATP formation by ATP synthase, driven by the proton gradient. Alternatively, this system can serve to generate a proton gradient at the expense of ATP during fermentative growth on arginine. [4] electrogenic sodium/proton antiporter; [5] sodium gradient-driven inward amino acids transport; [6] potassium uniport, driven by the membrane potential; [7] light-independent chloride transport system, probably coupled with inward transport of sodium. [8] halorhodopsin, the primary, light-driven chloride pump. For details see text.

In the Halobacteriales, respiratory electron transport with oxygen or other electron acceptors is accompanied by the extrusion of protons [1], generating a primary proton electrochemical gradient (acidic outside, alkaline inside, positive outside, negative inside). Those species that contain the retinal protein bacteriorhodopsin in their membranes may also use light energy for the direct generation of the proton electrochemical gradient [2]. The primary proton gradient is the driving force for all energy-requiring processes within the cell. Thus, ATP formation is mediated by the membrane-bound ATP synthase that couples phosphorylation of ADP with an inward flux of H^+ [3]. The membrane ATP synthase may also be used in the reverse direction, the build-up of a proton electrochemical gradient at the expense of ATP. This process is relevant in cases in which ATP formation by substrate-level phosphorylation is the primary energy-yielding process in the cell. This is the case (e.g., in *Halobacterium salinarum*) when growing anaerobically by fermentation of arginine (Hartmann et al., 1980), or in the anaerobic Bacteria of the order Haloanaerobiales, which obtain their energy by fermentation of sugars or amino acids (Oren, 1992).

The membranes of all halophiles investigated possess high activities of Na^+/H^+ antiporters, which use the proton electrochemical gradient as the driving force for the extrusion of Na^+ from the cell [4] (Hamaide et al., 1983; Lanyi and MacDonald, 1976; Luisi et al., 1980). In *Halobacterium salinarum*, the antiporter was shown to be electrogenic and probably has a stoichiometry of 2 H^+/Na^+ (Lanyi and Silverman, 1979). In addition to its function of keeping intracellular Na^+ concentrations at the desired low levels, the Na^+/H^+ antiporter activity can be expected to play an important role in the regulation of the intracellular pH.

The sodium gradient thus established can in its turn be used to drive certain endergonic processes. Thus, many of the membrane transport systems for amino acids and other compounds in the aerobic halophilic Archaea are energized by

cotransport with Na^+ ions [5]. The same is true for many moderately halophilic Bacteria, which also maintain a relatively low intracellular Na^+ concentration (Shindler et al., 1977; Ventosa et al., 1998). The Na^+ gradient thus serves to some extent as an energy reserve.

It is generally accepted that the negative inside membrane potential is the driving force for the massive K^+ accumulation. The membranes of halophilic Archaea were found to be highly permeable to potassium. K^+ ions probably enter the cells via a uniport system in response to the membrane potential (Wagner et al., 1978) [6]. K^+ enters the cell as Na^+ is ejected by the electrogenic Na^+/H^+ antiporter, thus maintaining electroneutrality. Evidence for such a mechanism was found in experiments showing accumulation of radioactively labeled rubidium (a potassium analog) ions in right-side-out vesicles of *Halobacterium salinarum* as a reaction to sodium extrusion, following excitation of the light-driven primary proton pump bacteriorhodopsin (Kanner and Racker, 1975). In addition, a K^+ transport system analogous to the Kdp system (the P-type K^+-translocating ATPase) of *Escherichia coli* was detected in *Haloferax volcanii* (Meury and Kohiyama, 1989). This system requires ATP for activation.

The high internal Cl^- concentration is not in equilibrium with the large negative-inside electrical potential that accompanies the H^+ circulation and the Na^+ efflux. Thus, electrical potential-driven passive chloride movement can result only in a loss of chloride from the cells rather than in the required uptake. An increase in the amount of intracellular Cl^- is essential if the cells should increase their volume during growth and cell division. It has been suggested that during growth the net flux of ions should result in K^+ uptake and excess Na^+ loss, and that Cl^- uptake should be equal to the difference, and thereby provide a net gain of intracellular KCl commensurate with the gain in intracellular volume (Lanyi, 1986; Schobert and Lanyi, 1982).

Two energy-dependent inward chloride pumps have been identified in *Halobacterium* cells. The first is a light-independent transport system, which is probably driven by symport with Na^+ (Duschl and Wagner, 1986) [7]. The second is light-driven, and is based on the retinal protein halorhodopsin, a primary inward Cl^- pump present in *Halobacterium salinarum*, in *Natronomonas pharaonis*, and probably also in additional halophilic Archaea (Lanyi, 1986; Schobert and Lanyi, 1982) [8].

The presence of molar concentrations of salts is generally devastating to proteins and other macromolecules. It causes aggregation or collapse of the protein structure by enhancing hydrophobic interactions within and between protein molecules and interferes with essential electrostatic interactions within or between macromolecules by charge shielding. And because of salt ion hydration, it reduces the availability of free water below the level required to sustain essential biological processes (Dennis and Shimmin, 1997; Zaccai and Eisenberg, 1991). The presence of high intracellular salt concentrations thus requires special adaptations of the whole enzymatic machinery of the cell. Cells thus adapted are able to function in the presence of high salt. However, these adaptations make the cells strictly dependent on the continuous presence of high salt concentrations for the maintenance of structural integrity and viability (Ebel et al., 1999; Eisenberg, 1995; Eisenberg and Wachtel, 1987; Eisenberg et al., 1992; Lanyi, 1974). As a result, the aerobic halophilic Archaea display little flexibility and adaptability to changes in the external salt concentration.

Most enzymes and other proteins of the Halobacteriales denature when suspended in solutions containing less than 1–2 M salt. Many enzymes are more active in the presence of KCl than of NaCl, agreeing well with the finding that K^+ is intracellularly the dominating cation. "Salting-out" salts stabilize, while "salting-in" salts inactivate halophilic enzymes. The behavior of different salts coincides with the lyotropic Hofmeister series (Lanyi, 1974). Similarly, intracellular enzymes from the fermentative anaerobic Bacteria (order Haloanaerobiales) generally function better in the presence of molar concentrations of salts than in salt-free medium, and they can be expected to be fully active at the actual salt concentrations present in the cytoplasm (Oren and Gurevich, 1993; Rengpipat et al., 1988; Zavarzin et al., 1994).

Most proteins of the Halobacteriales contain a large excess of the acidic amino acids, glutamate and aspartate, and few basic amino acids, lysine and arginine. The high content of acidic side groups was first recognized during analyses of the bulk protein of *Halobacterium* and *Halococcus* (Reistad, 1970). The malate dehydrogenase of *Haloarcula marismortui* has a 10.4 mol% excess of acidic residues and the cell envelope glycoprotein of *Halobacterium salinarum* even 19–20 mol%. Owing to the high acidity of the proteins of the halophilic Archaea, isoelectric focusing is of little use for protein characterization and isolation. In *Halococcus salifodinae*, all proteins were found to have isoelectric points between 3.8 and 4.5 (Denner et al., 1994). The bulk cellular protein of the members of the Haloanaerobiales tested is also highly acidic (Oren, 1986).

It has been argued that the excess of acidic residues may be a major factor determining the halophilic character of the proteins: excess of

negative charges on the protein surface makes the structure unstable because of the mutual repulsion of the side groups. Only when high concentrations of cations are added to shield the negative charges can the protein maintain its proper conformation required for structural stability and enzymatic activity.

Shielding of negative charges by cations undoubtedly plays an important part in the effects of salt on the enzymes and other proteins of the halophiles. A theoretical analysis of the contribution of electrostatic interactions in *Haloarcula marismortui* ferredoxin and malate dehydrogenase shows that the repulsive interactions between the acidic residues at the protein surface are a major factor in the destabilization of halophilic proteins in low-salt conditions (Elcock and McCammon, 1998). However, Lanyi (1974) and Lanyi and Stevenson (1970) stated that all the effects of salts cannot be due to charge-shielding action alone, as the concentrations required are too high. Maximal electrostatic-charge shielding would be achieved already in about 0.1 M salt or 0.5 M at most, and in even much lower concentrations of divalent cations. However, a high content especially of glutamate may be favorable, as glutamate has the greatest water binding ability of any amino acid residue. This may have important implications when considering the need of any functional protein to maintain a proper hydration shell.

Another prominent feature of the proteins of the Halobacteriales is their low content of hydrophobic amino acid residues, generally offset by an increased content of the borderline hydrophobic amino acids, serine and threonine (Lanyi, 1974). The requirement for extremely high salt concentrations for structural stability of the proteins can probably to a large extent be attributed to the low content of hydrophobic residues and the accordingly weak hydrophobic interactions within the protein molecules. High salt is then needed to maintain the weak hydrophobic interactions. Entropy increases when non-polar groups turn away from the water phase and interact with each other to form hydrophobic interactions. These interactions seem to be driven more by an avoidance of water than by an active attraction between the non-polar molecules (Lanyi, 1974). At higher salt concentrations, new hydrophobic interactions are formed having insufficient stability in water, and the molecule assumes a more tightly folded conformation. The possible involvement of the weak hydrophobic interactions in the salt requirement of the halophilic proteins is supported by the finding that certain enzymes from halophilic Archaea (including threonine deaminase, aspartate carbamoyltransferase, and alanine dehydrogenase) show cold lability: their maximal stability is reached at temperatures greater than 0°C and decreases at lower temperatures. The effect may be considered in terms of water structure: at lower temperature the size of the cluster of water molecules is increased, and hydrophobic groups can interact more easily, breaking the hydrophobic interactions (Lanyi, 1974).

Detailed studies of the malate dehydrogenase of *Haloarcula marismortui* have contributed much valuable information on the possible mechanisms involved in the halophilic behavior of proteins. Techniques such as velocity sedimentation, light scattering, neutron scattering, and circular dichroism measurements have been used to obtain information on the structural changes occurring as a function of changing salt concentrations and the hydration properties of the protein (Eisenberg, 1995; Eisenberg and Wachtel, 1987; Mevarech and Neumann, 1977; Pundak and Eisenberg, 1981; Pundak et al., 1981). These studies have shown that the halophilic properties of the enzyme are related to its capacity of associating with unusually high amounts of salts, and led to the formulation of a thermodynamic "solvation-stabilization model," in which the halophilic protein has adapted to bind hydrated ions cooperatively via a network of acidic groups on its surface (Ebel et al., 1999).

X-ray diffraction studies on crystals of the halophilic malate dehydrogenase and the ferredoxin of *Haloarcula marismortui* and the dihydrofolate reductase of *Haloferax volcanii* have added much important information (Dym et al., 1995; Frolow et al., 1996; Pieper et al., 1998). These studies showed how the carboxylic groups on the acidic residues are used to sequester, organize, and arrange a tight network of water and hydrated K^+ ions at the surface of the protein, and how an unusually large number of internal salt bridges between strategically located basic amino acid residues are formed to give the protein its internal structural rigidity. These salt bridges appear to be important determinants in the stabilization of the three-dimensional structure of halophilic proteins. Intervening solvent molecules shield the negative charges of the carboxylic acid groups on the protein surface from each other.

Comparison of the *Haloarcula marismortui* ferredoxin with the plant-type 2Fe-2S ferredoxin showed that the surface of the halophilic protein is coated with acidic residues, except for the vicinity of the iron-sulfur cluster, and that the halophilic protein contains two additional helices near the N-terminus. These helices form a separate hyperacidic domain, postulated to provide extra surface carboxylates for solvation. Bound water molecules on the protein surface have on the average 40% more hydrogen bonds than in a typical non-halophilic protein crystal

structure. These water molecules are thus tightly bound within the hydration shell by protein-water and water-water hydrogen bonds and by hydration of interspersed K^+ ions (Frolow et al., 1996).

A recent study of the glutamate dehydrogenase of *Halobacterium salinarum* showed the surface of the molecule being covered with acidic residues and displaying a significant reduction in exposed hydrophobic character as compared to non-halophilic counterparts. The low lysine content helps to increase the overall negative charge on the protein surface but also serves to decrease the hydrophobic fraction of the solvent-accessible surface (Britton et al., 1998).

The "Low Salt-In" Strategy

The second option, realized in most halophilic and halotolerant representatives of the Bacteria and also in the halophilic methanogenic Archaea, involves the maintenance of a cytoplasm much lower in salt than the outside medium. Table 4 summarizes estimates of intracellular salt concentrations in a number of aerobic halophilic Bacteria. While in some cases the apparent intracellular ionic concentrations are in the molar range (possibly in part due to technical difficulties related to the exact assessment of the intracellular water volumes in cell pellets) (Ventosa et al., 1998), it is clear that the intracellular salt concentrations are generally insufficient to provide osmotic balance. Generally the intracellular Na^+ concentrations are kept low. Outward-directed sodium transporters in the cytoplasmic membrane (in most cases electrogenic Na^+/H^+ antiporters) are highly important both in maintaining the proper intracellular ionic environment and in pH regulation (Hamaide et al., 1983; Ventosa et al., 1998). Outward-directed Na^+ transporters may include primary respiration-driven Na^+ pumps detected in some moderate halophiles such as *Salinivibrio costicola* (Tokuda and Unemoto, 1983).

Organic compatible solutes make up the major part of the osmotically active compounds in the cells' cytoplasm. Compatible solutes are polar, highly soluble molecules, most of them uncharged or zwitterionic at the physiological pH. The list of compounds known to be synthesized as compatible solutes by halophilic microorganisms is steadily growing (Galinski, 1993, 1995; Galinski and Trüper, 1994; Reed, 1986; Trüper et al., 1991; Ventosa et al., 1998; Wohlfarth et al., 1990). Figure 10 shows the main osmotic solutes identified thus far in prokaryotes, and Table 5 provides information on the taxonomic groups in which the different solutes have been detected.

The accumulation of "compatible" osmotic solutes achieves osmotic equilibrium while still enabling activity of "conventional", non-salt-adapted enzymes (Galinski, 1993, 1995). Many prokaryotic cells contain cocktails of different compatible solutes rather than relying on a single compound (Galinski, 1995). The concentrations of the osmotic solutes are regulated according to the salt concentration in which the cells are found (Galinski and Louis, 1999), and can be rapidly adjusted as required when the outside salinity is changed (by synthesis or uptake from the medium upon salt upshock; by degradation or transformation into osmotically inactive forms; or by excretion following dilution stress) (Trüper and Galinski, 1990). The use of organic osmotic solutes thus bestows a high degree of flexibility and adaptability.

Compatible solutes are strong, water structure formers and as such they are probably excluded from the hydration shell of proteins. This "preferential exclusion" probably explains their function as effective stabilizers of the hydration shell of proteins. This phenomenon of nonspecific exclusion is often described in terms of increased

Table 4. Intracellular ionic concentrations of selected aerobic halophilic Bacteria.

	Medium concentration			Intracellular concentration		
Species	Na^+	K^+	Cl^-	Na^+	K^+	Cl^-
Halomonas elongata	1.38	0.02		0.31	0.02	
	3.4	0.01		0.63	0.02	
Halomonas canadensis	4.4	0.04		0.62	0.58	
Halomonas halodenitrificans	1.0	0.04	1.0	0.31	0.47	0.055
	3.0		3.0	1.07	0.12	
"Pseudomonas halosaccharolytica"	2.0	0.006	2.0	1.15	0.89	0.98
	3.0	0.006	3.0	1.04	0.67	0.70
Salinivibrio costicola	2.0	0.008		0.90	0.57	

All data relate to exponentially growing cells. Data were derived from Christian and Waltho (1962), Masui and Wada (1973), Matheson et al. (1976), Shindler et al. (1977), and Vreeland et al. (1983). For more extensive data, see Table 5 in Ventosa et al. (1998).

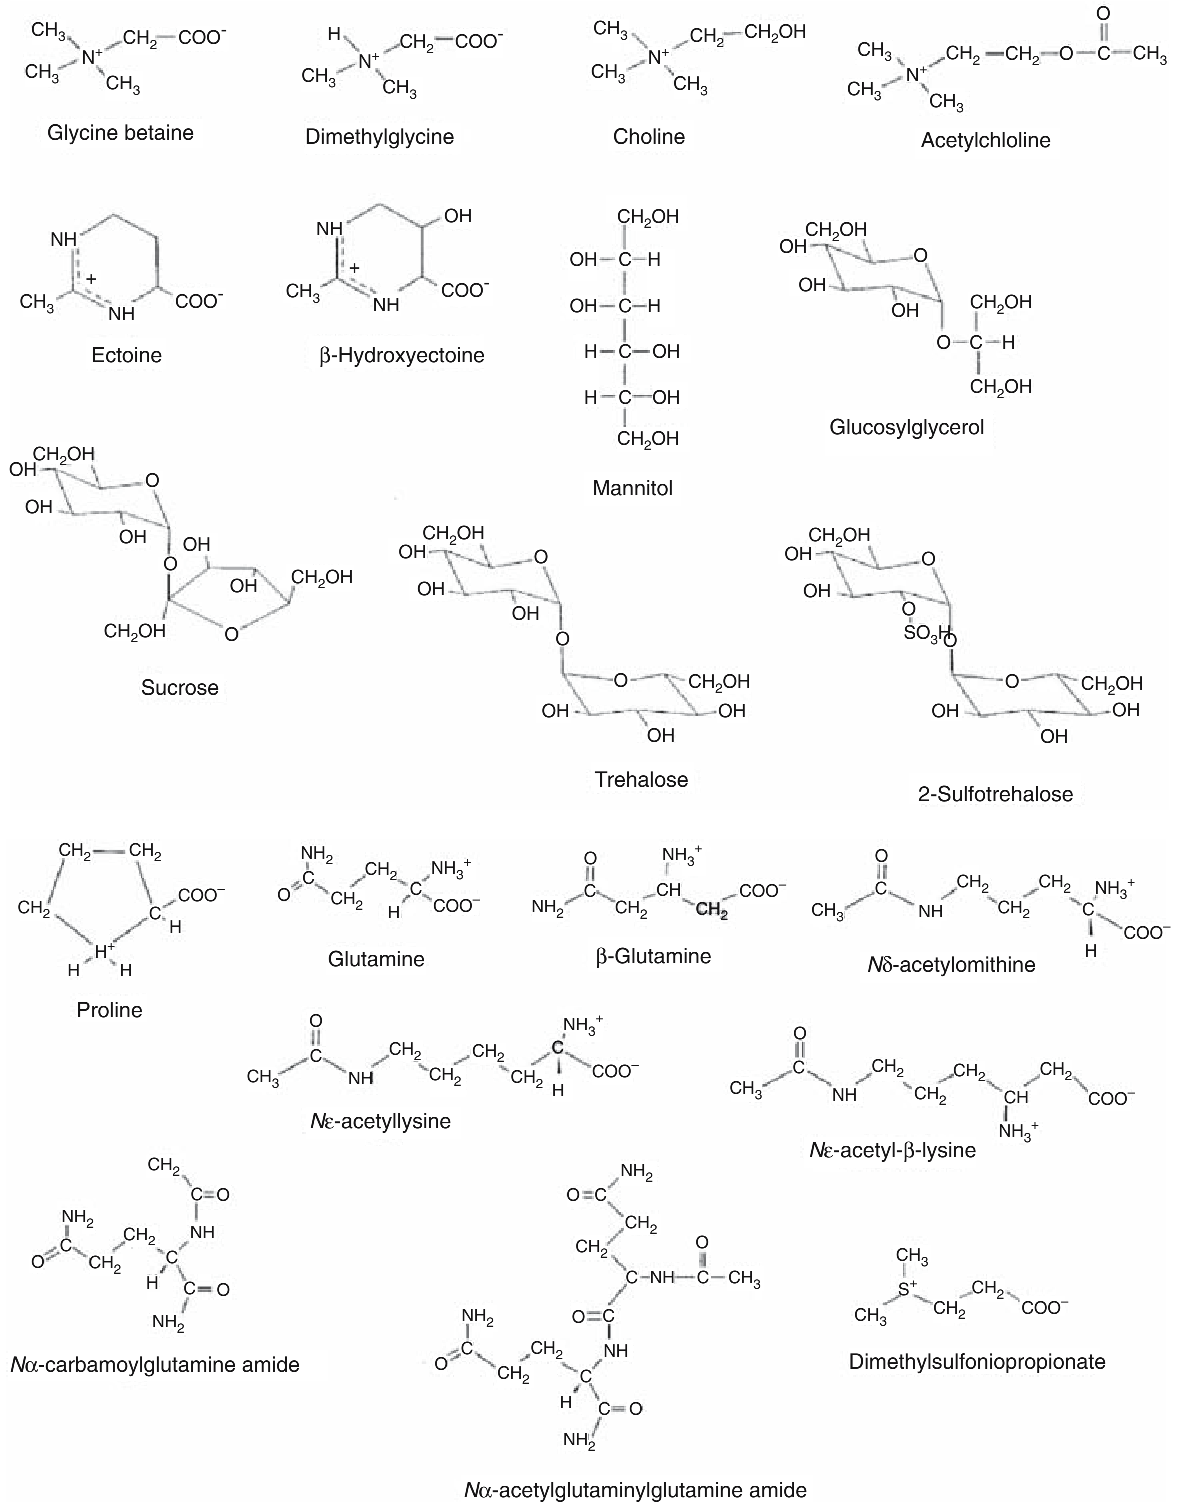

Fig. 10. Organic osmotic solutes documented to occur in halophilic and halotolerant Bacteria and Archaea.

surface tension of water, with the presence of solutes affecting the forces of cohesion between water molecules, minimization of entropy, and reinforcement of the hydrophobic effect. Compatible solutes display a general stabilizing effect by preventing the unfolding and denaturation of proteins caused by heating, freezing, and drying (Galinski, 1993, 1995).

Table 5. Distribution of selected organic osmotic solutes within the bacterial and the archaeal domains.

Solute	Distribution
Glycine betaine	Cyanobacteria, Anoxygenic phototrophic bacteria; Methanogenic bacteria; *Actinopolyspora halophila*; Is taken up by many heterotrophic bacteria and used as osmotic solute.
Dimethylglycine	Methanogenic bacteria
Choline, Acetylcholine	*Lactobacillus plantarum*
Ectoine, Hydroxyectoine	Heterotrophic Proteobacteria of the γ-subdivision; *Halorhodospira* spp., *Rhodobacter sulfidophilus; Micrococcus* spp., many bacilli; *Marinococcus* spp., *Sporosarcina halophila; Brevibacterium*
Proline	Bacilli; *Planococcus citreus*; *Salinicoccus* sp.
Glutamine	Corynebacteria
β-Glutamine	Methanogenic bacteria
Nε-acetyllysine	*Halobacillus halophilus*, other bacilli
Nδ-acetylornithine	*Halobacillus halophilus*, other bacilli
Nε-acetyl-β-lysine	Methanogenic bacteria
Nα-carbamoyl-glutamine amide	*Ectothiorhodospira marismortui*
Nα-acetylglutaminyl-glutamine amide	*Halochromatium; Thiohalocapsa; Rhodopseudomonas* sp.; *Azospirillum brasilense; Rhizobium meliloti; Pseudomonas aeruginosa*
Sucrose	Cyanobacteria
Trehalose	Cyanobacteria, *Halorhodospira* spp.
2-Sulfotrehalose	Alkaliphilic members of the Halobacteriales
Mannitol	*Pseudomonas putida*
Glucosylglycerol	Cyanobacteria; *Rhodobacter sulfidophilus*; *Pseudomonas mendocina*
Dimethylsulfonio-propionate	Marine cyanobacteria

For additional information see e.g., Desmarais et al. (1997); Galinski (1993, 1995); Hagemann et al. (1999); Imhoff (1993); Oren (1999); Trüper et al. (1991); Ventosa et al. (1998); and Wohlfarth et al. (1990).

Concluding Remarks

A comparison of the two strategies of adaptation to high salt concentrations ("salt-in" versus use of organic osmotic solutes) shows that the salt-in strategy is energetically much less costly than the synthesis of organic, compatible solutes (Oren, unpublished data). However, it requires a far-going adaptation of the whole intracellular machinery to the presence of high ionic concentrations. This energetically relatively cheap solution of balancing "salt-out" with "salt-in" is not widely used in nature. Evolutionary processes toward such adaptation, as described by Dennis and Shimmin (1997), have led to the establishment of two specialized groups, the aerobic extremely halophilic Archaea (Tindall, 1992) and the fermentative obligatory anaerobic Bacteria (Oren, 1992).

The use of organic compatible solutes allows much more flexibility with respect to the range of salt concentrations tolerated, and does not require a high degree of adaptation of the intracellular enzymes. The enzymes do not greatly differ from those of non-halophilic prokaryotes, although they may have a somewhat increased content of acidic amino acids (Gandbhir et al., 1995). Many taxonomic groups, displaying a great metabolic diversity, use this strategy. Thus, many of the dissimilatory processes identified in freshwater environments can also take place at high salinity. Certain metabolic types, however, such as methanogenesis from $H_2 + CO_2$ or from acetate, autotrophic nitrification, and others, seem to be absent above 10–15% salt. It is tempting to speculate that it is the too high energetic cost connected with adaptation to life at the highest salt concentrations that has prevented the evolution of halophiles performing these reactions. In any case, also in hypersaline environments, the prokaryotes display an amazing diversity that is well worth being studied in-depth on the level of community structure and metabolism, phylogenetic diversity, and the molecular mechanisms of their adaptation to high salt.

Acknowledgments. I thank Carol D. Litchfield (George Mason University, Fairfax, VA) for her helpful comments on the manuscript.

CHAPTER 1.10

Alkaliphilic Prokaryotes

TERRY ANN KRULWICH

Introduction and Definitions

Alkaliphilic prokaryotes offer a wealth of opportunities for the isolation of natural products that can be advantageously applied to diverse industrial processes (Horikoshi and Akiba, 1982; Horikoshi, 1991; Horikoshi, 1996). Alkaliphiles also offer a wealth of opportunities to understand the mechanisms by which organisms thrive at pH 10–11.5, often present with other environmental challenges, such as high salt and high temperature (Krulwich, 1995; Krulwich et al., 1998). The diversity of alkaliphiles, which occur among aerobic and anaerobic archaea and prokaryotes as well as eukaryotic fungi (Grant et al., 1990; Jones et al., 1994; Horikoshi, 1991), likely broadens their industrial application. All alkaliphiles confront protein structure and function problems that involve catalysis at the external pH and regulation of cytoplasmic pH. However, among different alkaliphile groups, such as anaerobes, aerobes, ammonium-requiring sulfate-reducing thermophiles, halophiles, methylotrophs, methanogens, and photosynthetic bacteria, different approaches or features to the solution of these central as well as other group-specific problems are likely. Alkaliphiles, an extraordinarily diverse group of bacteria that may have evolved over a very long period, provide us with the opportunity to probe their many adaptive strategies (Zavarzin, 1993; Duckworth et al., 1996; Jones et al., 1998). Also, understanding how alkaliphiles meet extreme challenges of pH homeostasis and other challenges can provide insights that are often translatable to the nonextremophile setting.

Various definitions of an alkaliphile have been used. The only common standard is that the organism's optimal pH for growth must be at least 2 units above neutrality (Kroll, 1990). To clearly distinguish between alkaliphiles and the more abundant alkaline-tolerant prokaryotes, most investigators of these organisms propose a higher pH standard and sometimes (Horikoshi, 1998) include an inability to grow well or grow at all at near-neutral pH values such as 6.5. As discussed below, growth at near-neutral pH may be inversely related to how functional an alkaliphile is at the upper pH limit. The lower pH limit and pattern of growth over a broad pH range also depends upon the particular growth substrate (Gilmour and Krulwich, 1997; Krulwich et al., 1997) and on strain differences that are incompletely understood (Guffanti et al., 1986). My laboratory has used the term alkaliphile for bacteria that grow optimally on substrates (suitable for high pH growth) at pH values above 9.5. This value is chosen because it approximates the upper limit of cytoplasmic pH that is compatible with the growth of bacteria so far studied (Sturr et al., 1994; Krulwich et al., 1998). The term facultative alkaliphile has been applied to species and strains that are able to grow at both pH 6.5–7.5 and above 9.5, whereas alkaliphiles that grow only at 9.5 are termed obligate alkaliphiles.

Historical Notes

Koki Horikoshi, a leading investigator of alkaliphiles, was the first to initiate broad-based studies of these bacteria, starting in the late 1960s. He has commented that when he began he found only sixteen prior literature references to alkaliphilic bacteria (Horikoshi, 1998). The earliest reports of bona fide alkaliphiles were those of *Bacillus pasteurii* by Gibson, 1934 and of *Bacillus alcalophilus* by Vedder, 1934. Investigators of physiology and protein structure have returned to these two alkaliphilic *Bacillus* species in recent years. In the early 1960s, Takahara and colleagues (Takahara et al., 1961; Takahara and Tanobe, 1960; Takahara and Tanobe, 1962) demonstrated that indigo dye reduction depends on maintaining sufficient alkalinity, and they improved the fermentation process by adding alkaliphilic *Bacillus* sp strain S-8, which they had isolated from an indigo ball undergoing fermentation at high pH. Over the years, Horikoshi and colleagues (Horikoshi, 1996) and others (e.g., van der Laan et al., 1991; Ito et al., 1998) advanced this tradition of optimizing alkaliphile fermentation processes or their products while

also contributing to alkaliphile taxonomy and characterization.

The diversity of alkaliphiles was subsequently extended by Grant and colleagues (Tindall et al., 1984; Grant et al., 1990; Grant et al., 1999; Jones et al., 1998), Zhilina and Zavarzin, 1994, and others who enumerated and identified bacteria and archaea that thrive in natural, selective environments such as the highly alkaline soda lakes in Africa and Asia. The number of known alkaliphiles and their diversity has vastly increased as a result of such systematic investigations. These studies also extended the earlier finding by (Kurono and Horikoshi, 1973; Horikoshi, 1991) that alkaliphiles require and thrive in added Na^+, by showing that many categories of alkaliphiles are haloalkaliphiles.

During the 1970s, my laboratory began to study energetic dilemmas of alkaliphiles, taking the chemiosmotic view of energy coupling found in bacterial and eukaryotic membrane systems (Mitchell, 1961). We studied the dilemma of how aerobic alkaliphilic bacteria can both extrude protons during respiration and achieve—as initially presumed and subsequently shown to be necessary—net acidification of the cytoplasm relative to the outside (Krulwich, 1995). As also noted by Garland, 1977, there was the further dilemma of what effect a "reversed pH gradient" would have on reducing chemiosmotic gradients (acid and cations out) and in turn on reducing the energetic driving force, which could create a problem with solute transport, flagellar rotation energization, and ATP synthesis. Perhaps some alkaliphiles generate compensatory electrical potentials across the membrane or use Na^+ as a coupling ion, or perhaps some or all alkaliphiles had developed other interesting mechanisms for bioenergetic work under such circumstances. This area of study became and remains active in several laboratories (Krulwich and Guffanti, 1983; Krulwich and Guffanti, 1989; Krulwich and Ivey, 1990; Krulwich et al., 1998; Hirota and Imae, 1983; Sugiyama et al., 1985; Koyama et al., 1986; Koyama and Nosoh, 1995; Aono and Ohtani, 1990; Hamamoto et al., 1994).

More recent investigations of alkaliphilic enzyme pH stability and optimum have drawn upon 3-dimensional crystal structures (Sobek et al., 1990; Sobek et al., 1992; van der Laan et al., 1992; Martin et al., 1997; Shirai et al., 1997) and properties that can be modeled or deduced from molecular characterizations (Teplyakov et al., 1992; van der Laan et al., 1996; Kobayashi et al., 1999). The physiology and study of bioenergetic properties of alkaliphiles also are enhanced by modern molecular biological techniques as well as proteome and genomic insights. Numerous alkaliphile genes have been sequenced, physical maps have been presented for three genes (Southerland et al., 1993; Park et al., 1994; Gronstad et al., 1998; Takami et al., 1999b), and the genome of an alkaliphilic *BacillusM*, *Bacillus halodurans* C-125, is currently being sequenced (Takami et al., 1999c).

By consensus, there has been a shift in nomenclature from the use of the term "alkalophily" to use of the term "alkaliphily" during the 1990s. The more etymologically correct "alkali" has now become the convention.

Distribution and Taxonomic Groups

Distribution

Alkaliphiles are found in natural and industrial (or other man-made enrichments). In addition to the indigo dye process that has already been noted, sodium hydroxide has been used extensively in paper and pulp processing and calcium hydroxide in cement manufacture. Mining operations and certain food-processing activities also are settings for alkaliphile enrichment (Jones et al., 1998). Similarly, natural enrichments are diverse. Many of these, such as alkaline hot springs, are the source of interesting, generally alkaline-tolerant organisms but are insufficiently buffered to support the extraordinarily high pH values that are consistently maintained (Jones et al., 1998). On the other hand, naturally occurring soda lakes are stable, extremely alkaline environments (e.g., pH >11.5) that are widely distributed and typically found inland (e.g., soda lakes of the East African Rift Valley and of Central Asia). Their NaCl concentrations range from about 5% w/v to >15% w/v. The soda lakes have a paucity of calcium and magnesium ions because they are depressions formed from nonsedimentary rocks, and the sodium, chloride, and bicarbonate/carbonate are the dominant ions. The soda lakes often exhibit the pronounced color of organisms (e.g., cyanobacteria) that are the primary, photosynthetic actors in the nutrient cycle, and the hypersaline lakes often are the color of haloalkaliphiles. Both aerobic and anaerobic cycles occur (Jones et al., 1994; Jones et al., 1998). Alkaliphiles found in the soda lakes are diverse; some organisms are unique to these lakes and some (e.g. the fastidious haloalkaliphiles) appear to represent distinct lineages (McGenity and Grant, 1993; Jones et al., 1998; Grant et al., 1999). Also, evidence from fossil soda lakes, which are similar to those found today, suggests that these environments are of great antiquity. Together, these observations have led to suggestion that substantial evolution of many prokaryotesfound in this type of environment occurred in the soda lakes, i.e., these

communities are very ancient sources of new species of bacteria (Zavarzin, 1993; Jones et al., 1998).

If indeed many alkaliphiles evolved in natural soda lake enrichments, they must have spread beyond those boundaries. Some of the same alkaliphiles that are found in the ancient enrichments of the soda lakes are almost ubiquitous. They are present in garden soils (Guffanti et al., 1980, 1986) and in deep-sea trenches (Takami et al., 1999a) where the pH is not conducive to a thriving alkaliphile presence. Horikoshi and Akiba, 1982 note a substantial presence of alkaliphiles in soils of various pH values, albeit greater in alkaline soils.

Taxonomic Groups

A summary of the taxonomic groups of prokaryotes isolated from soda lakes has been reproduced from a review by Jones et al., 1998 and presented at Table 1. The enormous taxonomic diversity of extreme alkaliphiles is evident and further reflected in the diversity of characteristics. Alkaliphilic cyanobacteria are among the primary photosynthetic organisms that produce oxygen; such organisms include *Spirulina*, *Cyanospira*, *Synechococcus* and *Chorococcus*. Anoxygenic phototrophic bacteria, such as *Ectothiorhodospira*, that use reduced sulfur compounds participate in the primary production via photosynthesis and also are part of the sulfur oxidizing limb of the sulfur cycle of the soda lakes. The sulfur cycle also includes aerobic sulfur oxidizing organisms (Sorokin et al., 1996) and anaerobic sulfate-reducing organisms such as *Spirochaetes* and *Desulfonatronovibrio* (Zhilina et al., 1996a; Zhilina et al., 1997).

Bacillus species are among the most commonly found aerobic, eubacterial alkaliphiles both in soda lakes and in less selective environments (Horikoshi and Akiba, 1982; Krulwich and Guffanti, 1983; Guffanti et al., 1980; Guffanti et al., 1986; Takami et al., 1999a). Fritze et al., 1990, using DNA-DNA hybridization, and Nielsen et al. (Nielsen et al., 1994; Nielsen et al., 1995) using forty-seven physiological and biochemical characteristics as well as DNA base composition, hybridization, and 16S rDNA analyses, proposed clusters of alkaliphiles and alkaline-tolerant *Bacillus*. The 16S rDNA structure indicated two distinct groups within the *Bacillus* radiation (RNA groups 6 and 7) in which most alkaliphilic *Bacillus* isolates are found (Nielsen et al., 1994; Jones et al., 1998). Interestingly, the application of this comprehensive analytic approach resulted in grouping of strains that correlated roughly with somewhat distinct regions of the soda lake environment. *B. alcalophilus* and associated strains were mainly found in muds at the shoreline or dry regions of soda soil where organisms are subjected to fluctuating water levels and concomitant fluctuations in pH and salt levels; many of these strains require only low concentrations of Na^+ for growth. The somewhat diverse "group 7" bacilli, related to *Bacillus clarkii* (Nielsen et al., 1994; Nielsen et al., 1995), are thought to be more prevalent in sediments and waters that are subject to less variability and these alkaliphiles typically exhibit requirements for higher Na^+ for growth (Jones et al., 1998). The molecular physiological studies of Na^+-dependent pH homeostasis in alkaliphiles are consistent with such differences among strains (Krulwich et al., 1982; Garcia et al., 1983), and are beginning to identify respiratory chain components, transporters and cell surface molecules that may be of particular importance to extremophiles that face transitions or fluctuations (Hicks et al., 1991; Ito et al., 1997b).

Some of the most intensely studied alkaliphilic Bacillus strains [i.e., *Bacillus* C-125 (Aono, 1995) and *Bacillus firmus* OF4 (Guffanti et al., 1986)] were characterized before the extensive matrix of physiological and molecular biological criteria, including 16S rDNA, were used to categorize them. In fact, their proposed species, *Bacillus lentus* and *Bacillus firmus*, respectively, were not included in the major alkaliphile clusters (Fritze, 1990; Nielsen et al., 1994; Nielsen et al., 1995). It was apparent that correlation of these alkaliphilic strains with their environmental patterns would require more precise placement. Therefore, recent work, including further biochemical tests and 16S rDNA sequencing, has resulted in proposals for reclassifying *Bacillus* C-125 from a probable *Bacillus lentus* strain to Bacillus halodurans C-125 (Takami and Horikoshi, 1999) and *Bacillus firmus* OF4 to *Bacillus pseudofirmus* OF4 (Takami and Krulwich, in press). The newly deduced relationships of these species to other *Bacillus* species are depicted in Figure 1.

Clostridium strains as well as other diverse anaerobes are well represented in the prokaryotes of soda lakes (Table 1), but detailed studies or major applications of anaerobic, eubacterial alkaliphiles lag behind those of aerobic alkaliphiles. Perhaps the first described alkaliphilic anaerobe, a facultatively anaerobic strain that was subsequently classified as a new genus and species—*Amphibacillus xylanus* (Niimura et al., 1987; Niimura et al., 1989)—is the best studied. This interesting alkaliphile evokes possible shared themes with *B. pasteurii*, inasmuch as it depends upon high concentrations of ammonium for optimal growth. The cells possess an unusual glutamate dehydrogenase that may be involved in the assimilation of the ammonium (Jahns, 1996). *A. xylanus* is deficient in cytochromes, quinones and catalase (Niimura et al., 1987;

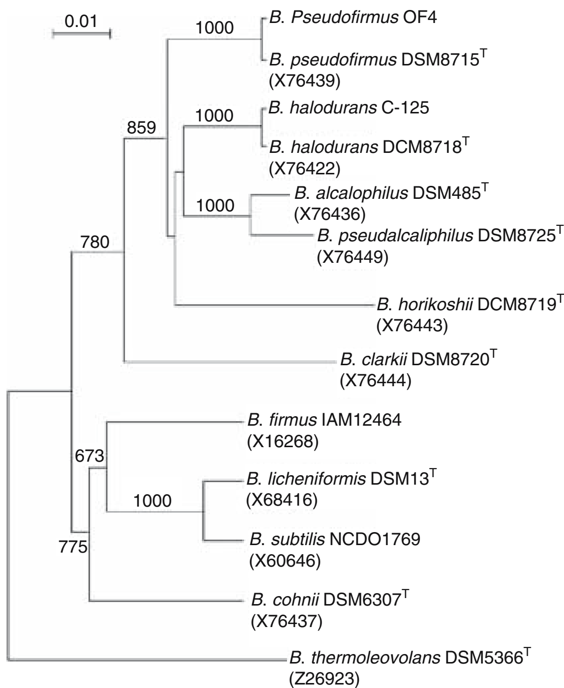

Fig. 1. Unrooted phylogenetic tree showing the relationship of *B. halodurans* C-125 and *B. pseudofirmus* OF4 to other *Bacillus* strains. This figure is a slightly modified version of a figure presented by Takami and Krulwich, in press. The numbers indicate bootstrap samples, from among 1000, that supported the internal branches (Felsenstein, 1985). Bar = 0.01 K_{nuc} unit.

Niimura et al., 1989), and possesses transporters that couple sugar or amino acid transport to Na^+ gradients (i.e., they are Na^+/solute symporters) and are markedly ammonium ion stimulated (Koyama, 1989; Koyama, 1993). Similarly, an apparently V-type NH_4^+- and Na^+-stimulated ATPase has been described (Koyama, 1996; Kaieda et al., 1998). The mechanism and significance of the ammonium effect in this alkaliphile will be of considerable interest as will any special role ammonium might play in pH homeostasis.

Because thermoalkaliphiles were not described in the earliest work on alkaliphiles, this combination of extreme adaptations was considered to be at first incompatible with life. However, during the past decade, major groups of at least moderately thermophilic alkaliphiles began to emerge. These include among others: a novel obligately alkaliphilic *Clostridium* species isolated from sewage (Li et al., 1993; Li et al., 1994; Wiegel, 1998); an asporogenous, Gram-positive ammonifying anaerobe from soda lake deposits, Tindallia magadii (Kevbrin et al., 1998); another xylan-degrading, anaerobic alkalithermophile, strain LB3A (Prowe et al., 1996; Sunna et al., 1997); and an actinomycete, Thermoactinomyces sp. strain HS682 (Tsuchiya et al., 1992). Stetter and colleagues have even described a hyperthermophilic, alkaliphilic archaeum, *Thermococcus alcaliphilus* (Keller et al., 1995), completely laying to rest the notion of incompatibility of thermophily and alkaliphily. Conversely, Kimura and Horikoshi (Kimura and Horikoshi, 1989; Kimura and Horikoshi, 1990) have studied an

alkalopsychrotrophic Micrococcus that produced an amylase that might be used in food processing.

Finally, the haloalkaliphilic Archaea isolated from hypersaline lakes represent a burgeoning and fascinating group of multiple extremophiles that are now the subjects of broad-based studies. Originally such organisms were classified as *Natronobacterium* or *Natronococcus* (Tindall et al., 1984), halophiles that were most often responsible for the red color of the hypersaline soda lakes (Jones et al., 1998). More recently, the diversity of novel species and lineages has continued to grow (see Kanai et al., 1995; Zhilina et al., 1996b), including many from polymerase chain reaction (PCR)-based analyses of organisms that cannot be cultivated as yet (Grant et al., 1999). Proposals for reorganizing the taxonomy of this group have been made (Kamekura et al., 1997) in what is clearly a "moving target" situation. It is likely that the categories of alkaliphilic methylotrophs and methanogens, which already have been isolated in significant numbers and examples (Boone et al., 1993; Zhilina and Zavarzin, 1994), also will continue to increase in complexity (Kevbrin et al., 1997; Khmelenina et al., 1997).

Adaptation of the Proteins on the Outer Surface and Exoenzymes

An initial set of generalizations describing the basis for protein stability under particular extreme conditions has begun to emerge from the results of experimental and modeling studies carried out on prokaryotic extremophile proteins from thermophiles (Chi et al., 1999; Elcock, 1998; Haney et al., 1999) and halophiles (Eisenberg et al., 1992; Elcock and McCammon, 1998). Generalizations that offer insight into the adaptation of alkaliphile proteins exposed to an extremely alkaline milieu are of similar interest. Many relevant observations have been reported, but broadly, applicable generalizations are not yet clearly in hand. Perhaps the reason lies with the proteins studied, which are often either thermophilic and/or halophilic or both, and therefore special subsets of highly alkaline enzymes or proteins. Or alkaliphily may mandate different responses by different functional categories of proteins. The deduced amino acid sequences, initially made available from genes that were cloned selectively from alkaliphile DNA libraries, revealed a significant number of examples in which the isoelectric point (pI) of the alkaliphile protein or protein domain was much lower than the homologues from other prokaryotes. These sequences had substantially increased aspartate and glutamate and strikingly reduced lysine and arginine. Examples included the prosequence (but not the mature form) of several alkaliphile proteases of the subtilisin type (van der Laan et al., 1991), SecY protein of *B. halodurans* C-125 (Kang et al., 1992), the "periplasmic" cytochrome *c*-binding domain of Cta (cytochrome oxidase) subunit II of *B. pseudofirmus* OF4 (Quirk et al., 1993), and a putative "periplasmic" loop of the FtsH protein from *B. pseudofirmus* OF4 (Ito et al., 1997a). The differences between this latter protein, as deduced from hydropathy analysis and sequence, and the homologue from *Bacillus subtilis* are shown in Fig. 2. Although not shown, there was no pattern of sequence difference in the two putative membrane spanning regions. The extensive pattern of added and substituted acidic residues and loss of basic ones is present throughout the loop, including regions very close to the membrane. In the Cta subunit, the first apparent substitutions of acidic residues for conserved basic ones are within 20 residues of the start of the large hydrophilic domain (Quirk et al., 1993); the net changes in the domain relative to non-alkaliphile homologues is shown in Table 2. The proximity of some of the substitutions to the membrane, in membrane-associated proteins, such as CtaC and FtsH, suggests that the selective pressure that leads to this type of change is exerted very close to the outer surface of the cytoplasmic membrane (Krulwich, 1995).

These differences between alkaliphile and non-alkaliphile proteins or protein domains led to the suggestion that the alkaliphile might globally seek to minimize, in exposed proteins, the content of those basic residues that change charge over the range of external pH values to which the organism was regularly exposed (Krulwich et al., 1998). However, more complete and detailed information from both sequence and structural analyses of extracellular alkaliphile proteins and protein segments suggests that this explanation is unlikely and that the picture is more complex.

A number of laboratories have begun to make chimeras of alkaliphile and non-alkaliphile homologues (Nakamura et al., 1991) to identify domains or residues involved in alkali-tolerance by selective mutagenesis and to design enzymes with increased alkaline-tolerance (Park et al., 1993). These studies give some indication that particular types of enzymes (for example, a particular domain such as a C-terminal domain in cellulases) can be associated with the alkaliphilic property (Nakamura et al., 1991). Moreover, there are now clear-cut examples of "periplasmic" loops and exoenzymes of alkaliphiles in which no evident substitution of acidic for basic residues occurs, relative to non-alkaliphile homologues. Indeed, some exoenzyme proteins,

at least, show the opposite trend as will be discussed in detail in connection with subtilisin type proteases. Then how might the features of FtsH, CtaC, SecY and the prosequence of alkaline proteases be understood as an adaptation to high pH? Ikemura et al., 1987 and Chang et al., 1996 have suggested, based on findings from *B. subtilis* BPN and alkaliphilic *Bacillus* YaB protease studies, respectively, that the prosequence interacts (in trans, outside the cell) with the secreted but inactive protease to facilitate its folding to the active form. The highly charged nature of the prosequence (Ikemura et al., 1987), a feature that is conserved in alkaliphile and non-alkaliphile forms of the prosequence albeit with different sets of residues and vastly different isoelectric points, is proposed to effect this folding. van der Laan et al., 1991 accordingly argue that if acidic residues are not substituted for basic ones, then at the high pH values at which alkaline proteases function, the basic residues largely would be uncharged and protease activity compromised. By analogy the functions of other alkaliphile proteins that differ in the same way from non-alkaliphile homologues may involve interactions that require the protein or domain partner to be highly charged. This suggestion is plausible for at least some of the examples already noted. The hydrophilic domain of CtaC must move in the "periplasm," accepting an electron from complex III and then delivering it to CtaD. The chaperones and secretory proteins also must interact with various partners in specific ways that facilitate protection of conformation or movement. Following the expansion of this group of proteins will permit the adaptation to be more mechanistically elucidated.

What about proteins without a special functional need for high charge density? The most intensive structural and modeling work to date on alkaliphile enzymes has focused on proteases, especially those of the subtilisin, serine protease type. This work has included X-ray crystallographic analysis, modeling and engineering of the active site (Sobek et al., 1990; Sobek et al., 1992; Teplyakov et al., 1992; van der Laan et al., 1992; van der Laan et al., 1996; Martin et al., 1997; Shirai et al., 1997). van der Laan et al., 1992 concluded that the 3-dimensional structure of the alkaline subtilisin-like protease PB92

[1]The hydrophilic domain starts at amino acid residue 109 from the N-terminal methionine or at amino acid residue 87 of the mature protein of the CtaC sequences; the homologous regions were identified from alignments with the domains from other strains.

(also called SBA) revealed no "unique features" that could explain its very high pH optimum and suggested that sequence features could explain this optimum. In contrast to the observations on CtaC, FtsH, alkaline protease prosequences, and others already cited, PB92 and another highly alkaline protease, elastase YaB (Kaneko et al., 1989), had extremely high isoelectric points, as a result of decrease in aspartic acid residues and substitution of arginine for lysine residues, although not in equivalent positions. In addition, the number of tyrosines, which would be negatively charged at the enzyme's pH optimum, is reduced (van der Laan et al., 1992). Interestingly, tyrosines do not always follow the pattern of glutamic and aspartic acid residues, i.e., increasing substantially in alkaliphilic proteins such as FtsH or consistently decreasing in high alkaline proteases (Shirai et al., 1997). It will be of interest, as more correlations become possible, to see whether the number of tyrosine residues, which may be "counted" as a likely source of negative charge predominantly in strongly obligate alkaliphiles, varies with particularly high pH optima for growth. Other alkaliphiles, whose pH range includes lower alkaline values at which tyrosine would be uncharged, might not adapt with a dependence upon this residue.

In a report of the crystal structure of the alkaliphilic *Bacillus* M-protease, another subtilisin-type serine protease, Shirai et al., 1997 further discussed the importance of sequence features in adaptation to alkaline conditions. They noted that of the three alkaliphile proteases of the subtilisin type with very high pH optima (PB92, M-protease, and elastase YaB) all had elevated isoelectric points relative to homologues with lower pH optima. M-protease had a markedly lower aspartic and glutamic acid content, which contributed to raising the isoelectric point. As noted in the other highly alkaline proteases, arginine was increased relative to lysine. The neutral hydrophilic amino acid residues, asparagine, glutamine and histidine, were increased, maintaining the solubility of the protein in water, perhaps by compensating for lost acidic residues and lysine. The increased arginine could contribute to the elevated isoelectric point and since arginine can retain a positive charge under more alkaline conditions than lysine, it is more suitable for ion pair formation. Ion pairs, including a significant number with arginine partners, increased. Hydrogen bonds also increased in the alkaliphile proteases relative to non-alkaliphile homologues. The investigators suggest that these features are important components of alkaline adaptation. Moreover, the "substituted residues" in the 3-dimensional structure had a biased distribution that correlated with peptide shifts

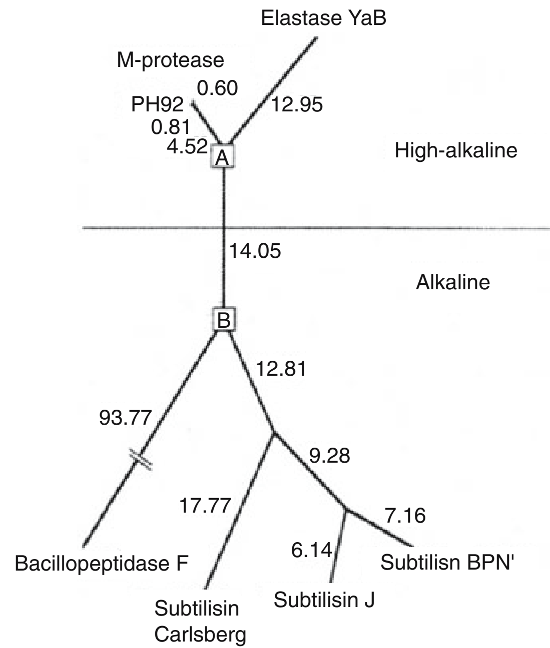

Fig. 3. The phyogenetic tree of M-protease and related proteases showing evolutionary distances. The evolutionary distances are shown on the branches in percent between accepted point mutations. Two boxes indicate positions of hypothetical ancestors A and B (see Fig. 4). All of the branches are more than 95% probable from 1000 bootstrap reconstructions. This figure was reproduced from Shirai et al. (1997), with permission from the publisher.

hypothesized to be responsible for stabilizing conformation under alkaline conditions. Shirai et al., 1997 visualized the high alkaline subtilisin type proteases and the non-alkaliphilic ones as having branched off, respectively, from hypothetical ancestor proteases A and B (see Figs. 3 and 4).

The caveat is that these fascinating proposals may apply to some categories of alkaliphile proteins but not to others. Table 3 shows a small selection of alkaliphile exoenzymes and some examples of enzymes other than proteases (e.g., pectate lyase Pel-7; Kobayashi et al., 1999) that have a highly alkaline pH optimum as well as a high pI. However, other enzymes, including other proteases, have high pH optima but not high pIs. Perhaps diverse sets of adaptations are associated with different catalytic activities and mechanisms, different 3-dimensional structural features, or both. Also important is the conjoining, in many alkaliphiles, of the constraints of thermophily or halophily or both with alkaliphily. Thus, the mature form of the α-amylase from haloalkaliphilic *Natronococcus* sp. Ah-36 was deduced to have a very high acidic amino acid content, but this is a general adaptation to halophily (Lanyi, 1974; Eisenberg et al., 1992).

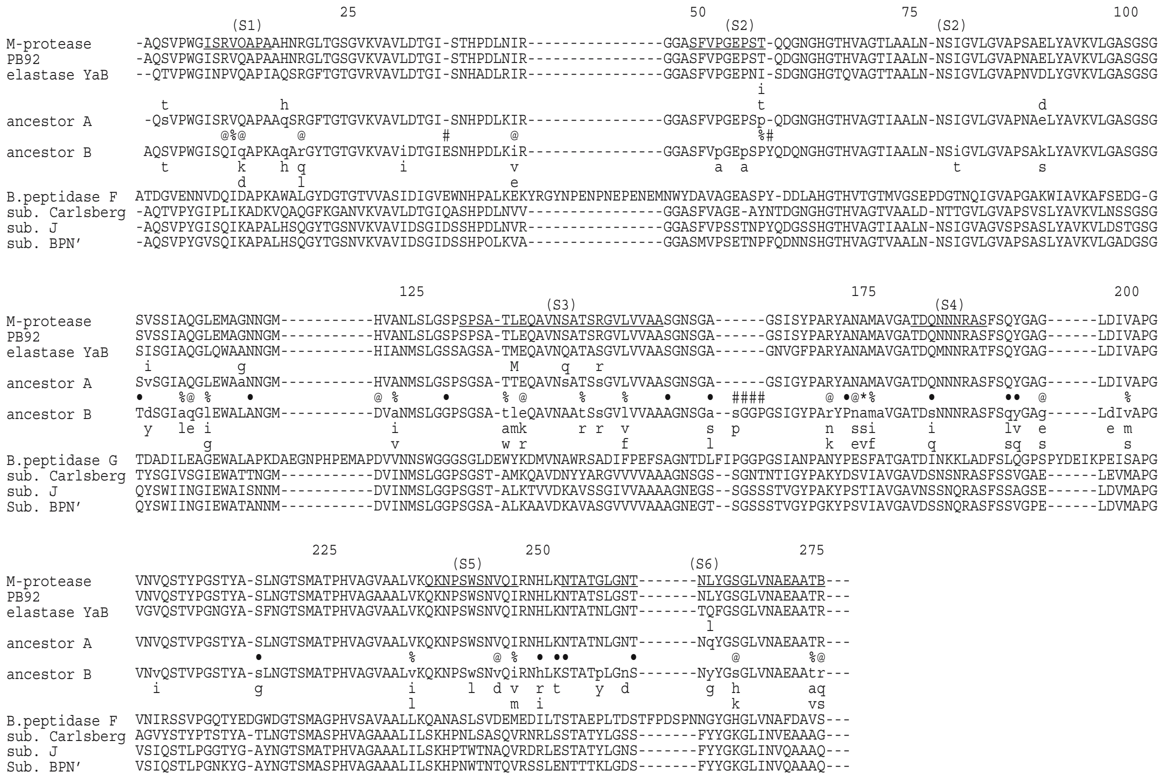

Fig. 4. An alignment of amino acid sequences of M-protease and related proteases showing the sequence of hypothetical ancestors A and B, with the "high-alkaline" protease sequences from Fig. 3 shown above ancestor A and the "alkaline" protease sequences from Fig. 3 shown below ancestor B. Residue numbers of M-protease are indicated. Symbols between the ancestral sequences indicate residues that have been substituted between them. Symbols @, %, and * indicate substitutions of ionizable residues, residues at the interface of shifted segments and others, respectively. Symbol # indicates inserted/deleted residue(s). In the M-protease sequence underlining is used to show positions of shifted sequences in the structural studies. This figure was reproduced, with permission from the publisher, from Shirai et al. (1997).

Are There Global Adaptations of the Cell Surface Layers?

Cytoplasmic Membrane

Little attention has been focused on the cytoplasmic membrane characteristics of extreme, non-haloalkaliphilic prokaryotes living in alkaline medium—their primary stress. Indications are that studies of membrane lipids will be important in elucidating major adaptations to such environments. Koga et al., 1982 and Nishihara et al., 1982 reported on the lipid composition of alkaliphilic *Bacillus* sp. strain A-007 and several other alkaliphilic *Bacillus* strains, in which they characterized a novel polar lipid identified as *bis*-(monoacylglycero)-phosphate (BMP). This lipid's presence in mammalian lysosomes but not in prokaryotes has been reported (Horikoshi, 1991). Other phospholipids found in *Bacillus* species included phosphatidylglycerol (PG), phosphatidylethanolamine (PE), and often car-

diolipin (CL) with an array of branched-chain and other fatty acids. Cardiolipin concentrations were generally significant, whereas glycolipids and glycophospholipids that often are found in Gram-positive bacteria were absent. The neutral lipid fraction contained diacylglycerol, both squalene and dehydrosqualene, as well as an uncharacterized component that accounted for about 20% of the neutral lipid (Koga et al., 1982).

Subsequently, Clejan et al., 1986 compared the lipid composition of several obligately and facultatively alkaliphilic strains. Again, high levels of CL were reported, i.e., 13% and 25% of the polar lipids in *B. pseudofirmus* RAB and OF4, respectively. The obligately alkaliphilic *B. pseudofirmus* RAB had a much higher neutral/polar lipid ratio than the facultatively alkaliphilic *B. pseudofirmus* OF4; the neutral lipid fraction contained squalene and dehydrosqualene, diacylglycerol and some incompletely characterized long-chain isoprenoid lipids. In a subsequent study (Clejan et al., 1988), the permeability of lipid vesicles prepared with different ratios of the diacylglycerol and isoprenoid fractions was found to be enhanced by diacylglycerol and decreased by the isoprenoid fraction. These neutral lipid components may be part of the balancing of fluidity with barrier functions of the coupling membrane. The obligately alkaliphilic *B. pseudofirmus* RAB also had 90% branched-chain fatty acids as opposed to 72% in the facultatively alkaliphilic *B. pseudofirmus* OF4, and whereas the facultative alkaliphile had no unsaturated fatty acids in its phospholipids, the obligate alkaliphile had a significant amount (Clejan et al., 1986). It was hypothesized that the obligate alkaliphile might have membrane lipid properties that functioned well at highly alkaline pH values but became too fluid and permeable at near neutral pH values. This hypothesis was supported by the finding that the presence of low concentrations of unsaturated fatty acid stops the facultative strain from growing in the low end of its former pH range for growth and upon incorporation of the unsaturated fatty acid into the membrane (Dunkley et al., 1991). Interestingly, a more recent alkaliphile isolate, *Bacillus cohnii* was noted to have an extraordinarily high content of unsaturated fatty acids (Spanka and Fritze, 1993). Aono et al., 1992 have noted the instability of protoplast membranes of *B. halodurans* C-125 at alkaline pH values that are well below the optimum for growth. Similarly, Krulwich et al., 1985a found during studies of cytoplasmic buffering capacities in *Bacillus* species with diverse pH optima for growth, that the alkaliphiles lost stability below pH 7. These phenomena may reflect the same general membrane property that limits the low range of growth pH. As indicated below, increased autolysis of the peptidoglycan also could be involved.

Recently, Gilmour et al. (manuscript submitted) conducted a study of the proteins found in pH 7.5- and pH 10.5-grown *B. pseudofirmus* OF4. Among the proteins that were strongly up-regulated at pH 10.5 were two enzymes that are likely to be involved in branched-chain fatty acid metabolism or production. The upregulation of these enzymes might relate to remodeling involved in adaptation to the high pH.

The membrane lipids of alkaliphilic *Bacillus* species clearly contain novel components whose role is unclear, high levels of CL and of branched-chain fatty acids. The more detailed characterization of the membrane lipid components and mutational analyses of their functions will be important areas for furthering our understanding of the physiology of this group.

Peptidoglycan and Associated Polymers

The alkaliphile peptidoglycan and associated polymers, especially in *Bacillus* species, have received more detailed attention than the membrane lipids. The data that have emerged from studies thus far indicate that both the turnover dynamics of the peptidoglycan itself and pH-dependent changes in associated, negatively charged polymers may be important contributors to alkaliphile physiology. Koyama and Nosoh, 1976 noted that cells of an alkaliphilic *Bacillus* strain were more negatively charged upon growth at pH 10 than at 8.2. Subsequent studies of the composition of a diverse group of alkaliphilic *Bacillus* species at different pH values for growth indicated that these organisms generally have the A1γ type of peptidoglycan in which *meso*-diaminopimelic acid, the third residue in the tetrapeptide of mature peptidoglycan units, is linked via its ε-amino group directly to the terminal D-alanine of another peptide (Aono et al., 1984); some variations have since been found, including the presence of ornithine instead of diaminopimelic acid in *B. cohnii* (Spanka and Fritze, 1993). Some alkaliphiles (e.g. *B. halodurans* C-125) are more susceptible to autolysis at near neutral pH and exhibit a lower (%) crosslinking of the peptidoglycan at lower growth pH than at alkaline pH (Aono and Sanada, 1994). These interesting differences, however, still do not account for the more negative charge of the surface layers at high pH.

Cell wall-associated polymers that are highly acidic appear to be responsible for pH-dependent changes in cell surface charge, and the polymers differ between groups of alkaliphilic *Bacillus* species. *Bacillus halodurans* C-125 was among those species that produced a teichuronic acid composed of *N*-acetyl-D-fucosamine, glucu-

ronic acid and galacturonic acid (Aono, 1985) and a teichuronopeptide composed of a polyglucuronic acid and a polyglutamate polymer (Aono, 1989; Aono et al., 1993). Mutants that were defective in one or both of these polymers were growth defective at high pH (Aono and Ohtani, 1990; Ito et al., 1994), which indicates that these polymers are important in the alkaliphily of this group of *Bacillus* species (Aono and Ohtani, 1990; Aono et al., 1995). Notably, these organisms were cultivated in glucose-containing media where alkaliphiles are often a bit less fastidious than when in a medium of nonfermentative carbon sources (Gilmour and Krulwich, 1997).

The uronic acid polymers are not found in other groups of alkaliphilic *Bacillus* species, e.g., *B. pseudofirmus* OF4 (Aono, 1985; Guffanti and Krulwich, 1994). On the other hand, recent studies have shown that *B. pseudofirmus* OF4 has an acidic S-layer polymer produced from a gene with strong homology to similar genes from *Bacillus anthracis* and *Bacillus licheniformis*. This S-layer polymer was identified in 2-dimensional gel electrophoretic patterns of membrane-associated proteins from pH 10.5- and pH 7.5-grown cells of *B. pseudofirmus* OF4, and characterized as a heterogeneous, apparently processed, protein that is present in greater amounts at high pH. By cloning, sequencing and disrupting the S-layer gene, the S-layer is found to be dispensable for alkaliphily in *B. pseudofirmus* OF4, but confers an advantage to cell growth at pH 10.5 and to cytoplasmic pH homeostasis in a sudden shift from pH 8.5 to 10.5 (Gilmour et al., manuscript submitted). *B. pseudofirmus* OF4 also may have an acidic capsule layer because a partial sequence for genes that are likely to encode enzymes synthetic for a polyglutamate capsule was identified in this species (Ito et al., 1997a). The characterization of the complete sequence and role of this locus will be interesting.

Are There Global Adaptations of Cytoplasmic Components?

Buffering Capacity

A comparison of the cytoplasmic buffering capacity of *Bacillus* species that grow in vastly different pH ranges indicated that alkaliphiles, grown on nonfermentable carbon sources, had higher cytoplasmic buffering capacities at alkaline pH than at lower pH (Krulwich et al., 1985a). In a recent study, Rius and Loren, 1998 reported comparative values for the cytoplasmic buffering capacity of *B. alcalophilus* grown on both fermentative and nonfermentative carbon sources. These investigators used the decay of an acid pulse (Maloney, 1979) to determine both cytoplasmic buffering capacity and membrane H+ conductance, thereby avoiding problems associated with permeabilizing cells. In media with either nonfermentative carbon sources or fermentative carbon sources, the cytoplasmic buffering capacity of *B. alcalophilus* was much higher in pH 10.5-grown than in pH 8.5-grown cells. Strikingly, the alkaliphile cells (and others, such as *Staphylococcus aureus* and *B. subtilis*) had vastly lower cytoplasmic buffering capacity when grown on malate-carbonate media than on media with fermentative carbon sources (Rius and Loren, 1998). Since malate-carbonate media support a more alkaline optimum for the growth pH, there is probably no direct relationship between overall cytoplasmic buffering capacity and the capacity to grow at the upper reaches of pH. On the other hand, it is quite possible that specific compounds play particular roles in connection with alkaliphily. For example, several studies have focused on a shift in the ratio of the major polyamine compounds such as spermidine, which predominates heavily at very alkaline pH values (Chen and Cheng, 1988; Hamana et al., 1989).

Alkali-Stability of Cytoplasmic Components

The general impression is that the cytoplasmic pH, for most alkaliphiles in their optimum pH range, is within about 0.5 pH units of the cytoplasmic pH optimum for most bacteria. Hence there may not be major or even discernible, global adaptations in the protein structure or pH profile (Horikoshi and Akiba, 1982; Horikoshi, 1991). But throughout the literature on alkaliphiles, at least some apparent cytoplasmic enzymes have unusually high pH profiles (Horikoshi and Akiba, 1982). Some reports would seem to beg for an explanation; for example, a putative "intracellular alkaline serine protease" from alkaliphilic *Thermoactinomyces* sp. HS682 was produced from its gene in *Escherichia coli*. The purified enzyme had a pH optimum of 11 (Tsuchiya et al., 1997).

In consideration of such observations and the recognition that some of the soda lake alkaliphiles have evolved over a long period in a consistently high alkaline environment, it may be well worth looking explicitly for exceptions to the expectation that cytoplasmic proteins have no global adaptations to a higher than conventional pH. In a non-alkaliphile that completely lacks active pH homeostatic mechanisms, such as *Clostridium fervidus* (Speelmans et al., 1993), the organism can only grow in a narrow pH range up to about pH 7.7. In the

especially effective pH homeostatic mechanisms of most well studied alkaliphiles (Krulwich et al., 1997), the upper pH limit is generally about pH 9 to 9.5. Even in those alkaliphiles, which have most often been soil isolates originally, subtle but important global adaptations in the cytoplasmic proteins are possible. Perhaps among the soda lake alkaliphiles there are organisms that are less dependent on remarkable pH homeostasis mechanisms because their cytoplasmic enzymes and functional assemblies (e.g., secretion and protein synthetic machinery) are all markedly alkali-adapted relative to those of conventional bacteria. A novel osmolyte has been noted in haloalkaliphilic archaea (Desmarais et al., 1997). Perhaps the cytoplasmic proteins of some of these organisms are not only salt-adapted but also at least unusually alkali-adapted.

It also will be of interest to carefully examine the properties of ribosomal and other proteins that must interact with nucleic acid molecules in a cytoplasm that is generally at least half a pH unit higher than the cytoplasm of conventional bacteria growing at optimal pH (Krulwich, 1995). Horikoshi, 1991 has noted a pH optimum for protein synthesis in an alkaliphilic *Bacillus* was about half a pH unit higher than that of *B. subtilis*. Genes for ribosomal proteins and major polymerases are beginning to be identified so that detailed examinations will be facilitated (Nakasone et al., 1998; Takami et al., 1999d). Thus far, homologous DNA-binding proteins from alkaliphiles and non-alkaliphiles have not been compared in great detail, the two small acid-soluble spore proteins (SASPs) sequenced from alkaliphiles (Quirk, 1993; Wei et al., 1999) have not been examined closely from this perspective.

Proteome Studies

The 2-dimensional gel analysis of proteins from steady-state pH 7.5- and pH 10.5-grown *B. pseudofirmus* OF4 cells, and from cells grown at lower pH and rapidly shifted to pH 10.5, revealed several interesting features that will merit further examination in this and other alkaliphiles (Gilmour et al., manuscript submitted). Significant numbers of proteins were found to be either up-regulated or down-regulated at high pH, but the extent of the change was typically greater for the up-regulated genes. In addition, a substantially greater number of genes were up-regulated transiently with rapid increase of pH to 10.5 than were ultimately up-regulated in the steady-state cells; this find correlates with other data indicating that there are groups of proteins that play a specific role in the initial adjustment to a major alkaline shift.

Genomics

The vastly increasing database on sequences of alkaliphile proteins will help clarify the issues already raised about global adaptations in cytoplasmic proteins or in functional cytoplasmic assemblies (e.g., ribosomes and secretory particles). The completion of the *B. halodurans* C-125 genome will be a major step in this process (Takami et al., 1999b, Takami et al., 1999d). The maps of alkaliphiles and gene order in several large pieces of DNA suggest that interesting features of alkaliphily may emerge (Takami et al., 1999b; Takami et al., 1999d; Gronstad et al., 1998; Wei et al., 1999).

Some, but probably not the majority, of the alkaliphilic *Bacillus* species and strains have been found to harbor endogenous plasmids. Most of these have been relatively small and have not been exciting candidates for development of host-vector systems. Rather, the plasmids that have been extensively developed for use in *B. subtilis* generally have been adapted and applied to molecular manipulations of alkaliphilic *Bacillus* species (Horikoshi, 1991). However, Fish et al., 1999 have recently found that eight alkaliphile halomonads, out of the seventeen they examined, possessed one or more plasmids in the size range of 5.3 to 33 kb; they concluded that some of these would be suitable for vector development. A large endogenous plasmid, approximately 30 kb, also has been found in *B. pseudofirmus* OF4 (Gronstad et al., 1998) and bears the cadmium-resistance locus (Ivey et al., 1992). There is no evidence to date for a role of plasmid-borne genes in alkaliphily.

Active pH Homeostasis and the Involvement of Secondary Na^+/H^+

Antiporters and Secondary Na^+/Solute Symporters

In alkaliphilic *Bacillus* species, active ion transport mechanisms are central to the crucial process of pH homeostasis, and this process appears to limit the upper pH limit for growth (Krulwich, 1995; Krulwich et al., 1997). Sturr et al., 1994 conducted studies of the bioenergetic parameters of *B. pseudofirmus* OF4 in a pH-controlled continuous culture apparatus in which the bacteria were grown aerobically on malate-containing media at various, fixed pH values from pH 7.5 to 11.4. In fact, the upper limit for growth was not found in this range, with a long but certainly viable generation time of 700 min found at pH 11.4. As shown in Fig. 5, *B. pseudofirmus* OF4 grows slightly better at pH 8.5 to 10.5 than at pH 7.5, and throughout this pH range, the cytoplas-

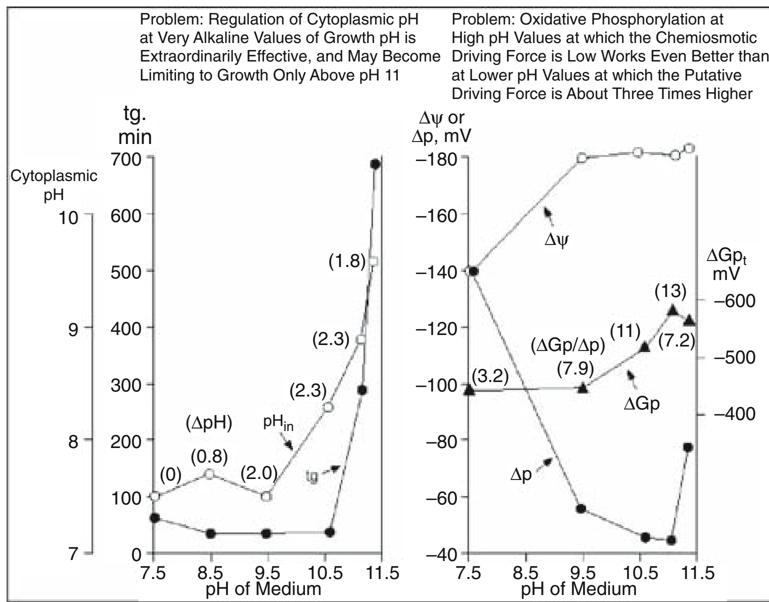

Fig. 5. Bioenergetic parameters of *B. pseudofirmus* OF4 during growth in continuous cultures at various controlled pH values. The data from Sturr et al., 1994 were replotted to highlight particular features of interest. Left: the doubling time (tg, min) and cytoplasmic pH (pH_{in}) are shown as a function of the growth pH. The numbers in parentheses above the points on the cytoplasmic pH curve are the values for δpH. Right: The transmembrane electrical potential, positive out (δ ψ), the total bulk electrochemical proton gradient (δp), and the phosphorylation potential (δgp) are all shown in mV as a function of growth pH. The numbers in parentheses are the δGp/δp, which would reflect the H^+ stoichiometry if coupling were strictly to a bulk gradient. This figure was reproduced with permission from the publisher from Krulwich (1995).

mic pH remains below 8.5; at external pH values of 9.5 and above, the δpH (transmembrane pH gradient) is 2 full pH units or more. At the highest external pH included in the study, pH 11.4, the internal pH was at about 9.6. The growth rate slowed dramatically, and in parallel, with the increasing cytoplasmic pH above a value of 8.2. Thus in this type of alkaliphilic *Bacillus*, pH homeostasis is remarkable: cytoplasmic pH is maintained at about pH 7.5 until the δpH exceeds 2 and thereafter, the rise in cytoplasmic pH is correlated with a decrease in growth rate (i.e., increase in generation time). The finding of optimal growth rates up to about pH 10.5, at which the cytoplasmic pH is maintained below pH 8.5, was corroborated in other chemostat studies (Guffanti and Hicks, 1991) as well as batch culture studies (Hirota and Imae, 1983; Aono et al., 1997). Under conditions in which the cells are well energized, the magnitude of the δpH found among different alkaliphilic *Bacillus* species using several different kinds of probes to assess this parameter has been very consistent. Significantly, the full δpH that the alkaliphiles maintain was not measured in the earliest studies (e.g., Guffanti et al., 1978) because the measurements were carried out in buffers without energy sources. Thus compendia of such measurements often contain citations to a mixture of experimental conditions which determine the extent to which alkaliphiles grow.

There is a large body of evidence for the crucial Na^+ cycle involvement in net acidification of the cytoplasm during growth of alkaliphilic prokaryotes at alkaline pH. That alkaliphiles required Na^+ and used Na^+ as the coupling ion for transport systems (Koyama et al., 1976; Kitada and Horikoshi, 1977; Guffanti et al., 1978) had already been demonstrated when work on both wild type alkaliphiles and pH homeostasis-negative non-alkaliphilic mutants began to implicate Na^+/H^+ antiporters as key mediators of cytoplasmic acidification (Mandel et al., 1980; Koyama et al., 1986; Krulwich and Guffanti, 1983, Krulwich and Guffanti, 1989). That maintenance of a cytoplasmic pH well below the external pH depends upon the availability of Na^+ (Mandel et al., 1980; Krulwich et al., 1982; McLaggan et al., 1984; Krulwich et al., 1985b) was established in several types of alkaliphiles. Diverse mutant strains, non-alkaliphiles that were specifically deficient in their ability to regulate cytoplasmic pH, also were shown to be deficient in Na^+/H^+ antiport (Mandel et al., 1980; Krulwich et al., 1982; Garcia et al., 1983; Hamamoto et al., 1994; Krulwich et al., 1996). Conversely, *B. pseudofirmus* OF4 cells taken from continuous cultures maintained at pH 11.4, contained variants with elevated Na^+/H^+ antiporter activity (Sturr et al., 1994).

Electrogenic Na^+/H^+ antiporters that catalyze exchange of intracellular Na^+ for a stoichiometrically greater number of H^+ from the external milieu transport net positive charge inward during each turnover. Accordingly, these fluxes can be energized by the transmembrane electrical potential component (δ) of the total electrochemical proton gradient (δp) that is established by the proton-extruding respiratory chain (or by H^+-extruding ATPases in anaerobic cells). Components of the respiratory chain and diverse, electrogenic Na^+/H^+ antiporters are depicted in a diagram of an aerobic alkaliphilic *Bacillus* in Fig. 6. Because the δ can energize the electro-

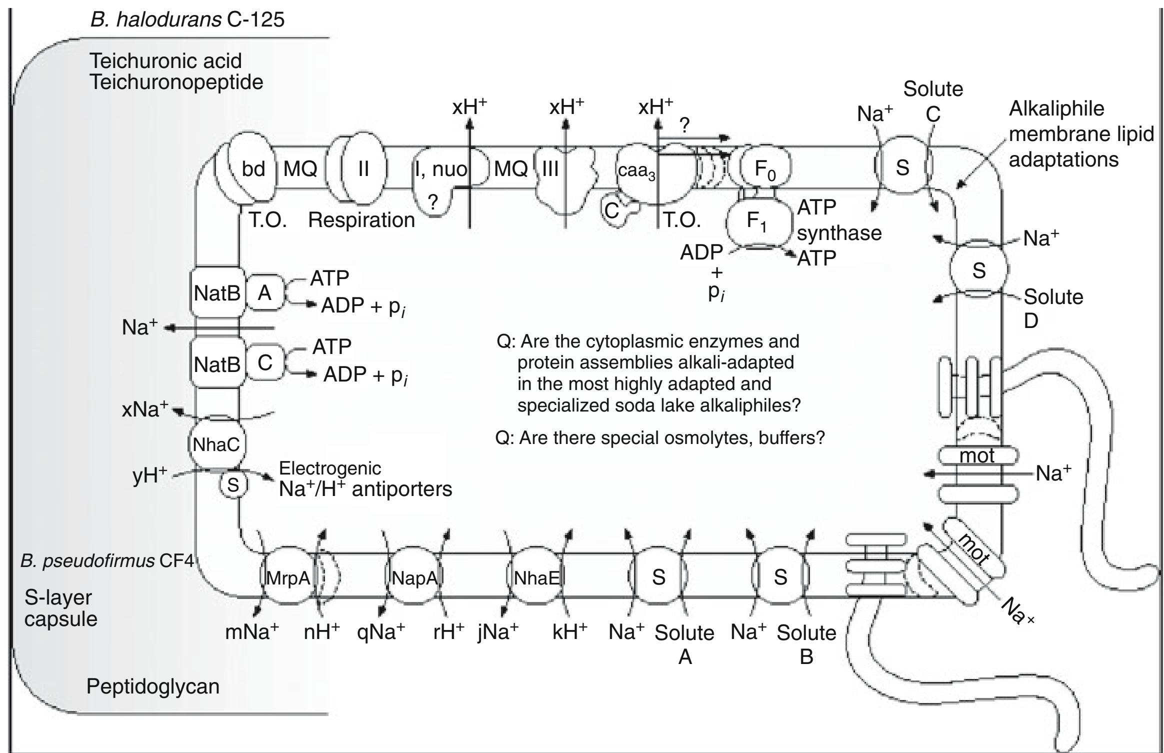

Fig. 6. A schematic of an alkaliphilic *Bacillus*, showing the membrane-associated ion-translocating proteins and complexes involved in the primary generation of a δp as well as the secondary antiporters (Mrp, Nap, Nha) and symporters (S) that together catalyze solute uptake and net proton accumulation to achieve a lower cytoplasmic than medium pH. Also shown are: the flagellar assembly and associated Na^+ channel that may provide another physiologically important Na^+ reentry route in addition to the Na^+-coupled symporters; and the F_1F_O-ATP synthase. This proton-coupled synthase may, at pH > 9.2, accept protons that are somehow sequestered as indicated by arrows parallel to, and either just above or just below, the membrane surface. The dotted outline of the caa_3-type oxidase represents a hypothetical route by which protons are transferred directly from this complex to the synthase in protein-protein interactions. The dotted outline of MrpA indicates that at least under some conditions this antiporter may function as part of a complex. Outlines of a cell-wall-associated layer reflect the finding that in *B. halodurans* C-125 and *B. pseudofirmus* OF4, different negatively charged polymers play at least some role in pH homeostasis. Other possibilities that are yet to be clarified are indicated by the questions (Q:) presented in the cytoplasmic space.

genic antiport, it is possible for such antiporters, working in concert with respiration, to acidify the cytoplasm relative to the medium (McNab and Castle, 1987). For such antiport to support pH homeostasis on a continuous basis, however, Na^+ must be recycled to maintain the source of the cytoplasmic substrate for the Na^+/H^+ antiporters. Compelling evidence has been presented for an important role of the numerous Na^+-coupled solute uptake systems, Na^+/solute symporters, in Na^+ reentry in support of pH homeostasis (Krulwich et al., 1985b). In fact, it was hypothesized, when pleiotropy was observed in some non-alkaliphilic mutant strains, that the alkaliphile Na^+/H^+ antiporter(s) and Na^+/solute symporter(s) playing critical roles in pH homeostasis might share a common subunit (Guffanti et al., 1981). However, both the ion specificity of the transporters (Sugiyama et al., 1985) and the many genes that now have been identified fail to support such a common structure. Rather, the pleiotropy of many non-alkaliphilic mutants likely relates to the complexity of the physiological networks surrounding the important cell functions of pH homeostasis, solute transport and Na^+-resistance (Krulwich et al., 1996, Krulwich et al., 1997, Krulwich et al., 1998) and the likely complexity of one of the major antipor/t systems (Hamamoto et al., 1994; Hashimoto et al., 1994; Ito et al., 1999). In addition to the symporters, some pH-sensitive mechanism for Na^+ reentry must complete the Na^+ cycle that supports pH homeostasis even when solutes are not present and Na^+ is not abundant (Booth, 1985; Krulwich and Guffanti, 1989; Krulwich et al., 1997). A good candidate for a pH-dependent Na^+ entry route of this sort, as depicted in Fig. 6, is the Na^+-translocating channel associated with flagellar rotation in the alkaliphilic *Bacillus* species (Sugiyama, 1995). Although much less complete pictures of the pH homeostasis cycle of alkaliphiles outside the genus *Bacillus* have been

presented, parameters of the cycle (Cook et al., 1996) and involvement of Na^+ or Na^+/H^+ antiporters or both in the central cell energetics of other alkaliphiles have been described (Buck and Smith, 1995; Prowe et al., 1996).

The cycle outlined above for pH homeostasis has been the model of this function in many non-alkaliphilic bacteria, but the alkaliphilic *Bacillus* species have an extraordinary capacity for pH homeostasis as well as some specificity that is not shared by non-alkaliphiles. *B. pseudofirmus* OF4 has at least 10 times the aggregate Na^+/H^+ antiporter activity as *B. subtilis* and has far more capacity for pH homeostasis than the non-alkaliphile. In addition, pH homeostasis in *B. subtilis* can draw upon K^+/H^+ antiport as well as well as Na^+/H^+ antiport, which is carried out by antiporters that can use either cation. On the other hand in the alkaliphilic *Bacillus* species, the process depends specifically on Na^+ (Krulwich et al., 1994, Krulwich et al., 1999). Although there is evidence for K^+/H^+ antiporters in alkaliphiles (Mandel et al., 1980; Kitada et al., 1997), and the first Na+(K+)/H^+ antiporter-encoding gene has now been identified in *B. pseudofirmus* OF4 (Wei et al., manuscript submitted), it is unclear what the role of the K^+/H^+ antiport is and why it does not come into play in any obvious way in pH homeostasis. If *B. subtilis* is subjected to a sudden shift in pH from 7.5 to 8.5, for example, the initial cytoplasmic pH of about 7.5 is maintained as long as either K^+ or Na^+ is present. Whereas in the alkaliphile, only Na^+ can support this homeostasis or comparable homeostasis during a pH 8.5 to 10.5 shift in the external pH (Krulwich et al., 1994; Krulwich et al., 1999; Ivey et al., 1998).

Most work on pH homeostasis of alkaliphilic *Bacillus* species has lately been carried out on *B. halodurans* C-125 and *B. pseudofirmus* OF4 and has focused upon identification of the antiporter-encoding genes that have roles in pH homeostasis. It has been clear for several years that, as in other bacteria (Padan and Schuldiner, 1996; Krulwich et al., 1999), alkaliphilic *Bacillus* species have more than one Na^+/H^+ antiporter system with a role in pH homeostasis (Kitada et al., 1994; Krulwich, 1995; Ito et al., 1997b). Currently, more Na^+/H^+ antiporters have been identified in *B. pseudofirmus* OF4 than in any other single organism; these are indicated in Fig. 6 as mrp, nhaC, napA, and nhaE. It is likely that one of these antiporters has the dominant role in pH homeostasis. This antiporter is encoded by a locus first identified and partially characterized by Horikoshi, Kudo and colleagues in *B. halodurans* C-125 (Kudo et al., 1990; Hamamoto et al., 1994). It is also found in *B. pseudofirmus* OF4 (Krulwich et al., 1998; Krulwich et al., 1999) and other bacteria (Putnoky et al., 1998; Hiramatsu et al., 1998) and has been named *mrp* (for multiple resistances and pH) in *B. subtilis* (Ito et al., 1999). The locus encoding all of these homologues is an intriguing 7-gene operon in which all of the deduced products are hydrophobic and several of them have sequence similarity to membrane-embedded subunits of the NDH-1 type of NADH dehydrogenase complexes (Yagi, 1993). A point mutation in the *mrpA* gene of *B. halodurans* C-125 renders the bacteria non-alkaliphilic and extremely defective in pH homeostasis (Hamamoto et al., 1994). Deletion of the mrpA of *B. subtilis* makes this strain extremely sensitive to Na^+ and modestly deficient in pH homeostasis in certain concentration ranges of Na^+ or K^+ (Ito et al., 1999). An unusual dependence of MrpA function on other genes in the operon (Hiramatsu et al., 1998; Ito et al. 1999) has led to the speculation that *mrp* might be an obligatory complex (Hiramatsu et al., 1998). Because it appears that MrpA can function as a secondary antiporter system in stoichiometric excess but not in the absence of the other gene products, another complex-involved mode of transport is still possible (Ito et al., 1999); this is indicated by the dotted lines in Fig. 6. The dissection of the structural form(s) of the active complex, their mechanism and roles in the alkaliphile, and their differences from homologues in non-alkaliphiles, are important areas of current investigation.

The *nhaC* gene of *B. pseudofirmus* OF4 was the first alkaliphile Na^+/H^+ antiporter-encoding gene to be cloned, which was achieved by functional complementation of an antiporter-deficient *Escherichia coli* mutant (Ivey et al., 1991). Subsequent deletion of the gene showed that the antiporter played a role in high affinity Na^+/H^+ antiport at both pH 7.5 and 10.5. It was the major antiporter with such affinity in pH 7.5-grown cells, whereas another high affinity system was induced during growth at pH 10.5 and the constitutive higher affinity antiport (MrpA-associated?) was preserved (Ito et al., 1997a). An antiporter that confers both Na^+/H^+ and K^+/H^+ antiporter activities upon E. coli has been designated *nhaE*; this antiporter also has a modest role at both pH 7.5 and 10.5 and is in fact expressed more at the lower pH as evidenced by northern analyses (Wei et al., manuscript submitted). Finally, a homologue of the napA antiporter, first described in *Enterococcus hirae* by Waser et al., 1992 and for which a homologue was subsequently reported in *Bacillus megaterium* (Tani et al., 1996), also has been found in *B. pseudofirmus* OF4 and shown to restore Na^+-resistance to antiporter-deficient *E. coli* strains (Wei, Y. and Ito, M. unpublished data).

One of the key tasks in further clarifying the basis for the alkaliphile's capacity for pH homeostasis is the enumeration of all the antiporters involved in a single species and the determination of their roles, mechanisms, and interplay. Another area of interest will be the development of information at a similar molecular level about the reentry routes; do secondary Na^+/solute symporters that play a role in pH homeostasis as well as simple solute uptake have particular properties associated with this dual role? Also, it will be important to further examine aerobes growing on fermentative substrates, where some sparing of Na^+-dependent, respiration-driven pH homeostasis has been observed (Gilmour and Krulwich, 1997) and to characterize the process in a broader spectrum of extreme alkaliphiles.

Primary Membrane Transport and Motility

Primary Active Membrane Transport Systems

Secondary active transport systems are centrally important both to Na^+-coupled uptake of many solutes and to a Na^+ cycle that functions in pH homeostasis. Increasingly, primary active transport systems also are being characterized in diverse alkaliphiles. Among the ATP-driven systems are: Na^+-translocating ATPases, at least one of which is a V-type system (Koyama, 1996; Kaieda et al., 1998; Prowe et al., 1996); a Na^+-translocating ABC-type transport system (*natCAB*; Wei et al., 1999) that is homologous to a similar system in *B. subtilis* (Cheng et al., 1997), and P-type ATPases that confer Cd^+- (Ivey et al., 1992) and Na^+-resistance (Koyoma, 1999). Other apparent ABC-type systems have been noted in sequences already presented, but studies that might indicate whether alkaliphile transporters have any common features have not been reported as yet. Among the haloalkaliphiles, retinal-based, light-driven primary transport systems have been found and characterized. Although the absence of bacteriorhodopsin-like pigments from these organisms was reported (Bivin and Stoeckenius, 1986), the chloride pump, halorhodopsin, has been characterized in considerable detail (Lanyi et al., 1990; Scharf et al., 1994; Varo et al., 1995; Varo et al., 1996).

Motility

Aono et al. (1992) noted that *B. halodurans* C-125 produced flagella only in the more alkaline part of its pH range for growth, and Sturr et al., 1994 made comparable observations on *B. pseudofirmus* OF4. The *hag* gene of the former alkaliphile has been sequenced (Sakamoto et al., 1992), whereas the amino acid composition of the flagellin from the latter alkaliphile was determined (Guffanti and Eisenstein, 1983). In both instances, a rather low calculated pI was observed relative to homologues from non-alkaliphiles. The identification of the remaining motility and flagellar assembly genes awaits completion of more genomic studies of alkaliphiles, but the *mot* assemblies were visualized by rapid freeze electron microscopy (Khan et al., 1992).

Imae and his colleagues (Hirota et al., 1981; Hirota and Imae, 1983; Sugiyama et al., 1986) first showed that motility in alkaliphilic *Bacillus* species was energized by an electrochemical gradient of Na^+ as opposed to the δp-driven systems of most non-alkaliphiles. Indeed, amiloride and some of its analogues, inhibitors of various Na^+ translocation pathways in eukaryotes, were found to inhibit alkaliphile flagellar rotation (Sugiyama et al., 1988; Atsumi et al., 1990). Because, however, the molecular characterization of the motility-related genes in alkaline-tolerant marine bacteria that also use an electrochemical Na^+ gradient is incomplete, extensive recent progress on specific properties of the Na^+-dependent motility mechanism has occurred in those systems rather than in alkaliphiles (McCarter, 1995; Yorimitsu et al., 1999).

Oxidative Phosphorylation

Respiratory Chain

Although diverse marine bacteria have been shown to have respiration-coupled, primary Na^+ extrusion systems (Tokuda and Unemoto, 1984; Tomb et al., 1993; Beattie et al., 1994; Skulachev, 1994; Pfenninger-Li et al., 1996; Park et al., 1996), thus far the non-marine, non-halophilic alkaliphiles—including the best studied *Bacillus* species—have been found to have H^+-translocating respiratory chains (Lewis et al., 1983; Krulwich and Guffanti, 1989). These respiratory chains are often branched, with multiple terminal oxidases, and the component cytochrome and iron sulfur protein components are characteristically present at high levels in the membranes (Hicks and Krulwich, 1995; Krulwich et al., 1998). The H^+-translocating respiratory chains may facilitate the support of pH homeostasis and the extra costs of oxidative phosphorylation at high pH; but, notably, the alkaliphilic *Bacillus* species have high molar growth yields on malate (Guffanti and Hicks, 1991; Sturr et al., 1994). In addition to the high concentration of membrane cytochromes and other respiratory chain components, especially at high pH (Lewis et al., 1981; Quirk et al., 1993;

Hicks and Krulwich, 1995; Aono et al., 1996), the respiratory chain components of alkaliphiles have characteristically low midpoint potentials (Lewis et al., 1981; Kitada et al., 1983; Yumoto et al., 1991) as shown for *c*-type cytochromes in Fig. 7. Yumoto et al., 1991 have suggested that the low midpoint potentials may facilitate electron movement in the inward direction in membranes that maintain a rather high (positive out) transmembrane electrical potential.

The respiratory chain components that have been characterized in alkaliphilic *Bacillus* species have been summarized (Hicks and Krulwich, 1995). Although there is some indirect indication a proton-translocating NADH dehydrogenase (complex I) is present (Hicks and Krulwich, 1995), this is far from established and awaits compelling biochemical and genomic evidence one way or the other. On the other hand, succinate dehydrogenases have been purified and characterized (Gilmour and Krulwich, 1996; Qureshi et al., 1996) and an incompletely characterized *bc* complex is evident (Lewis et al., 1981; Reidel et al., 1993). Also evident are diverse terminal oxidases, including a pH-regulated *caa*$_3$-type oxidase in *B. pseudofirmus* OF4 (Quirk et al., 1993), a comparable enzyme recently purified from *Bacillus* YN-1 (Higashibata et al., 1998), a *bd*-type cytochrome oxidase in the same species (Gilmour and Krulwich, 1997), and an aco3-type oxidase in *Bacillus* YN2000 (Qureshi et al., 1990; Yumoto et al., 1993). Engelhard and colleagues (Scharf et al., 1997) have begun to dissect the respiratory chain of the haloalkaliphilic archaeon *Natronobacterium pharaonis* and note the high respiratory-chain component content and possible presence of *bc* and *ba*$_3$ complexes; these investigations should help establish what may be more general properties of respiratory complexes in diverse alkaliphiles.

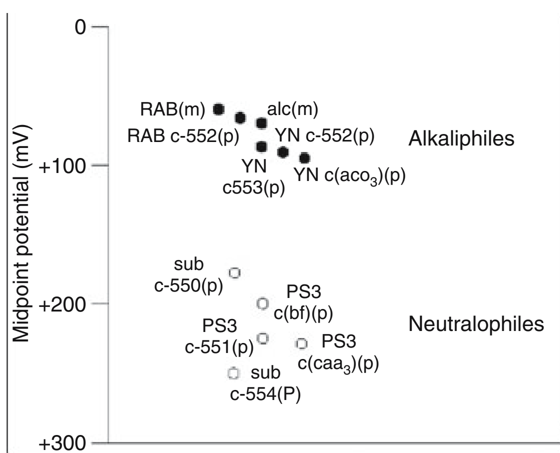

Fig. 7. Midpoint potentials from various alkaliphile c-cytochromes [RAB, *B. pseudofirmus* RAB; alc, *B. alcalophilus*; YN, *Bacillus* YN-2000] in comparison to those from non-alkaliphilic *Bacillus* species [sub, *B. subtilis*; PS3, *Bacillus* PS3]; m (composite membrane data); and p (purified protein). This figure was reproduced with permission from the publisher from Hicks and Krulwich, 1995.

While the status of energy-transducing NDH-1 type NADH dehydrogenases is still equivocal in alkaliphiles, the status of NDH-2 type NADH dehydrogenases are not (Xu et al., 1989; Niimura et al., 1995; Aono et al., 1996; Koyama et al., 1998). An interesting set of findings and proposals is emerging from recent studies that bring together the issue of peroxide toxicity, catalase, and the alkaliphile respiratory chain. Yumoto et al., 1990 first purified a protoheme-containing catalase from alkaliphilic *Bacillus* YN-2000 and reported that it was present in higher activity at elevated pH.

In *B. pseudofirmus* OF4, a complicated profile of three different catalase isozymes has been presented by Hicks, 1995 who also showed that this alkaliphile was more sensitive to killing by hydrogen peroxide at pH 10.5 than at pH 7.5, even though the aggregate catalase activity was about two-fold higher at pH 10.5. Niimura et al., 1995 observed that the NADH oxidase from *A. xylanus*, which, as described above, is cytochrome-deficient, reduces oxygen to hydrogen peroxide. When the 22-kDa AhpC disulfide-containing protein from *Salmonella typhimurium* was added to the reactions, the hydrogen peroxide was reduced to water. Under those circumstances, the net reaction is the oxygen-dependent oxidation of NADH with the production of NAD^+ and water. The NADH-2 from *Bacillus* YN-1 has now been shown to have similar properties to the *A. xylanus* enzyme, and there is an AhpC candidate upstream (Koyama et al., 1998). Thus NDH-2, as well as catalases, may be part of a detoxification system.

Studies of cyanide-sensitivity of oxygen reduction by obligately alkaliphilic *Bacillus* YN-1 (Higashibata et al., 1998) have indicated that the cyanide-sensitive component that is attributed to the *caa*$_3$-type terminal oxidase represents only 10% of the total. The majority, a cyanide-insensitive component, was associated with a low-molecular-weight nonproteinaceous material that has not been completely characterized. The investigators propose a model of alkaliphile respiration in which this cyanide-insensitive terminal respiratory component, in concert with catalase, is of major importance in the respiratory mechanisms.

Respiration-Dependent ATP Synthesis

Perhaps in the haloalkaliphilic Archaea, with primary light-driven pumps and unusual mem-

brane lipids, very high transmembrane electrical potentials are generated to offset the δpH (acid in) that alkaliphiles maintain. In the alkaliphilic aerobic *Bacillus* species, however, oxidative phosphorylation presents a clear conundrum, which relates to the higher total chemiosmotic driving force for a proton-coupled process, the electrochemical proton gradient or δp, at pH 7.5 than at pH 10.5. Most measurements (Hirota and Imae, 1983; Sturr et al., 1994) indicate that at the lower pH, the δp is about 3-times the magnitude of that at pH 10.5. Yet the phosphorylation potential, proportional to [ATP]/[ADP][Pi], which reflects the ATP sustained at equilibrium, is greater at pH 10.5 than at pH 7.5 (Fig. 5, right). While Hoffmann and Dimroth, 1991b have calculated somewhat lower discrepancies, their data on ATP synthesis by *B. alcalophilus* nonetheless show clearly better synthesis at higher pH values where the δp is lower than at near neutral pH values. Moreover, unlike motility and solute symport systems, ATP synthesis by alkaliphilic *Bacillus* species such as *B. alcalophilus* and *B. pseudofirmus* OF4 does not "avoid" the problem of the low electrochemical proton gradient, δp, by using a larger electrochemical Na^+ gradient instead. The F1FO-ATP synthases of these organisms were purified and functionally reconstituted into proteoliposomes (Hicks and Krulwich, 1990; Hoffmann and Dimroth, 1991) and shown to be H^+- and not Na^+-coupled. Thus while there do exist Na^+-coupled ATP synthases in several anaerobic marine organisms (Kluge et al., 1992; Forster et al., 1995), the alkaliphilic *Bacillus* species have not elected that solution. Yet they grow at high molar growth yields on non-fermentative substrates. This suggests that ATP synthesis either operates with a variable coupling stoichiometry, or that it operates well out of equilibrium with the bulk δp because some sort of proton sequestration or other basis for disequilibrium exists. The possibility of a variable stoichiometry merits ongoing consideration and has been proposed for H^+-coupled synthesis of ATP in cyanobacteria (Krenn et al., 1993; Van Walraven et al., 1997). In the alkaliphilic *Bacillus* species, though, the conundrum is further delineated by the observation that respiration-dependent ATP synthesis proceeds well at pH values above about 9, only when respiration itself is the energy source (i.e., artificially imposed gradients of the same magnitude are not efficacious; Guffanti et al., 1984; Guffanti and Krulwich, 1992; Guffanti and Krulwich, 1994; Ivey et al., 1998). This would not be expected if a variable stoichiometry could be employed. Moreover, Ivey et al., 1994 presented data that supportthe actuality of one ATP synthase assembly with an invariant subunit stoichiometry in *B. pseudofirmus* OF4.

A variety of sequestration models also merit consideration. Although discrete organelles of various sorts were suggested (Skulachev, 1991), fine structural evidence does not support the presence of pronounced organelles (Rhode et al., 1989; Sturr et al., 1994). Alternatives that are schematically suggested in Fig. 6, include some help from trapping of protons by cell-wall-associated polymers; however, the parameters of oxidative phosphorylation are present in right-side-out membrane vesicles that lack peptidoglycan assemblies (Guffanti and Krulwich, 1994) and oxidative phosphorylation is not restricted at least in *B. pseudofirmus* OF4, mutants lacking the S-layer (Gilmour et al., manuscript submitted). Protons might also be sequestered by being transferred from a proton-pumping respiratory chain complex, such as the caa3-type oxidase shown in Fig. 6, during a direct protein-protein interaction in the near membrane region of the phospholipid headgroups (Krulwich, 1995). Alternatively, protons might move rapidly along the surface as has been observed in some experimental systems (reviewed by Gutman and Nachliel, 1995). Such translocation, however, should be sensitive to ionic strength, which was not the case for oxidative phosphorylation by ADP and phosphate (Pi)-loaded right-side-out vesicles of *B. pseudofirmus* OF4 (Guffanti and Krulwich, 1994). It is notable that features, referred to as "alkaliphile-specific sequence motifs," have been found in important membrane-associated regions of FO subunits of several alkaliphilic *Bacillus* species (Ivey and Krulwich, 1991, Ivey and Krulwich, 1992; Krulwich et al., 1998). Thus one of the interesting experimental approaches that can be used to test various hypotheses in connection with the energization of alkaliphile oxidative phosphorylation is to alter these motifs and determine whether synthesis is particularly affected at highly alkaline pH.

Why Do Alkaliphiles Generally Grow Poorly or Fail to Grow at Near Neutral pH?

There are several indications that the alkaliphiles with the very highest upper edge or highest pH optimum for growth also may be obligate alkaliphiles that cannot grow at pH values much below 9 or 9.5. However, this conjecture has not been examined rigorously in carefully pH-controlled continuous culture conditions. In batch cultures, for example, Dunkley et al., 1991 noted that an obligate alkaliphile "outcompeted" a closely related facultative alkaliphile at pH 10.5. The putative inverse

relationship between maximally effective alkaliphily and the ability to thrive at conventional pH values can be viewed as adaptations that foster growth at the extreme but are disabling at lower pH values ("inverse adaptiveness"). Alternatively, the adaptation to high pH may not be directly injurious at lower pH values but constitute an energy cost that compromises growth ("irrelevant cost"). Or, growth at near-neutral pH may elicit essentially a "stress response" among those alkaliphiles that are maximally adapted to optimal growth at highly alkaline pH; some of the consequent shutdown, which is then manifest as a poorer growth rate, could be seen as a stress adaptation ("neutral pH as stress"). Possible examples of each of these may be found in connection with the cell surface. An example of the "inverse adaptiveness" scenario would be the hypothesis (Clejan et al., 1986; Clejan et al., 1988; Dunkley et al., 1991) that obligate alkaliphilic *Bacillus* strains have bulky branched-chain and unsaturated fatty acids that are adaptive for growth at the upper edges of their pH range but which render the membrane unstable at neutral pH. A possible example of the "irrelevant cost" hypothesis is the finding that the deletion of the S-layer gene from *B. pseudofirmus* OF4 causes a modest growth rate reduction and a correspondingly moderate compromise of pH homeostasis at pH 10.5 but increases the growth rate at pH 7.5 (Gilmour et al. manuscript submitted). A possible example of the "neutral pH as stress" scenario is autolysin activation in *B. halodurans* C-125 at the low end of its pH range for growth (Aono and Sanada, 1994).

Industrial Applications

Enzymes

Horikoshi (1991), (1996) has surveyed the applications of alkaliphiles in industrial processes, and Ito et al., 1998 have reviewed the alkaliphile enzymes that have been specifically used in laundry and dishwashing detergents. A major application of alkaliphile hydrolases, especially those that are also thermotolerant, is in laundry mixes that have alkaline pH. The recognition that these enzymes are useful fostered the rapid growth of information about alkaliphile proteases, in particular, but also of numerous additional hydrolases, including lipases, cellulases and pullulanases. Each of these classes of enzymes have other uses, such as the proteases in dehairing processes (Horikoshi, 1996) and in the degradation of gelatin-containing X-ray films for silver recapture (Fujiwara et al., 1991).

Pullulanases and amylases also have had applications in other settings (e.g., the food industry). Alkaliphilic amylases and pullulanases have been isolated from numerous alkaliphiles, even including a haloalkaliphilic amylase from *Natronococcus* (Kobayashi et al., 1994). Alkaliphilic *Bacillus* sp. strain KSM-1378 was found to produce an alkaline amylopullulanase that has two independent active sites for the individual reactions (Ara et al., 1995). In some of the food industry applications, cold-adapted rather than heat-adapted enzymes are more useful, and such enzymes have accordingly been sought (Kimura and Horikoshi, 1990).

Environmental concerns have created pressure to minimize the chlorine-intense processes used to bleach alkali-treated wood pulp. This, in turn, has encouraged the search for thermostable, alkaline xylanases that could substitute for the chemical process. Numerous xylanases have been characterized from alkaliphiles some of which were produced as exoenzymes and had desirable properties vis à vis the bleaching process, such as no cellulase activity (Nakamura et al., 1993; Nakamura et al., 1994; Blanco et al., 1995). Recent xylanase-producing alkaliphilic or alkalitolerant prokaryotes have been isolated from geothermal enrichments (Dimitrov et al., 1997; Lopez et al., 1998; Sunna et al., 1997). Horikoshi, 1991 also has noted reports of alkaliphilic enzymes that were being developed for possible use in the lignin-degradation processes that are important in pulping.

Pectinases have been isolated from alkaliphiles and evaluated for use in fruit and vegetable processing industries, including the degradation of pectin in wastewater from such industries; some efficacy of these enzymes has been reported for these uses as well as for the retting process involved in production of Japanese paper (see Horikoshi, 1991). Recently, a pectate lyase, designated Pel-7, was purified from alkaliphilic *Bacillus* sp. strain KSM-P7 and characterized as a thermostable, highly alkaline enzyme (Kobayashi et al., 1999).

Cyclomaltodextrin glucanotransferases (CGTases) produce cyclodextrins, which are homogeneous cyclic oligosaccharides, from starch. Cyclodextrins are used in industrial preparations of foods, pharmaceuticals and other chemicals. The application of CGTases from alkaliphiles has been an important application of alkaliphile enzymes (Horikoshi, 1991).

Antibiotic Production or Screening, Biotransformations

Many conventional antibiotics are unstable at very alkaline pH values, but it is nonetheless possible that the alkaliphiles themselves (e.g., alka-

liphilic *Bacillus* or actinomycetes) will produce alkali-stable antimicrobials. Among the published reports of such work are compounds isolated from alkaliphilic soil isolates (Sato et al., 1980; Tsujibo et al., 1992). It might be of particular interest to examine whether soda lake organisms, whose environment is more consistently and extremely alkaline, produce antibiotics. Since biological productivity is high, the capacity to produce antibiotics may well confer competitive advantage, and those antibiotics might have novel features of interest.

As noted by Hsieh et al., 1998 in connection with Staphylococcus aureus mutants that lack a major multidrug efflux pump, even wild type cells will exhibit a 15- to 60-fold increase in sensitivity to antimicrobials at an alkaline pH that favors accumulation of cations and weak bases. Thus alkaliphiles are particularly susceptible to inhibition by toxic cations and weak bases and might offer a way to detect small quantities of such antibiotic substances in impure test samples unless the organisms are equipped with correspondingly high activity, multidrug efflux protection. The completion of the *Bacillus halodurans* C-125 sequence may clarify whether the latter adaptation is likely.

Paavilainen and colleagues (Paavilainen et al., 1994; Paavilainen et al., 1995) have studied the dynamics of growth-induced changes in the medium pH and organic acid production by different alkaliphilic *Bacillus* species and have begun to characterize properties associated with alkaliphile catabolic patterns. When complete, the sequence of the *B. halodurans* C-125 genome may well provide clues for biotransformative and/or bioremediation capacities that will be of interest. Some heavy metal resistance determinants have been identified, for example, in alkaliphilic *B. pseudofirmus* OF4 (Ivey et al., 1992). Kimura et al., 1994 used a newly isolated alkaliphilic *Bacillus* to achieve conversions of hydroxyls of cholic acid to keto groups, in various combinations and at high yield.

Conclusions

Fossil evidence suggests that extremely alkaliphilic bacteria probably were part of an ancient group of prokaryotes that evolved in natural enrichments. An enormous diversity exists among alkaliphiles. Thus, there may be a corresponding diversity in the alkaline adaptations both in presently existing soda lakes alkaliphiles and in the widespread alkaliphiles that may now be found even in apparently nonselective settings. Much of the exploitation of a considerable industrial potential and most of the studies of fundamental physiological adaptations have focused on alkaliphilic *Bacillus* species. The current trend of increasing inclusion of haloalkaliphilic archaea and different anaerobic alkaliphiles in these efforts is salutory. Much has been learned about the major features of pH homeostasis, motility, membrane transport, cell structure, protein adaptation to high pH, and conundrums such as oxidative phosphorylation; but each finding has also provoked new and interesting questions for which the contemporary explosion of genomics, and novel ecological, molecular, structural and biophysical approaches will provide the basis for new understanding and applications for alkaliphilic prokaryotes.

Acknowledgments. Work from the author's laboratory was supported in part by research grants GM28454 from the National Institutes of Health and DE-FG0286ER13559 from the Department of Energy. I am grateful to many colleagues in my laboratory and from other laboratories for sharing ideas and questions. I especially wish to express my appreciation to Arthur Guffanti, David Hicks, and Yi Wei, of Mount Sinai School of Medicine, and Masahiro Ito, of Tokyo University.

CHAPTER 1.11

Syntrophism among Prokaryotes

BERNHARD SCHINK AND ALFONS J. M. STAMS

Introduction: Concepts of Cooperation in Microbial Communities, Terminology

The study of pure cultures in the laboratory has provided an amazingly diverse diorama of metabolic capacities among microorganisms, and has established the basis for our understanding of key transformation processes in nature. Pure culture studies are also prerequisites for research in microbial biochemistry and molecular biology. However, desire to understand how microorganisms act in natural systems requires the realization that microorganisms don't usually occur as pure cultures out there, but that every single cell has to cooperate or compete with other micro- or macroorganisms. The pure culture is, with some exceptions such as certain microbes in direct cooperation with higher organisms, a laboratory artifact. Information gained from the study of pure cultures can be transferred only with great caution to an understanding of the behavior of microbes in natural communities. Rather, a detailed analysis of the abiotic and biotic life conditions at the microscale is needed for a correct assessment of the metabolic activities and requirements of a microbe in its natural habitat.

In many cases, relationships of bacteria with other organisms may be relatively unimportant, as appears to be the case with most aerobes: they can usually degrade even fairly complex substrates to water and carbon dioxide without any significant cooperation with other organisms. Nutritional cooperation may exist, but may be restricted to the transfer of minor growth factors, such as vitamins, from one organism to the other. However, we have to realize that this assumption is based on experience gained from pure cultures that were typically enriched and isolated in simple media, and the selection aimed at organisms that were easy to handle, independent of possible interactions with others. Estimations assume that we know only a small fraction of the microorganisms present in nature, perhaps 0.1–1.0%. Thus, we cannot exclude that other bacteria out there might depend to a large extent on cooperation with partner microbes, and perhaps this is just one of the reasons why we failed so far to isolate them.

Anaerobic microorganisms, on the other hand, depend to a great extent on the cooperation of several metabolic types of bacteria in feeding chains. The complete conversion of complex organic matter, e.g., cellulose, to methane and carbon dioxide in a lake sediment is catalyzed by the concerted action of at least four different metabolic groups of bacteria, including primary fermenters, secondary fermenters, and at least two types of methanogenic archaeobacteria (Bryant, 1979; McInerney, 1988; Stams, 1994; Schink, 1991; Schink, 1997). The degree of mutual dependence among these different metabolic groups ("functional guilds") can vary considerably; whereas the latter members in the feeding line always depend on the former ones for substrate supply, they may also influence significantly the former chain members by removal of metabolic products. In an extreme case, this can mean that the fermenting bacterium depends entirely on cooperation with a methanogen to fulfill its function in, e.g., methanogenic fatty acid oxidation. This type of cooperation is called "syntrophic."

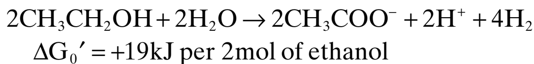
Mutual metabolic dependencies also can emerge from the cooperation of phototrophs with sulfur- or sulfate-reducing bacteria. Sulfur-reducing, acetate-oxidizing, chemotrophic bacteria such as *Desulfuromonas acetoxidans* and phototrophic green sulfide-oxidizing bacteria like *Chlorobium* sp. can cooperate closely in a phototrophic conversion of acetate plus CO_2 to bacterial cell mass, using a sulfide/sulfur cycle as an electron shuttle system between both. The two partners cooperate very closely also in this system for which the term "syntrophy" was originally coined (Biebl and Pfennig, 1978).

Syntrophy is a special case of symbiotic cooperation between two metabolically different types of bacteria which depend on each other for degradation of a certain substrate, typically

through transfer of one or more metabolic intermediate(s) between the partners. The pool size of the shuttling intermediate has to be kept low to allow efficient cooperation.

The term "syntrophy" should be restricted to those cooperations in which partners depend on each other to perform the metabolic activity observed and in which the mutual dependence cannot be overcome by simply adding a cosubstrate or any type of nutrient. A classical example is the "*Methanobacillus omelianskii*" culture (Barker, 1940), which was later shown to be a coculture of two partner organisms, the S strain and the strain M.o.H. (Bryant et al., 1967). Both strains cooperate in the conversion of ethanol to acetate and methane by interspecies hydrogen transfer, as follows:

Strain S:



$$2CH_3CH_2OH + 2H_2O \rightarrow 2CH_3COO^- + 2H^+ + 4H_2$$
$$\Delta G_0{}' = +19 \text{kJ per 2mol of ethanol}$$

Strain M.o.H.

$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$$
$$\Delta G_0{}' = -131 \text{kJ per mol of methane}$$

Corulture:

$$2CH_3CH_2OH + CO_2 \rightarrow 2CH_3COO^- + 3H^+ + CH_4$$
$$\Delta G_0{}' = -112 \text{kJ per mol of methane}$$

Thus, the fermenting bacterium cannot be grown with ethanol in the absence of the hydrogen-scavenging partner organism because it carries out a reaction that is endergonic under standard conditions. The first reaction can occur and provide energy for the first strain only if the hydrogen partial pressure is kept low enough ($<10^{-3}$ bar) by the methanogen. Therefore, neither partner can grow with ethanol alone, and the degradation of ethanol depends on the cooperating activities of both.

We avoid in this article the term "consortium" which is quite often used to describe any kind of enrichment cultures cooperating in whatever way. This term was originally coined for the structured phototrophic aggregates *Pelochromatium* and *Chlorochromatium* etc. and should be restricted to such spatially well-organized systems (Pfennig, 1980; Overmann, 2001).

Electron Flow in Methanogenic and Sulfate-Dependent Degradation

The degradation of complex organic matter to methane and CO_2 is a process widespread in anoxic environments which receive only a limited supply of oxygen, nitrate, sulfate, or oxidized iron or manganese species. Methanogenesis is the typical terminal electron-accepting process in freshwater sediments rich in organic matter, in swamps or water-logged soils such as rice paddies, or in anaerobic wastewater and sewage treatment plants. It is also an important process in fermentations occurring in the intestinal tract of animals, especially of ruminants. Methanogenic degradation is the least exergonic process in comparison to aerobic degradation or the alternative anaerobic respiration. Conversion of hexose to methane and carbon dioxide releases only 15% of the energy that would be available in aerobic degradation, and this small energy yield of methanogenic degradation may be the reason why methanogenensis is the last one to occur, after the other electron acceptors have been reduced.

The carbon and electron flow in methanogenic degradation of complex organic matter follows a rather simple pattern. Polymers (polysaccharides, proteins, nucleic acids, and also lipids) are first converted to oligo- and monomers (sugars, amino acids, purines, pyrimidines, fatty acids, and glycerol), typically through the action of extracellular hydrolytic enzymes. These enzymes are produced by the "classical" primary fermenting bacteria which ferment the monomers further to fatty acids, branched-chain fatty acids, succinate, lactate, alcohols, aromatic acids, etc. (group 1; Fig. 1). Some of these fermentation products, such as acetate, H_2, CO_2 and other one-carbon compounds, can be used directly by methanogens which convert them to methane and carbon dioxide (groups 2 and 3; Fig. 1). For methanogenic degradation of other fermentation products, e.g., fatty acids longer than two carbon atoms, alcohols longer than one carbon atom, branched-chain and aromatic fatty acids, a further group of fermenting bacteria, the so-called "secondary fermenters" or "obligate proton reducers" (group 4; Fig. 1) is needed. These bacteria convert their substrates to acetate, carbon dioxide, hydrogen, perhaps also formate, which are subsequently used by the methanogens.

The situation is slightly different in sulfate-rich anoxic habitats such as marine sediments. There, the primary processes of polymer degradation are carried out by primary fermenting bacteria which form the classical fermentation products. Different from methanogens, sulfate-reducing bacteria are metabolically versatile, and a broad community of sulfate reducers can use all products of primary fermentations, and oxidize them to carbon dioxide, simultaneously reducing sulfate to sulfide (Widdel, 1988). As a consequence, the complete oxidation of complex organic matter to carbon dioxide with simultaneous sulfate reduction proceeds in a two-step process and does not depend on syntrophic fermentations. One might add that this two-step scheme might be augmented also by cooperative sidepaths taken by different types of sulfate-reducing bac-

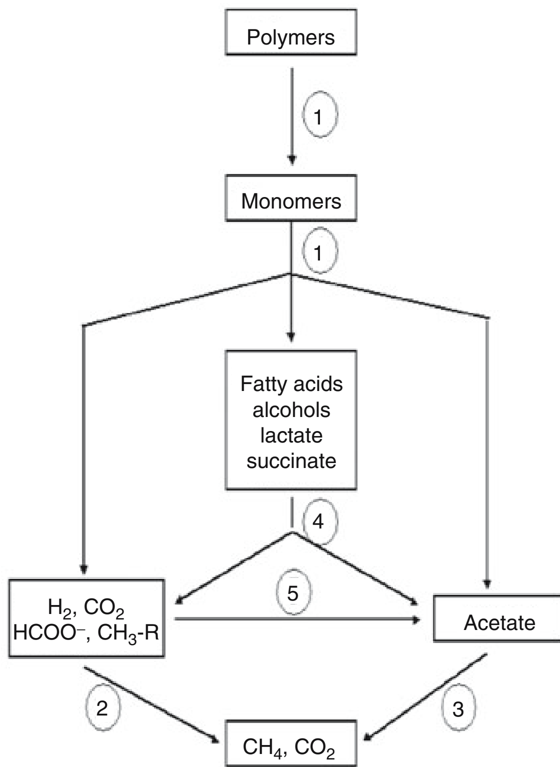


Fig. 1. Carbon and electron flow in the methanogenic degradation of complex organic matter. Groups of prokaryotes involved: 1) primary fermentative bacteria; 2) hydrogen-oxidizing methanogens; 3) acetate-cleaving methanogens; 4) secondary fermenting bacteria (syntrophs); and 5) homoacetogenic bacteria.

teria, e.g., completely and incompletely oxidizing ones (Küver and Widdel, 2001), but such cooperative activities are not required for complete sulfate-dependent oxidation of organic matter.

In methanogenic and sulfate-rich environments, the primary fermenting bacteria (group 1) profit from the activities of the hydrogen-oxidizing partners at the end of the degradation chain as well. A low hydrogen partial pressure ($<10^{-4}$ bar) allows electrons at the redox potential of NADH (–320 mV) to be released as molecular hydrogen, and fermentation patterns can shift to more acetate, CO_2, and hydrogen production rather than to ethanol or butyrate formation, thus allowing additional ATP synthesis via substrate-level phosphorylation, as opposed to production of reduced fermentation products (ethanol, lactate and butyrate). Thus, such fermenting bacteria may profit from hydrogen-oxidizing partners, but they do not depend on such cooperation.

In a well-balanced anoxic sediment in which an active hydrogen-utilizing community maintains a low hydrogen partial pressure, the flux of carbon and electrons goes nearly exclusively through the "outer" paths of the electron flow scheme (Fig. 1), and therefore reduced fermentation intermediates play only a minor role. Nonetheless, the flux through the "central" paths will never become zero because long-chain and branched-chain fatty acids and others are always produced in the fermentation of lipids, and amino acids as well. The reduced intermediates of the central path become more important if the hydrogen pool increases for any reason, e.g., excess supply of fermentable substrate, inhibition of hydrogenotrophic methanogens due to a drop in pH (<6.0), or to the presence of toxic compounds, etc. Under such conditions, the pools of fatty acids increase and might even shift the pH further downwards, thus inhibiting the hydrogenotrophic methanogens even further. The consequence may be that the whole system "turns over," meaning that methanogenesis ceases entirely and the fermentation stops with accumulation of huge amounts of foul-smelling fatty acids, as this is encountered with ill-balanced anaerobic sewage digestors. Obviously, the hydrogen/formate-utilizing methanogens act as the primary regulators in the total methanogenic conversion process (Bryant, 1979; Zehnder, 1978; Zehnder et al., 1982), and the syntrophically fatty acid-oxidizing bacteria are affected most severely by a failure in methanogenic hydrogen or formate removal.

The function of homoacetogenic bacteria (group 5; Fig. 1) in the overall process is less well understood. They connect the pool of one-carbon compounds and hydrogen with that of acetate. Owing to their metabolic versatility, they can participate also in sugar fermentation and degradation of special substrates such as *N*-methyl compounds or methoxylated phenols (Schink, 1994). In certain environments, e.g., at lower pH or low temperature, they may even successfully compete with hydrogenotrophic methanogens and take over their function to a varying extent (see below).

Energetic Aspects

Anaerobes grow with small amounts of energy, and syntrophically cooperating anaerobes are extremely skilled in the exploitation of minimal energy spans. Synthesis of ATP as the general currency of metabolic energy in living cells requires +32 kJ per mol at equilibrium under standard conditions; under the conditions assumed to prevail in an actively growing cell ([ATP] = 10 mM; [ADP] = 1 mM; and [P_i] = 10 mM), +49 kJ per mol is required (Thauer et al., 1977). In addition, part of the total energy

budget is always lost in irreversible reaction steps as heat, thus rendering the overall metabolic process irreversible. This heat loss (on average about 20 kJ per mol ATP) has to be added to the above value, which gives a total of about 70 kJ per mol ATP synthesized irreversibly in the living cell. This is the minimum amount of energy required for the synthesis of one mol of ATP in all known metabolic systems (Schink, 1990). One may argue that (especially under conditions of energy limitation) an organism may waste less energy in heat production, or that it may operate at an energy charge considerably lower than that quoted above for well-growing *Escherichia coli* cells. Nonetheless, one cannot expect the energy requirement for irreversible ATP synthesis to go substantially below about +60 kJ per mol.

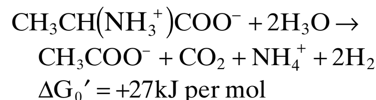
The key postulate of the Mitchell theory of respirative ATP synthesis is that ATP formation is coupled to a vectorial transport of charged groups, typically protons, across a semipermeable membrane (Mitchell, 1966). For several years, it was widely accepted that three protons cross the membrane (either of bacteria or mitochondria) per ATP hydrolyzed. As a consequence, the smallest quantum of metabolically convertible energy is that of an ion transported across the cytoplasmic membrane, equivalent to one third of an ATP unit. Combined with the calculations above, this means that a bacterium needs a minimum of about –20 kJ per mol reaction to exploit a reaction's free energy change (Schink and Thauer, 1988; Schink, 1990).

On the basis of studies on the structure and function of F_1-F_0 ATPases in recent years, the stoichiometry of ATP synthesis versus proton translocation appears not to be as strictly fixed as suggested above. Rather, the system may operate like a sliding clutch, meaning that at very low energy input, the energy transfer into ATP synthesis may be substoichiometric. Moreover, the stoichiometry is not necessarily three protons per one ATP, but is governed by the number of subunits arranged in the F_0 versus the F_1 complex. This concept would allow also stoichiometries of 4 to 1, perhaps even 5 to 1 (Engelbrecht and Junge, 1997; Cherepanov et al., 1999; Stock et al., 1999; Dimroth, 2000; Seelert et al., 2000). As a consequence, the minimum energy increment that can still be used for ATP synthesis may be as low as −15 or −12 kJ per mol reaction. In some cases, to make their living, bacteria cooperating in syntrophic fermentations are limited to this range of energy; Hoehler et al. (2001) calculated from metabolite concentrations in natural habitats for the partner bacteria cooperating in syntrophic conversions minimum amounts of exploitable energy in the range of −10 to −19 kJ per mol reaction.

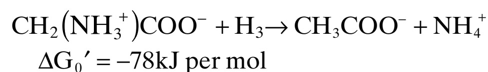
Degradation of Amino Acids

During protein hydrolysis, a complex mixture of amino acids and small peptides is produced. These amino acids and peptides can serve as energy substrates for anaerobic microorganisms. Detailed information on the anaerobic fermentation of amino acids can be found in Barker (1981) and McInerney (1988). Many anaerobic amino acid-degrading bacteria require complex mixtures of amino acids, perhaps because a one-sided diet causes a serious imbalance in the internal amino acid metabolism of these cells, but growth by fermentation of single amino acids is also common. Mixtures of amino acids are often degraded by coupled fermentation of pairs of amino acids via the Stickland reaction. Table 1 summarizes some oxidative conversions of amino acids. In the classical Stickland fermentation, these oxidation reactions are coupled within the same organism to reduction of other amino acids such as glycine or proline. Also phenylalanine, leucine, or compounds like sarcosine and betaine (Naumann et al., 1983; Gottschalk, 1986) can act as electron acceptors, and oxidation of leucine coupled to the reduction of acetate to butyrate has been described as well (Girbal et al., 1997).

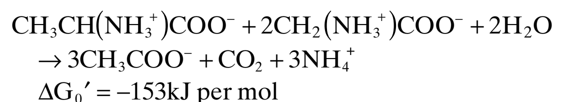
These pure culture fermentations can also be catalyzed by cooperation of two different bacteria via interspecies hydrogen transfer, according to the following reactions with a mixture of alanine and glycine:



$$CH_3CH(NH_3^+)COO^- + 2H_3O \rightarrow CH_3COO^- + CO_2 + NH_4^+ + 2H_2 \quad \Delta G_0' = +27 \text{kJ per mol}$$



$$CH_2(NH_3^+)COO^- + H_3 \rightarrow CH_3COO^- + NH_4^+ \quad \Delta G_0' = -78 \text{kJ per mol}$$



$$CH_3CH(NH_3^+)COO^- + 2CH_2(NH_3^+)COO^- + 2H_2O \rightarrow 3CH_3COO^- + CO_2 + 3NH_4^+ \quad \Delta G_0' = -153 \text{kJ per mol}$$

Thus, the electrons derived in amino acid degradation by a fermenting bacterium can be used in glycine reduction as shown, but can be transferred as well in the form of molecular hydrogen to sulfate-reducing, homoacetogenic or methanogenic partner bacteria, depending on the availability of such partner bacteria and their respective electron acceptors. That amino acid oxidation and glycine reduction can be uncoupled from each other has been shown in detail with *Eubacterium acidaminophilum* (Zindel et al., 1988). This bacterium can run either one of the first two reactions separately or combine them on its own, according to the third reaction, depending on the partner bacteria which act as hydrogen sources or sinks, and on the availability

Table 1. Changes of Gibbs free energies under standard conditions in hydrogen-releasing reactions during fermentation of amino acids.

Fermentation reaction	$\Delta G_0'$ (kJ per mol rct.)
Alanine + $2H_2O \rightarrow$ acetate$^-$ + CO_2 + NH_4^+ + $2H_2$	+2.7
Glycine + $2H_2O$ + H^+ $\rightarrow$ $2CO_2$ + NH_4^+ + $3H_2$	+17.8
Serine + $H_2O \rightarrow$ acetate$^-$ + CO_2 + NH_4^+ + H_2	–85.3[a]
Threonine + $H_2O \rightarrow$ propionate$^-$ + CO_2 + NH_4^+ + H_2	–83.0[a]
Histidine + $4H_2O$ + H^+ $\rightarrow$ glutamate$^-$ + CO_2 + $2NH_4^+$ + H_2	[b]
Proline + $2H_2O \rightarrow$ glutamate$^-$ + H^+ + $2H_2$	[b]
Glutamate$^-$ + $2H_2O$ + H^+ $\rightarrow$ propionate$^-$ + $2CO_2$ + NH_4^+ + $2H_2$	–16.6
Glutamate$^-$ + $2H_2O \rightarrow$ 2 acetate$^-$ + CO_2 + NH_4^+ + H_2	–38.6[a]
Aspartate$^-$ + $2H_2O$ + H^+ $\rightarrow$ acetate$^-$ + $2CO_2$ + NH_4^+ + $2H_2$	–24.1

[a]These fermentations may also allow growth in pure culture.
[b]These reactions are always coupled to further fermentation of glutamate.
All calculations are based on published tables (see Thauer et al., 1977; Dimroth, 1983). For H_2S and CO_2, values for the gaseous state were used.

of selenium in the medium which is required for expression of the active glycine reductase complex.

In methanogenic environments, methanogens can act as scavengers of reducing equivalents in the oxidation of amino acids, thus taking over the role of the reductive part of the Stickland reaction. Nagase and Matsuo (1982) observed that in mixed methanogenic communities, the degradation of alanine, valine and leucine was inhibited when methanogens were inhibited. Nanninga and Gottschal (1985) could stimulate the degradation of these amino acids by addition of hydrogen-scavenging sulfate-reducers. These early observations indicated a functional role for hydrogen consumption also in the degradation of amino acids.

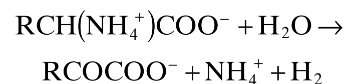
Influence of Methanogens

Methanogens can affect anaerobic oxidation in various ways. Fermentative oxidation of some amino acids can be coupled to hydrogen formation only if the hydrogen partial pressure is kept low, similar to the "*Methanobacillus omelianskii*" example described above. This results in an obligately syntrophic relationship between the fermenting microorganism and the methanogen. Some amino acids are degraded by the same fermenting bacterium either in pure culture or in mixed culture with methanogens; however, methanogens can cause a shift in metabolism resulting in a changed product formation pattern.

Clostridium sporogenes (Wildenauer and Winter, 1986; Winter et al., 1987), *Eubacterium acidaminophilum* (Zindel et al., 1988), *Acidaminobacter hydrogenoformans* (Stams and Hansen, 1984), *Aminomonas paucivorans* (Baena et al., 1999a), *Aminobacterium colombiense* and *Aminobacterium mobile* (Baena et al., 1998; Baena et al., 2000), as well as strain PA-1 (Barik et al., 1985) are mesophilic bacteria which degrade one or more amino acids in syntrophic association with hydrogen-consuming anaerobes. Moderately thermophilic bacteria include *Caloramator coolhaasii* (Plugge et al., 2000), *Caloramator proteoclasticus* (Tarlera et al., 1997; Tarlera and Stams, 1999), *Thermanaerovibrio acidaminovorans* (previously named *Selenomonas acidaminovorans*; Cheng et al., 1992; Baena et al., 1999b), *Gelria glutamica* (Plugge et al., 2002) and *Clostridium* P2 (Øygsson et al., 1993; Øygsson, 1994). There are probably many other fermenting bacteria with the ability to grow syntrophically with certain amino acids and to release reducing equivalents as molecular hydrogen; however, such capacities are only rarely checked.

Obligately Syntrophic Amino Acid Deamination

The initial step in the oxidative degradation of alanine, valine, leucine and isoleucine is an NAD(P)-dependent deamination to the corresponding α-keto acid, and the reaction, if coupled to reoxidation of NAD(P)H by proton reduction, would read as follows:



$$RCH(NH_4^+)COO^- + H_2O \rightarrow RCOCOO^- + NH_4^+ + H_2$$

The $\Delta G_0'$ of this reaction is about +55 kJ per mol; thus, very efficient hydrogen consumption would be required to pull this reaction. The α-keto acid is converted further via oxidative decarboxylation to a fatty acid:

$$RCOCOO^- + H_2O \rightarrow RCOO^- + CO_2 + H_2$$

a reaction which is much more favorable ($\Delta G_0'$ about –52 kJ per mol). Therefore, it is not surprising that one does not observe bacteria catalyzing the first reaction step only, and that the organisms involved—as far as they have been tested—can grow in pure culture with α-keto

acids. Such α-keto acids were used successfully for the isolation of amino acid-degrading proton-reducing bacteria (Stams and Plugge, 1990). Conversion of the keto acids to the corresponding fatty acids likely proceeds through energy-rich CoA and phosphate derivatives, thus allowing ATP synthesis via substrate-level phosphorylation.

Eubacterium acidaminophilum degrades aspartate to acetate in syntrophic association with methanogens (Zindel et al., 1988). The degradation pathway is not known. Aspartate is either oxidized directly to oxaloacetate by means of an aspartate dehydrogenase or is degraded first to fumarate by aspartase activity. Fumarate is then converted to malate which is subsequently oxidized to oxaloacetate. In this pathway, the conversion of malate to oxaloacetate plus H_2 is most unfavorable; the $\Delta G_0'$ is +48 kJ per mol. Recently, a moderately thermophilic sugar-fermenting bacterium, *Gelria glutamica*, was isolated which can grow also by the analogous conversion of glutamate to propionate, provided that the hydrogen partial pressure is kept low by a methanogen (Plugge et al., 2002). In this bacterium, glutamate is first oxidatively deaminated to α-ketoglutarate, which is subsequently oxidatively decarboxylated to succinyl-CoA and further to propionate (Plugge et al., 2001). In coculture with methanogens, it is also able to oxidize proline to propionate. This is remarkable because proline is generally thought to be reductively degraded to aminovalerate. Similar to the above-mentioned amino acids, the aromatic amino acids phenylalanine, tryptophan and tyrosine might also support growth by oxidative deamination leading to phenylacetate, indolylacetate, *p*-hydroxyphenylacetate, respectively, as products. This, however, has not yet been demonstrated for syntrophic amino acid-degrading bacteria.

Syntrophic Arginine, Threonine and Lysine Fermentation

Acidaminobacter hydrogenoformans, *Aminomonas paucivorans* and *T. acidaminovorans* can grow with histidine, ornithine, arginine, lysine and threonine when cocultured with hydrogenotrophic bacteria (Stams and Hansen, 1984; Cheng et al., 1992; Baena et al., 1999a). Remarkably, *T. acidaminovorans* and *A. paucivorans* grow in pure culture with arginine, forming citrulline and/or ornithine as products. In this conversion, carbamyl phosphate is formed as an intermediate, which is further converted to yield ATP (Plugge and Stams, 2001). Ornithine and citrulline could be degraded when these bacteria were cocultured with a hydrogenotrophic methanogen. It is not clear which pathway is used for ornithine degradation, and which metabolic step is hampering growth of these bacteria in pure culture.

Acidaminobacter hydrogenoformans degrades threonine and lysine in syntrophic association with a hydrogen-consuming anaerobe. Acetate is the main product of the degradation of these two amino acids, and large amounts of hydrogen are formed. In pure culture, these compounds do not support growth. The stoichiometry of the fermentation is not exactly known, and the pathways involved in these fermentations have not been resolved as yet.

Facultatively Syntrophic Growth with Amino Acids

The effect of methanogens on the metabolism of amino acid-fermenting anaerobes has been studied most extensively with glutamate. Glutamate fermentation is carried out by a variety of fastidious anaerobes, including a number of *Clostridium* species, *Peptostreptococcus asaccharolyticus*, and *Acidaminococcus fermentans* (Gottschalk, 1986). These microorganisms ferment glutamate to acetate and butyrate by two different pathways, the β-methylaspartate or the hydroxyglutarate pathway (Buckel and Barker, 1974). In this fermentation, reducing equivalents formed in the oxidation of glutamate to acetate are disposed of either partly or completely by reductive formation of butyrate from acetate (acetyl-CoA).

Anaeromusa acidaminophila ("*Selenomonas acidaminophila*") ferments glutamate to acetate plus propionate (Nanninga et al., 1987; Baena et al., 1999b). In this bacterium, reducing equivalents are disposed of by reduction of pyruvate to propionate. However, in the last decade, several bacteria have been isolated which during growth on glutamate release reducing equivalents exclusively as hydrogen, both in the formation of acetate and the formation of propionate (Table 1). These microorganisms ferment glutamate to acetate only (*Caloramator coolhaasii* [Plugge et al., 2000] and *Caloramator proteoclasticus* [Tarlera and Stams, 1999]), propionate only (*Aminobacterium colombiense* [Baena et al. 1998] and *Gelria glutamica* [Plugge et al., 2002]) or acetate plus propionate (*A. hydrogenoformans* [Stams and Hansen, 1984; Meijer et al., 1999], *T. acidaminovorans* [Cheng et al., 1992; Baena et al., 1999b], and *Aminomonas paucivorans* [Baena et al., 1999a]), with CO_2 as coproduct (Table 1).

Acidaminobacter hydrogenoformans ferments glutamate to 2 acetate, 1 CO_2, NH_3 and 1 H_2, or to 1 propionate, 2 CO_2, NH_3 and 2 H_2 (Table 1; Fig. 2). In pure culture, *A. hydrogenoformans* can also form formate. However, in the presence of the hydrogen-utilizing *Methanobrevibacter*

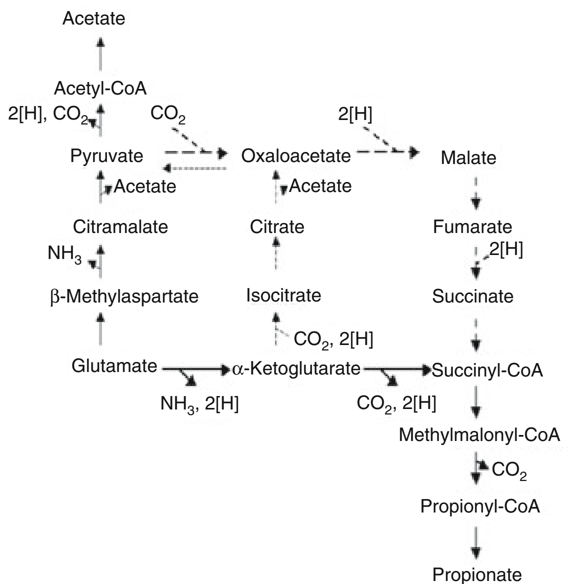


Fig. 2. Pathways involved in the fermentation of glutamate to propionate and acetate in anaerobic bacteria. Thin solid line (left part): acetate formation by the commonly used β-methylaspartate pathway. Thick solid line: oxidative formation of propionate as catalyzed by, e.g., *Gelria glutamica*. Dashed line: reductive formation of propionate as performed by *Anaeromusa acidaminophila*. Dotted line: acetate formation via enzymes of the reductive tricarboxylic acid (TCA) cycle as used by *Acidaminobacter hydrogenoformans* when cocultured with hydrogenotrophic methanogens.

arboriphilus, formate is not formed (Stams and Hansen, 1984). The ratio at which acetate and propionate are formed depends on the hydrogen partial pressure (Stams and Hansen, 1984). Propionate formation is favored at low hydrogen partial pressure, whereas at high hydrogen pressure mainly acetate is formed. Enzyme measurements revealed that the strain when grown in pure culture uses the β-methylaspartate pathway for acetate formation. However, if the bacterium is grown in coculture with a methanogen, both acetate and propionate appear to be formed via α-ketoglutarate (Stams et al., 1998). Reductive carboxylation of α-ketogluratate leads via isocitrate to citrate which is cleaved to acetate and pyruvate, and pyruvate is converted further to acetate. Propionate formation occurs via oxidative decarboxylation of α-ketoglutarate to succinyl-CoA, which is further converted to propionate. Apparently, a crucial step that determines the degradation pathway is the oxidative deamination of glutamate to α-ketoglutarate which is highly endergonic if coupled to hydrogen formation. Under standard conditions, this conversion is energetically impossible ($\Delta G_0' = +60$ kJ per mol). However, at a hydrogen partial pressure of 10^{-5} atm, the $\Delta G_0'$ of this reaction would be +30 kJ per mol, and if the intracellular NH^{4+} concentration would be 10 mM and the glutamate/α-ketoglutarate ratio about 500, the $\Delta G'$ of this reaction would become about zero. A similar shift in product formation was described for *Aminomonas paucivorans* (Baena et al., 1999a).

Thermanaerovibrio acidaminovorans also forms acetate and propionate as products. Unlike the mesophilic organisms, this thermophile forms propionate already in pure culture. This bacterium uses the β-methylaspartate pathway for acetate formation both in pure culture and in coculture with a methanogen (Plugge et al., 2002) Some of the glutamate-fermenting bacteria also are able to grow with histidine, forming similar products and shifts in product formation as with glutamate. Histidine is supposed to be degraded through glutamate as an intermediate (Gottschalk, 1986).

Stickland Reaction versus Methanogenesis

Some of the bacteria which can degrade amino acids syntropically, including *Clostridium sporogenes*, *Eubacterium acidaminophilum*, *Acidaminobacter hydrogenoformans* and *Caloramator proteoclasticus*, are able to perform a Stickland reaction. The environmental conditions under which the Stickland reaction is favored and conditions under which reducing equivalents are disposed of as molecular hydrogen remains to be determined. Energetically, the reductive conversion of glycine is more favorable than methanogenesis, homoacetogenesis, or sulfate reduction (Table 2). It is likely that in environments rich in amino acids, the Stickland reaction will dominate, whereas in environments with low amino acid supply and high methanogenic activity, reducing equivalents may be preferentially channeled to methanogenesis. Unfortunately, up to now little information was available on such comparative ecological aspects.

During growth of a coculture of *Caloramator proteoclasticus* and *Methanobacterium thermoautotrophium* Z245 in a medium with alanine plus glycine, about 60% of the reducing equivalents were channeled to methanogenesis when a dense culture of the methanogen was inoculated with 0.2% of a culture of *C. proteoclasticus*. However, if 1% inoculum was applied, all the reducing equivalents were used to reduce glycine.

Syntrophic Degradation of Fermentation Intermediates

Syntrophic Ethanol Oxidation

The case of "*Methanobacillus omelianskii*" is the classical example of interspecies hydrogen

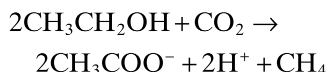
Table 2. Changes of Gibbs free energies under standard conditions in hydrogen-consuming reactions involved in interspecies hydrogen transfer.

	G_0' (kJ per mol rct.)	G_0' (kJ per electron pair)
$4H_2 + 2\,CO_2 \rightarrow CH_3COO^- + H^+ + 2H_2O$	–94.9	–23.8
$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$	–131.0	–32.7
$H_2 + S^0 \rightarrow H_2S$	–33.9	–33.9
$4H_2 + SO_4^{2-} + H^+ \rightarrow HS^- + 4H_2O$	–151.0	–37.6
$H_2C(NH_3^+)COO^- + H_2 \rightarrow CH_3COO^- + NH_4^+$	–78.0	–78.0
$Fumarate^{2-} + H_2 \rightarrow succinate^{2-}$	–86.0	–86.0

All calculations are based on published tables (see Thauer et al., 1977; Dimroth, 1983). For H_2S and CO_2, values for the gaseous state were used.

transfer. Both partners operate in an overall reaction process which becomes exergonic for the first partner only through maintenance of a low hydrogen partial pressure by the second partner. After description of the cooperative nature of this process, the original S-strain was lost, but other syntrophically ethanol-oxidizing bacteria have been isolated, such as *Thermoanaerobium brockii* (Ben-Bassat et al., 1981) and various *Pelobacter* strains (Schink, 1984; Schink, 1985a; Eichler and Schink, 1986). Also certain ethanol-oxidizing sulfate reducers such as *Desulfovibrio vulgaris* are able to oxidize ethanol in the absence of sulfate by hydrogen transfer to a hydrogen-oxidizing methanogenic partner.

Unfortunately, the energetics of this syntrophic cooperation are still unclear. The total reaction



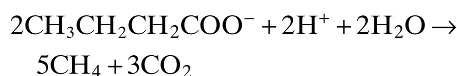
$$2CH_3CH_2OH + CO_2 \rightarrow 2CH_3COO^- + 2H^+ + CH_4$$

yields –112 kJ per 2 mol ethanol under standard conditions. On the side of the ethanol oxidizer, e.g., the "S-strain" of "*Methanobacillus omelianskii*" (Bryant et al., 1967) or other fermenting anaerobes with similar metabolic capacities such as *Pelobacter acetylenicus* (Schink, 1985a), ethanol dehydrogenase, acetaldehyde ferredoxin oxidoreductase (acetyl CoA-forming), phosphotransacetylase, and acetate kinase have been shown to be involved, forming one ATP per ethanol through substrate-level phosphorylation. Since the methanogenic hydrogen oxidizer requires at least one third of an ATP unit for growth (–20 kJ per reaction run, see above), only about –45 kJ is available to the ethanol oxidizer per mol ethanol oxidized, which is too little energy to form one full ATP. It has to be postulated, therefore, that part of the energy bound in ATP has to be reinvested somewhere to push the overall reaction and balance the energy budget, but this reverse electron transport system has not yet been identified. In syntrophically ethanol-oxidizing *Desulfovibrio* strains, the pathway leads from acetaldehyde directly to acetate, without a phosphorylation step, which explains why *Desulfovibrio* cannot grow in this syntrophic association (Kremer et al., 1988).

Syntrophic Butyrate Oxidation

Similar cooperations have been described with syntrophic cultures degrading fatty acids. An overview of the reactions catalyzed is presented in Table 3; a list of described strains of syntrophically fermenting bacteria follows in Table 4. In general, degradation of fatty acids to acetate and hydrogen or, in the case of propionate, to acetate, hydrogen and CO_2, are reactions far more endergonic under standard conditions than ethanol oxidation. Consequently, for fatty acid degradation, the hydrogen partial pressure has to be decreased to substantially lower values ($<10^{-4}$ bar) than with ethanol ($<10^{-3}$ bar).

The energetic situation of the partner bacteria involved in butyrate conversion to methane and CO_2 has been discussed in detail in earlier publications (Wallrabenstein and Schink, 1994a; Schink, 1997). The overall reaction



$$2CH_3CH_2CH_2COO^- + 2H^+ + 2H_2O \rightarrow 5CH_4 + 3CO_2$$

yields under standard conditions a $\Delta G_0'$ of –177 kJ per 2 mol of butyrate. With concentrations better comparable to those prevailing in a natural habitat, e.g., a freshwater sediment or a sewage sludge digestor (butyrate: 10 μM, CH_4: 0.7 bar, and CO_2: 0.3 bar), the free energy of this process changes to –140 kJ per 2 mol of butyrate. Since the overall process is shared by seven partial reactions (two are involved in the butyrate oxidation, one in CO_2 reduction to methane, and four in acetate cleavage) the free energy change is about –20 kJ per mol for every partial reaction, if the energy is shared by all reactions at equal rates. Measured partial pressures of hydrogen and acetate concentrations in active sewage sludge and various sediments (Zehnder et al., 1982) are in a range of 10^{-4}–10^{-5} bar and 10–100 μM, respectively, which is in good agreement with the assumption of equal energy sharing in

Table 3. Changes of Gibbs free energies under standard conditions in hydrogen-releasing reactions during oxidation of fermentation intermediates.

	G_0' (kJ per mol rct.)	No. of electron pairs
Primary alcohols		
$CH_3CH_2OH + H_2O \rightarrow CH_3COO^- + H^+ + 2H_2$	+9.6	2
Fatty acids		
$CH_3CH_2CH_2COO^- + 2H_2O \rightarrow 2CH_3COO^- + 2H^+ + 2H_2$	+48.3	2
$CH_3CH_2COO^- + 2H_2O \rightarrow CH_3COO^- + CO_2 + 3H_2$	+76.0	3
$CH_3COO^- + H^+ + 2H_2O \rightarrow 2CO_2 + 4H_2$	+94.9	4

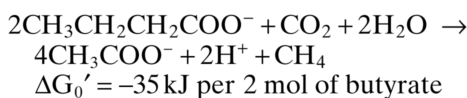
Amino acids		
$CH_3CH(NH_3^+)COO^- + 2H_2O \rightarrow CH_3COO^- + NH_4^+ + CO_2 + 2H_2$	+2.7	2

All calculations are based on published tables (see Thauer et al., 1977; Dimroth 1983). For H_2S and CO_2, values for the gaseous state were used.

such a cooperative community. The corresponding energy yields of about –20 kJ per mol reaction are confirmed by growth yield determinations with pure cultures of methanogens (Schönheit et al., 1980; Zehnder et al., 1982).

On the side of the syntrophic fermenting partner, 1 ATP is synthesized by substrate-level phosphorylation through thiolytic acetoacetyl-CoA cleavage (Wofford et al., 1986), but part of this energy has to be reinvested in reverse electron transport to allow proton reduction with electrons from the butyryl CoA dehydrogenase reaction at a hydrogen partial pressure of 10^{-4}–10^{-5} bar (Thauer and Morris, 1984). Experimental evidence of a reverse electron transport system between the crotonyl-CoA/butyryl-CoA couple ($E^{\circ\prime}$ = –125 mV) and the H^+/H_2 couple has been provided with *Syntrophomonas wolfei* (Wallrabenstein and Schink, 1994a). If two protons are transferred in this reverse electron transport system, one third of the ATP synthesized by substrate-level phosphorylation (equivalent to –20 kJ per mol) would remain for growth and maintenance of the fatty acid-oxidizing bacterium, in accordance with the above assumptions.

The energetic situation of a binary mixed culture degrading butyrate to acetate and methane is considerably more difficult:



$$2CH_3CH_2CH_2COO^- + CO_2 + 2H_2O \rightarrow 4CH_3COO^- + 2H^+ + CH_4$$
$$\Delta G_0' = -35\,\text{kJ per 2 mol of butyrate}$$

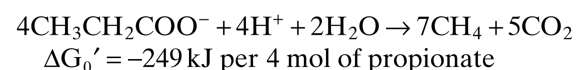
This overall reaction has to feed two organisms in three partial reactions, so each step has only –12 kJ available under standard conditions, and the total changes to –46 kJ at butyrate and acetate concentrations in the range of 10 mM as used in laboratory cultures. Under these conditions, the energetic situation for the partners gets tough (–15 kJ per mol reaction), especially at the end of the substrate conversion process. Very slow, often nonexponential growth and substrate turnover as usually observed with such binary mixed cultures (Dwyer et al., 1988) indicates that the energy supply is insufficient. We have often observed, as did other authors, that accumulating acetate (>10 mM) inhibits butyrate degradation in such cultures substantially.

The energetic difference between the ternary mixed culture and an artificial binary mixed culture demonstrates that the acetate-cleaving methanogens fill an important function in removal of acetate, and with this, "pull" the butyrate oxidation reaction. The above calculations also explain why addition of an acetate-cleaving methanogen to a defined binary mixed culture enhances growth and substrate turnover considerably (Ahring and Westermann, 1988; Beaty and McInerney, 1989).

Syntrophic oxidation of long-chain fatty acids from lipid hydrolysis probably proceeds via β-oxidation with concomitant release of electrons as hydrogen via reverse electron transport, analogous to the process described above for butyrate oxidation. Long-chain dicarboxylic acids are degraded stepwise by β-oxidation, analogous to fatty acids, and decarboxylation occurs at the C-5 or C-4 state (glutarate or succinate; Matthies and Schink, 1993).

Syntrophic Propionate Oxidation

For syntrophic propionate oxidation according to the equation



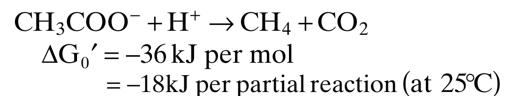
$$4CH_3CH_2COO^- + 4H^+ + 2H_2O \rightarrow 7CH_4 + 5CO_2$$
$$\Delta G_0' = -249\,\text{kJ per 4 mol of propionate}$$

a metabolic flow scheme can be drawn, leaving a free energy change in the range of –22 to –23 kJ per mol reaction (11 partial reactions) to all partners involved (Stams et al., 1989; Schink, 1991). Studies in defined mixed cultures and in undefined communities in rice field soil have basically confirmed this assumption, although the amount of energy available to the propionate oxidizer may be sometimes substantially lower (Scholten and Conrad, 2000; Fey and Conrad, 2000). The pathway of propionate oxidation in such bacteria is basically a reversal of fermentative propionate formation, including methylmalonyl CoA, succinate, malate, pyruvate, and acetyl CoA as intermediates (Koch et al., 1983; Schink, 1985b; Schink, 1991; Houwen et al. 1987; Houwen et al., 1990). The initial substrate activation is accomplished by CoA transfer from acetyl CoA (Houwen et al., 1990; Plugge et al., 1993) or succinyl CoA. Of the redox reactions involved, succinate oxidation and malate oxidation are the most difficult ones to couple to proton reduction: hydrogen partial pressures of 10^{-15} or 10^{-8} bar would be required, respectively, which are far lower concentrations than a methanogen can maintain. The enzymes and electron transfer components involved in propionate oxidation were studied with *Syntrophobacter wolinii* (Houwen et al., 1990; Plugge et al., 1993) and *Syntrophobacter pfennigii* (Wallrabenstein et al., 1995b). Experiments on hydrogen formation in the presence and absence of protonophores (carbonyl cyanide *m*-chlorophenyl hydrazone [CCCP] or dicyclohexyl carbodiimide [DCCD]) indicated again that an intact proton or sodium motive force maintained by ATP hydrolysis is required for hydrogen release, probably in the first oxidation step (Dörner, 1992). The situation is complicated further by the fact that all syntrophically propionate-oxidizing bacteria known so far have turned out to be able also to reduce sulfate (Harmsen et al., 1993; Harmsen et al., 1995; Wallrabenstein et al., 1994b; Wallrabenstein et al., 1995b). Thus, electron transport components detected in these bacteria (even after growth in syntrophic mixed culture) do not necessarily refer to a function in syntrophic oxidation but may be involved in the sulfate-reducing apparatus.

Studies with *Syntrophobacter fumaroxidans* have shown that not only hydrogen but also formate could contribute to interspecies electron transport in this system. Syntrophic propionate oxidation was possible only in cooperation with formate- and hydrogen-oxidizing methanogens, not with *Methanobrevibacter* strains that are unable to oxidize formate (Dong et al., 1994b). This view was further supported by enzyme measurements: cells grown syntrophically with propionate contained tenfold higher formate dehydrogenase activity in comparison with cells grown in pure culture with fumarate; the hydrogenase activity was unchanged (F. A. M.de Bok, unpublished observation). An alternative for syntrophic propionate degradation was discovered in the late 1990s. *Smithella propionica* (Liu et al., 1999) converts propionate to a mixture of acetate and butyrate in the presence of a hydrogen- and formate-oxidizing partner bacterium. The labelling patterns of products formed from specifically labelled propionate indicate that propionate degradation by this bacterium proceeds neither through methylmalonyl CoA nor through the acrylyl CoA pathway but through dimerization to a six-carbon intermediate that is subsequently cleaved to an acetyl and a butyryl moiety, with partial further oxidation (de Bok et al., 2001). This new pathway could also explain the results of labelling experiments with an enrichment culture which were first interpreted as indicative of a reductive carboxylation of propionate to a butyryl residue (Tholozan et al., 1988; Tholozan et al., 1990).

Syntrophic Acetate Oxidation

A special case is the syntrophic conversion of acetate to $2CO_2$ and $4H_2$ which was described first for a moderately thermophilic (58°C) bacterium, strain AOR (Zinder and Koch, 1984). This syntrophic acetate oxidizer could be grown in pure culture like a homoacetogen by hydrogen-dependent reduction of CO_2 to acetate, thus reversing syntrophic acetate oxidation (Lee and Zinder, 1988b; Lee and Zinder, 1988c). Biochemical studies revealed that it uses the carbon monoxide dehydrogenase pathway (“Wood pathway”), as do other homoacetogens (Lee and Zinder, 1988a). The small energy span available in acetate conversion to methane and CO_2 is hardly sufficient to feed two bacteria:



$$CH_3COO^- + H^+ \rightarrow CH_4 + CO_2$$
$$\Delta G_0' = -36\,\text{kJ per mol} = -18\,\text{kJ per partial reaction (at 25°C)}$$

The free energy change is slightly higher at 58°C (–42 kJ per mol) than under standard conditions (25°C). However, a syntrophic acetate-oxidizing culture has been described as well which operates at 35°C (Schnürer et al., 1994; Schnürer et al., 1996) and thus proves that this free-energy change (–38°C) is sufficient for acetate degradation and (very little) growth at this temperature. Another interesting feature of this type of metabolism is that these bacteria can run acetate formation and acetate degradation, in both directions, with probably the same biochemical reaction apparatus, just depending on the prevailing concentrations of substrates and

products, and even can synthesize ATP both ways. This example shows how close to the thermodynamic equilibrium the energy metabolism of an anaerobic bacterium can operate.

The higher energy yield at elevated temperature may explain why at 35°C and lower this reaction is typically carried out by one single bacterium, e.g., *Methanosarcina barkeri* or *Methanosaeta soehngenii*, and why cooperations of syntrophic associations of the above-mentioned type are found nearly exclusively at elevated temperatures. Nonetheless, acetate conversion to methane at higher temperatures can as well be catalyzed by a single aceticlastic methanogen, e.g., *Methanosarcina thermophila*. Syntrophic acetate oxidation at lower temperatures is found only if further stress factors such as high ammonium concentrations inhibit aceticlastic methanogens (Schnürer et al., 1994).

Unfortunately, strain AOR was lost only few years after its description. Another thermophilic strain with similar properties, *Thermoacetogenium phaeum*, was isolated recently (Hattori et al., 2000), and was found to use the CO dehydrogenase pathway (the Wood pathway) for acetate oxidation, too (S. Hattori et al., unpublished observation), and the same is true for the mesophilic acetate-oxidizing *Clostridium ultunense* (Schnürer et al., 1997). However, we do not know yet to what extent and in which steps energy is conserved by these bacteria: either in the acetate synthesis or the acetate oxidation reaction chain.

Syntrophic acetate oxidation was observed also in a coculture of the iron-reducing bacterium *Geobacter sulfurreducens* together with the nitrate-reducing anaerobe *Wolinella succinogenes* (Cord-Ruwisch et al., 1998). In this coculture, the hydrogen partial pressures were far below the levels observed in the cultures mentioned above, and it was hypothesized that perhaps an extracellular cytochrome could act as electron shuttling vector in these cultures. We found out recently that not the cytochrome but cysteine added to the cultures as reducing agent actually mediates interspecies electron transfer in this artificially composed syntrophic coculture (J. Kaden and B. Schink, in preparation).

Syntrophic Glycolate Oxidation

Glycolate is not a fermentation intermediate but an important excretion product of algal cells. It is syntrophically oxidized by homoacetogenic and methanogenic cocultures to two molecules of CO_2, and hydrogen is the electron carrier between the fermenting bacterium (*Syntrophobotulus glycolicus*) and a hydrogen-oxidizing partner bacterium (Friedrich et al., 1991; Friedrich et al., 1996). The primary fermentation is an endergonic process under standard conditions (Table 3) and needs coupling to, e.g., a methanogenic partner. The degradation pathway includes oxidation of glycolate to glyoxylate, condensation of glyoxylate with acetyl CoA to form malyl CoA, ATP formation in a malyl CoA synthetase reaction, malate oxidation and decarboxylation by the malic enzyme, and oxidative decarboxylation of pyruvate to acetyl CoA through pyruvate synthase, thus closing the chain for a new reaction cycle (Friedrich et al., 1991). In this cycle, the oxidation of glycolate to glyoxylate is the critical oxidation step ($E^{\circ\prime} = -92$ mV) which, if coupled to proton reduction, requires a reverse electron transport which has to be fueled by partial hydrolysis of the ATP formed in substrate-level phosphorylation. Proof of proton gradient-dependent hydrogen release was provided in experiments with membrane vesicles: Such vesicles converted glycolate stoichiometrically to glyoxylate and hydrogen in the presence of ATP. This hydrogen formation was abolished entirely by addition of CCCP and other protonophores, as well as by DCCD. Monensin and other sodium ionophores had no specific effect (Friedrich and Schink, 1993). The process is even reversible: Membrane vesicles incubated in the presence of glyoxylate and hydrogen catalyzed a substrate-dependent net synthesis of ATP from ADP and P_i. The ratio of hydrogen-dependent glyoxylate reduction over ATP formation in isolated membrane vesicle preparations (0.2–0.5 mol per mol; Friedrich and Schink, 1995) indicates that probably two thirds of an ATP unit can be formed this way per reaction run. Thus, at least with this system, we have rather reliable data on the reaction stoichiometry.

Syntrophic Oxidation of Aromatic Compounds

So far, defined syntrophic cocultures for methanogenic degradation of aromatic substrates exist only for benzoate, gentisate, and hydroquinone (Table 3). The biochemistry of anaerobic degradation of aromatic compounds has been studied in most detail so far with benzoate, and a degradation pathway has been elaborated in the last years mainly with phototrophic and nitrate-reducing bacteria (for reviews of this subject, see Fuchs et al., 1994; Heider and Fuchs, 1997; Schink et al., 2000). The basic concept is an initial activation to benzoyl-CoA by an acyl CoA synthetase reaction requiring two ATP equivalents, followed by partial ring saturation and subsequent ring opening by a mechanism analogous to β-oxidation of fatty acids. The resulting C_7-dicarboxylic acid undergoes further β-oxidation to form three acetate residues and one CO_2.

The reductive dearomatization of benzoyl CoA in nitrate reducers requires two ATP equivalents and leads to cyclohexa-2,6-diene carboxyl CoA which undergoes further hydration and oxidation (Heider and Fuchs, 1997). This makes the initial steps in the total process rather ATP consuming (4 ATP equivalents consumed before ring cleavage). Nitrate reducers will gain these ATP investments back during subsequent oxidation of the acetyl residues. Syntrophically benzoate-oxidizing bacteria (Auburger and Winter, 1992; Schöcke and Schink, 1997; Elshahed et al., 2001) activate benzoate through a benzoyl-CoA ligase reaction, too, which consumes two ATP units and forms pyrophosphate as side product. Part of the energy invested can be regained through a membrane-bound, proton-translocating pyrophosphatase (Schöcke and Schink, 1998), and another fraction of an ATP can be conserved by the action of a membrane-bound, sodium ion-translocating glutaconyl-CoA decarboxylase which stores the energy of the C_5 dicarboxylic acid decarboxylation to crotonate in a transmembrane sodium ion gradient (Schöcke and Schink, 1999).

The overall energy budget of these fermenting bacteria can be balanced to a net gain of 1/3 to 2/3 ATP (about –45 kJ per reaction run in the ternary coculture) per benzoate oxidized, only if the ring dearomatization consumes significantly less ATP than observed with the nitrate reducers. Product patterns obtained from incubation experiments with labeled benzoate indicate that indeed a different primary reduction reaction is involved (Schöcke and Schink, 1999; Elshahed et al., 2001), but these results are not conclusive as yet. If degradation of benzoate and phthalates (carboxy-benzoates) by granular sludge was inhibited by bromoethane sulfonate, substantial amounts of cyclohexane carboxylate were formed (Kleerebezem et al., 2000), indicating again that such reduced derivatives may be side products of benzoyl CoA reduction in fermentative benzoate degraders.

Although the energetic situation of syntrophic benzoate oxidizers in methanogenic cocultures is substantially better than that of butyrate oxidizers, it appears that these bacteria depend on efficient acetate removal as well. Benzoate was nearly completely converted to acetate, methane and CO_2 in binary mixed cultures with *Methanospirillum hungatei* as hydrogen scavenger. Remnant benzoate concentrations at apparent equilibrium (in the range of 20–70 μM) increased in the presence of added acetate or propionate, and decreased in the presence of a more efficient hydrogen consumer, e.g., a sulfate-reducing partner. The corresponding hydrogen concentrations measured in such cultures were in the range of $0.5–5 \times 10^{-5}$ bar, leaving a total ΔG of –30 to –45 kJ per mol reaction for the benzoate degrader. Similar results were obtained during studies on the kinetics of benzoate degradation with *Syntrophus aciditrophicus* in the presence of a sulfate-reducing partner bacterium (Warikoo et al., 1996).

Syntrophic Oxidation of Branched-Chain Fatty Acids

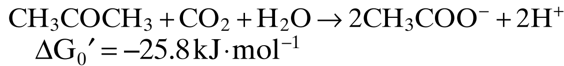
Branched-chain fatty acids are formed during fermentative degradation of the corresponding amino acids by oxidative deamination and decarboxylation, or reductive deamination (see above). The further degradation is not difficult with 2-methyl butyrate (neovalerate) because it can be β-oxidized, analogous to the degradation of butyrate to acetate and propionate by, e.g., *Syntrophospora bryantii* (Stieb and Schink, 1985). Methanogenic degradation of isobutyrate proceeds via isomerization to butyrate and further β-oxidation (Stieb and Schink, 1989); the isobutyrate/butyrate isomerization has been described in a defined culture as a coenzyme B_{12}-dependent rearrangement of the carbon skeleton (Matthies and Schink, 1992). A similar isomerization may also occur as a side reaction with valerate, leading to formation of 2-methylbutyrate (Wu et al., 1994a). Whether a similar isomerization occurs also during isobutyrate degradation by the thermophilic *Syntrophothermus lipocalidus* (Sekiguchi et al., 2000) still remains to be examined.

So far, only one defined culture has been described as capable of fermentative degradation of 3-methyl butyrate (isovalerate; Stieb and Schink, 1986), and this culture specializes in degradation of this substrate, converting it with CO_2 as cosubstrate to three molecules of acetate and one molecule of hydrogen (Tables 3 and 4). The pathway is rather complicated and involves a carboxylation, a dehydrogenation of a saturated fatty acid residue, and one substrate-level phosphorylation step (Stieb and Schink, 1986). The whole conversion is endergonic under standard conditions and depends on syntrophic hydrogen removal. Since three acetate residues are released per substrate molecule oxidized, acetate should have a far more pronounced influence on the total energetics. Details of the energetics of metabolism of this bacterium have been discussed earlier (Schink, 1991).

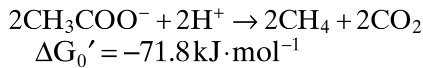
Fermentation of Acetone

A special situation is the fermentative conversion of acetone to methane and CO_2, which is catalyzed by syntrophically cooperating bacteria as well. In this case, acetate is the only interme-

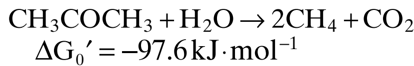
diate between both partners, as illustrated by the following equations:



$$CH_3COCH_3 + CO_2 + H_2O \rightarrow 2CH_3COO^- + 2H^+ \quad \Delta G_0' = -25.8\,kJ \cdot mol^{-1}$$



$$2CH_3COO^- + 2H^+ \rightarrow 2CH_4 + 2CO_2 \quad \Delta G_0' = -71.8\,kJ \cdot mol^{-1}$$



$$CH_3COCH_3 + H_2O \rightarrow 2CH_4 + CO_2 \quad \Delta G_0' = -97.6\,kJ \cdot mol^{-1}$$

Although in this case all partial reactions are exergonic under standard conditons, the primary fermenting bacterium depends on the methanogenic partner, and acetone degradation in the mixed culture is substantially impaired in the presence of acetylene as an inhibitor of methanogens (Platen and Schink, 1987). Experiments with the primary acetone-fermenting bacterium in dialysis cultures revealed that acetate accumulation at concentrations higher than 10 mM inhibited growth and acetone degradation (Platen et al., 1994). Under these conditions, the free energy available to the acetone fermenter is still in the range of –40 kJ per mol. Since acetone metabolism by these bacteria starts with an endergonic carboxylation reaction, this might be the amount of energy that they need to invest into this primary substrate activation reaction, perhaps through a membrane-associated enzyme system (Dimroth, 1987). Unfortunately, the acetone-fermenting bacterium was never obtained in pure culture and hence detailed studies on its biochemistry and energetics were never performed.

Interspecies Metabolite Transfer

Although hydrogen due to its small size and fast diffusion appears to be an ideal carrier for electrons between bacteria of different metabolic types, formate also could act in a similar manner. A possible alternative involvement of formate in such electron transfer processes had been considered from the very beginning (Bryant et al., 1967; McInerney and Wofford, 1992) because the original partner bacteria used could oxidize both hydrogen and formate. The standard redox potential of the CO_2/formate couple is nearly identical with that of H^+/H_2 at pH 7.0 (–420 versus –414 mV) and hence the energetic problems are the same with both. Because both electron carrier systems couple inside the cell with similar, if not the same electron transfer components, e.g., ferredoxins, most bacteria involved in interspecies electron transfer exchange hydrogen against formate and vice versa (e.g., Wu et al., 1993; Bleicher and Winter, 1994). This renders a differentiation between both electron transfer systems rather difficult, and in many cases, both carriers may even be used simultaneously (Schink, 1991). Thus, a formate/CO_2 shuttle could replace hydrogen transfer, and this idea has been brought up again on the basis of experiments with undefined floc cultures from methanogenic fermenters (Thiele and Zeikus, 1988) and with pure cultures (Thiele and Zeikus, 1988; Zindel et al., 1988), as well as on the basis of calculations of diffusion kinetics (Boone et al., 1989a; Boone et al., 1989b).

Exclusive action of hydrogen as electron carrier has been proven so far only for the butyrate-oxidizing coculture *Syntrophomonas wolfei* (Wofford et al., 1986), the glycolate-oxidizing *Syntrophobotulus glycolicus* (Friedrich and Schink, 1993) and the thermophilic, syntrophically acetate-oxidizing strain AOR (Lee and Zinder, 1988a; Lee and Zinder, 1988b; Lee and Zinder, 1988c); all these strains exhibit in coculture high hydrogenase and very little formate dehydrogenase activity. Syntrophic oxidation of propionate by *Syntrophobacter fumaroxidans* or of butyrate by *Syntrophospora bryantii* require partner bacteria that are able to use both hydrogen and formate, indicating that both carriers are involved in interspecies electron transfer (Dörner, 1992; Dong et al., 1994a; Dong et al., 1994b; Dong and Stams, 1995a; Dong and Stams, 1995b). Nonetheless, hydrogenase activities in these cultures exceeded formate dehydrogenase activities substantially indicating that hydrogen played a dominant role as well. Similar conclusions were drawn from hydrogen and formate transfer experiments with thermophilic granular sludge preparations and different partner bacteria (Schnürer et al., 1994). In isobutyrate-degrading cocultures, formate appeared to play a role besides hydrogen as an electron carrier (Wu et al., 1996). On the basis of calculations of diffusion kinetics (Boone et al., 1989a; Boone et al., 1989b), one can speculate that formate/CO_2 would be the preferred electron transfer system in suspended cultures of single cells where the carrier molecule has to diffuse over long distances through an aqueous phase, whereas hydrogen would be more efficient in densely packed aggregates which dominate in anaerobic digestors and probably also in sediments.

A key problem in an assessment of the relative importance of formate as electron shuttle is a reliable measurement of formate at low concentrations: at 0.3 bar CO_2 as typical of e.g., sewage sludge or sediments, a hydrogen partial pressure of 10^{-4}–10^{-5} bar (as required for the redox reactions discussed) is equivalent to formate concentrations of about 1–10 μM (Schink, 1994). Whereas hydrogen partial pressures can today be measured reliably down to 10^{-7} bar with mercury oxide based detectors, there is hardly an

efficient method available which allows measurement of formate in concentrations of few micromolar and less. Moreover, most indications of formate formation were obtained in the presence of inhibitors that caused accumulation of measurable amounts of formate, but it remains doubtful whether such experiments describe adequately the electron flow in the undisturbed system.

Beyond hydrogen and formate, acetate is also excreted by syntrophically fermenting bacteria and is further metabolized by methanogens. The model used above shows that also acetate removal can have a profound influence on the total energetics of syntrophic degradation of fatty acids or benzoate. Its importance may be even higher with, e.g., isovalerate degradation, since three molecules of acetate and only one hydrogen molecule are formed (Table 3). Indeed, inhibition by acetate accumulations or by addition of acetate has been reported for syntrophic degradation of fatty acids and for benzoate (Ahring and Westermann, 1988; Fukuzaki et al., 1990; van Lier et al., 1993; Warikoo et al., 1996; Schöcke and Schink, 1997).

In the recently reported acetate-oxidizing coculture of *Geobacter sulfurreducens* with *Wolinella succinogenes*, we observed that cysteine acted as electron carrier between both partners (J. Kaden and B. Schink, unpublished observation). The use of this carrier system of higher redox potential ($E°' = -270$ mV) than the hydrogen or formate system makes sense in the coupling to the comparably positive electron acceptor used by this coculture. Perhaps the same carrier is active also in other syntrophic associations which exhibit fast electron transfer to an acceptor system of comparably high redox potential (Daniel et al., 1999; Meckenstock, 1999). In the natural environment, also exogenous electron carriers such as humic substances may play a role as interspecies electron carriers, as suggested for electron transfer from iron-reducing bacteria to insoluble iron minerals (Lovley et al., 1996). Cervantes et al. (2000) observed recently that the oxidation of phenolic compounds in methanogenic sewage sludge can be coupled to the reduction of the humic compound analogue anthraquinone-2,6-disulfonate, indicating that this acceptor could perhaps be reduced also by syntrophic phenol oxidizers.

Anaerobic Methane Oxidation

Anaerobic, sulfate-dependent methane oxidation is an important reaction in anoxic marine sediments, as documented on the basis of measurements of sulfate and methane gradients in such sediments (Reeburgh, 1980; Iversen and Jørgensen, 1985). The process could also be demonstrated with radiolabelled methane in anoxic incubations of sediment samples. Zehnder and Brock (1979) showed by similar experiments that methanogenic bacteria were responsible for this oxidation of labelled methane and that methane oxidation and formation were simultaneous. However, in their assays, methane production always exceeded methane oxidation by two to three orders of magnitude, and thus this process could hardly explain the net methane oxidation observed in sediments. For a long time, no cultures were available to study this process in detail because all efforts to isolate anaerobic methane oxidizers failed, and all reports on putative methane-oxidizing anaerobes in the literature have turned out to be unsubstantiated due to lack of sufficient controls.

From a thermodynamic point of view, sulfate-dependent methane oxidation is an exergonic reaction

$$CH_4 + SO_4^{2-} + 2H^+ \rightarrow CO_2 + H_2S + 2H_2O$$

which yields under standard conditions a $\Delta G_0'$ of –18 kJ per mol. Concentrations of the reaction partners in situ in the active sediment layers are in the range of 10^{-2} bar methane, and 1–3 mM of both sulfate and free hydrogen sulfide. Thus, the overall energetics become only slightly more favorable if in situ conditions are taken into consideration. This amount of energy can feed only one bacterium, provided that the bacterium is able to exploit this biological minimum energy quantum. Based on the observation that methanogens can catalyze an oxygen-independent methane oxidation (Zehnder and Brock, 1979) and the description of a reversal of homoacetogenic fermentation by strain AOR and others (see above; Table 3), it was speculated that "reversed methanogenesis" may be the key to an understanding of this process (Hoehler et al., 1994; Schink, 1997). If the overall reaction is actually a syntrophic cooperation involving a methanogen running methane formation backwards and a sulfate-reducing bacterium, it is obvious that only one of the partners can gain metabolic energy from the reaction, and the other one has to run this process only as a cometabolic activity. This would explain at least why scientists have always failed to enrich for methane-oxidizing sulfate reducers in the past, simply because one cannot enrich for a bacterium on the basis of a cometabolic activity.

The last three years have advanced our view of anaerobic methane oxidation dramatically (Valentine and Reeburgh, 2000a). Analysis of lipids of marine archaea and sulfate-reducing bacteria in anoxic sediment layers indicated that these organisms fed on (^{13}C-depleted) methane

(Pancost et al., 2000), and similar findings, combined with molecular population analysis, were reported for archaeal/bacterial communities in marine sediments and close to submarine methane seeps and gas hydrates (Hinrichs et al., 1999; Orphan et al., 2001; Thomsen et al., 2001). In sediments overlying methane hydrates off the coast of Oregon, United States, active anaerobic methane oxidation was found to be associated with discrete, spherical microbial aggregates which consisted, according to fluorecent in-situ hybridization analysis (FISH), of *Methanosarcina*-like archaea in the center, surrounded by *Desulfosarcina*-related sulfate-reducing bacteria (Boetius et al., 2000). The energetics of sulfate-dependent methane oxidation at these gas hydrate sites (with methane pressures of about 80 bar) are considerably more favorable than in deeplying marine sediments, and the overall free energy change of the reaction in situ (–40 kJ per mol) may really allow energy conservation and growth for both partners in this cooperation. Thus, these aggregates represent a first model system to understand sulfate-dependent methane oxidation as a syntrophic cooperation phenomenon, but it still needs to be proven whether this model can also be applied to methane oxidation in deeplying, methane-poor marine sediments.

It is also still open whether methane activation proceeds through a reversal of the methyl-coenzyme M reductase reaction, and which metabolites are transferred between the two partners. Representatives of both genera, *Methanosarcina* sp. and *Desulfosarcina* sp., are metabolically rather versatile, and could metabolize either hydrogen, formate, methanol or acetate. Various cultures of methanogens failed to produce significant amounts of hydrogen from methane (Valentine et al., 2000b), indicating that "reverse methanogenesis" is not a widespread capacity among methanogens. From an energetic point of view, a transfer of acetate between both partners appears the easiest solution, but this is still a matter of speculation.

"Obligately Syntrophic" Bacteria: Cultivation and Biochemical Studies

The mutual dependence of partner bacteria in syntrophic associations has caused severe difficulties in the cultivation of such organisms, and defined cocultures have been obtained only recently. For isolation, pure cultures of known methanogenic or sulfate-reducing partner bacteria are usually provided in excess as a background "lawn" during the cultivation and dilution process to isolate the syntrophically fermenting bacterium in defined binary or ternary mixed culture. Today, all well-described syntrophically fermenting bacteria can be cultivated also in pure culture with different substrate combinations (see below). Hence, we should no longer talk about "obligately syntrophic bacteria" (because they are not obligately syntrophic) but only about syntrophic relationships or syntrophic conversion processes.

Many efforts have been made to grow syntrophically fermenting bacteria in the absence of partner bacteria. Removal of hydrogen by nonbiological procedures (low pressure, and gas diffusion through thin membranes) had only little success with ethanol oxidation, and no success at all with fatty acid oxidation. In other cases, hydrogen removal by palladium catalysts spread on either charcoal or $CaCO_3$ surfaces, with alkenes or alkynes as oxidant have shown some success (Mountfort et al., 1986), as did efforts to couple hydrogen release to reoxidation by electrochemically controlled platinum electrodes. Whether a new cultivation apparatus which maintains the hydrogen partial pressure at subnanomolar concentrations (Valentine et al., 2000c) will hold more promise has still to be proven. More successful was the use of fumarate as external electron acceptor in cultivation of syntrophic propionate degraders (Stams et al., 1993). Today, pure cultures of syntrophically fermenting bacteria of all known metabolic types have been isolated. Typically, this has been accomplished with substrates that are more oxidized than the original one, and can be fermented by dismutation. As an example, ethanol-oxidizing syntrophs can be grown in pure culture with acetaldehyde analogues such as acetoin or acetylene (Schink, 1985a; Eichler and Schink, 1986), butyrate- or benzoate-degrading syntrophs with crotonate (Beaty and McInerney, 1987a; Zhao et al., 1989; Wallrabenstein et al., 1995a) or with pentenoate as external electron acceptor (Dong et al., 1994a), and syntrophically propionate-degrading bacteria with pyruvate (Wallrabenstein et al., 1994b) or propionate plus fumarate (Stams et al., 1993). Beyond that, all syntrophic propionate oxidizers (with the exception of *Smithella propionica*) have been shown to be able also to reduce sulfate, and can be isolated in pure culture with propionate plus sulfate, although they grow only very slowly with this substrate combination (Harmsen et al., 1993; Harmsen et al., 1995; Wallrabenstein et al., 1994b; Wallrabenstein et al., 1995b).

Biochemical studies with defined cocultures of syntrophically fermenting bacteria have been carried out successfully with cell-free extracts prepared by, e.g., lysozyme (Wofford et al., 1986) or mutanolysin (Wallrabenstein and Schink,

1994a) treatment, which opens selectively only the fermenting bacterium and leaves the methanogenic partner intact, owing to its archaeal cell wall chemistry. In another approach, the partner organisms were separated by centrifugation in Percoll gradients before cell disruption and enzyme assays (Beaty et al., 1987b).

Homoacetogenic Conversions and the Effect of Temperature

Under standard conditions, methanogenic hydrogen oxidation yields more energy than homoacetogenic hydrogen oxidation (Table 2), and one would therefore assume that homoacetogens have little chance to compete successfully against methanogens for hydrogen at limiting concentrations. The function of homoacetogens in the complex electron flow scheme depicted in Fig. 1 remains unclear, therefore, and the general assumption is that they take advantage of their metabolic versatility which allows them to compete with several partners of various metabolic types, and consume two or more substrates simultaneously (Schink, 1994). Such simultaneous utilization of more than one substrate may increase the effective affinity for every single substrate, as studies with *Escherichia coli* in continuous cultures with multiple substrate supply have proven (Egli, 1995; Lendenmann et al., 1996). However, there are exceptional situations in which homoacetogens may definitively outcompete methanogens in their function as hydrogen consumers in sulfate-poor anoxic environments. One such situation may be slightly acidic lake sediments such as that found in Knaack Lake, Wisconsin, United States, where at pH 6.1 the total electron flow goes through the acetate pool, and no methane is formed by direct CO_2 reduction (Phelps and Zeikus, 1984). Obviously, hydrogen-oxidizing methanogens do not perform sufficiently well under these conditions. Thus, homoacetogens take over their function, however, only at low acetate concentration (at 10^{-4} bar H_2 and 10 μM acetate), homoacetogenic hydrogen oxidation yields a ΔG of –26 kJ per mol of acetate and has to be maintained by aceticlastic methanogens.

Temperature is a further effector which improves the ability of homoacetogens to compete successfully against methanogens for hydrogen. At temperatures lower than 20°C, homoacetogens appear to take over significant parts of hydrogen oxidation in paddy soil and lake sediments (Conrad et al., 1989; Conrad and Wetter, 1990). The known species of hydrogen-oxidizing methanogens are not significantly active at such temperatures (Zeikus and Winfrey, 1976), and homoacetogens appear to be less restricted in this respect. Dominance of homoacetogenesis in the total electron flow is even more expressed in tundra wetland soils at temperatures lower than 10°C (Kotsyurbenko et al., 1996). This effect becomes understandable from a look at the temperature dependence of hydrogen-dependent methanogenesis and homoacetogenesis. At hydrogen partial pressures lower than 10^{-4} bar and acetate concentrations at 10 mM, homoacetogenesis reaches at 5°C the same energy gain as hydrogen-dependent methanogenesis does at 35°C. Thus, the general scheme of electron flow in methanogenic environments (Fig. 1) has to be modified for slightly acidic or for low temperature habitats (Fig. 3a). Under these conditions, there is no significant hydrogen-dependent methanogenesis (group 2), and the electrons flow nearly exclusively via acetogenesis and aceticlastic methanogenesis (groups 5 and 3).

The opposite situation emerges at high temperature habitats as discussed already above in the context of syntrophic acetate oxidation. Under these conditions, homoacetogenesis can operate in the opposite direction, and the electron flow goes from acetate through the C-1 pool and hydrogen towards methane (Fig. 3b). Thus, the general flow scheme in Fig. 1 represents kind of an intermediate situation that probably describes the situation of a sewage sludge digestor correctly, but has to be modified for high and low temperature situations in the way indicated.

Structure and Growth Dynamics of Syntrophic Associations

The separation of metabolic functions and their distribution within metabolically different microorganisms, i.e., substrate oxidation and hydrogen formation in the one and hydrogen oxidation and CO_2 reduction in the other organism, is a rather unusual strategy that we do not observe, at least not to this extent, in oxic environments. It may have its advantages because it allows a high degree of metabolic specialization to the single organisms concerned, which requires very little effort into refined regulation of energy metabolism. However, the metabolic efficiency of such cooperating communities depends on an efficient metabolite transfer between the partners involved: the flux of, e.g., hydrogen between the hydrogen-forming fermenter and the hydrogen-consuming methanogen is inversely proportional to the distance between both (Schink and Thauer, 1988). Optimal metabolite transfer can be achieved

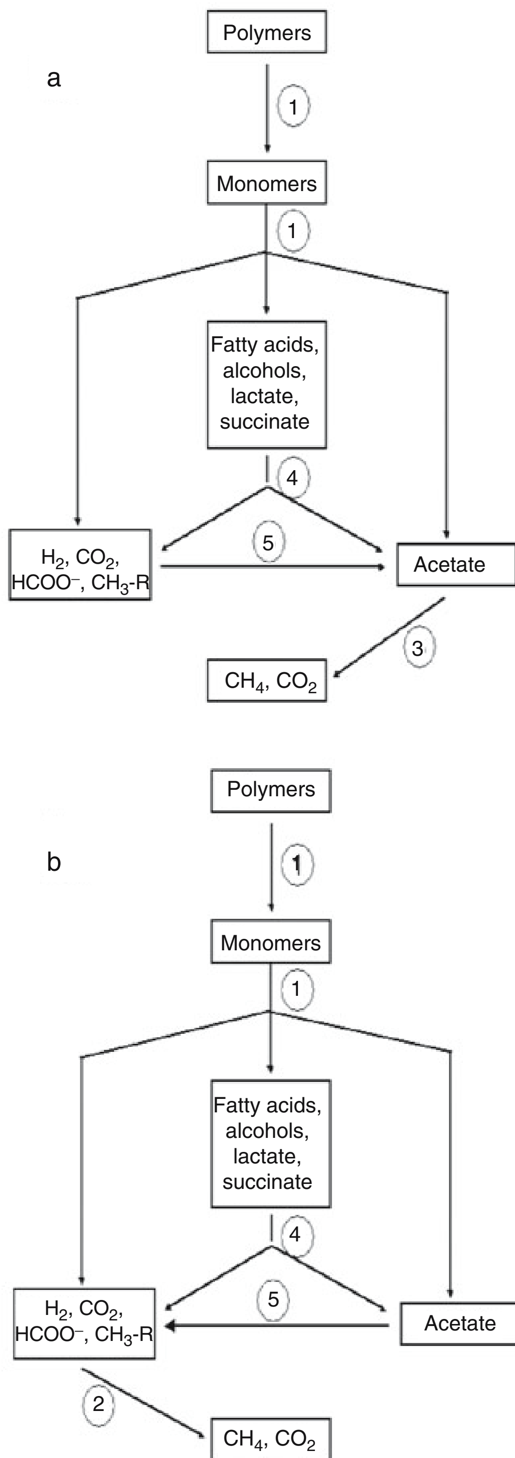


Fig. 3. Carbon and electron flow in methanogenic degradation of complex organic matter. Groups of prokaryotes involved: 1) primary fermentative bacteria; 2) hydrogen-oxidizing methanogens; 3) acetate-cleaving methanogens; 4) secondary fermenting bacteria (syntrophs); and 5) homoacetogenic bacteria. Carbon and electron flow a) at low temperature; and b) at high temperature.

best when both partners are in close contact (i.e., directly attached to each other, forming an aggregate or floc). Such flocs form preferentially in anaerobic digestors in which fatty acids are degraded, although the establishment of stable floc formation may require substantial amounts of time, sometimes even several months after start-up (Lettinga et al., 1988). Indirect evidence of aggregate formation in sediments and sludges has been obtained on the basis of hydrogen exchange measurements (Conrad et al., 1985; Conrad et al., 1986), and the recently discovered aggregates involved in sulfate-dependent methane formation (Boetius et al., 2000) exhibit even a high degree of spatial organization.

Efforts to synthesize stable aggregates (granules) of microbiologically defined composition from pure cultures have been made, and the success depended very specifically on the type of partners used. Butyrate-degrading aggregates with only two partners were stable only with *Methanobacterium formicicum*, not with *Methanospirillum hungatei*, whereas propionate-degrading granules depended on the additional presence of an acetate-degrading partner (Wu et al., 1996). In suspended cultures, *M. hungatei* is often the dominant hydrogen utilizer, but it is obviously not the ideal partner for formation of efficient granules. This experiment demonstrates again that our enrichment and cultivation techniques influence to a high degree the results obtained, and may give a rather incorrect picture of the situation prevailing in the natural or seminatural system. The composition and stability of the formed granules is further influenced by the fact that methanogenic granules in waste-degrading reactors have to deal with mixed substrate supplies that add further microbial constituents into the architecture of the resulting granule, including, e.g., sulfate-reducing bacteria (Wu et al., 1991). In any case, optimal cooperation will be secured in granules in which the partner organisms are randomly mixed to near homogeneity, rather than in situations in which the partners form “nests” of identical subpopulations.

A basic problem remains in that each partner bacterium multiplies and produces offspring only of its own kind. Thus, the situation given in Fig. 4a will change after several generations into one similar to that depicted in Fig. 4b, and the efficiency of metabolite transfer will decrease with age of the aggregates unless there are ways of internal mixing of the aggregates. Thin sections of methanogenic granules have shown examples of fully mixed as well as of nest structures (Dubourguier et al., 1988), and similar pictures were recently obtained with thin sections in which the partner bacteria were identified by specifically RNA-directed probes (Harmsen et

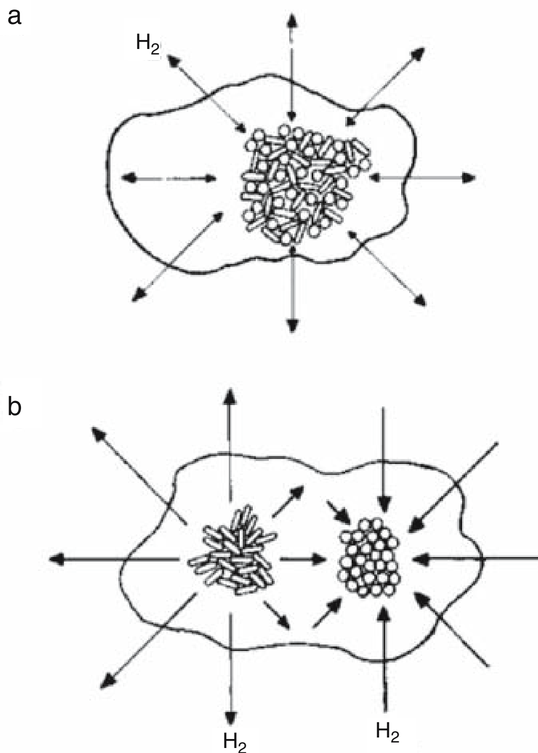

Fig. 4. Exchange of hydrogen (or other intermediates) in anaerobic bacterial flocs containing a) a homogenously mixed community of hydrogen formers and hydrogen consumers or b) hydrogen producers and hydrogen consumers in spatially separated nests.

al., 1996). The largely segregated arrangement of the two partners in the spherical aggregates active in syntrophic sulfate-dependent methane oxidation (Boetius et al., 2000) probably represents a terminal stage in the growth of these partners, and the rather regular size of these aggregates indicates that it is limited by metabolite diffusion kinetics. The dynamics of growth and internal structure development in syntrophic aggregates appears to be an interesting object of research now that gene probes provide excellent tools for direct in situ identification of the various microbial components involved. First efforts in this respect have shown that there are clear functional separations between the subpopulations in granular sludge, especially if also some sulfate is available for fatty acid oxidation (Oude Elferink et al., 1998; Santegoeds et al., 1999). A similar study on syntrophic propionate oxidizers in thermophilic granular sludge revealed that these organisms were localized mainly in the centers of the granules, closely associated with hydrogen-scavenging methanogens (Imachi et al., 2000).

It may be worth mentioning in this context that the observed maximum specific growth rates of syntrophic amino acid-degrading associations are much lower than those of other amino acid-fermenting bacteria. For example, the μ_{max} of *Clostridium* sp. growing on glutamate is 0.3–0.6 h^{-1} (Laanbroek et al., 1979) and that of *S. acidaminophila* is 0.13 h^{-1} (Nanninga et al., 1987). These bacteria use a butyric acid and propionic acid fermentation for the degradation of glutamate, respectively. However, the μ_{max} of *A. hydrogenoformans* growing on glutamate in syntrophic association with a hydrogenotrophic anaerobe is only 0.10 h^{-1}. The μ_{max} of a *Campylobacter* sp. growing on aspartate is about 0.17 h^{-1} (Laanbroek et al., 1978), whereas the μ_{max} of a coculture of *E. acidaminophilum* and a methanogen is below 0.1 h^{-1} (Zindel et al., 1988). Nevertheless, in environments with a high methanogenic activity, e.g., granular sludge from anaerobic bioreactors, high numbers of bacteria can be counted which grow syntrophically with methanogens. Three explanations can be given for this: 1) the growth rates of the syntrophic associations at low substrate concentrations are higher than those of other amino acid-fermenting bacteria, i.e., the syntrophic associations have a higher affinity for the substrate; 2) the syntrophic associations grow on mixtures of substrates rather than on single substrates; and 3) the growth rates of the syntrophic associations are higher than the ones that have been measured. The reported growth rates of the cocultures refer to suspended growth, whereas in methanogenic biofilms and aggregates growth rates might be much higher because of the shorter interbacterial distances. These observations give further support to the assumption that the growth rates of syntrophic associations are limited by the rate of interspecies metabolite transfer.

Cooperation with Protozoa, Hydrogenosomes

The function of the primary fermenting bacteria (group 1) in conversion of complex organic matter to methane and CO_2 (Fig. 1) may be taken over also by eukaryotic organisms. Anaerobic fungi, ciliates and flagellates, are known which thrive in entirely anoxic environments under reducing conditions (Finlay and Fenchel, 1992; Fenchel and Finlay, 1995), and some of them are extremely oxygen-sensitive. Since aerobic respiration is not possible in such habitats, anaerobic protozoa do not contain mitochondria. Instead, intracellular organelles are present which release hydrogen and have been called

"hydrogenosomes." The metabolism of these protozoa is fermentative; particles, especially bacterial cells, are ingested into food vacuoles and digested by hydrolysis and further fermentation, and acetate is probably the most important fermentation product.

Anaerobic protozoa can be associated with symbiotic methanogens, either extracellularly or intracellularly. Ciliates living in strictly anoxic, eutrophic sediments carry methanogenic partner bacteria inside the cell (van Bruggen et al., 1983; van Bruggen et al., 1985), often closely associated with the hydrogenosomes. The advantage of this cooperation with hydrogenotrophic methanogens for the protozoan host is obvious: removal of hydrogen and maintenance of a low hydrogen/formate concentration in the cell allows fermentation of complex organic matter mainly to acetate and CO_2. Thus, waste of organic precursors into reduced endproducts such as ethanol, fatty acids, etc. can be avoided, and the fermenting protozoon obtains a maximum ATP yield. The symbiotic methanogen takes over part of the function that mitochondria have in aerobic higher cells. Reducing equivalents are removed by the symbiotic partner, and the eukaryotic host cell runs a fermentative metabolism with maximum ATP yield.

It is assumed that the hydrogen released by hydrogenosomes stems mainly from pyruvate oxidation to acetyl CoA (pyruvate synthase reaction; Müller, 1988). Hydrogenosomes contain this enzyme, as well as ferredoxin and hydrogenase. In some cases, especially with the larger types of anaerobic protozoa, close associations of methanogenic endosymbionts with hydrogenosomes have been observed. Smaller protozoa may achieve the same effect of hydrogen release also with an extracellular partner bacteria because the diffusion distance to the surface may be short enough. The same applies to the rumen ciliates which in their comparably rich habitat cooperate only occasionally with symbiotic partners on their cell surface (Stumm et al., 1982).

Hydrogenosome and methanogenic endosymbiont together form a functional entity. In some cases, especially with the comparably big ciliates such as *Plagiopyla frontata*, hydrogenosomes and methanogens are organized in an alternating sandwich arrangement that allows optimal hydrogen transfer in highly refined structures (Finlay and Fenchel, 1992). It has been speculated that hydrogenosomes of strictly anaerobic protozoa have evolved from mitochondria of their aerobic predecessors; other speculations assume a relationship of hydrogenosomes to clostridia. The high structural development of hydrogenosomes in some protozoa may suggest that such arrangements could operate also in transfer of hydrogen from less easily available electron donors than the pyruvate synthase system represents. Unfortunately, detailed studies on the cooperation of methanogenic endosymbionts with their protozoan hosts have been hampered so far by extreme difficulties in handling defined cultures of strictly anaerobic protozoa.

Taxonomy of Syntrophs

The survey of described bacteria active in syntrophic oxidation of alcohols, fatty acids, and aromatic compounds (Table 4) documents that these bacteria are found only in two groups within the taxonomic system based on sequence similarities of the 16S rRNA, namely, the Gram-positive bacteria with low G+C content, and the Δ-Proteobacteria. Some metabolic specializations are clustered in certain taxonomic groups, e.g., ethanol, propionate and benzoate oxidation in the Δ-Proteobacteria (with the exception of *Thermoanaerobium brockii*), or fatty acid β-oxidation and acetate oxidation in the Gram-positive bacteria with low G+C content. Nonetheless, these groups are not really homogenous but encompass representatives of many other metabolic types, e.g., sulfate reducers that do not exhibit any tendency to transfer electrons to partner organisms. Finally, as pointed out above, the fermentative degradation of amino acids includes so many different expressions of obligate and facultative syntrophy within taxonomically extremely different groups of organisms that syntrophy can hardly be assumed to be associated with a single evolutionary trait. Rather, syntrophy appears to be kind of a lifestyle that is experienced and perfected by many different organisms to varying extents.

Conclusions

The energetics of syntrophic fatty acid and alcohol-oxidizing processes represent exciting examples of energy metabolism based on the smallest energy quantum that, to our present understanding, can be exploited by living cells. This minimum amount of energy which can be converted into ATP in the living cell is in the range of –20 kJ per reaction run or even lower, and this is the amount of energy available to the respective partners in most of the degradation processes discussed here. Models of metabolic cooperation and energy sharing between syntrophic partners can be based on this assumption, and experimental evidence of reverse electron transport systems to balance the energy

Table 4. Pure or defined mixed cultures of bacteria catalyzing syntrophic substrate oxidations via interspecies hydrogen transfer.

Isolate	Substrate range	Gram type	Phylogenetic position	Reference (s)
a) Oxidation of primary alcohols				
S-strain	Ethanol	–	Unknown	Bryant et al., 1967
Desulfovibrio vulgaris	Ethanol + sulfate	–	δ-Proteobacteria	Bryant et al., 1977
Thermoanaerobacter brockii	Ethanol, sugars etc.	+	Low G+C Gram positives	Ben-Bassat et al., 1981
Pelobacter venetianus	Ethanol, propanol		δ-Proteobacteria	Schink and Stieb, 1983
Pelobacter acetylenicus	Ethanol, acetylene	–	δ-Proteobacteria	Schink, 1985
Pelobacter carbinolicus	Ethanol, 2,3-butanediol		δ-Proteobacteria	Schink, 1984
b) Oxidation of butyrate and higher homologues				
Syntrophomonas wolfei	C_4–C_8	–	Low G+C Gram positives	McInerney et al., 1979, 1981
Syntrophomonas sapovorans	C_4–C_{18}	–	Low G+C Gram positives	Roy et al., 1986
Syntrophospora bryantii	C_4–C_{11}, 2-methylvalerate	+	Low G+C Gram positives	Stieb and Schink, 1985; Zhao et al., 1989
Thermosyntropha lipolytica	C_4–C_{18}, crotonate, and betaine	+	Low G+C Gram positives	Svetlichnyi et al., 1996
Syntrophothermus lipocalidus	C_4–C_{10}, isobutyrate, and crotonate	+	Low G+C Gram positives	Sekiguchi et al., 2000
c) Oxidation of propionate				
Syntrophobacter wolinii	Propionate,	–	δ-Proteobacteria	Boone and Bryant, 1980
Syntrophobacter pfennigii	Pyruvate	–	δ-Proteobacteria	Wallrabenstein et al., 1995a
Syntrophobacter fumaroxidans	Propionate + fumarate	–	δ-Proteobacteria	Harmsen et al., 1998
Smithella propionica	Propionate	–	δ-Proteobacteria	Liu et al., 1999
d) Oxidation of acetate				
Thermoacetogenium phaeum	Acetate, pyruvate, glycine, cysteine, formate, and H_2/CO_2	+	Low G+C Gram positives	Hattori et al., 2000
Clostridium ultunense	Acetate, formate, and cysteine	+	Low G+C Gram positives	Schnürer et al., 1996
e) Oxidation of isovalerate				
Strain GraIva1	Isovalerate only	+	Unknown	Stieb and Schink, 1986
f) Oxidation of glycolate				
Syntrophobotulus glycolicus	Glycolate and glyoxylate	+	Low G+C Gram positives	Friedrich et al., 1991, 1996
g) Oxidation of aromatic compounds				
Syntrophus buswellii	Benzoate and crotonate	–	δ-Proteobacteria	Mountfort and Bryant, 1982
Syntrophus gentianae	Benzoate, gentisate, and hydroquinone	–	δ-Proteobacteria	Wallrabenstein et al., 1995b
Syntrophus aciditrophicus	Benzoate and crotonate	–	δ-Proteobacteria	Jackson et al., 1999

requirements for hydrogen release have been obtained in several instances.

Recent studies on the biochemistry of syntrophic fatty acid oxidizers revealed that these bacteria are by no means "primitive" but actually admirable creatures from the point of view of energy conservation and efficient energy utilization. Most of these bacteria grow in plain mineral media and synthesize all their cellular components on the basis of only the minimum quantum of energy which can be exploited by living cells at all. They are spectacular examples of how diligently nature has organized the components of global energy flux down to those environments where very little energy is available to their living inhabitants.

Acknowledgments. This article is dedicated to the late Marvin Bryant who made fundamental contributions to our present understanding of cooperations in methanogenic microbial communities. The text is based on other reviews written earlier on the same or related subjects (Stams, 1994; Schink, 1991; Schink, 1994; Schink, 1997). The authors express their gratitude to Marvin P. Bryant, Ralph Wolfe, Norbert Pfennig, Rudolf Thauer, Fritz Widdel, Alex Zehnder, and Ralf Conrad for numerous fruitful discussions about the biology and energetics of syntrophic anaerobes, and to their former and present coworkers for their dedicated work on these extremely fastidious bacteria.

CHAPTER 1.12

Quorum Sensing

BONNIE L. BASSLER AND MELISSA B. MILLER

Introduction

Bacteria have an exquisite ability to sense and adapt to a constantly fluctuating environment. They have evolved the capacity to detect a variety of temporal and spatial cues, and in response to such stimuli, bacteria initiate signal transduction cascades that culminate in changes in gene expression. The ability to rapidly alter gene expression, and consequently behavior, in response to a dynamic environment presumably gives bacteria the plasticity to survive in rich, neutral and hostile situations.

One changing parameter that bacteria encounter is cell population density. Bacteria experience situations in which they exist essentially alone (low cell density) and also situations in which they exist in a community (high cell density). Furthermore, in the high cell density situation, bacteria can be in either a mono-culture or in a mixed species consortium. Bacteria sense and respond to fluctuations in cell population density, as well as changes in the species composition of the community, using a cell-cell communication system that is called "quorum sensing."

Quorum-sensing bacteria produce, release, detect and respond to small hormone-like molecules called "autoinducers." As a population of autoinducer-producing bacteria grows, the concentration of released autoinducer increases. When a critical threshold concentration of the signal molecule is achieved, the bacteria are able to detect its presence and initiate a signaling cascade that results in changes in target gene expression. Therefore, regulation of gene expression by quorum sensing allows bacteria to behave differently when they exist alone versus when they exist in a community. Furthermore, communication via quorum sensing enables bacteria to coordinate the gene expression of the entire community, thereby allowing the bacteria to behave as a multicellular organism.

Bacteria use quorum sensing to communicate both within and between species. Both species-specific and species-nonspecific autoinducers exist. As mentioned, these signals enable bacteria to distinguish low from high cell population density, but, further, independent responses to the species-specific and species-nonspecific signaling molecules allow the bacteria to behave differently when they exist in a pure culture versus when they exist in a consortium. Presumably this facet of quorum sensing allows mixed-populations to act synergistically to take advantage of metabolic or other processes that are not common to all the species in the mixture. Therefore, quorum sensing could allow species in the mixed-population to succeed better than each species could in isolation. Conversely, interspecies quorum sensing could also allow bacteria to measure and respond appropriately to increases in numbers of competitor bacteria. Detection of the presence of competitors coupled with the initiation of defensive behaviors could allow a population of quorum-sensing bacteria to slow or stop the growth of competing species.

This chapter describes several different model bacterial quorum-sensing signaling circuits and their uses. The first quorum-sensing circuit, that of the bioluminescent marine bacterium *Vibrio fischeri*, was identified and reported in 1983 (Engebrecht et al., 1983). At that time, cell-cell communication in bacteria was assumed to be a very limited phenomenon. Therefore, intercellular communication in *V. fischeri* was considered an interesting anomaly of no real significance. However, in the last decade, dozens of other species of Gram-negative bacteria have been identified that use a very similar quorum-sensing circuit to that of *V. fischeri* (De Kievit and Iglewski, 2000). Quorum sensing has also now been described in numerous Gram-positive bacterial species, and an interspecies quorum-sensing system has also been discovered that is shared by both Gram-negative and Gram-positive bacteria. In these latter cases, the signal molecules and the detection machinery are different from that of *V. fischeri* and other Gram-negative bacteria (Bassler, 1999b; Kleerebezem et al., 1997). However, all quorum-sensing systems allow bacteria to accomplish the same task, i.e., to count one another and regulate gene expression in response to cell number. The findings of the last ten years indicate that quorum

sensing is a widespread, fundamental signaling process that is critical for bacterial life in the wild. As this is a burgeoning field of research, we suspect that novel signals, unique detection and response apparatuses and additional, as yet undescribed, quorum-sensing behaviors await discovery.

Quorum Sensing in Gram-Negative Bacteria: The LuxI/LuxR Paradigm

Initial investigations of quorum sensing centered on *Vibrio fischeri*, a bioluminescent marine bacterium that exists as a symbiont inhabiting specialized light organs of several animal hosts, including the squid *Euprymna scolopes* and the fish *Monocentris japonicus* (for review see Visick and McFall-Ngai, 2000). In the eukaryote-*V. fischeri* association, the animal host provides a nutrient-rich environment for the bacteria, and the bacteria provide light (bioluminescence) to the host. The hosts use the light produced by the bacteria for different purposes including attraction of mates and escape from predators.

In the case of the *E. scolopes*-*V. fischeri* symbiosis, *V. fischeri* exists in pure culture and grows to extremely high cell densities (approximately 10^{11} cells/ml) in the squid light organ (Ruby and McFall-Ngai, 1992). As *V. fischeri* grows, it produces an autoinducer hormone that accumulates in the light organ. Presumably the build-up of autoinducer communicates to the bacteria that they exist "inside" a light organ as opposed to "outside" in the ocean, an environment where the autoinducer would diffuse away and therefore never accumulate to any significant concentration. In the squid light organ, when a critical autoinducer concentration is achieved, a signaling cascade is initiated that results in induction of the expression of the genes required for light production. These genes, *luxCDABE* (*lux*) encode the structural components of the luciferase enzyme complex (Engebrecht and Silverman, 1984). Therefore, *V. fischeri* only produces light at high cell density and only in the light organ of the host.

The squid *E. scolopes*-*V. fischeri* association is fascinating. *Euprymna scolopes* is a nocturnal animal that lives in shallow coastal waters, and it uses the light made from *V. fischeri* for counter-illumination at night. The light organ inhabited by *V. fischeri* resides on the underside of the squid. At night, the squid senses the ambient starlight or moonlight penetrating the water and shining onto its back. By opening and closing a shutter beneath the specialized light organ, the squid is able to modulate the amount of light emanating from the symbiotic *V. fischeri* culture. The squid appropriately opens and closes this shutter to make the amount of light shining down from the light organ exactly match the amount of light shining onto its back from the stars and moon. Therefore, using the light from *V. fischeri*, *E. scolopes* manages to avoid casting a shadow beneath itself and thereby avoids predation (Ruby and McFall-Ngai, 1992).

In summary, *V. fischeri* exists at high cell density only in the light organ of the squid, and this is the only niche where autoinducer concentration is above the required threshold for *lux* expression. Therefore, under this condition, the bacteria make light. Conversely, when the bacteria are shed from the light organ into the seawater (which occurs at sunrise and is regulated by the circadian rhythm of the squid), both the bacterial cell density and the autoinducer diminish to below the required level for signaling, and the bacteria make no light (Lee and Ruby, 1994). Quorum sensing thus enables *V. fischeri* to determine when it exists in a symbiotic association with a eukaryotic host versus when it exists free-living in the ocean. This sensory transduction system thereby grants *V. fischeri* the benefits of life as a symbiont.

The *Vibrio fischeri* LuxI/LuxR System

In *V. fischeri*, quorum sensing is regulated by two proteins called LuxI and LuxR (Engebrecht and Silverman, 1987). The LuxI protein is the autoinducer synthase, and it is responsible for production of the autoinducer signal molecule. The autoinducer is an acylated-homoserine lactone (AHL, described in LuxI-Directed Autoinducer Biosynthesis), and it freely diffuses through the cell membrane (Kaplan and Greenberg, 1985). The second protein, LuxR, is a regulatory protein that binds both the autoinducer and DNA (Stevens and Greenberg, 1999; Salmond et al., 1995).

Engebrecht and Silverman discovered and cloned both the regulatory components (*luxI* and *luxR*) and the luciferase structural genes (*luxCDABE*) from *V. fischeri* (Engebrecht and Silverman, 1984; Engebrecht and Silverman, 1987). They also determined how this first quorum-sensing circuit functioned. Their work demonstrated that the bioluminescence structural and regulatory genes were arranged in two divergently transcribed units, *luxR* and *luxICDABE* (Fig. 1). In dilute culture, the *luxICDABE* operon has weak constitutive expression, and *V. fischeri* produces almost no light. Conversely, significant transcription of *luxR* occurs at low cell density. As the cell density increases, autoinducer accumulates due to the low level expression of the *luxI* gene in the *luxICDABE* operon. Therefore, when a critical concentration of the autoinducer molecule is reached, LuxR binds it

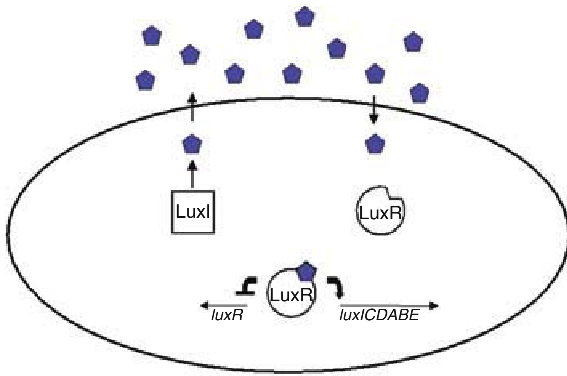

Fig. 1. The LuxI/R Quorum Sensing Paradigm-*V. fischeri*. This figure depicts the prototypical *V. fischeri* quorum sensing system. LuxI is the protein responsible for autoinducer production, and LuxR is the protein necessary for detecting and responding to autoinducer. Following LuxI-directed synthesis, autoinducer molecules (blue pentagons) accumulate thereby allowing interaction with LuxR. The LuxR-autoinducer complex is a transcriptional activator of the *luxICDABE* operon. Activation of the *luxICDABE* operon establishes a positive feedback loop, increasing the level of autoinducer production (*via luxI*) and the amount of light the bacterium emits (*via luxCDABE*). Conversely, the LuxR-autoinducer complex inhibits the transcription of *luxR*, which provides a compensatory mechanism for the regulation of light production. The oval represents a bacterium; the square and circle demarcate the proteins LuxI and LuxR respectively.

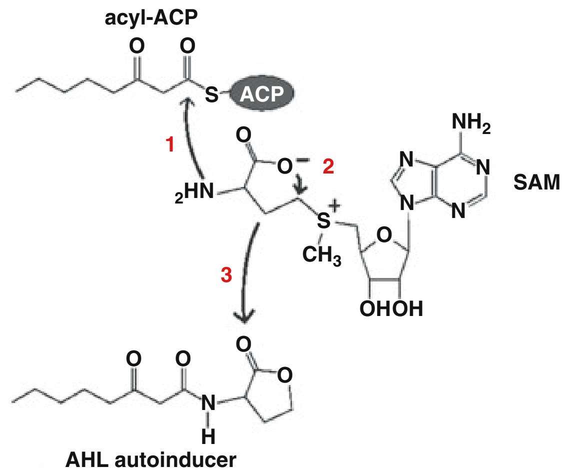

Fig. 2. The Biosynthetic Pathway for Acylated Homoserine Lactone (AHL) Autoinducers. *S*-adenosyl methionine (SAM) and acyl-acyl carrier proteins (acyl-ACP) are the substrates in autoinducer synthesis by LuxI-like enzymes. LuxI promotes the formation of an amide bond between SAM and the acyl side chain from acyl-ACP (1). This intermediate subsequently undergoes lactonization (2) and releases methylthioadenosine (MTA) as a side product. The result is the formation of an acylated-homoserine lactone (3). The autoinducer structure shown in the model is N-(3-oxooctanoyl)-homoserine lactone, the autoinducer of *Agrobacterium tumefaciens*. Adapted and reprinted with permission of S.C. Winans.

and together they activate expression of the *luxICDABE* operon. This action results in a positive feedback circuit. Specifically, an exponential increase in autoinducer production occurs (from the increase in *luxI* transcription), and because the luciferase structural genes *luxCDABE* reside downstream of *luxI*, an exponential increase in light production occurs. Furthermore, the LuxR-autoinducer complex, while acting positively on *luxICDABE* transcription, acts negatively to control *luxR* expression. Negative regulation of *luxR* transcription by the LuxR-autoinducer complex is a compensatory mechanism for modulating *luxICDABE* expression. Together, these two autoregulatory loops tightly control light production in response to autoinducer concentration and therefore in response to increasing cell population density (Engebrecht et al., 1983).

Homologues of the *V. fischeri* LuxI and LuxR proteins have now been identified in over 25 species of Gram-negative bacteria (Fuqua et al., 1996; De Kievit and Iglewski, 2000). In each documented case, the LuxI enzymes control the synthesis of an acylated-homoserine lactone autoinducer. The LuxR proteins bind a specific partner autoinducer and together the cognate pair activates the transcription of some target gene(s) in response to increasing cell population density. Although the genetic arrangement of the regulatory genes and target genes differ, in every case the mechanism of regulation is conserved. A variety of functions are controlled by LuxI-R quorum-sensing systems, as described in The *Pseudomonas aeruginosa* LasI/LasR-RhlI/RhlR Systems, The *Agrobacterium tumefaciens* TraI/TraR System, and The *Erwinia carotovora* ExpI/ExpR System.

LuxI-Directed Autoinducer Biosynthesis: Autoinducer Homoserine Lactone

The autoinducer synthesized by LuxI in *V. fischeri* is *N*-(3-oxohexanoyl)-homoserine lactone (AHL; Eberhard et al., 1981). *S*-Adenosylmethionine (SAM) and acyl-acyl carrier protein (acyl-ACP), an intermediate in fatty acid biosynthesis, are the substrates for AHL synthesis (Hanzelka and Greenberg, 1996; Val and Cronan, 1998). The LuxI enzyme promotes the formation of an amide bond joining the acyl side chain from the acyl-ACP to SAM (More et al., 1996). Lactonization of the ligated intermediate with the concomitant release of methylthioadenosine (MTA) results in AHL. The complete biosynthetic pathway for AHL autoinducers is shown in Fig. 2.

The biochemical mechanism of using SAM and a fatty acid-acyl ACP as substrates for AHL

autoinducer synthesis has been demonstrated for several autoinducers produced by LuxI homologues, indicating that this biosynthetic pathway is likely conserved among the entire family of LuxI autoinducer synthases (Parsek et al., 1999). Although not proven, because the AHL class of autoinducers are very similar, it is assumed that most AHL autoinducers are freely permeable to the Gram-negative cell membrane, similar to what has been demonstrated for the *V. fischeri* AHL (Kaplan and Greenberg, 1985). However, in the case of the *Pseudomonas aeruginosa* autoinducer *N*-(3-oxododecanoyl)-HSL, there is evidence suggesting that the MexAB-OprM multidrug efflux pump is involved in export of that particular AHL signal (Evans et al., 1998). Structurally, AHLs differ only in the acylated side chains, suggesting that the LuxI interaction with a particular acyl-ACP provides the specificity in AHL autoinducer biosynthesis (Fuqua and Eberhard, 1999). However, because AHL autoinducers act by binding to a particular LuxR protein, the LuxR homologues also contribute to the specificity inherent in quorum-sensing systems by binding to their cognate autoinducer at a higher affinity than to other autoinducers.

Specificity appears crucial to the simple signal-response quorum-sensing systems of the LuxI-R type. Whereas the LuxI's produce a highly similar family of signaling molecules, the autoinducers are typically not crossreactive (Gray et al., 1994). The selectivity of the LuxRs for their partner autoinducers presumably makes the LuxI bacterial language quite species-specific. Table 1 lists the bacterial species known to possess LuxI proteins, the structures of the autoinducers and the regulated functions.

The *Pseudomonas aeruginosa* LasI/LasR-RhlI/RhlR Systems

Quorum sensing in the opportunistic pathogen *P. aeruginosa* is controlled by a more complex LuxI/LuxR quorum-sensing circuit than that described for *Vibrio fischeri* (De Kievit and Iglewski, 2000). Specifically, two pairs of LuxI/LuxR homologues have been identified in *P. aeruginosa*, LasI/LasR and RhlI/RhlR. LasI and RhlI are autoinducer synthases that produce the AHL signals *N*-(3-oxododecanoyl)-homoserine lactone and *N*-(butyryl)-homoserine lactone, respectively (Winson et al., 1995; Pearson et al., 1995). These two quorum-sensing systems function in tandem to control virulence in *P. aeruginosa* (Pesci and Iglewski, 1997).

The LasI/LasR system was the first quorum-sensing system identified in *P. aeruginosa*, and as in the *V. fischeri* system, the transcriptional activator LasR was shown to bind to its cognate AHL autoinducer whose synthesis was dependent on LasI (Passador et al., 1993). The LasR-autoinducer complex is responsible for activation of several target virulence genes, the products of which are secreted and are involved in host tissue destruction during the establishment of infection (Jones et al., 1993). These virulence targets include *lasB*, encoding elastase; *lasA*, encoding a protease; *toxA*, encoding exotoxin A; and *aprA*, encoding an alkaline phosphatase. In addition to these virulence factors, and similar to the prototypical *V. fischeri* LuxI/LuxR system, the *P. aeruginosa* LasI/LasR system also activates *lasI* to establish an autoregulatory circuit.

However, in contrast to the *V. fischeri* system, the LasI/LasR system also activates a second quorum-sensing system, composed of RhlI/RhlR, by promoting the expression of the transcriptional activator *rhlR* (Ochsner and Reiser, 1995). Again, like LasI/LasR, in the RhlI/RhlR system, the RhlI synthesized AHL autoinducer binds to the transcriptional activator RhlR to regulate specific genes that display density-dependent expression. The genes regulated by RhlR bound to its cognate autoinducer include *lasB* and *aprA*, which are also under the control of the LasI-R system; *rpoS*, encoding the stationary phase σ factor required for stress response; *rhlAB*, encoding rhamnosyltransferase that is involved in the production of the biosurfactant/hemolysin rhamnolipid; pyocyanin, a phenazine antibiotic; and *rhlI*, encoding the autoinducer synthase (Pesci and Iglewski, 1999a).

In addition to the activation of *rhlR* by the LasI/LasR system, the LasI-dependent AHL autoinducer also acts to inhibit the RhlI autoinducer from binding RhlR, when the concentration of the LasI-dependent autoinducer is significantly higher than the RhlI-dependent autoinducer. It is hypothesized that this dual regulation by the LasI-R quorum-sensing system ensures that the RhlI-R quorum-sensing system will only be activated once the LasI-R controlled regulon has been established. Presumably, this hierarchy allows P. aeruginosa to precisely and specifically time expression of the different density-dependent target genes (Fig. 3).

A third autoinducer has recently been identified in *P. aeruginosa*. This autoinducer is especially interesting because it is not an AHL, but rather, 2-heptyl-3-hydroxy-4-quinolone (Pesci et al., 1999b). This third signal is referred to as the *Pseudomonas* quinolone signal (PQS). Similar to the Las and Rhl quorum-sensing systems, the PQS regulates the expression of *lasB*, the gene encoding the virulence factor elastase. Recent evidence suggests that the PQS could be the link between the Las and Rhl quorum-sensing hierarchy, because PQS production requires LasR, and also because PQS significantly stimulates rhlI expression (McKnight et al., 2000). It is

Table 1. Summary of the LuxI/LuxR-like quorum sensing systems that have been described.

Organism	LuxI/LuxR homologue(s)	Autoinducer identity[a]	Target genes and functions	References

[a]Generally, only the primary autoinducer are listed, but it should be noted that in a few species, multiple autoinducers have been demonstrated to be synthesized by the one LuxI-type protein.
Adapted from De Kievit and Iglewski, 2000.

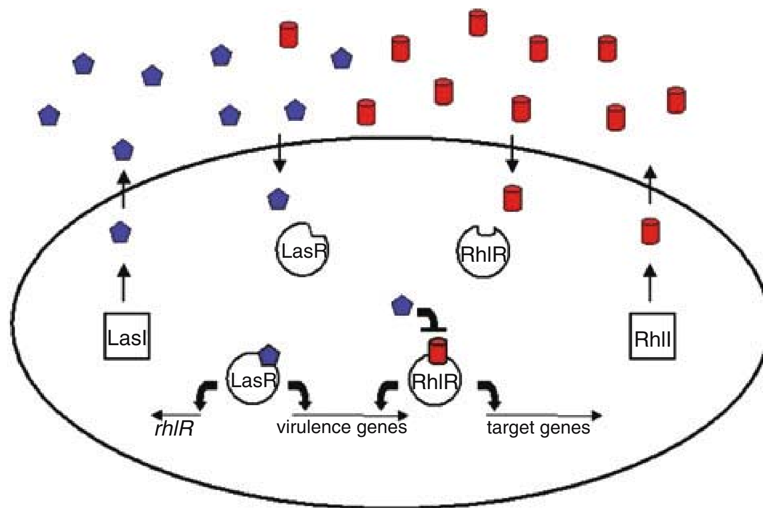

Fig. 3. Hierarchical Quorum Sensing in *P. aeruginosa*. Similar to many Gram-negative bacteria, *P. aeruginosa* uses a LuxI/R type quorum sensing system. *P. aeruginosa* has two LuxI/LuxR homologue pairs (LasI/LasR and RhlI/RhlR) that function in tandem to regulate gene expression in response to cell number. As in the *V. fischeri* model, the AHL autoinducers of *P. aeruginosa* are produced by the synthases LasI and RhlI. As the cell population density increases, and autoinducer concentration increases, the AHL autoinducers bind their corresponding transcriptional activators (LasR and RhlR). The transcriptional activator-autoinducer complexes then positively regulate target gene expression. The target genes for the LasR-autoinducer complex include secreted virulence factors and the *rhlR* gene encoding the activator RhlR of the second quorum sensing system. Upon activation by the LasI/R quorum sensing system, the RhlI/R system induces the transcription of a subset of the LasI/R regulated virulence genes, as well as RhlI/R-specific target genes. In addition to activating the RhlI/R system, the LasI/R system also negatively regulates the binding of the RhlI-dependent autoinducer to RhlR through competitive inhibition by the LasI-dependent autoinducer. The quinolone signal (PQS) also links the regulation of the Las and Rhl systems (see text). The oval represents a bacterium. The LasI-dependent autoinducer is represented by a blue hexagon, while the RhlI-dependent autoinducer is depicted as a red cylinder. The squares represent the autoinducer synthases LasI and RhlI; the circles represent the transcriptional activators LasR and RhlR.

interesting that this autoinducer is a member of the quinolone family because halogenated quinolones are commonly used as potent antibiotics against both Gram-negative and Gram-positive bacteria. It is possible that *P. aeruginosa* uses this compound both for intercellular communication and as an antimicrobial agent.

The *Agrobacterium tumefaciens* TraI/TraR System

The plant pathogen *A. tumefaciens* causes crown gall tumors in part by the transfer of its tumor-inducing (Ti) plasmid to the plant host nuclei. Though quorum sensing is not directly involved in the transfer of the Ti plasmid to the plant host, it does control the inter-bacterial specific transfer of the Ti plasmid by conjugation (Zhang et al., 1993; Piper et al., 1993). Conjugation in *A. tumefaciens* requires two signals: one from the host plant (opine) and an AHL autoinducer signal produced by the autoinducer synthase TraI. Opines produced at the tumor site in plants are a nutritive source for the infecting bacteria, but opines also indirectly activate expression of the quorum-sensing regulator *traR* via an opine-specific regulator. Therefore, in *A. tumefaciens*, bacterial conjugation is jointly controlled by both plant and bacterial signals.

The quorum-sensing system of *A. tumefaciens* is comprised of TraI/TraR, both of which are encoded on the transmissible Ti plasmid. The autoinducer synthase, TraI, produces *N*-(3-oxooctanoyl)-homoserine lactone. As in *Vibrio fischeri*, *traI* is expressed at a low basal level, so only low amounts of autoinducer are produced. After activation of the expression of *traR* by plant opines, TraR binds the autoinducer and together the complex activates the transcription of traI to establish the characteristic autoinduction loop. In addition to activating *traI*, the TraR-autoinducer complex activates the *tra* operon required for mobilization of the Ti plasmid, the *trb* operon that encodes the mating pore, and an additional regulator encoded by *traM* (Winans et al., 1999). The TraM protein, although activated by TraI/TraR, acts as a negative regulator of quorum sensing by inhibiting TraR-autoinducer-specific target activation by binding directly to TraR and inhibiting the DNA-binding and target gene activation functions of TraR (Luo et al., 2000). This additional layer of regulation in the

A. tumefaciens system that apparently does not exist in the *V. fischeri* or the *P. aeruginosa* system indicates that the different quorum-sensing bacteria have evolved specific regulatory controls to precisely adapt their specific density-dependent regulons to particular niches.

The *Erwinia carotovora* ExpI/ExpR System

Erwinia carotovora is a plant pathogen that causes soft rot in its host. Virulence in *E. carotovora* depends on several factors, many of which are exoenzymes that act to degrade plant tissue, enabling the bacterium to successfully establish an infection (Jones et al., 1993). The LuxI/LuxR homologues ExpI/ExpR are hypothesized to be involved in the regulation of many of the secreted enzymes (Pirhonen et al., 1993). An *expI* mutant displays pleiotropic defects in exoenzyme production, but a distinct role for ExpR (and therefore quorum sensing) in regulation of exoenzyme production has not been demonstrated.

The role of a second quorum-sensing system in *E. carotovora*, CarI/CarR, is less ambiguous. The CarI/CarR system positively regulates the biosynthesis of carbapenem antibiotics (Bainton et al., 1992; Williams et al., 1992). Carbapenem production is density dependent, and furthermore, occurs simultaneous with exoenzyme production. It is theorized that, during infection, *E. carotovora* not only destroys the plant tissue for nutrients, but it also kills competing/invading bacteria of other species with antibiotics. In addition, CarI/CarR activate the production of exoenzymes, and this activity is suggested to be coupled to the activity of ExpR through the *rex* (regulation of exoenzymes) gene product (Pierson et al., 1999). Interestingly, both ExpI and CarI produce the same AHL signaling molecule, *N*-(3-oxohexanoyl)-homoserine lactone. It is noteworthy that ExpI and CarI were identified in separate isolates of *E. carotovora*, and whereas the proteins show only 70% identity, they may prove to be functionally identical in the independent isolates. Although the understanding of ExpI and CarI is limited, it is apparent that the functions of the two transcriptional activators, ExpR and CarR, are somehow integrated through the use of the same AHL signal molecule.

Gram-Positive Quorum Sensing: Peptide Signals and Two-Component Signal Transduction

Like Gram-negative bacteria, quorum sensing also occurs in Gram-positive bacterial species. Although the fundamental purpose of quorum sensing in Gram-negative and Gram-positive bacteria is identical, i.e., the density-dependent expression of target genes via the secretion and detection of an autoinducer signaling molecule, the signaling molecules, mechanism of their synthesis and the secretion and detection apparatus used by Gram-positive bacteria are not similar to those of Gram-negative bacteria (see Quorum Sensing in Gram-Negative Bacteria: The LuxI/LuxR Paradigm).

Gram-positive quorum-sensing bacteria use a secreted peptide as the autoinducer. Typically, the peptide signal molecule is secreted by a dedicated ATP-binding cassette (ABC) transporter (Kleerebezem et al., 1997). Also in contrast to the simple detection/response mechanism of the LuxR-like transcriptional regulators, autoinducer detection and response are mediated by two-component adaptive response circuits in Gram-positive bacteria (Kleerebezem et al., 1997). Two-component systems consist of a family of homologous proteins that exist in a wide variety of both Gram-negative and Gram-positive bacteria. These systems enable bacteria to adapt to alterations in a wide variety of environmental conditions. Two-component systems relay sensory information by phosphorylation/dephosphorylation cascades. The two components are a membrane-bound sensor kinase protein, that initiates information transfer by autophosphorylation, and a response regulator protein, which following phosphotransfer from a cognate sensor kinase, typically controls transcription of downstream target genes. (For a detailed review of two-component systems see Stock et al., 1989 and Parkinson, 1995.) Gram-positive quorum-sensing bacteria use two-component systems to detect and respond to the accumulation of a threshold concentration of a peptide autoinducer. A general scheme for Gram-positive quorum sensing is shown in Fig. 4, and several Gram-positive quorum-sensing regulatory systems and the targets they control are described in The *Streptococcus pneumoniae* Competence System, The *Bacillus subtilis* Competence System, and The *Staphylococcus aureus* Agr System.

The *Streptococcus pneumoniae* Competence System

Genetic transformation of bacteria was first described in *S. pneumoniae* (see Havarstein and Morrison, 1999 and references therein). Transformation by foreign DNA requires the bacterium to possess the ability to take up exogenous DNA. This ability is known as "competence" for transformation. *Streptococcus pneumoniae* is a naturally competent bacterium, and it uses peptide quorum sensing to regulate development of

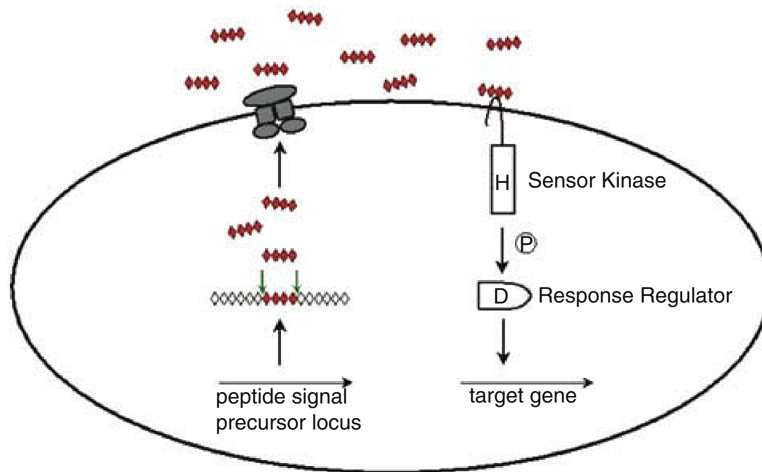

Fig. 4. A General Model for Gram-Positive Quorum Sensing. In Gram-positive bacteria, the autoinducer is a peptide signal that is processed from a larger precursor peptide. The peptide signal precursor locus is translated into a precursor protein, which is subsequently cleaved to produce the peptide signal. In most cases, the peptide signal is transported out of the cell *via* an ATP-binding cassette (ABC) transporter. As the bacterial population grows, the peptide signal accumulates extracellularly, where the signal can then be detected by a two-component system. Following interaction with the peptide signal, the sensor kinase protein of the two-component system autophosphorylates on a conserved histidine residue (H). This autophosphorylation event initiates a phospho-relay cascade that results in phosphorylation of the cognate response regulator protein on a conserved aspartic acid residue (D). The phosphorylated response regulator activates the transcription of the target gene(s). The oval represents a bacterium; diamonds are units of the precursor protein with the red diamonds representing the signal peptide. The green arrows indicate the processing of the precursor protein into the peptide signal. The gray proteins represent an ABC transporter. The P in the circle represents the phosphorylation cascade. Note that the length of the precursor and processed peptides do not imply a specific number of amino acids.

the competent state. Unlike most other naturally competent organisms, *S. pneumoniae* can assimilate DNA regardless of sequence and, thus, regardless of the species of origin of the DNA. By using quorum sensing to regulate competence genes, these promiscuous organisms are presumed to enhance their likelihood of acquiring DNA from a variety of sources that could contain a vast assortment of genes specifying beneficial functions that have not evolved within their own species.

The peptide signal for density-dependent competence development in *S. pneumoniae* is called the "competence-stimulating peptide" (CSP), which contains 17 amino acids and is produced by the cleavage of a 41-residue peptide precursor called "ComC" (Tortosa and Dubnau, 1999). The CSP is secreted by the ABC-transporter encoded by *comAB*. Similar to AHL-autoinducers, the concentration of CSP molecule increases in the extracellular environment as the bacterial population grows. Accumulated CSP is detected by the two-component sensor kinase ComD, which initiates a phosphorylation cascade that results in phosphorylation of the cognate response regulator protein ComE (Kleerebezem et al., 1997). Phosphorylation of ComE activates it, and phospho-ComE, in turn, activates transcription of the gene *comX*. The protein encoded by *comX*, is an alternative σ factor that is required for the downstream expression of genes necessary for development of the competent state (Havarstein and Morrison, 1999). Competence in *S. pneumoniae* occurs only during exponential growth, and competence is transient. The benefit *S. pneumoniae* derives from a temporary competent state is unclear, but it is likely that additional regulatory mechanisms exist to eliminate the transient density-dependent expression of competence.

The *Bacillus subtilis* Competence System

Bacillus subtilis is a commensal soil organism that, like *Streptococcus pneumoniae*, uses quorum sensing to control genes required for the acquisition of extracellular DNA (Lazazzera and Grossman, 1998). The development of competence in *B. subtilis* occurs in about 10% of the bacterial population at the transition between logarithmic growth and stationary phase, when cell lysis and the concomitant release of DNA likely occurs. Therefore, competence for uptake of exogenous DNA in a small fraction of the population could allow this subpopulation to use these fragments of DNA as a repository for repair of mutated and broken chromosomes (Lazazzera et al., 1999). Unlike *S. pneumoniae*, which is postulated to use competence in early log phase to acquire heterologous DNA, *B.*

subtilis is proposed to use quorum sensing and competence at higher cell density to inherit its own species' DNA.

Density-dependent control of competence in *B. subtilis* is mediated by two peptide signals called "ComX" and "CSF" (competence and sporulation factor). These two autoinducer signals are secreted as the cell population density increases. The ComX peptide is translated as a 55-amino-acid precursor protein, but is subsequently post-translationally modified on a tryptophan residue, and the precursor protein is cleaved (Lazazzera and Grossman, 1998). The final exported ComX signal molecule is a modified decapeptide. A protein called "ComQ" is required for production of the ComX peptide. The ComQ protein is hypothesized to be involved in the processing, modification and/or secretion of the ComX peptide, however, the exact function of ComQ has not been established (Lazazzera et al., 1999). The concentration of external ComX increases as the culture grows, and detection of the peptide is via the two-component system ComP/ComA. The ComP protein is the sensor kinase and ComA is the response regulator. Phosphorylated ComA is responsible for the activation of *comS*. The function of the ComS protein is to protect another protein called "ComK" from proteolytic degradation (Tortosa and Dubnau, 1999). The ComK protein is the transcriptional activator of competence genes. Finally, this complicated quorum-sensing circuit allows *B. subtilis* to become competent for transformation by exogenous DNA only at high cell density.

As mentioned, two peptide signals (ComX and CSF) are involved in quorum sensing and competence development in *B. subtilis*. The CSF pentapeptide is produced by the processing of the C-terminus of a peptide precursor called "PhrC" (Lazazzera and Grossman, 1998). Although the CSF peptide signal is produced in a density-dependent manner, its mechanism of action is different than that of other peptide quorum-sensing autoinducers. Specifically, secreted CSF is internalized via an oligopeptide-permease, and intracellular CSF acts to modulate the levels of phosphorylated ComA by inhibiting the activity of a phosphatase called "RapC" (Lazazzera et al., 1999). As described, ComA is a response regulator protein, and the inhibition of a specific ComA phosphatase results in an increase in the level of phospho-ComA in the cell. Phospho-ComA activates expression of a set of genes required for competence development. Thus, whereas CSF may not itself be a typical quorum-sensing signaling molecule, it is clearly involved in the modulation of competence gene expression in a density-dependent manner.

The *Staphylococcus aureus* Agr System

Staphylococcus aureus is an invasive pathogen that can cause disease in almost any tissue or organ in the human body, primarily in compromised individuals. Staphylococcal infections such as pneumonia, endocarditis, septicemia, toxic shock syndrome and food poisoning require several virulence factors, most of which are secreted enzymes or toxins. Expression of many of the virulence factors of *S. aureus* is dependent on cell density and peptide quorum sensing.

Density-dependent virulence in *S. aureus* is regulated by an RNA molecule called "RNAIII" (Kleerebezem et al., 1997). Levels of RNAIII are controlled by three loci, one of which encodes a peptide quorum-sensing system. The *agrBDCA* operon encodes the quorum-sensing components, and this operon is divergently transcribed from the *hld* locus which encodes the RNAIII transcript. In the *S. aureus* quorum-sensing circuit, the 46-residue signal peptide precursor is encoded by *agrD* (Morfeldt et al., 1996). The AgrD precursor protein is subsequently cleaved to an octapeptide, and this processing step requires the product of the *agrB* gene (Novick, 1999). The processed autoinducing peptide (AIP) is unique in that it contains a thiolactone ring (Mayville et al., 1999). The products of the *agrC* and *agrA* genes, AgrC and AgrA respectively, comprise the two-component sensor kinase and response regulator signaling pair. Following the build-up and detection of AIP, the AgrC/AgrA two-component phosphorylation cascade culminates in phosphorylation of AgrA. Phospho-AgrA is responsible for increasing RNAIII levels in the cell, although the exact mechanism of activation has not been determined. The RNAIII, through another unknown mechanism, subsequently functions to activate the expression of a variety of exported virulence factors in *S. aureus*.

Quorum Sensing in *Vibrio harveyi*: Integration of AHL and Two-Component Signaling

Vibrio harveyi is a marine bacterium that uses quorum sensing, among other environmental cues, to modulate bioluminescence (Bassler, 1999a). However, unlike *Vibrio fischeri*, *V. harveyi* is not known to exist in symbiotic relationships, and the benefit it receives from producing light remains a mystery. Although *V. harveyi* is a Gram-negative bacterium, its quorum-sensing circuit possesses features reminiscent of both Gram-negative (see Quorum Sensing in Gram-Negative Bacteria: The LuxI/LuxR Para-

digm) and Gram-positive bacteria (see Gram-Positive Quorum Sensing: Peptide Signals and Two-Component Signal Transduction; Bassler, 1999b). For this reason, we have chosen to discuss the *V. harveyi* quorum-sensing circuit separately from the other Gram-negative systems.

Analogous to other Gram-negative bacteria, *V. harveyi* produces and responds to an AHL autoinducer (Bassler et al., 1993; Cao and Meighen, 1989). In contrast to Gram-negative bacteria, but similar to Gram-positive bacteria, detection of and response to autoinducer is carried out by a two-component circuit (Bassler et al., 1993; Bassler et al., 1994a; Bassler et al., 1994b). Additionally, *V. harveyi* possesses a novel autoinducer signaling molecule, called "AI-2" (Bassler et al., 1993; Surette and Bassler, 1998). The AI-2 molecule and the gene required for its production have recently been demonstrated to occur in a wide variety of Gram-negative and Gram-positive bacteria (Surette and Bassler, 1998; Surette et al., 1999). The AI-2 molecule could be the common link that connects the evolution of the two major classes of quorum-sensing circuits.

Multiple Systems Regulate Quorum Sensing in *Vibrio harveyi*

Vibrio harveyi was the first bacterium in which the use of multiple autoinducers was described (Bassler et al., 1994a). Specifically, two parallel quorum-sensing systems converge to regulate *luxCDABE*, the luciferase structural operon in *V. harveyi*. System 1 is comprised of autoinducer-1 (AI-1) and Sensor 1 (LuxN); System 2 consists of autoinducer-2 (AI-2) and Sensor 2 (LuxPQ) (Bassler et al., 1993; Bassler et al., 1994a). While the two sensors detect independent autoinducer signals, the parallel signaling systems converge at a downstream integrator protein called "LuxU" (Freeman and Bassler, 1999b). Integration of the two autoinducer cues allows light production in *V. harveyi* to be modulated by multiple inputs (Fig. 5).

Both LuxN and LuxQ are members of a family of two-component proteins called "hybrid kinases." Members of the hybrid sensor kinase family contain multiple signaling modules. In the case of LuxN and LuxQ, each possesses both a sensor kinase domain and an attached response-regulator domain. In *V. harveyi*, at low cell density, when little autoinducer is present, the hybrid sensor kinases LuxN and LuxQ initiate a phospho-relay cascade that results in phosphorylation of the signal integrator protein LuxU, and finally the phosphoryl group is transferred to a response regulator protein called "LuxO" (Freeman et al., 2000). When LuxO is phosphorylated, the luciferase operon (*luxCDABE*) is not transcribed, and the bacteria do not make light (Bassler et al., 1994b; Freeman and Bassler,

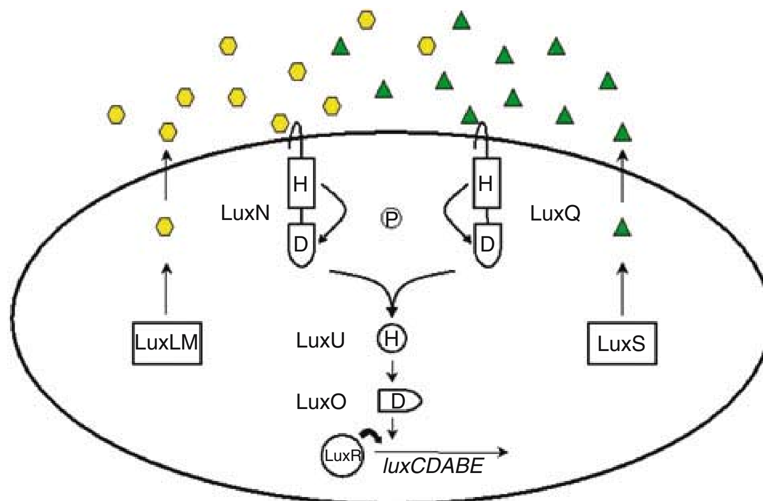

Fig. 5. Quorum Sensing in *V. harveyi*. This model demonstrates how *V. harveyi* uses both an AHL (AI-1, yellow hexagons) and a novel autoinducer signal (AI-2, green triangles) as autoinducers to regulate quorum sensing. *V. harveyi* has two parallel two-component signaling circuits. LuxN is the hybrid sensor kinase for AI-1 (synthesized by LuxLM), and LuxQ senses and responds to AI-2 (synthesized by LuxS). At low cell density and low autoinducer concentration, LuxN and LuxQ autophosphorylate and initiate phosphoryl flow through LuxU to the response regulator, LuxO. When LuxO is phosphorylated, *luxCDABE* is not transcribed and the bacteria make no light. Conversely, at high cell density and high autoinducer concentration, the sensor kinases switch from being kinases to phosphatases, which results in the draining of phosphate out of the system. When LuxO is dephosphorylated, *luxCDABE* is transcribed and the bacteria make light. Additionally, the transcriptional activator LuxR (not homologous to the *V. fischeri* LuxR) is required for the transcription of *luxCDABE*. The oval represents a bacterium, H: Histidine, D: Aspartic Acid. The P in the circle represents the phosphorylation cascade.

1999a). Conversely, at high cell density, when autoinducer is abundant, the sensors switch from being kinases to being phosphatases. Phosphatase activity leads to the dephosphorylation of LuxO and subsequent transcription of *luxCDABE*. As in *V. fischeri*, transcription of *luxCDABE* in *V. harveyi* results in luciferase production and light emission. Additionally, a transcriptional activator, LuxR, is absolutely required for the transcription of the *V. harveyi luxCDABE* operon (Martin et al., 1989; Showalter et al., 1990). However, the *V. harveyi* LuxR protein shares no homology to the *V. fischeri* family of LuxR transcriptional activators (The *Vibrio fischeri* LuxI/LuxR System).

Apparently *V. harveyi* does not possess LuxI/LuxR homologues. This finding is surprising because the *V. harveyi* AI-1 is an AHL, *N*-(3-hydroxybutanoyl)-homoserine lactone (Cao and Meighen, 1989). Synthesis of AI-1 however, is not dependent on a *luxI* gene. Rather synthesis of the *V. harveyi* AHL autoinducer is dependent on the *luxLM* locus (Bassler et al., 1993). The genes luxL and *luxM* share no homology with the *luxI* gene family. The second *V. harveyi* autoinducer, AI-2, is not an AHL, as its structure has recently been determined (Schauder and B.L. Bassler, manuscript in preparation). Synthesis of AI-2 is dependent on the gene *luxS* (Surette et al., 1999). Again, the *luxS* gene is not similar to the *luxI* gene.

Although no quorum-sensing components similar to *V. fischeri* LuxI and LuxR have been identified in *V. harveyi*, the opposite is not the case. A LuxM homologue (called "AinS") and homologues of the two-component proteins LuxU and LuxO have recently been identified in *V. fischeri* (Kuo et al., 1994; Gilson et al., 1995; Miyamoto et al., 2000). The AinS protein directs the synthesis of an AHL autoinducer, and LuxU and LuxO play a role in density-dependent regulation of *lux* expression in *V. fischeri*. It is now becoming apparent that multiple signaling circuits could be involved in quorum sensing in *V. fischeri* similar to what is known about quorum-sensing regulation in *V. harveyi*.

Recently many Gram-negative and Gram-positive bacteria have been shown to produce a *V. harveyi* AI-2-like activity, whereas only one closely related species, *Vibrio parahaemolyticus*, has been identified to produce a *V. harveyi* AI-1-like activity (Bassler et al., 1997). This finding led to the hypothesis that, in *V. harveyi*, AI-1 and System 1 are involved in intraspecies quorum sensing, while AI-2 and System 2 could be used by *V. harveyi* for interspecies cell-cell communication. The convergence of these two quorum-sensing systems allows *V. harveyi* to regulate light production in response to its own high cell density and also in response to the presence of other species of bacteria. This observation is noteworthy because in its natural habitat, *V. harveyi* is expected to exist in mixed populations containing many species of bacteria. Multiple autoinducer languages could grant *V. harveyi* a selective advantage in the wild. If *V. harveyi* can detect its own species as well as the presence of other species of bacteria, this ability could allow *V. harveyi* to determine when it is likely to be in intense competition for scarce nutrients. In addition, *V. harveyi* could specifically and appropriately modulate gene expression in response to the presence of other species of bacteria. Distinct roles for the two *V. harveyi* quorum-sensing systems are further supported by the recent discovery that *V. harveyi* regulates many different genes in addition to *lux* by these two autoinducers. In addition, AI-1- and AI-2-specific targets have now been identified in *V. harveyi* indicating that not all of the quorum-sensing information is channeled to LuxU and LuxO to control gene expression (B.L. Bassler, unpublished data).

LuxS and AI-2: The Language of Inter-Species Communication

As mentioned, a gene called *luxS* is required for the production of AI-2 in *V. harveyi* (Surette et al., 1999). DNA database analysis revealed that highly conserved homologues of this novel gene are present in over 30 species of both Gram-negative and Gram-positive bacteria, including, but not limited to, *Escherichia coli*, *Salmonella typhimurium*, *Salmonella typhi*, *Salmonella paratyphi*, *Hemophilus influenzae*, *Helicobacter pylori*, *B. subtilis*, *Borrelia burgdorferi*, *Neisseria meningitidis*, *Yersinia pestis*, *Campylobacter jejuni*, *Vibrio cholerae*, *Mycobacterium tuberculosis*, *Enterococcus faecalis*, *S. pneumoniae*, *Streptococcus pyogenes*, *S. aureus*, *Clostridium perfringens*, *Clostridium difficile* and *Klebsiella pneumoniae*. Most of these species have now been shown to produce an AI-2 activity, and mutation of *luxS* in a number of these species, including *V. harveyi*, *S. typhimurium* and *E. coli*, eliminates AI-2 production. These results suggest that *luxS* is responsible for AI-2 production in all of these bacteria. Because both Gram-negative and Gram-positive bacterial species are represented, and because preliminary evidence indicates that many of these bacteria are producing an identical signaling molecule, AI-2 is considered a universal bacterial language that bacteria could use for interspecies communication (Bassler, 1999b). Therefore, in contrast to AHL and peptide quorum-sensing systems, which represent species-specific bacterial languages, AI-2 and LuxS could be the foundation of a species nonspecific bacterial language.

The identities of the genes regulated by the AI-2 signal are being actively sought in a number of bacteria. Initial evidence in several bacterial species indicates that AI-2 is involved in regulation of pathogenicity. For example, AI-2-specific activation of the locus of enterocyte effacement (LEE) pathogenicity island, encoding a type III secretion system in *E. coli* O157 has been reported (Sperandio et al., 1999). Secretion of virulence factors in *Vibrio vulnificus* has been shown to be controlled by AI-2, and furthermore, the LD50 of a *V. vulnificus luxS* mutant is greatly increased (Kim et al., 2000). Presently there are only a few reports of AI-2 regulated target gene expression, but this is most likely because the *luxS* gene and its widespread nature have only recently been discovered. It will be interesting to determine how bacteria that live in diverse habitats have adapted the use of the AI-2 quorum-sensing language to enhance survival in their particular niches.

Quorum Sensing in *Myxococcus xanthus*: A Unique Sensory System

Myxococcus xanthus is a Gram-negative soil bacterium that displays complex social behaviors. *Myxococcus xanthus* moves by gliding. Specifically, it glides over and colonizes solid surfaces such as decaying plant material that it subsequently uses for nutrients. The *M. xanthus* bacteria hunt for food in swarms, a behavior that allows the individual cells to take advantage of secreted hydrolytic enzymes produced by neighboring cells (Dworkin, 1973; Dworkin and Kaiser, 1985). At high cell density under nutrient limiting conditions, *M. xanthus* forms complex structures called fruiting bodies. Bacterial cells inside the fruiting body undergo a developmental process that leads to spore formation. Spore formation is partially controlled by a quorum-sensing circuit. However, in contrast to other Gram-negative quorum-sensing bacteria, in *M. xanthus*, quorum sensing is not dependent on an AHL autoinducer. Therefore, because *M. xanthus* has a unique quorum-sensing system, as in the *Vibrio harveyi* case (Quorum Sensing in *Vibrio harveyi*: Integration of AHL and Two-Component Signaling), this system is discussed separately.

A secreted signal called "A-signal" is required for quorum sensing in *M. xanthus* (Hagen et al., 1978; LaRossa et al., 1983). The A-signal is a mixture of amino acids that are produced as a consequence of the enzymatic action of extracellular proteases (Kupsa et al., 1992a; 1992b; Plamann et al., 1992). Similar to other quorum-sensing bacteria, the extracellular concentration of the signal increases as the cell population density increases. Three genes are necessary for production of A-signal. These genes are called *asgA*, *asgB* and *asgC*. The AsgA protein is a two-component sensor kinase, AsgB is a DNA-binding transcriptional regulator, and AsgC encodes the housekeeping σ factor for *M. xanthus* (Davis et al., 1995; Plamann et al., 1994; Plamann et al., 1995). These proteins, as well as others that remain to be identified, function in a signaling circuit that activates the expression of genes encoding the secreted proteases required for A-signal generation.

Detection of A-signal is via a two-component sensor kinase called "SasS." The SasS protein transfers phosphate to a response regulator called "SasR" (Kaplan et al., 1991; Yang and Kaplan, 1997). Phosphorylated-SasR, in conjunction with the alternative sigma factor σ^{54}, activates downstream target genes. These genes are hypothesized to encode structural and possibly regulatory proteins that are required for the spore differentiation process. A negative regulatory protein, called "SasN," must also be inactivated for *M. xanthus* to respond to A-signal. The function of SasN is not known, and SasN is not homologous to any other identified protein (Gorski et al., 2000; Xu et al., 1998). This system is remarkable because it is so different from every other described quorum-sensing system. Apparently, some facet(s) of the complicated social lifestyle of *M. xanthus* warrants the use of a distinct quorum-sensing mechanism.

Eukaryotic Interference with Quorum Sensing

Outlined in this chapter (Quorum Sensing in Gram-Negative Bacteria: The LuxI/LuxR Paradigm, Gram-Positive Quorum Sensing: Peptide Signals and Two-Component Signal Transduction, Quorum Sensing in *Vibrio harveyi*: Integration of AHL and Two-Component Signaling, Quorum Sensing in *Myxococcus xanthus*: A Unique Quorum Sensing System) are just a few examples of the many known quorum-sensing systems. Identification of new quorum-sensing systems continues at a rapid pace, in part owing to the use of PCR amplification of quorum-sensing genes based on homology to known quorum-sensing regulators, and also owing to the development of easy-to-use bioassays that facilitate the cloning and identification of new quorum-sensing genes (Swift et al., 1993). However, in general, defining and understanding the regulons controlled by new quorum-sensing regulatory proteins typically lags behind the identification of the autoinducer/sensor pair.

Although we know that over 25 LuxI/LuxR systems exist, and at least as many species of bacteria produce AI-2 and possess a LuxS homologue, in most cases we do not yet know what targets these autoinducer systems control.

It is clear, however, that several quorum-sensing systems have been demonstrated to modulate the expression of virulence factors, and interest in designing and implementing novel antimicrobial strategies that target quorum sensing in pathogenic bacteria is high (Zhu et al., 1998). In addition to synthetic strategies for drug design based on autoinducers, it seemed likely that eukaryotes that are susceptible to infection by quorum-sensing bacteria could have already evolved natural therapies to thwart bacterial invasion by inhibiting quorum sensing. One such example of the evolution of a naturally occurring antibacterial agent that specifically counteracts invasion of a eukaryotic host by quorum-sensing bacteria is documented (Givskov et al., 1996). The seaweed *Delisea pulchra* produces halogenated-furanones, molecules that are structurally related to AHL autoinducers. The furanone of *D. pulchra* has the ability to inhibit a social motility phenotype called "swarming" in *Serratia liquefaciens* and other bacterial species. Swarming motility allows bacteria to move over and colonize a surface. Swarming in *S. liquefaciens* is controlled by an AHL quorum-sensing system (Eberl et al., 1996). The halogenated-furanone produced by the eukaryotic host specifically binds with high affinity to the *Vibrio fischeri* LuxR protein, and presumably to the S. liquefaciens LuxR homologue to inhibit motility (Manefield et al., 1999). Although *D. pulchra* and *S. liquefaciens* do not encounter each other in nature, the ability of *D. pulchra* to inhibit swarming is likely a general host defense mechanism that prevents colonization of the plant surface by bacteria (Givskov et al., 1997). While the details and in vivo significance of eukaryotic interference with bacterial quorum sensing are yet to be defined, it remains an intriguing eukaryotic defense mechanism that may have long-range implications in antimicrobial therapy. Likewise, competing bacterial populations might also inhibit each other's quorum sensing by developing autoinducer antagonists. To date, there is only one documented example of such a process between populations of coexisting bacteria (Dong et al., 2000). It has recently been shown that AiiA, an enzyme produced by *B. subtilis* inactivates the *E. carotovora* AHL quorum-sensing signal, thereby attenuating the virulence of *E. carotovora*. The AiiA enzyme is similar to members of a zinc-binding metallohydrolase family of proteins. Much emphasis is now being placed on identifying such antagonistic eukaryotic-bacterial and bacterial-bacterial interactions and the molecules that control these interactions.

Conclusions

Quorum-sensing systems have been widely adapted for a variety of uses by bacteria. However, in every case, quorum sensing confers on bacteria the ability to communicate, and further to alter gene expression in response to the presence of other bacteria. This ability allows a population of small organisms to behave as a multicellular unit, and to gain power and reap benefits that would otherwise be exclusive to eukaryotes. The study of quorum sensing is in its infancy. We need to learn more about how quorum sensing is used by bacteria to communicate both within and between species, how it is used by bacteria to act synergistically and to overcome competitors. We need to understand the variety of signals produced and how information contained within those signals is transduced and integrated to control an elaborate series of responses. Further, the knowledge we gain from studies of quorum sensing can be used as the basis for the design of novel antibacterial therapies. This is especially important at a time when new antibacterial pharmaceuticals are required to combat the ever-increasing problem of multidrug resistance in bacteria.

Finally, the phenomenon of quorum sensing and how bacteria talk to each other is a fascinating one, and its study could reveal fundamental principles about cell-cell communication and information flow. Additionally, if antibiotics can be designed that specifically counteract quorum sensing, these fundamental quorum-sensing studies could prove to have enormous practical application.

CHAPTER 1.13

Acetogenic Prokaryotes

HAROLD L. DRAKE, KIRSTEN KÜSEL AND CAROLA MATTHIES

Introduction to Acetogenic Bacteria and the Process of Acetogenesis

This chapter presents an overview of the history, taxonomy, phylogenetics, biochemistry, physiology, ecology, and applied aspects of acetogens. Acetogenic prokaryotes have only been found in the domain Bacteria. These prokaryotes utilize a reductive one-carbon pathway for the synthesis of acetyl-CoA, a metabolic precursor of both acetate and biomass. This pathway fixes CO_2 and is termed "the acetyl-CoA pathway." This pathway is often referred to as "the Wood-Ljungdahl pathway" in recognition of the two individuals, Harland G. Wood and Lars G. Ljungdahl, who were responsible for elucidating most of its enzymological features from the model acetogen *Moorella thermoacetica* (Fig. 1; see the section on Historical Perspectives in this Chapter). Acetogenesis (i.e., the process by which acetogens synthesize acetate) is often regarded as a fermentation process; however, as outlined in the subsection on CO_2 as Terminal Electron Acceptor and the Concept of Fermentation, acetogenesis is very dissimilar to classic fermentations. Purinolytic bacteria that synthesize acetate via the glycine pathway will not be considered in this chapter. However, certain features of this CO_2-fixing, glycine reductase-dependent pathway are similar to those of the acetyl-CoA pathway, and the reader is directed to the review of Andreesen (1994) for a detailed assessment of this pathway and organisms that use it.

Acetogens Defined

Usage of the term "acetogen" has not been consistent in the literature, and this inconsistent usage has caused a small amount of confusion regarding which organisms utilize the acetyl-CoA pathway for the synthesis of acetate. The following definition for the term acetogen has been previously proposed (Drake, 1994) and is applied in this chapter:

> Acetogen: an anaerobe that can use the acetyl-CoA pathway as a 1) mechanism for the reductive synthesis of acetyl-CoA from CO2, 2) terminal electron-accepting, energy-conserving process, and 3) mechanism for the fixation (assimilation) of CO2 in the synthesis of cell carbon.

Per this definition, the formation of acetate as an end product is unimportant, i.e., the fate of acetyl-CoA is less important than the process by which it is formed. For example, *Eubacterium limosum*, "*Butyribacterium methylotrophicum*" and *Caloramator pfennigii* (formerly *Clostridium pfennigii*), organisms that qualify as acetogens per the above definition, form butyrate from the acetyl-CoA that is formed via the acetyl-CoA pathway (Lynd and Zeikus, 1983; Zeikus, 1983; Krumholz and Bryant, 1985; Zeikus et al., 1985; Loubiere et al., 1992). Likewise, the acetogen *Acetobacterium woodii* forms ethanol from acetyl-CoA under certain conditions (Buschhorn et al., 1989).

The term "acetogenic" is an adjective that could be used to describe any organism that makes acetate or acetic acid. However, the metabolic processes by which acetate can be formed during either the aerobic or anaerobic growth of diverse microorganisms might not be equivalent. The mechanism by which acetate is formed via the oxidation of ethanol by *Acetobacter aceti* is fundamentally different from that used by certain obligate anaerobes that synthesize acetate from CO_2 via the reductive acetyl-CoA pathway. Thus, it is important that a differential nomenclature be applied to distinguish between acetate-forming bacteria because failure to do so results in unnecessary confusion in the literature. For example, *Thermobacteroides proteolyticus* and the syntroph PA-1 have been referred to as acetogens because they form acetate from glucose (Ollivier et al., 1985b; Brulla and Bryant, 1989). However, these organisms use protons, not CO_2, as terminal electron acceptors and form H_2, not acetate, as their main reduced end product; in short, they do not appear to use the acetyl-CoA pathway for the synthesis of acetate. Likewise, the butyrate-degrading syntroph *Syntrophomonas wolfei* has been described as an

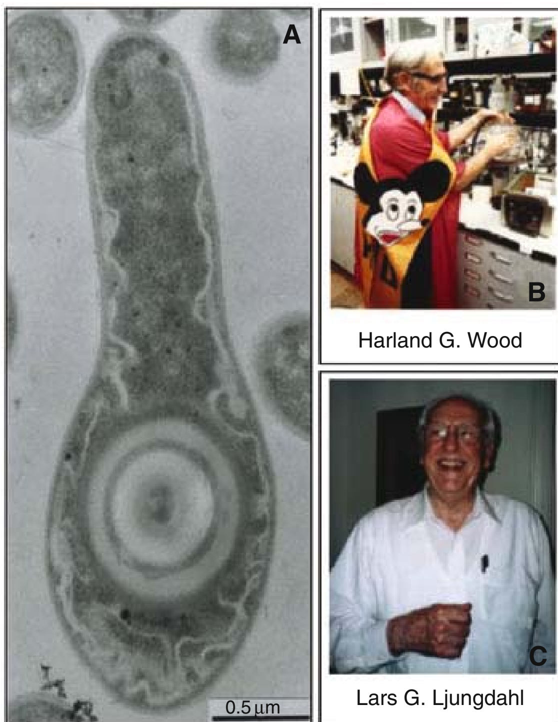

Fig. 1. A. Electron micrograph of a sporulated cell of *Clostridium thermoaceticum*, which was reclassified as *Moorella thermoacetica* (Collins et al., 1994). From Drake (1994), used with permission from Kluwer Academic. B, C. The two biochemists who were primarily responsible for resolving the enzymological features of the acetyl-CoA "Wood-Ljungdahl" pathway in *M. thermoacetica*. From Drake and Daniel (2004), used with permission from Elsevier. The dates of the photos for B and C are September 1977 (taken after Harland Wood's 70th birthday celebration/ symposium at Case Western Reserve University, during which Wood was "roasted" and given the honorary degree of Doctor of Mouse Science [the image on the hood symbolizes the shape of transcarboxylase as seen by electron microscopy]) and May 2000 (taken during the symposium honoring Harry D. Peck, Jr., at The University of Georgia), respectively.

acetogen (Stams and Doug, 1995). However, this organism 1) converts butyrate to acetate and H_2 (which can subsequently be used to reduce CO_2 to formate) by β-oxidation via the crotonyl-CoA pathway (Wofford et al., 1986), 2) does not reduce CO_2 to acetate, and 3) is not known to utilized the acetyl-CoA pathway.

Usage of the Terms "Acetogenesis," "Homoacetogen," and "Homoacetogenesis"

The term "acetogenesis" could be used to describe the process by which any organism forms acetate. For example, the term acetogenesis has been used to describe the 1) oxygen-dependent process by which *Enterococcus* RfL6 oxidizes lactate to acetate (Tholen et al., 1997) and 2) the production of acetate during proteolysis by *Treponema denticola* (Mikx, 1997). No evidence suggests that these organisms utilize the acetyl-CoA pathway for acetate synthesis. Since such usage makes it difficult to understand what process is being referred to, it has been suggested that usage of the term acetogenesis be restricted to processes by which two molecules of CO_2 are used to form one molecule of acetate (Wood and Ljungdahl, 1991b). Unfortunately such usage fails to adequately distinguish between the three known metabolic processes by which acetate is formed from CO_2: 1) the acetyl-CoA pathway, 2) the glycine synthase-dependent pathway, and 3) the reductive citric acid cycle (Fuchs, 1986; Fuchs, 1989; Thauer, 1988; Wood and Ljungdahl, 1991b).

The term "homoacetogen" is often used to distinguish between organisms that use the acetyl-CoA pathway and those that do not (Schink and Bomar, 1992). This term implies that acetate is the sole product formed by a particular organism. However, organisms that use the acetyl-CoA pathway usually do not form acetate as their sole end product. Their capacity to form any particular end product, including acetate, is dependent upon cultivation conditions. Butyrate (Lynd and Zeikus, 1983; Krumholz and Bryant, 1985; Worden et al., 1989; Grethlein et al., 1991), ethanol (Buschhorn et al., 1989), lactate (Lorowitz and Bryant, 1984; Drake, 1993; Misoph and Drake, 1996a), succinate (Dorn et al., 1978; Lorowitz and Bryant, 1984; Matthies et al., 1993; Misoph and Drake, 1996a), reduced aromatic acrylates (Tschech and Pfennig, 1984; Parekh et al., 1992; Misoph et al., 1996b), reduced aromatic aldehydes (Lux et al., 1990), CO (Diekert et al., 1986), H_2 (Martin et al., 1983; Lorowitz and Bryant, 1984; Savage et al., 1987), CH_4 (Savage et al., 1987; Buschhorn et al., 1989), sulfide (Heijthuijsen and Hansen, 1989; Beaty and Ljungdahl, 1991), dimethylsulfide (Beaty and Ljungdahl, 1991), nitrite (Seifritz et al., 1993; Fröstl et al., 1996), and ammonium (Seifritz et al., 1993; Seifritz et al., 2003; Fröstl et al., 1996) are examples of reduced end products of so-called "homoacetogens." Indeed, the production of such products can constitute the sole energy-conserving, growth-supportive process of the cell (see the subsection on Use of Diverse Terminal Electron Acceptors in this Chapter). Thus, the conditions under which an acetogen forms acetate should be qualified, rather than merely referring to the organism as a homoacetogen. For example, *Ruminococcus productus* (formerly *Peptostreptococcus productus*) is homoacetogenic on pyruvate but forms acetate, lactate, succinate, and formate when cultivated on fructose; this acetogen can also form large amounts of ethanol during glycerol-dependent growth

(Misoph and Drake, 1996a). Likewise, *Moorella thermoacetica* is homoacetogenic when cultivated on H_2/CO_2, but does not form acetate when cultivated on H_2/CO_2 in the presence of nitrate; under this condition, the dissimilation of nitrate is used preferentially to acetogenesis for the conservation of energy (Fröstl et al., 1996). Lastly, the term "homoacetate production" has been used to describe the process by which a genetically modified strain of *Escherichia coli* anaerobically produces 2 moles of acetate per mole glucose fermented (Causey et al., 2003), yet this process is not homoacetogenic (i.e., does not yield 3 moles of acetate per mole glucose) and the acetyl-CoA pathway is not involved.

Independent of these problems of usage, the production of acetate as the sole end product from certain sugars, H_2/CO_2, or CO/CO_2 strongly suggests that the organism in question utilizes the acetyl-CoA pathway per the definition for the term acetogen (see the subsection on Acetogens Defined in this Chapter).

Global Impact and Evolutionary Perspectives

Acetogens were initially viewed as obscure, poorly defined microorganisms. For nearly five decades following the discovery of acetogens in the 1930s, the major interest in them was restricted to resolving the biochemical features of the acetyl-CoA pathway (see the section on Historical Perspectives in this Chapter). The microbiology of acetogens drew little interest until the 1980s when it started to become apparent that acetogens were a widely distributed, phylogenetically diverse group of microorganisms. Added interest in the acetyl-CoA pathway occurred when it was discovered that methanogens and sulfate-reducing bacteria used metabolic pathways that contained acetyl-CoA synthase, one of the key enzymes in the acetyl-CoA pathway (Fuchs, 1986; Fuchs, 1989; Schauder et al., 1986; Thauer et al., 1989; see the subsection on Occurrence of the Acetyl-CoA Pathway in Nonacetogenic Microorganisms in this Chapter). Major bacterial groups employing this pathway in either the direction of acetate/biomass synthesis or acetate degradation include acetogens, methanogens, and sulfate-reducing bacteria.

It is not possible to determine how much carbon is processed globally via acetogens and pathways that make use of acetyl-CoA synthase. However, several facts are noteworthy:

1) The Calvin cycle, the reductive tricarboxylic acid cycle, the hydroxypropionate cycle, and the acetyl-CoA Wood-Ljungdahl pathway facilitate the complete autotrophic fixation of CO_2. Of these pathways, the one-carbon acetyl-CoA pathway is biochemically the most simple. For example, the acetyl-CoA pathway requires less ATP to fix a molecule CO_2 than does the Calvin cycle. Furthermore, the acetyl-CoA pathway is a linear process that does not depend on preformed, complex molecules to which CO_2 is fixed in a cyclic process (e.g., the Calvin cycle, the reductive tricarboxylic acid cycle, the hydroxypropionate cycle are dependent upon ribulose biphosphate, oxalacetate, and acetyl-CoA, respectively, for the fixation of CO_2) (see section on The Acetyl-CoA Pathway and Bioenergetics in this Chapter). Methanogens utilize an acetyl-CoA synthase-dependent pathway that is biochemically very similar to the acetyl-CoA pathway utilized by acetogenic bacteria (see the subsection on Occurrence of the Acetyl-CoA Pathway in Nonacetogneic Microorganisms in this Chapter), and methanogens (or ancestors of methanogens) may have been the first autotrophs (Schopf et al., 1983; Brock, 1989). Thus, and since life originated under anoxic conditions, the acetyl-CoA pathway or a pathway closely related to it may have been the first process used for the autotrophic fixation of CO_2 (Fuchs, 1986; Wood and Ljungdahl, 1991b; Lindahl and Chang, 2001).

2) Approximately half of the human population contain low numbers of methanogens in their gastrointestinal systems and produce relatively little CH_4; the colon of these individuals, as well as those who more actively emit CH_4, are heavily colonized by acetogens (Wolin and Miller, 1983). Indeed, the gastrointestinal systems of mammals, whether they harbor methanogens or not, are heavily colonized with acetogens (Prins and Lankhorst, 1977; Breznak and Kane, 1990; Mackie and Bryant, 1994; Wolin and Miller, 1994; Leedle et al., 1995).

3) Acetogens inhabit the human colon. In this habitat, acetogens produce 10^{10} kg of acetate per year from H_2-CO_2, and acetogenesis is one of the dominant processes in the overall metabolism of carbohydrate in the human colon (Lajoie et al., 1988; Wolin and Miller, 1994; Doréet al., 1995; Bernalier et al., 1996a; Bernalier et al., 1996b; Miller and Wolin, 1996; Wolin et al., 1999).

4) Totally, 10^{12} kg of acetate are produced each year via the reduction of CO_2 by acetogens in the hindgut of termites, a number that is fivefold greater than the annual amount of methane formed globally via the biogenic reduction of CO_2 (Breznak and Kane, 1990). One-third of the energy requirements of the termite is provided by the acetate that is synthesized by the reduction of CO_2 by gut acetogens (Breznak, 1994).

5) Totally, 10^{13} kg of acetate are formed and further metabolized annually in terrestrial habitats such as soils and sediments, and a minimum of 10% of this acetate is likely formed by the reduction of CO_2 via the acetyl-CoA pathway (Wood and Ljungdahl, 1991b).

6) Up to 25% of the total organic carbon of soil can be turned over through acetate under low temperature, anoxic conditions (equivalent to nearly 40 g acetate per kg dry wt. of soil; Küsel and Drake, 1994). The capacity to form acetate in soils is concomitant with acetogenic activities and the occurrence of H_2-utilizing acetogens (Küsel and Drake, 1995; Wagner et al., 1996; Küsel et al., 1999c). Acetate is a dominant organic compound in soil solution (Tani et al., 1993), and concentrations can be in the mM range following a rainfall event (Küsel and Drake, 1999a). Assuming a weight of 10^{17} kg for the first meter of the global terrestrial surface (based on a surface area of 10^{14} m^2 [Whitman et al., 1998] and using a weight conversion of 10^3 kg per m^3) and an acetate concentration of 0.1 mmol per kg of this material, it can be estimated that 10^{12} kg of acetate is present in the first meter of the terrestrial surface at any one moment (i.e., per "snapshot"). Even if only a small percentage of this acetate were formed by acetogens, given the turnover dynamics of acetate, the annual magnitude of the acetogen-derived acetate in the terrestrial biosphere would be enormous. The number of prokaryotes in the terrestrial subsurface might exceed that of the terrestrial surface by a factor of ten (Whitman et al., 1998). It can be projected that acetate and acetogens are also involved in the cycling of carbon in this poorly explored compartment of the terrestrial ecosphere (see the subsection on Diverse Habitats in this Chapter).

7) The acetate formed by acetogenesis is an essential trophic link during the turnover of carbon in diverse anoxic habitats (McInerney and Bryant, 1981).

Such observations not only illustrate that nature's ability to form acetate is enormous, they also demonstrate that the acetyl-CoA Wood/Ljungdahl pathway is fundamental to the carbon cycle of earth.

Historical Perspectives

Discovery of Acetogenic Bacteria and Acetogenesis

Acetogenesis was first reported in 1932, when unknown organisms in sewage were shown to catalyze the H_2-dependent reduction of CO_2 to acetate (Fischer et al., 1932). Shortly thereafter, the Dutch microbiologist Wieringa reported the isolation of the first acetogen (Wieringa, 1936; Wieringa, 1939–40; Wieringa, 1941). The organism, *Clostridium aceticum*, was a sporeforming, mesophilic rod, and grew at the expense of the following reaction:

$$4H_2 + 2CO_2 \rightarrow CH_2COOH + 2H_2O \quad (1)$$

Such a reaction had not been observed earlier. With the exception of a small study on the nutritional requirements of *C. aceticum* (Karlsson et al., 1948), no further work was published with this acetogen until it was reisolated in 1980–1981 (Adamse, 1980; Braun et al., 1981; Gottschalk and Braun, 1981; Fig. 2).

Clostridium thermoaceticum was discovered a few years after the isolation of *C. aceticum* (Fontaine et al., 1942) and was the only acetogen available for laboratory study for several decades (Fig. 1). This bacterium was reclassified as *Moorella thermoacetica* (Collins et al., 1994) and will be referred to by this name hereafter. *Moorella thermoacetica* was isolated as an obligate heterotroph and was observed to convert glucose to acetate; the stoichiometry of this process approximated the following reaction:

$$C_6H_{12}O_6 \rightarrow 3CH_3COOH \quad (2)$$

In the early 1940s, no known metabolic process could explain this reaction, and it was proposed that the CO_2 produced via oxidation was subsequently utilized in the synthesis of acetate:

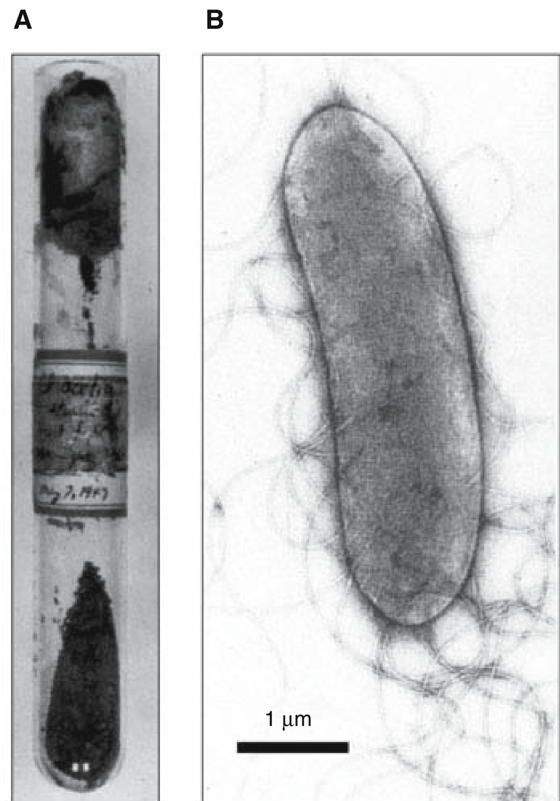

Fig. 2. A. Tube containing dried soil and spores of the first acetogen to be isolated, *Clostridium aceticum*. The tube was obtained from H. A. Barker; the date on the tube is May 7, 1947. B. Electron micrograph of a peritrichously flagellated cell of *C. aceticum*. From Braun et al. (1981), used with permission from Springer. The photograph (panel A) was kindly provided by G. Gottschalk.

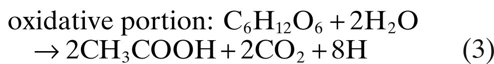
> Since, in this fermentation, 2.5 moles of a two-carbon compound (acetic acid) are obtained from 1 mole of glucose, it seems probable that either there is some primary cleavage of glucose other than the classical 3-3 split, or that a one-carbon compound is being reabsorbed. Of these two possibilities, the recent work on carbon dioxide uptake makes the latter seem more likely (Fontaine et al., 1942).

The latter statement was in reference to the discovery of CO_2 fixation in heterotrophs (Wood and Werkman, 1936; Wood and Werkman, 1938; Wood et al., 1941a; Wood et al., 1941b). Subsequent proposals for the acetogenic conversion of glucose or pyruvate to acetate made it possible to see that both the autotrophic and heterotrophic acetogenic processes likely involved the reductive synthesis of acetate from CO_2 (Barker, 1944).

Conversion of glucose to acetate:

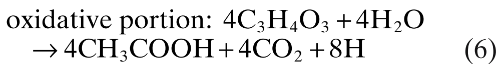


$$\text{oxidative portion: } C_6H_{12}O_6 + 2H_2O \rightarrow 2CH_3COOH + 2CO_2 + 8H \quad (3)$$

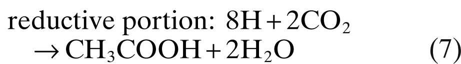
$$\text{reductive portion: } 8H + 2CO_2 \rightarrow CH_3COOH + 2H_2O \quad (4)$$

$$\text{net reaction: } C_6H_{12}O_6 \rightarrow 3CH_3COOH \quad (5)$$

Conversion of pyruvate to acetate:



$$\text{oxidative portion: } 4C_3H_4O_3 + 4H_2O \rightarrow 4CH_3COOH + 4CO_2 + 8H \quad (6)$$



$$\text{reductive portion: } 8H + 2CO_2 \rightarrow CH_3COOH + 2H_2O \quad (7)$$

$$\text{net reaction: } 4C_3H_4O_3 + 2H_2O \rightarrow 5CH_3COOH + 2CO_2 \quad (8)$$

The overlap between reactions 1, 4, and 7 indicated that a unique reductive process was likely responsible for acetate synthesis from CO_2.

Resolution of the Acetyl-CoA "Wood/Ljungdahl" Pathway

Barker and Kamen (1945) demonstrated in the first published biological experiments with ^{14}C (Kamen, 1963) that *M. thermoacetica* incorporated $^{14}CO_2$ equally into both carbon atoms of acetate. This landmark experiment with ^{14}C demonstrated that the capacity of *M. thermoacetica* to synthesize acetate from glucose was, in fact, similar to the capacity of *C. aceticum* to synthesize acetate from H_2/CO_2:

> *It may be concluded that the acetic acid fermentation of glucose by C. thermoaceticum involves a partial oxidation of the substrate to two moles each of acetic acid and carbon dioxide followed by a reduction and condensation of the carbon dioxide to a third mole of acetic acid* (Barker and Kamen, 1945).

In 1952, Wood repeated the ^{14}C-experiments of Barker and Kamen with $^{13}CO_2$ and confirmed that *M. thermoacetica* synthesized acetate from two molecules of CO_2 (Wood, 1952a). In this work, mass spectrometry conclusively demonstrated that CO_2 was uniformly fixed into both the carboxyl and methyl carbons of the third molecule of acetate from glucose. Utilizing [3,4-^{14}C]-glucose, it was also shown that carbons 3 and 4 of glucose were converted to CO_2 (Wood, 1952b). These early studies by Barker, Kamen and Wood demonstrated that 1) glucose was subject to a classic 3-3 split between carbons 3 and 4, and 2) CO_2 was fixed via an unknown CO_2-fixing process into acetate (Fig. 3).

It took decades of continued research before the enzymology of this CO_2-fixing process was fully resolved (see the section on The Acetyl-CoA Pathway and Bioenergetics in this Chapter). It is an irony of the history of acetogenesis that the model organism (i.e., *M. thermoacetica*)

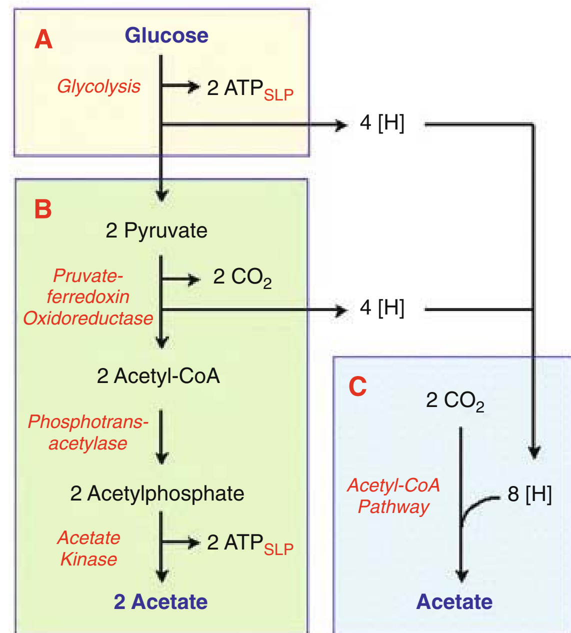


Fig. 3. Homoacetogenic conversion of glucose to acetate. Glucose is first converted to two molecules of pyruvate via glycolysis (Box A); glycolysis yields ATP by substrate-level phosphorylation (SLP). Pyruvate is then oxidized and decarboxylated, yielding acetyl-CoA, CO_2, and reducing equivalents (Box B). The two acetyl-CoA molecules that are produced from pyruvate are converted to two molecules of acetate; this process yields additional ATP by SLP. The 8 reducing equivalents that are produced via glycolysis and pyruvate-ferredoxin oxidoreductase are utilized in the acetyl-CoA pathway to reduce two molecules of CO_2 to an additional molecule of acetate (Box C). The CO_2 that is reduced in the acetyl-CoA pathway is likely derived primarily from supplemental CO_2 rather than the CO_2 derived via the decarboxylation of pyruvate. Modified from Drake (1994).

used to resolve the biochemistry of this autotrophic process was thought to be an obligate heterotroph during these decades of research. Indeed, the chemolithoautotrophic nature of *M. thermoacetica* (Daniel et al., 1990) was resolved nearly five decades after its isolation and well after the enzymological details of the acetyl-CoA pathway were firmly established. The milestones of the numerous studies that resolved both the enzymology of the acetyl-CoA pathway and the chemolithoautotrophic abilities of the model acetogen used in these studies can be found in numerous review articles (Ljungdahl and Wood, 1969; Wood, 1972; Wood, 1976; Wood, 1982; Wood, 1985; Wood, 1989; Wood, 1991a; Ljungdahl, 1986; Wood and Ljungdahl, 1991b; Drake, 1992; Drake, 1994; Ragsdale, 1991; Ragsdale, 1994; Ragsdale, 1997) and are outlined in Table 1. For additional insights into the early career years of Harland G. Wood, see the recent excellent historical treatments by Singleton (Singleton, 1997a; Singleton, 1997b; Singleton, 2000).

Isolates to Date and Microbiological Methods

The number of known acetogens has increased significantly in the last two decades, and approximately 100 different species have been isolated to date from extremely diverse habitats. Acetogens can be found in almost all anoxic environments, including some extreme habitats, as indicated by the isolation of strain SS1 (Liu and Suflita, 1993) and "*Acetobacterium psammolithicum*" from deep subsurface sediment and sandstone, respectively (Krumholz et al., 1999). Although most isolates to date are mesophilic, thermophilic and psychrotolerant species have also been isolated. The occurrence and ecological roles of acetogens in various habitats is discussed in the section on acetogen ecology (see the section on Ecology of Acetogens in this Chapter).

Bacteria considered to be acetogens as defined above (see the subsection on Acetogens Defined in this Chapter) are listed in Table 2.

Table 1. Milestones that led to resolving the acetyl-CoA pathway and chemolithoautotrophic abilities of *Moorella thermoacetica*.

Year	Event*
1932	H_2-dependent conversion of CO_2 to acetate in sewage sludge (Fischer et al., 1932)
1936	Isolation of the first acetogen, *Clotridium aceticum*; total synthesis of acetate from H_2-CO_2 (Note: culture was lost, Wieringa, 1936, 1939–40)
1942	Discovery of the second acetogen, *Moorella thermoacetica* (formerly *Clostridium thermoaceticum*); conversion of one glucose to three acetate molecules (Fontaine et al., 1942)
1944	Acetogenic conversion of pyruvate to acetate (Barker, 1944)
1945–52	Synthesis of acetate from $^{14}CO_2$ (Barker and Kamen, 1945) or $^{13}CO_2$ (Wood, 1952a, b)
1955	Formate as a methyl-group precursor (Lentz and Wood, 1955)
1964	Methylcobalamin as methyl-group precursor (Poston et al., 1964)
1965	Autotrophic synthesis of cell-carbon precursors from CO_2 (Ljungdahl and Wood, 1965)
1966–69	Proposal of one-carbon pathway for the tetrahydrofolate/corrinoid-mediated synthesis of acetate from CO_2 (Ljungdahl and Wood, 1966, 1969)
1973–86	Resolution of the tetrahydrofolate pathway (reviewed in Ljungdahl [1986])
1978–80	Discovery of CO dehydrogenase as a nickel-containing enzyme (Diekert and Thauer, 1978; Drake et al., 1980)
1981	Resolution of enzymes required for synthesis of acetyl-CoA from pyruvate and methyltetrahydrofolate (Drake et al., 1981a)
1981–82	Demonstration that CO replaces the carboxyl-group of pyruvate and undergoes an exchange reaction with acetyl-CoA (Drake et al., 1981b; Hu et al., 1982)
1982	Discovery of hydrogenase (Drake, 1982)
1983	Purification of CO dehydrogenase (Diekert and Ritter, 1983; Ragsdale et al., 1983)
1983	Use of H_2 and CO under organotrophic conditions (Kerby and Zeikus, 1983)
1984	Resolution of nutritional requirements (Lundie and Drake, 1984)
1984	Enzyme system for H_2-dependent synthesis of acetyl-CoA (Pezacka and Wood, 1984b)
1984–86	CO dehydrogenase is acetyl-CoA synthase (Pezacka and Wood, 1984a, b; Regsdale and Wood, 1985) and CO is the carbonyl precursor in the acetyl-CoA pathway under growth conditions (Diekert et al., 1984; Martin et al., 1985)
1985–91	Catalytic mechanism of acetyl-CoA synthase (reviewed in Ragsdale [1991])
1986–90	H_2- and CO-dependent electron transport system coupled to the synthesis of ATP (Ivey and Ljungdahl, 1986; Hugenholtz and Ljungdahl, 1989, 1990; Das et al., 1989)
1990	Chemolithoautotrophic growth on H_2-CO_2 and CO-CO_2 (Daniel et al., 1990)
1991	Integrated model for catabolic, anabolic, and bioenergetic features of the acetyl-CoA "Wood-Ljungdahl" pathway (Wood and Ljungdahl, 1991)

*Events prior to the isolation of *Moorella thermoacetica*.
Modified from Drake 1994.

Table 2. Acetogenic bacteria isolated to date.[a]

Acetogen	Source of isolate	Gram type[b]	Cell morphology	Growth temperature[c]	G+C (mol%)	Deposited as	References
Acetoanaerobium ruminis	Rumen fluid, steer	+	Rod	Mesophilic	34	ATCC 43876[I]	Greening and Leedle, 1989
Acetoanaerobium noterae	Sediment	–	Rod	Mesophilic	37	ATCC 35199[I]	Sleat et al., 1985
"Acetoanaerobium romashkovii"	Oil field	+	Rod	Mesophilic	40	n.d.	Davydova-Charakhch'yan et al., 1992
Acetobacterium baloï	Wastewater sediment	+	Rod	Psychrotrophic	42	DSM 8239[I]	Kotsyurbenko et al., 1995
Acetobacterium carbinolicum	Freshwater sediment	+	Rod	Mesophilic	38	DSM 2925[I]	Eichler and Schink, 1984
"Acetobacterium dehalogenans"	Sewage digester sludge	+	Coccus	Mesophilic	48	DSM 11527	Traunecker et al., 1991
Acetobacterium fimetarium	Digested cattle manure	+	Rod	Psychrotrophic	46	DSM 8238[I]	Kotsyurbenko et al., 1995
Acetobacterium malicum	Freshwater sediment	+	Rod	Mesophilic	44	DSM 4132[I]	Tanaka and Pfennig, 1988
Acetobacterium paludosum	Fen sediment	+	Rod	Psychrotrophic	42	DSM 8237[I]	Kotsyurbenko et al., 1995
"Acetobacterium psammolithicum"	Subsurface sandstone	–	Rod	Mesophilic	n.r.	SMCC/W 751[I]	Krumholz et al., 1999
Acetobacterium tundrae	Tundra soil	+	Rod	Psychrotrophic	39	DSM 9173[I]	Simankova et al., 2000
Acetobacterium wieringae	Sewage digester	+	Rod	Mesophilic	43	DSM 1911[I]	Braun and Gottschalk, 1982
Acetobacterium woodii	Marine sediment	+	Rod	Mesophilic	39	ATCC 29683[I]	Balch et al., 1977
Acetobacterium sp. AmMan1	Freshwater sediment	+	Rod	Mesophilic	36	n.d.	Dörner and Schink, 1991
Acetobacterium sp. B10	Wastewater pond	+	Rod	Mesophilic	n.r.	n.d.	Sembining and Winter, 1989, 1990
Acetobacterium sp. HA1	Sewage sludge	+	Rod	Mesophilic	n.r.	n.d.	Schramm and Schink, 1991
Acetobacterium sp. HP4	Lake sediment	+	Rod	Psychrotrophic	n.r.	n.d.	Conrad et al., 1989
Acetobacterium sp. KoB58	Sewage sludge	+	Rod	Mesophilic	44	n.d.	Wagener and Schink, 1988
Acetobacterium sp. LuPhet1	Sewage sludge	+	Rod	Mesophilic	44	DSM 9077	Frings and Schink, 1994
Acetobacterium sp. LuTria3	Sewage sludge	+	Rod	Mesophilic	35	DSM 8909	Frings et al., 1994
Acetobacterium sp. MrTac1	Marine sediment	+	Rod	Mesophilic	n.r.	n.d.	Emde and Schink, 1987
Acetobacterium sp. OyTac1	Freshwater sediment	+	Rod	Mesophilic	n.r.	n.d.	Emde and Schink, 1987
Acetobacterium sp. RMMac1	Marine sediment	–	Rod	Mesophilic	48	n.d.	Schuppert and Schink, 1990
Acetobacterium sp. 69	Sea sediment	+	Rod	Mesophilic	48	n.d.	Inoue et al., 1992
Acetobacterium sp.	Tundra wetland soil	+	Rod	Psychrotrophic	39	n.d.	Kotsyurbenko et al., 1996
Acetohalobium arabaticum	Saline lagoon	–	Rod	Mesophilic	34	DSM 5501[I]	Zhilina and Zavarzin, 1990
Acetonema longum	Wood-eating termite, gut	–	Rod	Mesophilic	52	DSM 6540[I]	Kane and Breznak, 1991
"Bryantella formatexigens"	Human feces	+	Rod	Mesophilic	50	DSM 14469[I]	Wolin et al., 2003
"Butyribacterium methylotrophicum"	Sewage digester	+	Rod	Mesophilic	49	ATCC 33266[I]	Zeikus et al., 1980
Caloramator fervidus (?)	Hot spring	–	Rod	Thermophilic	39	ATCC 43204[I]	Patel et al., 1987

"New acetogenic bacterium"	Rumen, 15-hour-old lamb	+	Coccoid rod	Mesophilic	46	DSM 12568	Rieu-Lesme et al., 1996a

Symbols and Abbreviations: +, positive; –, negative; +/–, variable; n.d., not deposited; n.r., not reported; [T], type strain; ATCC, American Type Culture Collection; DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH, Braunschweig, Germany; SMCC, and Subsurface Microbial Culture Collection.

[a]Bacteria listed appear to use the acetyl-CoA pathway for the synthesis of acetate and growth (modified from Drake [1992, 1994]). If the acetogenic nature of an organism is uncertain, a question mark occurs after the name of the organism (see text). Organisms not having validated names are enclosed in quotation marks. Unless otherwise indicated, type strains (marked with a "T" adjacent to the deposition number) are available from American Type Culture Collection (ATCC), 10801 University Boulevard, Manassas, Virginia, U.S.A., and Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH (DSMZ) Mascheroder Weg 1b, Braunschweig, Germany.

[b]Gram type is based on electron microscopic analyses of the cell wall structure if reported. Otherwise, Gram type is based on the Gram-stain reaction. (Note: results of the Gram-stain reaction are not always in agreement with the electron microscopic analysis of the cell wall.)

[c]General temperature preference: psychrophilic (5–10°C), psychrotolerant (16–18°C), mesophilic (31–34°C), and thermophilic (58–62°C).

[d]See also Adamse (1980).

[e]See also E1 Ghazzawi (1967).

[f]See also Moore and Cato (1965).

[g]Isolate F21 is phylogenetically closely related to *M. thermoacetica* ET-5a, which was also isolated from soil (Gößner et al., 1999; Karita et al., 2003).

[h]*Sporomusa* sp. DR6 appears to be identical to *Sporomusa* sp. DR15 and *Sporomusa* sp. DR16, which were isolated in the same study (Rosencrantz et al., 1999).

[i]Strain may be a species of *Streptococcus* (Bernalier et al., 1996a).

[j]Strain may be a species of *Acetobacterium* (Nozhevnikova et al., 1994).

However, relatively few of these bacteria have been examined in detail, and a good understanding of the metabolic capabilities of most of the isolates is lacking. In compiling the list, the apparent acetogenic capability (see the subsection on Usage of the Terms "Acetogenesis," Homoacetogen" and "Homoacetogenesis" in this Chapter) of each organism has been taken into account. In this regard, three main metabolic features of these organisms (Drake, 1994) are 1) the use of chemolithoautotrophic substrates (H_2-CO_2 or CO-CO_2) as sole sources of carbon and energy under anoxic conditions, 2) the capacity to convert certain sugars stoichiometrically to acetate, and 3) the ability to *O*-demethylate methoxylated aromatic compounds and metabolize the *O*-methyl group via the acetyl-CoA pathway. Many acetogens display all three of these metabolic capabilities.

Most acetogenic isolates are rod-shaped, but coccoid forms have also been observed (Table 2). Staining properties vary, sometimes within a genus, and both Gram-negative and Gram-positive species have been reported (Table 2). Some acetogens have flagella and are motile. Some form spores that remain viable for long periods; the thermophilic spore-formers are fairly resistant to high temperatures. Indeed, spores of *M. thermoacetica* have a decimal reduction time (i.e., the time required to decrease the population of viable spores by 90%) of 111 min at 121°C (Byrer et al., 2000). Cells of the acetogen *Clostridium glycolicum* RD-1 are tethered by connecting filaments, a morphological structure recently described for *Clostridium akagii* and *Clostridium uliginosum* (Kuhner et al., 2000; Matthies et al., 2001). Thus, the ultrastructural features of acetogens are highly variable.

Description of Species

Acetogens have been assigned to 21 different genera and differ in their morphological, cytological and physiological properties (Table 2). The genera *Clostridium* and *Acetobacterium* harbor the most acetogenic species isolated to date. The first acetogen was classified as a clostridial species, *C. aceticum* (Wieringa, 1936). The second acetogenic genus *Acetobacterium* was established when the first Gram-positive, nonsporeforming acetogen (*Acetobacterium woodii*; Balch et al., 1977; Fig. 4) was isolated and could not be grouped with the acetogenic clostridia. Conspicuously, all the heretofore isolated psychrotolerant acetogens and many N_2-fixing acetogens belong to the genus *Acetobacterium* (Schink and Bomar, 1992; Table 2). About half of the genera that harbor acetogens only contain one acetogenic species (e.g., *Holophaga foetida*, *Acetohalobium arabaticum*, *Oxobacter pfennigii*, *Acetonema longum*; Table 2). Recently, acetogenesis has been observed in spirochetes ("*Treponema primitia*") isolated from termite guts (Leadbetter et al., 1999; Graber and Breznak, 2004a; Graber et al., 2004b; Fig. 5).

A brief overview of acetogenic species having validated names is given in the following paragraphs. The names of those organisms not validated are in quotation marks. Earlier compilations include Breznak (1992), Diekert (1992), Hippe et al. (1992), Schink and Bomar (1992), Mackie and Bryant (1994), and Schink (1994). Although relatively few of the acetogens listed below have been evaluated for their ability to tolerate O_2, it should be anticipated that many acetogens possess the ability to both tolerate and consume small amounts of oxygen (Küsel et al., 2001; Karnholz et al., 2002; Boga and Brune, 2003).

ACETITOMACULUM RUMINIS. This species was isolated from steer rumen fluid (Greening and Leedle, 1989). Cells are Gram-positive, nonsporeforming, motile, slightly curved rods. Growth-supportive substrates include H_2-CO_2, CO, formate, cellobiose, glucose, ferulate and syringate. With all substrates, acetate is the sole reduced end product (Greening and Leedle, 1989).

ACETOANAEROBIUM NOTERAE. This species was isolated from sediment samples of the Notera oil exploration site in Israel (Sleat et al., 1985). Cells are Gram-positive, nonsporeforming, motile, straight rods. *Acetoanaerobium noterae* grows with H_2-CO_2, glucose, and maltose, and produces acetate as the sole product. Propionate, butyrate, isobutyrate, and isovalerate are also formed when yeast extract serves as the growth-supportive substrate (Sleat et al., 1985).

"ACETOANAEROBIUM ROMASHKOVII." This organism was isolated from the Romashkin oil field in Tatarstan (Davydova-Charakhch'yan et al., 1992). Cells are Gram-positive, nonsporeforming, motile rods with rounded ends. Growth-supportive substrates include H_2-CO_2, formate, methanol, pyruvate, lactate, ethylene glycol, sugars, and amino acids. Acetate is the sole product from carbohydrates and H_2-CO_2; propionate is also formed during growth on sucrose. "*Acetoanaerobium romashkovii*" produces and excretes polysaccharides during growth on H_2-CO_2 or methanol (Davydova-Charakhch'yan et al., 1992).

ACETOBACTERIUM BAKII, ACETOBACTERIUM FIMETARIUM, AND ACETOBACTERIUM PALUDOSUM. These species were isolated from cold habitats (<6°C) or from

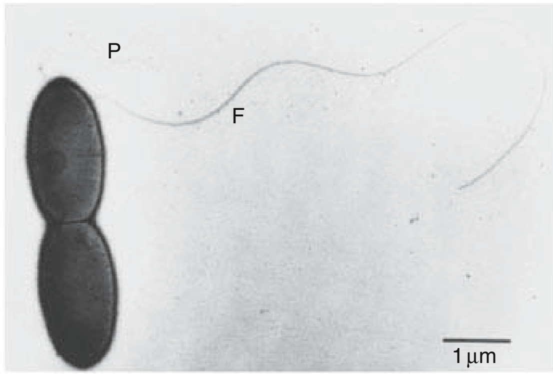

Fig. 4. Electron micrograph of cells of *Acetobacterium woodii* (ATCC 29683[T], DSM 1030[T]) with a single subterminal flagellum (F) and pili-like structures (P). From Balch et al. (1977), used with permission from International Union of Microbiological Societies. The micrograph was kindly provided by R. S. Wolfe.

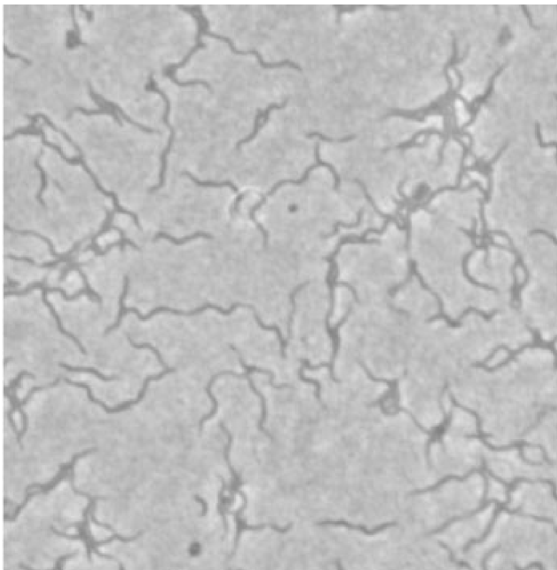

Fig. 5. Phase contrast micrograph of spirochete *Treponema* sp., strain ZAS-2. The length of cells varies from 3 to 7 µm. The micrograph was kindly provided by J. Breznak.

samples that were kept for more than one year at 6°C (Kotsyurbenko et al., 1995). Cells of all three species are Gram-positive, oval-shaped, and motile rods. Although these species were isolated at 6°C, their optimum growth temperatures are 20°C (*A. bakii* and *A. paludosum*) and 30°C (*A. fimetarium*). However, their ability to grow at a temperature as low as 1°C qualifies them as psychrotolerant bacteria. *Acetobacterium bakii*, *A. fimetarium* and *A. paludosum* grow with H_2-CO_2, CO, formate and certain sugars, and stoichiometrically convert these substrates to acetate as the sole product (Kotsyurbenko et al., 1995). Although these three species are very similar, DNA-DNA hybridization supported the designation of three different species.

ACETOBACTERIUM CARBOLINICUM. This species was isolated from freshwater sediments (Eichler and Schink, 1984). Cells are Gram-positive, nonsporeforming, rods with slightly pointed ends; some strains are motile. The type strain grows with ethanol, propanol, butanol, 1,2-propanediol, and 2,3-butanediol and oxidizes these substrates incompletely to the corresponding fatty acids and uses the reducing equivalents to reduce CO_2 to acetate via the acetyl-CoA pathway (Eichler and Schink, 1984). Other growth-supportive substrates include H_2-CO_2, formate, pyruvate, lactate, methanol, hexoses, ethylene glycol, and methoxylated aromatic acids. Strain *A. carbinolicum* KoMac1 (DSM 5193) was isolated with the methylalkylether methoxyacetate and can also grow on glycol ethers. The ether bond of these compounds is cleaved and acetate is formed as the sole product (Schuppert and Schink, 1990). Strain KoMac1 also utilizes the *O*-methyl group of methoxylated aromatics and betaine (Schuppert and Schink, 1990).

"ACETOBACTERIUM DEHALOGENANS." This organism (also termed "strain MC") was isolated from sewage sludge (Traunecker et al., 1991). Cells are Gram-positive, nonsporeforming, nonmotile, elongated cocci. "*Acetobacterium dehalogenans*" is the only known acetogen able to utilize and grow with methyl chloride. Methyl chloride is dehalogenated via a methyl chloride dehalogenase (Meßmer et al., 1996) and is further metabolized to acetate via the acetyl CoA pathway. Other substrates supporting growth of the organism include H_2-CO_2, CO, glucose, fumarate, methanol, and methoxylated aromatic compounds.

ACETOBACTERIUM MALICUM. This species was enriched and isolated with 2-methoxyethanol as growth substrate from a freshwater sediment (Tanaka and Pfennig, 1988). Cells are Gram-positive, nonsporeforming, motile rods with slightly pointed ends. Similar to a few other species of *Acetobacterium*, *A. malicum* can grow at the expense of the ether compounds 2-methoxymethanol and 2-ethoxyethanol, which are metabolized to acetate and the corresponding alcohols. Other growth-supportive substrates include malate, H_2-CO_2, formate, pyruvate, fructose, betaine, and the *O*-methyl groups of methoxylated aromatic compounds (Tanaka and

Pfennig, 1988). Acetate is the sole product of these substrates.

"ACETOBACTERIUM PSAMMOLITHICUM." This species was isolated from subsurface sandstone and represents the second acetogen isolated from a subsurface ecosystem (Krumholz et al., 1999). (The first acetogenic isolate from a subsurface habitat was the unclassified strain SS1; Liu and Suflita, 1993). Cells are Gram-negative, nonsporeforming, nonmotile rods. Growth is very slow in mineral medium. In medium supplemented with yeast extract, growth is very good on H_2-CO_2, methanol, formate, glucose, syringate, alcohols, and organic acids (Krumholz et al., 1999). Acetate is the product of H_2-CO_2-dependent growth; products of other growth-supportive substrates are not reported.

ACETOBACTERIUM TUNDRAE. This organism is psychrotolerant and was isolated from a tundra wetland soil (Simankova et al., 2000). Cells are Gram-positive, nonsporeforming, motile rods. Growth-supportive substrates include H_2-CO_2, CO, formate, methanol, and sugars; acetate is the sole reduced end product. As with the psychrotrophic acetogens *A. bakii* and *A. paludosum*, *A. tundrae* has a minimum growth temperature of 1°C and an optimal growth temperature of 20°C.

ACETOBACTERIUM WIERINGAE. This species was isolated from a sewage digester (Braun and Gottschalk, 1982). Cells are Gram-positive, nonsporeforming, motile rods. H_2-CO_2, fructose, and lactate are growth-supportive substrates; acetate is the sole reduced end product (Braun and Gottschalk, 1982). *Acetobacterium wieringae* tolerates 300 mM acetate (Menzel and Gottschalk, 1985).

ACETOBACTERIUM WOODII. The type strain of *A. woodii* was enriched and isolated from black sediment of a marine estuary with H_2-CO_2 as substrate (Balch et al., 1977). Cells are Gram-positive, nonsporeforming, motile rods with slightly pointed ends (Fig. 4). Growth-supportive substrates include H_2-CO_2, CO, formate, methanol, 2,3-butandiol, ethylene glycol, acetoin, glycerol, sugars, betaine, and several methoxylated aromatic acids (Balch et al., 1977; Bache and Pfennig, 1981; Eichler and Schink, 1984; Sharak Genthner and Bryant, 1987; Schink and Bomar, 1992). Cultures demethylate the osmolytes dimethylsulfoniopropionate and glycine-betaine to methylthiopropionate and dimethylglycine, respectively; however, only the demethylation of glycine-betaine supported growth of the organism (Jansen and Hansen, 2001). *Acetobacterium woodii* growths mixotrophically on (i.e., can simultaneously utilize) H_2-CO_2 and organic compounds (e.g., fructose; Braun and Gottschalk, 1981) and can use aromatic acrylates as energy-conserving, growth-supportive terminal electron acceptors (Bache and Pfennig, 1981; Tschech and Pfennig, 1984). Growth, motility, and acetate formation from H_2-CO_2 are strictly dependent on sodium ions (Heise et al., 1989; Müller and Bowien, 1995; Aufurth et al., 1998). Several Na^+-dependent reactions in the metabolism of *A. woodii* have been identified, and associated enzymes have been purified and characterized (Heise et al., 1989; Heise et al., 1991; Heise et al., 1992; Heise et al., 1993; Müller and Gottschalk, 1994; Reidlinger and Müller, 1994a; Reidlinger et al., 1994b; Müller et al., 2001). Cells reductively dechlorinate carbon tetrachloride (Egli et al., 1988; Stromeyer et al., 1992); dechlorination is enhanced by the addition of hydroxocobalamin (Hashsham and Freedman, 1999). Cells also tolerate and consume small amounts of oxygen (Karnholz et al., 2002).

ACETOHALOBIUM ARABATICUM. This organism was isolated from a cyanobacterial mat in a saline lagoon and was the first obligately halophilic acetogen to be described (Zhilina and Zavarzin, 1990). Sodium chloride (10–25%) is necessary for growth. Cells are motile, straight rods often aggregated in palisades. H_2-CO_2, CO, trimethylamine, formate, betaine, lactate, pyruvate, and histidine are growth-supportive substrates. Acetate is the main product during growth on trimethylamine and betaine and is accompanied by minor amounts of methylamines (Zhilina and Zavarzin, 1990; Zavarzin et al., 1994). Cell extracts have CO dehydrogenase and hydrogenase activities, which are stimulated by increased salt concentrations.

ACETONEMA LONGUM. This organism was isolated from the gut contents of the wood-feeding termite *Pterotermes occidentis* (Kane and Breznak, 1991a). Cells are sporeforming, motile rods of unusually large size; cells can be up to 60 µm in length. Growth-supportive substrates include H_2-CO_2, pyruvate, fumarate, glucose, mannitol, and ribose; poor growth occurs on citrate, propanol, ethylene glycol, and 3,4,5-trimethoxybenzoate. Homoacetogenesis only occurs with H_2-CO_2. Butyrate and acetate are the main products from carbohydrates and pyruvate; fumarate is metabolized to propionate and acetate, and rhamnose yields 1,2-propanediol as the major product (Kane and Breznak, 1991a).

"BRYANELLA FORMATEXIGENS." This species was isolated from human feces (Wolin et al., 2003). Cells are Gram-positive, nonmotile short rods (approx. 1.2 × 0.7 µm). Single cells, and pairs and short chains of cells, are apparent. Upon isolation, the type strain (I-52; Wolin and Miller, 1994) fermented vegetable cellulose and carboxymethylcellulose but lost this ability after storage under frozen conditions. No growth occurs on H_2-CO_2 or formate, and formate is

required for optimal homoacetogenic conversion of glucose. The lack of supplemental formate yields succinate, lactate and acetate as products from glucose. These characteristics indicate that the formate dehydrogenase is negliable. Growth is supported by stachyose, sucrose, lactose, maltose, galactose, mannose, and xylose. Cells are catalase and oxidase negative, and nitrate is not reduced.

"BUTYRIBACTERIUM METHYLOTROPHICUM." This organism was isolated from a sewage digestor (Zeikus et al., 1980). Cells are Gram-positive, sporeforming, nonmotile rods. Growth is supported by H_2-CO_2, formate, methanol, glucose, fructose, sucrose, pyruvate, lactate and glycerol (Zeikus et al., 1980; Kerby and Zeikus, 1987). Homoacetogenic utilization of substrates only occurs with H_2-CO_2 and formate. With other substrates, butyrate and H_2 are also produced (Zeikus et al., 1980; Lynd and Zeikus, 1983). After prolonged incubation in medium with CO in the gas phase, the type strain grew on and utilized CO; acetate was the sole product from CO (Lynd et al., 1982). There is substantial evidence that "*B. methylotrophicum*" and *Eubacterium limosum* are the same species: 1) the metabolic properties of the two organisms are nearly identical, and 2) the 16S rRNA gene sequences of the two organisms are very similar (99.4% sequence similarity; Moore and Cato, 1965; Sharak Genthner et al., 1981; Tanner et al., 1981; Sharak Genther and Bryant, 1982; Tanner and Woese, 1994; Jansen and Hansen, 2001).

CALORAMATOR FERVIDUS. This species was isolated from a hot spring in New Zealand and was first described as *Clostridium fervidus* (Patel et al., 1987). Cells are Gram-negative, sporeforming, motile rods. Carbohydrates support growth, and acetate is the major end product. However, growth on one-carbon compounds (e.g., formate) or other typical acetogenic substrates (e.g., H_2-CO_2) has not been reported, and substrate/product stoichiometries of carbohydrate utilization are not available. Thus, the true acetogenic nature of this organism has not been estabilished. Until otherwise proven, one should assume that the organism might not be an acetogen.

CLOSTRIDIUM ACETICUM. This species was the first acetogen to be isolated (Fig. 2). It was isolated from soil and described by Wieringa (Wieringa, 1936; Wieringa, 1939–40). After early studies with the organism (Karlsson et al., 1948), it was lost for about 30 years. However, *C. aceticum* was reisolated from soil using Wieringa's enrichment procedure, and almost at the same time spores of the original Wieringa strain in sterile dried soil were found in Barker's laboratory and revived (Adamse, 1980; Braun et al., 1981). Cells are Gram-negative, sporeforming, motile rods (Wieringa, 1939–40; Braun et al., 1981). Growth-supportive substrates include H_2-CO_2, CO, fructose, glutamate fumarate, pyruvate, aldehyde groups of aromatic compounds, and methoxylated aromatic compounds (Wieringa, 1939–40; Braun et al., 1981; Lux and Drake, 1992; Matthies et al., 1993; Gößer et al., 1994). As with *C. formicoaceticum* (see below), fumarate is dismutated by *C. aceticum* to acetate and succinate, and is metabolized independent of the acetyl-CoA pathway; fumarate also serves as an alternative electron acceptor and is reduced to succinate (Matthies et al., 1993). N_2 is fixed (Cato et al., 1986).

"CLOSTRIDIUM AUTOETHANOGENUM." This organism was isolated from rabbit feces (Abrini et al., 1994). Cells are Gram-positive, sporeforming, motile rods. The range of substrates includes H_2-CO_2, CO, pyruvate, hexoses, pentoses, and glutamate, and is similar to the range of substrates used by *Clostridium ljungdahlii* (Abrini et al., 1994; Tanner et al., 1993). CO is converted to acetate and ethanol (Abrini et al., 1994). Ethanol production from CO was also reported for *C. ljungdahlii*; however, this metabolic potential is not necessarily stable (Barik et al., 1988; Tanner et al., 1993). The 16S rRNA gene sequences of "*C. autoethanogenum*" and *C. ljungdahlii* are essentially identical (Stackebrandt et al., 1999).

CLOSTRIDIUM COCCOIDES. Two acetogenic strains of *C. coccoides* (strains 1410 and 3110) were isolated from the human intestinal tract (Kamlage et al., 1997). The type strain of *C. coccoides* isolated from mouse feces was not initially described as an acetogen; however, it has recently been shown to contain all the enzymes of the acetyl CoA pathway when grown on H_2-CO_2-formate (Kaneuchi et al., 1976; Kamlage et al., 1997). Cells of *C. coccoides* strain 1410 (which is probably identical to strain 3110) are Gram-variable, coccoid rods. *Clostridium coccoides* strain 1410 grows on a variety of hexoses, pentoses, sugar alcohols, H_2-CO_2-formate, and H_2-CO_2-vanillate. Products from growth have not been reported. However, resting cells convert formate, H_2-CO_2, and *O*-methyl groups of vanillate to acetate at stoichiometries indicative of acetogenesis; the aromatic ring of vanillate remains intact (Kamlage et al., 1997). Resting cells of *C. coccoides* strain 1410 convert glucose to acetate, succinate, and D-lactate.

CLOSTRIDIUM DIFFICILE. Five acetogenic strains of *C. difficile* were isolated from the rumen of newborn lambs; strain AA1 is considered as a representative strain (Rieu-Lesme et al., 1998). No acetogenic potentials have been documented for the type strain of *C. difficile*. Cells of *C. difficile* strain AA1 are Gram-positive, sporeforming, giant filamentous rods. Growth of

strain AA1 is supported by H_2-CO_2, fructose, glucose, cellobiose, maltose, mannose, and syringate. Acetate is the sole product from H_2-CO_2 and the substrate/product stoichiometry is indicative of acetogenesis; however, glucose and fructose are metabolized to almost equal amounts of acetate and butyrate, and small amounts of ethanol and isovalerate (Rieu-Lesme et al., 1998).

CLOSTRIDIUM FORMICOACETICUM. The first strain of *C. formicoaceticum* was probably isolated from pond sediment by El Ghazzawi (1967). Although the organism was called *Clostridium aceticum* in the title of the German publication, El Ghazzawi stated that his isolate differed from *C. aceticum* and tentatively named his organism "*Clostridium formicoaceticum*" because it produced both formate and acetate (El Ghazzawi, 1967). The type strain of *C. formicoaceticum* was isolated from sewage sludge (Andreesen et al., 1970). Cells are Gram-negative, sporeforming, motile, straight or slightly curved rods. The range of substrates is very similar to that of *C. aceticum* (see above) but also includes glycerol, gluconate, glucuronate, and glycerate (Andreesen et al., 1970). *Clostridium formicoaceticum* can be differentiated from *C. aceticum* by its inability to grow with H_2-CO_2 and its ability to grow with methanol and lactate (Andreesen et al., 1970; Lux and Drake, 1992). As with *C. aceticum*, the utilization of fumarate by *C. formicoaceticum* does not involve the acetyl-CoA pathway; fumarate is dismutated to acetate and succinate (Dorn et al., 1978). Fumarate can also serve as an alternative electron acceptor (Matthies et al., 1993), and N_2 is fixed (Bogdahn et al., 1983). Reductant derived from the oxidation of the aldehyde groups of certain aromatic compounds (e.g., 4-hydroxybenzaldehyde) is growth supportive (Gößer et al., 1994), preferentially used in the acetyl-CoA pathway, and inhibits the use of fructose (Frank et al., 1998).

CLOSTRIDIUM GLYCOLICUM. Two acetogenic strains of *C. glycolicum* have been isolated. Strain 22 was isolated from sewage sludge, grows on H_2-CO_2, and produces mainly acetate; cells are Gram-positive rods that form oval, subterminal spores (Ohwaki and Hungate, 1977). Strain 22 has been deposited at the American Type Culture Collection (ATCC) and has been identified as a strain of *Clostridium glycolicum*; however, the 16S rRNA gene sequence is not available (per information from the ATCC Bacteriology Program). Strain RD-1 was isolated from sea grass roots and was identified as an acetogenic strain of *C. glycolicum* by analysis of the 16S rRNA gene sequence (Küsel et al., 2001). Cells of strain RD-1 are Gram-positive, sporeforming, motile rods that can be linked by connecting filaments. Growth-supportive substrates of strain RD-1 include H_2-CO_2, formate, pyruvate, lactate, ethylene glycol, and certain sugars. Except for growth on sugars and ethylene glycol, acetate is the sole reduced end product. Strain RD-1 is aerotolerant and grows at O_2 concentrations of up to 6% in the headspace of static liquid cultures and up to 4% in the headspace of shaken liquid cultures; ethanol, lactate and H_2 are the reduced end products under oxic conditions (Küsel et al., 2001; see the subsection on Tolerance to Oxic Conditions and Metabolism of O_2 in this Chapter). No acetogenic potentials have been found for the type strain of *C. glycolicum* (Gaston and Stadtman, 1963; Küsel et al., 2001).

CLOSTRIDIUM LJUNGDAHLII. This organism was isolated from chicken manure/waste (Barik et al., 1988; Tanner et al., 1993). Cells are Gram-positive, sporeforming, motile rods (Fig. 6). The organism grows autotrophically on H_2-CO_2 and CO; heterotrophic growth occurs on formate, ethanol, pyruvate, fumarate, and sugars (including fructose and xylose; Tanner et al., 1993). The sole product from H_2-CO_2 and fructose is acetate; however, from synthesis gas (a mixture of H_2, CO, and CO_2), acetate and ethanol are produced (Tanner et al., 1993; Phillips et al., 1994). Nitrate is reduced to ammonium; however, unlike the dissimilation of nitrate by *M. thermoacetica* (see the sections on Use of Diverse Terminal Electron Acceptors and Regulation of the Acetyl-CoA Pathway and Other Metabolic Abilities in this Chapter), the reduction of nitrate does not have a regulatory effect on acetogenesis and likewise does not enhance the growth of the organism (Seifritz et al., 1993; Fröstl et al., 1996; Laopaiboon and Tanner, 1999).

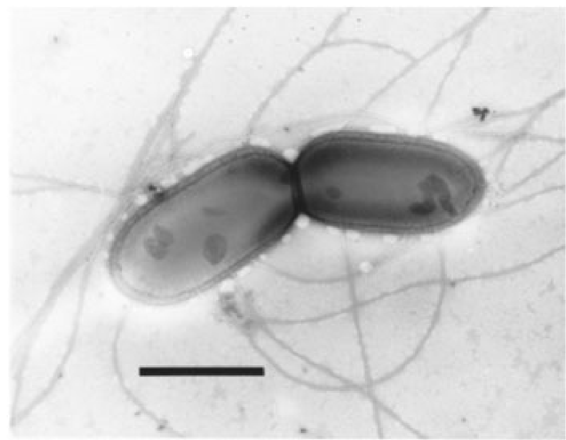

Fig. 6. Electron micrograph of cells from a young culture (16 h, fructose-grown) of *Clostridium ljungdahlii* (ATCC 55383^T) with peritrichously inserted flagella. Bar equals 1 µm. The micrograph was kindly provided by R.S. Tanner.

CLOSTRIDIUM MAGNUM. This species was isolated from pasteurized freshwater sediment (Schink, 1984). Cells are Gram-positive, sporeforming, motile, large straight rods. H_2-CO_2, formate, methanol, 2,3-butandiol, acetoin, malate, citrate, and a few sugars are substrates, and acetate is the sole reduced end product. N_2 is fixed (Bomar et al., 1991) and small amounts of O_2 are tolerated and consumed (Karnholz et al., 2002).

CLOSTRIDIUM MaOMBEI. This organism was isolated from the gut of a soil-feeding termite (Kane et al., 1991b). Cells are Gram-positive, sporeforming, motile, straight rods. Growth occurs on H_2-CO_2, sugars, sugar alcohols, organic acids, and amino acids. The main reduced end product is acetate; however, succinate is metabolized to CO_2 and propionate (Kane et al., 1991b).

CLOSTRIDIUM METHOXYBENZOVORANS. This species was isolated from an olive mill wastewater digester (Mechichi et al., 1999). Cells of *C. methoxybenzovorans* are Gram-positive, sporeforming, nonmotile rods. Growth occurs on H_2-CO_2, methanol, lactate, sugars, methoxylated aromatic compounds, betaine, dimethylglycine, dimethylsulfide, casaminoacids, and peptone. H_2-CO_2 is metabolized to acetate and formate. Metabolism of betaine, dimethylglycine, and dimethylsulfide yields acetate, and sugars are metabolized to acetate, formate, ethanol, H_2, and CO_2. *O*-methyl groups, methanol, and lactate are metabolized to acetate and butyrate (Mechichi et al., 1999). Since no substrate/product stoichiometries have been reported for the organism, the acetogenic utilization of most substrates is uncertain.

CLOSTRIDIUM SCATOLOGENES. An acetogenic strain of *C. scatologenes* (SL1) was isolated from sediment of an acidic coal mine pond (Küsel et al., 2000). The type strain of *C. scatologenes* was isolated from soil and was not originally described as an acetogen (Holdeman et al., 1977). However, both strain SL1 and the type strain utilize H_2 and CO with the concomitant production of acetate, and cell extracts of both organisms have CO dehydrogenase, hydrogenase, and formate dehydrogenase activities (Küsel et al., 2000). Cells are Gram-positive, sporeforming, motile, long rods and produce skatole, a dung odor component (Holdeman et al., 1977; Küsel et al., 2000). Substrates include fructose, arabinose, ethanol, formate, vanillate, H_2-CO_2, and CO. The major reduced end product is acetate. However, in addition to acetate, butyrate and traces of H_2 are also produced from sugars (Küsel et al., 2000).

CLOSTRIDIUM ULTUNENSE. This species was isolated from an anaerobic acetate-oxidizing triculture that was enriched from a digester fed with swine manure (Schnürer et al., 1994; Schnürer et al., 1996). Cells are Gram-positive, sporeforming rods that change cell size, cell form, and motility during growth. The only known growth-supportive substrates are formate, betaine, glucose, pyruvate, ethylene glycol, and cysteine. The main end products are acetate, formate, and traces of H_2. H_2-CO_2 does not support growth; however, H_2-CO_2 is converted to acetate by resting cells (Schnürer et al., 1996). Acetate is oxidized in coculture with a methanogen, and the oxidation of acetate appears to occur via a reversal of the acetyl-CoA pathway (Schnürer et al., 1997). An acetogen (strain AOR) that also oxidized acetate in coculture with a methanogen was previously isolated (Lee and Zinder, 1988); however, this strain has been lost (S.H. Zinder, personal communication).

EUBACTERIUM AGGREGANS. This organism was isolated from an olive mill wastewater digestor (Mechichi et al., 1998). Cells are Gram-positive, nonsporeforming, nonmotile rods that form aggregates. Substrates include H_2-CO_2, glucose, fructose, sucrose, lactate, formate, methanol, betaine, and numerous methoxylated aromatic compounds. Although *E. aggregans* is described as homoacetogenic, H_2, formate, acetate, and butyrate are produced from sugars (Mechichi et al., 1998). Acetate is the sole reduced end product with formate and methanol. Methoxylated aromatic compounds are *O*-demethylated, and acetate, butyrate, and the corresponding hydroxylated aromatic compounds are formed. Aldehyde groups of methoxylated aromatic compounds are oxidized to carboxylate groups.

EUBACTERIUM LIMOSUM. This species was isolated from sheep rumen and digester sludge (Sharak Genthner et al., 1981). Cells are Gram-positive, nonsporeforming, nonmotile straight rods that become more pleomorphic after prolonged incubation. *Eubacterium limosum* is metabolically very versatile; its substrate range includes sugars, amino acids, methoxylated aromatic compounds, glycine, betaine, lactate, methanol, H_2-CO_2 and CO (Sharak Genthner et al., 1981; Sharak Genthner and Bryant, 1982; Sharak Genthner and Bryant, 1987; Jansen and Hansen, 2001). Both acetate and butyrate are produced from one-carbon compounds (Sharak Genthner et al., 1981; Pacaud et al., 1985; see "*Butyribacterium methylotrophicum*," above). Cultures demethylate the osmolytes dimethylsulfoniopropionate and glycine-betaine to methylthiopropionate and dimethylglycine, respectively; however, only the demethylation of glycine-betaine supports growth of the organism (Jansen and Hansen, 2001).

HOLOPHAGA FOETIDA. This organism (strain TMBS4) was isolated from freshwater

sediment (Bak et al., 1992; Liesack et al., 1994). Cells are Gram-negative, nonsporeforming, nonmotile rods. The substrate range is rather small and mainly consists of pyruvate and aromatic compounds, especially methylated and nonmethylated trihydroxybenzenes. Acetate is the main reduced end product. In contrast to other acetogens, *H. foetida* degrades aromatic rings to acetate (Bak et al., 1992; Kreft and Schink, 1993). Dimethylsulfide and methanediol are produced from methoxylated aromatic compounds when cells are cultured in sulfide-containing media, indicating that sulfide can serve as a methyl acceptor (Bak et al., 1992). CO_2 and CO can also be used as methyl acceptors with the subsequent formation of acetate. CO dehydrogenase activity is present in cells grown on methoxylated aromatic compounds (Kreft and Schink, 1993). *Holophaga foetida* occupies a fairly isolated position in the phylogenetic tree of the Bacteria (Liesack et al., 1994; Ludwig et al., 1997; see the section on Taxonomy and Phylogeny).

MOORELLA GLYCERINI. This species is a thermophilic acetogen and was isolated from the sediment of a hot spring at Yellowstone National Park (Slobodkin et al., 1997). The cells are Gram-positive, sporeforming, motile, straight rods. Growth is supported by glycerol, sugars, lactate, glycerate, pyruvate, and yeast extract; however, H_2-CO_2 is not growth supportive. Acetate is the only product from glycerol and glucose. Fumarate is reduced to succinate, and the reduction of thiosulfate yields elemental sulfur. Nitrate is not dissimilated. Optimum growth occurs at 58°C.

"MOORELLA MULDERI." This organism is a thermophilic acetogen and was isolated from a high-temperature bioreactor (Balk et al., 2003). The cells are Gram-positive, sporeforming rods. Growth is supported by H_2-CO_2, formate, methanol, hexoses, cellobiose, lactate and pyruvate. The reduction of thiosulfate yields sulfide. Nitrate is not dissimilated.

MOORELLA THERMOACETICA. This organism is a thermophilic acetogen that was isolated from horse manure and was first described as *Clostridium thermoaceticum* (Fontaine et al., 1942). On the basis of phylogenetic analysis of the 16S rRNA gene sequence, *C. thermoaceticum* was reclassified as *M. thermoacetica* (Collins et al., 1994). Although the organism was originally isolated from horse manure, the organism is a common inhabitant of soils (Gößner and Drake, 1997; Gößner et al., 1998; Gößner et al., 1999; Karita et al., 2003). Cells are Gram-variable, sporeforming, variably motile, straight rods (Fig. 1). The optimum temperature of growth is 55–60°C (Fontaine et al., 1942), and the vitamin nicotinic acid is required for growth (Lundie and Drake, 1984). *Moorella thermoacetica* was the first bacterium that was shown to produce 3 moles of acetate from 1 mole of hexose (Fontaine et al., 1942), and is one of the most metabolically robust acetogens characterized to date. *Moorella thermoacetica* was originally isolated as an obligate heterotroph (Fontaine et al., 1942), but nearly five decades later, it was shown to be capable of autotrophic growth (Daniel et al., 1990). This bacterium displays very diverse physiological capabilities (Drake and Daniel, 2004). Growth-supportive substrates include CO, H_2-CO_2, formate, methanol, hexoses, pentoses, methoxylated benzoic acids, and several two-carbon compounds (e.g., oxalate, glycolate, and glyoxylate; Fontaine et al., 1942; Daniel et al., 1990; Daniel and Drake, 1993; Daniel et al., 2004; Drake et al., 1997; Seifritz et al., 1999; Kim et al., 2002). Carboxyl groups of aromatic compounds can serve as CO_2 equivalents in the acetyl-CoA pathway (Hsu et al., 1990a; Hsu et al., 1990b). Thiosulfate (Beaty and Ljungdahl, 1990; Beaty and Ljungdahl, 1991), nitrate (Seifritz et al., 1993), and nitrite (Seifritz et al., 2003) serve as alternative electron acceptors. Nitrate is dissimilated to both nitrite and ammonium, and nitrite is dissimilated to ammonium. Ethanol and *n*-propanol are oxidized and are growth-supportive substrates when nitrate is dissimilated; neither ethanol nor *n*-propanol is utilized as an acetogenic substrate (Fröstl et al., 1996). Reductively dechlorinates carbon tetrachloride (Egli et al., 1988). Tolerates and consumes small amounts of oxygen (Karnholz et al., 2002). A recent isolate that is phylogenetcially nearly identical to *M. thermoacetica* is cellulolytic (Karita et al., 2003). *Moorella thermoacetica* is the most studied acetogen, and the enzymology of the acetyl-CoA pathway was resolved with this organism (see the section on Historical Perspectives and Table 1 in this Chapter).

MOORELLA THERMOAUTOTROPHICA. This organism is a thermophilic acetogen that was isolated from a hot spring at Yellowstone National Park and was first described as *Clostridium thermoautotrophicum* (Wiegel et al., 1981). On the basis of phylogenetic analysis of the 16S rRNA gene sequence, *C. thermoautotrophicum* was reclassified as *M. thermoautotrophica* (Collins et al., 1994). Cells are Gram-variable, sporeforming, motile rods (Wiegel et al., 1981). *Moorella thermoautotrophica* was initially described as being metabolically distinct from the closely related *M. thermoacetica* (Collins et al., 1994); this distinction was primarily based on the H_2-dependent acetogenic abilities of the former bacterium (Wiegel et al., 1981). However, later studies demonstrated that *M. thermoacetica* grows chemolithoautotrophically on H_2-CO_2 (Daniel et al., 1990). Both of these species of

Moorella display a similar substrate range. Both species also require the vitamin nicotinic acid for growth (Lundie and Drake, 1984; Savage and Drake, 1986). The substrate range of *M. thermoautotrophica* includes H_2-CO_2, CO, formate, methanol, glucose, fructose, glycerate, glycolate, and methoxylated aromatic compounds (Wiegel et al., 1981; Fröstl et al., 1996; Seifritz et al., 1999). Nitrate is utilized as an alternative electron acceptor and is dissimilated to nitrite and ammonium; ethanol and *n*-propanol are growth-supportive substrates only when nitrate is available for dissimilation (Fröstl et al., 1996).

NATRONIELLA ACETIGENA. This organism is a haloalkaliphilic acetogen and was isolated from the soda deposits at Lake Magadi, Kenya (Zhilina et al., 1996). Cells are Gram-negative, sporeforming, motile, large rods. The substrate range is limited and includes lactate, pyruvate, ethanol, glutamate, and propanol. Growth does not occur on H_2-CO_2 or CO-CO_2. Acetate is the sole reduced end product. Propionate is formed during growth on propanol. The optimal pH is 10, and the optimal salinity for growth is 12% NaCl (w/v).

NATRONINCOLA HISTINOVORANS. This species is a moderately haloalkaliphilic acetogen and was isolated from soda deposits at Lake Magadi, Kenya (Zhilina et al., 1998). Cells are Gram-positive, motile rods; sporeforming and nonsporeforming strains have been isolated. *Natronincola histidinovorans* is specialized in using amino acids (histidine, glutamate, and casaminoacids) as sources of energy. Neither H_2-CO_2 nor CO-CO_2 support growth. Optimal growth occurs at pH 9 and a salinity of 9% NaCl. Acetate and ammonium are the main end products.

OXOBACTER PFENNIGII. This organism was isolated from the rumen fluid of a steer and was first described as *Clostridium pfennigii* (Krumholz and Bryant, 1985). On the basis of phylogenetic analysis of the 16S rRNA gene sequence, *C. pfennigii* was reclassified as *O. pfennigii* (Collins et al., 1994). Cells are Gram-positive, motile, sporeforming, slightly curved rods. Substrates include CO, pyruvate, vanillate, vanillin, ferulate, syringate, and trimethoxybenzoate. In contrast to most other acetogens, acetate is not produced from methoxybenzenoids (*O*-methyl groups are utilized, and butyrate and the respective hydroxybenzenoids are formed; Krumholz and Bryant 1985). During growth on CO or pyruvate, acetate is formed in addition to butyrate or is the sole product, respectively.

RUMINOCOCCUS HYDROGENOTROPHICUS. This species is a nonsporeforming coccobacillus that was isolated from human feces (Bernalier et al., 1996c). *Ruminococcus hydrogenotrophicus* grows on H_2-CO_2, formate, pyruvate, and several sugars. Acetate is the sole product from H_2-CO_2-dependent growth; however, glucose and fructose are metabolized to acetate, lactate, ethanol, and small amounts of isobutyrate and isovalerate (Bernalier et al., 1996c). Thus, the metabolism of sugars involves several fermentative processes.

RUMINOCOCCUS PRODUCTUS. This organism was originally isolated from various mammalian gastrointestinal tracts and was described as *Peptostreptococcus productus*; the original isolates were not described as acetogens (Moore and Holdeman, 1974; Varel et al., 1974; Holdeman-Moore et al., 1986). On the basis of phylogenetic analysis of the 16S rRNA gene sequence, *P. productus* was reclassified as *R. productus* (Ezaki et al., 1994). Two acetogenic strains (strain U-1 [ATCC 35244] and strain Marburg [ATCC 43917]) of *R. productus* have been isolated from sewage sludge (Lorowitz and Bryant, 1984; Geerligs et al., 1987). Cells are Gram-positive, nonsporeforming, nonmotile elongated cocci occuring often in pairs or chains (Lorowitz and Bryant, 1984; Holdeman-Moore et al., 1986; Geerligs et al., 1987). Growth-supportive substrates of the acetogenic strains include CO, H_2-CO_2, monomeric and dimeric sugars, and methoxylated aromatic compounds; growth is particularly good on CO (Lorowitz and Bryant, 1984; Geerligs et al., 1987; Parekh et al., 1992). The acrylate side chain of methoxylated and nonmethoxylated phenylacrylates can be used as alternative electron acceptor (Parekh et al., 1992; Misoph et al., 1996b). The major reduced end product is acetate; however, under CO_2-limited conditions or when substrate concentrations are high (e.g., 10 mM fructose), lactate, succinate, and formate are also formed (Misoph and Drake, 1996a).

RUMINOCOCCUS SCHINKII. This organism was isolated from rumen content of 1–3 days-old lambs (Rieu-Lesme et al., 1996b). Cells are Gram-positive, nonsporeforming, nonmotile cocci. Substrates include H_2-CO_2, various sugars, glycerol, syringate, and ferulate. Acetate is the sole reduced end product.

SPOROMUSA ACIDOVORANS. This species was isolated from a distillation wastewater fermentor (Ollivier et al., 1985a). Cells are Gram-negative, sporeforming, motile, curved rods. Growth-supportive substrates mainly include organic acids, H_2-CO_2, methanol, glycerol, and a few sugars; acetate is the sole reduced end product with all substrates.

SPOROMUSA AERIVORANS. This organism was isolated from a soil-feeding termite (Boga et al., 2003). Cells are Gram-negative, sporeforming, motile, curved rods. Growth-supportive substrates include H_2-CO_2, formate,

methanol, ethanol, lactate, pyruvate, mannitol, citrate, and various methoxylated aromatic compounds; hexoses are not utilized. Cells tolerate and consume small amounts of oxygen and are catalase positive (Boga and Brune, 2003).

SPOROMUSA MALONICA. This species was isolated from freshwater sediment (Dehning et al., 1989). Cells are Gram-negative, sporeforming, motile, curved rods. The organism exhibits a very versatile metabolism and utilizes H_2-CO_2 and numerous organic compounds, including formate, pyruvate, alcohols, dicarboxylic acids, fructose and trimethoxycinnamate. Acetate is the reduced end product when typical acetogenic substrates such as H_2-CO_2, formate, methanol, fructose, pyruvate, or the *O*-methyl groups of trimethoxycinnamate are metabolized (Dehning et al., 1989). Alcohols yield acetate and the respective fatty acids, and crotonate and 3-hydroxybutyrate yield acetate and butyrate. As with relatively few anaerobes, *S. malonica* metabolizes simple dicarboxylic acids (e.g., malonate and succinate) by decarboxylation to the respective fatty acids.

SPOROMUSA OVATA. This organism was isolated from sugar beet leaf silage (Möller et al., 1984). Cells are Gram-negative, sporeforming, motile, curved rods. Growth is supported by a variety of substrates including H_2-CO_2, pyruvate, lactate, alcohols, fructose, betaine, dimethylglycine, and sarcosine. Acetate is the sole reduced end product; methylamines are formed from *N*-methyl compounds. Reductively dechlorinates tetrachloroethylene to trichloroethylene (Terzenbach and Blaut, 1994). Cultures demethylate the osmolytes dimethylsulfoniopropionate and glycine-betaine to methylthiopropionate and dimethylglycine, respectively; however, only the demethylation of glycine-betaine supports growth of the organism (Jansen and Hansen, 2001).

SPOROMUSA PAUCIVORANS. This species was isolated from lake sediment (Hermann et al., 1987). Cells are Gram-negative, nonsporeforming, motile, slightly curved rods. H_2-CO_2, formate, methanol, pyruvate, serine, betaine, alcohols, and ethylene glycol support growth. Acetate is the sole reduced end product. Oxidation of alcohols yields the corresponding fatty acids. Sugars are not utilized.

SPOROMUSA SILVACETICA. This organism was isolated from forest soil (Kuhner et al., 1997). Cells are Gram-negative, sporeforming, motile, slightly curved rods (Fig. 7). Growth occurs on H_2-CO_2, formate, methanol, pyruvate, vanillate, ferulate, fructose, betaine, fumarate, 2,3-butanediol, ethanol, lactate and glycerol. With most substrates, acetate is the main reduced end product. Fumarate is dismutated to acetate and succinate. Vanillate and ferulate are *O*-demethylated and reduced, respectively. Cells tolerate and consume small amounts of oxygen (Karnholz et al., 2002).

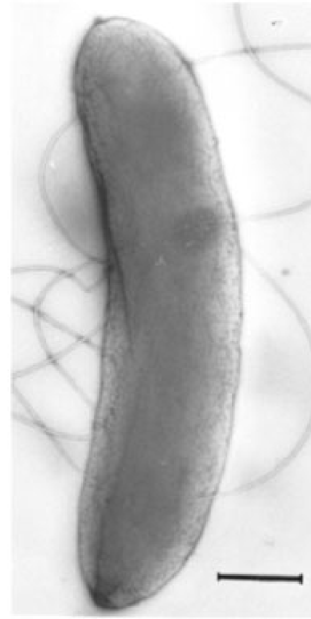

Fig. 7. Electron micrograph of a vegetative cell of *Sporomusa silvacetica* (DSM 10669^T) showing flagella inserting at the concave side of the cell. From Kuhner et al. (1997), used with permission from International Union of Microbiological Societies.

SPOROMUSA SPHAEROIDES. This species was isolated from river mud (Möller et al., 1984). Cells are Gram-negative, sporeforming, motile, curved rods. Growth occurs on H_2-CO_2, pyruvate, lactate, alcohols, glycerol, serine, ethyleneglycol, betaine, and other N-methyl compounds. Acetate is the sole reduced end product; methylamines are formed from N-methyl compounds. Cultures demethylate the osmolytes dimethylsulfoniopropionate and glycine-betaine to methylthiopropionate and dimethylglycine, respectively; however, only the demethylation of glycine-betaine supports growth of the organism (Jansen and Hansen, 2001).

SPOROMUSA TERMITIDA. This organism was isolated from the gut of a wood-feeding termite (Breznak et al., 1988). Cells of *S. termitida* are Gram-negative, sporeforming, motile, straight to slightly curved rods. Substrates include H_2-CO_2, CO, formate, methanol, ethanol, betaine, sarcosine, lactate, pyruvate, oxaloacetate, citrate, malonate, succinate, mannitol and trimethoxybenzoate. Acetate is the main reduced end product. As with *S. malonica*, *S. termitida* decarboxylates succinate to propionate (Breznak et al., 1988; Dehning et al., 1989). *Sporomusa termitida* grows mixotrophically, e.g., by utilizing H_2 and methanol or lactate at the same time (Breznak and Switzer Blum, 1991).

SYNTROPHOCOCCUS SUCROMUTANS. This organism is a Gram-negative, nonsporeforming, nonmotile, coccoid bacterium that was isolated as a dominant methoxybenzenoids-utilizer from the rumen contents of a steer (Krumholz and Bryant, 1986). *Syntrophococcus sucromutans* has a unique metabolism: growth with carbohydrates or pyruvate is only possible in the presence of electron acceptors such as formate, *O*-methyl groups, or a hydrogenotrophic methanogen (Krumholz and Bryant, 1986). Formate and *O*-methyl groups are metabolized via an acetyl CoA pathway that lacks formate dehydrogenase and is therefore incomplete (Doré and Bryant, 1990).

THERMOACETOGENIUM PHAEUM. This species is a thermophilic acetogen that was isolated from an anoxic pulp wastewater reactor (Hattori et al., 2000). Cells are Gram-positive, sporeforming, nonmotile, straight or slightly curved rods. Substrates include H_2-CO_2, formate, methanol, *n*-propanol, methoxylated benzoic acids, glycine and cysteine. Acetate is the sole reduced end product. Acetate is oxidized in the presence of hydrogenotrophic methanogens or an alternative electron acceptor (e.g., sulfate or thiosulfate); concomitantly, methane is produced by the syntrophic methanogen or the alternative electron acceptor is reduced. Its ability to oxidize acetate in syntrophic association with hydrogenotrophic methanogens is similar to that of two other anaerobic acetate oxidizers, strain AOR and *Clostridium ultunense* (Zinder and Koch, 1984; Lee and Zinder, 1988; Schnürer et al., 1996).

THERMOANAEROBACTER KIVUI. This species is a thermophilic acetogen that was isolated from lake sediments of Lake Kivu, Africa, and was first described as *Acetogenium kivui* (Leigh et al., 1981). On the basis of phylogenetic analysis of the 16S rRNA gene sequence, *A. kivui* was reclassified as *T. kivui* (Rainey et al., 1993; Collins et al., 1994). Cells are nonmotile, nonsporeforming rods often occurring in pairs or chains (Leigh et al., 1981; Fig. 8). The cell wall is covered by a hexagonally structured S-layer consisting of an 80-kDa protein (Rasch et al., 1984; Lupas et al., 1994). The temperature optimum is 66°C. Autotrophic growth occurs on H_2-CO_2, and heterotrophic growth occurs on glucose, mannose, fructose, pyruvate and formate; acetate is the main reduced end product (Leigh et al., 1981). Growth does not occur on CO-CO_2 (Daniel et al., 1990). *Thermoanaerobacter kivui* grows robustly on H_2-CO_2, a substrate that yields very slow, poor growth with most acetogens, and displays exceptionally high specific activities of hydrogenase and CO dehydrogenase (i.e., acetyl-CoA synthase) when cultivated chemolithoautotrophically on H_2-CO_2 (Daniel et al., 1990).

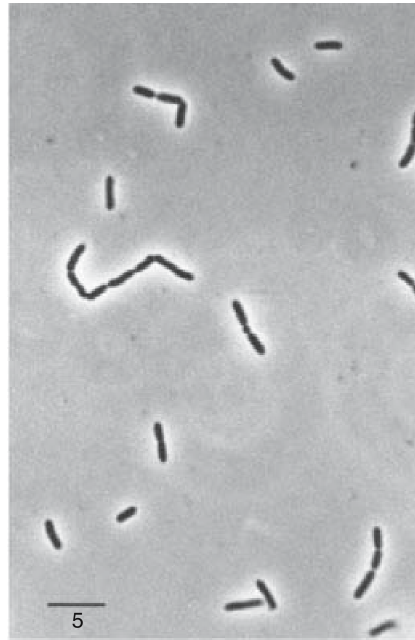

Fig. 8. Phase contrast photomicrograph of cells of *Thermoanaerobacter kivui*. Bar equals 5 μm. From Leigh et al. (1981), used with permission from Springer. The micrograph was kindly provided by R.S. Wolfe.

Cells tolerate and consume small amounts of oxygen (Karnholz et al., 2002).

"TREPONEMA PRIMITIA." This acetogenic spirochete was isolated from the hindgut of termites (Graber et al., 2004b; Graber and Breznak, 2004a). Growth occurs on H_2-CO_2, certain mono- and disaccharides, and methoxybenzoids. Can use H_2-CO_2 and organic compounds simultaneously. Requires folate for growth. Can tolerant low amounts of O_2; cells have NADH peroxidase and NADH oxidase activities.

Cultivation Methods

Even though many acetogens likely have the ability to tolerate small amounts of O_2 (Küsel et al., 2001; Karnholz et al., 2002; Boga and Brune, 2003), acetogens should be considered obligate anaerobes, and care should be taken in the laboratory to protect them from oxic conditions. The Hungate technique (Hungate, 1969) or modifications thereof are recommended for cultivation purposes. Growth media should be anoxic; sodium sulfide, cysteine, dithionite, or dithiothreitol are often used in cultivation media. Titanium (III) reducer has also been used; it may be less toxic than sulfide-based reducers (Zehnder and Wuhrman, 1976; Moench and Zeikus, 1983). Sulfide-based reducers can decrease the number of acetogens obtained from aerated soils (Küsel et al., 1999c). Cadmium

chloride ($CdCl_2$) has also been used as reducing agent for acetogen media (Breznak and Switzer, 1986; Breznak et al., 1988).

Table 3 outlines the contents of a medium that can be used for the cultivation of most known acetogens. In general, acetogens prefer near neutral to slightly alkaline pH. However, many decades ago, Wieringa (1941) reported that enrichment of acetogens under alkaline conditions (pH 8–9) might favor their isolation. It is thus noteworthy that the first haloalkaliphilic acetogens, *N. histidinovorans* and *N. acetigena*, were recently isolated from soda-depositing lakes; these acetogens only grow between pH 8 and 11 (Zhilina et al., 1996; Zhilina et al., 1998). Obviously, designing media for the cultivation of acetogens must take into consideration the in situ conditions of the habit under investigation.

Since CO_2 is used as a terminal electron acceptor by acetogens, many acetogens cannot grow under certain conditions unless CO_2 is readily available (see the section on CO_2 as Terminal Electron Acceptor and the Concept of Fermentation in this Chapter). Thus, acetogenesis is optimized in acetogen media containing a source of CO_2. Although some chemolithoautotrophic acetogens grow without any trace organic nutrients (e.g., *T. kivui*; Leigh et al., 1981), many acetogens require supplemental vitamins. The inclusion of trace metals in acetogen media is important because acetogens are rich in metalloenzymes (Ljungdahl, 1986). Many acetogens have unknown nutritional factors. For example, the protocol used to elucidate the nutritional requirements of *M. thermoacetica* (Lundie and Drake, 1984) and *M. thermoautotrophica* (Savage and Drake, 1986) was not successfully applied to *R. productus* (supplemental vitamins, amino acids, fatty acids, and other nutrients did not substitute for unknown growth factors in yeast extract; thus, the nutritional requirements for *R. productus* remain unresolved; H. L. Drake and coworkers, unpublished data).

The substrate used to enrich and isolate an acetogen can be selective for a certain catabolic type. H_2-CO_2 is quite often selective for acetogens and has been used for the isolation of numerous acetogens (e.g., *T. kivui* [Leigh et al., 1981], *A. woodii* [Balch et al., 1977], and *S. termitida* [Breznak et al., 1988]). CO-CO_2 is also selective (e.g., *R. productus*; Lorowitz and Bryant, 1984; Geerligs et al., 1987). The capacity to utilize methoxylated aromatic compounds is a widespread catabolic potential of acetogens; thus, methoxylated aromatic compounds can also be used to selectively enrich and isolate acetogens (e.g., *A. woodii*; Bache and Pfennig, 1981). Many isolates have been enriched and isolated with compounds not typically utilized by anaerobes. Examples of such substrates include mandelate (*Acetobacterium* strain AmMan1; Dörner and Schink, 1991), trimethylamine (*A.*

Table 3. Contents of a typical acetogen medium.[a]

Salts	mg/liter	Vitamins	mg/liter
NaCl	400	Nicotinic acid	0.25
NH_4Cl	400	Cyanocobalamin	0.25
$MgCl_2 \cdot 6H_2O$	330	*p*-Aminobenzoic acid	0.25
$CaCl_2 \cdot 2H_2O$	50	Calcium d-pantothenate	0.25
		Thiamine·HCl	0.25
Trace elements	**mg/liter**	Riboflavin	0.25
$MnSO_4 \cdot H_2O$	2.5	Lipoic acid	0.30
$FeSO_4 \cdot 7H_2O$	0.5	Folic acid	0.1
$Co(NO_3)_2 \cdot 6H_2O$	0.5	Biotin	0.1
$ZnCl_2$	0.5	Pyridoxal HCl	0.05
$NiCl_2 \cdot 6H_2O$	0.25		
H_2SeO_4	0.25	**Buffer for pH 6.7 media**	**mg/liter**
$CuSO_4 \cdot 5H_2O$	0.05	$NaHCO_3$	7,500
$AlK(SO_4)_2 \cdot 12H_2O$	0.05	KH_2PO_4	500
H_3BO_3	0.05	Gas phase	100% CO_2
$Na_2MoO_4 \cdot 2H_2O$	0.05		
$Na_2WO_4 \cdot 2H_2O$	0.05		
		Buffer for pH 7.8 media	**mg/liter**
Reducers	**mg/liter**	$NaCO_3$	6,000
Cysteine·HCl·H_2O	250	$Na_2CO_3 \cdot 10H_2O$	16,500
Sodium sulfide	250	KH_2PO_4	500
		Gas phase	100% N_2

[a]Media should be prepared using anoxic techniques, and resazurin (1 mg/liter) can be used as a redox indicator. Media can be enriched with yeast extract (0.5–2 g/liter), tryptone (0.5–2 g/liter), clarified rumen fluid (50 ml/liter), or casamino acids (0.5–2 g/liter). Crimp-sealed tubes or bottles are recommended for cultivation. Compiled from Daniel et al. (1990) and Matthies et al. (1993).

arabaticum; Zhilina and Zavarzin, 1990), methoxyacetate (strain RMMac1; Schuppert and Schink, 1990), and methyl chloride ("*Acetobacterium dehalogenans*" [formerly named "strain MC"; Traunecker et al., 1991]). Isolation can be accomplished by various methods, such as the roll-tube method of Hungate (1969), agar shake dilution series (Pfennig, 1978), or streaking/plating on agar or Gelrite® (preferred for thermophiles because of its increased capacity to remain solid at higher temperatures). Methanogens can usually be excluded during enrichment and isolation with 10–50 mM bromoethanesulfonate (an analog of coenzyme M; Gunsalus et al., 1978; Zehnder et al., 1980; Smith and Mah, 1981; Greening and Leedle, 1989; Kane and Breznak, 1991a). Lumazine (2,4-[1H,3H]-pteridinedione) is also an inhibitor of methanogens (*Methanobacterium thermoautotrophicum* does not grow in media containing 0.1 mM Lumazine; Nagaranthal and Nagle, 1992) and might also be useful in such enrichments. Lumazine appears to inhibit methyl-S-CoM reductase (Nagaranthal and Nagle, 1992). Likewise, N-substituted derivatives of *p*-aminobenzoic acid inhibit the enzyme responsible for the synthesis of methanopterin (an intermediate in methanogenesis) and can block the growth of certain methanogens but do not interfere with the growth of acetogens (Dumitru et al., 2003).

Taxonomy and Phylogeny

Acetogens do not form a taxonomic group of closely related organisms. Although utilization of the acetyl-CoA pathway unifies them, they are extremely diverse genetically; the G+C content of their genomes varies from 22 mol% for *C. ljungdahlii* to 62 mol% for *H. foetida* (Table 2). However, all acetogenic isolates to date are members of the domain Bacteria, including the extreme halophilic and haloalkaliphilic isolates *A. arabaticum* and *N. acetigena*, respectively (Zhilina and Zavarzin, 1990; Zhilina et al., 1996). The phylogeny of most acetogens with validated genus and species names and a couple of other acetogens not yet included in the "List of Bacterial Names with Standing in Nomenclature" (http://www.bacterio.cict.fr) has been determined in either comprehensive analyses of bacteria (e.g., within a certain bacterial group, such as the clostridia) or in the first description of a respective species. Analyses of phylogenetic relationships resulted in the reclassification of several acetogenic species (Table 4).

Within the phylogenetic tree of the Bacteria, acetogens are found in more than one phylum and do not form tight clusters like methanogens or sulfate-reducing bacteria. However, most acetogens are affiliated with the phylum of the Gram-positive bacteria with low DNA G+C-content (Fig. 9). One genus that harbors acetogenic species, *Treponema* (Fig. 5), is affiliated with the phylum Spirochetes. *Holophaga*, a genus with only one species isolated to date, *H. foetida*, represents a new line of descent; together with the non-acetogen *Geothrix fermentans*, *H. foetida* was one of the two founding species of the phylum *Holophaga*/*Acidobacterium* (Liesack et al., 1994; Ludwig et al., 1997; Leadbetter et al., 1999; Lilburn et al., 1999). The 16S rRNA genes of the species belonging to the genus *Acetoanaerobium* have not been sequenced; thus, the phylogenetic positions of the acetogens *A. notorae* and "*A. romashkovii*" are unclear. On the basis of morphological and physiological properties, *A. notorae* has been tentatively assigned to the Bacteroidaceae (Sleat et al., 1985).

Acetogens affiliate with 8 (I, V, VI, IX, XI, XII, XIVa, XV) out of the 19 *Clostridium* clusters within the phylum of the Gram-positive bacteria with low DNA G+C-content (Collins et al., 1994; Zhilina et al., 1998; Stackebrandt et al., 1999; Fig. 9). Although some genera (e.g., *Acetobacterium*, *Sporomusa* and *Moorella*) are composed exclusively of acetogenic species, many acetogens in these phylogenetic clusters are very closely related to non-acetogenic bacteria (Fig. 10). Indeed, genera often include acetogenic and non-acetogenic species (e.g., *Clostridium*, *Ruminococcus*, *Eubacterium* and *Thermoanaerobacter*). For example, the closest relative of *C. formicoaceticum* is the non-acetogen *Clostridium felsineum* (99.3% sequence similarity). In

Table 4. Acetogens that have been reclassified.

Described as	Reclassified as	Reference
Acetogenium kivui	*Thermoanaerobacter kivui*	Collins et al., 1994
Clostridium fervidus[a]	*Caloramator fervidus*	Collins et al., 1994
Clostridium thermoaceticum	*Moorella thermoacetica*	Collins et al., 1994
Clostridium thermoautotrophicum	*Moorella thermoautotrophica*	Collins et al., 1994
Clostridium pfennigii	*Oxobacter pfennigii*	Collins et al., 1994
Peptostreptococcus productus	*Ruminococcus productus*	Ezaki et al., 1994

[a]It is not certain that this organism is an acetogen.

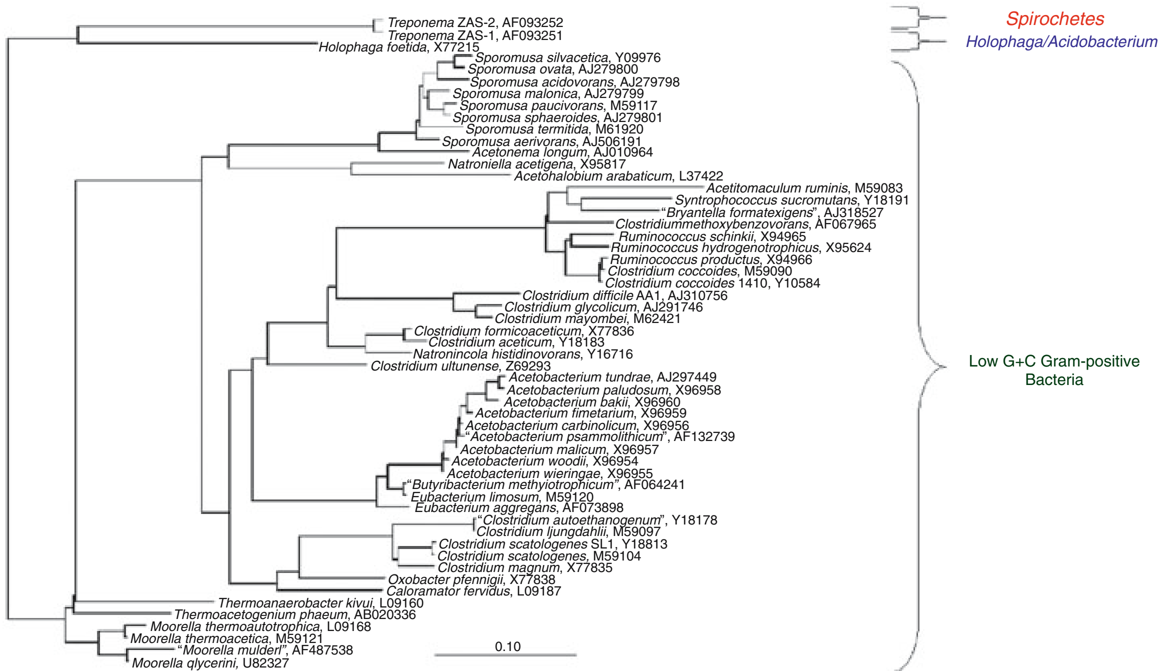

Fig. 9. Parsimony tree containing 20 genera of acetogenic bacteria; tree is based on full length 16S rRNA sequences (ARB-release June 2002). The genus *Acetoanaerobium* (Table 2) is not represented in the tree because a sequence for a species of this genus is not available. Comparison of the tree topology with maximum-likelihood and neighbor-joining based trees suggests that the phylogeny of acetogens remains to be resolved. Numbers are sequence accession numbers. Bar corresponds to 10 nucleotide substitutions per 100 sequence positions. Though unavailable when the tree was constructed, please note that the two *Treponema* strains have been recently named "*T. primitia*" (Graber et al., 2004b).

some cases, clostridial species were not originally described as acetogens but were later discovered to possess acetogenic capabilities. For example, *C. coccoides* strain 1410 and *C. scatologenes* strain SL1 were isolated as acetogens, and subsequent physiological studies revealed that the type strains of these two species also have acetogenic capabilities (Kamlage et al., 1997; Küsel et al., 2000). The opposite is also true, as seen in the case of *C. glycolicum*. Two strains of *C. glycolicum*, strain RD-1 and strain 22, are acetogens, yet the type strain of *C. glycolicum* does not grow acetogenically (Ohwaki and Hungate, 1977; Küsel et al., 2001). Thus, certain acetogens might lose their acetogenic capabilities after prolonged laboratory cultivation. An acetogenic strain of *C. difficile* (AA1) has been isolated from the rumen contents of a newborn lamb; whether the pathogenic type strain of *C. difficile* has acetogenic capabilities is unknown (Hall and O'Toole, 1935; Cato et al., 1986; Rieu-Lesme et al., 1998).

Detection of Acetogens

On agar or Gelrite®acetogenic colonies can be differentiated from non-acetogenic colonies by their ability to form 1) clear zones on media containing calcium carbonate (Balch et al., 1977) or 2) colored zones on media supplemented with a pH indicator (e.g., bromocresol green; Braun et al., 1979; Leedle and Greening, 1988). A colorimetric most-probable-number assay can be utilized to enumerate acetogens that are capable of *O*-demethylating methoxylated lignin derivatives (e.g., vanillate; Harriott and Frazer, 1997). This method based on a yellowing colorimetric reaction between Ti(III) and the vicinal hydroxyl groups of the *O*-demethylated aromatic product (Moench and Zeikus, 1983; Kreft and Schink, 1993; Harriott and Frazer, 1997) has been used to detect acetogens on the roots of the sea grass *Halodule wrightii* (Küsel et al., 1999b).

The occurrence of acetyl-CoA synthase in an isolate can be considered good evidence that the organism is an acetogen. As outlined in the subsection on Enzymology of the Acetyl-CoA Pathway, this enzyme catalyzes two reactions that can be assayed. One of these reactions, i.e., that of CO dehydrogenase, is inexpensive and easily measured by monitoring the reduction of an artificial electron carrier (e.g., methyl viologen) with a spectrophotometer. Thus, CO dehydrogenase activity is often used to assess

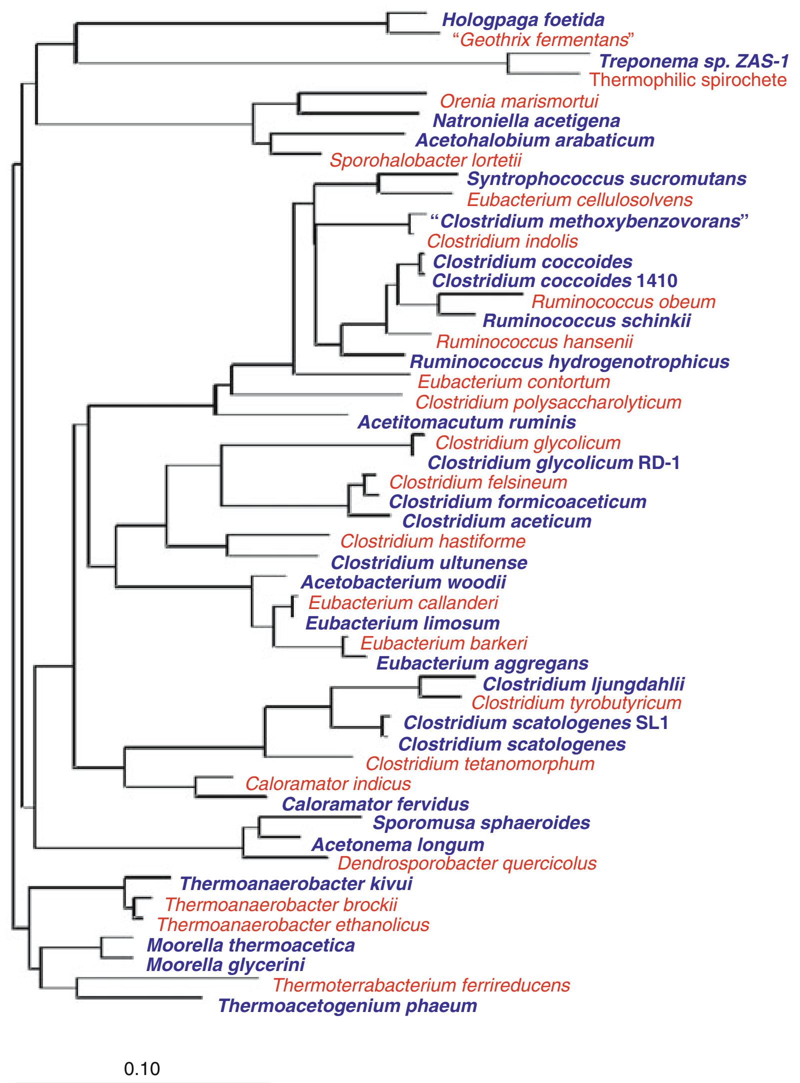

Fig. 10. Parsimony tree of selected acetogenic bacteria (blue, bold font) and their closest nonacetogenic relatives (red, non-bold font) based on full length 16S rRNA sequences (ARB-release December 1998). Bar corresponds to 10 nucleotide substitutions per 100 sequence positions.

acetyl-CoA synthase. However, the occurrence of CO dehydrogenase activity can be misleading and cannot be taken as definitive evidence that an organism utilizes the acetyl-CoA pathway. For example, the CO dehydrogenase activity of *Clostridium pasteurianum* (Fuchs et al., 1974; Thauer et al., 1974; Diekert and Thauer, 1978) implies that this bacterium is an acetogen, but it is not. It is therefore essential that additional evidence (e.g., precise substrate/product stoichiometries or additional enzymological information) be obtained before concluding that an organism is an acetogen (i.e., utilizes the acetyl-CoA pathway). Although the acetyl-CoA synthase assay is more difficult than that for CO dehydrogenase, acetyl-CoA synthase activity can be assayed with the pyruvate/CO-coupled methyltetrahydrofolate assay (Schulman et al., 1973; Drake et al., 1981a; Hu et al., 1982). This activity is much more conclusive relative to the acetogenic nature of an organism. The acetyl-CoA synthase assay is classically based on the use of [$^{14}CH_3$]-methyltetrahydrofolate and the measurement of ^{14}C-labeled acetate (which is derived from the ^{14}C-labeled acetyl-CoA that is formed by acetyl-CoA synthase). However, a method that does not involve the use of ^{14}C can also be used; in this assay, the acetyl-CoA formed by acetyl-CoA synthase is converted to acetate, which is then measured by high performance liquid chromatography (Fröstl et al., 1996). The activities obtained with the CO dehydrogenase and acetyl-CoA synthase activity assays do not always yield parallel results, and the two respective activities can vary differentially (Kellum and Drake, 1986). In general, caution is needed when drawing conclusions based on results obtained with these assays.

The apparent importance of acetogens to the overall flow of carbon, reductant, and energy in

many habitats has generated an interest in assessing acetogenic populations in environmental samples with molecular methods. Unfortunately, based on their 16S rRNA gene sequences, acetogens are not a monophyletic group, and many acetogens are very closely related to non-acetogenic species (see the subsection on Taxonomy and Phylogeny in this Chapter). Thus, the development of 16S rRNA oligonucleotide probes and primers that exclusively target all known acetogens is likely an impossible task. Nonetheless, a 16S rRNA oligonucleotide probe (probe AW) has been developed that targets the acetogenic species that form a phylogenetically tight cluster in the genus *Acetobacterium*; this probe is also specific for the acetogen *E. limosum* (Küsel et al., 1999b). Another 16S rRNA oligonucleotide probe (probe Clost I) is specific for a few acetogens and many non-acetogens in clostridial clusters I and II (Küsel et al., 1999b).

Oligonucleotide probes or primers that target functional genes can also be used to assess microorganisms in environmental samples, and this approach has been used to evaluate several microbial groups, including ammonia-oxidizing bacteria, denitrifying bacteria, and nitrogen-fixing bacteria (Rotthauwe et al., 1997; Braker et al., 2000; Lovell et al., 2000). Formyltetrahydrofolate synthetase (FTHFS) is one of the key enzymes in the acetyl-CoA pathway and catalyzes the ATP-dependent synthesis of formyltetrahydrofolate from formate and tetrahydrofolate. FTHFS is highly conserved in acetogens. A FTHFS-based functional group-specific DNA probe and FTHFS-based primers for polymerase chain reaction (PCR) amplification of partial FTHFS gene sequences have been utilized for evaluating the occurrence of acetogens in environmental samples and complex natural populations (Lovell and Hui, 1991; Lovell, 1994; Leaphart and Lovell, 2001; Leaphart et al., 2003; Salmassi and Leadbetter, 2003).

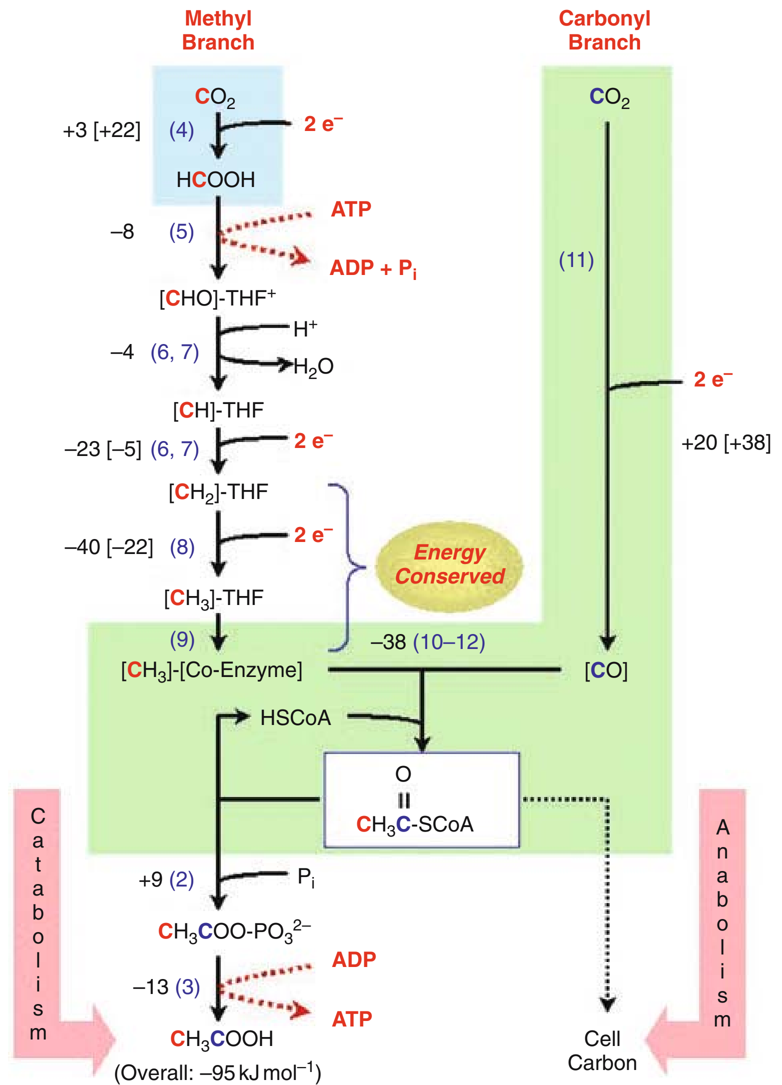
The Acetyl-CoA Pathway and Bioenergetics

The acetyl-CoA pathway is composed of two reductive branches (i.e., the methyl branch and the carbonyl branch), both of which reduce CO_2 and fix CO_2-derived carbon into covalently bond forms (Fig. 11). The acetyl-CoA pathway can be presented in a cyclic form (e.g., Wood and Ljungdahl, 1991b; Ragsdale, 1997); however, it is a linear process that does not depend on multicarbon intermediates to which CO_2 is fixed in a cyclic fashion (e.g., the Calvin cycle and the reductive tricarboxylic acid cycle are cyclic, CO_2-fixing processes that are dependent upon ribulose biphosphate and oxalacetate, respectively, for the initial fixation of CO_2). Although the cofactors and electron carriers of the pathway cycle between different states, the pathway itself is linear relative to carbon flow (Fig. 11).

The acetyl-CoA pathway is a terminal electron-accepting process that also provides a mechanism for the assimilation of CO_2 and other sources of carbon into biomass (Ljungdahl and Wood, 1965; Eden and Fuchs, 1982; Eden and Fuchs, 1983; Ljungdahl, 1986). The main function of the pathway may vary with the growth conditions of the cell. The biochemistry of the acetyl-CoA pathway has been described in numerous reviews (Ljungdahl, 1986; Ragsdale, 1991; Ragsdale, 1994; Ragsdale, 1997; Ragsdale, 2004; Wood, 1991a; Wood and Ljungdahl, 1991b; Diekert and Wohlfarth, 1994a; Diekert and Wohlfarth, 1994b; Drake, 1994; Ragsdale and Kumar, 1996; Drake et al., 1997; Das and Ljungdahl, 2000; Drake and Küsel, 2003); many of these references also provide historical perspectives on the studies that resolved the enzymological features of the pathway. A gateway to some of the more recent studies on the enzymology of the acetyl-CoA pathway can be found in the following references: Maynard and Lindahl (Maynard and Lindahl, 1999; Maynard and Lindahl, 2001), Furdui and Ragsdale (2000), Radfar et al. (2000), Ragsdale (Ragsdale, 2000; Ragsdale, 2003a; Ragsdale, 2003b; Ragsdale, 2004), Müller et al. (2001), Müller et al. (2004), Leaphart et al. (2002), Lindahl (2002), Banerjee and Ragsdale (2003), Das and Ljungdahl (2003), Bramlett et al. (2003), Darnault et al. (2003), Grahame (2003), and Loke and Lindahl (2003).

Acetyl-CoA synthase is a centrally important enzyme of the acetyl-CoA pathway, and many prokaryotes make use of enzymes that are closely related to the acetyl-CoA synthase of acetogens (see the subsections on Enzymology of the Acetyl-CoA Pathway and Occurrence of the Acetyl-CoA Pathway in Nonacetogenic Microorganisms in this Chapter). Numerous theortetical considerations suggest that an acetyl-CoA synthase-dependent pathway may have constituted the first autotrophic process on earth (Fuchs, 1986; Wood and Ljungdahl, 1991b; Lindahl and Chang, 2001). It is uncertain whether the pathway first evolved for the purpose of carbon assimilation (i.e., the reduction and fixation of CO_2) or the oxidation of acetate. Phylogenetic evaluations of acetyl-CoA synthases indicate that microorganisms (e.g., acetogens and methanogens) that have this enzyme, or enzymes that are closely related to it, had a common ancestor (Lindahl and Chang, 2001). This section will focus on some of the biochemical and enzymological features of the acetyl-CoA pathway of acetogens.

Fig. 11. The acetyl-CoA "Wood-Ljungdahl" pathway. The numbers (in black) adjacent to the reactions are standard Gibb's free energies in kJ mol^{-1} (values have been rounded off). For the four reactions in which reducing equivalents are involved, the bracketed and non-bracketed values are Gibb's free energies when the reducing equivalents are derived from either H_2 or reduced NAD/NADP, respectively. For the reactions in which acetyl-CoA is synthesized from CH_3-THF, HSCoA, and [CO], the Gibb's free energy is not known. Different values have been calculated for this reaction (e.g., –22 kJ mol^{-1} in Fuchs [1986], and –49 kJ mol^{-1} in Fuchs [1994]). The value shown in the figure is an estimate that is based on the overall thermodynamic value of the pathway (i.e., –95 kJ mol^{-1} [Fuchs, 1986; Fuchs, 1994]). The parenthetically enclosed numbers (in blue) identify the different enzymes involved (see Table 5 for characteristics of enzymes). The two enzymes responsible for the initial reduction of CO_2 are formate dehydrogenase and acetyl-CoA synthase; reactions in which these two enzymes are involved are shaded in blue and green, respectively. Abbreviations: THF, tetrahydrofolate; HSCoA, coenzyme A; P_i, inorganic phosphate; e^-, reducing equivalent; and Co-Enzyme, corrinoid enzyme.



CO_2 as Terminal Electron Acceptor and the Concept of Fermentation

The main function of the acetyl-CoA pathway during growth on sugars is the recycling of reduced electron carriers (NAD, ferredoxin, etc.; Fig. 12). The 8 reducing equivalents that are collectively generated during glycolysis and the oxidation of pyruvate are used to reduce CO_2 to acetate via the acetyl-CoA pathway. During growth on glucose, the cell has ready access to ATP formed via substrate-level phosphorylation and to biosynthetic precursors (via the breakdown of glucose). Thus, the lithoautotrophic functions of the pathway (i.e., the conservation of energy and the production of acetyl-CoA for anabolism and the assimilation of carbon) are probably of minor importance under such conditions.

CO_2 is the terminal electron acceptor of acetogens when they are grown under acetogenic conditions (see the subsection on Use of Diverse Terminal Electron Acceptors in this Chapter); it is therefore important to include an adequate supply of CO_2 (or carbonates) in the growth medium when acetogens are cultivated in the laboratory (see the subsection on Cultivation Methods in this Chapter). This point may seem obvious, but it is not generally appreciated why supplemental CO_2 is essential to the growth of acetogens, since the stoichiometries for the synthesis of acetate from numerous substrates do not indicate that supplemental CO_2 is required. For example, even though the stoichiometric conversion of sugars (e.g., glucose or fructose) to acetate (reaction 2 above) indicates that supplemental CO_2 is not required for acetogenesis, growth on sugars, as well as the metabolism of

Table 5. Properties of the enzymes in the Acetyl CoA pathways.[a]

Number in the figures[a]	Enzyme	M_r	Subunit composition	Function in pathways[a]	ΔG^{r}_{o} ($kJ\,mol^{-1}$)[b]	Primary/historical reference
1	Pyruvate-Fd oxidoreductase	225,000	α_2	Oxidation/decarboxylation of pyruvate to acetyl-CoA	–19	Drake et al., 1981a
2	Phosphotransacetylase	88,100	α_4	Conversion of acetyl-CoA to acetylphosphate	+9	Drake et al., 1981a
3	Acetate kinase	60,000	n.r.	Conversion of acetyl-CoA and ADP to acetate and ATP	–13	Schaupp and Ljungdahl, 1974
4	Formate dehydrogenase	340,000	$\alpha_2\beta_2$ (96,000 and 76,000)	NADPH-dependent reduction of CO_2 to formate	+3 (+22)	Yamamoto et al., 1983
5	Formyltetrahydrofolate (HCO-THF) synthetase	240,000	α_4	Conversion of formate to HCO-THF	–8	Mayer et al., 1982
6, 7	Methenyltetrahydrofolate (CH-THF) cyclohydrolase and methylenetetrahydrofolate (CH_2-THF) dehydrogenase complex	55,000	α_2	HCO-THF converted to CH-THF, and CH-THF reduced to CH_2-THF	–4 –23 (–5)	O'Brien et al., 1973
8	Methylenetetrahydrofolate (CH_2-THF) reductase	289,000	α_8	Reduction of CH_2-THF to CH_3-THF	–40 (–22)	Park et al., 1991
9	Methyltransferase	58,900	α_2	Transfer of methyl unit from CH_3-THF to coninoid enzyme		Drake et al., 1981a, b
10	Coninoid enzyme	89,000	$\alpha\beta$ (34,000 and 55,000)	methylation of acetyl-CoA synthase		Hu et al., 1984
11	Acetyl-CoA synthase	440,000	$\alpha_3\beta_3$ (78,000 and 71,000) (81,730 and 72,928)[c]	Reduction of CO_2 to the CO level, and synthesis of acetyl-CoA from CH_3-THF, CO, and CoASH	+20 (+38) –22, –49[d]	Ragsdale et al., 1983 Diekert and Ritter, 1983
12	Acetyl-CoA synthase disulfide reductase	225,000	α_4	Reduction of disulfide of CoA binding site of acetyl-CoA synthase		Pezacka, Wood, 1986

Abbreviations: n.r., not reported; THF, tetrahydrofolate; CoA, coenzyme A; and Fd, ferredoxin.

[a]See Figs. 11 and 12. Enzymes indicated have been purified from *M. thermoacetica*.

[b]Gibb's free energies (G^{r}_{o}) have been rounded off and were obtained from Thauer et al. (1977) and Fuchs (1986). Parenthetical values for reactions catalyzed by oxidoreductases are the Gibb's free energies when the reducing equivalents are derived from reduced NAD/NADP rather than H_2.

[c]Based on amino acid composition. Current information indicates that the correct composition is $\alpha_2\beta_2$.

[d]Actual value is unknown. Different values have been calculated for this reaction (e.g., $-22\,kJ\,mol^{-1}$ in Fuchs [1986], and $-49\,kJ\,mol^{-1}$ in Fuchs [1994]).

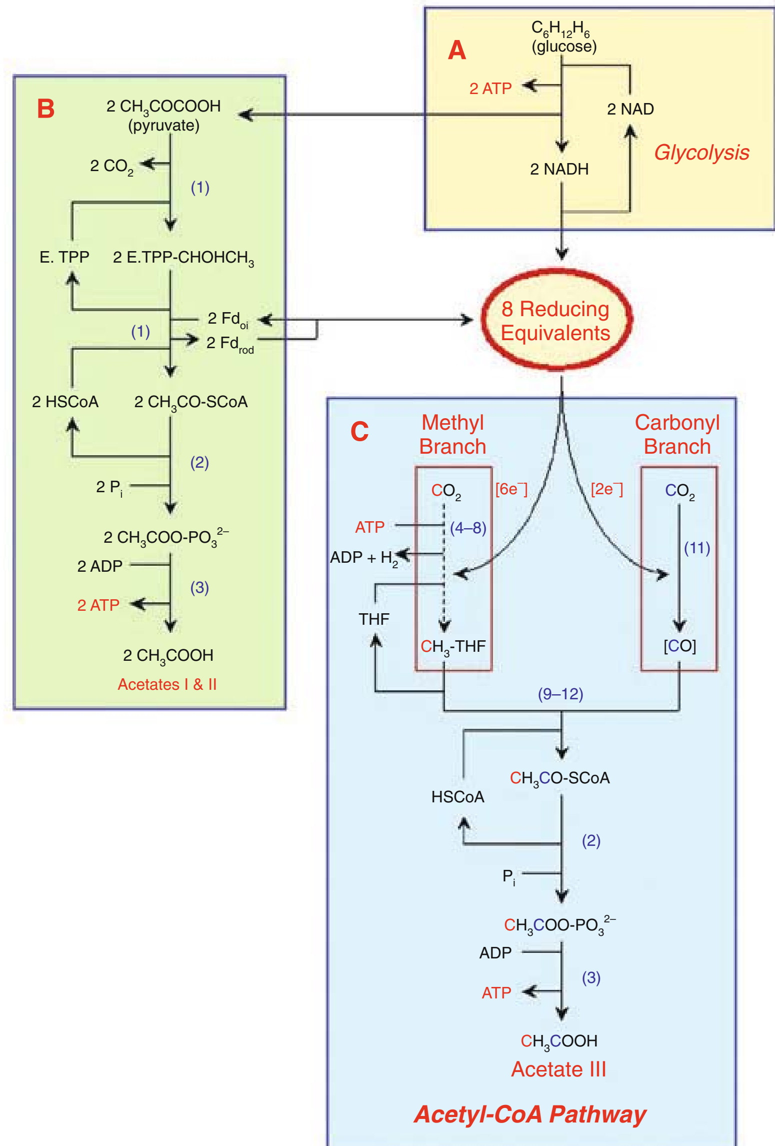


Fig. 12. Transfer of reductant from glycolysis (Box A) and the oxidation of pyruvate (Box B) to the acetyl-CoA pathway (Box C). The overall scheme was elucidated from studies with *Moorella thermoacetica*. The parenthetically enclosed numbers (in blue) identify the different enzymes involved (see Table 5 for characteristics of enzymes). Abbreviations: THF, tetrahydrofolate; E.TPP, enzyme.thiamine pyrophosphate; Fd, ferredoxin; HSCoA, coenzyme A; P_i, inorganic phosphate; and e^-, reducing equivalent.

sugars, may be significantly impaired in the absence of supplemental CO_2 (Andreesen et al., 1970; O'Brien and Ljungdahl, 1972; Braun and Gottschalk, 1981).

The reason why exogenous CO_2 is required for optimal growth on glucose is illustrated in Fig. 13. Supplemental CO_2 is required for the recycling of reduced electron carriers, and this intracellular management of reductant must occur before glucose-derived CO_2 becomes available via the decarboxylation of pyruvate. In support of the scheme illustrated in Fig. 12, early ^{14}C studies demonstrated that carbons 3 and 4 of glucose mostly enter the pool of CO_2 rather than acetate (Wood, 1952b; O'Brien and Ljungdahl, 1972). Thus, approximately one-third of the ^{14}C from [U-^{14}C]glucose is recovered in the exogenous CO_2 pool when *M. thermoacetica* is grown on [U-^{14}C]glucose; the other two-thirds of the ^{14}C is recovered as [^{14}C]acetate (D. R. Martin and H. L. Drake, unpublished data; see also Martin et al., 1985).

Exogenous CO_2 can even be required for CO-dependent acetogenesis, a process that generates excess CO_2 (Savage et al., 1987):

$$4CO + 2H_2O \rightarrow CH_3COOH + 2CO_2 \quad (9)$$

The acetogenic utilization of highly reduced one-carbon substrates is strictly dependent upon the availability of exogenous CO_2. Thus, acetogenic cultures of *M. thermoacetica* and *C. formicoaceticum* cannot be maintained on methanol in the absence of supplemental CO_2 (Hsu et al., 1990a; Matthies et al., 1993). The importance of CO_2 to acetogens is exemplified by their ability to

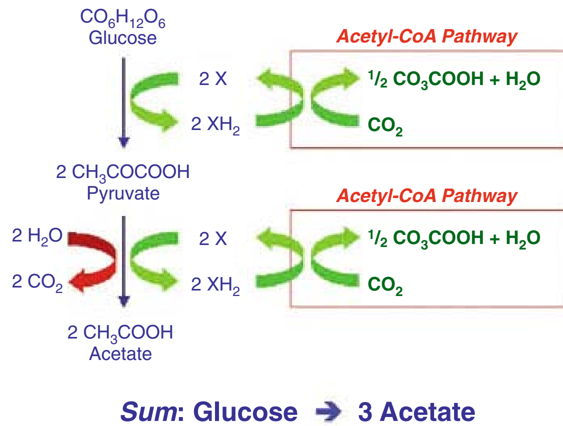

Fig. 13. Importance of CO_2 for the recycling of reduced electron carriers (XH_2) during the acetogenic oxidation of glucose. Under certain growth conditions, exogenous CO_2 is required for growth, even though CO_2 is produced during catabolism (e.g., via the decarboxylation of pyruvate). Modified from Drake (1994).

generate growth-essential CO_2-equivalents from various compounds, including carboxylated lignin derivatives (e.g., vanillate; Hsu et al., 1990a; Hsu et al., 1990b).

Acetogenesis is often referred to as a fermentation. Since the term "fermentation" implies that an organism uses a partially oxidized carbonaceous intermediate as a terminal electron acceptor (e.g., when pyruvate is reduced to lactate in lactate fermentation), usage of this term for acetogenesis in not fully valid. For example, as outlined above, it appears that exogenous CO_2 rather than that generated from the decarboxylation of pruvate is used as the terminal electron acceptor when glucose is metabolized. Likewise, the CO_2 that is derived from the decarboxylation of aromatic compounds and subsequently used as a terminal electron acceptor in the acetyl-CoA pathway is fundamentally dissimilar to the use of an oxidized intermediate as a terminal electron acceptor in fermentation. Furthermore, referring to acetogenesis as a fermentation does not properly reflect the chemiosmotic manner in which energy is conserved via the acetyl-CoA pathway and plasma membrane ATPases (see the subsection on Conservation of Energy and Bioenergetics in this Chapter).

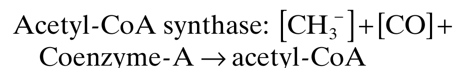
Enzymology of the Acetyl-CoA Pathway

The initial reactions on the methyl and carbonyl branches of the pathway are catalyzed by formate dehydrogenase and acetyl-CoA synthase, respectively. These two enzymes are responsible for reductive reactions that are thermodynamically very unfavorable (i.e., have positive Gibb's free energies under standard conditions; Fig. 11). Formate dehydrogenase from *M. thermoacetica* is rich in metals (2 moles of selenium, 2 moles of tungsten, and approximately 36 moles of iron per mole of enzyme) and was the first enzyme in which tungsten was shown to be a biologically active trace metal (Yamamoto et al., 1983; Ljungdahl, 1986). The tetrahydrofolate pathway facilitates the subsequent reduction of formate to the methyl level (Ljungdahl, 1986). Acetyl-CoA synthase is a nickel-containing enzyme, reduces CO_2 to the carbonyl (CO) level, and facilitates the synthesis of acetyl-CoA (Wood and Ljungdahl, 1991b). The acetyl-CoA that is formed by acetyl-CoA synthase is subsequently converted to acetate during catabolism or utilized in the synthesis of cell carbon during anabolism (Fig. 11). The Gibb's free energy for the overall reduction of 2 moles of CO_2 to 1 mole of acetate is approximately –95 kJ mol^{-1}.

The general properties of the enzymes involved in the acetyl-CoA pathway are outlined in Table 5. Many of the enzymes from acetogens are extremely susceptible to inactivation by oxidation. For example, formate dehydrogenase and acetyl-CoA synthase are among the most oxygen-sensitive enzymes known. Thus, the use of O_2-free chambers has become routine for studying the enzymes central to acetogenesis. Although all of the enzymes of the acetyl-CoA pathway are important to the functionality of the pathway, several of the enzymes are worthy of special note:

a) Acetyl-CoA synthase catalyzes two reactions and is often referred to by two names (Diekert and Thauer, 1978; Drake et al., 1980; Ragsdale et al., 1983; Wood and Ljungdahl, 1991b; Ragsdale, 1994):

CO dehydrogenase:
$$CO + H_2O \rightarrow CO_2 + 2H^+ + 2e^- \quad (10)$$



$$\text{Acetyl-CoA synthase: } [CH_3^-] + [CO] + \text{Coenzyme-A} \rightarrow \text{acetyl-CoA} \quad (11)$$

The discovery of the ability of this enzyme to catalyze reaction 10 (Diekert and Thauer, 1978) was paramount to later studies that resolved the physiological importance of the enzyme in reaction 11 (see Table 1 and the section on Historical Perspectives in this Chapter). In the acetyl-CoA pathway, acetyl-CoA synthase reduces CO_2 to CO and subsequently fixes this CO_2-derived carbon (i.e., CO) into an organic form (i.e., in acetyl-CoA). Acetyl-CoA synthase catalyzes the thermodynamically least favorable reaction in the pathway (Fig. 11), a fact that might partially explain why this enzyme can represent up to 2% of the soluble cell protein of an acetogen (Ragsdale et al., 1983). That acetyl-CoA synthase was discovered as CO dehydrogenase resulted in the

acetyl-CoA pathway being sometimes referred to as the "CO dehydrogenase pathway." This nomenclature is less than ideal as it does not accurately portray the physiological function of the enzyme in the pathway and also does not differentiate the enzyme (and thus the pathway) from the CO dehydrogenase used by aerobic carboxydotrophs that grow via the oxidation of CO to CO_2 (Meyer, 1988; Meyer et al., 1993; Meyer et al., 2000).

Recent studies on the crystal structure of the enzyme from *M. thermoacetica* have shown that the α subunits of acetyl-CoA synthase display both closed and open conformations, and that the active form of the enzyme has an Ni-Ni-[Fe_4-S_4] cluster at the active site (Darnault et al., 2003). Copper, once thought to be a part of this nickel-containing metal cluster (Doukov et al., 2002), is an inhibitor of acetyl-CoA synthase and not a component of the catalytically active enzyme (Bramlett et al., 2003; Darnault et al., 2003). A nickel insertase is involved in the biosynthesis of acetyl-CoA synthase (Loke and Lindahl, 2003).

b) Formate dehydrogenase (Yamamoto et al., 1983) and formyltetrahydrofolate synthetase (Lovell et al., 1990) are also centrally important because formate dehydrogenase "reductively fixes" CO_2 to formate, and formyltetrahydrofolate synthetase subsequently "covalently fixes" this CO_2-derived carbon (i.e., formate) into an organic form on the methyl branch of the pathway. A functional gene probe for the detection of acetogens is based on the gene sequence of formyltetrahydrofolate synthetase (Lovell and Hui, 1991; Lovell, 1994; Leaphart and Lovell, 2001; see the subsection on Detection of Acetogens in this Chapter).

c) Under chemolithoautotrophic conditions (e.g., during growth on H_2-CO_2), the pathway must not only fix carbon but also conserve energy. Reactions that appear to be associated with this conservation of energy are facilitated by methlylenetetrahydrofolate reductase and methyltransferase (Clark and Ljungdahl, 1984; Park et al., 1991; Wohlfarth and Diekert, 1991; Müller et al., 2001; Müller, 2003; see the subsection on Conservation of Energy and Bioenergetics in this Chapter).

d) H_2-dependent growth under chemolithotrophic conditions is considered to be a hallmark of acetogens, and this capability requires the activation of H_2-derived reductant via hydrogenase. Though seldom highlighted in the pathway, hydrogenase thus catalyzes the first step in the chemolithoautotrophic fixation of CO_2 (i.e., without utilizable reductant, CO_2 cannot be fixed). Though the activities and properties of hydrogenases from different acetogens have been documented (e.g., Braun and Gottschalk, 1981; Kellum and Drake, 1984; Ragsdale and Ljungdahl, 1984; Dobrindt and Blaut, 1996; Drake et al., 1997), relatively little information has been published on hydrogenases from autotrophically grown acetogens. Acetogens can contain multiple hydrogenases (Kellum and Drake, 1984), and levels of hydrogenase activity in the membrane can increase when acetogens are cultivated at the expense of H_2-CO_2 (Braus-Stromeyer and Drake, 1996), indicating that the function and intracellular localization of hydrogenases in acetogens are affected by cultivation conditions.

e) Carbonic anhydrase catalyzes the following reversible reaction (Lindskog et al., 1971; Karrasch et al., 1989; Albers and Ferry, 1994; Kisker et al., 1996; Vandenberg et al., 1996):

$$CO_2 + H_2O \leftrightarrow HCO_3^- + H^+ \qquad (12)$$

This enzyme has been demonstrated in numerous acetogens, including *A. woodii* and *S. silvacetica* (Braus-Stromeyer et al., 1997). Carbonic anhydrase is widespread in nature, occurs in an extensive number of organisms, including humans, plants and prokaryotes, and has multiple functions, including pH homeostasis, facilitated diffusion of CO_2, interconversion of CO_2 and HCO_3^-, and ion transport. Since CO_2 is important to the acetyl-CoA pathway, one physiological function of carbonic anhydrase in acetogens might be to increase intracellular levels of CO_2. Carbonic anhydrase has been purified approximately 300-fold from *A. woodii*; that specific activities of carbonic anhydrase in *A. woodii* are very high in both autotrophically and organotrophically grown cells indicate that this enzyme is physiologically important during acetogenesis (Braus-Stromeyer et al., 1997).

Conservation of Energy and Bioenergetics

Acetogens can conserve energy by substrate-level phosphorylation and chemiosmotic mechanisms. Under certain growth conditions, both processes can be utilized simultaneously. However, when acetogens grow chemolithoautotrophically (e.g., on H_2-CO_2), energy can only be conserved via a chemiosmotic mechanism.

SUBSTRATE-LEVEL PHOSPHORYLATION. Under homoacetogenic conditions, certain hexoses are converted stoichiometrically to acetate, and a net of 4 ATP (per hexose metabolized) are formed by substrate-level phosphorylation (Figs. 3 and 12). A point that is often overlooked when comparing acetogens to other anaerobes is that acetogens conserve more energy by substrate-level phosphorylation than do the more classic fermenters (Table 6). For example, twice as much energy is conserved via

Table 6. Amount of ATP formed via substrate-level phosphorylation (ATPSLP) during glucose-dependent acetogenesis and fermentative processes.

Process	Stoichiometry of the process	ATP_{SLP}
Acetogenesis	Glucose → 3 acetate	4
Butyrate fermentation	Glucose → butyrate + $2CO_2$ + $2H_2$	3
Bifidum fermentation	Glucose → 1.5 acetate + lactate	2.5
Ethanol fermentation	Glucose → 2 ethanol + $2CO_2$	2
Homolactate fermentation	Glucose → 2 lactate	2
Heterolactate fermentation	Glucose → lactate + ethanol + CO_2	1

substrate-level phosphorylation during the homoacetogenic metabolism of glucose than during glucose-dependent ethanol fermentation. It should be noted that when hexoses are metabolized, the net energy that is conserved via substrate-level phosphorylation is only indirectly linked to the acetyl-CoA pathway (see panels A and B in both Figs. 3 and 12). The ability of acetogens to conserve more energy via substrate-level phosphorylation than certain other anaerobes (i.e., on a per-mole-substrate-utilized basis) might make acetogens more competitive under certain in situ conditions.

MEMBRANOUS ELECTROCHEMICAL GRADIENTS AND ATPASES. Although the above comments suggest that the ability to conserve energy via substrate-level phosphorylation is important to the bioenergetics of acetogens, the net production of ATP via substrate-level phosphorylation does not directly occur in the acetyl-CoA pathway. During the reductive synthesis of acetate from CO_2, one ATP is consumed when formate is activated and one ATP is gained at the level of acetate kinase, thus yielding a break even relative to net ATP gain via substrate-level events (Fig. 11). In addition, the reduction of CO_2 to the carbonyl level on the carbonyl branch is thermodynamically unfavorable and requires energy (estimated at one-third ATP equivalent; Diekert, 1992). Thus, in the absence of chemiosmotic processes, the acetyl-CoA pathway does not directly yield net utilizable energy via substrate-level phosphorylation.

However, cell yields of acetogens are in excess of cell yields that can be explained from energy conserved via substrate-level phosphorylation. One mole of ATP yields approximately 10 g dry weight of microbial biomass, and cell yields of acetogens (e.g., *C. aceticum* and *A. woodii*) are 50–70 g cell dry weight per mole of glucose-equivalent (Andreesen et al., 1973; Tschech and Pfennig, 1984). Since a maximal cell yield of 40 g cell dry weight per mole of glucose is predicted from substrate-level phosphorylation (4 moles ATP_{SLP} per mole of glucose), the higher than expected cell yields indicate that acetogens conserve energy by chemiosmotic processes. The capacity of acetogens to grow chemolithoautotrophically on H_2-CO_2 likewise indicates that acetogens are capable of conserving energy via electron transport phosphorylation or chemiosmotic mechanisms (since there is no net ATP gain via substrate-level phoshorylation in the acetyl-CoA pathway).

Acetogens appear to use two different mechanisms for conserving energy by chemiosmotic processes. One process involves the generation of a membranous proton gradient and the synthesis of ATP by proton-dependent ATPase (Ljungdahl, 1994; Fig. 14A), and the other process involves the generation of a membranous sodium gradient and the synthesis of ATP by sodium-dependent ATPase (Müller and Gottschalk, 1994; Müller et al., 2001; Fig. 14B). Although the precise biochemical mechanisms for these two processes are not known, several generalizations can be made as to how these processes occur:

a) Acetogens are rich in electron carriers (e.g., ferredoxins, rubredoxins, quinones and cytochromes), and certain acetogens have membranous electron transport systems that can generate proton gradients across the membrane which can subsequently be used by proton-dependent ATP synthases (ATPases) to synthesize ATP (Das et al., 1989; Das et al., 1997; Kamlage and Blaut, 1993a; Kamlage et al., 1993b; Ljungdahl, 1994; Das and Ljungdahl, 2003). Likewise, certain oxidoreductases (e.g., hydrogenase) may be membrane-associated and also involved in generating proton gradients across the membrane (Ljungdahl, 1994; Drake et. al., 1997; Fig. 14A). The large, negative Gibb's free energy for the methylenetetrahydrofolate reductase-mediated step in the acetyl-CoA pathway (Table 5) suggests that this enzyme is associated with energy conservation (Wohlfarth and Diekert, 1991). This enzyme can be membrane-bound (Hugenholtz et al., 1987) and might function in close association with the other catalysts responsible for the synthesis of acetyl-CoA that might also be loosely associated with the membrane (e.g., acetyl-CoA synthase activity occurs in the cell membrane of *M. thermoautotrophica* [Hugenholtz et al., 1987; Hugenholtz and

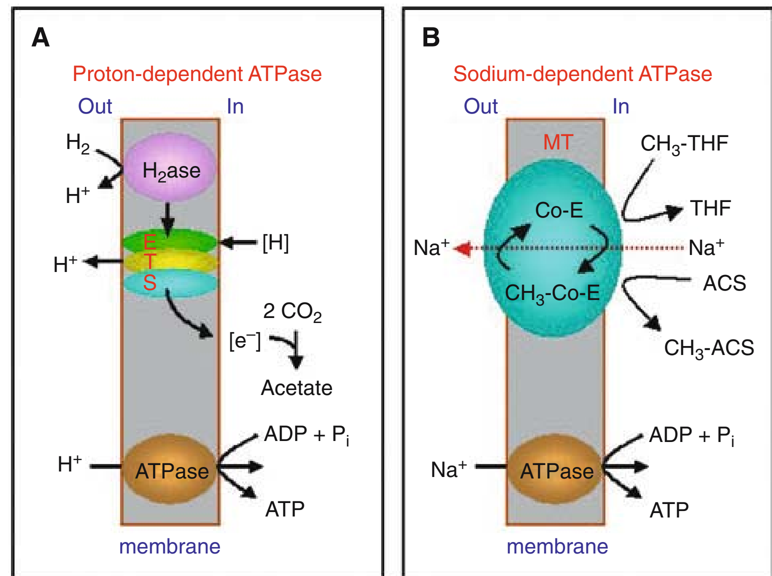


Fig. 14. Proton- (A) and sodium-dependent (B) mechanisms for the chemiosmotic conservation of energy by acetogens. Panel A is based on the work of Ljungdahl and coworkers, and Panel B is based on the work of Müller and coworkers. Abbreviations: H_2ase, hydrogenase; ETS, membranous electron transport system that is composed of various electron carriers (the system facilitates both the transport of electrons and translocation of protons); ATPase, ATP synthase; MT, methyltransferase, Co-E, corrinoid enzyme; THF, tetrahydrofolate, e^-, reducing equivalent; and ACS, acetyl-CoA synthase.

Ljungdahl, 1989] and *T. kivui* [Braus-Stromeyer et al., 1996; Drake et al., 1997]). The membranous *b*-type cytochrome that is linked to the activity of methylenetetrahydrofolate reductase and repressed during nitrate dissimilation (see the subsection on Regulation of the Acetyl-CoA Pathway and Other Metabolic Abilities in this Chapter) is closely interfaced to proton translocation by membranous menaquinone during the transport of electrons (Das and Ljungdahl, 2003). Examples of acetogens that have membranous electron-transport systems and proton-dependent ATPases include *M. thermoacetica*, *M. thermoautotrophica* and *S. sphaeroides*.

b) Some acetogens require sodium for growth, motility, and the optimal synthesis of acetate under certain conditions (Geerligs et al., 1989; Heise et al., 1989; Yang and Drake, 1990; Müller and Bowien, 1995). For example, *T. kivui* requires sodium for chemolithoautotrophic growth but not for organotrophic growth (Yang and Drake, 1990). In contrast, *M. thermoacetica* does not require sodium for either chemolithoautotrophic or organotrophic growth (Yang and Drake, 1990). Although the biochemical mechanism is not fully resolved, a membrane-associated complex that is interfaced to the methyl branch of the acetyl-CoA pathway appears to facilitate the translocation of sodium ions across the cell membrane (Müller and Gottschalk, 1994; Müller et al., 2001; Müller, 2003). The joint reaction catalyzed by methyltransferase and the corrinoid enzyme appears to be centrally important in the translocation of sodium ions, and the model proposed in Fig. 14B illustrates how the generation of a sodium gradient is interfaced to the synthesis of ATP via sodium-dependent ATPase (Reidlinger and Müller, 1994a; Spruth et al., 1995). Although this model is only hypothetical, numerous observations indicate that it has a sound theoretical basis. The reader is referred to Müller et al. (2001), Müller (2003) and Müller et al. (2004) for a more thorough treatment of this topic. *Acetobacterium woodii* and *T. kivui* are examples of acetogens that use sodium translocation and sodium-dependent ATPases for the conservation of energy.

c) Sodium-proton antiporters may facilitate specific changes in the type of electrochemical gradient that is used to conserve energy in acetogens (Terracciano et al., 1987; Yang and Drake, 1990; Müller and Gottschalk, 1994). For example, harmaline, an inhibitor of sodium-proton antiporters, uncouples the growth of *T. kivui* from the synthesis of acetate under chemolithoautotrophic conditions (i.e., the H_2-dependent production of acetate continues in the absence of growth when harmaline is added to the growth medium; Yang and Drake, 1990). Such observations suggest that sodium-proton antiporters are important to the ability of acetogens to conserve energy under certain conditions.

ADDITIONAL PERSPECTIVES ON THE BIOENERGETICS OF ACETOGENS. Pyrophosphate is a utilizable source of energy for certain anaerobes (Liu et al., 1982; Varma and Peck, 1983). *Moorella thermoacetica* forms and subsequently consumes intracellular pyrophosphate during growth (Heinonen and Drake, 1988). However, no direct correlation has been established between the intracellular turnover of pyrophosphate and cellular bioenergetics of acetogens.

Acetogens display different growth efficiencies with identical substrates. For example, the cell yields of *T. kivui* on H_2 and glucose are approximately twofold higher than those of *M. thermoacetica* (Daniel et al., 1990). The biochemical explanations for such differences have not been resolved. However, the different mechanisms by which acetogens conserve energy may in part be responsible for such differences in growth efficiencies. With *Sporomusa*, different cytochromes are utilized for H_2- and betaine-derived reductant (Kamlage and Blaut, 1993a; Kamlage et al., 1993b); thus, the engagement of different electron transport systems for different substrates might account for some of the differences in growth efficiencies (i.e., the bioenergetics of growth) of acetogens.

Occurrence of the Acetyl-CoA Pathway in Non-Acetogenic Microorganisms

Metabolic schemes that bear close biochemical resemblance to the acetyl-CoA pathway of acetogens are utilized by non-acetogenic bacteria (e.g., sulfate-reducing bacteria) and members of the domain Archaea (e.g., methanogens) for either the assimilation of CO_2 (i.e., carbon) into biomass or the oxidation of acetate (Table 7). Thus, many of the biochemical and physiological features of the acetyl-CoA pathway are widely distributed in the prokaryotes. It must be remembered that these metabolic processes are not exactly the same, and that different metabolic co-factors and enzymes are involved. Nonetheless, the general features of these different forms of the acetyl-CoA pathway are very similar. Different species of the sulfate-reducing bacteria have been observed to have acetogenic capabilities (Klemps et al., 1985; Min and Zinder, 1990; Madsen and Licht, 1992; Tasaki et al., 1992; Tasaki et al., 1993; Kuever et al., 1993; Kuever et al., 1999; Christiansen and Ahring, 1996; Sanford et al., 1996); however, definitive, enzymological information on this metabolic capability is scant. The acetyl-CoA pathway is the dominant biological mechanism for the anaerobic oxidation of acetate (Fuchs, 1990).

Diverse Physiological Talents of Acetogens

The standard redox potential of the CO_2/acetate, CO_2/methane, and sulfate/sulfide half-cell reactions approximates –290, –240 and –220 mV, respectively. Thus, under standard conditions, the reductive synthesis of acetate from CO_2 is thermodynamically less favorable than methanogenesis or the reduction of sulfate to sulfide. Such thermodynamic limitations are often cited to explain why acetogens are physiologically less competitive for available reductant than methanogens and sulfate-reducing bacteria. However, as outlined in this section, acetogens have very diverse metabolic abilities that would theoretically increase their in situ competitiveness.

Diverse Electron Donors

Diverse substrates can be oxidized and deliver reductant to the acetyl-CoA pathway and the reductive synthesis of acetate (Table 8). Oxidizable substrates include CO, H_2, carbohydrates, alcohols, carboxylic acids, dicarboxylic acids, aldehydes, substituent groups of aromatic compounds, and numerous other organic and halogenated substrates. By virtue of their ability to use a wide range of substrates, acetogens have

Table 7. Functions of acetyl-CoA synthase and the acetyl-CoA pathway in obligate anaerobes.[a]

Function	Group	Process	References[b]
Acetyl-CoA forming	Acetogens	CO_2 + [H] → [acetyl-CoA] → acetate + biomass	Drake, 1994
Acetyl-CoA forming	Autotrophic methanogens e.g., *Methanobacterium thermoautotrophicum*	CO_2 + [H] → [acetyl-CoA] → biomass	Whitman, 1994
Acetyl-CoA forming	Autotrophic S-reducers e.g., *Desulfobacterium autotrophicum*	CO_2 + [H] → [acetyl-CoA] → biomass	Fuchs, 1994
Acetyl-CoA degrading	Acetate-oxidizing methanogens e.g., *Methanosarcina barkert*	Acetate → [acetyl-CoA] → CO_2 + CH_4	Ferry, 1994
Acetyl-CoA degrading	Acetate-oxidizing S-reducers e.g., *Desulfotomaculum acetoxidans*	Acetate → [acetyl-CoA] → CO_2 + [H]	Fuchs, 1994
Bidirectional	Bidirectional acetogens e.g., "Reversibacterium strain AOR"	Acetate ⇆ [acetyl-CoA] ⇆ CO_2 + [H]	Zinder, 1994

[a][H] is reductant. Acetyl-CoA is bracketed to indicate that it is an intracellular intermediate.

Modified from Drake (1992, 1994).

Table 8. Representative growth-supportive substrates and overall substrate-product stoichiometries of acetogens that can form acetate as their predominant reduced product.[a]

Substrate	Overall stoichiometry for acetate production	Representative acetogen
Acetoin	$2\ CH_3COCHOHCH_3 + 2\ CO_2 + 2\ H_2O \rightarrow 5\ CH_3COOH$	*Acetobacterium carbinolicum*
Alcoxyethanols	$4\ RO\text{-}CH_2CH_2OH + 2\ CO_2\ 2\ H_2O \rightarrow 4\ ROH + 5\ CH_3COOH$	*Acetobacterium malicum*
e.g., 2-methoxyethanol	$4\ CH_3OCH_2CH_2OH + 2\ CO_2 + 2\ H_2O \rightarrow 4\ CH_3OH + 5\ CH_3COOH$	*Acetobacterium malicum*
e.g., 2-ethoxyethanol	$4\ C_2H_5OCH_2CH_2OH + 2\ CO_2 + 2\ H_2O \rightarrow 4\ C_2H_5OH + 5\ CH_3COOH$	*Acetobacterium malicum*
2,3-butanediol	$4\ CH_3CHOHCHOHCH_3 + 6\ CO_2 + 2\ H_2O \rightarrow 11\ CH_3COOH$	*Clostridium magnum*
Cellobiose	$C_{12}H_{22}O_{11} + H_2O \rightarrow 6\ CH_3COOH$	*Ruminococcus productus*
Citrate	$4\ C_6H_8O_7 + 2\ H_2O \rightarrow 9\ CH_3COOH + 6\ CO_2$	*Clostridium magnum*
CO	$4\ CO + 2\ H_2O \rightarrow CH_3COOH + 2\ CO_2$	*Moorella thermoacetica*
Ethanol	$2\ CH_3CH_2OH + 2\ CO_2 \rightarrow 3\ CH_3COOH$	*Clostridium formicoaceticum*
Formate	$4\ HCOOH \rightarrow CH_3COOH + 2\ CO_2 + 2\ H_2O$	*Moorella thermoacetica*
Fructose	$C_6H_{12}O_6 \rightarrow 3\ CH_3COOH$	*Clostridium formicoaceticum*
Glucose	$C_6H_{12}O_6 \rightarrow 3\ CH_3COOH$	*Clostridium thermoaceticum*
Glycerol	$4\ HOCH_2CHOHCH_2OH + 2\ CO_2 \rightarrow 7\ CH_3COOH + 2\ H_2O$	*Acetobacterium carbinolicum*
Glycolate	$4\ CH_2OHCOOH \rightarrow 3\ CH_3COOH + 2\ CO_2 + 2\ H_2O$	*Moorella thermoacetica*
Glyoxylate	$2\ HOCCOOH \rightarrow CH_3COOH + 2\ CO_2$	*Moorella thermoacetica*
$H_2 + CO_2$	$4\ H_2 + 2\ CO_2 \rightarrow CH_3COOH + 2\ H_2O$	*Clostridium aceticum*
$H_2 + CO$	$2\ H_2 + 2\ CO \rightarrow CH_3COOH$	*Moorella thermoacetica*
H_2 + formate	$2\ H_2 + 2\ HCOOH \rightarrow CH_3COOH + 2\ H_2O$	*Moorella thermoacetica*
4-hydroxybenzaldehyde	4, 4-hydroxybenzaldehyde + $2\ CO_2 + 2\ H_2O \rightarrow CH_3COOH$ + 4-hydroxybenzoate	*Clostridium formicoaceticum*
Malate	$2\ HOOCCHOHCH_2COOH \rightarrow 3\ CH_3COOH + 2\ CO_2$	*Clostridium magnum*
Methanol	$4\ CH_3OH + 2\ CO_2 \rightarrow 3\ CH_3COOH + 2\ H_2O$	*Moorella thermoacetica*
Methoxyacetate	$4\ CH_3OCH_2COOH + 2\ CO_2 + 2\ H_2O \rightarrow 3\ CH_3COOH + 4\ HOCH_2COOH$	*Acetobacterium* sp. RMMac1
Methoxylated aromatics	4 aromatic-$[OCH_3] + 2\ CO_2 + 2\ H_2O \rightarrow$ 4 aromatic-$[OH] + 3\ CH_3COOH$	(Many acetogens)
e.g., syringate	2 syringate$[\text{-}OCH_3]_2 + 2\ CO_2 + 2\ H_2O \rightarrow$ 2 gallate$[\text{-}OH]_2 + 3\ CH_3COOH$	*Acetobacterium woodii*
e.g., vanillate	4 vanillate$[\text{-}OCH_3] + 2\ CO_2 + 2\ H_2O \rightarrow$ 4 protocatechuate$[\text{-}OH] + 3\ CH_3COOH$	*Acetobacterium woodii*
e.g., syringate + H_2-CO_2	syringate$[\text{-}OCH_3]_2 + 2\ CO_2 + 2\ H_2 \rightarrow$ gallate$[\text{-}OH]_2 + 2\ CH_3COOH$	Strain SS1
Methyl chloride	$4\ CH_3Cl + 2\ CO_2 + 2\ H_2O \rightarrow 3\ CH_3COOH + 4\ HCl$	*"Acetobacterium dehalogenans"*
Oxalate	$4\ HOOCCOOH \rightarrow CH_3COOH + 6\ CO_2 + 2\ H_2O$	*Moorella thermoacetica*
Pyruvate	$4\ CH_3COCOOH + 2\ H_2O \rightarrow 5\ CH_3COOH + 2\ CO_2$	*Moorella thermoacetica*
Xylose	$2\ C_5H_{10}O_5 \rightarrow 5\ CH_3COOH$	*Moorella thermoacetica*

[a]No distinction is made (a) between acids and their dissociated salt forms or (b) between CO_2 and its carbonate or bicarbonate forms. Although only one representative acetogen is listed per substrate, many acetogens may be capable of utilizing each substrate (e.g., almost all acetogens can synthesize acetate from H_2/CO_2 or methoxylated aromatic compounds).

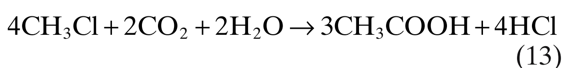
numerous trophic links to other organisms under in situ conditions.

Most acetogens have not been observed to degrade complex polymers, such as lignin or cellulose. However, little effort has gone into finding such acetogenic isolates. The recently described acetogen "*B. formatexigens*," isolated from human feces, utilized amorphous (cabbage) cellulose and carboxymethylcellulose when isolated, but lost this ability upon storage under frozen conditions (Wolin and Miller, 1994; Wolin et al., 2003). Another acetogen phylogenetically closely related to *M. thermoacetica*, strain F21 (isolated in a roll tube containing Avicel® [crystalline cellulose]), is cellulolytic and has carboxymethylcellulase and xylanase activities (Karita et al., 2003). The cellulolytic capabilities of these two organisms suggest that certain acetogens may be able to degrade certain polymers.

An organism referred to as "*M. thermoautotrophica*" (*C. thermoautotrophicum* at the time of publication) was reported to degrade inulin, a large (M_r ca. 5,000; Budavari, 1989) storage polysaccharide of plants (Drent and Gottschal, 1991). However, the product profile (1.0 hexose → 0.4 formate + 0.7 acetate + 1.3 ethanol + 1.0 H_2 + 1.0 CO_2 + 0.6 cell carbon; Drent and Gottschal, 1991) of this isolate is very inconsistent with that of *M. thermoautotrophica* (Wiegel et al., 1981), and also of acetogens. In the absence of additional information, it cannot be assumed that this organism is either *M. thermoautotrophica* or an acetogen.

The ability to utilize methoxyl groups of aromatic compounds (e.g., vanillate) is a widespread metabolic potential of acetogens (Bache and Pfennig, 1981; Frazer and Young, 1985; Daniel et al., 1991; Frazer, 1994). Figure 15 illustrates how methyl groups can be metabolized by acetogens. This metabolic scheme is based on the work of several laboratories (see below), and it must be remembered that the demethylase system varies, depending on the substrate that is demethylated. Furthermore, there may be secondary ATP-dependent activation steps that maintain corrinoid proteins (which may be involved in demethylation and transfer of methyl groups) in a reduced, active form (Kaufmann et al., 1997; Kaufmann et al., 1998).

The methylotrophic potential of acetogens to utilize methyl groups makes physiological sense, given the importance of methyl-level intermediates in the acetyl-CoA pathway. An unusual and apparently highly specialized methylotrophic metabolism is seen in the ability of "*A. dehalogenans*" to utilize methyl chloride according to the following reaction (Traunecker et al., 1991):



$$4CH_3Cl + 2CO_2 + 2H_2O \rightarrow 3CH_3COOH + 4HCl \quad (13)$$

Methyl chloride is dehalogenated by methyl chloride dehalogenase, which yields chloride and methyltetrahydrofolate (Meßner et al., 1993; Meßner et al., 1996). The methyl unit of methyltetrahydrofolate is oxidized to CO_2 by reversal of the methyl branch of the acetyl-CoA pathway, the reductant being subsequently used for the reduction of CO_2 to CO on the carbonyl branch of the pathway (Fig. 15). "*Acetobacterium dehalogenans*" also utilizes methoxylated aromatic compounds, and the *O*-demethylase of "*A. dehalogenans*" consists of two distinct methyltransferases. Methyltransferase I *O*-demethylates the methoxylated aromatic compound and transfers the methyl group to a corrinoid protein. Methyltransferase II transfers the methyl group of the methylated corrinoid protein to tetrahydrofolate (Kaufmann et al., 1997; Kaufmann et al., 1998). The methyltetrahydrofolate is metabolized in the same manner as the methyltetrahydrofolate that is derived from methyl chloride, i.e., the methyl group of methyltetrahydrofolate 1) serves as a methyl donor at the terminal stage of the methyl branch of the acetyl-CoA pathway or 2) is oxidized, and thus serves as a source of reductant for the reductive formation of CO on the carbonyl branch of the acetyl-CoA pathway (Fig. 15). *Acetobacterium woodii* and *M. thermoacetica* appear to utilize *O*-demethylating systems that are similar to that of "*A. dehalogenans*" (Berman and Frazer, 1992; Frazer, 1994; Naidu and Ragsdale, 2001).

An *O*-demethylating methyltransferase system that is involved in the metabolism of methoxyl groups of aromatic compounds has also been characterized from *H. foetida* (Kreft and Schink, 1997). *Holophaga foetida* is an unusual acetogen that can 1) degrade aromatic rings (Bak et al., 1992; Kreft and Schink, 1993; Liesack et al., 1994) and 2) methylate sulfide to dimethylsulfide via a non-energy conserving, methyltransferase-mediated reaction (Kappler et al., 1997). The *O*-demethylating methyltransferase system of *H. foetida* does not appear to be identical to the methyltransferase system characterized from "*A. dehalogenans*" (Kaufmann et al., 1998). *O*-demethylating methyltransferases of acetogens are inducible and may be either specific or nonspecific for the methoxyl group that is *O*-demethylated (Wu et al., 1988; Daniel et al., 1991; Häggblom et al., 1993; Kreft and Schink, 1997). Certain acetogens can *O*-demethylate halogenated aromatic compounds; however, the residual aromatic compound may not be subject to dehalogenation (Häggblom et al., 1993).

The acetyl-CoA pathway can be considered a one-carbon pathway, in that each of the two branches of the pathway facilitate the reduction

Fig. 15. Pathway illustrating how methyl groups from methoxylated aromatic compounds (e.g., vanillate) or methyl chloride can be metabolized by acetogens. Abbreviations: THF, tetrahydrofolate; CoA, coenzyme A; e^-, reducing equivalent; and Co-Protein, corrinoid enzyme.

of one-carbon substrates. Thus, entry-level, one-carbon substrates are particularly well suited for use by acetogens, especially under co-substrate conditions. For example, CO and the methoxyl group of aromatic compounds can be simultaneously and readily metabolized via the carbonyl or methyl branches of the acetyl-CoA pathway, respectively. Methyl groups of osmolytes can also be metabolized by acetogens (Jansen and Hansen, 2001). Certain acetogens also utilize two-carbon substrates, such as oxalate, glyoxylate and glycolate; however, how these two-carbon molecules are metabolized is not well resolved (Daniel and Drake, 1993; Daniel et al., 2004; Seifritz et al., 1999; Seifritz et al., 2002).

Acetogens are specialized in the use of short-chain substituent groups of aromatic compounds, and the use of such substituent groups can have regulatory effects on the flow of carbon and reductant. For example, use of the aldehyde group of certain lignin-derived aromatic compounds by *C. formicoaceticum* inhibits the cell's ability to use fructose (i.e., in the presence of both fructose and 4-hydroxybenzaldehyde, reductant for the acetyl-CoA pathway and the reduction of CO_2 is preferentially derived from the aldehyde group of 4-hydroxybenzaldehyde; Gößer et al., 1994; Frank et al., 1998; Drake and Küsel, 2003, 2005).

Use of Diverse Terminal Electron Acceptors

The acetyl-CoA pathway is the hallmark of acetogens, and, as outlined in the previous subsection Diverse Electron Donors, diverse substrates can be oxidized by acetogens and thus utilized for the reductive synthesis of acetate from CO_2. However, the acetyl-CoA pathway is not the only terminal electron-accepting process utilized by acetogens (Table 9). Thus, the trophic relationships and adaptation strategies of acetogens under in situ conditions may not be solely determined by their acetogenic capabilities (i.e., their use of the acetyl-CoA pathway). A few generalizations can be made about the ability of acetogens to engage in these alternative metabolic processes:

a) Almost all known acetogens can use more than one terminal electron acceptor, and therefore can produce other reduced end products in addition to acetate (Table 9). The capacity to utilize a particular terminal electron acceptor is dependent on the availability of both reductant and terminal electron acceptor. Thus, homoacetogenesis is usually a conditional capacity of an acetogen, and referring to an acetogen as a homoacetogen is almost always a misnomer.

b) The availability of CO_2 can determine how a particular substrate is metabolized by an acetogen. Indeed, for acetogenic growth, exogenous

Table 9. Terminal electron acceptors used by acetogens.[a]

Electron acceptor	Reduced end product	Representative acetogen	References
Acetaldehyde	Ethanol	*Ruminococcus productus*	Misoph and Drake, 1996

[c]See also Fröstl et al. (1996) and Seifritz et al. (2002).
[d]The H_2 formed can be used by an H_2-utilizing methanogen for interspecies hydrogen transfer.

(i.e., supplemental) CO_2 is often essential for growth (see the subsection on CO_2 as Terminal Electron Acceptor and the Concept of Fermentation in this Chapter). However, even when exogenous CO_2 is readily available, an acetogen may utilize other terminal electron acceptors, either in preference to or simultaneously with CO_2. For example, *R. productus* simultaneously reduces CO_2 to acetate and phenylacrylates to phenylpropionates (Misoph et al., 1996b), and also forms lactate as a fermentation end product concomitant to the reductive synthesis of acetate from CO_2 during the metabolism of fructose (Misoph and Drake, 1996a).

c) H_2-dependent acetogenesis is thermodynamically difficult because of the thermodynamic constraints of the entry-level redox reactions for CO_2 in the acetyl-CoA pathway (Fig. 11). For example, the standard redox potential of the CO_2/CO half-cell (–520 mV) is approximately 100 mV more negative than that of the $2H^+ + 2e^-/H_2$ half-cell (–420 mV). However, the capacity of an acetogen to consume H_2 can be significantly improved when an alternative electron acceptor is utilized. The H_2 threshold of *A. woodii* is 520 parts per million (ppm) when CO_2 is utilized as the terminal electron acceptor but decreases to 3 ppm when aromatic acrylates (e.g., caffeate) are utilized as terminal acceptors (Cord-Ruwisch et al., 1988). Likewise, the amount of biomass synthesized per mole of H_2 consumed increases eightfold when nitrate instead of CO_2 is utilized as the terminal electron acceptor by *M. thermoautotrophicum* during growth on low concentrations of H_2 (Fröstl et al., 1996). Thus, the capacity of an acetogen to compete for H_2 can increase significantly when alternative electron acceptors are utilized.

d) The use of diverse electron acceptors by acetogens indicates that acetogens can accommodate a wide range of redox conditions. For example, nitrate is the preferred terminal electron acceptor of the classic acetogen *M. thermoacetica* (Seifritz et al., 1993; Seifritz et al., 2002; Fröstl et al., 1996), suggesting that this acetogen does not require stringently reduced conditions (i.e., the standard redox potential of the nitrate/ammonium half-cell approximates +360 mV while that of the CO_2/acetate half-cell approximates –290 mV). Indeed, *M. thermoacetica* is easily isolated from aerated soils that have fluctuating redox conditions (Gößner and Drake, 1997; Gößner et al., 1998; Gößner et al., 1999).

e) The use of an alternative electron acceptor can have regulatory effects on the acetyl-CoA pathway (see the subsection on Regulation of the Acetyl-CoA Pathway and Other Metabolic Abilities in this Chapter).

f) The use of an alternative electron acceptor can conserve energy and increase the general efficiency of growth. For example, when *A. woodii* is grown at the expense of methanol, growth yields are significantly greater when aromatic acrylates (e.g., caffeate or ferulate) are used as terminal electron acceptors rather than CO_2 (Tschech and Pfennig, 1984). The sodium-dependent reduction of aromatic acrylates by *A. woodii* is coupled to the synthesis of ATP (Hansen et al., 1988; Imkamp and Müller, 2002). Likewise, growth yields of *M. thermoacetica* and *M. thermoautotrophica* increase significantly when reductant flow is directed to the dissimilation of nitrate rather than the reduction of CO_2 to acetate (Seifritz et al., 1993; Fröstl et al., 1996). In fact, ethanol or propanol are not acetogenic substrates for these two acetogens, yet both alcohols are oxidized and growth supportive when nitrate is dissimilated (Fröstl et al., 1996). Thus, the use of alternative electron acceptors by an acetogen can increase the likelihood that certain

compounds can be oxidized and be growth supportive.

g) Energy might not always be conserved by the reduction of a given terminal electron acceptor. For example, H_2 is produced as an end product by *M. thermoacetica* even though the production of H_2 is very likely not directly linked to the conservation of energy (Martin et al., 1983; Martin et al., 1985; Fröstl et al., 1996). However, the ability of certain acetogens (e.g., *A. woodii*) to produce H_2 as a substrate for the interspecies transfer of H_2 indicates that the production of H_2 can be coupled to the conservation of energy under certain in situ conditions (Winter and Wolfe, 1980; Cord-Ruwisch and Olliver, 1986; Heijthuijsen and Hansen, 1986).

h) Certain acetogens have the ability to reductively dehalogenate small molecular weight halogenated compounds (e.g., carbon tetrachloride and tetrachloroethylene; Egli et al., 1988; Freedman and Gossett, 1991; Traunecker et al., 1991; Holliger and Schraa, 1994; Terzenbach and Blaut, 1994; Hashsham and Freedman, 1999). Thus, halogenated compounds can be an electron sink for acetogens. Reductive dehalogenation occurs concomitantly with acetogenesis. However, results to date indicate that reductive dehalogenation 1) is not directly linked to an enzymatic process, 2) is due to chemical reactions with reduced corrinoids that normally serve as cofactors during normal acetogenic metabolism, and 3) does not conserve energy.

Regulation of the Acetyl-CoA Pathway and Other Metabolic Abilities

Acetogenesis was initially thought of as a constitutive trait of the classic acetogen *M. thermoacetica*. Since our understanding of acetogens was largely influenced by the decades of work on this acetogen (see the section on Historical Perspectives in this Chapter), it has only been in more recent times that we have learned that this view is a misconception regarding not only *M. thermoacetica* but acetogens in general. Although the molecular details are not yet well understood, it is now clear that many of the diverse metabolic processes of acetogens are regulated. Indeed, because acetogens have so many diverse metabolic capabilities, it is essential that these capabilities can be regulated. Numerous examples with many acetogens can be cited to reinforce this fact: 1) hydrogenase, formate dehydrogenase, and acetyl-CoA synthase activities are significantly influenced by growth substrates (Braun and Gottschalk, 1981; Kellum and Drake, 1986; Daniel et al., 1990; Lux and Drake, 1992), 2) the capacity to utilize the carboxyl, methoxyl, and acrylate groups of certain aromatic compounds is inducible (Wu et al., 1988; DeWeerd et al., 1988; Hsu et al., 1990b; Imkamp and Müller, 2002), 3) the ability to dehalogenate methyl chloride is inducible (Meßner et al., 1993; Meßner et al., 1996), and 4) electron transport systems are regulated (Kamlage et al., 1993b; Fröstl et al., 1996; Seifritz et al., 2002; Seifritz et al., 2003). Several genes encoding enzymes of the acetyl-CoA pathway of *M. thermoacetica* have been cloned and successfully expressed in *Escherichia coli* (Morton et al., 1992); however, regulation is not well understood at the molecular level.

Relatively few studies have directly assessed the regulation of the acetyl-CoA pathway. The first evidence that the acetyl-CoA pathway is subject to regulation was obtained with *A. woodii*. The use of acrylate groups of certain aromatic compounds (e.g., caffeate) as an alternative electron acceptor when *A. woodii* (grown at the expense of methanol) results in the total shutdown in the cell's ability to produce acetate (Tschech and Pfennig, 1984). Thus, the use of an alternative electron acceptor can have regulatory effects on the acetyl-CoA pathway.

How the acetyl-CoA pathway can be regulated is best understood from information obtained with *M. thermoacetica*. The dissimilation of nitrate represses the function or engagement of the acetyl-CoA pathway by repressing the synthesis of a membranous *b*-type cytochrome that is essential for the formation of methyltetrahydrofolate on the methyl branch of the pathway (Nitrate Block Site 1; Fröstl et al., 1996; Drake et al., 2002; Fig. 16). The amount of certain enzymes of the acetyl-CoA pathway might be less under nitrate-dissimilating conditions than under acetogenic conditions (Arendsen et al., 1999). However, all of the enzymes responsible for the flow of carbon in the acetyl-CoA pathway are expressed and functionally present in the cell when the cell is dissimilating nitrate but not reductively synthesizing acetate from CO_2 (Fröstl et al., 1996). Thus, the membranous *b*-type cytochrome is a key element in regulating the flow of both reductant and carbon in the acetyl-CoA pathway. Hydrogenase activity is strongly repressed when cells dissimilate nitrate, and a second metabolic block occurs at the level of acetyl-CoA synthase on the carbonyl branch of the pathway by an unknown mechanism that might also involve the flow of reductant to CO_2 (Nitrate Block Site 2; Fig. 16). Since acetyl-CoA synthase and hydrogenase can be associated with the cell membrane of certain acetogens (Hugenholtz et al., 1987; Hugenholtz and Ljungdahl, 1989; Braus-Stromeyer et al., 1996; Dobrindt and Blaut, 1996; Drake et al., 1997), it could be that the membranous *b*-type cytochrome and/or membranous hydrogenase is important for electron flow on the carbonyl

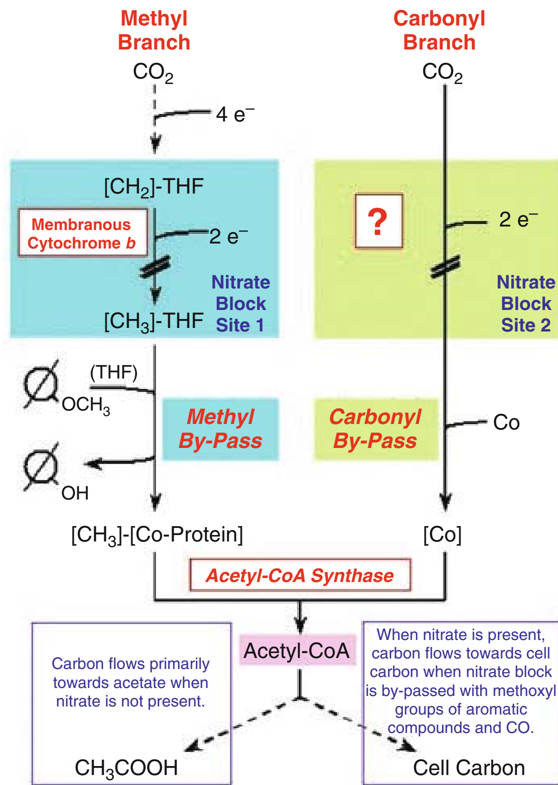

Fig. 16. Pathway illustrating where nitrate blocks the flow of carbon in the acetyl-CoA pathway when nitrate is dissimilated to ammonium by *Moorella thermoacetica*. Abbreviations: THF, tetrahydrofolate; CoA, coenzyme-A; and Co-Protein, corrinoid enzyme. The dissimilation of nitrite to ammonium appears to have the same effect (Seifritz et al., 2002a). Modified from Drake et al. (2003).

branch of the pathway. Although the different functions of hydrogenase(s) during growth of acetogens on sugars are unknown, this oxidoreductase might be essential for the proper flow of sugar-derived reductant during the reduction of CO_2 to acetate (Drake and Küsel, 2003).

Tolerance to Oxic Conditions and Metabolism of O_2

Acetogens have been mostly isolated from habitats that are anoxic (Table 2) and are routinely cultivated under anoxic conditions. Furthermore, many enzymes of the acetyl-CoA pathway are extremely sensitive to O_2. Thus, acetogens have been classically referred to as strict anaerobes. However, acetogens are also present in aerated soils and colonize habitats with fluctuating redox conditions (e.g., the rhizosphere of sea grass). It should therefore come as no surprise that acetogens, like other so-called "strict anaerobes" (e.g., sulfate-reducing bacteria [Marschall et al., 1993; Johnson et al., 1997; Teske et al., 1998; Cypionka, 2000]), are able to cope with oxidative stress. Indeed, acetogens isolated from aerated soils and the rhizosphere of sea grass have the ability to tolerate and consume O_2 (Küsel et al., 2001; Karnholz et al., 2002). Acetogens isolated from the termite gut can also tolerate transient, moderately oxic conditions (Boga and Brune, 2003; Graber and Breznak, 2004a). Although acetogens such as *A. woodii*, *C. magnum*, *C. glycolicum* RD-1, *M. thermoacetica* and *S. silvacetica* can tolerate 0.5–6% O_2 (amount is dependent upon the acetogen and the conditions of incubation) in the headspace of culture tubes, the ability of acetogens to metabolize O_2 does not appear to be directly coupled to the conservation of energy. The capacity of acetogens to metabolize O_2 is likely used as a means to remove trace amounts of O_2 (or toxic products derived from O_2 [e.g., superoxides and peroxides]) from acetogen-colonized microniches that are subject to transient oxic conditions.

Information to date suggests that there are three basic ways that acetogens can cope with oxic conditions:

1) When certain acetogens are challenged with oxic conditions, they make use of alternative electron acceptors and metabolically bypass the need to use the acetyl-CoA pathway. For example, the ability of *M. thermoacetica* to dissimilate nitrate negates the need of the cell to use CO_2 as a terminal electron acceptor when conditions become more oxic. Another example is *C. glycolicum* RD-1, an aerotolerant acetogen that was isolated from sea grass roots and can tolerate up to 4% O_2 in the headspace of shaken culture tubes (Küsel et al., 2001). *Clostridium glycolicum* RD-1 is unusual in that it simultaneously utilizes acetogenesis and ethanol fermentation under anoxic conditions (Fig. 17). However, when conditions become more oxic, acetaldehyde, pyruvate, and protons are exclusively used as terminal electron acceptors, and ethanol, lactate and H_2 become the reduced end products (Fig. 17). Thus, the ability of certain acetogens to cope with oxidative stress appears to be maximized when sugars or other fermentable substrates are available. Such findings indicate that certain acetogens can shift the flow of reductant towards catabolic processes that are less sensitive to O_2 when conditions become more oxic.

2) Several acetogens have been examined at either the enzyme-activity level or gene level for the presence of enzymes that might be involved in the removal (i.e., metabolism) of O_2 or its toxic by-products (Table 10; it should be noted that, thus far, not very many acetogens have been examined for these enzymes). The enzymes that have been detected at either the activity or gene level include NADH-oxidase, peroxidase, super-

oxide dismutase, rubredoxin oxidoreductase, and rubrerythrin. Unlike aerobes that utilize superoxide dismutase, an enzyme that forms O_2 (Table 10), only one acetogen (*C. glycolicum* RD1, an acetogen that displays a very high tolerance to O_2 [above]) has been found to have this enzyme (Küsel et al., 2001). *Clostridium glycolicum* RD1 also contains peroxidase and NADH-oxidase. To date, catalase, which also forms O_2, has only been detected in the termite isolates of *A. longum*, *S. termitida* and *S. aerivorans* (Kane and Breznak, 1991a; Boga and Brune, 2003; Boga et al., 2003). *Clostridium magnum*, *M. thermoacetica* and *S. silvacetica* contain peroxidase and NADH-oxidase activities, but lack catalase and superoxide dismutase (Karnholz et al., 2002). Rubredoxin oxidoreductase and rubrerythrin are oxidative stress enzymes in certain sulfate-reducing bacteria (Lumppio et al., 2001; Kurtz, 2003), and genes for similar proteins occur in *M. thermoacetica* (Das and Ljungdahl, 2001). A flavoprotein/rubredoxin combination (derived from *M. thermoacetica*) functions as an NADH:O_2 oxidoreductase (Silaghi-Dumitrescu et al., 2003). Although these enzymatic capabilities vary from one acetogen to another, it can be concluded that acetogens have the capacity to reductively remove O_2, peroxide and superoxide.

3) Close trophic relationships between acetogens and microaerophiles that consume trace amounts of oxygen is also a means by which acetogens might cope with transient oxic conditions (Gößner et al., 1999). This trophic relationship is discussed in the subsection on Metabolic Interactions in Pure Culture and Complex Ecosystems in this Chapter.

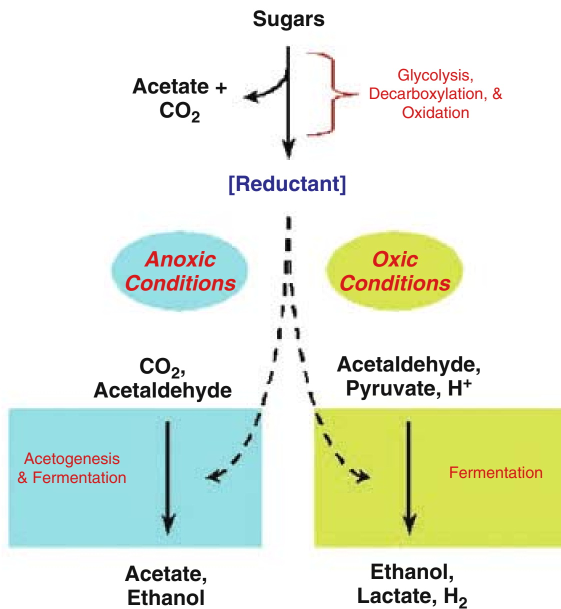

Fig. 17. Flow of sugar-derived reductant during the metabolism of *Clostridium glycolicum* RD-1. Under anoxic conditions, intracellular CO_2 (taken up from exogenous sources or produced from the decarboxylation of pyruvate) and acetaldehyde (produced during catabolism) serve as terminal electron acceptors and are reduced to acetate and ethanol, respectively. Under oxic conditions, intracellular acetaldehyde, pyruvate, and protons (all produced during catabolism) serve as terminal electron acceptors and are reduced to ethanol, lactate and H_2, respectively. Modified from Küsel et al. (2001).

Ecology of Acetogens

There is a general paradox regarding the ecology of acetogens: although theoretical considerations suggest that acetogenesis should not be a highly competitive microbial process, acetogens occur in highly diverse habitats and their activity can sometimes compete with and even overshadow that of other anaerobes. This section will evaluate both sides of this paradox and will focus on the metabolic interactions of acetogens in certain ecosystems.

Table 10. Possible oxidative stress enzymes in acetogens.

Enzyme	Reaction	Detected	References
NADH-oxidase	$O_2 + 2\ NADH + 2\ H^+ \rightarrow 2\ NAD^+ + 2\ H_2O$	Activity	Küsel et al., 2001 Karnholz et al., 2002
Peroxidase	$H_2O_2 + XH_2 \rightarrow X + 2\ H_2O$	Activity	Küsel et al., 2001 Karnholz et al., 2002
Superoxide dismutase	$2\ O_2^- + 2\ H^+ \rightarrow O_2 + H_2O_2$	Activity	Küsel et al., 2001
Catalase	$2\ H_2O_2 \rightarrow O_2 + 2\ H_2O$	Activity	Kane and Breznak, 1991 Boga et al., 2003
FprA/Hrb[a]	$O_2 + 2\ NADH + 2\ H^+ \rightarrow 2\ NAD^+ + 2\ H_2O$	Activity	Silaghi-Dumitrescu et al., 2003
Rubredoxin oxidoreductase	$e^- + O_2^- + 2\ H^+ \rightarrow H_2O_2$	Gene	Das et al., 2001
Rubrerythrin	$H_2O_2 + XH_2 \rightarrow X + 2\ H_2O$	Gene	Das et al., 2001

Abbreviations: NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; FprA, type A flavoprotein; and Hrb, rubredoxin.
[a]This combination also displays NO reductase activity.

Metabolic Interactions of Acetogens in Pure Cultures and Complex Ecosystems

In anoxic environments, acetogens compete with primary fermenters for monomeric compounds that are derived from the degradation of polymers and with secondary fermenters for typical fermentation products such as lactate, ethanol or H_2 (McInerney and Bryant, 1981). Acetogenesis yields more ATP per mole of sugar than classic fermentations do, which might increase the competitiveness of acetogens under certain conditions (see the subsection on Conservation of Energy and Bioenergetics and Table 6 in this Chapter). However, in pure culture, acetogens tend to grow slower on sugars than do classic fermenters (e.g., *Clostridium butyricum*; Schink, 1994). Nonetheless, acetogenesis is the most important anaerobic glucose-consuming process in anoxic paddy soils and lake sediments (Krumböck and Conrad, 1991). When H_2 is utilized as a substrate, acetogens must compete with Fe(III) reducers, sulfate reducers, and methanogens. In most anoxic habitats with low amounts of Fe(III) and sulfate, CO_2-dependent methanogenesis dominates as the terminal reductive process during the oxidation of organic matter. H_2-CO_2-dependent methanogenesis ($\Delta G'_o = -130$ kJ per mole reaction) is more exergonic than H_2-CO_2-dependent acetogenesis ($\Delta G'_o = -95$ kJ per mole reaction; Diekert and Wohlfarth, 1994b; Fuchs, 1994). At the in situ concentrations of reactants and products found in many anoxic environments, methanogenesis may be energetically more favorable than acetogenesis (Dolfing, 1988). H_2-thresholds (i.e., the minimum concentration of H_2 required for the uptake of H_2 by a cell) decrease with increasing redox potential of the energy-yielding reaction (Conrad, 1996). The redox potential of the CO_2/acetate half-cell reaction is –290 mV and is more negative than that of most other terminal electron-accepting processes. Thus, under pure culture conditions, the H_2 threshold of acetogens is higher than that of other hydrogenotrophic anaerobic bacteria (Cord-Ruwisch et al., 1988). For example, the H_2 threshold for acetogens when CO_2 is utilized as a terminal electron acceptor (362–4660 ppm) is 10- to 100-fold higher than that of methanogens. Thus, on these theoretical grounds, H_2-dependent acetogenesis is not a competitive process at low concentrations of H_2.

The capacity of acetogens to utilize various substrates simultaneously might contribute to their competitiveness in nature. Aromatic methoxyl groups are more readily utilized by deep subsurface acetogens in the presence of H_2 (Liu and Suflita, 1993). During mixotrophic growth on H_2 and lactate, *A. woodii* can utilize lower concentrations of H_2; however, the residual partial pressure is still too high for a successful competition with H_2-utilizing methanogens (Peters et al., 1998).

In certain complex microbial habitats (e.g., soils and sediments), the metabolic interactions of anaerobic populations are influenced by unstable physical and chemical parameters such as pH, temperature, periodic oxygenation, spatial arrangements, and different sizes of microbial populations. In certain cases, these complex factors might be favorable for the theoretically disadvantaged acetogens. For example, in freshwater sediments with low pH and low temperature, acetogens can outcompete methanogens for H_2 (Phelps and Zeikus, 1984; Conrad et al., 1989; Nozhevnikova et al., 1994; Zavarzin et al., 1994; see the subsection on Diverse Habitats in this Chapter). In contrast to laboratory cultures, most in situ microbial habitats are not composed of homogeneous or well-mixed microbial populations. Thus, the success of acetogens to compete for H_2 in situ could be enhanced by being spatially associated with H_2-producing cells in a heterogenic system. However, information about the in situ spatial distribution of acetogens at the microscale level is scant, mainly because broad-based, group-specific 16S rRNA-based probes cannot be developed for the phylogenetically diverse acetogens (see the subsection on Detection of Acetogens in this Chapter). Furthermore, the functional gene probe that has been developed for acetogens appears to be restricted to a subgroup of acetogens and, likewise, is not absolutely specific for acetogens (Lovell and Hui, 1991).

Methanogens appear to be more sensitive to O_2 than acetogens, and acetogens can occur in higher cultured numbers than methanogens in habitats that are subject to fluctuating concentrations of O_2 (e.g., soils). In the hindgut of termites, a microbial habitat that can have volumes of 1 μl or less, only the inner portion of the microbe-packed paunch is completely anoxic; the epithelial surface of the paunch is characterized by a diminishing O_2 gradient (Brune et al., 1995; Brune et al., 2000). H_2-utilizing acetogens from the rumen are more competitive for H_2 than H_2-utilizing methanogens in certain termite guts (Brauman et al., 1992). The extent to which H_2-derived reductant flows towards the reduction of CO_2 to acetate rather than the reduction of CO_2 to methane varies with the feeding guild of the termite (Brauman et al., 1992). Although acetogens are usually obligate anaerobes, acetogens are relatively tolerant to fluxes of O_2 in terrestrial soils (Wagner et al., 1996). The enumerability of acetogenic bacteria in well drained, oxic soils and freshly fallen litter (Peters and Conrad, 1995; Küsel et al., 1999c; Reith et al., 2002), as well as the isolation of *S. silvacetica* and *M. ther-*

moacetica from different soils (Gößer and Drake, 1997; Kuhner et al., 1997; Gößer et al., 1999; Karita et al., 2003), attests to the ability of acetogens to cope with fluxes of aeration and to withstand drying under oxic conditions (Wagner et al., 1996). In contrast, the cultured numbers of other so-called "obligate anaerobes," like sulfate reducers or methanogens, are negligible in well-drained soils and litter (Peters and Conrad, 1995; Küsel et al., 1999c).

The ability of acetogens to survive in habitats that are subject to fluctuations in O_2 is due in part to their ability to reductively remove traces of O_2 (see the subsection on Tolerance to Oxic Conditions and Metabolism of O_2 in this Chapter). Their survival in such habitats can also be enhanced by trophic interactions with facultative anaerobes. The classic acetogen *M. thermoacetica* and the fermentative microaerophile *Thermicanus aegyptius* were co-isolated as a commensal pair from an oxic high-temperature soil (Gößer et al., 1999). The two organisms grow commensally on oligosaccharides (Fig. 18). In addition to the production of fermentation products by *T. aegyptius* that can be used by the juxtaposed acetogen, the fermentative microaerophile also minimizes the level of incoming O_2 in microzones inhabited by acetogens. Collectively, these findings demonstrate that the ecological roles of acetogens are not restricted to anoxic and water-saturated habitats.

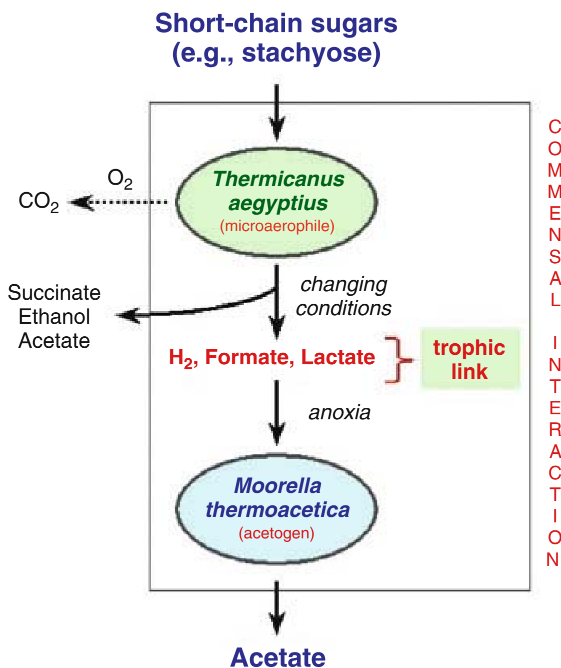

Fig. 18. Scheme illustrating the hypothetical trophic interaction of *Thermicanus aegyptius* ET-5b and *Moorella thermoacetica* ET-5a. Modified from Gößer et al. (1999).

Diverse Habitats

Acetogens have been mostly obtained from habitats that are permanently anoxic, such as freshwater or marine sediments, sewage sludge, and gastrointestinal tracts (see the subsection on Description of Species in this Chapter). However, during more recent years, the presence and ecological role of acetogens has also been investigated in other habitats, such as hypersaline sediments, deep aquifers, oxic soils, and plant roots. Although the magnitude and consequence of acetogenesis in these diverse habitats is often unclear, the occurrence of acetogens in such diverse habitats underscores the potential importance of acetogenesis at a more global level.

HUMAN COLON. The gastrointestinal tracts of mammals are colonized by acetogens (Prins and Lankhorst, 1977; Breznak and Kane, 1990; Mackie and Bryant, 1994; Wolin and Miller, 1994; Leedle et al., 1995). In humans, dietary components (cellulose, hemicellulose, pectin and starch) not absorbed in the upper digestive tract reach the colon where they are fermented by the cooperative metabolism of a great variety of bacterial species (Wolin and Miller, 1983). Short-chain fatty acids (acetate, propionate and butyrate) and gases (CO_2 and H_2) are the main fermentation products in the colon, and it is estimated that 95% of the short-chain fatty acids are absorbed and utilized by the host. Part of the daily production of acetate in the intestine (10–30 g of acetate; Royall et al., 1990) can be attributed to the activity of acetogens, as evidenced by the formation of [1,2-^{14}C]acetate from [3,4-^{14}C] glucose in fecal incubations (Miller and Wolin, 1996).

Part of the H_2 formed during colonic fermentation is exhaled in breath and vented in flatus. A large amount of the H_2 that is produced in the colon is consumed via the interspecies transfer of H_2. Humans (30–50% of the European population) who harbor large populations of methanogens (10^8–10^{10} cultured methanogens per gram dry wt. of feces) exhale CH_4 in detectable concentrations (i.e., >1 ppm of CH_4; Miller and Wolin, 1982; Pochart et al., 1992). In the colon of these humans, methanogenesis is probably the main hydrogenotrophic process. H_2-utilizing *Methanobrevibacter smithii* is believed to be primarily responsible for producing almost all colonic CH_4 (Wolin and Miller, 1983). Depending of the human sampled, the cultured number of methanogens in human feces range from undetectable to 10^{10} per gram dry wt. of feces. In contrast, the cultured numbers of H_2-utilizing sulfate reducers in the feces of both CH_4-excreting and non-CH_4-excreting humans are similar (10^7 per gram dry wt. of feces; Doré et al., 1995). However, cultured numbers of H_2-utilizing fecal

acetogens of non-CH_4-excreting humans are higher than those of CH_4-excreting humans (10^7 versus 10^5 H_2-utilizing acetogens per gram dry wt. of feces, respectively). A negative correlation between the numbers of acetogens and methanogens also exist in the rumens of lambs and in the feces of rats (Prins and Lankhorst, 1977). These correlations in the relative distributions of H_2-dependent anaerobes suggest that H_2-dependent acetogenesis is important in gastrointestinal ecosystems which have low numbers of methanogens (Doré et al., 1995; Bernalier et al., 1996a). The synthesis of [^{13}C]acetate from $^{13}CO_2$ by human fecal suspensions is supportive evidence of the hypothesis that reductive acetogenesis is a major colonic process of non-CH_4 excreting humans (Lajoie et al., 1988). Numerous H_2-utilizing acetogens have been isolated from human feces (Wolin and Miller, 1993; Bernalier et al., 1996b; Bernalier et al., 1996c; Kamlage et al., 1997; Leclerc et al., 1997a), and some of these isolates (i.e., *R. hydrogenotrophicus* and *C. coccoides* 1410) form a separate subgroup within the clostridial cluster XIVa (Collins et al., 1994).

RUMEN ECOSYSTEMS. The rumen is arguably the most completely described, intensively investigated gastrointestinal ecosystem, and the classic studies of Hungate (1966) and coworkers were formative to our general understanding of gut ecosystems and the various symbiotic relationships of gut microbiota. CH_4 is the main reduced end product that is produced in the rumen (Mackie and Bryant, 1994).

The major metabolic groups of microorganisms involved in the overall decomposition of organic matter in the rumen are described in the frequently cited three-stage model of McInerney and Bryant (1981). The molar proportions of short-chain fatty acids produced in the rumen approximate 63% acetic, 21% propionic, 14% butyric, and 2% higher acids. Most (60–80%) of the daily energy needs of the ruminant are provided by absorption of short-chain fatty acids from the rumen. The loss of energy in the end product CH_4 approximates 5–15% of the feed energy consumed by the host animal (Mackie and Bryant, 1994). It would theoretically be beneficial to the host animal if the H_2 and CO_2 that otherwise are consumed in the production of CH_4 were instead converted to acetate by acetogens (Wood and Ljungdahl, 1991b). CH_4 is a greenhouse gas, and, since ruminants produce approximately 50% of the global biogenic emission of CH_4 (Mackie and Bryant, 1994), a reduction in the emission of methane by ruminants would likewise have theoretically positive effects on the global greenhouse gas budget.

In general, methanogens are the dominant H_2-utilizers in the rumen (Hungate, 1976; Bryant, 1979). Thus, the addition of a specific inhibitor for methanogens (e.g., bromoethanesulfonic acid) is usually necessary to enrich or isolate H_2-utilizing acetogens. The addition of rumen fluid may be stimulatory to the growth of acetogens found in the rumen (Rieu-Lesme et al., 1995). The capacity of acetogens to utilize methanol, sugars or methoxylated aromatic compounds has been used to isolate or enumerate ruminal acetogens. Depending on the host animal and substrate used, the number of cultured acetogenic bacteria in the rumen range from 10^6 to 10^9 acetogens per gram of ruminal content (Sharak-Genthner et al., 1981; Krumholz and Bryant, 1986; Leedle and Greening, 1988). The number of cultured methanogens in the rumen approximates 10^8–10^9 methanogens per gram of ruminal content (Leedle and Greening, 1988). Postprandial changes in the population profiles of ruminal acetogens and methanogens occur in steers fed either high- or low-forage diets. After a shift from a low-forage diet to a higher input of readily available carbohydrate, a twofold increase in the cultured numbers of both H_2-oxidizing methanogens and acetogens occurs after 1–2 hours of feeding. The cultured numbers of ruminal acetogens obtained from steers maintained on a high-forage diet are higher than the cultured numbers of ruminal methanogens, suggesting that acetogens capable of utilizing H_2 grow preferentially on organic substrates in the rumen (Leedle and Greening, 1988). Numerous acetogens have been isolated from the rumen (Sharak-Genthner et al., 1981; Krumholz and Bryant, 1986; Greening and Leedle, 1989; Rieu-Lesme et al., 1995; Rieu-Lesme et al., 1996a; Rieu-Lesme et al., 1996b; Rieu-Lesme et al., 1998; see the subsection on Description of Species). However, the diversity and ecology of acetogens and the competition between acetogens and methanogens in ruminal ecosystems remain poorly resolved, and a substantial amount of information in these areas will be needed before the methanogenic nature of the rumen can be reasonably and successfully manipulated. In this regard, inhibitors (i.e., N-substituted derivatives of *p*-aminobenzoic acid) of the enzyme responsible for the synthesis of methanopterin (an intermediate in methanogenesis) can block the growth of certain methanogens but not interfere with the growth of acetogens (Dumitru et al., 2003).

TERMITE GUTS. About 4% of the plant material synthesized annually in terrestrial ecosystems is consumed by termites (Ljungdahl and Eriksson, 1985). Termites can be divided into four different feeding guilds: the wood-, grass-, and soil-feeding, and the fungus-growing termites (Brauman et al., 1992). The digestion of lignocellulose by wood-feeding termites has

been studied for over seven decades (e.g., Cleveland, 1925; Hungate, 1943; Varma et al., 1994). The wood-feeding termites include the so-called "lower" termites, like the well-studied *Reticulitermes flavipes*, and also some "higher" termites like *Nasutitermes nigriceps*. All termites harbor a diverse and dense hindgut microbial community that aids in digestion and is the source of fermentation products such as acetate, H_2 and CH_4.

The hindgut microbiota of the wood-feeding lower termites is composed of cellulolytic protozoa and bacteria that symbiotically affect an essentially acetogenic decomposition of wood polysaccharides (Brauman et al., 1992). Acetate constitutes 94–99% of the short-chain fatty acid pool in the extracellular hindgut fluid of *R. flavipes*. Protozoa initially convert cellulose to acetate, H_2 and CO_2 in a 1:2:1 ratio, and acetogenic bacteria subsequently convert the H_2 and CO_2 to acetate (Breznak and Switzer, 1986). Acetate 1) is absorbed in the hindgut, 2) is oxidized by the termite, and 3) can support up to 100% of the insect's energy requirement (Breznak, 1994). Thus, H_2-utilizing acetogens outcompete H_2-utilizing methanogens in wood-feeding termites; similar patterns occur for grass-feeding termites (Breznak, 1994). In contrast, H_2-dependent acetogenesis is of little significance in fungus-growing and soil-feeding termites, both of which evolve more methane than do wood- and grass-feeding termites (Brauman et al., 1992). It is not known whether the nature of the food consumed or other parameters, like a modified gut anatomy or digestive physiology, affect the terminal electron flow in the hindgut microbiota.

The core of dissected hindguts in *R. flavipes* is anoxic, whereas the peripheral lumen of dissected hindguts exhibits high oxygen uptake rates, suggesting that the hindgut has an oxic periphery and an anoxic center under in situ conditions (Brune et al., 1995; Ebert and Brune, 1997). The influx of oxygen via the gut epithelium and its reduction in the hindgut periphery appears to have a significant impact on the flow of carbon and reductant within the hindgut microbial community (Tholen and Brune, 2000). Although acetogenic bacteria are obligate anaerobes, it is now well known that some of them are not only quite tolerant to oxygen exposure, but can also reduce oxygen (Küsel et al., 2001; Karnholz et al., 2002; Drake et al., 2002; Boga and Brune, 2003; Drake and Küsel, 2003). The highest concentration of H_2 in the hindgut occurs in the central region in which H_2-producing protozoa also occur. The central region of the hindgut is also the major zone of H_2 consumption. Excess H_2 diffuses radially outward to the gut epithelium where it seems to be consumed by methanogens, which, for unknown reasons, appear to preferentially colonize the region near the gut wall (Leadbetter and Breznak, 1996; Ebert and Brune, 1997). Spirochetes occur in the central region of the hindgut and are among and often attached to the H_2-producing protozoa. Pure cultures of termite gut spirochetes (e.g., "*Treponema primitia*") catalyze the synthesis of acetate from H_2 and CO_2 (Leadbetter et al., 1999; Graber and Breznak 2004a; Graber et al., 2004b). Attachment of acetogenic spirochetes to termite gut protozoa yields a syntrophy that is based on the interspecies transfer of H_2 to the acetogen; this symbiosis provides H_2 concentrations well above the known H_2-threshold values for acetogens.

In situ activity measurements of acetogenic bacteria in combination with axial H_2 profiles in the highly compartmentalized hindgut of soil-feeding higher termites (*Cubitermes* spp.) revealed that acetogenesis might have a larger impact on the overall carbon flow than expected from previous observations. Acetogens in the posterior hindgut seem to be supported by either substrates other than H_2 or by a cross-epithelial H_2 transfer from anterior gut regions, which may create microniches favorable for H_2-dependent acetogenesis (Schmitt-Wagner and Brune, 1999; Tholen and Brune, 1999). Thus, the in situ spatial distribution of acetogens and their orientation in metabolic gradients contributes to their ability to successfully compete for H_2 in the termite gut.

MARINE, ESTUARINE, AND FRESHWATER SEDIMENTS. Acetogens are ubiquitous and plentiful in the sediments of aquatic habitats. The first species of the genus *Acetobacterium* was isolated from an estuarine sediment (Balch et al., 1977), but other *Acetobacterium* species have been isolated from freshwater and marine sediments, and from waterlogged terrestrial soils, such as subsurface sandstone, tundra wetland soils, and fens (see the subsection on Description of Species in this Chapter). In such habitats, acetogens might have to compete for H_2. Theoretically, sulfate reducers and methanogens can maintain H_2 concentrations at levels lower that that needed for the acetogenic reduction of CO_2 (Cord-Ruwisch et al., 1988). However, in certain sediments, mildly acidic conditions or low temperatures appear to favor acetogenesis.

Acetogens can outcompete methanogens for H_2 at the in situ pH of 6.2 and also at more acidic pH values (Phelps and Zeikus, 1984). *Clostridium scatologenes* SL1 is an H_2-utilizing acetogen isolated from acidic freshwater sediments and is capable of growing at pH 4 (Küsel et al., 2000). Sodium-proton antiporters (see the subsection on Conservation of Energy and Bioenergetics in this Chapter) might enable certain acetogens to cope with broad variations in pH (Schink, 1994).

Acetogens successfully compete with methanogens for H_2 at an in situ temperature of 4°C in

sediments of Lake Constanz (Conrad et al., 1989). Although the partial pressure of H_2 measured in the pore water is too low for the utilization of H_2 by pure cultures of acetogens, the actual in situ partial pressure of H_2 might be higher for acetogens living in close proximity to H_2-producing organisms. Acetogenic bacteria are important during the degradation of organic matter in permanently cold sediments, and acetate serves as the primary substrate for methanogenesis. Hydrogenotrophic methanogens from sediments of Lake Constanz can be enumerated and activated only at incubation temperatures of 20°C or higher (Schulz and Conrad, 1996). In tundra wetland soils or sediments polluted with paper-mill wastewater, acetogens can successfully compete with methanogens for H_2 and methanol at temperatures below 15°C (Nozhevnikova et al., 1994; Zavarzin et al., 1994). Acetate accumulates during the first phase of activity and is followed by a slow acetoclastic methanogenesis. The isolation of psychrophilic or psychrotrophic acetogens from these habitats and from cold lake sediments (Conrad et al., 1989; Kotsyurbenko et al., 1995; Kotsyurbenko et al., 1996; Simankova et al., 2000; Nozhevnikova et al., 2001) underscores the potential importance of acetogenesis in low temperature ecosystems.

Very little information is available on the occurrence and activity of acetogens in marine habitats. Cultured numbers of H_2-utilizing acetogens and acetate-utilizing sulfate reducers from a marine sediment approximated 10^5 and 10^7 cells per g wet wt. of sediment, respectively (Küsel et al., 1999b). The concentration of sulfate in the pore-water of marine sediments can vary owing to seasonal thermal stratification. Owing to the depletion of sulfate in the sediment, the flow of carbon and reductant shifts from sulfate reduction to methanogenesis (Hoehler et al., 1999). During this transition period, the concentration of acetate increases, which might be due to a temporary decoupling of acetate-producing and acetate-consuming processes (Sansone and Martens, 1982). The concentration of H_2 in the sediment is elevated at the beginning of this transition period, thus making the acetogenic reduction of CO_2 more favorable. The production of [^{14}C]-acetate from $^{14}CO_2$ occurs at rates comparable to those of methanogenesis or sulfate reduction during their respective period of dominance (Hoehler et al., 1999). Thus, the transient acetogenic reduction of CO_2 may be important in marine sediments and also in other ecosytems that experience geochemical fluctuations.

HYPERSALINE ENVIRONMENTS. Little is known about the presence of halotolerant or halophilic anaerobes or the anaerobic breakdown of organic matter in hypersaline ecosystems (e.g., inland lake and marine salterns). In hypersaline ecosystems, the salinity ranges from 9 to over 20% (wt./vol.) and the pH ranges from 7 to 10 (Ollivier et al., 1994). The concentration of sulfate, which can be an important electron acceptor, varies from 0.5 g per liter (Dead Sea, Israel) to 21 g per liter (Soap Lake, Washington State, United States). High salt concentrations prevent the growth of vertebrates, and only invertebrates, algae and prokaryotes are present when the salinity exceeds 10% (wt./vol.; Ollivier et al., 1994).

The concentrations of volatile fatty acids and H_2 present in sediments increase when the concentration of salt is high (Oren, 1988), indicating that the anaerobic mineralization of organic matter is inhibited by salinity. Bacteria maintain high intracellular salt concentrations or accumulate organic osmolytes (e.g., betaine) to maintain cell turgor at high salt concentrations (Oren, 1999). Betaine does not appear to be a substrate for methanogens or sulfate reducers. However, halophilic acetogens (e.g., *A. arabaticum*) decompose betaine to trimethylamine and acetate (Zhilina and Zavarzin, 1990). Trimethylamine is subsequently utilized by methylotrophic methanogens and, thus, is a trophic link between acetogens and methanogens. Since halophilic acetoclastic methanogens are unknown, and since acetate-consuming sulfate reducers are inhibited at high salinity (Widdel, 1988), the anoxic fate of acetate in these habitats is unresolved (Zavarzin et al., 1994). The haloalkaliphilic acetogens *N. acetigena* (Zhilina et al., 1996) and *N. histidinovorans* (Zhilina et al., 1998) were isolated from soda-depositing lakes and utilize glutamate, which can also be accumulated as an osmolyte by moderate halophiles. The anaerobic decomposition of osmoregulatory compounds in halophilic communities might therefore be coupled to the activity of *Acetohalobium*-type and *Natroniella*-type acetogens. Species of the acetogenic genera *Eubacterium*, *Sporomusa* and *Acetobacterium* demethylate the osmolytes dimethylsulfoniopropionate and glycine-betaine to methylthiopropionate and dimethylglycine, respectively; however, only the demethylation of glycine-betaine supported growth of the organism (Jansen and Hansen, 2001), indicating that certain in situ transformations of osmolytes by acetogens are not coupled to growth.

WATER-LOGGED SOILS. The flow of carbon and reductant in flooded rice paddy soils occurs mainly under anoxic conditions, and CH_4 is the major reduced end product of organic matter breakdown (Conrad, 1993). Root exudates and rice straw are important sources of energy and carbon for microbial activity (Chidthaisong et al., 1999). Approximately 80% of the CH_4 formed is derived from acetoclastic methanogen-

esis, which is proportionally more than the amount of CH_4 formed in a normal methanogenic food web (Chin and Conrad, 1995). Thus, acetogens may be important to the formation of acetate in such water-logged habitats. Hydrogenotrophic methanogenesis in flooded paddy soils and tundra wetland soils is inhibited by low temperatures (Conrad et al., 1989; Nozhevnikova et al., 1994; Chin and Conrad, 1995), and low incubation temperatures have been used to select against hydrogenotrophic methanogens during the enrichment of H_2-utilizing acetogens from paddy soils (Conrad et al., 1989). Cultured numbers of acetogens in the soil of rice plant microcosms range from 10^3 to 10^5 cells per g dry wt. of soil, and most dominant cultured acetogens belong to the genus *Sporomusa* (Rosencrantz et al., 1999). However, the occurrence of acetogens in the rhizosphere of rice plants is not resolved. Fluorescent in situ hybridization analysis has revealed the occurrence of Archaea on the surfaces of rice roots (Großkopf et al., 1998).

PLANT ROOTS. The rhizosphere is an important microhabitat where complex biogeochemical processes occur at accelerated rates. Plant roots exude easily degradable organic compounds that can chemotactically attract microorganisms (Waisel and Agami, 1996). Most rhizosphere bacteria are thought to live near the root tips or in the rhizoplane, which is defined as the root surface and outermost cells of the root. However, little is known about the colonization of the rhizosphere and plant roots by anaerobic bacteria (Großkopf et al., 1998; Hines et al., 1999). Although the rhizospheres of salt marsh vegetation and rice plants might be thought of as anoxic, a gradient of O_2 is generated around roots via the transport of O_2 that is produced by leaf photosynthesis during the day (Gilbert and Frenzel, 1995; Revsbech et al., 1999). Thus, obligate anaerobes colonizing such rhizospheres experience periods of elevated O_2 tension.

Sea grass rhizosphere has higher numbers of acetogenic bacteria than unvegetated soil, and acetogenic *O*-demethylation activity is tightly associated with sea grass roots (Küsel et al., 1999b). Hybridization of root thin sections with ^{33}P-labeled probes specific for *Acetobacterium* revealed the intercellular colonization of sea grass roots by *Acetobacterium*-like bacteria (Küsel et al., 1999b). The *Acetobacterium*-like bacteria occur mostly in the rhizoplane and outermost cell layers of the cortex. An H_2-utilizing acetogen, RD1, was obtained from the highest, growth-positive dilution of a sea grass root most-probable number series, and analysis of the 16S rRNA gene sequence indicated that the acetogen was closely related to a bacterium (*Clostridium glycolicum*; 99.7% gene sequence similarity) not previously known to be an acetogen (Küsel

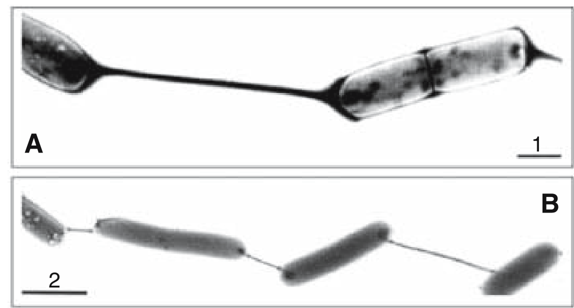

Fig. 19. Electron micrographs of (A) the acetogen *Clostridium glycolicum* RD-1 that was isolated from a sea grass root (used with permission from Küsel et al., 2001) and (B) the nitrogen-fixing soil bacterium *Clostridium akagii* (Kuhner et al., 2000). These organisms have connecting filaments that might provide cells with a means of remaining in close proximity to one another for either structural or communication purposes under certain in situ conditions. The structural nature of the filaments are not fully resolved, but recent ultra structural analyses suggest that the outer portion of the filament is an extension of the outer surface layer of the cell. Bars are in micrometers.

et al., 2001; Fig. 19). Retrieval of formyltetrahydrofolate synthetase sequences from salt marsh plant roots indicates that such roots are colonized by diverse acetogens most closely related to the genera *Sporomusa*, *Acetobacterium*, *Clostridium* and *Eubacterium* (Leaphart et al., 2003). Acetogens associated with salt marsh plant roots might also display a high tolerance to O_2 (Küsel et al., 2003). These results indicate that the biogeochemistry of the sea grass rhizosphere fosters the growth of acetogens in a habitat classically considered to be sulfate-reducing.

DEEP SUBSURFACE. Many subterranean environments are anoxic and habitats for anaerobic microorganisms. In the past, deep subsurface microbial communities have been thought to be supported by organic matter deposited with the formation of sediments, or by organic matter that migrated from the surface along different flowpaths (Krumholz, 2000). Thus, most studies have focused on the occurrence and activity of microorganisms within recently deposited or highly permeable sediments rather than from consolidated subterranean rock. However, diverse microbial communities also occur in subsurface fractured granitic rock, in suboceanic basalts, and in deep sediments of oceans (Krumholz, 2000; Kotelnikova, 2002). It is estimated that the global carbon content in subsurface prokaryota is comparable to the carbon content stored in terrestrial plants (Whitman et al., 1998). The density of a microbial community is limited by nutrient availability, which decreases in general with increasing depth. In deep, low organic carbon sediments in the Wood-

land Basin of the Pacific Ocean, numbers of cultured H_2-utilizing acetogens decrease with increasing depth from a surface maximum of approximately 10^6 cells per ml of sediment to negligible numbers at a depth of 800 m below the seafloor (Wellsbury et al., 1997; Wellsbury et al., 2002). However, microbial life might also be supported by other mechanisms, e.g., by the use of rock- or sediment-bound organic material previously thought to be unavailable.

Organic matter trapped in shales during deposition in the Cretaceous period (about 100 million years ago) can fuel heterotrophic microbial communities and the formation of acetate in adjacent permeable sandstones (Krumholz et al., 1997). From these sandstones, the acetogen *A. psammolithicum* was isolated with H_2-CO_2 as a substrate (Krumholz et al., 1999). However, the reduction of sulfate might be the dominant sink for H_2-derived reductant, and organic compounds might be the main substrates for acetogens in such terrestrial subsurface habitats (Krumholz et al., 1999).

In suboceanic sediments, bacterial populations and their activities can increase even in deeper layers near gas hydrate zones. Pore water concentrations of acetate can reach surprisingly high concentrations of approximately 15 mM at 700 meters below the seafloor, approximately 100 times higher than average near surface concentrations (Wellsbury et al., 1997; Wellsbury et al., 2000). Acetate seems to be the principal energy source for methane formation, and high turnover rates of acetate indicate an upward migration of high concentrations of dissolved organic carbon into the sediments. Apparently, the bioavailability of sedimentary organic matter appears to be enhanced by low-temperature heating during burial (Wellsbury et al., 1997). In addition to this biological enhanced formation of acetate, acetate can also be formed by thermogenic alteration of organic matter at temperatures above 80°C. The potential role of mesophilic and/or themophilic acetogens in the formation of acetate in these deep sediment layers is unclear.

Dissolved organic carbon may serve as a source of energy and carbon for microorganisms in deep subterranean groundwater of thin granitic fractures (Kotelnikova, 2002). In addition, concentrations of dissolved H_2 in these deep aquifers can be significantly higher (20–100 μM) than in other aquatic surface habitats (Krumholz, 2000). Acetogenic and acetotrophic methanogenic bacteria dominate the viable cell counts of different physiological groups in deep granitic groundwater that contains H_2 and CH_4 (Kotelnikova and Petersen, 1997; Kotelnikova and Petersen, 1998). The cultured numbers of H_2-utilizing acetogens approximate up to 10^4 cells per ml of groundwater. In microcosms containing granitic groundwater, $^{14}CH_4$ and ^{14}C-labeled acetate are formed from $^{14}CO_2$, and ^{14}C-labeled acetate is converted to $^{14}CH_4$. Thus, chemolithoautotrophic microorganisms that can grow on H_2-CO_2 might act as primary producers of organic carbon, initiating heterotrophic food chains in deep subterranean habitats. Acetogenesis appears to be involved in these H_2-based autotrophic biospheres (Haveman and Pedersen, 2002; Kotelnikova, 2002).

The origin of H_2 in subsurface habitats appears to be diverse. H_2 may result from mixed geochemical and biogenic reactions including the hydrolysis of water under strongly reduced conditions by ferrous iron present in basalt (Kotelnikova, 2002). In controlled laboratory experiments, basalts as well as granitic rock samples incubated with buffered water produce H_2 gas (Stevens and McKinley, 1995). However, whether those levels of H_2 could be produced at environmentally relevant pH values or sustained over geological time has been questioned (Anderson et al., 1998). Nonetheless, deep basalt aquifers can contain up to 60 μM dissolved H_2, and autotrophs outnumber heterotrophs in such habitats. Stable isotope measurements suggest that autotrophic methanogenesis dominates this lithoautotrophic microbial ecosystem in deep basalt aquifers (Stevens and McKinley, 1995).

OXIC SOILS. Anoxic microzones can occur in oxic soils and litter when the consumption of O_2 exceeds its supply (Tiedje et al., 1984; Sexstone et al., 1985; Smith and Arah, 1986; Van der Lee, 1999). Forest, agricultural, and grassland soils have a tremendous capacity to form acetate from endogenous organic matter under anoxic conditions (up to 15 g of C-acetate per kg dry wt. of soil; Küsel and Drake, 1994; Peters and Conrad, 1996; Wagner et al., 1996). Beech leaf litter and spruce litter display a spontaneous capacity to form aliphatic acids (mainly acetate), alcohols, H_2, and CO_2 under anoxic conditions, indicating that a subcommunity of the microbiota can respond rapidly to anoxic conditions (Küsel and Drake, 1996; Reith et al., 2002). Supplemental H_2, CO or ethanol are converted to acetate by soils under anoxic conditions in stoichiometries that approximate those associated with H_2-, CO-, or ethanol-dependent acetogenesis. The acetogen *S. silvacetica* was isolated from forest soil and utilizes H_2 and ethanol (Kuhner et al., 1997). Acetogenic activities of soils are relatively stable when soils are subjected to oxic drying or fluxes of O_2 (Wagner et al., 1996). At in situ temperatures and independent of moisture content and the concentrations of acetate that are formed, acetate is a stable end product in anoxic soil and litter microcosms. After extended incubation periods (1–3 months), acetoclastic methanogenesis is induced (Küsel and Drake, 1995), which is

consisitent with 1) the view that oxic soils are not a significant source of methane (Boone, 1991; Tyler, 1991) and 2) the fact that the number of cultured methanogens is negligible in oxic soils (Peters and Conrad, 1995; Küsel et al., 1999c).

The cultured number of anaerobes from both forest mineral soil and litter is identical with the cultured number of acetate-producing anaerobes (Küsel et al., 1999c). H_2-utilizing acetogens are a dominant group of the cultured anaerobes and approximate 10^4 to 10^5 cells per g of dry soil or litter (Peters and Conrad, 1995; Küsel et al., 1999c). Because H_2 is thermodynamically less than an ideal substrate for acetogens, i.e., for reducing CO_2 to acetate (see the subsection on Use of Diverse Electron Acceptors in this Chapter), soil acetogens capable of utilizing organic molecules are likely to occur in greater numbers than those that respond to H_2 under laboratory conditions; thus, H_2 likely reveals only a small subset of the total acetogenic population. In addition to acetogens, other acetate-forming microorganisms (e.g., facultative members of the Enterobacteriacae) are plentiful in soils and are likely responsible for the majority of acetate formed anaerobically in soils (Küsel, 1999c). Independent of these considerations, only 1% of the cultured H_2-utilizing soil acetogens are detected after pasteurization (Küsel et al., 1999c), indicating that 1) a large percentage of the spore-forming soil acetogens are in a vegetative active state or 2) the dominant acetogens present in soil and litter are not spore-formers. The capacity of soils to form acetate from H_2-CO_2 is enhanced by elevated temperatures (e.g., 30 and 55°C; Küsel and Drake, 1995; Wagner et al., 1996), suggesting that high temperature soils harbor thermophilic acetogens. The isolation of different strains of *M. thermoacetica* from soils from Kansas, Egypt and Japan demonstrate that this classic acetogenic thermophile has a wide geographical distribution in oxic soils (Gößer and Drake, 1997; Gößer et al., 1998; Gößer et al., 1999; Karita et al., 2003).

Because of the apparent stability of acetate under anoxic conditions, and because of the temporal and spatial variability of O_2 in soils, the consumption of acetate that is formed anaerobically might be linked to oxidative processes. O_2 is rapidly consumed when it is added to litter or soil that has been incubated under anoxic conditions (Küsel and Drake, 1995; Wagner et al., 1996; Küsel et al., 1999c), and the consumption of O_2 is concomitant to an increase in CO_2 and the disappearance of anaerobically formed acetate according to the following stoichiometry:

$$CH_3COOH + 2O_2 \rightarrow 2CO_2 + 2H_2O \quad (14)$$

The rate at which acetate is consumed exceeds the rate at which acetate is formed, indicating that acetate undergoes a rapid in situ turnover. The turnover of acetate can also be linked to other oxidative processes in soils, such as denitrification (Küsel and Drake, 1995; Wagner et al., 1996) or Fe(III) reduction (Küsel et al., 2002). Thus, under in situ conditions, the acetate formed in anoxic microzones of oxic soils is likely subject to rapid consumption via 1) the diffusion of O_2 into formerly anoxic zones or 2) the transport of acetate with the soil solution into zones where electron acceptors like O_2, nitrate or Fe(III) are present (Fig. 20). These findings indicate that acetate is a trophic link between the different anaerobic and aerobic microbial populations that collectively decompose organic matter in oxic soils.

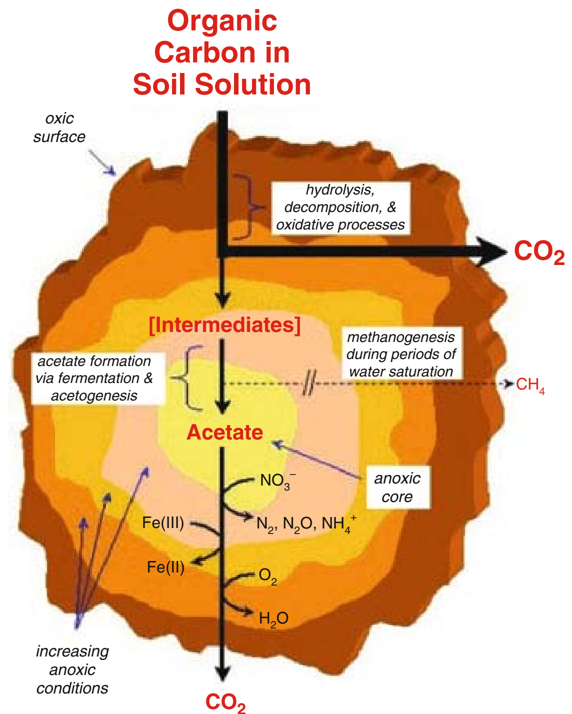

Fig. 20. Cross-section of a soil aggregate showing a hypothetical anoxic core and possible trophic links between acetate and other redox processes during the oxidation of soil organic carbon to CO_2. Modified from Drake et al. (1997).

Biotechnological Applications of Acetogens

The biotechnological application of acetogens has been the subject of numerous investigations. However, to date, a commercial-scale application of an acetogen or acetogenesis has not been reported. It is beyond the scope of this chapter to evaluate this topic in detail, and the reader is

directed to reviews for further information (Wiegel, 1990; Wiegel, 1994; Lowe et al., 1993).

Commercial Production of Acetic Acid from Sugars

Acetogens convert sugars stoichiometrically to acetate. This metabolic capacity has been the main focal point of studies designed to evaluate the commercial application of acetogens. Acetic acid is produced commercially from feedstock compounds (e.g., methanol), and global production in 2001 approximated 10^{10} kg (Anonymous, 2002; Causey et al., 2003). Acetic acid can be produced microbiologically from sugars. In the two-stage vinegar process, a hexose is converted to two molecules of acetic acid by the sequential activities of a yeast (e.g., *Saccharomyces cerevisiae*) that anaerobically produces two molecules of ethanol per hexose and of an aerobe (e.g., *A. aceti*) that only partially oxidizes ethanol to acetic acid. In contrast, the production of acetic acid by acetogenic bacteria is a single-stage process. Although acetogenesis conserves all of the carbon of glucose in the product acetic acid and might therefore be considered the ideal microbial process for the commercial production of acetic acid, the commercialization of the process has thus far not been realized. Furthermore, both microbiological processes are about 35% more expensive than the cost of the synthetic process from feedstock chemicals (estimated at $0.30/lb of acetic acid in 1991; Busche, 1991). *Escherichia coli* has been genetically modified to produce 2 moles of acetate per mole glucose fermented (Causey et al., 2003); such an organism might be competitive with the two-stage vinegar process.

The two main unsolved problems for the commercialization of the acetogenic process are: 1) acetogens are inhibited by high concentrations of acetate and 2) acetogens do not grow under acidic conditions. No known acetogen can adequately produce acetic acid at the concentrations required (i.e., 50 g of acetic acid per liter) for the process to be commercially feasible (Wiegel, 1994). These problems have been addressed in numerous studies, but significant breakthroughs in overcoming these problems have not been reported (Schwartz and Keller, 1982; Wang and Wang, 1983; Wang and Wang, 1984; Ljungdahl et al., 1985; Ljungdahl et al., 1989; Sugaya et al., 1986; Klemps et al., 1987; Brumm, 1988; Von Eysmondt et al., 1990; Ibba and Fynn, 1991; Parekh and Cheryan, 1991; Cheryan and Parekh, 1992). Commercialization of acetogenesis would theoretically become cost-competitive with the synthetic process if an acetogenic bacterium that could tolerate acidic conditions and produce high concentrations of acetic acid were either discovered or engineered (Brusche, 1991). Although mutants have been obtained that have increased tolerance to acidic acid and acidic conditions, such mutants grow poorly (Schwartz and Keller, 1982; Wiegel, 1994). The strong uncoupling effect of acetic acid and protons on the proton motive force (ΔpH) and transmembrane electrical potentials ($\Delta\Psi$) of acetogens results in a collapse of the cell's ability to conserve energy, and thus makes it unlikely that simple mutations could circumvent these problems and yield a mutant with tolerance to acetic acid and acidic conditions that is grossly different from the parent strain's tolerance (Baronofsky et al., 1984).

Although sugar dimers can be utilized by certain acetogens (e.g., cellobiose is a substrate for *R. productus*; Lorowitz and Bryant, 1984), a somewhat serious disadvantage of commercializing acetogenesis is that acetogens do not degrade large sugar polymers (e.g., cellulose). However, two acetogens, "*B. formatexigens*" (Wolin et al., 2003) and *M. thermoacetica* strain F21 (Karita et al., 2003), with the capacity to degrade cellulose have recently been found. In addition, cocultures of cellulolytic *Clostridium thermocellum* and the thermophilic acetogen *T. kivui* convert cellulose to acetate, with near full recovery of cellulose-derived carbon in acetate (Le Ruyet et al., 1984). Similar results were obtained with a coculture of a cellulolytic strain of *Ruminococcus albus* and the unclassified acetogen HA (Miller and Wolin, 1995). *Ruminococcus albus* forms ethanol and H_2 as reduced end products in the absence of the acetogen HA, but in coculture with HA, the reducing equivalents derived from the oxidation of cellulose-derived hexoses are utilized by the acetogen via the interspecies transfer of H_2. These findings suggest that acetogens can in fact be utilized for the conversion of cellulolytic material to acetate. *Clostridium lentocellum* strain SG6 forms high amounts of acetate from cellulose (Ravinder et al., 2001). Although the metabolism of this strain was described as acetogenic, significant amounts of ethanol are also produced and the engagement of the acetyl-CoA pathway during the degradation of cellulose is therefore uncertain.

Despite the limitations and cost barriers outlined above, the potential use of calcium-magnesium acetate as an environmentally safe road de-icer and in controlling sulfur emissions during the combustion of high sulfur coal have continued to foster interest in the commercial production of acetic acid by acetogens (Ljungdahl et al., 1985; Ljungdahl et al., 1989; Wiegel et al., 1990; Parekh and Cheryan, 1991; Cheryan and Parekh, 1992; Wiegel, 1994; Cheryan et al., 1997). Thermophilic species of acetogens (e.g., *M. thermoacetica* and *T. kivuii*) offer several theoretical advantages for the commercial production of environmentally safe

calcium-magnesium acetate: 1) thermophilic acetogenesis bypasses the need to use sterilized medium, the production of which is costly, 2) the dispersal of thermophiles or their spores in low temperature climates does not constitute an environmental threat, and 3) the growth of pathogens and their subsequent dispersal with the calcium-magnesium acetate would be highly unlikely owing to the thermophilic production conditions (Wiegel, 1994). Although *T. kivuii* displays one of the shortest doubling times of all known acetogens (approx. 2.5 h on either H_2-CO_2 or glucose [Leigh et al., 1981; Daniel et al., 1990]), it is more sensitive to acetic acid than certain strains of *M. thermoacetica* or *M. thermoautotrophica*, and therefore does not appear to be a model of choice for commercial purposes (Wiegel, 1994). *Moorella thermoacetica* and *Clostridium thermolacticum* can convert lactose to acetic acid when the two organisms are immobilized together in a fibrous-bed reactor (Talabardon et al., 2000). Under these conditions, *C. thermolacticum* forms lactate, which is subsequently used for lactate-dependent acetogenesis by *M. thermoacetica*. This trophic association mimics that exemplified by *M. thermoacetica* and *T. aegyptius* (Gößner et al., 1999; Fig. 20). Immobilization of acetogens with metabolic partners might offer certain advantages for commercializing the use of acetogens.

One approach to increasing the amount of acetate produced by acetogens is to uncouple growth from acetogenesis. Harmaline, a putative inhibitor of Na^+/H^+ antiporters, uncouples acetogenesis from the growth of *A. kivuii* (Yang and Drake, 1990). In the presence of harmaline, the acetate-to-biomass ratio during H_2-dependent acetogenesis increased 13-fold. Thus, use of agents that uncouple growth from the production of acetate might be of value in making acetogenesis more commercially feasible.

Bioconversion of Synthesis Gas to Acetic Acid, Ethanol, and Other Chemicals

Synthesis gas is obtained by the indirect liquefaction of coal and mainly consists of H_2, CO, and CO_2. These gaseous molecules can be converted to acetate by acetogenic bacteria, and the potential use of acetogens for the bioconversion of synthesis gas to acetic acid has been evaluated (Grethlein and Jain, 1992). Butyrate and *n*-butanol are additional products that can be produced from synthesis gas by "*B. methylotrophicum*" (Worden et al., 1989; Grethlein et al., 1991). Likewise, metabolically altered or unique strains of acetogens (e.g., *C. ljungdahlii*) can produce ethanol from the components of synthesis gas (Buschhorn et al., 1989; Grethlein and Jain, 1992; Tanner et al., 1993; Phillips et al., 1994). Electrochemical processes for converting CO_2 to acetate with enzymes from *M. thermoacetica* have been reported (Shin et al., 2001).

Bioremediation, Bioreactors, and Landfills

Although acetogens have robust metabolic capabilities and might be thought of as having significant bioremediation potentials, such potentials have not been extensively examined. Certain acetogens (e.g., "*A. dehalogenans*") can dehalogenate toxic compounds (Egli et al., 1988; Freedman and Gossett, 1991; Traunecker et al., 1991; Meßner et al., 1996). However, few studies have addressed this potential. On the basis of information to date, the ability to degrade aromatic rings is not a widespread metabolic potential of acetogens. A noted exception is *H. foetida* (Liesack et al., 1994). Acetyl-CoA synthase can transform 2,4,6-trinitrotoluene (TNT), a highly explosive anthropogenic compound that contaminates certain soils (Preuss et al., 1993; Huang et al., 2000); however, a commercial (or environmental) application of the potential of acetogens to transform TNT has not been reported.

Moorella thermoacetica has been shown to be effective in sequestering (i.e., precipitating) the heavy metal cadmium, suggesting that acetogens might be of applied value in the cleanup of environments or materials contaminated with heavy metals (Cunningham and Lundie, 1993). By virtue of their ability to oxidize and consume CO, acetogens have been cited as being significant in the detoxification of environmental CO (Ragsdale, 1991). However, the detoxification of environmental CO occurs mainly by abiotic processes in the atmosphere or aerobic CO-oxidizers (e.g., soil carboxydotrophs; Meyer, 1988; Meyer et al., 1993). The acetyl-CoA synthase of acetogens transforms 2,4,6-trinitrotoluene (TNT; Preuss et al., 1993; Huang et al., 2000); application of this catalytic potential has not been reported.

In methanogenic bioreactors and landfills, acetate that is produced by acetogens is a substrate for acetoclastic methanogens. Thus, acetogens contribute significantly to the turnover of organic matter in methanogenic bioreactors and landfills (McInerney and Bryant, 1981; Ibba and Fynn, 1991; Wiegel, 1994; Barlaz, 1997).

Other Potential Applications

The commercial production of corrinoids (i.e., vitamin B_{12}) and cysteine by acetogens has been evaluated; however, commercial-scale production has not been reported (Koesnandar et al., 1991; Inoue et al., 1992; Lebloas et al., 1994).

Acetate kinase from *M. thermoacetica* is very stable, and its industrial use in the immobilized form has been patented in Japan (Wiegel, 1994). A variety of fine chemicals (e.g., enantiomers of malic acid) have been produced with *C. formicoaceticum* (Eck and Simon, 1994a; Eck and Simon, 1994b). *Moorella thermoacetica* has been utilized for the electromicrobial regeneration of pyridine nucleotides (Schulz et al., 1995; see also Günther et al., 2000). Enhancement of acetogenesis in the rumen might enhance the cost-efficiency of ruminant husbandry and also decrease the emission of the greenhouse gas methane by ruminants; this topic is discussed in the subsection on Diverse Habitats.

Summary and Conclusions

The following items summarize the main characteristics of acetogens and the acetyl-CoA pathway:

1) Acetogens belong to the domain Bacteria and use the acetyl-CoA "Wood Ljungdahl" pathway as a terminal electron accepting process.

2) The acetyl-CoA pathway fixes CO_2, conserves energy, and produces acetyl-CoA that is utilized in the synthesis of either acetate or biomass.

3) Pathways that are biochemically very similar to the acetyl-CoA pathway are used by methanogens and sulfate reducers for the oxidation of acetate or the autotrophic fixation of CO_2 and the synthesis of biomass. The collective use of acetyl-CoA synthase-dependent pathways by acetogens, methanogens, and sulfate reducers facilitates an enormous turnover of carbon in the global carbon cycle. An acetyl-CoA synthase-dependent process may have been the first autotrophic process on earth.

4) Acetogens can grow autotrophically and heterotrophically, and can oxidize a wide range of carbonaceous substrates, including aromatic compounds and small-molecular-weight halogenated compounds. Two recent isolates are cellulolytic.

5) Twenty-one genera of acetogens have been isolated from very diverse habitats, ranging from the gastrointestinal tracts of mammals and insects to sea grass rhizospheres. Their closest 16S rRNA-phylogenetic neighbor is very often not an acetogen, making it impossible to develop a broad-based, 16S rRNA-acetogen probe.
