Novel N_2 fixers may be found if the enrichment conditions for their isolation are more varied so as to include aerobic, anaerobic or microaerobic conditions, a variety of carbon sources at varying concentrations (copiotrophic and oligotrophic conditions; Kuznetsov et al., 1979), and media formulations that include or exclude Mo or V. The discovery of a molybdenum-dinitrogenase and a manganese-superoxide oxidoreductase from *Streptomyces thermoautothrophicus* (Ribbe et al., 1997) opens a new avenue in N_2 fixation research. Undoubtedly, other microorganisms containing this nitrogenase have yet to be identified. This nitrogenase may prove to be more amenable for introduction into plants because of its lower energy requirements and its higher tolerance to oxygen.

Elevated CO_2 levels provided to legumes were found to stimulate N_2 fixation indicating that N_2 fixation was limited by the availability of photosynthate (Zanetti et al., 1996). Environmental and management constraints to legume growth (basic agronomy, nutrition, water supply, diseases, and pests) are the major limiting factors of N_2 fixation in many parts of the world. Crop production on 33% of the world's arable land is limited by phosphorus availability (Sánchez and Vehara, 1980). Efforts to maximize the input of biologically fixed nitrogen into agriculture will require concurrent approaches, which include the alleviation of phosphorus and water limitation, the enhancement of photosynthate availability, as well as sound agricultural management practices.

Biochemistry and Physiology of Dinitrogen Fixation

Although the chemical nature of the primary product of N_2 fixation was the subject of debate for many years, the issue was clarified with the use of ^{15}N. All diazotrophs were thought to use the same two-component nitrogenases (consisting of an iron and an molybdenum-iron protein). Alternative nitrogenases were reported subsequently (Hales et al., 1986; Robson et al., 1986) and found in very different bacteria including *Anabaena variabilis*, *Azospirillum brasilense*, *Clostridium pasteurianum*, *Heliobacter gestii*, *Rhodobacter capsulatus*, *Rhodospirillum rubrum*, and bacteria corresponding to Gammaproteobacteria such as *Pseudomonas* (Saah and Bishop, 1999). *Azotobacter vinelandii*, an aerobic soil bacterium, was the first diazotroph shown to have three distinct nitrogenases: the classical molybdenum (Mo)-containing nitrogenase (nitrogenase 1), the vanadium (V)-containing (nitrogenase 2), and the iron-only nitrogenase (nitrogenase 3; Maynard et al., 1994). The alternative nitrogenases (nitrogenase 2) use V instead of Mo, and this substitution is advantageous under conditions where Mo is limiting (Jacobitz and Bishop, 1992). Similarly, the iron nitrogenase (nitrogenase 3) is expressed only in Mo- and V-deficient, nitrogen-free media. The V-containing nitrogenase produces around three times more hydrogen than the Mo-nitrogenase (Eady, 1996).

A Mo-dinitrogenase and a manganese-superoxide oxidoreductase have been found to couple N_2 reduction to the oxidation of superoxide. This nitrogenase is more efficient than the classical enzyme, which requires a fourfold greater input of ATP. This N_2-fixing system, which is not sensitive to oxygen, has only been described in *Streptomyces thermoautotrophicus* (Ribbe et al., 1997), and the genomic DNA of this bacterium does not hybridize to DNA probes for the classical *nif* genes. Although the overall reactions catalyzed by *S. thermoautotrophicus* are similar to those of previously characterized nitrogenases (e.g., the production of H_2), it is the subunit structure, polypeptides, and inability to reduce acetylene that distinguishes the nitrogenase of this system from other nitrogenases (Ribbe et al., 1997). The currently known dinitrogenase reductases are ca. 63-kDa γ_2 dimeric iron proteins that contain 4 Fe and 4 S^{-2} per dimer. In contrast, the St2 protein of *S. thermoautotrophicus* has been identified as a member of the manganese-superoxide oxidoreductases (SODs) with molecular mass ~48 kDa and no Fe or S^{-2}. Unlike other SODs, St2 cannot convert O^-_2 into O_2 and H_2O_2. Some diazotrophs are able to utilize the H_2 evolved from N_2 fixation via uptake hydrogenases (Evans et al., 1985). These enzymes are found in N_2-fixing and non-N_2-fixing bacteria and in cyanobacteria. The uptake hydrogenases in *Anabaena* are present only in heterocysts, which are the specialized N_2-fixing cells of cyanobacteria; interestingly, the hydrogenase genes are rearranged during heterocyst differentiation (Carrasco et al., 1995).

Hitherto, ammonium has been accepted as the primary product of N_2 fixation and as a reactant in the biosynthesis of all nitrogen-containing molecules made by N_2-fixing organisms. Because ammonia excretion has been considered a beneficial characteristic enabling N_2 fixers to establish symbioses with other organisms such as plants, it has been generally assumed that the ammonium assimilation enzymes are depressed in symbiotic bacteria. However, *Bradyrhizobium japonicum*, which forms nodules and fixes nitrogen in soybean plants has been shown to excrete alanine preferentially and not ammonium (Waters et al., 1998). Whether this generally occurs in rhizobia is still controversial (Youzhong et al., 2002; Lodwig et al., 2003; Lodwig et al., 2004). The ratio of alanine to ammonia excretion seems to be related to the oxygen concentration and the rate of respiration (Li et al., 1999). For the cyanobacterium *Nostoc*, which can establish symbiosis with many organisms including *Gunnera*, ammonia excretion accounts for only 40% of the nitrogen released (Peters and Meeks, 1989). Different plant endophytes have been found to release (excrete) riboflavin during N_2 fixation (Phillips et al., 1999b). Lumichrome, a compound obtained from riboflavin, has been reported to stimulate root respiration and promote alfalfa seedling growth (Phillips et al., 1999a). Production of riboflavin-lumichrome by plant-associated bacteria is favored by a high N-to-C ratio in the media, and possibly N_2 fixation also promotes the synthesis of nitrogen-containing compounds (other than ammonia), such as lumichrome, that can benefit plants.

Nitrogenase Structure The classical nitrogenase is a complex, two-component metalloprotein composed of an iron (Fe) protein and a molybdenum-iron (MoFe) protein. The properties of nitrogenase have been reviewed (Howard and Rees, 1994; Burgess and Lowe, 1996; Eady, 1996; Seefeldt and Dean, 1997). The iron-molybdenum cofactor (Fe-Moco), the prototype of a small family of cofactors, is a unique prosthetic group that contains Mo, Fe, S, and homocitrate in a ratio of 1 : 7 : 9 : 1, and it is the active site of substrate reduction (Hoover et al., 1989; Kim and Rees, 1992b). All substrate reduction reactions catalyzed by nitrogenase require the sequential association and dissociation of the two nitrogenase components.

A great deal of effort to define the structure of nitrogenases has been expended. *Azotobacter vinelandii* has been suitable for these studies because it produces large amounts of the enzyme, it is amenable to genetic manipulation, and it has *nif* and *nif*-associated genes of known sequence (Brigle et al., 1985; Jacobson et al., 1989; Bishop and Premakumar, 1992). A major achievement in the biochemistry of nitrogenases has been the establishment of the structure of the Fe (Georgiadis et al., 1992) and the MoFe proteins (Kim and Rees, 1992b; Bolin et al., 1993; Schindelin et al., 1997) involving high resolution X-ray crystallographic analysis (Peters et al., 1997; Schlessman et al., 1998). A ~2.2 Å resolution has been reported for the *Azotobacter vinelandii* MoFe-protein (Peters et al., 1997), the *A. vinelandii* Fe-protein (Av2), and the *Clostridium pasteurianum* Fe-protein (Schlessman et al., 1998). The knowledge of the Fe protein structure has contributed to understanding how MgATP functions in nitrogenase catalysis. The Fe-protein is a homodimer with two ATP-binding sites, and the nucleotide binding causes conformational changes in the protein. ATP hydrolysis occurs in the transient complex formed between the component proteins. Molecular interactions were proposed from mutagenesis studies of the nitrogenases (Kent et al., 1989; Dean et al., 1990; Scott et al., 1990). Site-specific mutagenesis studies based on the FeMo protein crystal structure (Kim and Rees, 1992a) have been aimed at amino acids related to the FeMo-cofactor (espe-

cially at the residues proposed to be involved in the entry and exit path for substrates, inhibitors and products) and also at those residues involved in FeMo-cofactor insertion during biosynthesis. The spectroscopic and kinetic properties of the resulting mutant proteins are studied (Dilworth et al., 1998).

The use of biophysical, biochemical and genetic approaches have facilitated the analysis of the assembly and catalytic mechanisms of nitrogenases. The synthesis of the prosthetic groups of nitrogenases has been a challenge for chemists. The different substrates utilized by the nitrogenases seem to bind to different areas of the FeMo-cofactor (Shen et al., 1997). Nitrogenase structural changes that occur after the formation of the active complex are thought to produce transient cavities within the FeMo protein, which when opened allows the active site to become accessible (Fisher et al., 1998). The FeMo-cofactor also is found associated with the alternative nitrogenase, *anf*-encoded proteins (AnfDGK; Gollan et al., 1993; Pau et al., 1993).

The *nifDK* genes of *Azotobacter vinelandii* were fused and then translated into a single large nitrogenase protein that interestingly has nitrogen fixation activity (Suh et al., 2003). This shows that the MoFe protein is flexible. However a substitution of tungsten for Mo abolished nitrogenase activity (Siemann et al., 2003).

Nitrogen Fixation Genes The complete nucleotide sequence of the *Klebsiella pneumoniae* 24-kb region required for N_2 fixation was reported in 1988 (Arnold et al., 1988). Genes for transcriptional regulators were found to cluster contiguously with the structural genes for the nitrogenase components and genes for their assembly. The N_2 fixation (*nif*) genes are organized in seven or eight operons containing the following *nif* genes: *J*, *H*, *D*, *K*, *T*, *Y*, *E*, *N*, *X*, *U*, *S*, *V*, *W*, *Z*, *M*, *F*, *L*, *A*, *B* and *Q* (Fig. 2). The products of at least six N_2 fixation (*nif*) genes are required for the synthesis of the iron-molybdenum cofactor (FeMo-co): *nifH*, *nifB*, *nifE*, *nifN*, *nifQ*, and *nifV*. NifU and NifS might have complementary functions mobilizing the Fe and S respectively needed for nitrogenase metallocluster assembly in *A. vinelandii*. Notably, some of the gene products required for forma-

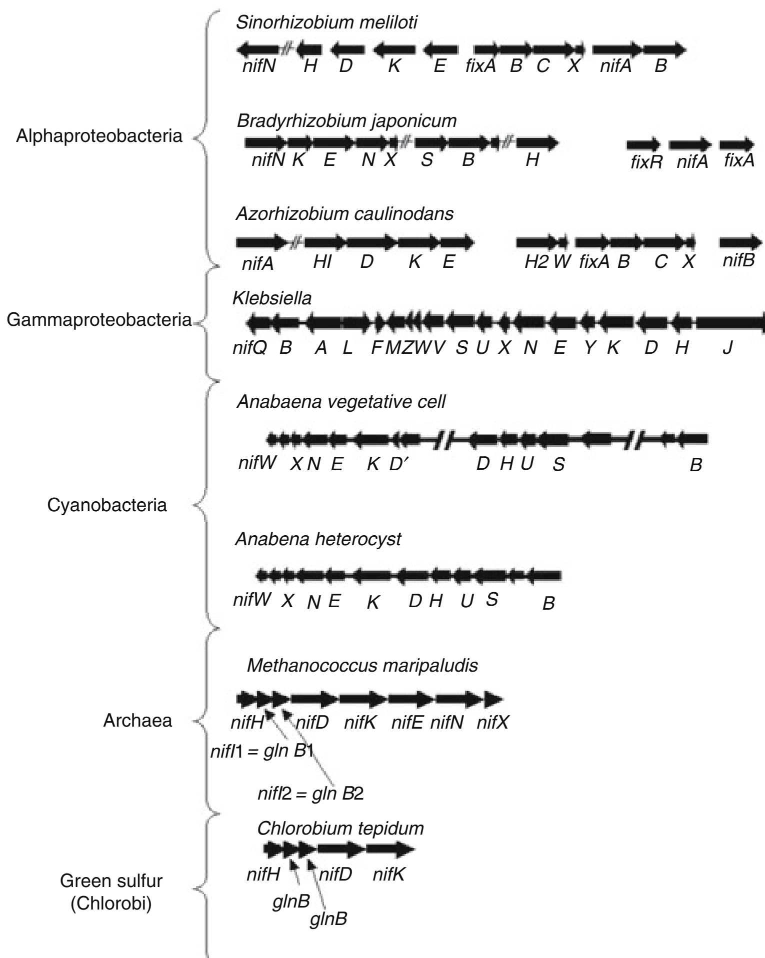

Fig. 2. Arrangements of *nif* genes in dinitrogen-fixing prokaryotes. The *nif* gene organization in *Methanococcus maripaludis* is from Kessler et al. (2001).

tion of the Mo-dependent enzyme are also required for maturation of alternative nitrogenases (Kennedy and Dean, 1992). The *nifJ* gene of *Klebsiella* is required for N_2 fixation, but in the cyanobacterium *Anabaena*, NifJ is required for N_2 fixation only when Fe is limiting (Bauer et al., 1993), whereas in *R. rubrum*, a NifJ protein does not seem to be required for N_2 fixation (Lindblad et al., 1993). The organization of *nif* genes in *Anabaena* is unique and different from that of other N_2 fixers because *nifD* is split between two DNA fragments separated by 11 kb. Recombination events are required to rearrange a contiguous *nifD* gene in N_2-fixing cells (Haselkorn and Buikema, 1992; Fig. 2).

A detailed analysis of the gene products of *nifDK* and *nifEN* (Brigle et al., 1987) revealed a possible evolutionary history involving two successive duplication events. A duplication of an ancestral gene that encoded a primitive enzyme with a low substrate specificity might have occurred before the last common ancestor of all living organisms emerged (Fani et al., 1999).

Nitrogenase structural genes are located on plasmids in some bacteria (such as *Rahnella aquatilis* [Berge et al., 1991], *Enterobacter*, and *Rhizobium* spp. [Martńez et al., 1990]) but are chromosomally encoded in the majority of prokaryotes including bradyrhizobia and most mesorhizobia.

The repeated sequences clustered around the *nif* region of the *Bradyrhizobium japonicum* genome may be involved in recombination thereby facilitating the formation of deletions (Kaluza et al., 1985). In *R. etli* bv. *phaseoli*, multiple copies of the *nif* operon promote major rearrangements in the symbiotic plasmid at high frequency (Romero and Palacios, 1997). Differences in the promoter sequences of the *nifH* regions in *R. etli* are correlated with the different levels of *nif* gene expression (Valderrama et al., 1996). The symbiotic plasmid of *R. etli* bv. *mimosae* is closely related to that of bv. *phaseoli* but its *nif* gene has a different restriction fragment length polymorphism (RFLP) pattern as revealed by *nifH* gene hybridization (Wang et al., 1999a).

A conserved short nucleotide sequence upstream of genes regulated by oxygen (i.e., an anaerobox) has been detected upstream of *Azorhizobium caulinodans nifA* (Nees et al., 1988), *Bradyrhizobium japonicum hemA*, *S. meliloti fixL*, *fixN*, *fixG*, in front of an open reading frame located downstream of *S. meliloti fixS*, within the coding region of *R. leguminosarum* bv. *viciae fixC*, i.e., upstream of the *nifA* gene and upstream of the *fnr* gene (*fixK*-like).

Alternative nitrogenase genes, *anfH*, *anfD* and *anfG* (Mo-independent) are found in the termite gut diazotrophs. The sequences of these genes are similar to those found in bacteria even though the gene organization with contiguous GlnB-like proteins resembles that found in the Archaea (Noda et al., 1999).

The existence of structural genes for three different nitrogenases was revealed when the complete genome sequence of the photosynthetic bacterium *Rhodopseudomonas palustris* was determined (Larimer et al., 2004). Previously, only *Azotobacter* sp. was known to possess three nitrogenases. The expression of *nif* genes of *Azotobacter vinelandii* was determined directly in soil by PCR amplification of reverse transcribed *nifH* gene fragments using *nifH* primers specific for *A. vinelandii* (Bürgmann et al., 2003).

Regulation of Nitrogen Fixation Genes Since nitrogen fixation is an energy expensive process, it is finely tuned, with transcriptional as well as posttranslational regulation. *nif* genes are normally not expressed and require transcriptional activation when N is limiting and conditions are appropriate for nitrogenase functioning. If little is known about the extant diazotrophs, less is known about N_2 fixation gene regulation from a global phylogenetic perspective. Most studies have been directed to Proteobacteria. For actinobacteria and firmicutes there is almost no information. Cyanobacteria and more recently Archaea were studied and showed very different regulation mechanisms from the ones observed in Proteobacteria. In Archaea, a repressor of *nif* genes has been identified (Lie and Leigh, 2003) and no *nifA* has been found in cyanobacteria (Herrero et al., 2001).

Novel regulatory elements, their fine interaction, and a huge complexity of regulatory networks are being revealed as the regulation of nitrogen fixation is studied in depth in model bacterial species. The results are revealing a very complicated sequence of regulatory cascades (Dixon, 1998; Nordlund, 2000; Forchhammer, 2003; Zhang et al., 2003). Regulatory elements such as P_{II} (also known as *glnB*), DRAT (that transfers a ribosyl to nitrogenase and interferes with its activity), and DRAG (that removes the ribosyl) have been found in many diverse nitrogen fixing or non-nitrogen fixing Proteobacteria, Actinobacteria and Archaea (Ludden, 1994; Zhang et al., 2003). Very diverse modes of regulation of *nif* genes have been described that vary between species or even between strains in a single species (D'hooghe et al., 1995; Girard et al., 2000). Detailed studies have been carried out in *Klebsiella pneumoniae*, *Azotobacter vinelandii*, *Azospirillum brasilense*, *Rhodobacter capsulatus*, *Rhodospirillum rubrum*, *Sinorhizobium meliloti*, *Bradyrhizobium japonicum*, etc. The most common nitrogenases studied are inactivated by oxygen, and accordingly, the expression

of *nif* genes is negatively regulated by high oxygen concentrations. Different oxygen protection mechanisms have been described (reviewed by Vance, 1998).

Some of the bacterial diazotrophs share a common mechanism of transcriptional initiation of *nif* genes using a RNA polymerase holoenzyme containing the alternative sigma factor σ^N (σ^{54}) and the transcriptional activator NifA (Kustu et al., 1989). Regulators of NifA vary among different diazotrophs. Factor σ^N is competent to bind DNA, but the formation of the open promoter complex (active for transcriptional initiation) is catalyzed by NifA in a reaction requiring nucleoside triphosphate hydrolysis (Lee et al., 1993; Austin et al., 1994). The dual regulation by σ^{54} and NifA may be required to ensure a stringent regulation of *nif* gene expression, and this may be so because biological N_2 fixation represents a major energy drain for the cell. In addition it seems reasonable that *nif* genes are negatively regulated by ammonia to avoid production of the enzyme in the presence of available fixed nitrogen; accordingly, nitrogenase enzymes are inactivated by ammonia but to a lesser degree in *Gluconacetobacter diazotrophicus* (Perlova et al., 2003).

In vivo DNA protection analysis demonstrated that NifA binds to the upstream activator sequences of *nif* genes (Morett and Buck, 1988). In the Alpha- and Betaproteobacteria, the activity of NifA is modulated negatively by the antiactivator NifL, which is a flavoprotein. The integrated responses to fixed nitrogen, oxygen, and energy status are mediated via NifL. The oxidized form of NifL inhibits NifA activity. A potential candidate Fe-containing electron donor involved in the signal transduction of NifL may be a flavohemoglobin, which may act as a global intracellular oxygen sensor (Poole et al., 1994). The expression of *nifL* and *nifA* in *Klebsiella pneumoniae* are coupled at the translational level (Govantes et al., 1998). Mutant forms of NifA were obtained that are no longer inhibited by NifL in *Azotobacter vinelandii* (Reyes-Ramŕez, 2002).

In other diazotrophic Proteobacteria, the NifA protein itself senses oxygen probably via a cysteine-rich motif between the central domain and the C-terminal DNA-binding domain (Fischer et al., 1988). Oxygen-tolerant variants of the *S. meliloti* NifA proteins have been obtained (Krey et al., 1992). Ammonium-insensitive NifA mutants have been reported with modifications involved in the N-terminus of the molecule in *Herbaspirillum seropedicae*, *Azospirillum brasilense* and *Rhodobacter capsulatus* (Souza et al., 1995; Arsene et al., 1996; Kern et al., 1998).

In *Klebsiella pneumoniae*, the *nif* mRNAs were found to be very stable under conditions favorable to N_2 fixation, but the half lives of the *nifHDKTY* were reduced several fold when adding O_2 or fixed nitrogen. A fragment of the *nifH* sequence is required for the O_2-regulation of mRNA stability, and NifY may be involved in the sensing process (Simon et al., 1999).

Symbiotic nitrogen fixation shares common elements with free-living nitrogen fixation, but there are substantial differences as well. In *Rhizobium*, N_2 fixation only takes place inside the nodule. Still not well understood is how the plant partner influences the N_2-fixing activity of the microsymbiont, and the same is true for termite-diazotroph symbioses as well as for cyanobacteria in plants. In the latter case, the plant seems to stimulate the formation of heterocysts, which are differentiated cells that fix N_2 (Wolk, 1996). Even among symbiotic bacteria of legumes (*Sinorhizobium*, *Rhizobium*, *Azorhizobium* and *Bradyrhizobium*), differences in the fine mechanisms regulating N_2 fixation exist and have been reviewed (Fischer, 1994; Kaminski et al., 1998). In *S. meliloti*, *fixLJ* (David et al., 1988) gene products belong to a two-component regulatory family of proteins that are responsive to oxygen. FixL is a high affinity oxygen sensor hemoprotein that has kinase-phosphate activity and is involved in phosphorylation of FixJ in microoxic or anoxic conditions (Gilles-Gonzalez et al., 1994). Upon phosphorylation, FixJ binds to the *nifA* and *fixK* promoters and allows their transcriptional activation (Waelkens et al., 1992).

Nitrogen fixation takes place in heterocysts in some cyanobacteria. Heterocyst differentiation is regulated by HetR, a protease (Haselkorn et al., 1999), and is inhibited by ammonia (Wolk, 1996). The expression of *nif* genes is also downregulated by ammonium or nitrate (Thiel et al., 1995; Muro-Pastor et al., 1999). NtcA is a regulator required for expression of ammonium-repressible genes; in a *ntcA* mutant, induction of *nifHDK* and *hetR* is abolished or minimal (Frias et al., 1994; Wei et al., 1994). The *ntcA* gene, which is conserved among cyanobacteria, bears a DNA-binding motif close to the C-terminus and is homologous to *E. coli* Crp and to *S. meliloti* FixK. The NtcA protein binds to defined sequence signatures that are located upstream of ammonium-regulated promoters (Luque et al., 1994). However, no such signature has been identified upstream of *nif* or *hetR* genes. The *ntcA* gene is autoregulated and presumed activators or cofactors may render NtcA active (Muro-Pastor et al., 1999).

Biological N_2 fixation requires a minimum of 16 ATP molecules and 8 reducing equivalents per molecule of N_2 reduced. Under physiological conditions, a small electron carrier such as a ferredoxin or a flavodoxin is thought to transfer electrons to nitrogenase. In the photosynthetic

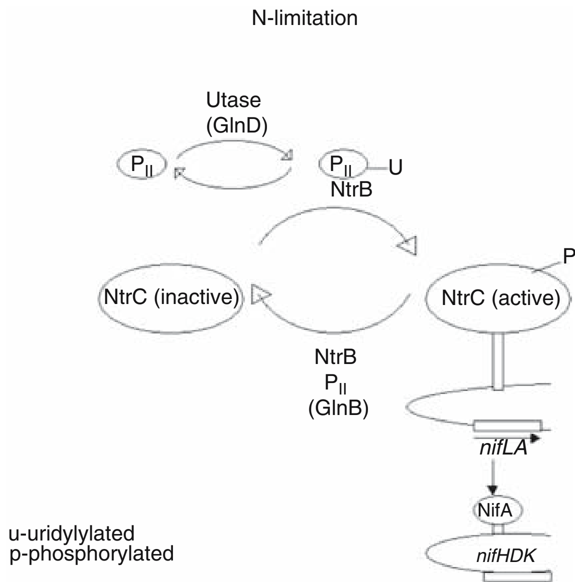

Fig. 3. Cascade regulatory mechanisms in the γ and β *Proteobacteria* under N-limited conditions. Uridylylated P_{II}, as a cofactor of NtrB promotes the phosphorylation of NtrC that then becomes active to bind the upstream regulatory sequences (UAS) of the *nifLA* promoter. NifA in turn binds the UAS of the nitrogenase structural genes in many dinitrogen-fixing prokaryotes studied, allowing their expression and consequentely nitrogen fixation.

bacterium *Rhodobacter capsulatus*, a ferredoxin Fd1 was identified as the major electron donor to nitrogenase (Schatt et al., 1989; Schmehl et al., 1993).

Conclusions Dinitrogen fixation is an important biological process carried out only by prokaryotes. Research on nitrogen fixation has followed a multidisciplinary approach that ranges from studies at the molecular level to practical agricultural applications. Support for research in this area has been driven by economic and environmental imperatives on the problems associated with the use of chemically synthesized nitrogen fertilizer in agriculture (Brewin and Legocki, 1996; Vance, 1998). However, the contributions of researchers in N_2 fixation to gene regulation, biochemistry, physiology, microbial ecology, protein assembly, and structure, and more recently to genomics are highly meritorious achievements in themselves.

Dinitrogen fixation research is a fast evolving field with specific model systems studied in great depth and an extensive knowledge of a larger diversity of N_2-fixing prokaryotes more slowly developing. The advent of molecular biology has certainly enriched our knowledge of the reservoir of N_2-fixing microorganisms and their ecology, but still the estimates of the amounts of nitrogen fixed in nature are uncertain. Human activities are liberating huge amounts of fixed nitrogen to the environment (Socolow, 1999; Karl et al., 2002; McIsaac et al., 2002; Van Breemen et al., 2002), and as a consequence, nitrogen could become less limiting in nature and this may counterselect N_2-fixing prokaryotes. Will some of them disappear without ever been known? After more than a century of research on N_2 fixation, there are still ambitious goals to achieve.

CHAPTER 1.25

Root and Stem Nodule Bacteria of Legumes

MICHAEL J. SADOWSKY AND P. H. GRAHAM

Introduction

The root and stem nodule bacteria of legumes (collectively called the rhizobia) comprise a genetically diverse group of organisms characterized by the ability to produce swellings or nodules on the stems or roots of most, but not all, leguminous plants (peas, beans, clover, etc.). Not all legumes form nodules with rhizobia.

Within the nodules, rhizobia convert atmospheric dinitrogen (N_2) gas into ammonia. This fixed nitrogen (N) is subsequently assimilated by the host, and improves plant growth and productivity. Approximately 300 million hectares (Mha) of legumes are grown worldwide, and they collectively fix about 60 tere grams (Tg) (6×10^7 metric tons) of N each year (Kinzig and Socolow, 1994). Overall, N_2 fixation supplies about 50% of the N used in agriculture, and because the fixed N is used directly by the host plant without initial passage through the soil, the process is generally considered environmentally friendly (Vance, 1998). Fixation rates vary with plant species, length of the growing season, presence of a suitable microsymbiont, and environmental conditions, but rates commonly are in the range of 100–200 kg of N_2 fixed ha^{-1} yr^{-1} (Sparrow et al., 1995; Unkovich et al., 1997). Because of the practical benefits of nodulation and N_2 fixation, the rhizobia have been extensively studied, particularly the genetic basis for their symbiotic interactions. However, the rhizobia are also good *saprophytes*, with soil populations of 10^3 to 10^4 rhizobia g^{-1} being common in soils previously used for legume growth. Thus, the ecological attributes of these organisms also have been studied extensively.

Phylogeny

The taxonomy of the organisms producing root and stem nodules on legumes is in a state of flux. Though this ever-changing taxonomy affects what the organisms are called and how they are distinguished, it has little impact on their phylogenetic relationships. Small subunit rRNA sequence analysis (SSU rRNA) supports division of these organisms into three major groups (*Rhizobium* [including *Agrobacterium*, *Allorhizobium*, *Sinorhizobium*, and *Mesorhizobium*], *Bradyrhizobium* and *Azorhizobium*) within the ∀ subclass of the Proteobacteria (Martinez-Romero and Caballero-Mellado, 1996; Young and Haukka, 1996b).

Wang et al., 1998 show that *Bradyrhizobium* and *Azorhizobium* are only distantly related to fast-growing *Rhizobium* and their relatives. Figure 1 also highlights divisions within *Rhizobium* that in the late 1980s through 1990s, led to subdivision of this genus as indicated above (Chen et al., 1988; DeLajudie et al., 1994; de Lajudie et al., 1998a; Jarvis et al., 1997). These changes, however, are currently under challenge (Kuykendall et al., 2000). Also notable in this figure is the overlap between species of *Rhizobium* and *Agrobacterium*. Amalgamation of *Rhizobium* and *Agrobacterium* has been proposed on a number of occasions (Graham, 1964; Heberlein et al., 1967; De Ley, 1968; Sawada et al., 1993; Parker, 1957), suggesting that the rhizobia may have evolved from plant pathogenic bacteria. Nonpathogenic *Agrobacterium* are well known as nodule contaminants (Hofer, 1941; Graham, 1976; de Lajudie et al., 1999), and often are confused with the nodule-forming rhizobia. Relative to the large number of species of *Rhizobium* that have been described, only a limited number of *Bradyrhizobium* and *Azorhizobium* species have been distinguished. This is likely to change as additional tropical legume species are studied. Additional groups of bradyrhizobia have already been identified, but not detailed phylogenetically (So et al., 1994; Graham et al., 1995). Moreover, links between *Rhizobium* and related root nodule bacteria (*Phyllobacterium*, *Brucella*, and Bartonella) and between *Bradyrhizobium* and *Rhodopseudmonas*, *Blastobacter*, and *Afipia* have been described, but need additional study.

The ability to form nodules is restricted to a clade of plants including both legume and actinorhizal species. Not all legumes bear nodules, the percentage of plant species with nodules increasing from only 23% in the more primitive

Fig. 1. Initiation of nodule formation on the roots of *Phaseolus vulgaris* (L.) by *Rhizobium etli* 8 days after inoculation. Photo by permission of M. H. Chaverra.

Caesalpinioideae to 97% in the *Papilionoideae*. Because these groups of legumes differ in the frequency of nodulation (and because *Rhizobium*, *Bradyrhizobium*, and *Azorhizobium* are so different), it has been suggested that the ability to nodulate and fix N_2 could have arisen on more than one occasion (Parker, 1968; Doyle, 1994; Doyle and Doyle, 1997). Doyle, 1994 suggested that nodulation has arisen on at least three previous occasions, including in the genus *Chamaecrista*. Species within *Chamaecrista* can be distinguished from the non-nodulated, but closely related, Cassia on the basis of randomly amplified polymorphic DNA (RAPD) analysis (Whitty et al., 1994). Within Chamaecrista, species differ in the retention and release of rhizobia from infection threads during differentiation (Naisbitt et al., 1992). It seems unlikely that legumes as different as *Phaseolus* and *Acacia* could nodulate with both *Rhizobium* and *Bradyrhizobium* (Lange, 1961; Michiels et al., 1998).

The rhizobia associated with a particular legume host can show significant diversity (Pinero et al., 1988; Souza et al., 1994). However, some caution in interpreting results from biodiversity studies is advisable because a number of studies predate recent phylogenetic advances and changes in rhizobial taxonomy and could have included more than one species of rhizobia. As new legumes are commercialized and exploited, studies to examine the extent of legume/microsymbiont biodiversity near the legume's center of origin, and to explore the consequences of founder effects are warranted.

Taxonomy

Rhizobia have traditionally been a difficult group to classify. Early researchers considered all rhizobia part of a single species that could nodulate any legume. Subsequently each rhizobial strain was shown to only nodulate certain specific legumes. This led to the concept of cross inoculation groups, with rhizobia being distinguished according to the legumes each could nodulate. Thus, rhizobia from alfalfa would generally nodulate medic species and vice versa, but neither would nodulate clover. Using this approach, more than 20 different cross-inoculation groups were identified, and a number of these were raised to species status within the *Rhizobium* (Fred et al., 1932). Fred et al. (1932) stated, "It seems true that the ability of an organism to infect certain plants and not others is as fixed and definite as any phase of the physiology of the organism . . . we feel justified in regarding it as the prime character in species differentiation." Host specificity is still important in the identification of rhizobia but is often at odds with results from numerical and phylogenetic studies (Graham, 1964; DeLey and Rassell, 1965; Heberlein et al., 1967; Moffett and Colwell, 1968). The demonstration that the nodulation genes in *Rhizobium* may be plasmid borne (Nuti et al., 1979; Brewin et al., 1980) or located on chromosomal symbiotic islands and move between organisms has further weakened infection-based taxonomic analyses.

The 1984 edition of *Bergey's Manual of Systematic Bacteriology* divides the *Rhizobiaceae* into four groups, including three genera of nodule- or gall-forming bacteria, *Rhizobium*, *Bradyrhizobium* and *Agrobacterium* (Jordan, 1984). The reduced emphasis on host range and the availability of several new phenotypic and phylogenetic techniques has resulted in the proliferation of new species and genera of nodule bacteria. Currently, 6 genera and 28 species of rhizobia are recognized (Table 1). Kuykendall et al. (2000) question the need for separation of *Rhizobium*, *Agrobacterium*, *Allorhizobium* and *Sinorhizobium*, and instead suggest the consolidation of these organisms into a single genus *Rhizobium*, having three subgenera. In the classification they propose, undicola, galegae and huautlense are included in the subgenus

1. *Az. caulinodans*	Dreyfus et al., 1988

Agrobacterium, with three species of plant pathogenic agrobacteria.

With new species of root-nodule bacteria now justified using a polyphasic approach that includes both phenotypic and phylogenetic traits (Graham et al., 1991), the further description of new species of rhizobia based solely on simple characteristics has become increasingly problematic. In the second edition of *The Prokaryotes*, (Elkan and Bunn, 1994) listed phenotypic traits useful in the distinction of *Rhizobium*, *Azorhizobium* and *Bradyrhizobium*. To do so again is a daunting and perhaps not a useful task because older species descriptions may include more than one organism, and because differences in the tests applied and methods used can impact results and their interpretation.

Table 2 lists carbon source utilization differences for many of the species of root and stem nodule bacteria. It was compiled from a number of different studies (Jarvis et al., 1997; de Lajudie et al., 1998b; Wang et al., 1999) and will likely change as new species are identified. Additional distinctive phenotypic differences are urgently needed.

Analysis of rhizobial fatty acid methyl esters (FAME), using gas chromatography (Jarvis and Tighe, 1994; Jarvis et al., 1996), has been recommended as a relatively simple and inexpensive method for the identification of fast-growing rhizobia. Rhizobial FAME profiles correctly identified nearly 95% of almost 200 strains evaluated by (Jarvis and Tighe, 1994 and Jarvis et al., 1996). These studies only erred in identifying some fredii as meliloti and etli as leguminosarum and vice versa (Graham et al., 1999). Ballen and Graham (unpublished observations) have also shown that etli, gallicum, and strains from Dalea and Onobrychisoverlap. Similarly, FAME profiles have been used to distinguish slow-growing japonicum and elkanii (Kuykendall et al., 1992; So et al., 1994; Graham et al., 1995), though in each case additional isolates were identified that did not group with these species.

Table 2. Differences among genera of root nodule bacteria in the carbon compounds used for growth[1].

	Genus of nodule bacteria					
Carbon source	*Rhizobium*	*Sinorhizobium*	*Mesorhizobium*	*Allorhizobium*	*Bradyrhizobium*	*Azorhizobium*

[1]Includes data from Elkan and Brunn, 1992; de Lajudie et al., 1994, 1998; Rome et al., 1996; Jarvis et al., 1997 and Wang et al., 1999.

Habitat

Rhizobia through their ability to fix N_2 in symbiosis with legumes play a central role in the N supply of most natural ecosystems. The American tall grass prairie is but one ecosystem in which plant diversity and productivity is controlled in large measure by N availability (Collins et al., 1998). Rhizobia, although thought to be solely soil saprophytes, can also be found in aquatic systems associated with water-growing leguminous plants. Owing to cultural and agricultural practices, the migration of birds and animals, and atmospheric deposition of soil particles, there are relatively few soils in the world that do not contain some rhizobia. Rhizobia have been shown to exist in soils for a relatively long time in the absence of a host plant (Bottomley, 1992; Brunel et al., 1988; Kucey and Hynes, 1989; Sanginga et al., 1994; Slattery and Coventry, 1993; Weaver et al., 1972).

Rhizobia have been recognized as being important for the functioning of soil ecosystems for centuries (Fred et al., 1932). Shortly, after legume root nodules were shown conclusively to assimilate atmospheric N_2 (Hellriegel and Wilfarth, 1888), Nodbe and Hiltner applied for, and were granted, a patent for the use of these microorganisms as legume inoculants (Elkan and Bunn, 1994). This and subsequent farming and cultural practices have led to the dissemination of rhizobia on a global basis.

Rhizobia in soils may be introduced by application of commercial inoculants or, as in many cases, be the normal flora present as microsymbionts of an indigenous legume. Inoculants applied to seed, as recommended by their manufacturer, achieve inoculation rates of 10^3–10^6 rhizobia seed^{-1} (Somasegaran and Hoben, 1994). This corresponds to application rates of up to 8 $\times$ 10^{10} rhizobia ha^{-1} (Brockwell and Bottomley, 1995). At these rates, inoculant strains often dominate in nodulation in the first year of a newly introduced crop (Brockwell et al., 1982; Gibson et al., 1976; Singleton and Tavares, 1986). Moreover, inoculant strains contribute to the rapid buildup of rhizobia in the soil once nodulessenesce and release large numbers of viable rhizobia into the soil system (McDermott et al., 1987; Sutton, 1983). Several studies have documented that inoculant strains dominate in nodules 5–15 years after initial inoculation (Brunel et al., 1988; Diatloff, 1977; Lindstrom et al., 1990). It should be noted, however, that not all introduced legumes receive inoculation, and in such situations, seed, soil or aerial contamination will usually lead to some initial nodule formation, and over a period of 4–5 years, a buildup of soil rhizobial populations (Sadowsky and Graham, 1998a). Moreover, diverse rhizobial populations can develop in association with species that are not initially indigenous to a particular region (Leung et al., 1994). Although it is thought that rhizobia in soil have a clonal

population structure, genetic recombination between groups of soil rhizobia may be contributing to diversity in soils (Demezas et al., 1995; Sullivan et al., 1995). It has been demonstrated that soil rhizobia can transfer plasmids (Jarvis et al., 1989; Kinkle and Schmidt, 1991; Thomas et al., 1994; Young and Wexler, 1988) and chromosomal symbiotic genes (Sullivan et al., 1995).

The rhizobia obtained from any given soil habitat are drastically influenced by the common method of isolation. This usually involves the use of serial dilutions of soil and inoculation on a trap host, followed by recovery from nodules (Somasegaran and Hoben, 1994). This procedure often underestimates the numbers of rhizobia in the soil and biases diversity determinations (Dye et al., 1995). Numerous studies have documented the influence of a trap host on the recovery of particular groups of rhizobia from soils (Bottomley et al., 1994; Bromfield et al., 1995; Brunel et al., 1996; Keatinge et al., 1995; Kumar Rao et al., 1982; van Berkum et al., 1995). Selective culture media, when available, will most likely prove useful in determining the identity of natural populations of rhizobia in soil (Gault and Schwinghamer, 1993; Tong and Sadowsky, 1993).

Lastly, the legume host itself has been shown to strongly influence the prevalence and type of rhizobia in soils (Bottomley, 1992). How this occurs is not known, but it is thought to be due to nonspecific, root-exudate enhanced growth of rhizobia in the rhizosphere, multiplication and release of rhizobia from the nodule, and selection by the trap host of particular groups of rhizobia from mixed soil populations (Sadowsky and Graham, 1998a).

Isolation

Date (1982); Date and Halliday (1987) and Somasegaran and Hoben (1994) have detailed methods for the collection, sampling, isolation, authentication and maintenance of rhizobia. Extensive collection and conservation is necessary because many isolates will prove to be ineffective in symbiosis, or host/strain interactions will be significant. In the case of Stylosanthusscabia, more than 1,000 isolates were evaluated before a strain suitable for use in commercial legume inoculation was identified (Date, 1997).

Collection

The collection of rhizobia is most commonly undertaken as part of a plant introduction program, to supply suitable host germplasm with the rhizobia they need for symbiosis (see the National Plant Germplasm Collection System http://www.ars-grin.gov). Ideally, the collection of nodules should coincide with early season growth and well watered conditions. However, where collection involves remote geographic regions, sample acquisition may be delayed until plant maturity when most nodules may have senesced. Nodule collection may also be limited where the plant species in question is endangered, and no plant harvest is permitted. In both of these cases, soil may be used as a source of rhizobia, using surface-sterilized seed of an appropriate host to "trap" nodule bacteria. Collection of rhizobia also may be undertaken to study the biodiversity of indigenous organisms, or to study success in nodulation, or the soil establishment of bioengineered organisms. In some cases, the culture of rhizobia from nodules may be unnecessary because enough cell material may be present in soils or plant tissue to directly characterize nodule occupants using serological or phylogenetic methods (Sadowsky and Graham, 1998). Somasegaran and Hoben (1994) list several culture collections of rhizobia throughout the world. In addition, the USDA-ARS (National Rhizobium Resource Collectionl) (bldg6.arsusda.gov) provides a searchable database of rhizobia grouped by legume host.

Sampling

Sampling of plants and nodules should be done from undisturbed locations and, where possible, from healthy plants. Accurate site description and record keeping are essential. The number of nodules needed can vary with the reason for collection. Where the aim is to identify inoculant-quality rhizobia, 15–20 nodules per plant, taken from the crown region of the host root system, are usually sufficient. Where the goal is to evaluate strain biodiversity in soil, a large number of nodules should be collected from as much of the root system as possible. Ease of collection may vary; stoloniferous species may have nodules on adventitious roots within 1–2 cm of the surface (Date, 1982), while nodules on tree species may be at a great depth in the soil at some distance from the trunk of the tree. Collected nodules should be protected in *vacutainers* or in vials containing a dessicant (e.g., silica gel) overlain by cotton wool (Somasegaran and Hoben, 1994).

Isolation

Successful isolation of rhizobia from nodules depends on the quality of nodules recovered. When nodules have been stored dry over silica gel or $CaCl_2$, they must first be allowed to imbibe (sterile) water fully before being surface sterilized. Rhizobia also can be frequently recovered from nodules obtained from intact root system frozen at –20°C. Sodium hypochlorite (3%),

hydrogen peroxide (3%) and acidified mercuric chloride (0.1%) are all effective surface sterilants. The former is usually preferred due to its low cost, ready availability and ease of disposal. Surface sterilization procedures are described in detail by Vincent (1970) and Somasegaran and Hoben (1994).

Yeast extract mannitol (YEM) medium is commonly used in the routine isolation and subculture of of rhizobia. Many different formulations for this medium exist (Vincent, 1970; Somasegaran and Hoben, 1994). That used in our laboratory contains:

Mannitol	10.0 g
$MgSO_4 \cdot 7H_2O$	0.2 g
NaCl	0.1 g
K_2HPO_4	0.5 g
$CaCl_2 \cdot 2H_2O$	0.2 g
$FeCl_3 \cdot 6H_2O$	0.01 g
Yeast extract	1.0 g
Agar	20.0 g
Distilled water	1 liter
pH	6.7–7.0

Sterilize by autoclaving 20 min at 103 H 10_3 pascal (15 lb/in_2) pressure.

The medium may be amended with cycloheximide (20 microgram/ml) to reduce fungal contamination and bromthymol blue (BTB; 25 microgram/ml) or Congo red (25 microgram/ml) to facilitate identification of rhizobia. These should be filter-sterilized separately and added to autoclaved, molten YEM medium before plates are poured (Vincent, 1970). Tong and Sadowsky (1993) described a selective medium specific for *Bradyrhizobium*, based primarily on the heavy metal tolerance of these organisms. Media selective for fast-growing rhizobia have been described (Barber, 1979; Louvrier et al., 1995), but they have not proven generally effective.

Rhizobium, *Mesorhizobium*, *Sinorhizobium*, and *Allorhizobium* strains will generally produce moist, gummy colonies on YEM medium that are 4–6 mm in diameter after 7 days incubation. On medium containing BTB, the colonies and surrounding medium are yellow due to acid production by the microorganisms. Slower growing bradyrhizobia produce smaller colonies, usually only 1–2 mm diameter after 7–10 days incubation, which are raised and mucoid. The colonies and surrounding medum are blue in color on YEM containing BTB. Most nodule isolates will produce white or cream colored colonies, though some isolates produce melanin (Cubo et al., 1988), or in the case of bradyrhizobia, a rust red pigmentation in older colonies.

Authentication

Authentication of rhizobia usually involves completion of Koch's postulates with the host from which strains were originally isolated. Somasegaran and Hoben (1994) provide details of this methodology. Inoculated seedlings produced from surface-sterilized seed of a suitable legume host are typically grown in sterile low N medium or on seedling agar in large test tubes, growth pouches or Leonard jars. Plants are examined for nodulation after 25–30 days of incubation under lights. The presence of nodules on uninoculated control plants invalidates the experiment.

Identification

The identity of rhizobia or bradyrhizobia often requires a multiphasic approach using many of the techniques employed in naming new genera, species and strains of rhizobia (Graham et al., 1991). Members of the International Subcommittee on *Rhizobium* and *Agrobacterium*, a subcommittee of the International Committee on Systematic Bacteriology of the International Union of Microbiological Societies, have recommended a minimal set of criteria for naming new species and genera of nodule bacteria (Graham et al., 1995). These criteria are also useful for identifying the genus and species status of unknown rhizobia isolated from nodules. In addition to biochemical, cultural, and symbiotic data, 16S rRNA (rDNA) sequencing (Young, 1996a; Young and Haukka, 1996b), DNA-DNA hybridization (Scholla et al., 1984), FAME (Graham et al., 1995), and multilocus enzyme electrophoresis, (MLEE) (Strain et al., 1995) data are of primary importance for identifying rhizobia isolated from newly surveyed legumes.

Following strain authentication, it is often useful to mark these isolates to facilitate identification in subsequent ecological, genetic or plant studies. This can be done using a variety of techniques. These include intrinsic resistance to a series of different antibiotics (Josey et al., 1979) or the selection of mutants resistant to high levels of antibiotics. In the latter case, selected mutants must be evaluated to show that the acquisition of antibiotic resistance has not influenced nodulation, N_2 fixation or competitive abilities.

Strains can also be identified using strain or group-specific antibodies (Sadowsky et al., 1987a; Schmidt et al., 1968). Antibodies, which are typically produced in rabbits to somatic whole-cell antigens, are useful in strain identification because they do not require genetic modification of strains. Agglutination, immunodiffusion, immunoflourescence, and ELISA techniques all have found wide acceptance in serological identification of rhizobia (Dudman, 1977; Humphrey and Vincent, 1965; Kishinevsky and Jones, 1987; Schmidt et al., 1968). The fluo-

rescent antibody technique is especially useful because it allows for the direct *in situ* examination of rhizobia in soil and nodules (Bohlool and Schmidt, 1973), using direct or sandwich labeling procedures.

Strains also can be genetically modified with β∃-glucuronidase reporter (GUS) (Wilson et al., 1995; Wilson et al., 1999) and lux (Chabot et al., 1996) genes, and these strains have proven especially useful in ecological studies. Again, however, it is essential that such genetically marked strains be plant tested before use in ecological, symbiotic, or field studies.

DNA fingerprinting techniques have been used to identify and study biodiversity of rhizobial strains (Sadowsky, 1994; Versalovic et al., 1998; Sadowsky and Hur, 1998b; Demezas, 1998). Initially, DNA fingerprints of strains were generated following restriction enzyme digestion of total genomic DNA (Glynn et al., 1985; Demezas, 1998). More recently, however, restriction fragment polymorphism (RFLP) analysis techniques, DNA hybridization probes, and DNA primers corresponding to repetitive elements, coupled to the polymerase chain reaction (PCR) technique, have been used in strain identification, competition, and biodiversity studies (de Bruijn, 1992; Judd et al., 1993; Sadowsky, 1994; Sadowsky et al., 1990; Wheatcroft and Watson, 1988).

Cultivation

Rhizobia are relatively robust, ubiquitous, aerobic bacteria with the ability to utilize many different substrates (carbon [C] and nitrogen [N] sources) for growth (Parke and Ornston, 1984). Consequently, rhizobia can be cultivated on a large variety of complex and defined culture media. Only a limited number of rhizobia grow on highly enriched media, such as nutrient broth or LB medium. Medium used in the cultivation of rhizobia depends on the species of nodule bacteria, growth characteristics desired, and the method of cultivation. Most rhizobia are mesophiles and can grow in shake cultures at 25–30°C. However, rhizobia isolated from legumes grown in the Canadian High Arctic grow well at 5°C (Prevost et al., 1987), and high temperature tolerant strains have been isolated in Africa and Brazil.

As stated earlier, most rhizobia grow well in YEM medium (Vincent, 1970), though most produce copious quantities of capsular- and exo-polysaccharides in this medium, limiting its use in biochemical and genetic studies. The bradyrhizobia grow fairly slowly in this medium, with generation times greater than 6 hours. Rhizobia and bradyrhizbia shift the pH of this medium, the rhizobia produce acid and the bradyrhizobia, alkaline byproducts, from growth. Polysaccharide production can be drastically reduced in fast-growing rhizobia by cultivation in TY medium (Beringer, 1978), containing (g/liter): Tryptone (5.0), Yeast extract (3.0) and $CaCl_2 2H_2O$ (0.87), pH 6.9. In this medium turbid cultures, up to 10^9 cells ml^{-1}, can be obtained after overnight incubation at 28°C. The slow-growing bradyrhizobia do not grow in TY medium. A growth medium useful for polysaccharide-free growth by bradyrhizobia is AG medium (Sadowsky et al., 1987b). This medium, which promotes rapid growth of japonicum and elkanii strains, contains (g/liter): HEPES (0.13), MES (0.11), $FeCl_3 6H_2O$ (0.0067), $MgSO_4 7H_2O$ (0.18), $CaCl_2 2H_2O$ (0.013), Na_2SO_4 (0.25), NH_4Cl (0.32), Na_2HPO_4 (0.125), arabinose (1.0), Na-gluconate (1.0) and yeast extract (1.0), pH 6.9. Several defined, minimal, media are also used for the growth of rhizobia (Vincent, 1970; Somasegaran and Hoben, 1994), especially for biochemical and molecular biological studies. We also use AG medium without arabinose, gluconate, and yeast extract, as a minimal medium for the cultivation of prototrophic rhizobia and in genetic mating studies.

Rhizobia for legume inoculants can be grown in shake flasks or fermentors (Somasegaran and Hoben, 1994). Lorda and Balatti (1996) described a glycerol-based culture medium capable of producing approximately 10^{10} cells/ml, even in shake flask culture. In contrast, Stephens and Rask (2000) suggest that carbon-limited media be used to produce legume inoculants, to condition rhizobia to the less favorable conditions found in soil.

Preservation

Rhizobium strains in frequent use are usually maintained on YMA slants in screw capped test tubes stored at 6–10°C. Longer-term storage is achieved by lyophilization with 10% glycerol or 10% sucrose and 5% peptone as cryoprotectants, or by storage at –70°C in 15% glycerol. Gherna (1994) details methodologies for lyophilization and storage at –70°C. Change in *Rhizobium* characteristics with repeated growth on laboratory media has been reported (Herridge and Roughley, 1975) and must be of concern. Some inoculant companies maintain large numbers of ampoules of each *Rhizobium* strain in the freeze-dried state *Rhizobium* and routinely replace all working cultures at 3-month to 1-year intervals.

The Nodulation Process

The nodulation process requires molecular communication between both symbiotic part-

ners and involves the induction and repression of a large number of bacterial and plant genes. Free-living rhizobia infect and form N_2-fixing symbioses with legumes in a series of discrete stages or steps. Stages in the process include: proliferation of rhizobia in the rhizosphere, recognition of host by rhizobia, attachment of rhizobia to susceptible root hair cells, root-hair curling and infection-thread formation, initiation of nodule primordium, and transformation of free-living rhizobia into N_2-fixing bacteroids.

Rhizobia infect their respective host plants and induce root or stem nodules using several different mechanisms. Infection through root hairs is commonly seen with most legumes (Hadri et al., 1998). Rhizobia can also invade the host plant by entry through wounds, cracks, or lesions caused by emergence of secondary roots (Boogerd and van Rossum, 1997), as occurs in peanut and Stylosanthes. In these cases, rhizobia spread intercellularly. There are instances where the same rhizobia infect one legume through root hairs and another via cracks or wounds (Sen and Weaver, 1988). Lastly, rhizobia may initiate infection of the host via cavities surrounding adventitious root primordia on the stems of Sesbania, Aeschynomene, Neptunia, and Discolobium (Boivin et al., 1997). As above, one bacterium may produce both stem and root nodules on different legume plants.

Nodule shape in legumes is determined by the host plant and is regulated by the pattern of cortical cell divisions. There are two basic types of nodules that are formed on legumes: determinant and indeterminant (Franssen et al., 1992). Indeterminant nodules are most commonly formed in symbioses between the fast-growing nodule bacteria and temperate legumes (pea, clover, and alfalfa). Determinate nodules, which are normally induced by bradyrhizobia, are more common on tropical legumes, such as soybean and bean. Morphologically, indeterminate nodules have defined, persistent apical meristems and are elongated and sometimes lobed, whereas determinant nodules do not have persistent meristems and are usually round (Hadri et al., 1998).

In root hair infection, rhizobia attach to susceptible root hairs within minutes of inoculation or contact with the host plant. Rhizobial cells often attach perpendicular to the root hair cell. It has been suggested that adhesion is initially mediated by the calcium (Ca)-binding protein rhicadhesin, or by plant lectins, and subsequent bonding via production of cellulose fibrils (Kijne, 1992). It is hypothesized that rhizobia produce localized hydrolysis of the root hair cell wall. Subsequent penetration of rhizobia through the cell wall leads to root-hair curling, which may be visible 6–18 hours after inoculation. The proportion of root hairs infected is low, the percentage of these giving rise to nodules is low and highly variable, and aborted root hairs can frequently be found.

Within the root hair, rhizobia are enclosed within a plant-derived infection thread, and move down the root hair in the direction of the root cortex. Cell division in the root cortex, in advance of the approaching infection thread, leads to the production of nodule primordia (Kijne, 1992). Spread of the infection thread among cells of the nodule primordium follows, with the release of rhizobia into host cortex by an endocytotic process. Rhizobia are never free in the cytoplasm, but rather are surrounded by a host-derived peribacteroid membrane, which serves to compartmentalize the rhizobia into a symbiosome. One to several rhizobia can be confined to a single symbiosome. Nodulation is usually visible 6–18 days after inoculation, but this varies considerably with the selection of bacterial strain and host cultivar, the inoculant density and placement, and the temperature. Initially nodulation is heaviest in the crown of the root, with secondary nodules appearing on lateral roots as the first-formed nodules senesce. The number of nodules produced on each legume host is tightly controlled by the host and rhizobial genotype, the efficiency of the symbiotic interaction, by environmental factors such as soil N level and the presence of existing nodules (Caetano-Annoles, 1997; Sagan and Gresshoff, 1996; Singleton and Stockinger, 1983).

Genetics

The genetics of the rhizobia has, in most cases, centered on the genetics of nodulation and symbiotic N_2-fixation, key characters that set the rhizobia apart from other soil bacteria. Recent advances in molecular biology and genetics have elucidated a large number of genes with symbiotic functions. Though many of these genes are clustered together (on the chromosome in some organisms and on symbiotic plasmids in others), additional genes may be dispersed or located on different replicons. Consequently, all symbiotically related genes will most likely not be found until total sequencing and functional genomic efforts are completed. Because the scope of this chapter is broad, more detailed information on the genetics of nodulation and N_2 fixation can be found in several recent reviews (Boivin et al., 1997; van der Drift et al., 1998; Schultze and Kondorosi, 1998; Niner and Hirsch, 1998; Denarie et al., 1996; Pueppke, 1996; Spaink, 1995).

Nodulation Genes

In the last several years, a large number of bacterial genes have been identified which are involved in the formation of nodules on leguminous plants. Collectively, more than 65 nodulation genes have been identified in rhizobia, although each strain may only have a subset of these. Niner and Hirsch (1998); Pueppke (1996); and Bladergroen and Spaink (1998) provide a more complete description of the function of a majority of these genes.

Several studies have shown that relatively few genes are required for nodulation of legumes (Göttfert, 1993; Long et al., 1985; Long, 1989; van Rhijn and Vanderleyden, 1995). In the case of the fast-growing rhizobia, a majority of nodulation genes are located on large, indigenous, symbiotic (Sym), and often self-transmissible, plasmids (Broughton et al., 1984; Hombrecher et al., 1981; Kondorosi et al., 1989). The complete genomic sequence of the symbiotic plasmid from *Rhizobium* sp. strain NGR-234, a *Rhizobium* strain with broad nodulation ability (Pueppke and Broughton, 1999), is currently available. In meliloti, the symbiont of alfalfa, nodulation genes (located on an 8.5 kb fragment of the Sym plasmid) contain sequences necessary for the nodulation of a wide variety of legume hosts (Kondorosi et al., 1989; Truchet et al., 1991). These genes, referred to as "common nodulation" genes and designated nodA, nodB and nodC, have homologues in other fast- and slow-growing species. In leguminosarum bvs. trifolii and viceae and meliloti, the common nodulation genes are organized in a similar cluster (Downie et al., 1985; Egelhoff and Long, 1985; Fisher et al., 1985; Nieuwkoop et al., 1987; Putnoky and Kondorosi, 1986; Rolfe et al., 1985; Russell et al., 1985; Schofield and Watson, 1986; van Rhijn and Vanderleyden, 1995). A fourth gene, nodD, is regulatory and together with plant flavonoid signals (see below) activates transcription of other inducible nod genes (Long, 1989; Martinez et. al, 1990; van Brussel et al., 1990). Leguminosarm bvs. viceae and trifolii have single copies of *nodD*. The symbionts meliloti and japonicum have multiple copies of nodD (Göttfert et al., 1986; Göttfert et al., 1990; Honma and Ausubel, 1987). In some instances, nodD also appears to impart host-specificity functions (Spaink et al., 1987). Another nodulation gene cluster, originally designated hsn (for host-specific nodulation), is closely linked to the common nodulation region in meliloti and controls nodulation of specific legume genera (Bachem et al., 1986; Horvath et al., 1986). Mutations in the *hsn* genes (designated *nodFEGH*) cannot be complemented with Sym plasmids from other species of *Rhizobium*. Analogous *hsn* genes also have been isolated from leguminosarum bv. *trifolii* (Djordjevic et al., 1985; Rolfe et al., 1985), leguminosarum bv. *viceae* (Wijffelman et al., 1985), and from *Rhizobium* strain MPIK3030 (Bachem et al., 1986; Bassam et al., 1986; Broughton et al., 1984; Lewin et al., 1987). An *hsn* gene linked to the common nodulation region in japonicum strain USDA 110 has also been reported (Nieuwkoop et al., 1987). This sequence, subsequently called nodZ (Dockendorff et al.,1994), was shown to be involved in the host-specific nodulation of siratro, but not soybean. Hahn and Hennecke (1988) and Göttfert et al. (1990) have identified another *hsn* locus in japonicum strain 110, nodVW, which is essential for the nodulation of siratro, mungbean and cowpea, but not soybean. In japonicum strain USDA 110, the essential nodulation genes are located on the chromosome in several transcriptional units in the order: nolZ, nolA, nodD2, nodD1, nodYABCSUIJmolMNO (Dockendorff et al., 1994). Unlike other rhizobial nodD genes, the japonicum nodD1 is induced by the flavonoids genistein and daidzein (Banfalvi et al., 1988; Kosslak et al., 1987) and by xanthones (Zaat et al., 1987).

Genotype-Specific Nodulation Genes

Although many hsn genes have been identified in *Rhizobium* and *Bradyrhizobium*, there are only limited reports on the identification of genotype-specific nodulation (GSN) genes in the rhizobia (Sadowsky et al., 1991). The GSN genes specifically refer to those bacterial genes that allow nodulation of specific plant genotypes within a given legume species. For example, strain TOM nodulates the pea genotype Pisum sativum cv. Afghanistan (Lie, 1978a; Lie et al., 1978b), but European leguminosarum bv. *viceae* strains fail to nodulate this host. Some GSN-like genes have been found on plasmid pRL5JI of strain TOM (Gotz et al., 1985; Hombrecher et al., 1984). Davis et al. (1988) have identified a single gene on this plasmid, nodX, mediating the O-acetylation of Nod factors (Firmin et al., 1993), which is necessary for the nodulation of "Afghanistan" peas. In fredii strain USDA 257, two other GSN-like loci, nolC (Krishnan and Pueppke, 1991) and nolBTUVW (Meinhardt et al., 1993), allow this strain to nodulate primitive lines of soybean, but not improved soybean varieties, such as "McCall" (Heron et al., 1989). In each case, Tn5 insertions in the gene regions allow fredii to nodulate commercial soybean cultivars. Phenotypically, these regions are similar to that reported by Djordjevic et al. (1985) and Innes et al. (1985) for clover rhizobia. More recently, however, Lewis-Henderson and Djord-

jevic (1991a) reported that nodM in leguminosarum bv. trifolii is a GSN which prevents effective nodulation of subterraneum cv. Woogenellup (Lewis-Henderson and Djordjevic, 1991b). Analysis of leguminosarum bv. trifolii strain TA1 demonstrated that this strain also lacks nodT, and that introduction of nodT from leguminosarum bv. viceae strain ANU843 into TA1 allows effective nodulation of "Woogenellup" (Lewis-Henderson Djordjevic, 1991a). The GSN genes can act in either a positive or negative manner (Djordjevic et al., 1987a; Sadowsky et al., 1990), insertions in a negatively acting nodulation gene extending host-range and insertions in a positively acting GSN gene limiting host range. *Bradyrhizobium* japonicum serogroup 123 strains are restricted for nodulation by PI 377578 (Cregan and Keyser, 1986). The japonicum nolA gene, identified in strain USDA 110, is a positively acting gene that allows serogroup 123 strains to nodulate PI 377578 (Sadowsky et al., 1991). We recently identified a mutant of japonicum strain USDA 110 that has the ability to overcome nodulation restriction conditioned by soybean PI 417566 (Lohrke et al., 1995).

Signal Exchange and Induction of Nod Genes

Although the regulation of nodulation genes in rhizobia is still not fully understood, we know a lot about communication between rhizobia and susceptible legume hosts. Flavonoid signal molecules present in root and seed exudates are necessary for *nod* gene expression (Banfalvi et al., 1988; Boundy-Mills et al., 1994; Djordjevic et al., 1987a; Fellay et al., 1995; Göttfert et al., 1988; Innes et al., 1985; Kosslak et al., 1987; Long, 1989; Mulligan and Long, 1985; Olson et al., 1985; Peters et al., 1986; Price et al., 1992; Sadowsky et al., 1988; van Brussel et al., 1990; Zaat et al., 1987). Other Sym plasmid-borne genes are also induced by root exudates in fredii and *Rhizobium* sp. strain NGR234 (Boundy-Mills et al., 1994; Fellay et al., 1995; Olson et al., 1985; Sadowsky et al., 1988). Flavones, isoflavones, flavanols, flavanones, and closely related compounds have been identified as *nod* gene inducers, and each is specific for a particular legume-*Rhizobium* interaction (Schlaman et al., 1998). Flavanoid compounds are only one of several determinants of host specificity. Spaink et al. (1991) reported differential induction of nodD in various fast-growing rhizobia by a range of flavonoids and exudates. Induction of nodulation genes requires the regulatory *nodD* gene product (Long, 1989; Mulligan and Long, 1985; Shearman et al., 1986). The inducer apparently binds NodD, causing a change in conformation (Kondorosi et al., 1988; Fisher and Long, 1989). Activated NodD then binds to a regulatory, promoter-like sequence, found upstream of rhizobial nod genes, the nod box (Hong et al., 1987; Horvath et al., 1986; Kondorosi et al., 1988; Rostas et al., 1986; Shearman et al., 1986). Repressor proteins have also been suggested to play a role in nod gene regulation (Kondorosi et al., 1988), a repressor encoded by the nolR gene has been identified in S. meliloti strain 41 (Kondorosi et al., 1989; Kondorosi et al., 1991).

Extracellular Nodulation Factors

One of the primary functions of nod genes is the production of extracellular lipochitinoligosaccharide (LCO) molecules, also known as Nod factors (Carlson et al., 1993; Carlson et al., 1994). These molecules, acting at 10^{-8} to 10^{-9} M, can: 1) stimulate the plant to produce more *nod* gene inducers (van Brussel et al., 1990); 2) deform root hairs on homologous hosts (Banfalvi et al., 1989; Faucher et al., 1989); and 3) initiate cell division in the root cortex (Lerouge et al., 1990; Price et al., 1992; Sanjuan et al., 1992; Schultze et al., 1992; Relic et al., 1993; Spaink et al., 1991). In meliloti these signal molecules are acetylated and sulfated glucosamine oligosaccharides (Lerouge et al., 1990). Similar molecules have been identified in other legume symbiotic systems (Pueppke, 1996 and Downie, 1998 for a review). Numerous observations support the theory that hsn genes control host specificity by decorating Nod factors with various substituents. For example, the meliloti genes nodP, nodQ and nodH are involved in the sulfation of the Nod factor reducing sugar (Faucher et al., 1989; Roche et al., 1991). Disruption of any of these genes affects host specificity. *Rhizobium* spp. NGR234, which can nodulate over 125 different legume species (Pueppke and Broughton, 1999), produces diverse (more than 18) Nod factors, which vary in the substituents attached to a similar backbone structure (Price et al., 1992).

Purified Nod factors, which are structurally similar to those produced by the appropriate rhizobial symbiont, can induce nodules on the specific host plant in the absence of a bacterium (Downie, 1998; Mergaert et al., 1993; Relic et al., 1993, Schultze et al., 1992; Truchet et al., 1991). Nod factors from several strains of japonicum have been characterized (Carlson et al., 1993; Sanjuan et al., 1992). The functions of nod genes and the basic structure of Nod factors for japonicum and several species of the genus *Rhizobium* can be found in (Downie, 1998).

Nitrogen Fixation Genes

Two major types of N_2 fixation genes have been described, *nif* genes and *fix* genes. The *nif* refer

to genes involved in the N_2 fixation process and have structurally and functionally related genes in the free-living diazotrophic microorganism, Klebsiella pneumoniae. pneumoniae was the first N_2-fixing microorganism studied in detail (Kennedy, 1989). As with the nodulation genes, a majority of the *nif* genes are plasmid borne and contiguous in the rhizobia, but chromosomally located in the bradyrhizobia. The N_2 fixation process is catalyzed by the enzyme complex nitrogenase, encoded by the nifDK and nifH genes. The *fix* genes are also involved in the N_2 fixation process, but have no similar structural or functional homologues in pneumoniae. The organization of *nif* genes varies in the rhizobia (Kaminski et al., 1998).

Nitrogenase consists of two protein subunits, a molybdenum-iron (MoFe) protein and an iron-containing (Fe) protein. These structural components of the nitrogenase enzyme complex are often referred to as subunits I and II, respectively. The *nifK* and nifD genes encode the MoFe protein subunits. A FeMo cofactor (FeMo-Co) is required for activation of the MoFe protein and is assembled from the nifB, V, N, and E genes. The nifH gene encodes the Fe subunit protein. In pneumoniae there are at least 20 *nif*-specific genes that are localized in about 8 operons (Dean and Jacobson, 1992). Though the organization of *nif* genes in other organisms varies tremendously (Downie, 1998), nifHD and nifK are conserved in disparate N_2-fixing organisms and rhizobia (Ruvkin and Ausubel, 1980). The gene products NifA and NifL control the regulation of all other nif genes. Whereas NifA is positive activator of transcription of *nif* operons, NifL is involved in negative control. In K. pneumoniae and several other free-living diazotrophic microbes, *nif* gene expression is regulated by oxygen and nitrogen levels (Merrick, 1992). Ammonia (NH_3) causes NifL to act as a negative control and prevents the activator function of NifA. This has been referred to as the N control system, and has been shown to regulate several enzymes that are capable of producing NH_3. Merrick (1992) and Dean and Jacobson (1992) give excellent in-depth reviews of the structure and regulation of N_2 fixation in free-living and symbiotic bacteria.

Other Genes Involved in Symbiotic Nitrogen Fixation

Other plasmid and chromosomally borne bacterial genes also have been found to function indirectly in nodulation and symbiotic N_2-fixation in rhozobia (Table 3). Recent review articles on the structure and function of these and other symbiosis-related genes are provided by Pueppke et al. (1996) and Spaink (1995) and Long (1999).

Ecology

Rhizobia are relatively unique among the majority of soil microorganisms in that they have an extensive soil phase as free-living, saprophytic, heterotrophic microorganisms, yet in conjunction with leguminous plants, they have the ability to form species-specific, N_2-fixing symbiotic associations. The ability to form N_2-fixing nodules affords unique opportunities for the rhizobia. When a legume crop is grown in soil for the first time, few rhizobia are likely to be present and, in most instances, inoculation will most likely be needed for adequate nodulation and subsequent N_2 fixation (Date, 1991; Diatloff, 1977). In contrast, soils surrounding legumes that have been planted for several years usually contain relatively large numbers of rhizobia and do not require added rhizobia. Numerous studies have documented that legume inoculants added to soils containing relatively small populations of rhizobia usually give rise to only a small percentage of the nodules formed (Thies et al., 1991; Date, 1991; Ellis et al., 1984; Ham, 1978). Despite intensive investigations over the last 30 years, however, some of the factors that influence the survival and the persistence of rhizobia in the soil, their ecology and competitiveness for nodulation sites on the host, are only now beginning to be understood. It is beyond the scope of this

Table 3. Some other bacterial genes involved in symbiotic nitrogen fixation.

chapter to present all that is known about the ecology and soil biology of the rhizobia. The reader is directed to more extensive reviews by Bottomley (1992) and Sadowsky and Graham (1998a) on this material.

The establishment of the symbiotic state results in the production of a nodule populations of more than 10^{10} rhizobia g^{-1} nodule tissue (McDermott et al., 1987). When these nodules senesce at the end of the growing season, large numbers of rhizobia are released into the soil. Nodule bacteroids are subject to changes in surface chemistry (Roest et al., 1995) and are susceptible to osmotic and other soil stresses (Sutton, 1983). However, many of the released organisms manage to persist as free-living, heterotrophic, saprophytes in the soil until a susceptible legume is again planted. As a consequence of this, most soils contain at least some rhizobia, and a dramatic buildup in their numbers occurs when a leguminous host is included in a crop rotation, pasture or natural setting.

Ellis et al. (1984) reported soil populations of bradyrhizobia approaching 10^6 cells g^{-1} in soils of the American Midwest following cultivation of soybean, and rhizosphere populations can reach 10^8 cells g^{-1} (Bottomley, 1992). The distribution of rhizobia in soil is not uniform. Postma et al. (1990) reported that the greatest number of rhizobia are associated with soil aggregates of larger than 50 µm, and Mendes and Bottomley (1998) noted that the percentage of *Rhizobium* recovered from aggregates of different sizes varied over the course of a growing season.

Rhizobia are excellent soil saprophytes and can persist for many years in the absence of their host (Brunel et al., 1988; Kucey and Hynes, 1989; Bottomley, 1992). Chatel et al. (1968) used the term saprophytic competence to describe this ability, but the factors involved have yet to be determined. Even though Bushby, 1990 noted surface electrophoretic charge in bradyrhizobia correlated to the pH of soils from which they came, Rynne et al., 1994 found no correlation between catabolic ability and strain persistence. Inoculant strains used at the time a particular host was introduced may still occupy a large percentage of the nodules formed on that host 10–15 years after their introduction (Diatloff, 1977; Brunel et al., 1988; Lindstrom et al., 1990). However, many studies have shown that inoculant strains may also decline in nodule representation over time, or quite quickly disappear from soil.

The growth of rhizobia in the rhizosphere may also be stimulated by specific root exudates (Van Egaraat, 1975). Rhizobia, in turn, also stimulate growth and respiration of leguminous plants (Phillips et al., 1999). Several research studies have sought to create biased rhizospheres, in which plants transformed to synthesize opines, favor the growth of rhizosphere bacteria utilizing this substrate (Rossbach et al., 1994; Oger et al., 1997; Savka and Farrand, 1997). The inability of strains to compete for nodulation sites on the host legume does not necessarily mean their displacement from the soil population. Bromfield et al. (1995) compared populations of meliloti recovered from soil and nodules and found significant differences in the frequency with which particular genotypes were recovered. Similarly, Segovia et al. (1991) found the population of noninfective bean rhizobia in soil numerically superior to those capable of inducing nodule formation.

Environmental factors, particularly soil pH, temperature and water availability, often affect rhizobial survival in soil, and the balance between particular genotypes. In soils of pH >7.0, Brockwell et al., 1991 found an average of 89,000 meliloti g^{-1} soil, whereas in soils of pH <6.0, the number was only 37 g^{-1}. Even more striking is the replacement of the normal bean microsymbiont etli, by the acid-tolerant tropici to which beans were introduced (Anyango et al., 1995; Hungria et al., 1997). This change occurred in the relatively short time since Spanish and Portuguese colonization of Latin America, and despite the fact that tropici is less competitive than etli in nodule formation with beans (Martinez-Romero and Rosenblueth, 1990; Chaverra and Graham, 1992). In contrast, Richardson and Simpson (1989) found that many rhizobia from acid soils are sensitive to acidity, suggesting that microniches in soils protect these microorganisms from extremes of soil pH.

Temperature also has a marked influence on survival and persistence of rhizobial strains. (Eaglesham et al., 1981) found cowpea rhizobia from the hot, dry Sahelian savannah of West Africa to be temperature tolerant, with good growth at 37°C. More than 90% of the strains isolated from this region grew well to 40°C, whereas rhizobia from the more humid Onne region of West Africa generally failed to grow at this temperature. Soil temperature might contribute to the number of noninfective rhizobia found in some soils (Segovia et al., 1991). Temperature effects appear to be both strain and soil dependent. Marshall (1964) studied a clover nodulation problem in which autumn-sown plants nodulated well, but frequently failed to do so in subsequent regrowth. He found *Bradyrhizobium* sp. (Lupinus) less susceptible than leguminosarum bv. *trifolii* to high soil temperatures, but also noted amelioration of this problem in sandy soils amended with montmorillonite and illite.

Although rhizobia comprise only 0.1 to 8.0% of the total bacterial population in soil, and 0.01 to 0.14% of its biomass (Bottomley, 1992; Schor-

temeyer et al., 1997), their biodiversity in soil, and the factors which can affect it, have been extensively studied.

The development of improved techniques for strain fingerprinting, particularly restriction fragment length polymorphism (RFLP) and PCR analyses (de Bruijn, 1992; Judd et al., 1993; Dye et al., 1995; Madrzak et al., 1995; Richardson et al., 1995; Brunel et al., 1996; Labes et al., 1996; Paffetti et al., 1996; Rome et al., 1996; Sadowsky and Hur, 1998b), multilocus enzyme electrophoresis (MEE) (Pinero et al., 1988; Eardly et al., 1990; Demezas et al., 1991; Demezas et al., 1995; Bottomley et al., 1994; Dupuy et al., 1994; Souza et al., 1994; Strain et al., 1994; Strain et al., 1995) and SDS-PAGE analysis of total cell proteins (Roberts et al., 1980; Dupuy et al., 1994) have been used extensively to study strain biodiversity.

Population biodiversity among the rhizobia for a particular legume species tends to be greatest near the center of origin/domestication of that legume (Lie et al., 1987). Pinero et al. (1988) recorded a mean genetic distance per enzyme locus of 0.691 for 51 isolates of etli from the Mesoamerican center of origin for Phaseolus vulgaris (L.), while Souza et al. (1994) grouped 372 bean rhizobia into 7 clusters comprising 95 electrophoretic types. In the later study, rhizobia isolated from wild bean populations grouped by location and Phaseolus species, whereas those from cultivated beans were very heterogeneous. An emerging consideration in data such as this is the promiscuity of *Phaseolus vulgaris*. This host is nodulated by at least five different species of rhizobia (Michiels et al., 1998), necessitating care in distinguishing between intra- and extraspecific diversity. At the other extreme, the movement of rhizobia as seed-borne contaminants (Perez-Ramirez et al., 1998) can give the impression of limited biodiversity, more properly identified as founder effects (Hagen and Hamrick, 1996).

Environmental stresses noted above also can have profound effects on the biodiversity of rhizobia in soil. In an extreme case (Hirsch et al., 1996), application of manure containing heavy metals reduced the biodiversity of leguminosarum bv. trifolii in soil to a single biotype. Caballero-Mellado and Martinez-Romero (1999) also reported fertilizer effects on strain biodiversity in soil.

Applications

It is unlikely that soils contain appropriate rhizobia when a legume species is planted in a new area for the first time. In these cases, inoculation is usually required for adequate nodulation and N_2 fixation. Yield increases following inoculation with appropriate inoculant-quality rhizobia can exceed 50%, with clear differences between inoculated and uninoculated plants as shown in the figure.

Fig. 3. Response of soybean to inoculation in newly cultivated areas of Puerto Rico. The yellow-green plants in the center of the picture were not inoculated with *Rhizobium*. Courtesy of R. Stewart Smith.

Where plants are not inoculated with rhizobia in the first year of introduction into a new area, nodulation will most likely be limited to that coming from seed-borne or aerial contaminants. It is common that these rhizobia are less than fully effective in symbiosis with their host (Guar and Lowther, 1980). Over several years of cultivation these rhizobia will increase in numbers in the soil, limiting subsequent inoculation response. It is important, therefore, that inoculation with an inoculant-quality organism lead to early establishment and persistence of effective rhizobia in the soil, ensuring long-term benefits. Where this is done, the original inoculant strain(s) may still dominate in nodulation 10–15 years later (Brunel et al., 1988; Kucey and Hines, 1989; Bottomley, 1992). In Thailand, an interesting result of the need for inoculation in the establishment year is illustrated by farmer's willingness to adopt inoculant technologies: 80% of farmers in new areas of soybean production but only 30% of farmers in older established areas are willing to inoculate, and many of the latter apply fertilizer N (Hall and Clark, 1995).

Inoculation of legumes with suitable rhizobia has been practiced for more than 100 years. Initially this involved the collection of soil from areas where particular legumes had established successfully, and the mixing of soil and seed prior to planting. Inoculation with pure cultures of rhizobia followed, and today the provision of rhizobial inoculants to farmers, home gardeners and others is a multimillion dollar industry with approximately 4 tons peat culture sold annually in the United States alone (Burton, 1980). More than 80% of this is for two crops, soybean and

Fig. 4. PulseR.™ A presterilized-peat based inoculant for soybean. Photograph: H. Mc Ives, Agribiotics.

alfalfa. In Brazil where there was an early commitment to N_2 fixation as the principal source of plant N, Dobereiner et al. (1995) estimate the benefits of symbiotic and associative symbioses at more than \$1.8 billion each year. Most inoculant preparations are peat based (Smith, 1992; Brockwell and Bottomley, 1995), but frozen, granular, liquid, and other preparations also are used. Applied as recommended, these preparations will supply between 10^9 and 10^{13} rhizobia ha^{-1}, equivalent to 10^3 to 10^6 rhizobia $seed^{-1}$ (Lupwayi et al., 1999).

Many factors have to be considered if inoculation is to function properly. This website (www.Rhizobium.umn.edu) also provides linkages to a range of inoculant manufacturers and inoculant-related information. Most important in legume inoculation is use of the correct rhizobia. Specificity in nodule formation between host and rhizobia has been referred to already; specificities between host and *Rhizobium* in terms of N_2 fixation also exist (Burton, 1967) and impact inoculant strain selection. Liphatec (Milwaukee, WI) provides more than 100 different strain preparations for legume inoculation (Smith, 1988).

Consistent quality in the inoculant material is also essential, but can be surprisingly variable. A number of countries regulate inoculant quality. Thus, for example, inoculants sold in Canada, Australia, Uruguay and France must contain in excess of 108 or 109 rhizobia g^{-1} peat carrier, and be essentially contaminant free (Lupwayi et al., 1999). Inoculant quality in these countries is often controlled by a government testing agency and, subject to law. Best results have traditionally been with inoculant formulations that are sterilized before introduction of the rhizobia (D. J. Hume and J. A. Omelian, personal communication). These maintain higher numbers of rhizobia and have a longer shelf life than unsterile peat or granular inoculants. Whereas the large-scale production of inoculants is a relatively simple process, not all inoculants meet the quality standards mentioned above. For example, the 18 Argentine inoculants examined by Gomez et al. (1997) ranged in cell count from 0 to 10^9 rhizobia g^{-1}, and 14 contained more contaminants than rhizobia.

Environmental conditions also can affect inoculation success. The effect of soil acidity on rhizobia has already been mentioned, and has necessitated both a search for more acid-tolerant rhizobia (Graham et al., 1982; Graham, 1994; Howieson et al., 1988; Howieson and Ewing, 1989) or the use of pelleted, inoculated seed that provides a neutral environment prior to infection (Somasegaran and Hoben, 1994). Higher inoculation rates may be needed where high temperatures at seeding limit rhizobial survival (Smith et al., 1981; Smith and del Rio Escurra, 1982). A recent trend is for mixed inoculants, for example containing *Rhizobium* plus biocontrol, phosphate-solubilizing or growth hormone-producing organisms (Rice et al., 1995; Burdmann et al., 1996; Xi et al., 1996; Zhang et al., 1997). Results of coinoculation experiments with Azospirillum are promising; more detailed field experimentation is needed to establish the value of the other combined formulations. A concern in all such preparations must be the compatability and survival of the various inoculant organisms used.

CHAPTER 1.26

Magnetotactic Bacteria

STEFAN SPRING AND DENNIS A. BAZYLINSKI

Introduction

Magnetotactic bacteria are Gram-negative, motile prokaryotes that synthesize intracellular crystals of magnetic iron oxide or iron sulfide minerals. These apparently membrane-bounded crystals are called magnetosomes (Balkwill et al., 1980) and cause the bacteria to orient and migrate along geomagnetic field lines. Magnetotactic bacteria are indigenous in sediments or stratified water columns where they occur predominantly at the oxic-anoxic transition zone (OATZ) and the anoxic regions of the habitat or both. They represent a diverse group of microorganisms with respect to morphology, physiology and phylogeny. Despite the efforts of a number of different research groups, only a few representatives of this group of bacteria have been isolated in axenic culture since their discovery by (Richard P. Blakemore, 1975), and even fewer have been adequately described in the literature. Therefore, little is known about their metabolic plasticity, whereas their diverse morphology and phylogeny has been analyzed to some extent by culture-independent methods. To date, the only validly described species of magnetotactic bacteria are members of the genus *Magnetospirillum*. Representatives of this genus have been isolated reproducibly from various aquatic environments and can be grown relatively easily in mass culture. Therefore, most of the knowledge about the metabolism and biochemistry of magnetotactic bacteria relies on results obtained with strains of this genus.

Ecology

Magnetotactic bacteria are ubiquitous and common in sediments of freshwater or marine habitats, but also in stratified water columns (Bazylinski et al., 1995) and wet soils (Fassbinder et al., 1990). The occurrence of magnetotactic bacteria appears to be dependent on the presence of opposing gradients of reduced and oxidized compounds, usually represented by reduced sulfur species and oxygen, in the sediments or water columns. It has been shown in some cases that the distribution and abundance of these bacteria in the environment might also be dependent on the availability of soluble iron (Stolz et al., 1986). The highest numbers of magnetotactic bacteria are observed at the OATZ of sediments or stratified water columns. Magnetotactic bacteria can therefore be considered as typical examples of gradient organisms. In one study (Fig. 1), the number of a morphologically-distinct magnetotactic bacterium, "*Magnetobacterium bavaricum*," at the OATZ in a freshwater sediment was determined to be up to 7×10^5 live cells per cm^3 (Spring et al., 1993).

"*Magnetobacterium bavaricum*" is very large (average volume ca. 25.8 ± 4.1 μm^3) and could account for approximately 30% of the microbial biovolume in this layer of the sediment. In some environments, magnetotactic bacteria, particularly those that produce iron sulfide minerals, can also be detected in the anoxic region of the habitat, but are only rarely found at sites or regions of water columns or sediments exposed to high levels of oxygen.

The detection of magnetotactic bacteria in environmental samples is relatively easy due to their permanent magnetic dipole moment. One simple method is to put a drop of water or sediment on a microscope slide and place a bar magnet on the microscope stage in such a way that all the magnetotactic bacteria are guided in one direction until they reach and accumulate at the edge of a drop of water and/or sediment where they can be visualized. Alternatively, it is possible to magnetically enrich for higher numbers of cells by placing the south pole (in the Northern Hemisphere; the north pole of the magnet is used in the Southern Hemisphere) of a bar magnet adjacent to the outer wall of a jar filled with sediment and water. If magnetotactic bacteria are abundant in the sample, a brownish or sometimes grayish to white (if the cells contain elemental sulfur globules) spot consisting mainly of magnetotactic bacteria will form next to the inside of the glass wall closest to the south pole of the bar magnet. This material can easily be removed from the jar with a Pasteur pipette and

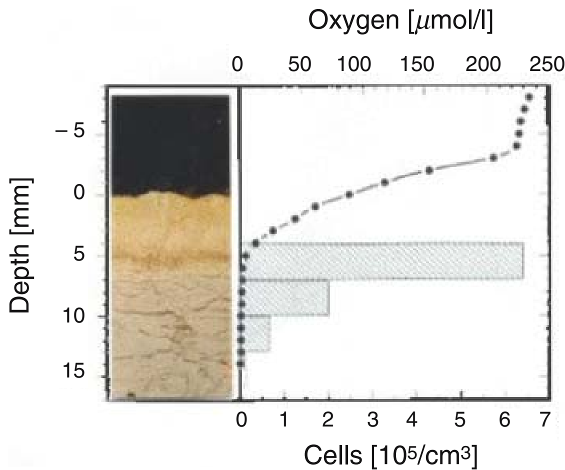

Fig. 1. Vertical distribution of "*Magnetobacterium bavaricum*" in the stratified sediment of a freshwater lake in Bavaria, Germany (Lake Chiemsee). The analyzed sediment sample was stored in an aquarium for several weeks before the measurements. The crosshatched bars indicate counts for successive depth fractions (3 mm intervals). Oxygen was measured every 1 mm (solid circles). A color photograph of the corresponding section of the aquarium is shown on the left. The upper brownish gray layer followed by a thin reddish brown and then a gray layer is characteristic of Lake Chiemsee sediments. The water-sediment interface corresponds to 0 mm.

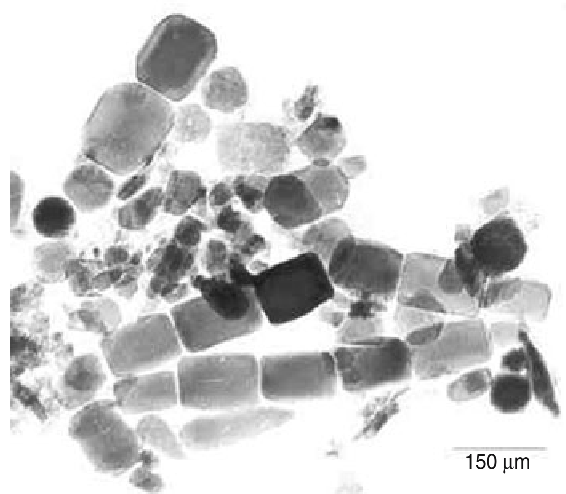

Fig. 2. Brightfield TEM image of a magnetic separate from surface sediments collected from the Irish Sea. Note the presence of parallelepipedal, cubo-octahedral, and tooth-shaped crystals of magnetite, presumed "magnetofossils" left from magnetotactic bacteria. Courtesy of Z. Gibbs.

examined as described above. Magnetotactic bacteria commonly enrich (i.e., increase in numbers) in sediment samples in jars or aquaria stored in dim light at room temperature. The process may take several weeks to months, however. In several cases, successions of different magnetotactic bacterial morphotypes have been observed during the enrichment process. Astonishingly, magnetotactic bacteria sometimes remain active for several years in the aquaria without addition of any nutrients.

When magnetotactic bacteria die and lyse, magnetosome crystals sometimes remain stable in sediments at sites where these bacteria were abundant, resulting in a change of the remanent magnetization of those sediments. Fossil magnetosome crystals consisting of magnetite ("magnetofossils") have been retrieved from many sites including deep sea sediments up to 50 million years old (Petersen et al., 1986) and ancient consolidated sediments up to 2 billion years old (Chang and Kirschvink, 1989a; Chang et al., 1989b). The bacterial origin of particles like those shown in Fig. 2 is assumed based on the unique morphology and size distribution of these magnetite crystals (see Magnetite-type Magnetosomes in this Chapter). Magnetite particles of similar sizes and shapes to those of magnetotactic bacteria have also been discovered within the Martian meteorite ALH84001 where they are thought to be the result of biological processes and therefore have been used as evidence for the presence of life on ancient Mars (McKay et al., 1996).

Nanometer-sized magnetite particles have also been found in soil samples. There the occurrence of magnetite seems to be strongly dependent on environmental conditions favoring the growth of magnetotactic bacteria, a fact which is also of some archaeological interest. It has been speculated that changes in the magnetic susceptibility of top soils, which frequently indicate locations of buried remains of archaeological objects, are caused by magnetotactic bacteria (Fassbinder and Stanjek, 1993). It is thought that the decay of wooden posts or palisades in wet soil leads to localized sites rich in organic material where the growth of magnetotactic bacteria is stimulated, thereby leading to the localized production and accumulation of magnetite. However, it is also possible that the magnetite is produced by iron-reducing bacteria through a biologically-induced mineralization process. In this case, Fe^{2+}, resulting from the bacterial enzymatic reduction of Fe^{3+}, reacts chemically with ferrihydrite to form extracellular magnetite.

Magnetotaxis, Chemotaxis and Aerotaxis

Soon after the discovery of magnetotactic bacteria, a model was proposed to explain the function of the bacterial magnetosome and the biological advantage of magnetotaxis. The original theory,

proposed by Blakemore (1975), was based on the assumption that all magnetotactic bacteria are microaerophilic and indigenous in sediments. Richard B. Frankel and co-workers clearly showed that these bacteria passively align and actively swim along the inclined geomagnetic field lines as a result of their magnetic dipole moment. Blakemore called this behavior magnetotaxis and proposed that magnetotaxis helps to guide the cells down to less oxygenated regions of aquatic habitats at the surface of sediments. Once cells have reached their preferred microhabitat they would presumably stop swimming and adhere to sediment particles until conditions changed, as for example, when additional oxygen was introduced. By this mechanism, a conventional aerotactic response which is a three dimensional search problem could be reduced to an one dimensional search problem in which cells only swim downward, thereby increasing the efficiency of the organism in finding an optimal oxygen concentration in the sediments. This theory is supported by the predominant occurrence of magnetotactic bacteria that are North-seeking (i.e., swim in the direction indicated by the North-seeking pole of a magnetic compass needle) under oxic conditions in the Northern hemisphere whereas bacteria are predominately South-seeking in the Southern hemisphere. Due to the negative and positive sign of the geomagnetic field inclination in the Northern and Southern hemispheres, respectively, magnetotactic bacteria in both hemispheres therefore swim downward toward the sediments (Blakemore, 1982).

Recent findings, including the discovery of large populations of magnetotactic bacteria at the OATZ of chemically stratified aquatic habitats and the isolation of obligately microaerophilic, coccoid magnetotactic bacterial strains, make it necessary to rethink this view of magnetotaxis. The traditional model does not completely explain how bacteria in the anoxic zone of a water column benefit from magnetotaxis, nor does it explain how the magnetotactic cocci form microaerophilic bands of cells in semi-solid oxygen gradient medium. Spormann and Wolfe (1984) showed earlier that magnetotaxis is somehow controlled by aerotaxis in some magnetotactic bacteria, but this alone does not help to explain all observed effects of magnetotaxis. More recently, it was demonstrated (with pure cultures of magnetite-producing magnetotactic bacteria) that magnetotaxis and aerotaxis work together in these bacteria (Frankel et al., 1997). The behavior observed in these strains has been referred to as "magneto-aerotaxis," which is a more accurate description than magnetotaxis because these cells do not try to reach a distinct magnetic pole or field as the term magnetotaxis implies. Thus, the term magnetotaxis is a misnomer.

The traditional model also fails to explain the various types of magnetotactic behavior which had been observed by several authors but without recognizing the fundamental differences between these behaviors (Moench and Konetzka, 1978; Blakemore et al., 1980; Spormann and Wolfe, 1984). Only when distinct morphotypes of magnetotactic bacteria were isolated and grown in pure culture for detailed studies using thin, flattened capillaries (Frankel et al., 1997), it became clear that two types of mechanisms have been observed, which apparently occur in different bacteria, termed polar and axial.

The distinction can be seen by examination of cells in wet mounts under oxic conditions using a microscope and a magnet of a few gauss parallel to the plane of the slide (Fig. 3). Polar magnetotactic bacteria, particularly the magnetotactic cocci, swim persistently along the magnetic field lines without reversing their direction or turning. If the magnetic field is reversed, the bacteria reverse their swimming direction and continue swimming persistently in the same direction relative to the magnetic field. Bacteria from Northern hemisphere habitats predominately swim parallel to the magnetic field, corresponding to northward migration in the geomagnetic field. Bacteria from the Southern hemisphere swim antiparallel to the magnetic field. It was this consistent swimming behavior that led to the discovery of magnetotactic bacteria by Blakemore (1975). On the other hand, axial magnetotactic bacteria, especially the freshwater spirilla, orient and swim in both directions along the magnetic field lines with frequent reversals of swimming direction and some accumulating in approximately equal numbers on both sides of the water drop (Fig. 3a).

The distinction between polar and axial magneto-aerotaxis can also be seen in flattened capillary tubes containing suspensions of cells in reduced medium with one or both ends of the capillary tube open. In the first situation, where one end of the capillary is open (the right end of the capillaries in Fig. 3b) and the other sealed, a single oxygen gradient forms beginning at the open end of the capillary. Cells of strain MC-1 in these capillaries rotate 180° after a reversal of B, the magnetic field, and the band separates into groups of cells swimming in opposite directions along B, away from the position of the band before the reversal. A second reversal results in the reformation of a single band. Cells of *M. magnetotacticum* also rotate 180° in these capillaries but the band of cells does not separate and remains intact (Fig. 3). In the second situation (not shown), where both ends of the capillary

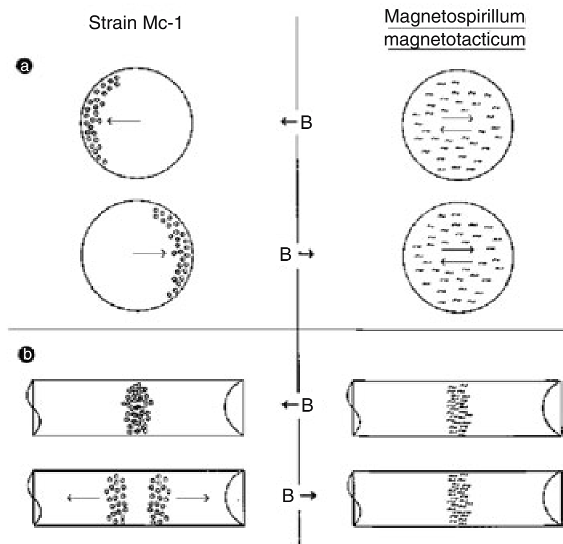

Fig. 3. Two types of magnetotaxis. (a) Depictions of the polar magnetotactic behavior of strain MC-1 and axial magnetotactic behavior of *Magnetospirillum magnetotacticum* in water drops under oxic conditions on a microscope slide (B, magnetic field; arrow points northward). Cells of strain MC-1 swim persistently parallel to B (North-seeking motility) and accumulate at the edge of the drop. When B is reversed, cells continue to swim parallel to B (North-seeking motility) and accumulate at the other side of the drop. Cells of *M. magnetotacticum* swim in either direction relative to B and continue to do so when the field is reversed. (b) Illustrations of aerotactic bands of strain MC-1 and *M. magnetotacticum* in flat capillaries. The right ends of the capillaries are open to air and the left ends are sealed. After reversal of B, cells of strain MC-1 rotate 180° and the band separates into groups of cells swimming in opposite directions along B, away from the position of the band before the reversal. A second reversal results in the reformation of a single band. Cells of *M. magnetotacticum* also rotate 180° but the band of cells remains intact. Figure adapted from Frankel et al. (1997).

tubes are open, diffusion of oxygen into the ends of the tubes creates an oxygen gradient at each end of the tube, oriented in opposite directions. Polar magnetotactic bacteria incubated in a magnetic field oriented along the long axis of the tube form an aerotactic band at only one end of the tube, whereas axial magnetotactic bacteria form bands at both ends of the tube. Thus for polar magnetotactic bacteria the magnetic field provides an axis and direction for motility, whereas for axial magnetotactic bacteria the magnetic field only provides an axis of motility, pointing to different magneto-aerotactic mechanisms occurring in two types of bacteria.

Axial Magneto-Aerotaxis

Almost all magnetotactic spirilla available in axenic culture and grown in liquid media, exhibit axial magneto-aerotaxis (Figs. 3 and 4). Other bacteria that show axial magnetotaxis are microaerophilic or anaerobic chemoheterotrophs, or facultative chemolithoautotrophic bacteria that are either monopolarly or bipolarly flagellated. In most habitats, axial magnetotactic bacteria appear to represent only a very small fraction of the total count of magnetotactic bacteria, although these organisms are harder to detect in wet mounts using a microscope. Cells representing this type of magnetotaxis were referred to as two-way swimmers because in a homogeneous medium they swim in either direction along the magnetic field, B (Fig. 4). In the presence of an oxygen gradient, cells swim parallel or antiparallel to B with aerotaxis determining the direction of migration. Therefore, an aerotactic band of cells forms at both ends of the tube in capillaries where both ends are open, whereas cells displaying a polar magnetotaxis form only one band at the end of the tube corresponding to their magnetic polarity. The aerotactic, axial magnetotactic spirilla appear to use a temporal sensory mechanism for oxygen detection as do most microaerophilic bacteria studied so far (Frankel et al., 1998). Changes in oxygen concentration measured during swimming determine the sense of flagellar rotation. Cells moving away from the optimal oxygen concentration consequently reverse their swimming direction. In this model, changes in oxygen concentration are measured within short intervals implying that these bacteria must be actively motile in order to quickly measure and respond to concentration gradients in their habitat. The combination of a passive alignment along geomagnetic field lines with an active, temporal, aerotactic response provides the organism with an efficient mechanism to find the microoxic or suboxic zone in its habitat. Therefore the term magneto-aerotaxis is also an appropriate descriptive term for this tactic behavior.

Fig. 4. Sequence showing magnetotactic spirilla displaying axial magnetotaxis. For the video, see the online version of *The Prokaryotes*.

Polar Magneto-Aerotaxis

The large majority of naturally-occurring magnetotactic bacteria display polar magnetotaxis (Figs. 3 and 5). The following mechanism for polar magnetotaxis was proposed based on experimental data obtained with an axenic culture of a marine magnetotactic coccus. It was demonstrated that these cocci can swim in both directions along a static magnetic field, B, without the need of turning around by reversing the sense of flagellar rotation. It seems that a two-state sensory mechanism determines the sense of flagella rotation leading to parallel or antiparallel swimming along the geomagnetic field lines.

Under higher than optimal oxygen tensions, the cell is presumably in an "oxidized state" and swims persistently parallel to B (Fig. 5), i.e., downward in the Northern hemisphere. Under reducing conditions or suboptimal oxygen concentrations, the cell switches to a second state, the "reduced state", which leads to a reversal of the flagellar rotation and to a swimming antiparallel to B (upward in the Northern hemisphere). This two-state sensing mechanism results in an efficient aerotactic response, provided that the oxygen-gradient is oriented correctly relative to B, so that the cell is guided in the right direction to find either reducing or oxidizing conditions. This is especially important because adaptation, which would lead to a spontaneous reversal of the swimming direction, was never observed in controlled experiments with the cocci. The redox sensor, which controls this two-state response, might be similar to the FNR (fumarate and nitrate reduction) transcription factor found in *Escherichia coli* and other bacteria. The FNR factor is sensitive to oxygen and activates gene expression in the reduced state thereby promoting the switch between aerobiosis and anaerobiosis in *E. coli* (De Graef et al., 1999). The sensory mechanism in the examined magnetotactic cocci is not only affected by oxygen. Cells exposed to light of short wavelengths (=500 nm) also showed a response similar to a switch to the "oxidized state" (Frankel et al., 1997).

Fig. 5. Sequence showing magnetotactic cocci displaying polar magnetotaxis. For the video, see the online version of *The Prokaryotes*.

Revised Model of Magnetotaxis

Based on these observations, we would like to extend the current model of a magnetically-guided aerotaxis (magneto-aerotaxis) to a more complex redoxtaxis. In this case, the unidirectional movement of magnetotactic bacteria in a drop of water would be only one aspect of a sophisticated redox-controlled response. One hint for the possible function of polar magnetotaxis could be that most of the representative microorganisms are characterized by possessing either large sulfur inclusions or magnetosomes consisting of iron-sulfides. Therefore, it may be speculated that the metabolism of these bacteria, being either chemolithoautotrophic or mixotrophic, is strongly dependent on the uptake of reduced sulfur compounds which occurs in many habitats only in deeper regions at or below the OATZ due to the rapid chemical oxidation of these reduced chemical species by oxygen or other oxidants in the upper layers. To overcome the problem of separated pools of electron donor and acceptor, several strategies have been developed by sulfide-oxidizing bacteria. Microorganisms belonging to the genus *Thioploca*, for example, use nitrate, which is stored intracellularly (most of the internal space of the cell is vacuolar) to oxidize sulfide and have developed vertical sheaths in which bundles of motile filaments are located. It is assumed that *Thioploca* uses these sheaths to efficiently move in a vertical direction in the sediment, thereby accumulating sulfide in deeper layers and nitrate in upper layers (Huettel et al., 1996). For some magnetotactic bacteria, it might also be necessary to perform excursions to anoxic zones of their habitat in order to accumulate reduced sulfur compounds. In our model, shown in Fig. 6, we propose that polar magnetotaxis helps to guide bacteria, depending on their internal redox-state, either downward to accumulate reduced sulfur species or upward to oxidize stored sulfur with oxygen. Thus, we hypothesize that magnetotactic bacteria displaying polar magnetotaxis alternate between two internal redox states. The "oxidized state" would result from the almost complete consumption of stored sulfur, the assumed electron donor. In this state, cells seek deeper anoxic layers where they could replenish the depleted stock of electron donor using nitrate or other compounds as alternative electron acceptor. Finally, they would reach a "reduced state." According to our model, cells in this redox state would have accumulated a large amount of sulfur which cannot be efficiently oxidized under anaerobic conditions leading to a surplus of reduction equivalents. Therefore, cells must return to the microoxic zone where oxygen is available to them as an electron acceptor. In addition, oxygen may be necessary for the synthesis of magnetosomes in some bacteria (Blakemore et al., 1985). The advantage of polar magnetotaxis is that an oxygen gradient is not necessary for efficient orientation in the anoxic zone, thereby enabling a rapid return of the cell along large distances to the preferred microoxic conditions. A further benefit would be that cells avoid the waste of energy by constant movement along gradients, but instead can attach to particles in preferred microniches until they reach an unfavorable internal redox state that triggers a magnetotactic response either parallel or antiparallel to the geomagnetic field lines. In any case, greater than optimal concentrations of oxygen would switch cells immediately to an "oxidized state" provoking the typical down-seeking response of magnetotactic bacteria visible under the microscope. The observation of significant numbers of microaerophilic, magnetotactic bacteria in the anoxic zone of some sediments and the attachment of "*Magnetobacterium bavaricum*" to sediment particles in

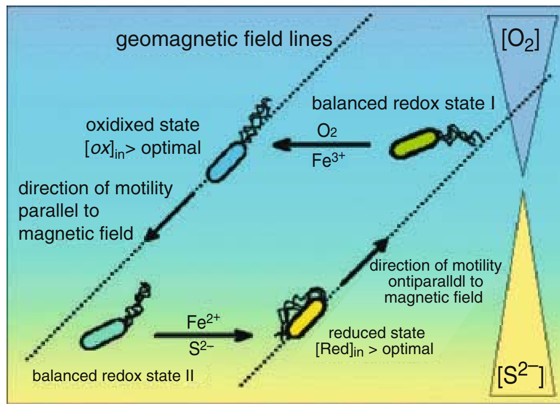

Fig. 6. Hypothetical model of the function of polar magnetotaxis in bacteria (Northern hemisphere). Cells are guided along the geomagnetic field lines depending on their "redox-state" either downward to the sulfide-rich zone or upward to the microoxic zone, thereby enabling a shuttling between different redox layers.

microcolony-like aggregates, fits well with this model, which is summarized in the following Fig. 6.

Morphologic and Phylogenetic Diversity

Morphotypes

The diversity of magnetotactic bacteria is reflected by the high number of different morphotypes found in environmental samples of water or sediment. Commonly observed morphotypes include coccoid to ovoid cells, rods, vibrios and spirilla of various dimensions. One of the more unique morphotypes is an apparently multicellular bacterium referred to as the MMP many-celled magnetotactic prokaryote.

Regardless of their morphology, all magnetotactic bacteria studied so far are motile by means of flagella and have a cell wall structure characteristic of Gram-negative bacteria. The arrangement of flagella differs and can be either polar, bipolar, or in tufts. Another trait which shows considerable diversity is the arrangement of magnetosomes inside the bacterial cell. In the majority of magnetotactic bacteria, the magnetosomes are aligned in chains of various lengths and numbers along the cell's long axis of the cell, which is magnetically the most efficient orientation. However, dispersed aggregates or clusters of magnetosomes occur in some magnetotactic bacteria usually at one side of the cell, which often corresponds to the site of flagellar insertion. Besides magnetosomes, large inclusion bodies containing elemental sulfur, polyphosphate, or poly-β-hydroxybutyrate are common in magnetotactic bacteria collected from the natural environment and in pure culture.

The most abundant type of magnetotactic bacteria occurring in environmental samples, especially sediments, are coccoid cells possessing two flagellar bundles on one somewhat flattened side. This bilophotrichous type of flagellation gave rise to the tentative genus "*Bilophococcus*" for these bacteria (Moench, 1988). One representative strain of this morphotype is in axenic culture (see Other Magnetotactic Strains in Pure Culture in this Chapter). In contrast, two of the morphologically more conspicuous magnetotactic bacteria, regularly observed in natural samples but never isolated in pure culture, are the MMP and a large rod containing large numbers of hook-shaped magnetosomes ("*Candidatus Magnetobacterium bavaricum*").

The MMP, a Many-Celled Magnetotactic Prokaryote A magnetotactic aggregation of cells that swims as an entire unit and not as separate cells was first reported and described by Farina et al. (1983). Similar morphotypes were later found also in sulfide-rich marine and brackish waters and in sediments along the coasts of North America and Europe (Mann et al., 1990a). The MMP (for many-celled magnetotactic prokaryote) consists of about 10 to 30 coccoid to ovoid Gram-negative cells, roughly arranged in a sphere with a diameter ranging from approximately 3 to 12 µm (Fig. 7).

Cells are asymmetrically multiflagellated on their outer surfaces exposed to the external surroundings. Magnetosomes consist of the magnetic iron-sulfide greigite, Fe_3S_4, and several nonmagnetic precursors to greigite (see "Iron-Sulfide Type Magnetosomes"). The magnetosome crystals are generally pleomorphic although cubo-octahedral, rectangular prismatic, and tooth-shaped particles have also been observed in cells. They are usually loosely arranged in short chains or clusters in individual cells. The total magnetic moment of the MMP was determined and ranges from 5×10^{-16} to 1×10^{-15} Am^2, which is sufficient for an effective magnetotactic response. The type of magnetotaxis displayed by the MMP appears to be polar, but aggregates have been observed to reverse direction. Under oxic conditions in a uniform magnetic field, the swimming speed in the preferred direction averages 105 µm/s. After reaching the edge of a water drop, aggregates sometimes spontaneously reverse their swimming direction and show short excursions of 100 to 500 µm with twice the speed of the forward motion in the opposite direction of their polarity (Rodgers et al., 1990) as shown in Fig. 8. This so

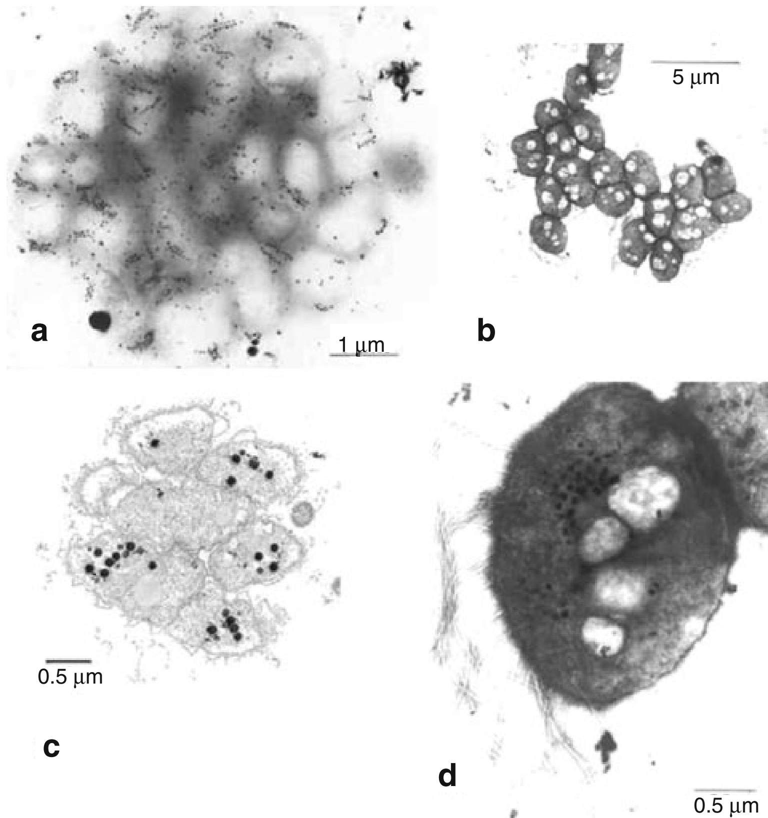

Fig. 7. Brightfield TEM micrographs of the many-celled magnetotactic prokaryote (MMP). (a) An unstained, single MMP revealing the numerous greigite-containing magnetosomes within the organism mostly arranged in short chains. (b) Negatively-stained preparation (2.5% ammonium molybdate, pH 7.0) of a single MMP that is disrupted to reveal separated individual cells. (c) Thin-section of an MMP again showing its many-celled nature. (d) Negatively-stained individual cell of the MMP. Note the asymmetric distribution of flagella which cover the cell on one side, the pleomorphism of the greigite-containing magnetosomes, and the electron-lucent vacuoles resembling poly-β-hydroxybutyrate (PHB) granules.

called "ping pong" motion seems to be a peculiarity of this organism.

Fig. 8. Sequence showing the typical "ping-pong" motility of the MMP. For the video, see the online version of *The Prokaryotes*.

In one study, it was reported that individual cells within the aggregate are connected by intercellular membrane junctions (Rodgers et al., 1990a; 1990b). However, the cohesive force among individual cells seems to be relatively weak because a lowering of the osmotic pressure leads to an immediate disruption of the aggregate into single nonmotile cells.

"*Candidatus Magnetobacterium bavaricum*" The first phenotypic description of this morphotype by Vali et al. (1987) was based on cells collected from material retrieved from the littoral sediments of a large freshwater lake in Southern Germany (Lake Chiemsee). Later, similar bacteria were also found in sediments of other freshwater habitats in Germany and Brazil. After the determination of its phylogenetic relationship (Spring et al., 1993), this organism was given the candidatus status due to its unusual phenotypic traits which distinguish it from all other magnetotactic bacteria. "*Magnetobacterium bavaricum*" displays polar magnetotaxis and is preferentially found in the microoxic zone of sediments, although significant numbers are also found in anoxic regions of their habitat (Fig. 1). In situ hybridizations using a specific fluorescently-labeled oligonucleotide probe targeting the 16S rRNA of this organism enabled the detection of microcolonies of this bacterium on microscope slides immersed into sediment for several weeks (Fig. 9). Thus, there appears to be a tendency for "*Magnetobacterium bavaricum*" to adhere to particles located in microsites with preferred environmental conditions.

Cells of "*M. bavaricum*" are large rods having dimensions of 1–1.5 x 6–9 μm and are motile by a polar tuft of flagella. The most impressive trait of this bacterium is the extremely high number of magnetosomes per cell. A single cell may contain up to a thousand hook-shaped magnetosomes usually arranged in 3–5 rope-shaped bundles oriented parallel to the long axis of the cell (Fig. 10).

The magnetosomes consist of magnetite (Fe_3O_4) and have a length of 110–150 nm. The average total magnetic moment per cell was experimentally determined to be approximately 3×10^{-14} Am^2, which is about an order of magnitude higher than that of most other magnetotactic bacteria. The presence of large sulfur inclusions is typical for this bacterium and seems

to be dependent on environmental conditions. In an unidirectional magnetic field, cells swim forward (i.e., northward in the Northern Hemisphere) with an average speed of 40 μm/s with the flagella wound around the rotating cell. Gradients of some chemical substances lead to a reversal of the sense of flagellar rotation resulting in a swimming in the opposite direction for a short time.

Composition and Structure of Magnetosome Crystals

The magnetosome mineral phase in magnetotactic bacteria are tens-of-nanometer-sized crystals of an iron oxide and/or an iron sulfide. The mineral composition of the magnetosome is specific enough for it to be likely under genetic control, in that cells of several cultured magnetite-producing magnetotactic bacteria still synthesize an iron oxide and not an iron sulfide, even when hydrogen sulfide is present in the growth medium

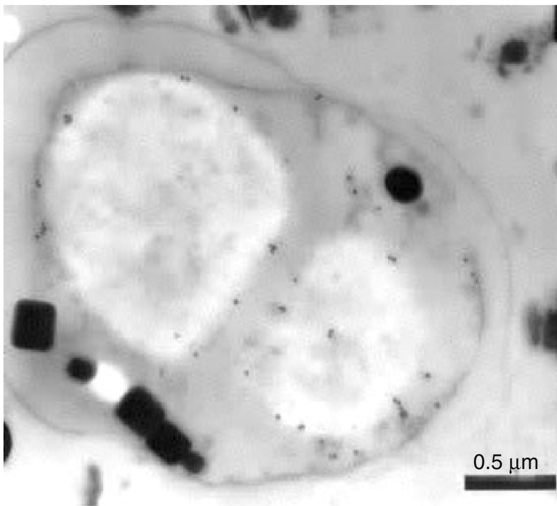

Fig. 11. Unusually large magnetite crystals identified in coccoid magnetotactic bacteria retrieved from a lagoon near Rio de Janeiro, Brazil. Small black dots represent gold-labeled antibodies detecting a specifically bound polynucleotide probe complementary to a highly variable region of the 16S rRNA of these cells.

(Meldrum et al., 1993a; Meldrum et al., 1993b). The size of the magnetosome mineral crystals also appears to be under control of the organism because the large majority of magnetotactic bacteria contain crystals displaying only a very narrow size range, from about 35 to 120 nm (Frankel et al., 1998). Magnetite and greigite particles in this range are stable single magnetic domains (Butler and Banerjee, 1975; Diaz-Rizzi and Kirschvink, 1992). Smaller particles would be superparamagnetic at ambient temperature and would not have stable, remanent magnetization. Larger particles would tend to form multiple domains, reducing the remanent magnetization. However, in some uncultured bacteria from the Southern Hemisphere exceptionally large magnetite-magnetosomes have been observed in some uncultured bacteria from the Southern hemisphere (Fig. 11), having dimensions well above the theoretically determined size limits of single domain magnetite (Spring et al., 1998). It remains unclear if the crystals in these bacteria are still of single-domain size or are multi-domain particles and why such unusually large crystals are formed by certain bacteria, but, interestingly, it seems that the crystal-size corresponds with the size and/or the growth phase of these bacteria, i.e., large cells possess larger crystals than smaller cells of the same type.

In contrast to chemically synthesized magnetite and greigite crystals, biologically produced magnetosome mineral particles display a range of well-defined morphologies which can be classified as distinct idealized types (Fig. 12).

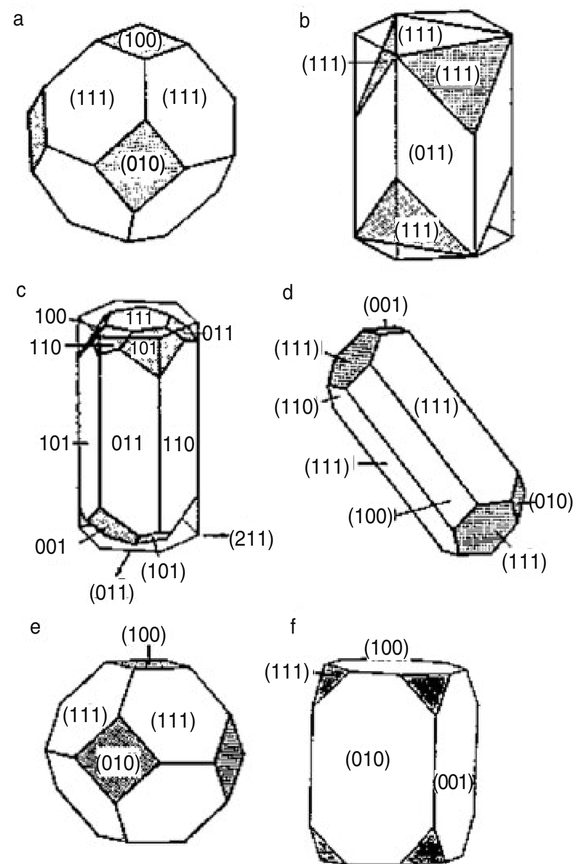

Fig. 12. Idealized magnetite (a–d) and greigite (e–f) crystal morphologies derived from high resolution TEM studies of magnetosome crystals from magnetotactic bacteria: (a) and (e) cubo-octahedrons; (b), (c), and (f) variations of pseudo-hexagonal prisms; (d) elongated cubo-octahedron. Numbers within parentheses refer to the faces of the crystal lattice planes on the surface of the crystal. Figure adapted from Heywood et al. (1991) and Mann and Frankel (1989).

The consistent narrow size range (Devouard et al., 1998) and morphologies of the intracellular magnetosome particles represent typical features of a biologically controlled mineralization and are clear indications that the magnetotactic bacteria exert a high degree of control over the biomineralization processes involved in magnetosome synthesis.

Magnetite-Type Magnetosomes The iron oxide-type magnetosomes consist solely of magnetite, Fe_3O_4. The particle morphology of the magnetite crystals in magnetotactic bacteria varies but is extraordinarily consistent within cells of a single bacterial species or strain (Bazylinski et al., 1994). Three general morphologies of magnetite particles have been observed in magnetotactic bacteria using transmission electron microscopy (TEM; Blakemore et al., 1989; Mann et al.,

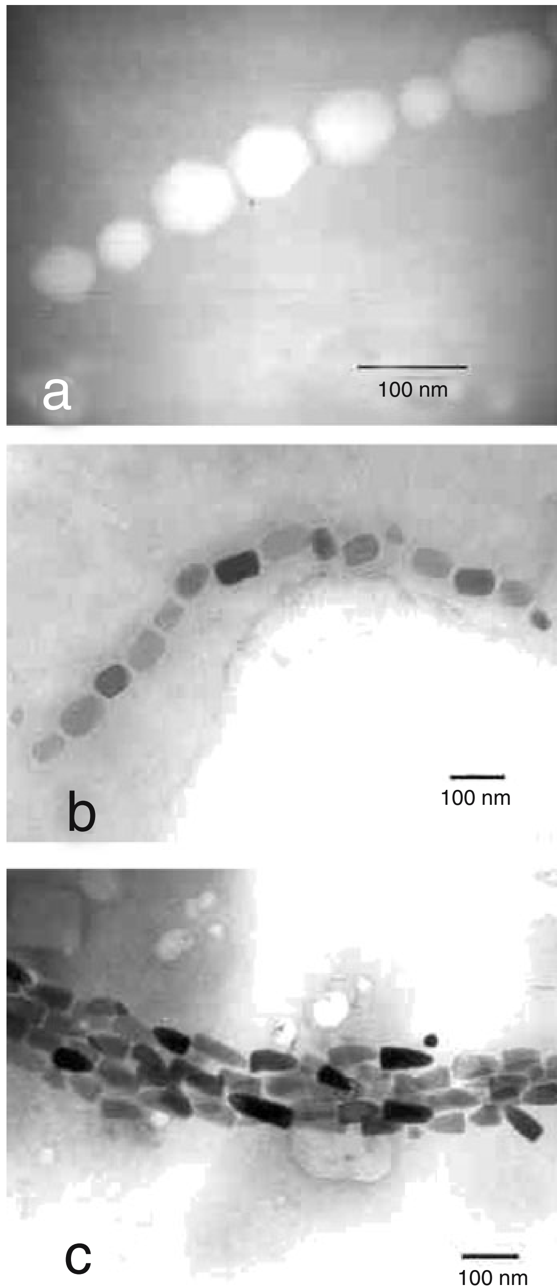

Fig. 13. Morphologies of intracellular magnetite (Fe_3O_4) particles produced by magnetotactic bacteria. (a) Darkfield scanning-transmission electron microscope (STEM) image of a chain of cubo-octahedra in cells of an unidentified rod-shaped bacterium collected from the Pettaquamscutt Estuary, Rhode Island, USA, viewed along a [111] zone axis for which the particle projections appear hexagonal. (b) Brightfield TEM image of a chain of prismatic crystals within a cell of strain MV-2, a marine vibrio, with parallelepipedal projections. (c) Brightfield TEM image of tooth-shaped (anisotropic) magnetosomes from an unidentified rod-shaped bacterium collected from the Pettaquamscutt Estuary.

1990a; Stolz, 1993; Bazylinski et al., 1994). They include: 1) roughly cuboidal (Balkwill et al., 1980; Mann et al., 1984); 2) parallelepipedal (rectangular in the horizontal plane of projection; Moench and Konetzka, 1978; Towe and Moench, 1981; Moench, 1988; Bazylinski et al., 1988); and 3) tooth-, bullet-, or arrowhead-shaped (anisotropic; Mann et al., 1987a; Mann et al., 1987b; Thornhill et al., 1994).

High resolution TEM and selected area electron diffraction studies have revealed that the magnetite particles within magnetotactic bacteria are of relatively high structural perfection and have been used to determine their idealized morphologies (Matsuda et al., 1983; Mann et al., 1984a; 1984b; 1987a; 1987b; Meldrum et al., 1993a; Meldrum et al., 1993b). These morphologies are all derived from combinations of {111}, {110} and {100} forms (a form refers to the equivalent symmetry related lattice planes of the crystal structure) with suitable distortions (Devouard et al., 1998). The roughly cuboidal particles are cubo-octahedra ([100] + [111]), and the parallelepipedal particles are either pseudohexahedral or pseudooctahedral prisms. Examples are shown in Fig. 12a–d. The cubo-octahedral crystal morphology preserves the symmetry of the face-centered cubic spinel structure, i.e., all equivalent crystal faces develop equally. The pseudo-hexahedral and pseudo-octahedral prismatic particles represent anisotropic growth in which equivalent faces develop unequally (Mann and Frankel, 1989; Devouard et al., 1998). The synthesis of the tooth-, bullet- and arrowhead-shaped magnetite particles (Figs. 10b, 13c) appears to be more complex than that of the other forms. They have been examined by high resolution TEM in one uncultured organism (Mann et al., 1987a; Mann et al., 1987b) and their idealized morphology suggests that growth of these particles occurs in two stages. The nascent crystals are cubo-octahedra which subsequently elongate along the [111] axis parallel to the chain direction.

Whereas the cubo-octahedral form of magnetite can occur in inorganically-formed magnetites (Palache, 1944), the prevalence of elongated pseudohexahedral or pseudo-octahedral habits in magnetosome crystals imply anisotropic growth conditions, e.g., a temperature gradient, a chemical concentration gradient, or an anisotropic ion flux (Mann and Frankel, 1989). This aspect of magnetosome particle morphology has been used to distinguish magnetosome magnetite from detrital or magnetite produced by biologically induced mineralization (by the anaerobic iron-reducing bacteria), using electron microscopy of magnetic extracts from sediments (e.g., Petersen et al., 1986; Chang and Kirschvink, 1989a; Chang et al., 1989b; Stolz et al., 1986; Stolz et al., 1990; Stolz, 1993).

Iron-Sulfide Type Magnetosomes Virtually all freshwater magnetotactic bacteria have been found to synthesize magnetite as the mineral phase of their magnetosomes. In contrast, many marine, estuarine, and salt marsh species produce iron sulfide-type magnetosomes consisting primarily of the magnetic iron sulfide, greigite, Fe_3S_4 (Heywood et al., 1990; Heywood et al., 1991; Mann et al., 1990b; Pósfai et al., 1998a; 1998b). Reports of non-magnetic iron pyrite (FeS_2; Mann et al., 1990b) and magnetic pyrrhotite (Fe_7S_8; Farina et al., 1990) have not been confirmed and may represent misidentifications of additional iron sulfide species occasionally observed with greigite in cells (Pósfai et al., 1998a; Pósfai et al., 1998b). Currently recognized greigite-producing magnetotactic bacteria includes the MMP (Farina et al., 1983; Rodgers et al., 1990a; 1990b; DeLong et al., 1993) and a variety of relatively large, rod-shaped bacteria (Bazylinski et al., 1990; Bazylinski et al., 1993a; Heywood et al., 1990; Heywood et al., 1991; Bazylinski and Frankel, 1992).

The iron sulfide-type magnetosomes contain either particles of greigite (Heywood et al., 1990; Heywood et al., 1991) or a mixture of greigite and transient non-magnetic iron sulfide phases that appear to represent mineral precursors to greigite (Pósfai et al., 1998a; Pósfai et al., 1998b). These phases include mackinawite (tetragonal FeS) and possibly a sphalerite-type cubic FeS (Pósfai et al., 1998a; Pósfai et al., 1998b). Based on TEM observations, electron diffraction, and known iron sulfide chemistry (Berner, 1967; Berner, 1970; Berner, 1974), the reaction scheme for greigite formation in the magnetotactic bacteria appears to be: cubic FeS $\rightarrow$ mackinawite (tetragonal FeS) $\rightarrow$ greigite (Fe_3S_4; Pósfai et al., 1998a; Pósfai et al., 1998b).

The de novo synthesis of non-magnetic crystalline iron sulfide precursors to greigite aligned along the magnetosome chain indicates that chain formation within the cell does not involve magnetic interactions. Interestingly, under the strongly reducing, sulfidic conditions at neutral pH in which the greigite-producing magnetotactic bacteria are found (Bazylinski et al., 1990; Bazylinski and Frankel, 1992), greigite particles would be expected to transform into pyrite (Berner, 1967; Berner, 1970) which has not been unequivocally identified in magnetotactic bacteria. It is not known if and how cells prevent this transformation.

As with magnetite, three particle morphologies of greigite have been observed in magnetotactic bacteria (Fig. 14): 1) cubo-octahedral (the equilibrium form of face-centered cubic greigite) (Heywood et al., 1990; Heywood et al., 1991); 2) pseudo-rectangular prismatic as shown in Fig. 14 and 12e–f (Heywood et al., 1990; Heywood et al.,

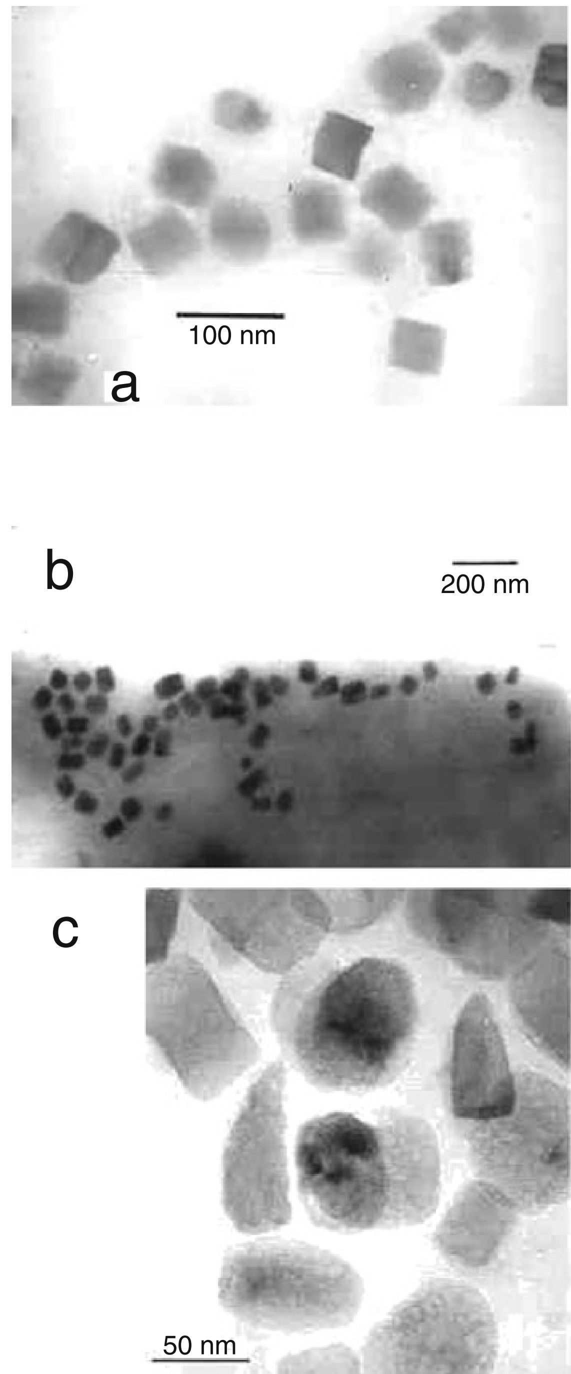

Fig. 14. Morphologies of intracellular greigite (Fe_3S_4) particles produced by magnetotactic bacteria. (a) Brightfield STEM image of cubo-octahedra in an unidentified rod-shaped bacterium collected from the Neponset River estuary, Massachusetts, USA. (b) Brightfield STEM image of rectangular prismatic particles in an unidentified rod-shaped bacterium collected from the Neponset River estuary, Massachusetts, USA. (c) Brightfield TEM image of tooth-shaped and rectangular prismatic particles from the many-celled magnetotactic prokaryote (MMP), courtesy of M. Pósfai and P. R. Buseck.

1991); and 3) tooth-shaped (Pósfai et al., 1998a; Pósfai et al., 1998b).

Like that of their magnetite counterparts, the morphology of the greigite particles also appears to be species- and/or strain-specific, although confirmation of this observation will require controlled studies of pure cultures of greigite-producing magnetotactic bacteria, none of which is currently available. One clear exception to this rule is the MMP (Farina et al., 1983; Bazylinski et al., 1990; Bazylinski et al., 1993a; Mann et al., 1990b; Rodgers et al., 1990a; 1990b; Bazylinski and Frankel, 1992). This unusual microorganism, found in salt marsh pools all over the world and some deep sea sediments, has been found to contain pleomorphic, pseudorectangular prismatic, tooth-shaped, and cubo-octahedral greigite particles. Some of these particle morphologies are shown in Fig. 7 and 14c. Therefore the biomineralization process(es) appear(s) to be more complicated in this organism than in the rods with greigite-containing magnetosomes or in magnetite-producing, magnetotactic bacteria.

Magnetite and Greigite Crystals in a Single Bacterium One slow-swimming, rod-shaped bacterium, collected from the OATZ from the Pettaquamscutt Estuary, was found to contain arrowhead-shaped crystals of magnetite and rectangular prismatic crystals of greigite co-organized within the same chains of magnetosomes (this organism usually contains two parallel chains of magnetosomes) (Bazylinski et al., 1993b; Bazylinski et al., 1995). In cells of this uncultured organism, the magnetite and greigite crystals occur with different, mineral-specific morphologies and sizes and are positioned with their long axes oriented along the chain direction. Both particle morphologies have been found in organisms with single mineral component chains (Mann et al., 1987a; Mann et al., 1987b; Heywood et al., 1990; Heywood et al., 1991), which suggests that the magnetosome membranes surrounding the magnetite and greigite particles contain different nucleation templates and that there are differences in magnetosome vesicle biosynthesis. Thus, it seems likely that two separate sets of genes control the biomineralization of magnetite and greigite in this organism.

Phylogeny

The phylogeny of many morphotypes of magnetotactic bacteria, including both those in pure culture and those collected from natural environments, has been determined by sequencing their 16S rRNA genes. To date, representatives of the magnetotactic prokaryotes are phylogenetically associated with three major lineages within the Bacteria. Although most are located within the *Proteobacteria*, "*Magnetobacterium bavaricum*" is affiliated with another phylum, the newly designated *Nitrospira* group. Those within the *Proteobacteria* are distributed among the delta- and alpha-subclasses. The uncultured greigite-producing, MMP and the magnetite-producing, sulfate-reducing magnetotactic bacterium RS-1, which is available in pure culture, are located in the delta-subclass, whereas members of the genus *Magnetospirillum* and various vibrios and coccoid magnetotactic bacteria, all of which produce magnetite, belong to the alpha-subclass (Fig. 15). Although these results suggest that the trait of magnetotaxis in bacteria has multiple evolutionary origins (DeLong et al., 1993), it is also possible that the ability of magnetosome

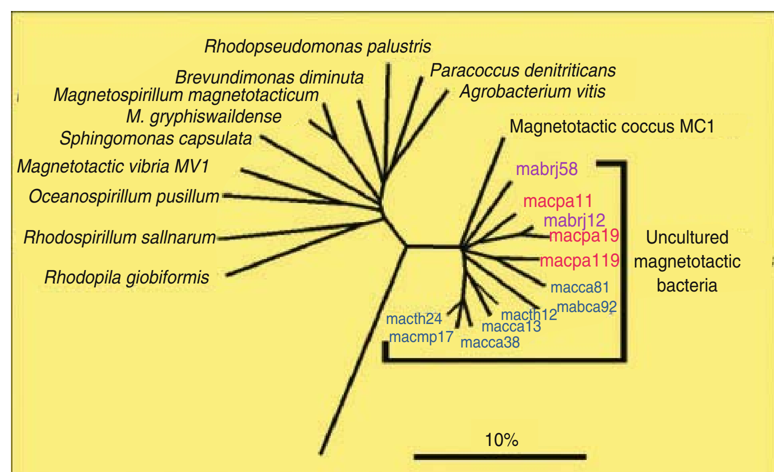

Fig. 15. Phylogenetic tree based on 16S rRNA sequences showing the positions of cultured and uncultured magnetotactic bacteria within the alpha-subclass of *Proteobacteria*. Sequences of uncultured magnetotactic bacteria retrieved from freshwater habitats are in blue, from marine habitats in red, and from a lagoon in pink.

formation was spread among various phylogenetic groups of bacteria and even eukaryotes by lateral gene transfer.

To date, most of the 16S rRNA sequences of magnetotactic bacteria retrieved from environmental samples form a deep-branching group within the alpha-subclass (Fig. 15). This phylogenetic assemblage consists (up to now) exclusively of bacteria displaying magnetotaxis. Similarity values of 16S rRNA sequences within this monophyletic group of magnetotactic bacteria range from 88.0 to 99.3%. Using in situ hybridization with fluorescently-labeled oligonucleotide probes, it was demonstrated that members of this coherent phylogenetic cluster represent the dominant fraction of magnetotactic bacteria in many environments like lagoons, marine and freshwater sediments (Spring et al., 1992; Spring et al., 1994; Spring et al., 1998). Magnetotactic bacterial morphotypes in this group, as evidenced by in situ hybridization, are mainly represented by coccoid to ovoid bacteria, but also include one rod- to vibrio-shaped bacterium (mabcs92; Fig. 15). Despite continuous effort in several laboratories, most members of this group have resisted attempts (in several laboratories) at isolation to axenic culture. One major reason may be their adaptation to and requirement for gradient systems not easily replicated in synthetic growth media. The only exception is the marine magnetotactic coccus strain MC-1, which can be cultivated in a synthetic oxygen gradient medium.

Cultivation and Physiology

The Genus *Magnetospirillum*

TAXONOMY Magnetospirilla are found in freshwater habitats where they usually occur in low numbers as, for example, compared with the magnetotactic cocci. These clockwise spirilla have dimensions of 0.2–0.7 by 1–20 μm and display an axial magneto-aerotaxis, at least when grown in liquid culture. The genus *Magnetospirillum* currently comprises the two validly described species, *M. magnetotacticum* and *M. gryphiswaldense*, and several partially characterized strains. *M. magnetotacticum* was the first magnetotactic bacterium isolated and grown in pure culture and was originally assigned to the genus *Aquaspirillum* based on a number of phenotypic characteristics (Maratea and Blakemore, 1981). At that time, this genus contained a large number of phylogenetically diverse, nonphototrophic, freshwater spirilla with the type species *A. serpens* phylogenetically located among the beta-subclass of the *Proteobacteria*. Phylogenetic analyses of *Magnetospirillum* strains later revealed that they all belong to a phylogenetic branch within the alpha-subclass of the *Proteobacteria* and are closely related to phototrophic spirilla of the genus Phaeospirillum (Fig. 15; Burgess et al., 1993; Schüler et al., 1999). Therefore, it was justified to propose the new genus *Magnetospirillum* for these strains (Schleifer et al., 1991). Members of this genus can be distinguished from other freshwater spirilla by their ability to produce membrane-enveloped cubo-octahedral magnetite crystals, averaging about 42 nm in diameter (Balkwill et al., 1980; Schleifer et al., 1991), arranged in a single chain within the cell. Other characteristic traits of members of this genus include bipolar monotrichous flagellation and a preference for microoxic growth conditions. Several strains of magnetospirilla can grow also anaerobically with nitrate as terminal electron acceptor or aerobically with atmospheric concentrations of oxygen. Magnetite synthesis appears to only occur under microaerobic conditions in most species while *Magnetospirillum* strain AMB-1 appears to synthesize magnetite under anaerobic conditions as well (Matsunaga and Tsujimura, 1993). Preferred substrates are intermediates of the tricarboxylic acid cycle and acetate. Carbohydrates are not utilized. Catalase and oxidase may be present or not. The guanine-plus-cytosine content of DNA ranges from 64 to 71 mol% (Burgess et al., 1993).

BIOCHEMISTRY AND MOLECULAR BIOLOGY OF MAGNETOSOME FORMATION There has been much interest in the elucidation of magnetosome formation because the crystals synthesized by magnetotactic bacteria are of great structural perfection, have consistent particle morphologies and narrow size distributions, possible indications that the particles may have novel magnetic, physical and/or electrical properties. Understanding the factors controlling the biomineralization of iron in magnetosome synthesis within bacteria could also be helpful for the elucidation of similar processes in animals and man or for the artificial synthesis of biominerals. Despite the dedicated and elaborate efforts in studying magnetosome synthesis in bacteria, published results are rather sparse. This is partly due to the lack of a significant number of magnetotactic bacteria strains and the difficulty in culturing them reproducibly in the laboratory, which would be a prerequisite for the establishing of biochemical or genetic model systems. Nevertheless, some interesting results have been obtained using the few available, but fastidious *Magnetospirillum* strains.

In general, the bacterial magnetite synthesis can be divided into three steps. Initially, extracellular iron has to be transported across the cell wall to the inside of the cell. Once within the cell, iron must accumulate in specialized compart-

ments, the magnetosome vesicles. There, the iron presumably precipitates and transforms or grows into a single-magnetic-domain magnetite crystal with a specific morphology. It is assumed that the membrane vesicle is synthesized prior to the precipitation of iron but since there is currently little evidence to support this idea, it is possible that the precipitation of iron and crystal nucleation occurs first and the magnetosome membrane then forms around the growing crystal. The uptake of iron from the surrounding environment by cells of *Magnetospirillum* strains has been analyzed by several groups (Paoletti and Blakemore, 1986; Nakamura et al., 1993b; Schüler and Baeuerlein, 1996; Schüler and Baeuerlein, 1998). Generally, the results suggest that iron is taken up by the cell in the ferric form and transported across the membrane by an energy-dependent reductive process. Iron-binding siderophores were thought to be involved in iron uptake by *M. magnetotacticum* (Paoletti and Blakemore, 1986), which appeared to produce a hydroxamate siderophore under high, but not low, iron conditions. However, this finding was never confirmed by other laboratories. Spent culture fluid stimulates the uptake of ferric iron in *M. gryphiswaldense* although there was no evidence for the production of a siderophore by this species. This stimulation may be due to the production of unknown compounds, produced by cells during growth, which mediate iron uptake by an unrecognized novel mechanism (Schüler and Baeuerlein, 1996). In this respect, it is noteworthy that most magnetotactic bacteria are adapted to microenvironments, like the oxic-anoxic transition zone of sediments, where soluble iron is available to the cell in sufficient quantities for magnetite synthesis (generally about 10–20 μM iron; Blakemore et al., 1979). Thus, magnetotactic bacteria probably have no need for high-affinity transport systems like many other aerobic bacteria growing under iron deficient conditions. This is consistent with experiments performed with cells of *M. gryphiswaldense*. Under iron deficient conditions, cells of *M. gryphiswaldense* do not or cannot distinguish between the use of incorporated iron either as a cofactor for cellular proteins or for magnetite synthesis and store this essential element as an inorganic mineral, magnetite, at the expense of their own growth (Schüler and Baeuerlein, 1996). The marine magnetotactic vibrio, strain MV-1, behaves similarly.

The fate of iron taken up by cells was studied by Frankel et al. (1983) in *M. magnetotacticum* using Fe^{57} Moessbauer spectroscopy. It was proposed that the ferrous iron taken up by cells is immediately reoxidized to form a low-density hydrous Fe(III) oxide. It is not yet clear if this step takes place in the cytoplasm or in the magnetosome vesicles. How iron is transported from the cell membrane into the magnetosome vesicle is also not known. Iron is precipitated within the magnetosome vesicle presumably through a dehydration step as ferrihydrite (a high-density Fe(III) hydroxide). Finally, magnetite (Fe_3O_4) is produced by the reduction of one-third of the Fe(III) ions in ferrihydrite and further dehydration steps. The crystallization process(es) involved in magnetite formation is apparently linked closely to the magnetosome membrane and may be controlled by specific proteins present in this membrane. The chemical transformation of amorphous Fe(III) precursors to crystalline magnetite is sensitive to environmental conditions like ion concentration, pH and redox potential (Mann et al., 1990c) which have to be therefore precisely regulated by the magnetosome membrane or by conditions within the magnetosome membrane vesicle. Growth of the magnetite crystal, i.e., its orientation, shape and size, must also be under strict control because these characteristics are specific for one strain and/or species of bacteria and to a great extent independent from the growth conditions (Bazylinski et al., 1994).

Because the magnetosome membrane seems to play a key role in the synthesis of magnetite crystals, its structure and composition has been analyzed in several studies. By analyzing the magnetosome membrane in this way, some clues relating to how magnetite biomineralization occurs within the cell may be found. Gorby et al. (1988) showed that the magnetosome membrane in *M. magnetotacticum* has an architecture similar to that of the cytoplasmic membrane and consists of a lipid bilayer and numerous proteins, some of which appear to be unique to the magnetosome membrane. Okuda et al. (1996) found three proteins with molecular weights of 12, 22 and 28 kDa, specifically associated with the magnetosome membrane in *M. magnetotacticum*. They successfully identified and sequenced the gene encoding for the 22 kDa protein, which was found to belong to a family of protein import receptors common in mitochondria and peroxisomes. The role of this protein in magnetosome synthesis remains unclear however. A gene likely involved in magnetite synthesis was identified and characterized by Matsunaga et al. (1992). They used a genetic approach using the microorganism *Magnetospirillum* strain AMB-1, which forms colonies of magnetite-forming cells on agar surfaces, thereby facilitating the screening for nonmagnetic mutants. The gene, designated *magA*, encodes for a membrane protein showing sequence similarities to some cation efflux proteins. Based on experiments with the recombinant protein, it was proposed that the MagA

protein plays a role in the energy-dependent transport of iron across membranes.

ENRICHMENT AND ISOLATION Magnetotactic spirilla have been repeatedly isolated from various freshwater habitats, so that it is possible to give some guidelines for their succesful enrichment and isolation.

Several morphotypes of magnetotactic bacteria can be enriched in the laboratory by putting mud and overlying water from a sampling site into aquaria or jars, which are loosely covered and stored in dim light. After several days to weeks, the number of magnetotactic bacterial cells generally increases significantly. Magnetotactic spirilla, however, are in most cases not among the dominating morphotypes and therefore are only rarely detected using light microscopy. Consequently, the usefulness of this method for the enrichment of representatives of the genus *Magnetospirillum* remains questionable. To date, no selective growth media are known for the cultivation of magnetotactic spirilla, so that a successful isolation procedure will in most cases depend on the purity of the inoculum. Because of the magnetic dipole moment of these bacteria, physical separation from nonmagnetotactic contaminants is possible. A commonly used method for the separation of magnetotactic bacteria from sediment samples was described by Moench and Konetzka (1978). They concentrated magnetotactic bacterial cells using a bar magnet (e.g., stirring bar) fixed to the outer wall of a jar filled with sediment and water. Directed magnetotactic bacteria eventually accumulate at the side of the jar and become concentrated enough to form (opposite to the magnet) a brownish spot from where they can be transferred into a sterile cap using a Pasteur pipette. The sample containing the concentrated magnetotactic cells still cotains non-magnetotactic bacteria, so that a further purification step is advisable before it is used as an inoculum for growth media. The "capillary racetrack" devised by Spormann and Wolfe (Wolfe et al., 1987) has been successfully used for this purpose (Schüler et al., 1999).

All isolated strains of magnetospirilla, with the possible exception of *Magnetospirillum* strain AMB-1, appear to prefer low oxygen tensions for growth and magnetite synthesis. Thus the creation and maintenance of microoxic conditions in growth media is especially important for the isolation of these organisms starting from small inocula. The growth medium should contain 10–20% of sterilized mud or water from the respective habitat and low concentrations of agar to allow the establishment of a semisolid oxygen gradient. Suitable carbon sources are intermediates of the tricarboxylic acid cycle, e.g., malate or succinate. An oxygen-sulfide gradient medium was successfully used by Schüler et al. (1999) for the effective isolation of magnetotactic spirilla from a freshwater pond. Screw-capped culture tubes are filled with 1 ml of solid sulfide agar (4 mM Na_2S, 1.5% agar, pH 7.4) and overlaid with 10 ml of slush-agar. The slush-agar consists of (per 800 ml deionized water): 200 ml of filtered pond water, 1 ml of vitamin elixir, 2 ml of mineral elixir (Wolin et al., 1963), 0.05 g, sodium succinate, 0.05 g, yeast extract, 0.05 g, NH_4Cl, 0.05 g, $MgSO_4$, 0.5 mM potassium phosphate buffer (pH 7.0); 2 mg of resazurin and 2 g of agar. After adjusting the pH to 7.0 and autoclaving, sterile solutions of ferric citrate and neutralized cysteineHCl are added (final concentrations 10 μM and 0.01%, respectively). The culture tubes can be inoculated after the establishment of sulfide and oxygen gradients within the medium, which takes about 24 hours. Several days to weeks of incubation at room temperature in the dark may be required until growth becomes apparent, usually as fluffy pinpoint colonies.

Although the original inoculum always contains various types of magnetotactic bacteria, in most cases only magnetotactic spirilla grow and are eventually isolated in pure culture. Modifications of this medium may eventually prove useful for the isolation of hitherto uncultured types of magnetotactic bacteria.

Following isolation, most strains of magnetospirilla can be cultured in liquid media without added water or mud from the sampling site. However, the gas composition of the headspace of the cultures is crucial for good growth and magnetite synthesis by most species. The maximum concentration of oxygen allowing growth and/or magnetite synthesis differs among the described *Magnetospirillum* strains. *M. magnetotacticum* grows optimally and produces the highest number of magnetosomes at an oxygen tension of 1% in the headspace and tolerates higher initial oxygen concentrations only if a large number of cells is inoculated into the growth medium. In contrast, *Magnetospirillum* strain AMB-1 grows (but does not produce magnetosomes) aerobically under atmospheric concentrations of oxygen (approximately 21% O_2; Matsunaga et al., 1991b). Magnetite synthesis is inhibited by all *Magnetospirillum* strains when cells are cultured under oxygen concentrations above 2 to 6% (Blakemore et al., 1985; Schüler and Baeuerlein, 1998).

Strain MV-1, a Facultatively Anaerobic Magnetotactic Vibrio

A marine magnetotactic vibrioid to helicoid bacterium, strain MV-1, was isolated by Bazylinski et al. (1988). Cells of strain MV-1 are small, rang-

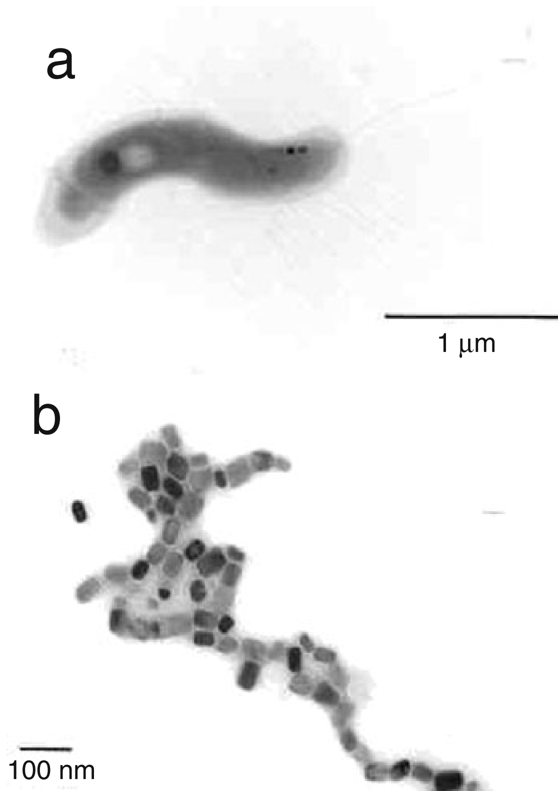

Fig. 16. Brightfield TEM image of negatively stained cell and magnetosomes of strain MV-1. (a) Cell stained with uranyl acetate showing a single polar flagellum and a chain of magnetite-containing magnetosomes. (b) Preparation of purified magnetosomes from strain MV-1 stained with 2% aqueous sodium phosphotungstate, pH 7.0. The "magnetosome membrane" is visualized as an electron-lucent area surrounding each individual crystal and is easily removed with detergents such as sodium deodecyl sulfate.

ing from 1–5 μm by 0.2–0.5 μm, and possess a single, unsheathed, polar flagellum (Fig. 16a). Cells grow and synthesize pseudohexahedral prismatic crystals of magnetite, averaging 53 by 35 nm in size (Fig. 16b; Sparks et al., 1990), in their magnetosomes microaerobically and anaerobically, with nitrous oxide as the terminal electron acceptor. Cells appear to produce more magnetite under anaerobic conditions than under microaerobic conditions (Bazylinski et al., 1988) and, like *M. magnetotacticum*, synthesize a number of magnetosome membrane proteins that are not present in other cellular fractions (Dubbels et al., 1998). A stable, spontaneous nonmagnetotactic mutant strain of MV-1 that does not produce magnetosomes has recently been isolated and partially characterized (Dubbels and Bazylinski, 1998).

Strain MV-1 is nutritionally versatile being able to grow chemoorganoheterotrophically with organic and some amino acids as carbon and energy sources, and chemolithoautotrophically with thiosulfate or sulfide as energy sources oxidizing them to sulfate, and carbon dioxide as the sole carbon source (Kimble and Bazylinski, 1996). Cells produce intracellular sulfur deposits when grown with sulfide (Kimble and Bazylinski, 1996). As do virtually all aerobic chemolithoautotrophic bacteria, strain MV-1 uses the Calvin-Benson cycle for autotrophic carbon dioxide fixation (McFadden and Shively, 1991). Cell-free extracts from thiosulfate-grown cells of strain MV-1 show ribulose bisphosphate carboxylase/oxygenase (rubisCO) activity (Kimble and Bazylinski, 1996), and recently (Dean and Bazylinski, 1999a) the gene for a form II rubisCO enzyme (*cbbM*) was cloned and sequenced from strain MV-1. There was no evidence for a *cbbL* gene (encodes for form I rubisCO enzymes) in DNA hybridization analyses despite using *cbbL* gene probes from several different organisms. Because many uncultured magnetotactic bacteria collected from natural habitats thrive in oxygen-sulfide inverse gradients, as previously mentioned, and contain internal sulfur deposits (Moench, 1988; Spring et al., 1993; Frankel and Bazylinski, 1994; Iida and Akai, 1996; Kimble and Bazylinski, 1996), it seems many species are likely chemolithoautotrophs that obtain energy from the oxidation of sulfide and perhaps other reduced sulfur sompounds. Using pulsed-field gel electrophoresis (PFGE), the genome of strain MV-1 was found to consist of a single, circular chromosome of approximately 3.7 Mb (Dean and Bazylinski, 1999b). There was no evidence of linear chromosomes or extrachromosomal DNA such as plasmids. The guanine-plus-cytosine content of the DNA of this strain is 52.9 mol% as determined by HPLC and 53.5 mol% by T_m.

A virtually identical strain to strain MV-1, designated MV-2, was isolated from the Pettaquamscutt Estuary (DeLong et al., 1993; Meldrum et al., 1993b). Cells of this strain produce the same morphological type of magnetite crystals as strain MV-1 (Meldrum et al., 1993b) and display many of the same phenotypic traits as strain MV-1 (such as anaerobic growth with nitrous oxide as a terminal electron acceptor, heterotrophic growth with organic and amino acids, and chemolithoautotrophic growth on reduced sulfur compounds). However, strain MV-2 shows slightly different restriction fragment patterns in pulsed-field gels than strain MV-1 using the same restriction enzymes (Dean and Bazylinski, 1999b). As with strain MV-1, the genome of strain MV-2 consists of a single, circular chromosome of a similar size, about 3.6 Mb (Dean and Bazylinski, 1999b). The guanine-plus-cytosine content of the DNA of this strain is 56.2 mol% as determined by HPLC and 56.6% by T_m.

Strain RS-1, a Sulfate-Reducing Magnetotactic Bacterium

It was thought for a long time that all magnetotactic bacteria are obligate or facultative microaerophiles (*Magnetospirillum* strain AMB-1 and the marine vibrio, strain MV-1, grow anaerobically with nitrate and nitrous oxide, respectively, as well as with oxygen) adapted to the microoxic zone of their environment. With the isolation of an obligately anaerobic strain from a sulfidic freshwater habitat by Sakaguchi et al. (1993), this assumption is clearly incorrect. Cells of this organism, designated strain RS-1, are 0.9–1.5 by 3–5 µm with a helicoid to rod-shaped morphology and possess a single polar flagellum. They exhibit an axial magnetotaxis coupled with a strong anaerotaxis reflecting their obligate anaerobic metabolism. According to the revised model of magnetotaxis, they may have developed an axial magnetotaxis because they do not have to oscillate between microoxic and anoxic zones of their habitat, which would select for polar magnetotaxis.

Strain RS-1 is a dissimilatory sulfate-reducing, chemoorganoheterotrophic bacterium that utilizes a variety of organic substrates, e.g., pyruvate, lactate, ethanol and fumarate). Cells can use sulfate or fumarate as electron acceptor but not oxygen. They are catalase positive and oxidase negative. The guanine-plus-cytosine content of DNA was determined by HPLC to be 66 mol%.

Sequencing of the 16S rRNA gene of strain RS-1 showed that it is phylogenetically affiliated to the delta-subclass of the *Proteobacteria* (Kawaguchi et al., 1995). The nearest neighbors in a phylogenetic tree are members of the genus *Desulfovibrio*, typical representatives of the obligately anaerobic, dissimilatory sulfate-reducing bacteria. In contrast to Desulfovibrio sp., cells of strain RS-1 are able to produce intracellular bean-shaped crystals of magnetite, responsible for its magnetotactic response. Consequently, the production of magnetosomes consisting of magnetite is found in bacteria belonging to three different phylogenetic groups, viz. the α- and δ-subclasses of *Proteobacteria* and the *Nitrospira* group ("*Magnetobacterium bavaricum*"), indicating multiple evolutionary origins of intracellular magnetite synthesis or lateral gene transfer between different phylogenetic groups.

Other Magnetotactic Strains in Pure Culture

Several other pure cultures of magnetotactic bacteria exist, but they appear to be obligate microaerophiles and grow poorly (D. A. Bazylinski, unpublished results). Hence, very little is known about them. Strain MC-1 (Fig. 17), a marine biliophotrichous coccus, was isolated from water collected from the Pettaquamscutt Estuary, a chemically-stratified semi-anaerobic basin in Rhode Island, USA. Cells of this strain produce pseudohexahedral prisms of magnetite, averaging 72 by 70 nm in size (when grown autotrophically), and grow chemolithoautotrophically with thiosulfate or sulfide as an electron and energy source (Meldrum et al., 1993a; Frankel et al., 1997). Cells may also be able to grow chemoorganoheterotrophically. Like all magnetotactic cocci observed, cells of strain MC-1 show polar magneto-aerotaxis regardless of whether they are grown in liquid or semi-solid oxygen gradient media. This strain has a genome size of approximately 4.5 Mb as determined by pulsed-field gel electrophoresis (Dean and Bazylinski, 1999b). The guanine-plus-cytosine content of the DNA of strain MC-1, as determined by HPLC, is 55.8 mol%. This organism has not been completely characterized and described.

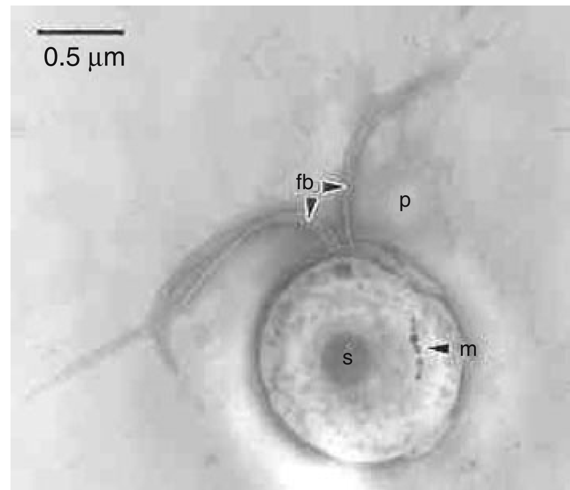

Fig. 17. Brightfield TEM image of a cell of the bilophotrichously flagellated marine coccus strain MC-1 negatively stained with uranyl acetate. Note the two flagellar bundles (fb), the presence of pili (p), sulfur globules(s), and chain of Fe_3O_4-containing magnetosomes (m).

Strain MV-4 (Fig. 18), a small marine spirillum, was isolated from sulfide-rich mud and water collected from School Street Marsh, Woods Hole, Massachusetts, USA. Cells of this strain produce elongated octahedrons of magnetite, averaging 61 by 52 nm in size, and grow chemolithoautotrophically with thiosulfate or chemoorganoheterotrophically with succinate (Meldrum et al., 1993b). Unlike most freshwater magnetotactic spirilla, this strain shows polar magneto-aerotaxis at least when grown in semi-solid oxygen gradient media. Like strain MC-1,

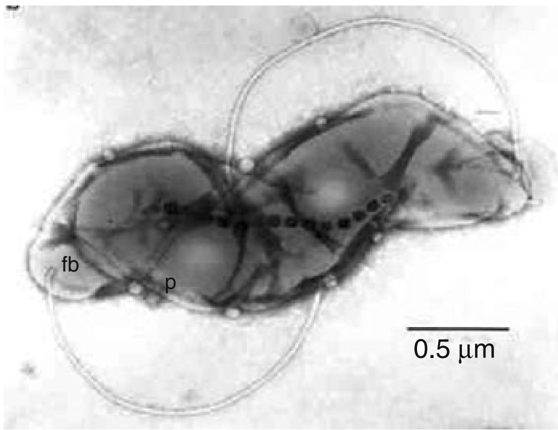

Fig. 18. Brightfield TEM image of a cell of the marine spirillum strain MV-4 negatively stained with uranyl acetate showing bipolar flagellation and a chain of Fe_3O_4-containing magnetosomes.

this strain has not been completely characterized and described.

Biotechnological Applications

It was not long after the discovery of magnetotactic bacteria that publications of physical studies and of commercial and medical applications involving the magnetotactic cells, isolated magnetosomes and/or magnetite crystals began to appear. It is clear that magnetotactic bacterial cells and their magnetic crystals have novel physical, magnetic and possibly electrical properties. In addition, in certain types of applications, bacterial magnetite offers several advantages compared to chemically synthesized magnetite. Bacterial magnetosome particles, unlike those produced chemically, have a consistent shape, a narrow size distribution within the single magnetic domain range, and a membrane coating consisting of lipids and proteins. The magnetosome envelope allows for easy couplings of bioactive substances to its surface, a characteristic important for many applications.

Magnetotactic bacterial cells have been used to determine south magnetic poles in meteorites and rocks containing fine-grained magnetic minerals (Funaki et al., 1989; Funaki et al., 1992) and for the separation of cells after the introduction of magnetotactic bacterial cells into granulocytes and monocytes by phagocytosis (Matsunaga et al., 1989). Magnetotactic bacterial magnetite crystals have been used in studies of magnetic domain analysis (Futschik et al., 1989) and in many commercial applications including: the immobilization of enzymes (Matsunaga and Kamiya, 1987); the formation of magnetic antibodies in various fluoroimmunoassays (Matsunaga et al., 1990) involving the detection of allergens (Nakamura and Matsunaga, 1993a) and squamous cell carcinoma cells (Matsunaga, 1991a), and the quantification of IgG (Nakamura et al., 1991); the detection and removal of *Escherichia coli* cells with a fluorescein isothiocyanate conjugated monoclonal antibody, immobilized on magnetotactic bacterial magnetite particles (Nakamura et al., 1993c); and the introduction of genes into cells, a technology in which magnetosomes are coated with DNA and "shot" using a particle gun into cells that are difficult to transform using more standard methods (Matsunaga, 1991a). Unfortunately, the prerequisite for any large scale commercial application is mass cultivation of magnetotactic bacteria or the introduction and expression of the genes responsible for magnetosome synthesis into a bacterium, e.g., *E. coli*, that can be grown relatively cheaply to extremely large yields. Although some progress has been made, the former has not been achieved with the available pure cultures.

CHAPTER 1.27

Luminous Bacteria

PAUL V. DUNLAP AND KUMIKO KITA-TSUKAMOTO

Introduction and Historical Perspective

"The smallest lamps in the world, luminous bacteria, are no different from ordinary bacteria except in their ability to luminesce."
—E. N. Harvey, 1940

The luminous bacteria are those bacteria that contain naturally acquired genes for light production, the *lux* genes. Most currently known luminous bacteria express the *lux* genes at high levels in laboratory culture (Fig. 1) or in nature, leading to the emission of easily visible levels of light. Bacterial light production is one of several biochemically distinct types of bioluminescence (Hastings, 1995).

The existence of bacterial luminescence and of many of the luminous bacteria themselves has been known for some time. During the 1700s and 1800s, various animal products (such as meats, fish and eggs), the decaying bodies of marine and terrestrial animals, and even human wounds and corpses, were reported to produce light (Harvey, 1940; Harvey, 1952). Many years before those observations and long before bacteria were known to exist, Boyle (1668) demonstrated that the "uncertain shining of Fish," the light coming from decaying fish, required air. Indeed, encounters with luminous objects and substances extend back to the beginnings of recorded history in Greece and China (Harvey, 1957), and they continue in modern times to be causes of concern and wonder. Many of these encounters can be attributed to the saprophytic or pathogenic growth of luminous bacteria on marine and terrestrial animals. According to Harvey (1940), J. F. Heller in 1854 was the first to give a name, *Sarcina noctiluca*, to the suspected responsible organism. As the science of bacteriology developed during the period from 1860 through 1910, individual types of light-producing bacteria were grown and distiguished from other bacteria, notably through the work of Bernhard Fischer (Fischer, 1887) and Martin Beijerinck (Beijerinck, 1889), among many others (Zobell, 1946; Harvey, 1952; Harvey, 1957). During the first half of the 20th century, luminous bacteria were isolated from various habitats, the chemistry of bacterial light production, and culture requirements for growth and luminescence were characterized, and they were placed in the evolving system of microbial taxonomy (e.g., Zobell and Upham, 1944; Farghaly, 1950; Johnson, 1951). In the latter half of the 20th century, those efforts paralleled the growth of microbiology, incorporating the tools and knowledge developing from advances in biochemistry, physiology and genetics (Baumann and Baumann, 1977; Baumann and Baumann, 1981; Farmer and Hickman-Farmer, 1992; Hastings and Nealson, 1977; Hastings and Nealson, 1981; Hendrie et al., 1970; Nealson and Hastings, 1992; Singleton and Skerman, 1973). Much has been learned during the past 50 years about the enzymes and genes involved in bacterial light production and about the phylogeny and ecology of light-emitting bacteria. However, much remains to be learned about these topics and about the evolutionary origins and cellular functions of bacterial luminescence.

In the past, the luminous bacteria were often considered to be a separate microbial group, distinguished by their distinctive and unifying phenotype, the production of light. They are seen now more properly as representative prokaryotes with much to reveal about the fundamental biology of bacteria. This view develops from (and is supported by) a deepening understanding of phylogenetic relationships and the realization that these bacteria are metabolically similar to other well-established bacteria (Baumann and Baumann, 1981; Baumann and Schubert, 1984a; Baumann et al., 1984b). Indeed, light-emission is a biochemical trait shared by several but not all species and strains of the genera *Vibrio*, *Photobacterium*, *Shewanella* and *Photorhabdus*. As members of these genera, the luminous bacteria are for the most part typical Gram negative bacteria similar in fundamental ways to terrestrial enterobacteria (Baumann and Baumann, 1977). They occur together with closely related nonluminous types in many habitats, responding in the same metabolic and physiological ways as other bacteria, and carrying out with them

Fig. 1. Bacterial luminescence. Colonies of the luminous marine bacterium *V. fischeri* growing on a seawater-based complete medium photographed by the light they produce. From Meighen and Dunlap (1993).

ecologically important activities unrelated to luminescence.

Supporting this view is a growing appreciation that light production in luminous bacteria is tightly integrated with cellular metabolism and global gene regulation (Ulitzur and Dunlap, 1995; Callahan and Dunlap, 2000). Light production is sensitive to the physiological state of the cell, and expression of the *lux* genes, along with many other sets of genes of diverse functions, is coordinately regulated in response to that state. Therefore, despite its phenotypic distinctiveness, luminescence is not an independent biochemical activity of the cell; it is instead an integral feature of the biology of these bacteria. Studies of luminescence therefore are likely to reveal basic processes in Gram-negative prokaryotes.

An example of how bacterial luminescence can lead to insights of fundamental importance in microbiology is quorum sensing. Previously called "autoinduction" and studied as the special cell density-dependent mechanism by which luminous bacteria control light production, quorum sensing has now been identified in many nonluminous Gram-negative bacteria, including several pathogens of animals and plants (Fuqua et al., 1996; Greenberg, 1997; Dunlap, 1997; Swift et al., 1999; Hastings and Greenberg, 1999). Early studies of luminous bacteria would not have led to predictions that autoinduction of luminescence would become a new bacterial regulatory paradigm (Nealson, 1999). However, the multitude of scientific advances and research opportunities opened up by the revelations of quorum-sensing control of luminescence suggest that studying luminous bacteria (as representative Gram-negative prokaryotes) and luminescence (as an integral aspect of their biology) will continue to reveal insights and themes of biological importance.

Biochemistry of Bacterial Light Production

Light emission in bacteria is catalyzed by luciferase, a heterodimeric protein of approximately 80 kD, composed of α (40-kDa) and β (37-kDa) subunits. Bacterial luciferase mediates the oxidation of reduced flavin mononucleotide ($FMNH_2$) and a long-chain aliphatic aldehyde (RCHO) by molecular oxygen (O_2) to produce blue-green light (Fig. 1) according to the following reaction.

$$FMNH_2 + O_2 + RCHO \xrightarrow{luciferase} FMN + H_2O + RCOOH + h\nu(490\ \text{nm})$$

In the luminescence reaction, binding of $FMNH_2$ by the enzyme is followed by interaction with O_2 to form a luciferase-bound 4a-peroxyflavin. Association of this complex with aldehyde forms a highly stable intermediate, the slow decay of which results in oxidation of the $FMNH_2$ and aldehyde substrates and the emission of light. Quantum yield for the reaction has been estimated at 0.1 to 1.0 photons. The reaction is highly specific for $FMNH_2$, and the aldehyde substrate in vivo is likely to be tetradecanal. Synthesis of the long-chain aldehyde is catalyzed by a fatty-acid reductase complex composed of three polypeptides, an NADPH-dependent acyl protein reductase (called "r," 54 kDa), an acyl transferase ("t," 33 kDa), and an ATP-dependent synthetase ("s," 42 kDa). The complex has a stoichiometry of $r_4s_4t_{2\text{-}4}$, and its activity is essential for the production of light in the absence of exogenously added aldehyde. The genes *luxA* and *luxB* for the α and β luciferase subunits and *luxC*, *luxD* and *luxE* for the r, s and t polypeptides of the fatty-acid reductase, respectively, are contiguous and coordinately expressed in all luminous bacteria examined to date. Furthermore, as described in a later section, luciferases from different species of luminous bacteria exhibit substantial sequence identity, consistent with a common evolutionary origin. For references and detailed information on the biochemistry of bacterial light production, the reader is directed to reviews by Hastings (1995), Hastings et al. (1985), Meighen (Meighen, 1988; Meighen, 1991) and Meighen and Dunlap (1993).

Species and Phylogeny of Luminous Bacteria

The currently known luminous bacteria are members of the genera *Vibrio*, *Photobacterium*, *Shewanella* and *Photorhabdus* (Table 1). These bacteria are Gram-negative γ-Proteobacteria, nonsporulating, chemoorganotrophic heterotrophs, most of which are facultatively aerobic. Two of the marine luminous bacteria, however, *Shewanella hanedai* (Jensen et al., 1980) and *Shewanella woodyi* (Makemson et al., 1997), differ from the other luminous bacteria in using only a respiratory mode of metabolism. Detailed information on the metabolism, physiology and morphology of these bacterial groups and individual species can be found in Baumann and Baumann (1981), Baumann et al. (1984b), Farmer and Hickman-Brenner (1992), Boemare et al. (1993) and Forst et al. (1997). The luminous *Photobacterium* and *Shewanella* species and most of the luminous *Vibrio* species occur in the marine environment, whereas *Photorhabdus* species are terrestrial. *Vibrio cholerae* may be the only species with luminous strains occurring in brackish environments and freshwater.

Certain of the species listed in Table 1 were described in the late 1990s (Makemson et al., 1997; Fischer-Le Saux et al., 1999). Furthermore, luminous strains of species previously described as nonluminous are being found. Examples include *Vibrio salmonicida*, a pathogen of salmonid fish (Fidopastis et al., 1999) and intensely luminous strains of *Photobacterium angustum* isolated from the Sea of Cortez (K. Kita-Tsukamoto et al., manuscript in preparation). Indeed, light production does not define a phylogenetically exclusive or consistent grouping. The genera *Vibrio*, *Photobacterium* and *Shewanella* contain many nonluminous species. Even species characterized as luminous can contain strains that do not produce light and that lack the genes necessary for light production. An example is a strain of *Photorhabdus luminescens* symbiotic with entomopathogenic nematodes (Akhurst and Boemare, 1986; Forst and Nealson, 1996). Adding to this complexity, some species or strains carry the *lux* genes and produce a high level of light under natural conditions but produce little or no light when grown in laboratory culture. Examples include luminous bacteria infecting crustaceans (Giard and Billet, 1889b) and strains of *V. fischeri* symbiotic with the Hawaiian sepiolid squid, *Euprymna scolopes* (Boettcher and Ruby, 1990). Furthermore, many nonluminous strains of *V. cholerae* carry *lux* genes (Palmer and Colwell, 1991; Ramaiah et al., 2000). Relevant to the question of which species and strains of bacteria produce light is the observation that luminescence often is not phenotypically stable. Strains luminous on primary isolation often become dim or dark in laboratory culture (Nealson and Hastings, 1979b; Akhurst, 1980; Silverman et al., 1989; Nealson and Hastings, 1992). Therefore, it is reasonable to assume that luminescence has been overlooked in many species, especially those represented primarily by laboratory strains or those studied under clinical settings at temperatures where luminescence may not be produced. With environmental isolates and previously characterized species, the use of cooler temperatures (10–20°C) for growth and examination, utilization of conditioned media, inducers and luciferase substrates (Fidopiastis et al., 1999), and the application of probes for *luxA* and other *lux* genes (Wimpee et al., 1991) will undoubtedly reveal many more types of bacteria with the ability to produce light.

From the perspective of 16S rRNA sequence-based phylogeny, the luminous bactera are representative members of the γ-Proteobacteria, with luminous species in four genera (*Vibrio*, *Photobacterium*, *Photorhabdus* and *Shewanella*) within three families (Vibrionaceae, Enterobacteriaceae and Alteromonadaceae; Fig. 2). Genera containing species or strains of luminous bacteria are a small fraction of the162 genera in 20 families of the γ-Proteobacteria (see *Bergey's Manual of Systematic Bacteriology*, May 2001). Most of the luminous species are members of the Vibrionaceae (genera *Vibrio* and *Photobacterium*), which also contain many nonluminous species. Diverging from lineages within the Vibrionaceae are several uncultured luminous symbionts of anomalopid (flashlight) and ceratioid (deep-sea) anglerfish (Fig. 2). The anomalopid and ceratioid symbionts form separate monophyletic groups, and these symbionts are sufficiently divergent from known luminous bacteria to suggest they represent new species or genera within the Vibrionaceae (Haygood, 1990; Haygood, 1993a; Haygood and Distel, 1993b).

The intermingling of luminous and nonluminous species in the Vibrionaceae contrasts with the phylogenetic separateness of the luminous species within the Enterobacteriaceae and Alteromonadaceae (Fig. 2). Within these latter two families, the luminous species occur on branches that appear distal to other species. Placement of *Photorhabdus* in the Enterobacteriaceae, though generally accepted, is controversial (Janse and Smits, 1990; Rainey et al., 1995), however. Characteristics of *Photorhabdus* species not typical of members of the Enterobacteriaceae include luminescence, synthesis of yellow and red pigments and the inability to reduce nitrate (Farmer et al., 1989; Forst and Nealson, 1996).

[a]Luminous strains. For additional information, see Baumann and Baumann (1981); Farmer and Hickman-Brenner (1992); Hastings and Nealson (1981); and Nealson and Hastings (1992).
[b] Ability of this species to luminesce is not well established.
[c]Symbiotic with entomopathogenic nematodes; on anatomical and behavioral grounds not considered here to be equivalent to bioluminescent symbiosis in fishes and squids.

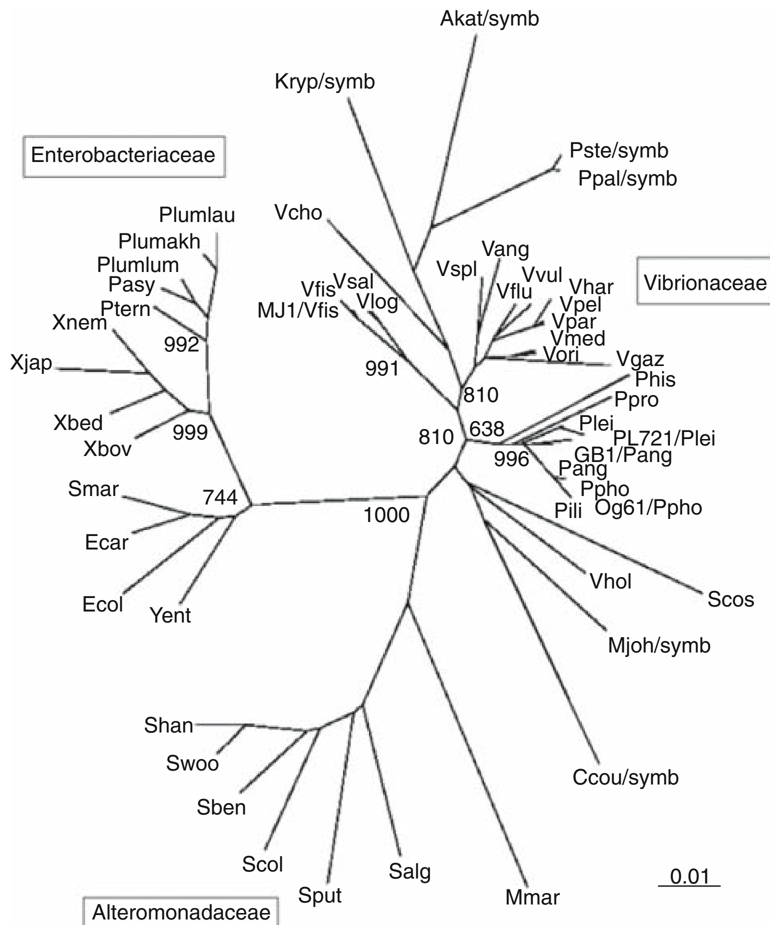

Fig. 2. 16S rDNA-based phylogenetic tree of luminous bacteria. Luminous species and strains are in boldface. Names are abbreviated as the first letter of the genus and the first three letters of species of the bacterium or its symbiotic host, along with the first three letters of the subspecies, where appropriate. See accession numbers as indicated for references. Included in the tree for comparison are sequences of species and strains related to luminous bacteria and sequences of uncultured symbiotic luminous bacteria. The neighbor-joining (NJ; Saitou and Nei, 1987) tree was constructed based on 1,163 unambiguously aligned positions. CLUSTAL W program (ver. 1.60; Thompson et al., 1994) was used for alignment of sequences and realigned manually using MacClade 3.05 (Maddison and Maddison, 1992). The NJ tree was developed from the distance matrix calculated by the algorithm of the Kimura two-parameter model (Kimura, 1980). Bootstrap analysis was done with 1,000 replicates. The scale bar represents 0.01 nucleotide substitutions per position. Alteromonadaceae: *Moritella marina* (T [type strain]), X82142; *Shewanella algae* (T), AF005249; *S. benthica* (T), X82131; *S. colwelliana* (T), AF170794; *S. hanedai* (T), X82132; *S. woodyi* (T), AF003549; and *S. putrefaciens* (T), X81623. Enterobacteriaceae: *Erwinia carotovora* subsp. carotovora (T), M59149; *Escherichia coli*, J01859; *Photorhabdus asymbiotica* (T), Z76755; *P. luminescens* subsp. *akhurstii* (T), AJ007359; *P. luminescens* subsp. *laumondii* (T), AJ007404; *P. luminescens* subsp. *luminescens* (T), X82248; *P. temperata* (T), AJ007405; *Serratia marcescens* (T), M59160; *Xenorhabdus beddingii* (T), X82254; *X. bovienii* (T), X82252; *X. japonicus* (T), Z76739; *X. nematophilus* (T), X82251; and *Yersinia enterocolitica* (T), M59292. Vibrionaceae: *Photobacterium angustum* (T), X74685; *P. angustum* GB-1 (K. Kita-Tsukamoto et al., manuscript in preparation); *P. histaminum*, D25308; *P. iliopiscarium* (T), AB000278; *P. leiognathi* (T), X74686; *P. leiognathi* PL-721, Z21730; *P. phosphoreum* (T), D25310; *P. phosphoreum* Og61, Z19107; *P. profundum*, AB003191; *Salinivibrio costicola* (T), X74699; *Vibrio anguillarum* (T), X16895; *V. cholerae*, X74694; *V. fischeri* (T), X74702; *V. fischeri* MJ-1, Z21729; *V. fluvialis* (T), X74703; *V. gazogenes* (T), X74705; *V. harveyi* (T), X74706; *V. hollisae* (T), X74707; *V. logei*, X74708; *V. mediterranei* (T), X74710; *V. orientalis* (T), X74719; *V. parahaemolyticus* (T), X74720; *V. pelagius* (T), X74722; *V. salmonicida* (T), X70643; *V. splendidus* (T), X74724; and *V. vulnificus* (T), X74726. Uncultured symbiotic luminous bacteria: *Anomalops katoptron* symbiont, Z19081; *Cryptosaras couesi* symbiont, Z19106; *Kryptophanaron alfredi* symbiont, Z19003; *Melanocetus johnsoni* symbiont, Z19105; *Photoblepharon palpebratus* symbiont, Z19085; and *Photoblepharon steinetzi* symbiont, Z19080.

Nonetheless, the separateness of the luminous species in these two families suggests a separate and relatively recent acquisition of *lux* genes by *Photorhabdus* (Forst et al., 1997) and luminous *Shewanella* (discussed below).

Habitats and Ecology of Luminous Bacteria

Marine

Luminous bacteria are globally distributed in the marine environment (Table 1) and can be isolated from seawater, sediment and suspended particulates. They also colonize marine animals as saprophytes, commensal enteric symbionts and parasites (Hastings and Nealson, 1981; Meighen and Dunlap, 1993; Makemson et al., 1997), and certain of them establish bioluminescent symbiosis with marine fish and squids (Dunlap and Greenberg, 1991b; Nealson and Hastings, 1992; Haygood, 1993a; Ruby, 1996). In seawater, numbers of luminous bacteria generally are low (from 0.01 to up to 40 cells per ml of seawater; Nealson and Hastings, 1992). In association with animals, however, luminous bacteria can attain very high numbers (up to 10^{11} cells per ml in symbiotic habitats; Ruby and Nealson, 1976; Dunlap, 1984; Nealson and Hastings, 1992). The very high numbers of luminous bacteria in saprophytic, commensal, parasitic and symbiotic habitats indicates the potential of these habitats to make substantial contributions to the density and distribution of luminous bacteria in seawater, sediments and marine snow (Reichelt et al., 1977; O'Brien and Sizemore, 1979; Ruby and Morin, 1979; Haygood et al., 1984; Nealson et al., 1984; Ramesh et al., 1987; Ruby and Lee, 1998), which in turn serve as environmental sources of these bacteria for re-colonization of animals (Nealson and Hastings, 1992). Except in bioluminescent symbiosis, which is specific to certain luminous bacteria, the luminous species coexist in these habitats with nonluminous bacteria.

Unlike marine animals, marine algae apparently are not commonly colonized by luminous bacteria. Only one luminous bacterium with the ability to digest agar has been reported, a strain of *V. harveyi* (Fukasawa et al., 1987). Although agar digestion is often observed among *Vibrio* spp. and other marine bacteria, searches for other luminous bacteria with this trait, including extensive examination of surfaces of marine algae, have not yet revealed other luminous strains. One can speculate that a rare bacteriophage-mediated transduction between *Vibrio* spp. (Baross et al., 1978a) might have been the mechanism by which the strain of *V. harveyi* acquired genes for agar hydrolysis. Regardless, the surfaces of marine algae are an additional habitat exploited, though apparently rarely, by luminous bacteria and shared with nonluminous forms.

The distributions and numbers of individual species of luminous bacteria correlate with certain environmental factors (Baumann and Baumann, 1981; Hastings and Nealson, 1981). Primary among these factors are temperature and depth (Ruby and Nealson, 1978b; Yetinson and Shilo, 1979; Ruby et al., 1980), salinity (Yetinson and Shilo, 1979; Feldman and Buck, 1984), nutrient limitation and sensitivity to photooxidation (Shilo and Yetinson, 1980). Temperature, along with being an important environmental factor, can influence whether luminous bacteria from environmental samples are detected. For example, *Shewanella hanedai* and *Vibrio logei*, which are psychrotrophic, grow and produce light at low temperature (e.g., 4°C to 15°C, and grow but do not produce light at room temperature (24°C). Therefore, incubation of platings of environmental samples at the lower temperatures may reveal the presence of other psychrotropic luminous species. Temperature relationships would appear to be species-specific, however. For example, *S. woodyi* (found in squid ink and seawater in the Alboran Sea near Gibraltar; Makemson et al., 1997) and *V. fischeri*, species closely related to *S. hanedai* and *V. logei*, respectively, grow and produce light at room temperature.

Studies of the distibution and density of luminous bacteria in the marine environment traditionally have used visual observation of luminescence to identify these bacteria. However, the presence of *lux* genes in bacteria that do not produce light in culture and the physiological crypticity of luminescence in some species (Boettcher and Ruby, 1990; Fidopiastis et al., 1999) reveal that luminous bacteria are more numerous and diverse than identified by the luminescence phenotype. Enzyme assay and antibody methods previously have been used to detect luciferase in several nonluminous *Vibrio* spp. (Nealson and Walton, 1978b; Makemson and Hastings, 1986b; Kou and Makemson, 1988), and *luxA*-based DNA probes from various seawater samples have been used to identify *lux* gene-containing bacteria not producing light in culture (Potrikus et al., 1984; Palmer and Colwell, 1991; Lee and Ruby, 1992; Wimpee et al., 1991; Ramaiah et al., 2000). The efficacy of species- and group-specific *luxA*-based probes for the identification of environmental isolates of luminous bacteria has been demonstrated for two species, *Photobacterium phosphoreum* from the Black Sea and *Vibrio splendidus* from coastal waters of Kuwait (Wimpee et al., 1991; Nealson et al., 1993).

Freshwater

Knowledge of luminous bacteria in freshwater environments is limited to reports that luminous *V. cholerae* exist in freshwater and infect freshwater crustaceans. Luminous strains of *V. cholerae* have been isolated from freshwater and brackish estuarine waters in various locations (Desmarchelier and Reichelt, 1981; West and Lee, 1982; West et al., 1983; Palmer and Colwell, 1991; Ramaiah et al., 2000; Table 1). The first such isolation, in 1893, apparently was by F. Kutscher from the Elbe River in Germany (Harvey, 1952). Then called "*Vibrio albensis*," that strain later was synonymized with *V. cholerae* (Reichelt et al., 1976).

With respect to infecting freshwater animals, Thulis and Bernard in 1786 described the luminescence of a freshwater crustacean (possibly the common amphipod *Gammarus pulex*, which apparently was infected with luminous bacteria) from a river in southern France (Harvey, 1957). Yasaki (1927) reported the isolation of luminous bacteria from intensely luminous specimens of the freshwater shrimp, *Xiphocaridina compressa*, in Lake Suwa, Japan. Initially characterized as *Microspira phosphoreum*, the bacterium was later redescribed as *Vibrio yasakii* (Majima, 1931). More recently, a bacterium responsible for this "light disease of shrimp" was isolated from freshwater shrimp in Lake Biwa, Japan, and identified as non-O1 *V. cholerae* (Shimada et al., 1995). Nonluminous *V. cholerae* also are associated with disease in freshwater crustaceans (Thune et al., 1991).

Terrestrial

Luminous bacteria in the terrestrial environment have been noticed mostly as parasites of insects that cause the infected animal to luminesce. Observations of luminous midges, caterpillars, mole-crickets, mayflies and ants, among other infected insects, have been reported from the 1700s into modern times (Harvey, 1952; Haneda, 1950). As described and summarized by Harvey (Harvey, 1952; Harvey, 1957), other early reports of terrestrial luminescence attributable to luminous bacteria include luminous mutton, veal, eggs of chickens and lizards, human corpses and battlefield wounds. Many, and perhaps all, of the observations of luminous insects result from colonization by members of the genus *Photorhabdus*, of which three species are currently described, *P. luminescens*, *P. temperata* and *P. asymbiotica* (Fischer-Le Saux et al., 1999; Table 1).

Photorhabdus luminescens and *P. temperata* occur as the mutualistic symbionts of entomopathogenic nematodes (commonly found in soil) of the family Heterorhaditidae (Akhurst and Dunphy, 1993; Forst and Nealson, 1996; Forst et al., 1997). They are carried in the intestine of the infective juvenile stage of the nematode and participate in a lethal infection of insect larvae. When the nematode enters the insect, via the digestive tract or other openings, and penetrates the insect's hemocele, the bacteria are released into the hemolymph, where they use its constituents for growth. The bacteria elaborate a variety of extracellular enzymes that presumably break down macromolecules of the hemolymph. Proliferation of the bacteria leads to death of the insect, and its carcass becomes luminous. The bacteria also produce various extracellular and cell surface-associated factors pathogenic for the insect, as well as bacteriocins and hydroxystilbene and anthraquinone antibiotics, which apparently inhibit the growth of other microorganisms in the insect cadaver (Akurst, 1982). Crystalline protein inclusion bodies of unknown function are also produced (Bintrim and Ensign, 1998). The nematodes feed on the bacteria or products of bacterial degradation of the hemolymph enabling them to develop and sexually reproduce (Boemare et al., 1997; Forst et al., 1997). Completion of the nematode life cycle involves reassociation with the bacteria and the emergence from the insect cadaver of the nonfeeding infective juveniles, carrying the bacteria in their intestines. Cells of *P. luminescens* presumably are present in soil, but association with the nematode apparently is important for their survival and dissemination. Luminescence of the infected insect larva might function to attract nocturnally active animals to feed on the glowing carcass, thereby increasing the opportunities for the bacterium and the nematode to be disseminated. However, luminescence is not required for successful symbiosis with the nematode; not all strains of *P. luminescens* produce luminescence (Akhurst and Boemare, 1986; Forst and Nealson, 1996). Furthermore, bacteria in the genus *Xenorhabdus*, which are symbiotic with entomopathogenic nematodes in the family Steinernematidae, are ecologically very similar to *Photorhabdus*, except that they do not produce light (Akhurst and Dunphy, 1993). The similarities between the lifestyles and activities of *Photorhabdus* and *Xenorhabdus* are postulated to be a case of ecological convergence (Forst and Nealson, 1996).

Human clinical infections have yielded *P. asymbiotica*, introduced apparently by spider and insect bites (Farmer et al., 1989; Peel et al., 1999). Luminous battlefield wounds are intriguing because luminescence apparently is a sign that the wound will heal well (Harvey, 1957). Indeed, luminous bacteria will grow and produce light on living mammalian tissue (Johnson, 1988). Perhaps antibiotic-producing *P. lumine-*

scens or *P. temperata* promoted wound healing by preventing the growth of putrefying, pathogenic bacteria. On the other hand, the human pathogenicity of *P. asymbiotica* suggests that this species might have killed rather than healed if introduced into wounds. The recent description of *P. asymbiotica* and *P. temperata*, and the presence of genetically distinct subspecies within *P. luminescens* and *P. temperata* (Fischer-Le Saux et al., 1999; Fig. 2) indicate that additional diversity, possibly at the species level, may exist in this genus.

Along with terrestrial *Photorhabdus* species, marine luminous bacteria might have been responsible for some of the early reports of luminous meats and eggs, especially if brine was used in their preparation or they otherwise were exposed to seawater. Haneda (1950), following the observation by Molisch (1925) of luminous bacteria growing on beef, demonstrated that luminous bacteria could be isolated from certain samples of beef, pork and chicken meat. These meats might have contained enough salt to support the growth of marine forms, and Haneda cultured the bacteria in media containing 0.5% salt. However, whether these bacteria were terrestrial (i. e., *Photorhabdus*), freshwater (i. e., *V. cholerae*), or marine in origin apparently is not known.

Parasitism of Marine Invertebrates

Most of the commonly encountered marine luminous bacteria are not known to be highly invasive or virulent in animals. Many or perhaps all luminous species, however, can act as opportunistic pathogens upon entering an animal's body through lesions resulting from injury or stress. First noted in marine animals apparently by Viviani in 1805 (Harvey, 1957), infections of marine crustaceans by luminous bacteria are common, causing the infected animal to luminesce (Giard, 1889a; Giard and Billet, 1889b; Inman, 1926; Hastings and Nealson, 1981). Luminous bacteria inhabit the gut tract and colonize external surfaces of marine crustaceans (Inman, 1926; Baross et al., 1978b; O'Brien and Sizemore, 1979; Lavilla-Pitogo et al., 1992); many are chitinolytic (Spencer, 1961; Baumann and Schubert, 1984a). The bacteria enter the hemocele of the animal through lesions in the gut or carapace, developing luminescence and killing the animal within a few days. The species of luminous bacteria infecting isopods and amphipods commonly encountered in coastal environments have not been identified in recent times, but they exhibit characters consistent with members of the genera *Vibrio* and *Photobacterium* (Hastings and Nealson, 1981; P. Dunlap, unpublished observation). Nonluminous bacteria undoubtedly cause similar infections that go unnoticed due to the lack of light production.

As opportunistic pathogens of marine crustaceans, luminous bacteria have had a profoundly deleterious effect on commercial prawn mariculture. The development of intensive monoculture of *Penaeus monodon*, the giant tiger prawn, and other penaeids during the 1980s led to a dramatic increase in disease and death of the animals due to luminous bacteria. Shrimp hatchery rearing ponds can become heavily infested with luminous bacteria, with shrimp larvae developing "luminescent vibriosis," a pathogenic state responsible for massive mortalities. The problem continues in grow-out ponds, where the infection localizes to the hepatopancreas in juveniles, limiting the growth of the animals and further increasing losses to mortality (Lavilla-Pitogo and de la Peñ, 1998). Primarily responsible are strains of *V. harveyi*, though other luminous and nonluminous vibrios have been identified (Lavilla-Pitogo et al., 1990; Karunasagar et al., 1994; Lavilla-Pitogo and de la Peñ, 1998; Leano et al., 1998).

Parasitism of Vertebrates

In contrast to the situation with marine invertebrates, luminous bacteria apparently only rarely infect vertebrate animals. The ability of *P. asymbiotica* to infect humans has been mentioned above. *Vibrio harveyi* has been identifed in fish disease, and recently, *V. salmonicida* (a pathogen of salmonids and cod) has been shown to produce light under certain conditions (Fidopiastis et al., 1999).

Clinical strains of *Vibrio vulnificus* and *V. cholerae* typically are nonluminous, but luminous strains of *V. vulnificus* have been isolated from dead humans (Oliver et al., 1986), and luminous strains of *V. cholerae* have been isolated from humans suffering from cholera (Jermoljewa, 1926). Furthermore, Weleminsky (1895) demonstrated that a nonluminous clinical isolate of *V. cholerae* developed luminescence apparently by passage through another animal. *Vibrio cholerae* strains that are luminous or that contain the *luxA* gene are present in relatively high percentages in freshwater and estuarine environments (West and Lee, 1982; West et al., 1983; Palmer and Colwell, 1991; Ramaiah et al., 2000). The light-producing and *luxA* gene-containing strains are the non-O1 type of *V. cholerae* (Palmer and Colwell, 1991; Ramaiah et al., 2000).

Bioluminescent Symbiosis

One of the most remarkable attributes of luminous bacteria is the ability of certain species to

establish luminescence-based symbiotic associations called "bioluminescent symbiosis" with marine animals. These associations have been found in certain teleost fish, some loliginid and sepiolid squids, and possibly in pyrosomes and salps. The treatise by Buchner (1965) and the review by Herring and Morin (1978b) provide comprehensive access to early literature. For pyrosomes and salps, bioluminescent symbiosis with luminous bacteria is controversial (Harvey, 1952; Buchner, 1965). Pyrosome zooids bear a pair of simple photophores containing intracellular bacteroids, but the involvement of bacteria in pyrosome luminescence has been both discounted and supported (Galt, 1978; Herring, 1978a; Mackie and Bone, 1978; Haygood, 1993a). Although the bacteroids have not been cultured, the presence of bacterial luciferase in photophores is consistent with a bacterial origin for pyrosome luminescence (Leisman et al., 1980). In myctophid and stomiiform fishes, a similar proposal that the luminescence of photophores is due to the presence of symbiotic luminous bacteria (Foran, 1991) was shown conclusively to be invalid (Haygood et al., 1994).

In bioluminescent symbiosis of fishes and squids with luminous bacteria (Table 1), the host animal bears one or a pair of specialized gland-like tissues, called "light organs," which house a pure culture of the species-specific symbiotic bacterium. Accessory structures associated with the light organ, i.e. lens, reflector, and light-absorbing shutters and barriers, control, direct and focus the light the bacteria produce. The host animal uses the bacterial light in luminescence displays associated with various behaviors, including predator avoidance by counterillumination and flashing, sex-specific signaling, attracting or locating prey, and orienting in dark and dimly lighted environments (Hastings, 1971; Morin et al., 1975; Nealson and Hastings, 1979b; McFall-Ngai and Dunlap, 1983; McFall-Ngai and Montgomery, 1990; McFall-Ngai and Morin, 1991a). In fishes, the light organs are internal, associated with the gut tract, or external, located below the eye (subocular light organ), in the lower jaw (mandibular light organ) or at the terminus of an elongated dorsal fin ray (escal light organ), whereas in squids, they are found as bilobed organs ventrally within the mantle cavity, associated with the ink sac (Herring, 1977; Hastings and Nealson, 1981; Haygood, 1993a; McFall-Ngai and Ruby, 1991b). Bioluminescent symbiosis, owing to the specificity between host and symbiont, contrasts with other associations of luminous bacteria with animals; the saprophytic, commensal and parasitic associations are nonspecific and often involve assemblages of luminous and nonluminous bacteria (Harvey, 1940; Nealson and Hastings, 1992). Furthermore, a trend toward greater integration between symbiont and host can be envisioned in bioluminescent symbiosis, with certain animals colonized by facultatively symbiotic (i.e., culturable) bacteria and others harboring obligately symbiotic (i.e., not yet cultured) bacteria (Haygood, 1993a). Bioluminescent symbiosis appears to be a unique kind of symbiosis; the bacterial metabolic product needed by the host animal is light, used in bioluminescence displays, rather than a nutrient needed for host development or growth (Claes and Dunlap, 2000).

Four species of luminous bacteria, *V. fischeri*, *V. logei*, *P. leiognathi* and *P. phosphoreum*, have been identified in bioluminescent symbiosis (Table 1). *Vibrio fischeri* and *P. leiognathi* colonize light organs of both fish and squids (Boettcher and Ruby, 1990; Fukasawa et al., 1986; Fukasawa et al., 1988; Reichelt et al., 1977), whereas *P. phosphoreum* so far has been found in association only with fish (Herring and Morin, 1978b; Hastings and Nealson, 1981). *Vibrio logei* was identified recently as the predominant symbiont of the sepiolid squids *Sepiola affinis* and *Sepiola robusta* (Fidopiastis et al., 1998). Two other groups of fishes, the flashlight fish (family Anomalopidae) and deep-sea anglerfish (suborder Ceratioidei) bear light organs with symbiotic luminous bacteria that so far have not been cultured. The anomalopid symbionts, based on analysis of the *luxA* and 16S rRNA genes, are likely to be members of the genus *Vibrio*, and different genera of the fish harbor bacteria that differ at greater than the strain level (Haygood, 1990; Wolfe and Haygood, 1991). The results of 16S rRNA gene sequence analysis of the bacterial symbionts of two ceratioids (representing different families of anglerfish) group these bacteria with other marine enterics phylogenetically similar to *Photobacterium* and *Vibrio* and suggest that these may be new bacterial species in each fish (Haygood and Distel, 1993b).

Symbiont-Host Specificity

Despite the presence of various different species of luminous bacteria in the habitats of animals that form bioluminescent symbiosis, these associations are highly specific. Members of a given family of fishes and of squids consistently harbor the same species of symbiont (Fitzgerald, 1977; Reichelt et al., 1977; Ruby and Morin, 1978a; Ruby and Nealson, 1976; Fukasawa et al., 1986; Hastings and Nealson, 1981; Ruby, 1996). Various selective pressures, alone or in combination might account for this specificity. Physiological conditions of the light organ, which derives from host biology and light organ anatomy, may be important. Light-organ osmolarity, oxygen and iron levels, and types of nutrients presum-

ably interface with the individual physiological capabilities of different symbiotic luminous species and strains, promoting adaptively high levels of luminescence and competitive growth dominance of one type over another (Ruby and Nealson, 1976; Ruby and Nealson, 1977; Nealson, 1979a; Dunlap, 1985a; Haygood and Nealson, 1985a; Haygood, 1993a; Hastings et al., 1987; Graf and Ruby, 1998; Lee and Ruby, 1994a; Visick et al., 2000). Specific recognition and other exclusion mechanisms (Ruby, 1996) also may play a major role. Local abundance of the host also may contribute to specificity (Hastings and Nealson, 1981; Ruby and Lee, 1998).

Along with host-related factors, temperature, as an environmental factor, might play a significant role in host-symbiont specificity. A loose concordance is seen between the temperature of the host's habitat and the temperature sensitivities of the symbiotic bacteria. Fishes dwelling in temperate and tropical shallow waters harbor the more mesophilic species *V. fischeri* or *P. leiognathi*, whereas fishes dwelling in cold, deeper waters tend to harbor the more psychrotrophic species *P. phosphoreum* (Hastings and Nealson, 1981). Indeed, temperature reveals an exception to the pattern of host-symbiont specificity. The closely related species *V. logei* and *V. fischeri* can colonize the same species of sepiolid squid, *Sepiola affinis* and *Sepiola robusta*, forming mixed symbiotic cultures. Whereas lower temperatures favor the more psychrotrophic *V. logei*, warmer temperatures favor the more mesophilic *V. fischeri* (Fidopiastis et al., 1998; Nishiguchi, 2000).

Symbiont Transmission

In the few cases studied, squids and fishes have been found to acquire their symbiotic luminous bacteria by horizontal transfer. Best documented is the sepiolid squid *Euprymna scolopes*, hatchlings of which carry no *V. fischeri* cells or other bacteria in their nascent light organs. Soon after hatching, the animal picks up its symbiotic bacterium from seawater, establishing bioluminescent symbiosis (Wei and Young, 1989; McFall-Ngai and Ruby, 1991b). Symbiont motility is required for this process (Graf et al., 1994). Nascent light organs of juvenile *Siphamia versicolor* (family Apogonidae) at the early larval stage lack bacteria but contain them later in development, consistent with acquisition of the bacteria from the seawater (Haneda, 1965; Leis and Bullock, 1986). Recently, Wada et al. (1999) provided evidence for horizontal transfer of *P. leiognathi* to juvenile *Leiognathus nuchalis* (family Leiognathidae). For anomalopid (flashlight) fish, no evidence was found that the symbiotic bacteria are associated with gonads or eggs, consistent with horizontal transfer in this group as well (Haygood, 1993a).

Symbiont Contributions to Host Survival, Growth, and Development

Bioluminescent symbiosis appears to be a special class of symbiosis, one in which the primary metabolic contribution the symbiotic bacteria make to the host is light. In most bacterial associations with animals and plants, the host is dependent nutritionally on its symbiotic bacteria, via bacterial fixation of carbon or nitrogen, the activity of bacterial extracellular degradative enzymes, such as cellulases, or bacterial provision of vitamins or other essential nutrients (Douglas, 1995). As a consequence, absence of the symbiotic bacteria can have a profound influence on the survival, growth and development of the host. In contrast, the sepiolid squid *E. scolopes* cultured aposymbiotically from hatching to reproductive adulthood survived, grew and developed equally as well as animals colonized by *V. fischeri* (Claes and Dunlap, 2000). These observations indicate that *V. fischeri* apparently makes no major nutritional contribution to the animal. The metabolic dependency of *E. scolopes* on *V. fischeri* therefore seems limited to light production. Selection for the association presumably is ecological, with the squid's ability to counterilluminate using light produced by *V. fischeri* (Singley, 1983; McFall-Ngai and Montgomery, 1990) playing an important role in survival. Whether a similar lack of nutritional dependency of the host on its symbiotic bacteria characterizes other bioluminescent symbioses remains to be determined.

Influence of Symbionts on Light-Organ Morphogenesis

Much progress in understanding host-symbiont relationships in bioluminescent symbiosis has developed from studies of the sepiolid squid *E. scolopes*. The animal maintains a species-specific (and strain-specific) association with *V. fischeri*, harboring the bacteria extracellularly in diverticulated epithelial tubules comprising the core of the bilobed ventral light organ. Associated with the light organ are accessory tissues, specifically the ink sac, and the reflectors and lens, which control and direct the light produced by *V. fischeri*. The tubules lead into a ciliated duct that connects each lobe of the light organ to the mantle cavity (McFall-Ngai and Ruby, 1991b; Ruby, 1996; McFall-Ngai, 1999).

Analysis of the colonization process in hatchling juvenile *E. scolopes* demonstrates a role for the symbiotic bacterium in morphological changes in the light organ. The nascent, rudimentary light organs in hatchlings bear a pair of

lateral ciliated epithelial appendages (CEAs) and contain a pair of three simple sac-like epithelial tubules embedded in the undifferentiated accessory tissues. The proximal portions of these tubules are ciliated and directly connect to the mantle cavity via a lateral pore. Colonization of the epithelial tubules, which is facilitated by ciliary beating of the CEAs, occurs through these lateral pores, which later coalesce, with the formation of a ciliated duct for each light organ lobe. Colonization triggers regression of the CEAs within approximately 4 days. Other morphological changes include alterations in the epithelial cells of the distal portions of the light organ tubules, which develop a dense microvillous brush border (McFall-Ngai and Ruby, 1991b; Montgomery and McFall-Ngai, 1993; Montgomery and McFall-Ngai, 1994; Doino and McFall-Ngai, 1995; Ruby, 1996; Lamarcq and McFall-Ngai, 1998; McFall-Ngai, 1999).

Presence of the bacteria, however, is not necessary for overall development of the light organ and its accessory tissues, which proceed normally in aposymbiotic animals (Claes and Dunlap, 2000). In possible contrast to light organ development in *E. scolopes*, light organs of the monocentrid fish, *M. japonicus*, had not developed by day 21 in larvae from artificially fertilized eggs (Yamada et al., 1979), suggesting that acquisition of *V. fischeri* may be necessary to initiate the light organ developmental program. Whether development of the light organ in aposymbiotic juvenile leiognathid fish requires colonization by *P. leiognathi* is not yet known (Wada et al., 1999).

Host Contribution to Symbiont Dissemination

Bioluminescent symbiosis is likely to have a significant impact on the density and distribution of the symbiotic bacteria in seawater. Growth of the bacterial population in the light organ leads to the continual or diurnal release of bacterial cells into the environment (Dunlap, 1984; Haygood et al., 1984; Nealson et al., 1984; Lee and Ruby, 1994b; Boettcher et al., 1995). The cells are released either directly into seawater, as in monocentrid fish and sepiolid squids, or indirectly via the gut tract, as in leiognathid fish. Estimates of growth rates for the bacteria indicate the population doubles once to a few times per day (Dunlap, 1984; Haygood et al., 1984; Lee and Ruby, 1994b), so each adult host may release as many as 10^7 to 10^8 symbiont cells per day. This release, which has the potential of dispersing the bacteria into other habitats they colonize (Nealson et al., 1984), may be essential for re-initiation of the association with the next generation of the host animal (Ruby and Lee, 1998).

Physiological Control of Luminescence

Growth conditions can strongly influence the amount of light produced by luminous bacteria in laboratory culture. Oxygen, amino acids, glucose, iron and osmolarity have distinct effects, depending on the species studied (Harvey, 1952; Nealson and Hastings, 1977b; Makemson and Hastings, 1982; Haygood and Nealson, 1985a; Hastings et al., 1987; Dunlap, 1991a). Those factors that stimulate growth rate, such as readily metabolized carbohydrates, tend to decrease light production and luciferase synthesis. They do so presumably by causing oxygen and reducing power ($FMNH_2$) to be directed away from luciferase (McElroy and Seliger, 1962; Coffey, 1967) and by indirectly or directly influencing *lux* gene expression (Dunlap and Greenberg, 1985b; Dunlap, 2000). Conversely, factors that restrict growth rate, such as limitation for iron, tend to stimulate the synthesis and activity of luciferase (Hastings and Nealson, 1977; Haygood and Nealson, 1985a; Hastings et al., 1987; Dunlap, 1991a). The mechanisms by which these factors operate, however, are not well understood (Haygood and Nealson, 1985b; Dunlap, 1992a; 1992b), indicating that much remains to be learned about the interplay between growth physiology of the cell and regulatory elements controlling *lux* gene expression.

Amino Acids, Catabolite Repression, and Control by cAMP

The amino acid arginine and certain structurally and metabolically related compounds can stimulate luminescence in *V. harveyi* growing in minimal medium (Coffey, 1967; Nealson et al., 1970; Hastings and Nealson, 1977). The mechanism for this activity remains unknown. Conversely, yet equally intriguing, mixtures of amino acids can transiently and in a dose-dependent manner block the increase in light production of inducing cultures of *P. leiognathi* (P. Dunlap, unpublished observation). Catabolism of the amino acids might account for this temporary repression of luminescence induction.

Catabolite repression of luminescence generally is attributed to effects on levels of 3′,5′-cyclic AMP (cAMP) and cAMP receptor protein (CRP; Nealson et al., 1972; Meighen and Dunlap, 1993; Dunlap, 1997). Different species of luminous bacteria, however, respond in different ways. In *V. harveyi*, catabolite repression by glucose in batch culture is permanent and is reversed by addition of cAMP (Nealson et al., 1972), whereas glucose repression of luminescence in *V. fischeri* is temporary, is not reversed

by addition of cAMP, and is eliminated by prior growth in the presence of glucose (Ruby and Nealson, 1976). Complicating these differences from studies in batch culture are studies of *V. fischeri* grown in phosphate-limited chemostat culture; glucose repression of luminescence then is permanent and reversible by cAMP (Friedrich and Greenberg, 1983). A further complication for studies of cAMP-control of luminescence in *V. fischeri* is the presence in this species of a novel, exceptionally potent periplasmic cyclic nucleotide phosphodiesterase specific for extracellular 3′, 5′-cyclic nucleotides; activity of the enzyme enables cells to grow on exogenously supplied cAMP as a sole source of carbon and energy, nitrogen and phosphorus (Dunlap et al., 1992d; Dunlap and Callahan, 1993; Callahan et al., 1995). Regardless of the differences in catabolite repression, mutants of *V. harveyi* and *V. fischeri* apparently defective in adenylate cyclase and unable to produce light in the absence of added cAMP have been isolated and characterized (Ulitzur and Yashphe, 1975; Dunlap, 1989a). Furthermore, CRP from *V. harveyi* has been purified and shown to be immunologically and functionally homologous to CRP of *Escherichia coli* (Chen et al., 1985), and the *cya* and *crp* genes of *V. fischeri* have been cloned and found to be highly similar in deduced amino acid residue sequence to *E. coli cya* and *crp* genes (P. Dunlap et al., unpublished observation). Consistent with these observations, the regions upstream of the luminescence operons of *V. harveyi* and *V. fischeri* contain a CRP binding site (Engebrecht and Silverman, 1987; Devine et al., 1988a; Miyamoto et al., 1988b). Studies with *V. fischeri* and with *E. coli* carrying the *V. fischeri* luminescence system indicate that a major effect of cAMP-CRP is to activate the production of LuxR, the luminescence operon transcriptional activator (see below; Dunlap and Greenberg, 1985b; Dunlap and Greenberg, 1988; Dunlap and Kuo, 1992c; Shadel et al., 1990a), although other important *lux* regulatory effects have also been described (Shadel and Baldwin, 1991; Shadel and Baldwin, 1992a; Shadel and Baldwin, 1992b). Regardless, control of the luminescence system by cAMP-CRP in *V. fischeri* demonstrates the integration of luminescence with cellular metabolism and suggests that activity of the luminescence system is part of the cellular response to stresses associated with nutrient limitation and decreasing growth rate. Consistent with that view, a heat-shock protein (GroESL) and a repressor of DNA repair (LexA) have been shown or are suspected of contributing to control of luminescence (Ulitzur and Dunlap, 1995). Those factors that can restrict growth rate while enhancing expression and activity of luciferase, e.g., limiting oxygen, limiting iron and high or low osmolarity (Dunlap, 1991a; Hastings et al., 1987; Meighen and Dunlap, 1993) might operate by influencing the cellular levels of cAMP and CRP or other stress-response elements.

The *Lux* Genes, Luminescence Autoinduction and Quorum Sensing

The *lux* Genes. The bacterial *lux* genes can be grouped in three categories: the core *lux*, accessory *lux* and regulatory genes. The five core *lux* genes, which provide the enzymatic capability for light production, are common to all luminous bacteria examined to date. These genes are *luxA* and *luxB*, encoding the luciferase subunits, and *luxC*, *luxD* and *luxE*, encoding the fatty-acid reductase subunits; they occur contiguously as an operon, *luxCDABE* (Fig. 3). The bacterial*lux*-genes have been used for a variety of applications, primarily as reporters for environmental and regulatory effects in heterologous systems (LaRossa, 1998).

Accessory *lux* genes, which are associated with light production, are found in different species and strains of luminous bacteria. In some cases, these genes are linked to the *lux* operon. *Photobacterium phosphoreum* (Fig. 3) and a strain of *P. leiognathi* bear *luxF*, a gene similar in sequence to *luxB*, between *luxB* and *luxE*, encoding a nonfluorescent flavoprotein. The *lux* operons of the marine luminous bacteria also contain *luxG*, which in *V. fischeri* is followed by a strong transcriptional terminator (Swartzman et al., 1990a). The LuxG protein may be a flavin reductase of the Fre/LuxG family of NAD(P)H-flavin oxidoreductases (Zenno and Saigo, 1994a; Zenno et al., 1994b). The last gene of the *lux* operon in *V. harveyi* is *luxH*. Protein LuxH is homologous to *E. coli* RibB (3,4-dihydroxy-2-butanone 4-phosphate synthase), a key enzyme in riboflavin synthesis (Swartzman et al., 1990b). Recently, the *ribB* gene of *V. fischeri* was identified. In contrast to *luxH* in *V. harveyi*, *ribB* in *V. fischeri* is unlinked to the *lux* operon; nonetheless its expression is controlled coordinately with the *lux* operon (Callahan and Dunlap, 2000). Additional genes involved in riboflavin synthesis have been identified downstream of the *lux* operon in *V. fischeri*, *P. leiognathi* and *P. phosphoreum* (Lee et al., 1994c). Other accessory luminescence genes have been described (O'Kane and Prasher, 1992; Meighen, 1994).

The third category, genes specifying regulatory proteins, has been identified to date only in *V. fischeri* and *V. harveyi* (Fig. 3). In *V. fischeri*, the main *lux* regulatory genes, *luxR*, encoding the acyl-homoserine lactone receptor/*lux* operon transcriptional activator, and *luxI*, encoding acyl-homoserine lactone synthase (Engebrecht et al., 1983; Engebrecht and Silverman, 1984; Schaefer

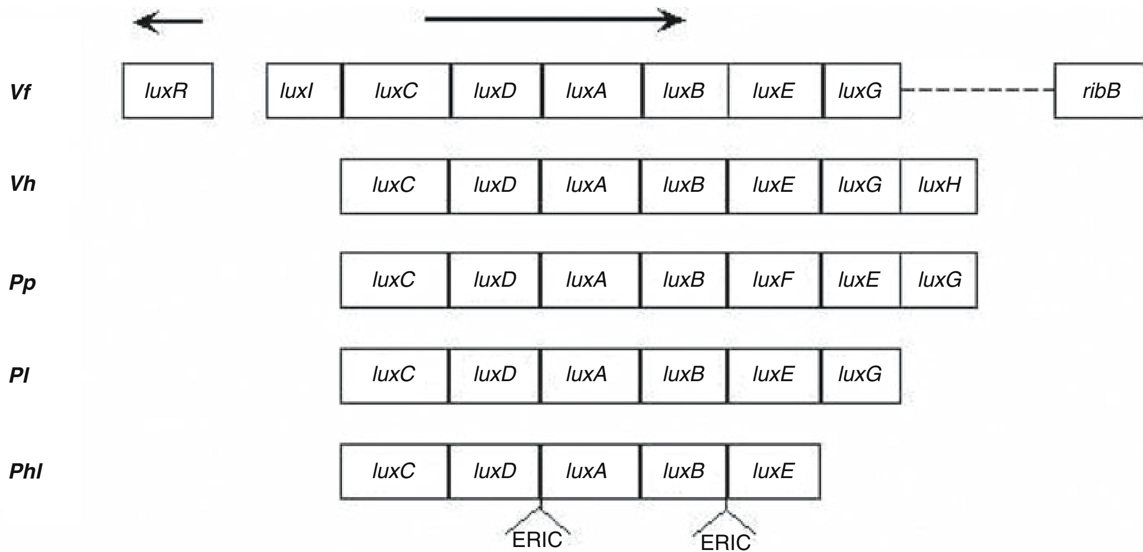

Fig. 3. Organization of the luminescence genes in luminous bacteria. Abbreviations and key references are: Vf, *V. fischeri* (Baldwin et al., 1989; Callahan and Dunlap, 2000; Devine et al., 1988a; Engebrecht et al., 1983; Engebrecht and Silverman, 1984; Engebrecht and Silverman, 1987; Foran and Brown, 1988; Swartzman et al., 1990a); Vh, *V. harveyi* (Cohn et al., 1985; Johnston et al., 1986; Johnston et al., 1989; Miyamoto et al., 1988a; Miyamoto et al., 1988b; Miyamoto et al., 1989; Swartzman et al., 1990b); Pp, *P. phosphoreum* (Soly et al., 1988); Pl, *P. leiognathi* (Baldwin et al., 1989; DeLong et al., 1987; Illarionov et al., 1990; Meighen, 1991; Meighen and Dunlap, 1993); Phl, *Ph. luminescens* (Frackman et al., 1990; Frackman et al., 1990; Johnston et al., 1990; Szittner and Meighen, 1990; Xi et al., 1991); and ERIC, enteric repetitive intergenic consensus sequence (Meighen and Szittner, 1992; Forst and Nealson, 1996). Additional regulatory genes in *V. fischeri* and regulatory genes in *V. harveyi* have been identified, as shown in Figs. 4 and 5. Regulatory genes controlling *luxCDAB(F)EG* expression in other species have not yet been identified. Arrows indicate direction of transcription, and genes are not drawn to scale.

et al., 1996; Stevens et al., 1994; Stevens and Greenberg, 1997), are contiguous with the *lux* operon. The *luxI* gene is part of the *lux* operon, whereas *luxR* is upstream and divergently expressed (Fig. 3). In *V. harveyi*, the *luxR* gene, which is not homologous to *V. fischeri luxR*, is not linked to the *lux* operon (Showalter et al., 1990; Swartzman et al., 1992). In other species, the *lux* regulatory genes have not been identified, but they apparently are unlinked to the *lux* operon. Additional *lux* regulatory genes have been identified in *V. fischeri* and *V. harveyi* and are described below.

Luminescence Autoinduction and Quorum-Sensing. Many luminous bacteria exhibit a distinctive pattern of luciferase synthesis and light production in laboratory culture, previously called "autoinduction" and now referred to as "quorum sensing." In *V. fischeri* and *V. harveyi*, expression of the *lux* operon, i.e., luciferase synthesis and luminescence, initially low in early exponential phase cultures, induces strongly as cultures attain the high cell densities associated with late exponential to early stationary phases of growth (Hastings and Greenberg, 1999; Dunlap, 2000). Early analyses of the "phases of luminescence" in culture (Baylor, 1949; Farghaly, 1950) were followed by the demonstration that luciferase synthesis is inducible and that complete medium contained a compound inhibitory to induction (Nealson et al., 1970; Eberhard, 1972). During growth, cells of *V. fischeri* and *V. harveyi* were found to release into the medium species-specific secondary metabolites, called "autoinducers." These compounds accumulate in the growth medium in a cell-density dependent manner, and once they attain threshold concentrations they induce luciferase synthesis (Nealson et al., 1970; Eberhard, 1972; Nealson, 1977a; Nealson and Hastings, 1979b; Ulitzur and Hastings, 1979; Rosson and Nealson, 1981). The cell density-dependent nature of autoinduction led to the coining of the term quorum sensing (Fuqua et al., 1996; Greenberg, 1997).

Analysis of autoinduction reached a notable fruition in the 1980s with the identification of autoinducer signal molecules and *lux* regulatory genes. The first autoinducer, 3-oxo-hexanoyl-HSL (3-oxo-C6-HSL), and the first *lux* regulatory genes, *luxI* (encoding 3-oxo-C6-HSL synthase; Schaefer et al., 1996) and *luxR* (encoding acyl-HSL receptor/transcriptional activator) were identified in *V. fischeri* (Eberhard et al., 1981; Engebrecht et al., 1983; Engebrecht and Silverman, 1984), followed by identification of 3-hydroxybutanoyl-HSL (3-OH-C4-HSL) and a

nonhomologous *luxR* gene in *V. harveyi* (Cao and Meighen, 1989; Showalter et al., 1990). From that base of knowledge, quorum sensing systems that are chemically and genetically homologous to those of *V. fischeri* and *V. harveyi* have been identified over the past decade in many species of nonluminous Gram-negative bacteria, including many terrestrial species and several pathogens of animals and plants. Quorum sensing plays important roles in the biology of these bacteria by regulating a wide variety of different kinds of genes, including those for the production of extracellular enzymes, plasmid transfer, antibiotic synthesis and biofilm formation, as well as luminescence (Fuqua et al., 1996; Dunlap, 1997; Swift et al., 1999). Thus, quorum sensing not only is common to luminous bacteria, but also widespread and evolutionarily conserved among Gram-negative bacteria.

Despite the importance of quorum sensing as a regulatory paradigm in Gram-negative luminous bacteria, it should be pointed out that apparently not every luminous bacterium can autoinduce luminescence. Certain strains identified as *P. leiognathi* lack the lag in luminescence and luciferase synthesis in batch culture that is characteristic of autoinduction (Katznelson and Ultizur, 1977); it is possible that expression of the *lux* system in these strains is independent of acyl-HSLs and that luciferase synthesis is essentially constitutive. These considerations highlight the likelihood that luminescence and quorum sensing had separate evolutionary origins, discussed below.

QUORUM SENSING CONTROL OF LUMINESCENCE IN *V. FISCHERI* AND *V. HARVEYI*. Intensive study of *V. fischeri* and *V. harveyi* over the past 20 years has developed the luminescence systems in these two species as prototypes for quorum sensing in bacteria (Bassler, 1999; Dunlap, 1997; Dunlap, 2000; Fuqua et al., 1994; Greenberg, 1997; Hastings and Greenberg, 1999). New and fundamental information, nonetheless, continues to accumulate on how these bacteria control light production and use quorum sensing. Indeed, the simple view that "quorum sensing signals accumulate in a cell density-dependent manner and trigger transcription of genes for the luminescence enzymes," though still entirely valid, has been replaced. The newer view is that quorum-sensing control of luminescence in these two species is remarkably complex, and that the mechanisms (Figs. 4 and 5) have intriguing genetic homologies and disparities.

In *V. fischeri*, luminescence is controlled by two quorum-sensing signals that coordinate a complex regulatory circuitry (Fig. 4). Major components of the quorum-sensing mechanism are: LuxI, the 3-oxo-C6-HSL synthase; LuxR, the transcriptional regulatory protein, which requires 3-oxo-C6-HSL for activity; GroEL, which is necessary for production of active LuxR; and AinS, octanoyl-HSL (C8-HSL) synthase (Engebrecht et al., 1983; Engebrecht and Silverman, 1984; Schaefer et al., 1996; Adar et al., 1992; Dolan and Greenberg, 1992; Adar and Ulitzur, 1993; Hanzelka et al., 1999; Kuo et al., 1994; Gilson et al., 1995; Kuo et al., 1996). A cell density-dependent accumulation of 3-oxo-C6-HSL, a membrane-permeant compound (Kaplan and Greenberg, 1985), triggers induction of *lux*operon expression by binding to LuxR, apparently a membrane-associated protein (Kolibachuk and Greenberg, 1993), forming a complex that facilitates the association of RNA polymerase with the *lux* operon promoter (Stevens and Greenberg, 1997). This activation initiates a positive feedback loop for synthesis of 3-oxo-C6-HSL (e.g., Eberhard et al., 1991), and LuxR/3-oxo-C6-HSL negatively autoregulate *luxR* expression (Dunlap and Greenberg, 1988; Dunlap and Ray, 1989b). The C8-HSL, which apparently interferes with 3-oxo-C6-HSL binding to LuxR, operates to limit premature *lux* operon induction (Eberhard et al., 1986; Kuo et al., 1996). Expression of *luxR* is activated by both cAMP and CRP (Dunlap and Greenberg, 1985b; Dunlap and Greenberg, 1988; Dunlap, 1989a; Dunlap and Kuo, 1992c), which also have other regulatory effects (Shadel and Baldwin, 1991) and thereby provide overall control over quorum sensing. Under anaerobic conditions, which are permissive of luciferase synthesis (Eberhard et al., 1979), a regulator of fumarate and nitrate reduction (Fnr) contributes to *lux* operon expression (Müller-Bretkreutz and Winkler, 1993). Recently, a homolog of the *V. harveyi* *luxO* gene was identified in *V. fischeri*. As is the case in *V. harveyi*, LuxO in *V. fischeri* apparently functions as a repressor of luminescence (Miyamoto et al., 2000). For details of*lux*gene regulation in *V. fischeri*, see Dunlap (2000).

Luminescence regulation in *V. harveyi* has several features in common with *V. fischeri*. Like *V. fischeri*, *V. harveyi* uses two different quorum-sensing signals, 3-OH-C4-HSL and Vh AI-2, an unidentified compound; two different genes (*luxLM* and *luxS*) direct synthesis of these respective signals. Luminescence in both species requires cAMP-CRP, and in both it is dependent on a transcriptional activator protein LuxR, although these proteins are not homologous (Bassler et al., 1993; Bassler et al., 1994b; Chen et al., 1985; Eberhard, 1972; Martin et al., 1989; Nealson et al., 1970; Nealson et al., 1972; Miyamoto et al., 1988b; Miyamoto et al., 1990; Miyamoto et al., 1994; Showalter et al., 1990; Swartzman et al., 1990a; Swartzman and Meighen, 1993; Ulitzur and Yashphe, 1975). Fur-

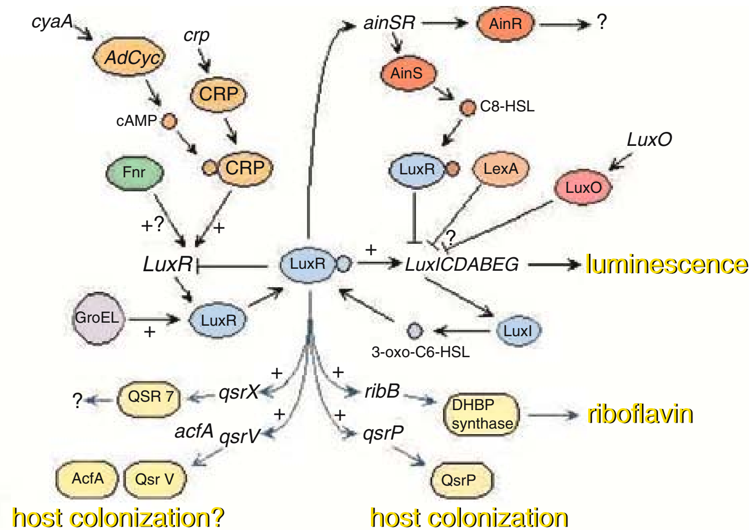

Fig. 4. Model for quorum-sensing control of luminescence and other genes of the quorum-sensing regulon of *V. fischeri*. Depicted in the upper portion of the figure are regulatory genes, proteins, effectors and positive and negative regulatory circuitry controlling *luxR*/*luxICDABEG* expression (summarized from Ulitzur and Dunlap, 1995; Dunlap, 2000; see also Lin et al., 2000). Abbreviations: AdCyc, adenylate cyclase; 3-oxo-C6-HSL, 3-oxo-hexanoyl-homoserine lactone; C8-HSL, octanoyl-homoserine lactone. Key elements of *lux* regulation are described in the text. The weak activation of *lux* operon expression by C8-HSL/LuxR is depicted as repression, due to the apparent competitive inhibition by C8-HSL of the interaction between 3-oxo-C6-HSL and LuxR (Kuo et al., 1996). The lower portion of the figure indicates genes downstream of the *lux* operon that are coordinately controlled with the *lux* operon, positively by LuxR/3-oxo-C6-HSL and negatively by LuxR/C8-HSL (Callahan and Dunlap, 2000).

thermore, the *lux* operons of these bacteria are similar in structure (Miyamoto et al., 1988a; Swartzman et al., 1990b), although regulatory genes apparently are not present in the region immediately upstream of *luxC* (Miyamoto et al., 1988b; Fig. 3). The recent identification of *ribB*, the *V. fischeri* homolog of *V. harveyi luxH*, which like the *lux* operon genes is controlled by LuxR and acyl-HSLs (Callahan and Dunlap, 2000) further demonstrates the overall similarity of *lux* genes in these two species.

A striking counterpoint to the general similarities in the *lux* operons and physiological control of luminescence in these bacteria is the qualitative difference in quorum sensing in *V. harveyi*. Expression of the *lux* operon in *V. harveyi* is regulated by a quorum-sensing phosphorelay signal transduction mechanism. The mechanism involves two separate two-component phosphorelay paths, each involving a transmembrane sensor/kinase, LuxN and LuxQ, responsive to a separate quorum-sensing signal (Fig. 5). The *luxLM* genes are necessary for synthesis of the 3-OH-C4-HSL signal. In the absence of 3-OH-C4-HSL, LuxN operates as a kinase, phosphorylating LuxU, a signal integrator, which in turn passes the phosphate on to LuxO; the phosphorylated LuxO represses the *lux* operon. In the presence of 3-OH-C4-HSL, the activity of LuxN is shifted from kinase to phosphatase, which draws phosphate from LuxU and thereby from LuxO; the dephosphorylated LuxO no longer represses *lux* operon expression. A similar activity is carried out by a second, as yet unidentified signal (Vh AI-2), which requires LuxS for its production. Operating via LuxP, a putative periplasmic protein, Vh AI-2 mediates the kinase/phosphatase activity of LuxQ, which in turn, like LuxN, feeds phosphate to or draws it from LuxO. Previously thought to directly repress *lux* operon expression, LuxO may operate indirectly, by controlling a negative regulator of luminescence. Expression of *luxO* itself is subject to repression by LuxT (Bassler, 1999; Bassler et al., 1994a; Cao and Meighen, 1989; Freeman and Bassler, 1999a; Freeman and Bassler, 1999b; Lilley and Bassler, 2000; Lin et al., 2000; Surete et al., 1999b). In a manner possibly analogous to LuxR in *V. fischeri*, LuxR in *V. harveyi* is autoregulatory and responsive to 3-OH-C4-HSL (Cao et al., 1995; Chatterjee et al., 1996; Miyamoto et al., 1996). The phosphorelay signal transduction mechanism of *V. harveyi* appears to differ substantially from the *V. fischeri* quorum-sensing paradigm of direct acyl-HSL/receptor protein activation of *lux* operon expression.

Despite this difference, evidence is growing that the quorum-sensing systems of these two species have significant overlaps at the genetic level. The first indication of genetic overlap was

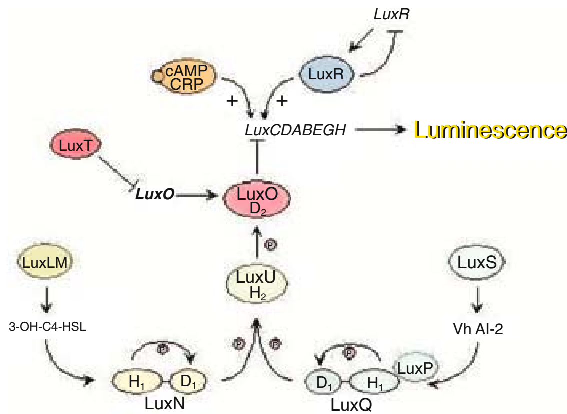

Fig. 5. Model for quorum-sensing control of luminescence in *V. harveyi*. Regulatory inputs positively (cAMP-CRP and LuxR) and negatively (LuxO) controlling the *lux* operon and negatively controlling *luxO* are shown. The circled P indicates the intramolecular phosphate transfer and the separate phosphorylation/dephosphorylation signal transduction circuits mediated by the quorum sensing signals 3-OH-C4-HSL and Vh AI-2. H_1 and D_1 refer to the conserved histidine and aspartate residues of the sensor kinase and response regulator domains, respectively, of LuxN and LuxQ. H_2 refers to a histidine residue of LuxU, which integrates signals from LuxN and LuxQ, and D_2 refers to an aspartate residue of LuxO, to which the signal is then transduced. The phosphoryl flow is from H_1 to D_1 of LuxN, and from H_1 to D_1 of LuxQ, to H_2 of LuxU to D_2 of LuxO. In the absence of the quorum-sensing signals, LuxN and LuxQ, the depicted phosphoryl flow leads to phosphorylation of LuxO, which may directly or indirectly repress the *lux* operon. Phosphorylase activity of LuxN and LuxQ is activated by the accumulation of the quorum-sensing signals, leading to dephosphorylation and inactivation of LuxO. Not shown are the membrane-permeant nature of the quorum-sensing signals and the membrane association of LuxN, LuxQ, and LuxP. Modified from Bassler (1999).

the finding that the C-terminal half of the *V. fischeri* AinS protein is 34% identical to the *V. harveyi* LuxM protein, and the N-terminal portion of *V. fischeri* AinR (encoded by *ainR*, a gene downstream of *ainS*) is 38% identical to the N-terminal portion of *V. harveyi* LuxN (Gilson et al., 1995). Whether AinR itself, possibly with C8-HSL, plays a role in *lux* regulation (Gilson et al., 1995; Kuo et al., 1994) has not been established. The recent identification in *V. fischeri* of *luxO* is another example. The deduced amino acid residue sequence of *V. fischeri* LuxO is approximately 70% identical to that of *V. harveyi* (Miyamoto et al., 2000). Furthermore, a gene immediately downstream of *luxO* in *V. fischeri* is likely to be a homolog of *V. harveyi luxU*. These homologies suggest that *V. fischeri* (like *V. harveyi*) uses a phosphorelay system for quorum sensing. Consequently, the extent of actual differences between the quorum-sensing mechanisms in *V. fischeri* and *V. harveyi* is not yet clear.

Nonetheless, the qualitative difference in the quorum sensing systems of *V. fischeri* and *V. harveyi* is surprising. One could reasonably anticipate that the mechanisms regulating light production in these two species would be very similar because these bacteria are closely related evolutionarily, and are metabolically and physiologically very similar. Furthermore, whereas *V. fischeri* and *V. harveyi* have ecological differences, the differences do not seem to provide a compelling rationale for the qualitative difference in*lux*regulation. *Vibrio fischeri*, a more temperate-water species, colonizes light organs of monocentrid fish and certain sepiolid squids, whereas *V. harveyi*, a species more abundant in warmer waters and able to utilize more sole carbon and energy sources for growth in laboratory culture, has not been found as a light organ symbiont. However, both species can be isolated from seawater, sediments, gut tracts of marine animals, and from infected crustaceans—habitats in which they commonly are found together (Baumann and Baumann, 1981). This ecological commonality suggests that the physiological and ecological importance of quorum sensing would be very similar in the two species. The mechanistic differences outlined above, however, even with genetic overlaps, indicate that the two systems are substantially different and that the difference might result from subtle ecological differences. An alternative possibility, however, is that the *lux* operons were acquired separately by *V. fischeri* and *V. harveyi*, under different circumstances. For example, selective pressures and chromosomal locations for *lux* operons may have differed at the times of acquisition, accounting for the different qualities of the regulatory mechanisms. Lateral transfer of the *lux* operon is discussed below. Regardless, the presence of multiple cross-acting quorum-sensing systems in *V. fischeri* and *V. harveyi* most likely indicates the importance in both species of sensing and responding to complex and changing conditions in a variety of different habitats.

Quorum-sensing Regulated Genes "Downstream" of *lux*. An emerging area in luminous bacteria biology is the identification of non-Lux activities controlled by quorum sensing. Quorum sensing is known to control various activities in nonluminous bacteria (Dunlap, 1997; Swift et al., 1999), but studies of quorum sensing in luminous bacteria have focused exclusively on luminescence until very recently. Studies of *V. harveyi* led to the first demonstration of quorum-sensing-regulated activities other than luminescence in luminous bacteria. In *V. harveyi*, the production of the fatty acid storage product poly-β-hydroxybutyrate is controlled in a cell density-dependent manner by 3-OH-C4-HSL (Sun et al., 1994; Miyamoto et al., 1998). The use of acyl-

HSL inhibitors has revealed that production of exotoxins by *V. harveyi* is linked to quorum-sensing control of luminescence (Harris and Owens, 1999a; Harris et al., 1999b). Furthermore, LuxO controls not only luminescence but also cell morphology and siderophore production in *V. harveyi* (Lilley and Bassler, 2000). Consistent with these observations, homologs of *V. harveyi* LuxO, LuxR and LuxS have been identified in several nonluminous bacteria (Jobling and Holmes, 1997; Klose et al., 1998; McCarter, 1998; Sperandio et al., 1999; Surete et al., 1999b; Joyce et al., 2000; McDougald et al., 2000), indicating that, as is the case for *V. fischeri*, elements of the *V. harveyi* quorum-sensing system are widespread in Gram-negative bacteria. In *V. fischeri*, proteomic analysis of mutants defective in *luxR*, *luxI* and *ainS* recently revealed the presence of several quorum-sensing regulated genes "downstream" of the *lux* operon (Callahan and Dunlap, 2000; Fig. 4). These genes code for an apparently diverse array of proteins, including proteins contributing to the ability of *V. fischeri* to colonize its squid host, *E. scolopes*. The identification of non-*lux* genes in luminous bacteria controlled by quorum sensing and the characterization of quorum-sensing regulatory genes in nonluminous bacteria serves to demonstrate the generality of quorum sensing and to indicate that quorum sensing and luminescence are functionally separate activities.

Independent Evolutionary Origins of Quorum Sensing and Luminescence

Knowledge of quorum sensing developed out of studies of luminescence autoinduction in *V. fischeri* and *V. harveyi* during the 1970s and 1980s, as described above. Despite the phenomenological and historical linkage between them, however, luminescence and quorum sensing apparently have separate evolutionary origins. The following considerations lead to this view.

1) The existence of strains that apparently do not regulate luciferase synthesis in an autoinducible manner (Katznelson and Ulitzur, 1977) suggests that bacterial luminescence is not necessarily subject to quorum sensing control.

2) The physical linkage of the *lux* structural and regulatory genes found in *V. fischeri*, which if consistently present in other species would imply an evolutionary link between light production and its regulation, is not found in other bacteria, e.g., *V. harveyi*. Furthermore, other luminous bacteria (e.g., *V. harveyi*) apparently lack homologs of the *V. fischeri* LuxR and LuxI proteins, and are very different from either *V. fischeri* or *V. harveyi* in the way they regulate light production. For example, luminescence in *Photorhabdus*, which does not exhibit autoinduction (Forst and Nealson, 1996), apparently is controlled at the posttranscriptional level (Wang and Dowds, 1991; Hosseini and Nealson, 1995).

3) Many nonluminous bacteria use acyl-HSL-mediated quorum sensing, indicating that quorum sensing is not exclusive to luminous bacteria.

4) Quorum sensing controls several activities in nonluminous bacteria (Dunlap, 1997; Swift et al., 1999) and controls activities in luminous bacteria unrelated to luminescence (Callahan and Dunlap, 2000; Sun et al., 1994; Harris et al., 1999b; Lilley and Bassler, 2000), indicating regulatory significance beyond and unrelated to light production.

There appears to be no necessary functional or physical connection between quorum sensing and luminescence. In the absence of that connection, one can then ask why *luxCDABE* is under quorum sensing control in some species but apparently not in others. We postulate that this apparent discordance points to different origins of *lux* genes among the different luminous bacteria.

Origin and Lateral Transfer of the *lux* Genes

Evolutionary Origin of Bacterial Luminescence

The presence of naturally acquired genes necessary for producing light defines the luminous bacteria. The necessary genes *luxA* and *luxB*, encoding the luciferase subunits, and *luxC*, *luxD* and *luxE*, for the fatty-acid reductase subunits, are consistently found together as a cotranscribed unit *luxCDABE* (Fig. 3). Furthermore, the individual *lux* proteins have a high degree of sequence identity, 54–88% and 45–77% for the α- and the β-subunits of luciferases, respectively, and 57–80%, 59–74%, and 59–81% for the fatty acid reductase subunits, LuxC, LuxD and LuxE, respectively (Meighen and Dunlap, 1993). The reason for this conservation as a unit is not known; it might be necessary for efficient light production, perhaps by ensuring an interaction of luciferase and fatty acid reductase that facilitates substrate generation and processing. Conservation as a unit to permit coordinate regulation would not seem to be the reason because quorum sensing coordinately regulates several widely separated sets of genes in *V. fischeri* (Callahan and Dunlap, 2000). The possibility exists therefore that newly identified luminous bacteria will be found to have *luxAB* and *luxCDE* in separate chromosomal locations.

These considerations lead to questions on the evolutionary origin of bacterial luminescence.

Seliger (1987) proposed that bacterial luminescence arose under ecological selection, as a biochemical analog of Darwin's principle of functional change in structural continuity. A flavoprotein catalyzing fatty acid α-oxidation reactions with low chemiluminescent quantum yields is postulated to have mutated under hypoxic conditions to accept $FMNH_2$ as the flavin cofactor, generating a fortuitously high fluorescence yield, termed "protobioluminescence," via the 4a-hydroxy-FMNH product. This flavin-dependent, aldehyde-oxidizing protoluciferase produced sufficient light, and with an appropriate emission spectrum, to be detected by phototactic organisms. Responses to the light by visually cueing animals (e.g., to ingest luminous particles), enhanced the growth of the protobioluminescence emitter by introducing it into the animal's nutrient-rich digestive system, ensuring the emitter's survival and presumably leading to selection for more intense light output. It is possible that early evolutionary steps leading to protoluciferase involved oxygen detoxification activity that permitted early anaerobic organisms to survive an increasingly aerobic environment (McElroy and Seliger, 1962; Rees et al., 1998).

A single gene has been hypothesized to encode bacterial protoluciferase (O'Kane and Prasher, 1992). Although a single-subunit protoluciferase presumably would have differed somewhat from the modern-day luciferase α-subunit and therefore might have produced light, the inability of either of the modern-day α- or β-subunits alone to produce light in vitro or in vivo (Li et al., 1993) argues against the single-gene hypothesis. Alternatively, bacterial luminescence may have arisen following a gene duplication event postulated to have created *luxB* from *luxA* (Baldwin et al., 1979; O'Kane and Prasher, 1992; Meighen and Dunlap, 1993). The association of the fatty-acid reductase genes with *luxA* might have predated the *luxA* to *luxB* gene duplication event. Alternatively, the presence of ERIC sequences flanking *luxA* and *luxB* in *P. luminescens* (Meighen and Szittner, 1992) might mark an insertion of the *luxAB* genes into the fatty aldehyde reductase operon during the evolution of the bacterial luminescence system. Origins and functions of other luminescence proteins have been discussed elsewhere (O'Kane and Prasher, 1992; Meighen and Dunlap, 1993).

A marine origin for bacterial luminescence, though speculative, seems reasonable. Most species of luminous bacteria are marine (Table 1), luminescence appears to have arisen independently in various (mainly marine) phylogenetic groups (Hastings, 1995), and present-day luminous organisms are much more common in the ocean than in terrestrial and freshwater environments. Palmer and Colwell (1991) have interpreted the high level of nucleotide sequence identity for a region of *luxA* among *V. cholerae* and marine vibrios as indicating a common luminescent marine ancestor. However, a growing number of terrestrial luminous species are being identified (Fischer-Le Saux et al., 1999), so the possibility of a terrestrial origin for bacterial luminescence should not be ruled out.

Lateral Transfer

Despite the conservation of the *luxCDABE* genes in luminous bacteria, the presence of these genes is not monophyletic. Genera with luminous members include the closely related and physiologically similar *Vibrio* and *Photobacterium* and the more distantly related and physiologically distinct *Photorhabdus* and *Shewanella* (Fig. 2). Various evolutionary scenarios can be envisioned to account for the polyphyletic distribution of*lux*genes and to accommodate the presence of luminous and nonluminous species and strains in *Vibrio* and *Photobacterium*:

1) The *lux* genes may have been present in the ancestor that diverged into the lines leading to modern-day members of the Vibrionaceae, Enterobacteriaceae and Alteromonadaceae. The *lux* genes were then lost from many descendents but retained by some. If this scenario is correct, one might expect to find more species in the Enterobacteriaceae and Alteromonadaceae that carry *lux* genes.

2) Alternatively, the *lux* genes might have arisen later, within the line leading to modern-day members of the Vibrionaceae. These genes then may have been lost from several descendents, retained by some, and transferred relatively recently from a member or members of the Vibrionaceae to *Photorhabdus* and *S. hanedai* and *S. woodyi*. The presence of the *luxCDABE* genes in *Photorhabdus* species has been interpreted as an instance of lateral gene transfer (Forst et al., 1997). Furthermore, the chromosomal locations of the *luxCDABE* genes in two ecologically distinct strains of *Ph. luminescens* apparently differ (Meighen and Szittner, 1992), raising the possibility that lateral transfer to this species occurred more than once (Forst et al., 1997).

3) Also possible is that the *lux* genes did not arise indigenously in the ancestral line that diverged into the Vibrionaceae, Enterobacteriaceae and Alteromonadaceae (scenario 1) or later within the Vibrionaceae (scenario 2). Instead, they may have been acquired relatively recently by certain species and strains in the Vibrionaceae by lateral gene transfer from an

unknown source. The same source might have transferred *lux* genes to *Photorhabdus*, *S. hanedai* and *S. woodyi*, or these genes might have been acquired secondarily by lateral transfer from a member or members of the Vibrionaceae. The recent identification of luminous strains of *V. salmonicida* (Fidopiastis et al., 1999) and *P. angustum* (K. Kita-Tsukamoto et al., manuscript in preparation), species previously characterized as nonluminous, is consistent with all three scenarios. Mapping the chromosomal locations of the *lux* genes in *Vibrio* and *Photobacterium* would help differentiate among these scenarios. Similar chromosomal locations for the *lux* genes would tend to support an evolutionary origin in an ancestor of or within the Vibrionaceae lineage (scenarios 1 and 2), whereas different chromosomal locations, as seen in *Ph. luminescens* (Meighen and Szittner, 1992), would be more consistent with lateral transfer to members of the Vibrionaceae (scenario 3). In regard to this latter possibility, the differences in DNA flanking *luxCDABE* in different members of the Vibrionaceae, for example in *V. fischeri* and *V. harveyi*, are intriguing. An issue that complicates each of these scenarios, however, is the possible mobility of the *lux* genes among members of the Vibrionaceae, with losses and recent lateral transfer events accounting for or contributing to the modern-day presence of luminous and nonluminous species and strains in this family.

Physiological Functions of the Luminescence System

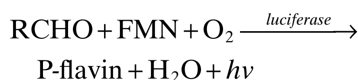
One the most interesting and long-standing questions about luminous bacteria is the physiological function of luminescence. In other words, "Why do bacteria produce light?" Despite extensive knowledge of the biochemistry and genetics of bacterial luminescence, the cellular role of luminescence in bacteria is not well understood. However, the benefit light production provides to bacteria has been variously hypothesized, and multiple ecological and physiological functions for luminescence seem likely.

Ecologically, in the realm of visually orienting animals, light production undoubtedly plays a role in the dissemination of luminous bacteria and may have been instrumental in the evolution of strongly luminous strains, as discussed above. The feeding of animals on luminous particles (decaying tissues, fecal pellets, and moribund animals infected by luminous bacteria) disperses the bacteria and brings them into the animal's nutrient-rich gut tract for further growth and dispersal (Nealson and Hastings, 1992). Bioluminescent symbiosis serves a similar role through a continual or diurnal release from the host animal, as mentioned above. Once bacteria developed the ability to emit light at levels that could be detected by animals, ecological interactions may then have selected for higher levels of light production (Seliger, 1987), fostering the development of progressively more specific, luminescence-based associations with animals, eventually leading to species-specific bioluminescent symbiosis. A high level of activity of the luminescence system might promote bacterial survival and growth in these associations, especially in bioluminescent symbiosis (Dunlap, 1984; Visick et al., 2000).

A strong case for a physiological role for bacterial luminescence can be made, despite the fact that the *lux*g enes are not essential for survival or growth of luminous bacteria, at least in laboratory culture (Kuo et al., 1994). Several genes are committed to the light-producing reaction, including structural genes for the luminescence proteins and regulatory genes controlling *lux* operon expression. Retention of these genes and the expenditure of energy for the synthesis and activity of their protein products (Dunlap and Greenberg, 1991b; Meighen and Dunlap, 1993) imply that the luminescence system carries out an activity beneficial to the cell. For example, luciferase activity can consume up to 20% of the oxygen taken up by luminous cells (Eymers and van Schouwenberg, 1937; Watanabe et al., 1975; Dunlap, 1985a; Makemson, 1986a). Furthermore, luminescence in many species is regulated, such that the *lux* genes are expressed under certain environmental conditions but not others, and *lux* regulation is deeply integrated into the physiologial response networks and gene regulatory circuitry (e.g., cAMP-CRP and quorum sensing) of the cell. Indeed, luminescence is just one of a suite of metabolic and physiological activities controlled by quorum sensing (Callahan and Dunlap, 2000). The coordinated expression of the *lux* genes with other sets of genes in response to the physiological state of the cell suggests that the luminescence system plays an integral physiological role in the biology of luminous bacteria.

Most attention to the question of that physiological role for bacterial luminescence has focused on oxygen. McElroy and Seliger (1962) proposed that light-emitting reactions arose evolutionarily as detoxifying reactions that removed oxygen and thereby allowed anaerobic organisms to survive. This hypothesis has been developed further from the perspective that luciferin substrates for luciferase are the evolutionary core of bioluminescent systems (Rees et al., 1998). The luminescence reaction, as a terminal oxidase or secondary respiratory chain that is active when oxygen or iron levels are too low for the cytochrome system to operate, would allow

reduced coenzymes to be reoxidized, thereby permitting cells under microaerobic conditions, such as in animal gut tracts, to continue to metabolize growth substrates (Nealson and Hastings, 1979b; Ulitzur et al., 1981; Makemson and Hastings, 1982; Seliger, 1987). Consistent with this possibility, luciferase activity can partially complement the lack of cytochromes (Makemson and Hastings, 1986b). In bioluminescent symbiosis, the luciferase reaction has been proposed to help protect cells from host-generated reactive oxygen species (ROS; Visick et al., 2000). Alternatively, the physiologically important function of the luciferase reaction may be the production of FP390 (P-flavin binding protein), including its prosthetic group, Q (P)-flavin (Kasai, 1997), according to the following reaction scheme:



$$\mathrm{RCHO + FMN + O_2 \xrightarrow{luciferase} P\text{-}flavin + H_2O + } h\nu$$

The protein FP_{390} functions as a substitute for flavodoxin, at high salt concentrations where flavodoxin is less active. Flavodoxin, e.g., FldA from *V. fischeri* (Kasai, 1999), functions to reactivate oxidatively inactivated cobalamin-dependent methionine synthase (CDMS; Hoover and Ludwig, 1997). It follows that bacteria would not produce light under conditions of low ionic strength because under these conditions cells would use flavodoxin for reoxidation of CDMS in lieu of producing FP390 (Farghaly, 1950; Kasai, 1997). It is tempting to speculate that the postulated relationship between conditions of high ionic strength, synthesis of P-flavin, and light production might account for the apparently exclusive occurence of luminous bacteria in habitats of relatively high ionic strength, i.e., seawater, brackish water, and tissues of marine, freshwater and terrestrial animals.

In each of the above cases, light production is an incidental though ecologically important byproduct of the luciferase reaction, and not its primary physiological function. An alternative to incidental light production is the recent proposal that bacterial luminescence serves as an internal light source for a photoreactivation-like repair of damaged DNA (Czytz et al., 2000). Studies of UV survival of *V. harveyi lux* mutants and an *E. coli lexA* mutant carrying the *V. harveyi lux* genes (Czytz et al., 2000) suggest that damaged DNA would be the "missing photoreceptor" for bacterial luminescence. It is intriguing that the *V. fischeri lux* operon *lux* box is similar to the *E. coli* LexA protein-binding site (Ulitzur and Kuhn, 1988; Devine et al., 1988b; Baldwin et al., 1989; Shadel et al., 1990a) and that various SOS-response-inducing and DNA-intercalating agents stimulate luminescence in bacteria (Weiser et al., 1981; Ulitzur and Dunlap, 1995). The strong link between oxidative stress and DNA damage (Hemnani and Parihar, 1998) is consistent with this role. Possibly, then, the luciferase reaction carries out the dual physiological functions of ROS detoxification and photoreactivation-like DNA damage repair. The induction of *lux* gene expression at high population density and the coordinate stimulation of superoxide dismutase (Colepicolo et al., 1992) suggest that DNA damage and oxidative stress become more significant in bacteria as nutrients are exhausted and growth begins to slow.

Isolation, Cultivation and Identification of Luminous Bacteria

Detailed information on the isolation, cultivation and phenotypic characterization of luminous bacteria can be found in Nealson (1978a), Baumann et al. (1984b), Baumann and Baumann (1981), and Farmer and Hickman-Brenner (1992). Methods and information not otherwise referenced here were introduced to the author by K. H. Nealson and E. P. Greenberg during summer courses at the Marine Biological Laboratory at Woods Hole, Massachusetts.

Isolation

Light-emitting bacteria can be isolated from most marine habitats, through direct plating of samples or by enrichment. For direct plating, 0.1–0.2 ml of coastal seawater is spread on nutritionally complete agar plates, such as Seawater Complete (SWC) agar (Nealson, 1978a; see below). Open-ocean water contains fewer bacteria, so cells from 10 ml to 1 liter are concentrated by filtration (pore size 0.2–0.45 mM), and then the filter is placed on SWC agar or a similar medium. Sediments and gut tracts contain higher numbers of bacteria and therefore usually are diluted 1,000 fold or more before spreading 0.1 to 0.2 ml. Media prepared with 4% agar (Baumann et al., 1984b) helps limit the spreading of swarming and gliding bacteria. Various crustaceans (e.g., gammarid and caprellid amphipods) are suitable sources for luminous bacteria, as they can become infected with luminous bacteria and develop a strong luminescence before and for several hours after dying. In a dark room, after dark-adapting for 12–15 min), one can pick out the infected, luminous crustaceans from collected seaweed. In a lighted room, the exoskeleton of the animal is punctured to obtain the hemolymph, which is streaked onto a suitable agar medium. The plates can be incubated at ambient or cool temperatures and are observed after 12–24 h for luminous colonies, which are then picked and streaked to obtain pure cultures.

Enrichments of marine luminous bacteria can be made from fresh fish (such as mackerel and flounder), other marine animals, and previously frozen fish. The entire animal or portions are placed in a tray and half covered with seawater, allowing part of the animal's body to be submerged and part to be exposed to air. This enrichment is then incubated at cool temperatures and observed daily in a darkened room. Luminous spots develop on the exposed portions of the animal within one to several days, depending on the temperature, and these are picked and steaked onto a suitable agar medium. Use of 4% agar (Baumann et al., 1984b) is recommended to limit the spreading of gliding and swarming bacteria.

Picking of luminous spots and luminous colonies is made easier by working in a darkened room with a red lamp on variable control. The intensity the lamp and angle of illumination can be adjusted so that luminous colonies are bluish and nonluminous colonies stand out as orange-red. Sterile toothpicks are convenient for picking luminous colonies.

Storage

Storing luminous bacteria on agar slants or in agar stabs for more than a week is not recommended inasmuch as dim and dark variants can easily arise with some species and survival can be poor. Similarly, survival under refrigeration is poor for some species. Lyophylization or storage in liquid nitrogen may be an option if appropriate equipment is available (Baumann et al., 1984b). Storage at ultra-low temperature, e.g., −75°C to −80°C, in a cryoprotective medium, however, works well for all species examined. An effective cryoprotective medium for luminous bacteria is filter-sterilized Deep Freeze Medium (2X DFM), prepared with 1% w/v yeast extract, 10% dimethyl sulfoxide (DMSO), 10% glycerol and 0.2M K_2HPO_4/NaH_2PO_4 (pH 7.0). E. F. DeLong recommended 2X DFM, originally developed by R. Rodriquez for storing yeast. For permanent storage of luminous bacteria, a dense culture is prepared by growing the strain to be stored for 12–18 h in a complete liquid medium, adding 0.5 ml each of the culture and 2X DFM to cryovials, briefly vortexing to mix, allowing the mixture to stand for 10 min before placing the vial into the ultra-low temperature freezer. Commercial containers that allow a slow rate of cooling work well as does quick freezing in an ethanol bath kept in the ultra-low temperature freezer or chilled with dry ice. Cultures of luminous bacteria stored in this manner retain viability apparently indefinitely when the tubes are kept at constant ultra-low temperature.

Cultivation

Most complete marine media, whether prepared with artificial or natural seawater to supply appropriate levels of Na^+, Ca^{2+} and Mg^{2+}, support the growth of luminous bacteria from most habitats. Nealson (1978a) listed and compared various formulations for complete and minimal media. A commonly used complete medium is SWC, prepared with natural seawater diluted to 70% or 75% with distilled water to minimize precipitation, 5 g per liter of tryptone or peptone, 3 g per liter of yeast extract and 3 ml per liter of glycerol, and with 1.5 g per liter of agar for solid medium. Traditionally, SWC has been buffered with 50 mM Tris or HEPES, or 1 g per liter of solid calcium carbonate has been incorporated into the agar medium to control acid production (Nealson, 1978a). Acid production in SWC apparently results, however, from the presence of glycerol, and elimination of this component avoids the problem (Dunlap et al., 1995) with no major effect on growth or luminescence. An easily prepared complete medium contains 10 g per liter of tryptone, 5 g per liter of yeast extract, 70% natural or artificial seawater, and 1.5% agar for solid medium. Artificial seawater can be prepared according to the formulation of MacLeod, as described by Nealson (1978a), or for routine culture work, a commercial aquarium marine salt mix can be used. Procedures for preparing minimal media have been described by Nealson (1978a).

Identification

A combination of phenotypic and genotypic traits is useful for the identification of luminous bacteria. Taxonomy of the marine luminous bacteria and their relationships to other marine enterobacteria were established during the 1970s and early 1980s through the use of an array of diagnostic physiological and molecular traits (Reichelt and Baumann, 1973; Reichelt et al., 1976; Baumann and Baumann, 1981). Using as few as 10–25 phenotypic traits, one can identify with good accuracy many of the commonly encountered species of marine luminous bacteria (Nealson, 1978a; Baumann and Baumann, 1981; Hastings and Nealson, 1981). Genotypic traits, specifically*lux*genes and 16S rRNA (Haygood, 1990; Haygood et al., 1992; Haygood and Distel, 1993b; Wimpee et al., 1991; Nealson et al., 1993), complement these diagnostic characters and can be particularly useful for rapid identification.

CHAPTER 1.28

Bacterial Toxins

VEGA MASIGNANI, MARIAGRAZIA PIZZA AND RINO RAPPUOLI

Introduction

Toxins were the first bacterial virulence factors to be identified and were also the first link between bacteria and cell biology. Cellular microbiology was, in fact, naturally born a long time ago with the study of toxins, and only recently, thanks to the sophisticated new technologies, has it expanded to include the study of many other aspects of the interactions between bacteria and host cells. This chapter covers mostly the molecules that have been classically known as toxins; however, the last section also mentions some recently identified molecules that cause cell intoxication and have many but not all of the properties of classical toxins. Tables 1 and 2 show the known properties of all bacterial toxins described in this chapter, while Figure 1 shows the subunit composition and the spatial organization of toxins whose structures have been solved either by X-ray crystallography or by quick-freeze deep-etch electron microscopy.

Abbreviations: SEA–SEI, staphylococcal enterotoxin A through I; TSST-1, toxic shock syndrome toxin 1; SPEA, B and C, streptococcal pyrogenic enterotoxins A, B and C; ETA and B, exfoliative toxins A and B; MHC, major histocompatibility complex; Vβ or Vγ, T-cell-receptor variable domains; LukF, leucocidin F; PA, protective antigen; RTX, repeats-in-toxin; CryIA, CytB, G_i, G_s, G_o, G_t, G_{olf}, GTP-binding proteins; MAPKK1 and 2, mitogen-activated protein kinases 1 and 2; EF2, elongation factor 2; Rho, Rac and Cdc42, GTP-binding proteins that control assembly of actin stress fibers; IL2, 4 and 5, interleukins 2, 4 and 5; TeNT, tetanus neurotoxin; VAMP, vesicle-associated membrane protein; BoNT, botulism neurotoxin; SNAP, synaptosome-associated protein; YOP, *Yersinia* outer-membrane proteins; AvrRxv, plant-pathogen virulence protein; Ipa, invasion-plasmid antigen; ICE, interleukin-converting enzyme; Sop, *Salmonella* outer-membrane protein; Tir, translational initiation region; CagA, cytotoxin-associated gene A; YpkA, *Yersinia* protein kinase A.

For abbreviations, refer to the footnote in Table 1.

Toxins have a target in most compartments of eukaryotic cells. For simplicity, the toxins are divided into three main categories (Fig. 2): 1) those that exert their powerful toxicity by acting on the surface of eukaryotic cells simply by touching important receptors, by cleaving surface-exposed molecules, or by punching holes in the cell membrane, thus breaking the cell permeability barrier (panel 1); 2) those that have an intracellular target and hence need to cross the cell membrane (these toxins need at least two active domains, one to cross the eukaryotic cell membrane and the other to modify the toxin target) (panel 2); and 3) those that have an intracellular target and are directly delivered by the bacteria into eukaryotic cells (panel 3).

Toxins Acting on the Cell Surface

See Tables 1 and 2 for a summary of the principal features of toxins described in this section.

Toxins Acting on the Immune System (Superantigens)

Superantigens (Fig. 2, panel 1) are bacterial and viral proteins that share the ability to activate a large fraction of T-lymphocytes. They are bivalent molecules that have been shown to simultaneously bind two distinct molecules, the major histocompatibility complex (MHC) and the T-cell receptor variable domains (Vβ or Vγ; Kotzin et al., 1993; Fig. 3). Binding of these molecules to MHC class II requires no prior processing and occurs outside the antigen-binding groove. This results in the activation of between 2–15% of all T cells, ultimately leading to T-cell proliferation, the production of a variety of cytokines, and expression of cytotoxic activity.

Bacterial superantigens, also known as pyrogenic toxins, comprise a class of secreted proteins mostly produced by *Staphylococcus aureus* and *Streptococcus pyogenes* (Bohach et al., 1990; Alouf and Muller-Alouf, 2003). So far, they include the group of staphylococcal enterotoxins (SEA, SEB, SECn, SED, SEE, SEG, SEH and

Table 1. Classes of toxins described in the text, their features and activity.

Class of toxin	Target	Toxin	Organism	Activity	Consequence	X-ray
Toxins acting on the cell surface	Immune system (Superantigens)	SEA-SEI, TSST-1, SPEA, SPEC, SPEL, SPEM, SSA, and SMEZ	*Staphylococcus aureus and Streptococcus pyogenes*	Binding to MHC class II molecules and to Vβ or Vγ of T cell receptor	T cell activation and cytokines secretion	SEB SEC2, SEC3, SED, SEH TSST1, SPEA SPEC
		MAM	*Mycoplasma arthritidis*	Binding to MHC class II molecules and to Vβ or Vγ of T cell receptor	Chronic inflammation	+
		YPMa	*Yersinia pseudotuberculosis*	Binding to MHC class II molecules and to Vβ or Vγ of T cell receptor	Chronic inflammation	–
		SPEB	*S. pyogenes*	Cysteine protease	Alteration in immunoglobulin-binding properties	+
		ETA, ETB, and ETD	*S. aureus*	Trypsin-like serine proteases	T-cell proliferation, intraepidermal layer separation	ETA, ETB
	Surface molecules	BFT enterotoxin	*Bacteroides fragilis*	Metalloprotease, cleavage of E-cadherin	Alteration of epithelial permeability	–
		AhyB	*Aeromonas hydrophyla*	Elastase, metalloprotease	Hydrolization of casein and elastine	–
		Aminopeptidase	*Pseudomonas aeruginosa*	Elastase, metalloprotease	Corneal infection, inflammation and ulceration	–
		ColH	*Clostridium histolyticum*	Collagenase, metalloprotease	Collagenolytic activity	–
		Nhe	*Bacillus cereus*	Metalloprotease and collagenase	Collagenolytic activity	–
	Cell membrane			Cell membrane permeabilization	Cell death	
	Large pore-forming toxins	PFO	*C. perfringens*	Thiol-activated cytolysin, cholesterol binding	Gas gangrene	+
		SLO	*S. pyogenes*	Thiol-activated cytolysin, cholesterol binding	Transfer of other toxins, cell death	–
		LLO	*Listeria monocytogenes*	Induction of lymphocyte apoptosis	Membrane damage	–
		Pneumolysin	*S. pneumoniae*	Induction of lymphocyte apoptosis	Complement activation, cytokine production, apoptosis	–
	Small pore-forming toxins	Alveolysin	*B. alvei*s	Induction of lymphocyte apoptosis	Complement activation, cytokine production, apoptosis	–

	ALO	*B. anthracis*	Induction of lymphocyte apoptosis	Complement activation, cytokine production, apoptosis	–
	α-Toxin	*S. aureus*	Binding of erythrocytes	Release of cytokines, cell lysis, apoptosis	+
	PVL leukocidin (LukS-LukF)	*S. aureus*	Cell membrane permeabilization	Necrotic enteritis, rapid shock-like syndrome	LukF
	γ-Hemolysins (HlgA-HlgB and HlgC-HlgB)	*S. aureus*	Cell membrane permeabilization	Necrotic enteritis, rapid shock-like syndrome	HlgB
	β-Toxin	*C. perfringens*	Cell membrane permeabilization	Necrotic enteritis, neurologic effects	–
RTX toxins	Hemolysin II	*B. cereus*	Cell membrane permeabilization	Hemolytic activity	–
	CytK	*B. cereus*	Cell membrane permeabilization	Necrotic enteritis	–
	HlyA	*E. coli*	Calcium-dependent formation of transmembrane pores	Cell permeabilization and lysis	–
Membrane-perturbing toxins	ApxI, ApxII, and ApxIII	*A. pleuropneumoniae*	Calcium-dependent formation of transmembrane pores	Lysis of erythrocytes and other nucleated cells	–
	LtxA	*A. actinomycetem-comitans*	Calcium-dependent formation of transmembrane pores	Apoptosis	–
	LktA	*P. haemolytica*	Calcium-dependent formation of transmembrane pores	Activity specific versus ruminant leukocytes	–
Other pore-forming toxins	δ-Hemolysin	*S. aureus*	Perturbation of the lipid bilayer	Cell permeabilization and lysis	–
	Aerolysin	*A. hydrophila*	Perturbation of the lipid bilayer	Cell permeabilization and lysis	+
	AT	*C. septicum*	Perturbation of the lipid bilayer	Cell permeabilization and lysis	+ (model)
Insecticidal toxins	PA	*B. anthracis*	Perturbation of the lipid bilayer	Cell permeabilization and lysis	+
	HlyE	*E. coli*	Perturbation of the lipid bilayer	Osmotic lysis of cells lining the midgut	+
	CryIA, CryIIA, CryIIIA, etc	*Bacillus thuringiensis*	Destruction of the transmembrane potential	Osmotic lysis of cells lining the midgut	CryIA, CryIIIA

(*Continued*)

Table 1. *Continued*

Class of toxin	Target	Toxin	Organism	Activity	Consequence	X-ray
		CytA, CytB	*B. thuringiensis*	Destruction of the transmembrane potential	Osmotic lysis of cells lining the midgut	CytB
		BT toxin	*B. thuringiensis*	Destruction of the transmembrane potential	Cytocidal activity on human cells	–
Toxins acting on intracellular targets	Protein synthesis	DT	*Corynebacterium diphtheriae*	ADP-ribosylation of EF-2	Cell death	+
		PAETA	*P. aeruginosa*	ADP-ribosylation of EF-2	Cell death	+
		SHT	*S. dysenteriae*	N-glycosidase activity on 28S RNA	Cell death, apoptosis	+
	Signal transduction	PT	*Bordetella pertussis*	ADP-ribosylation of G_i	cAMP increase	+
		CT	*Vibrio cholerae*	ADP-ribosylation of G_s	cAMP increase	+
		LT	*E. coli*	ADP-ribosylation of G_s	cAMP increase	+
		α-Toxin (PLC)	*C. perfringens*	Zinc-phospholipase C, hydrolase	Gas gangrene	+
		Toxins A and B (TcdA and TcdB)	*C. difficile*	Monoglucosylation of Rho, Rac, Cdc42	Breakdown of cellular actin stress fibers	–
		Adenylate cyclase (CyaA)	*B. pertussis*	Binding to calmodulin ATP→cAMP conversion	cAMP increase	–
		Anthrax edema factor (EF)	*B. anthracis*	Binding to calmodulin ATP→cAMP conversion	cAMP increase	+
		Anthrax lethal factor (LF)	*B. anthracis*	Cleavage of MAPKK1 and MAPKK2	Cell death, apoptosis	+
		Cytotoxin necrotizing factors 1 and 2 (CNF1, 2)	*E. coli*	Deamidation of Rho, Rac and Cdc42	Ruffling, stress fiber formation.	CNF1 (catalytic domain)
		DNT	*Bordetella species*	Transglutaminase, deamidation or polyamination of Rho GTPase	Ruffling, stress fiber formation	–
		CDT	*Several species*	DNA damage, formation of actin stress fibers via activation of RhoA	Cell-cycle arrest, cytotoxicity, apoptosis	–
	Cytoskeleton structure	Toxin C2 and related proteins	*C. botulinum*	ADP-ribosylation of monomeric G actin	Failure in actin polymerization	–

		Lymphostatin	*E. coli*	Block of interleukin production	Chronic diarrhea	–
		Iota toxin and related proteins	*C. perfringens*	Block of interleukin production	Chronic diarrhea	+ (C2I)
	Intracellular trafficking	TeNT	*C. tetanii*	Cleavage of VAMP/ synaptobrevin	Spastic paralysis	+ (Hc domain)
		BoNT-B, D, G and F neurotoxins	*C. botulinum*	Cleavage of VAMP/ synaptobrevin	Flaccid paralysis	BoNT-B
		BoNT-A, E neurotoxins	*C. botulinum*	Cleavage of SNAP-25	Flaccid paralysis	BoNT-A
		BoNT-C neurotoxin	*C. botulinum*	Cleavage of syntaxin, SNAP-25	Flaccid paralysis	–
		Vacuolating cytotoxin VacA	*H. pylori*	Alteration in the endocytic pathway	Vacuole formation, apoptosis	–
		NAD glycohydrolase	*S. pyogenes*	Keratinocyte apoptosis	Enhancement of GAS proliferation	–
Toxins injected into eukaryotic cells	Mediators of apoptosis	IpaB	*Shigella*	Binding to ICE	Apoptosis	–
		SipB	*Salmonella*	Cysteine proteases	Apoptosis	–
		YopP/YopJ	*Yersinia species*	Cysteine protease, blocks MAPK and NFkappaB pathways	Apoptosis	–
	Inositol phosphate metabolism	SopB	*Salmonella species*	Inositol phosphate phosphatase, cytoskeleton rearrangements	Increased chloride secretion (diarrhea)	–
		IpgD	*S. flexneri*	Inositol phosphate phosphatase, cytoskeleton rearrangements	Increased chloride secretion (diarrhea)	–
	Cytoskeleton	ExoS	*P. aeruginosa*	ADP-ribosylation of Ras, Rho GTPase	Collapse of cytoskeleton	+ (GAP domain)
		C3 exotoxin	*C. botulinum*	ADP-ribosylation of Rho	Breakdown of cellular actin stress fibers	+
		EDIN-A, B and C	*S. aureus*	ADP-ribosylation of Rho	Modification of actin cytoskeleton	EDIN-B
		SopE	*S. typhimurium*	Rac and Cdc42 activation	Membrane ruffling, cytoskeletal reorganization, proinflammatory cytokines production	+
		SipA	*S. typhimurium*	Rac and Cdc42 activation	Membrane ruffling, cytoskeletal reorganization, proinflammatory cytokines production	+

(*Continued*)

Table 1. *Continued*

Class of toxin	Target	Toxin	Organism	Activity	Consequence	X-ray
		IpaA	*Shigella species*	Vinculin binding	Depolymerization of actin filaments	–
		YopE	*Yersinia species*	GAP activity towards RhoA, Rac1 or Cdc42	Cytotoxicity, actin depolymerization	+
		YopT	*Yersinia species*	Cysteine protease, cleaves RhoA, Rac, and Cdc42 releasing them from the membrane	Disruption of actin cytoskeleton	–
		VirA	*Shigella flexneri*	Inhibition of tubulin polymerization	Microtubule destabilization and membrane ruffling	–
	Signal transduction	YpkA	*Yersinia species*	Protein serine/threonine kinase	Inhibition of phagocytosis	–
		YopH	*Yersinia species*	Tyrosine phosphatase	Inhibition of phagocytosis	+
		Tir	*E. coli EPEC*	Receptor for intimin	Actin nucleation and pedestalformation	–
		CagA	*H. pylori*	Tyrosine phosphorylated	Cortactin dephosphorylation	–
		YopM	*Yersinia species*	Interaction with PRK2 and RSK1 kinases	Cytotoxicity	+
		SptP	*S. typhimurium*	Inhibition of the MAP kinase pathway	Enhancement of Salmonella capacity to induce TNF-alpha secretion	+
		ExoU	*P. aeruginosa*	Lysophospholipase A activity	Lung injury	–
Toxins with unknown mechanism of action		Zot	*V. cholerae*	?	Modification of intestinal tight junction permeability	–
		Hemolysin BL (HBL)	*B. cereus*	Hemolytic, dermonecrotic and vascular permeability activities	Food poisoning, fluid accumulation and diarrhea	–
		BSH	*L. monocytogenes*	?	Increased bacterial survival and intestinal colonization	–

Abbreviations: SEA-SEI, staphylococcal enterotoxins; TSST, toxic shock syndrome toxin; SPE, streptococcal exotoxin; SSA, streptococcal superantigen; SMEZ, streptococcal mitogenic exotoxin z; MAM, *Mycoplasma* arthritidis mitogen; YPMa, *Y. pseudotuberculosis*-derived mitogen; ETA and ETB, exfoliative toxins; ColH, collagenase; Nhe, nonhemolytic entertoxin; PFO, perfringolysin O; SLO, streptolysin O; LLO, listeriolysin O; ALO, anthrolisin O; AT, α-toxin; PA, protective antigen; DT, diphtheria toxin; PAETA, *Pseudomonas aeruginosa* exotoxin A; SHT, Shiga toxin; PT, pertussis toxin; CT, cholera toxin; LT, heat-labile enterotoxin; DNT, dermonecrotic toxin; CDT, cytolethal distending toxin; TeNT, tetanus neurotoxin; RTX, repeats in the structural toxin; Hly, hemolysin; Cry, crystal; BoNT, botulinum neurotoxin; Ipa, invasion plasmid antigen; Sip, *Salmonella* invasion protein; EDIN, epidermal cell differentiation inhibitor; Sop, *Salmonella* outer protein; Ipg, invasion plasmid gene; Yop, *Yersinia* outer protein; GAP, GTPase-activating protein; GAS, group A *Streptococcus*; Vir, virulence protein; YpkA, *Yersinia* protein kinase A; Tir, translocated intimin receptor; EPEC, enteropathogenic *E. coli*; CagA, cytotoxin-associated gene A; SptP, *Salmonella* protein tyrosine phosphatase; VAMP, vesicle-associated membrane protein; ICE, interleukin-1β-converting enzyme; SNAP, synaptosome-associated protein; MAPKK, mitogen-activated protein kinase kinase; Zot, zonula. occludens toxin; and BSH, bile salt hydrolase.

Table 2. Toxins classified according to their enzymatic activities.

Toxin	Substrate	Effect
Glucosyl-transferases		
Clostridium difficile toxins A and B	Rho/Ras GTPases	Breakdown of cytoskeletal structure
Deamidases		
E. coli CNF1	Rho, Rac and CdC42	Stress fiber formation
Bordetella DNT	Rho	Stress fiber formation
ADP-ribosyltransferases		
DT	Elongation factor EF-2	Cell death
PAETA	Elongation factor EF-2	Cell death
PT	G_i, G_o and transducin	cAMP increase
CT	G_s, G_t and G_{olf}	cAMP increase
E. coli LT	G_s, G_t and G_{olf}	cAMP increase
Clostridium botulinum C2	Actin	Failure in actin polymerization
P. aeruginosa ExoS	Ras	Collapse of cytoskeleton
Clostridium botulinum C3	Rho	Breakdown of cellular actin stress fibers
N-Glycosidases		
Shiga toxin	Ribosomal RNA	Stop of protein synthesis
Metalloproteases		
Bacillus anthracis LF	Macrophages	Disruption of normal homoeostatic functions
Clostridium tetanii TeNT	VAMP/synaptobrevin	Spastic paralysis
C. botulinum BoNTs	VAMP/synaptobrevin, SNAP-25	Flaccid paralysis

Abbreviations: CNF1, cytotoxin necrotizing factor 1; DNT, dermonecrotic factor; DT, diphtheria toxin; PAETA, *Pseudomonas aeruginosa* exotoxin A; PT, pertussis toxin; CT, cholera toxin; LT, heat-labile enterotoxin; ExoS, exoenzyme S; LF, lethal factor; TeNT, tetanus neurotoxin; BoNT, botulinum neurotoxin; VAMP, vesicle associated membrane protein; and SNAP-25, synaptosome-associated protein of 25kDa.

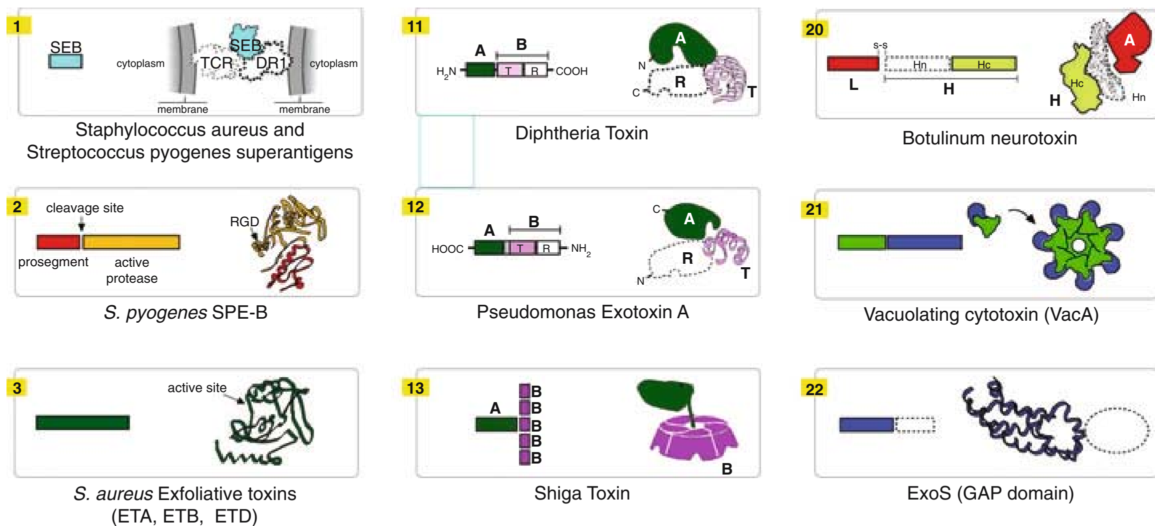

Fig. 1. Structural features of bacterial toxins. (Left) Scheme of the primary structure of each toxin. For the A/B toxins, the domain composition is also shown. The A (or S1 in PT) represents the catalytic domain, whereas the B represents the receptor-binding domain. The A subunit is divided into the enzymatically active A1 domain and the A2 linker domain in Shiga toxin, CT, *Escherichia coli* LTI and LTII, and PT. The B domain has either five subunits, which are identical in Shiga toxin, CT, and *E. coli* LTI and LTII and different in size and sequences in PT, or two subunits (the translocation [T] and the receptor-binding [R] subunits) in DT, Pseudomonas exotoxin A, botulinum toxin, and tetanus toxin. (Right) Schematic representation of the three-dimensional (3D) organization of each toxin. For *Staphylococcus* enterotoxin B, the protein is shown in the ternary complex with the human class II histocompatibility complex molecule (DR1) and the T-cell antigen receptor (TCR). For *Salmonella* SptP, the structure is shown in the transition state complex with the small GTP binding protein Rac1. Similarly, toxin SopE is represented in complex with its substrate Cdc42. In the case of *E. coli* CNF1 and *Pseudomonas* ExoS, only one domain has been crystallized. In the case of SipA, a 3D reconstruction of SipA bound to F-actin filaments is also reported. For all toxins, the schematic representation is based on the X-ray structure, except that for VacA, whose structure has been solved by quick-freeze, deep-etch electron microscopy.

(*Continued*)

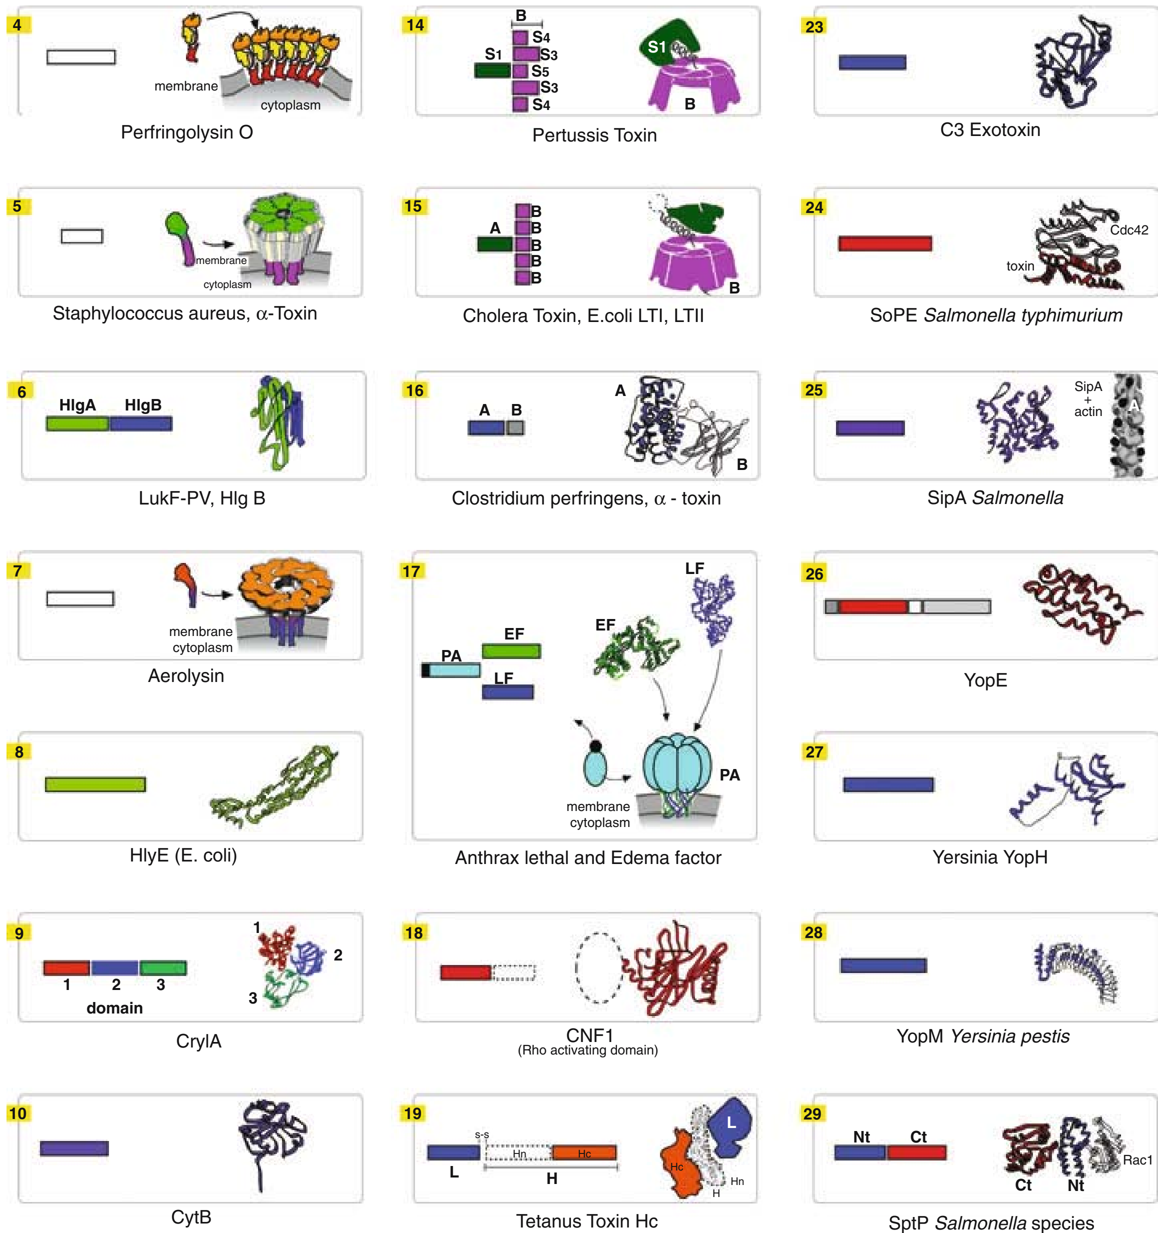

Fig. 1. *Continued.*

SEI), exfoliative toxins (ETA and ETB), the toxic shock syndrome toxin-1 (TSST-1; Dinges et al., 2000), the streptococcal pyrogenic enterotoxins (SPEA and SPEC; Papageorgiou et al., 1999) and streptococcal superantigen SSA (Sundberg and Jardetzky, 1999).

These toxins play an important role in diseases such as the staphylococcal toxic shock syndrome induced by TSST-1 (Schlievert et al., 1981), vomiting and diarrhea caused by staphylococcal enterotoxins, and the exanthemas caused by the pyrogenic streptococcal exotoxins. Furthermore, these toxins have been linked to the pathogenesis of several acute or chronic human disease states such as the Kawasaki syndrome (Leung et al., 1993), which is the leading cause of acquired heart disease among children in the United States, and to the pathogenesis of other life-threatening events such as food poisoning (Blackman and Woodland, 1995).

In addition to their functional similarities, the staphylococcal enterotoxins share a number of genetic and biochemical characteristics, as well as similar primary (Schlievert et al., 1995) and 3D structures (Swaminathan et al., 1992; Prasad et al., 1993; Papageorgiou et al., 1995; Schad et al., 1995). The genes for these toxins are generally carried on plasmids, bacteriophage chromosomes, or other heterologous genetic elements (Lindsay et al., 1998; Zhang et al., 1998), and all

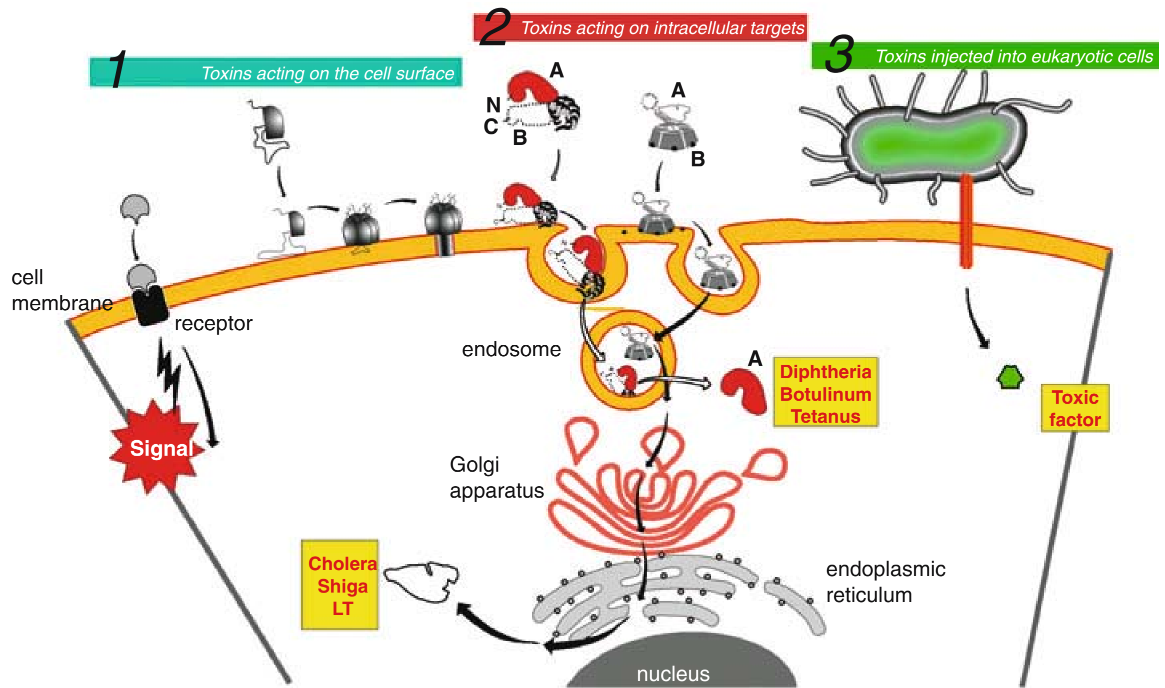

Fig. 2. Schematic representation of the three groups of bacterial toxins. Group 1 toxins act either by binding receptors on the cell membrane and sending a signal to the cell or by forming pores in the cell membrane, perturbing the cell permeability barrier. Group 2 toxins are A/B toxins, composed of a binding domain (B subunit) and an enzymatically active effector domain (A subunit). Following receptor binding, the toxins are internalized and located in endosomes, from which the A subunit can be transferred directly to the cytoplasm by using a pH-dependent conformational change or can be transported to the Golgi and the endoplasmic reticulum (ER), from which the A subunit is finally transferred to the cytoplasm. Group 3 toxins are injected directly from the bacterium into the cell by a specialized secretion apparatus (type III or type IV secretion system).

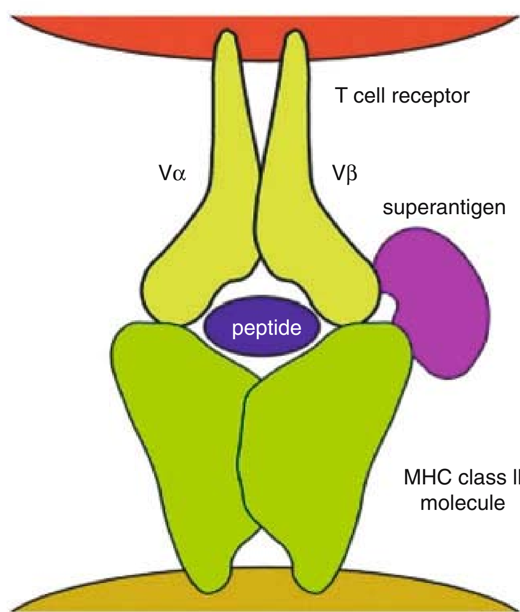

Fig. 3. Schematic representation of the interaction of a superantigen with a major histocompatibility complex (MHC) class II molecule and T-cell receptor.

of them are translated into a precursor protein containing an amino terminal signal sequence that is cleaved during export from the cell. The mature products are small nonglycosylated polypeptide molecules with molecular weights ranging from 20 kDa to 30 kDa and are moderately stable to chemical inactivation, proteolysis and denaturation by boiling.

Staphylococcal and streptococcal superantigens share 20–80% sequence similarity (Fig. 4); in particular, staphylococcal SEA is more related to SEE and SED, whereas SEB has greater homology with SEC, TSST-1, and streptococcal superantigens SPEA and SSA. The overall homology found in the staphylococcal enterotoxins has been suggested to stem from duplication of a gene encoding a common "ancestral" toxin (Iandolo, 1989).

Computer analysis of the *S. pyogenes* genome has revealed the presence of novel superantigen genes, and among them the one coding for the mitogenic exotoxin Z (SMEZ). This toxin is particularly similar to the SPE-C group of superantigens and, although present in all group A streptococci (GAS) strains, it shows extensive

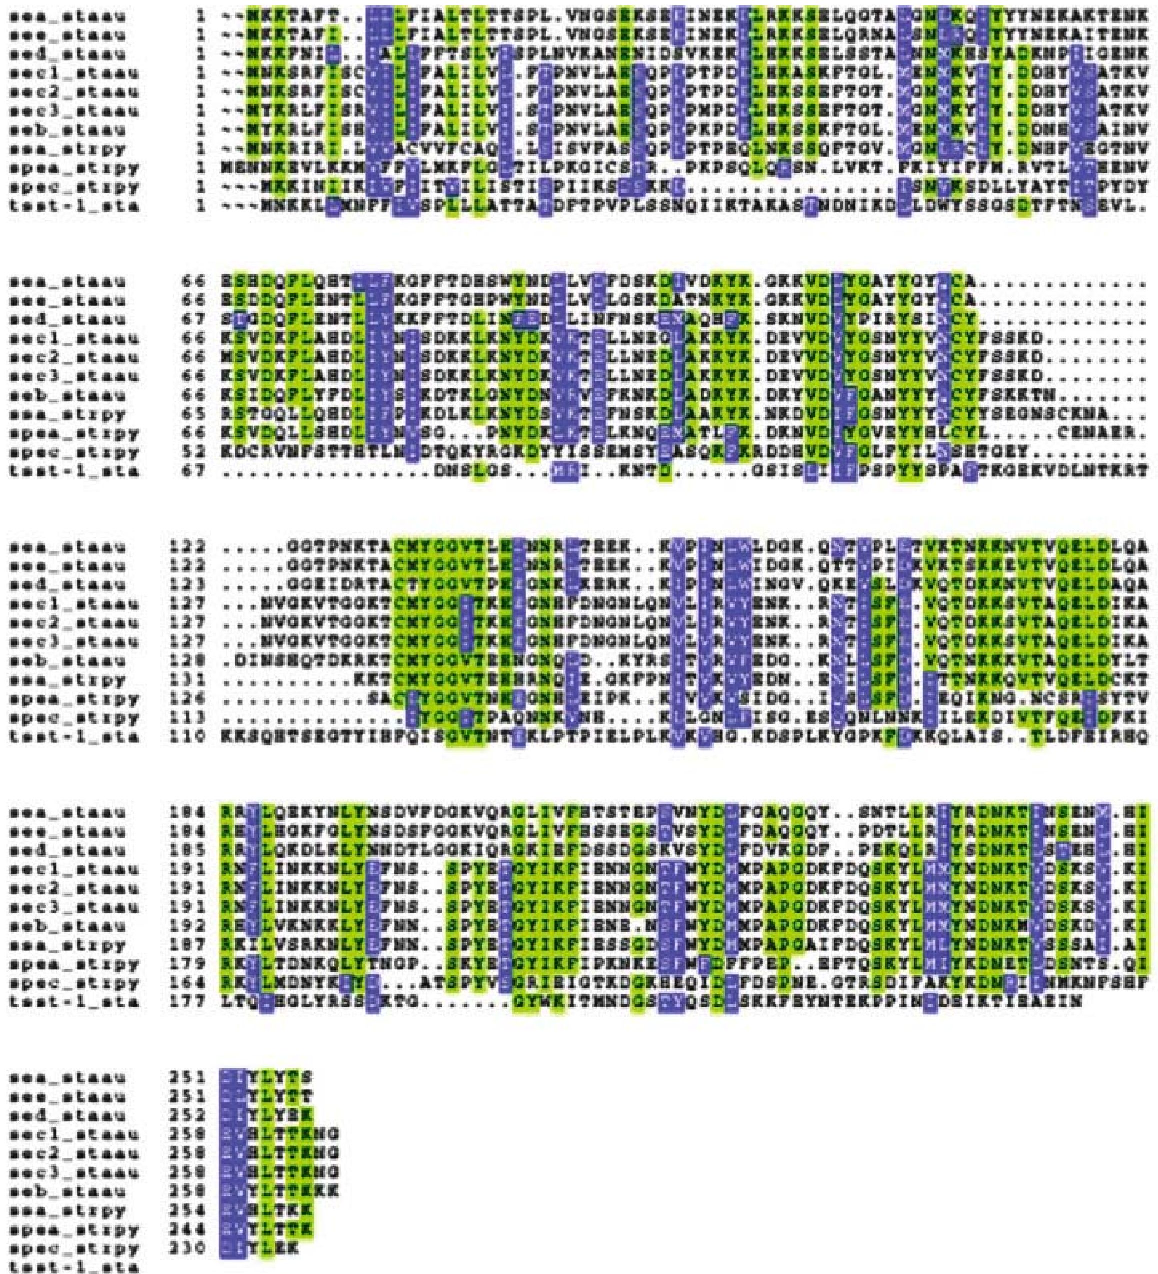

Fig. 4. Multiple sequence alignment of staphylococcal and streptococcal superantigens. Green indicates identity, whereas blue stands for amino acid similarity.

allelic variation. Further genetic characterization has shown that SMEZ is the most potent bacterial superantigen so far discovered and that it strongly contributes to the immunological effects of GAS both in vitro and in vivo by eliciting a robust cytokine production (Unnikrishnan et al., 2002).

Three novel streptococcal genes (*spe-g*, *spe-h* and *spe-j*) have been identified from the *Streptococcus pyogenes* M1 genomic sequence, while a fourth novel gene (*smez-2*) was isolated from the strain 2035. Of these, SMEZ-2, SPE-G and SPE-J are most closely related to streptococcal pyrogenic exotoxin SPEC, whereas SPE-H is more similar to the staphylococcal toxins than to any other streptococcal toxin (Proft et al., 1999).

Finally, other pyrogenic toxin superantigens recently discovered by genome mining include proteins SPEL and SPEM produced by several isolates of *S. pyogenes* of the M18 serotype. The corresponding genes are contiguous and coded within a bacteriophage. Both toxins were shown to be lethal in different animal models and to directly participate in the host-pathogen inter-

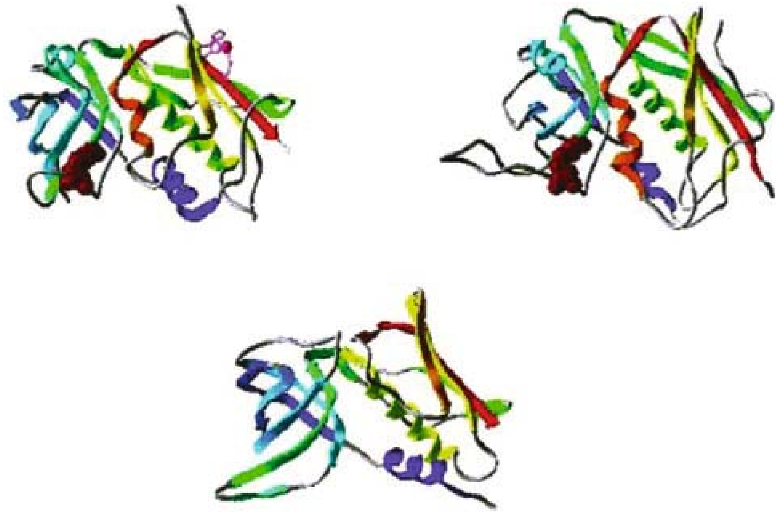

Fig. 5. Comparison of the X-ray structures of SEA (*left*), SEB (*right*) and TSST-1 (*below*). The colors follow the secondary structure succession where the N-terminus is blue, the C-terminus is red, and the long central helix is pale yellow. The zinc atom and the coordination site are colored pink and the cysteines involved in the disulfide bond are dark-red.

action in some acute rheumatic fever (ARF) patients (Proft et al., 2003).

Crystallographic structures are currently available for most of the described staphylococcal and streptococcal superantigens, such as SEA (Schad et al., 1995), SEB (Swaminathan et al., 1992), SEC2 (Papageorgiou et al., 1995), SEC3 (Fields et al., 1996), SED (Sundstrom et al., 1996), TSST-1 (Prasad et al., 1993; Prasad et al., 1997), SPEA (Papageorgiou et al., 1999), SPEB (Kagawa et al., 2000), SPEC (Roussel et al., 1997) and SSA (Sundberg et al., 1999). However, primary sequence homology among superantigens does not assure homology in their secondary and tertiary structures, and vice versa; in fact SEA, SEB, SEC and TSST-1, despite their low level of sequence similarity, all fold into very similar 3D structures. Below are the X-ray structures of SEA, SEB and TSST-1 that share a very similar fold despite low levels of sequence similarity that range from less than 20% identity in the case of SEA and TSST-1, to 33% in the case of SEA and SEB.

All of these toxins have a characteristic two-domain fold composed of a β-barrel at the *N*-terminus and a β-grasp at the C-terminus connected by a long α-helix that diagonally spans the center of the molecule (Fig. 5). Moreover, all of these toxins are characterized by a central disulfide bond (with the exception of TSST-1, which has no cysteines) and by a Zn^{+2} coordination site which is believed to be involved in MHC class II binding (Abrahmsen et al., 1995).

The presence of two zinc-binding sites in SpeC indicates different modes in the assembly of the MHC-superantigen-T-cell receptor (TcR) trimolecular complex.

The crystal structures of SEB and TSST-1 in complex with an MHC class II molecule, and those of SEC2/SEC3 in complex with a TcR Vβ chain have been solved (Li et al., 1998; Fields et al., 1996). As an example, the complex between SEB and the Vβ domain of a TcR is reported (Fig. 6).

Superantigen molecules have also been identified in other pathogens, where they represent important virulence determinants.

MaM is a T-cell mitogen produced by *Mycoplasma arthritidis*, which contributes to the acute and chronic inflammatory disease mediated by this organism (Cole and Atkin, 1991). The recently determined X-ray structure of MaM in complex with HLA-DR1 has revealed that this protein has a fold and a mode of binding, which are entirely different from those of the known pyrogenic superantigens (Zhao et al., 2004; Fig. 7).

Another superantigenic toxin is the YPMa produced by a subset of *Yersinia pseudotuberculosis* strains. This 14.5-kDa protein was originally purified from bacterial lysates and found to exert a mitogenic activity on human peripheral blood

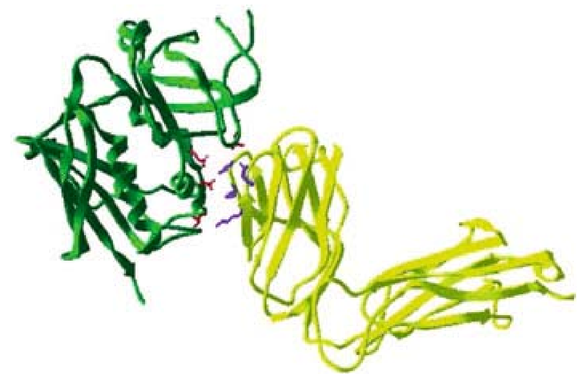

Fig. 6. Crystal structure of the complex between SEB (green) and TcR (yellow). The residues involved in hydrogen bonds between the two molecules have side-chains colored in red and blue, respectively.

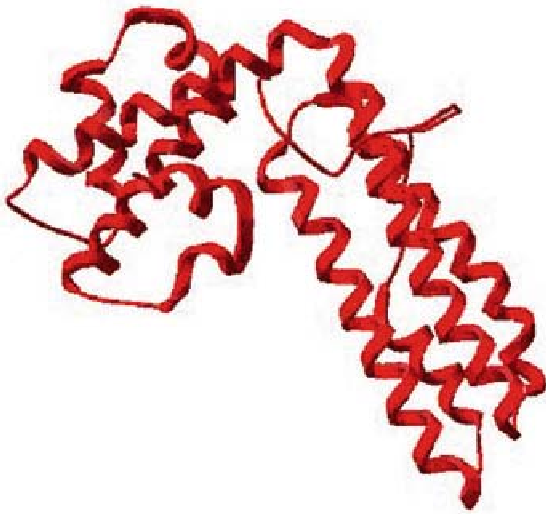

Fig. 7. Three-dimensional structure of MaM superantigen.

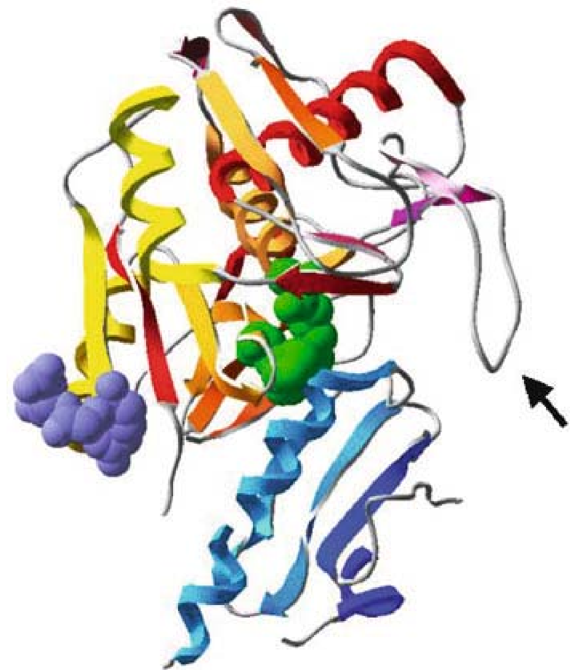

Fig. 8. The three-dimensional structure of the precursor form of streptococcal cysteine protease SpeB. The prosegment (blue) and active protease (yellow-orange) are indicated with different color scales. The solvent-exposed Arg-Gly-Asp (RGD) motif is violet, and the active site (Cys-47-His-195-Trp-212) is buried by the prosegment and is colored in green. The highly conserved finger loop is also indicated (arrow).

mononuclear cells. Although the precise role of this protein is currently unknown, the data show that YPMa contributes to the virulence of *Y. pseudotuberculosis* in systemic infection in mice (Carnoy et al., 2000).

Other toxins that have long been known as superantigens are the streptococcal pyrogenic exotoxin B (SPEB), a virulence factor with cysteine protease activity produced by all isolates of group A streptococci, and the exfoliative toxins A and B produced by *S. aureus* (Fig. 2, panels 2 and 3).

Although these proteins strongly contribute to the virulence of the corresponding microorganism, their role as mitogenic factors has been disproved when it was shown that all the nonrecombinant forms were in fact contaminated with trace amounts of the SMEZ superantigen (Unnikrishnan et al., 2002).

SPEB appears to contribute to *S. pyogenes* pathogenesis in several ways, including proteolytic cleavage of human fibronectin and vitronectin, two abundant extracellular matrix proteins involved in maintaining host tissue integrity. SPEB causes a cytopathic effect on human endothelial cells and represents a critical virulence factor in human infection and in mouse models of invasive disease. Despite low levels of sequence similarity, this toxin can be considered as a structural homologue of the papain superfamily that also includes the mammalian cathepsins B, K and L (Kagawa et al., 2000). Like other proteases, the enzyme SpeB is produced as an inactive precursor (zymogen) of 40 kDa which, following autolytic cleavage of the N-terminal 118 residues, is converted to the mature, active 27.6-kDa protease. The catalytic site lacks the Asn residue generally present in the catalytic Cys-His-Asn triad, which is in this case substituted by a Trp. The structure also reveals the presence of a surface-exposed integrin-binding Arg-Gly-Asp (RGD) motif that is a feature unique to SpeB among cysteine proteases and is linked to the pathogenesis of the most invasive strains of *S. pyogenes* (Stockbauer et al., 1999). Sequence analysis performed on more than 200 streptococcal isolates has revealed an overall limited structural variation in SPEB, with the entire active site being completely conserved. Interestingly, the prominent finger loop that extends from the N-terminal domain (Fig. 8) is also invariant, suggesting that antibodies directed against this region could be effective therapeutic agents.

The exfoliative toxins ETA and ETB of *Staphylococcus aureus* are produced during the exponential phase of growth and excreted from colonizing staphylococci before being absorbed into the systemic circulation. They have been recognized as the causative agents in staphylococcal scalded skin syndrome, an illness characterized by specific intraepidermal separation of the layers of skin between the stratum spinosum and the stratum granulosum (Ladhani et al., 1999). The two ETs are about 40% identical, with no apparent sequence homology to other bacterial

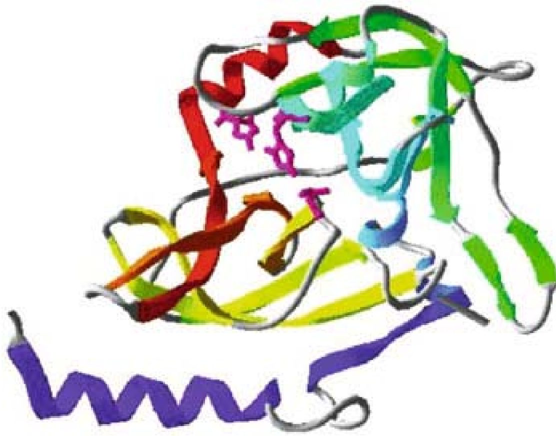

Fig. 9. Crystal structure of exfoliative toxin A (ETA) of *Staphylococcus aureus*. The three residues of the catalytic triad responsible for the serine protease activity are colored in magenta.

toxins. Both superantigens have been proved to act as serine proteases, and this enzymatic activity could be one of the mechanisms hypothesized as the cause of epidermal separation. In fact, at least in the case of ETA (Fig. 8), substitution of the active site serine residue with cysteine abolishes its ability to produce the characteristic separation of epidermal layers but not its ability to induce T-cell proliferation (Redpath et al., 1991). The two ETs are about 40% identical, with no apparent sequence homology to other bacterial toxins. The overall structures of ETA and ETB are similar to that of the chymotrypsin-like serine protease family of enzymes, with the catalytic triad being composed of His-57, Asp-102 and Ser-195 (Vath et al., 1997, 1999).

Recently, a novel member of the exfoliative group of toxins has been discovered in *S. aureus*. This protein, termed "ETD," is encoded within a pathogenicity island, which also contains the genes for a serine protease and the edin-B gene. When injected in neonatal mice as recombinant protein, ETD has been shown to induce exfoliation of the skin with loss of cell-to-cell adhesion in the upper part of the epidermis (Yamaguchi et al., 2002).

Toxins Acting on Surface Molecules

Bacteroides fragilis enterotoxin (BFT) is a protein of 186 residues that is secreted into the culture medium. The toxin has a zinc-binding consensus motif (HEXXH), characteristic of metalloproteases and other toxins such as tetanus and botulinum toxins. In vitro, the purified enterotoxin undergoes autodigestion and can cleave a number of substrates including gelatin, actin, tropomyosin and fibrinogen. When added to cells in tissue culture, the toxin cleaves the 33-kDa extracellular portion of E-cadherin, a 120-kDa transmembrane glycoprotein (responsible for calcium-dependent cell-cell adhesion in epithelial cells) that also serves as a receptor for *Listeria monocytogenes*. In vitro, BFT does not cleave E-cadherin, suggesting that the membrane-embedded form of E-cadherin is necessary for cleavage.

BFT causes diarrhea and fluid accumulation in ligated ileal loops. In vitro, it is nonlethal but causes morphological changes such as cell rounding and dissolution of tight clusters of cells. The morphological changes are associated with F-actin redistribution. In polarized cells, BFT is more active from the basolateral side than from the apical side, decreases the monolayer resistance, and causes dissolution of some tight junctions and rounding of some of the epithelial cells, which can separate from the epithelium. In monolayers of enterocytes, BFT increases the internalization of many enteric bacteria such as *Salmonella*, *Proteus*, *E. coli* and *Enterococcus* but decreases the internalization of *L. monocytogenes* (Sears, 2001).

BFT belongs to a large family of bacterial metalloproteases that usually cleave proteins of the extracellular matrix. *Pseudomonas aeruginosa* and *Aeromonas hydrophila* elastases (aminopeptidase and AhyB) and *Clostridium histolyticum* collagenase (ColH) are the best-known examples (Yoshihara et al., 1994; Cascon et al., 2000; Cahan et al., 2001).

Lately, a novel member of this family of protein toxins has been identified in *Bacillus cereus*. The protein, termed "Nhe" (nonhemolytic enterotoxin), is a 105-kDa metalloprotease, which shares homologies to the above-mentioned elastases and collagenases. Biochemical characterization has shown that Nhe possesses both gelatinolytic and collagenolytic activities (Lund and Granum, 1999).

Toxins Acting on the Cell Membrane

Protein toxins forming pores in biological membranes occur frequently in Gram-positive and Gram-negative bacteria (Braun and Focareta, 1991). Pore-forming toxins, also known as "lytic factors," work by punching holes in the plasma membrane of eukaryotic cells, thus breaking the permeability barrier that keeps macromolecules and small solutes selectively within the cells (Sugawara et al., 1997; Gilbert, 2002; Fig. 2, panel 1). Because erythrocytes have often been used to test the activity of these toxins, some of them are also called "hemolysins"; however, whereas erythrocytes appear to be very good targets in vitro, they are never the main physiological targets of this class of proteins in vivo (Tomita et al., 1997).

The pathogenicity of the toxin-producing organisms in eukaryotes is clearly related to the toxins they produce. Furthermore, pore-forming toxins represent the most potent and versatile tool with which invading microbes damage the host cell (Bhakdi et al., 1994). Cell permeabilization exerted by the toxic activity of these proteins generally results in release of cytokines, activation of intracellular proteases, induction of apoptosis, and finally, death of the eukaryotic cell (Alouf and Geoffrey, 1991).

To generate channels and holes in the cell membrane, this class of toxins must be able to fold in a characteristic amphipathic structure typical of porins (Weiss et al., 1991; Cowan et al., 1992), with one side facing the internal hydrophilic cavity, and the other side interacting with the lipid chains or the nonpolar segments of integral membrane proteins.

Most of the toxins are produced or stored in a protoxin inactive form. The activation step varies from the cleavage of an N_{term} acidic peptide as in the case of melittin, to a C_{term} proteolytic cleavage as in aerolysin (van der Goot et al., 1992); in the particular case of the Gram-negative hemolysins (cytolysins), these toxins are usually synthesized as precursor proteins, then covalently modified to an acylated, active form and finally secreted via specific export systems, which differ for various types of hemolysins (Issartel et al., 1991; Stanley et al., 1994). All such steps increase the affinity for the membrane, which appears to be essential for activity.

A large proportion of these proteins are produced by Gram-positive bacteria and can be divided into large pore-forming and small pore-forming toxins on the basis of the dimension of the holes produced on the plasma membrane and also of the kind of interaction that they establish with the eukaryotic receptor. In addition, the pore-forming, repeats-in-toxin (RTX) family of toxins includes a large group of Ca^{+2}-dependent hemolysins (secreted by both Gram-positive and Gram-negative bacteria), which are characterized by a conserved glycine- and aspartate-rich motif of nine amino acids (Welch, 1991; Coote, 1992). Given their predominant role on cellular membranes, we have included in this section also the so-called "membrane perturbing toxins" and the insecticidal toxins produced by *Bacillus thuringensis*.

Large Pore-Forming Toxins

This class of cytolysins (Fig. 2, panel 2) comprises more than 20 family members, which are generally secreted by taxonomically diverse species of Gram-positive bacteria and which have the common property of binding selectively to cholesterol on the eukaryotic cell membrane (Alouf and Geoffrey, 1991). Each toxin consists of a single 50- to 80-kDa polypeptide chain, and they are characterized by a pretty remarkable sequence similarity, also suggesting possible similar 3D structures. These proteins are produced by *Streptococcus pyogenes*, *S. pneumoniae*, *Bacillus*, a variety of *Clostridia*, including *Clostridium tetanii* and *C. perfringens*, and *Listeria*.

To date, the best characterized are perfringolysin O (PFO), a virulence factor of *Clostridium perfringens*, which causes gas gangrene (Rossjohn et al., 1997), streptolysin O, secreted by *Streptococcus pyogenes* (Kehoe et al., 1987), alveolysin, produced by Bacillus alvei (Geoffroy et al., 1990), and pneumolysin, the major causative agent of streptococcal pneumonia and meningitis (Rossjohn et al., 1998).

In addition to its role as a cytolysin, listeriolysin O (LLO), which is an essential virulence factor of *Listeria monocytogenes* (Gedde et al., 2000) has also been shown to induce lymphocyte apoptosis with rapid kinetics (Carrero et al., 2004).

These toxins share a similar mechanism of action, which consists of an interaction of monomeric toxin with target cells via cholesterol (their receptor), followed by oligomerization and insertion into the host cell membrane; this process ultimately results in serious membrane damage with formation of large pores with diameters exceeding 150 Å. All these toxins contain a common motif (boxed in Fig. 10), which is located approximately 40 amino acids from the carboxy terminus; this motif includes a Cys residue, which if oxidized abolishes the toxin's lytic activities. Lytic activity can be restored only upon addition of reducing agents such as thiols. However, despite their designation as "thiol-activated cytolysins," thiol activation is clearly not an important property of this group of toxins (Billington et al., 2000). Interestingly, the membrane-bound receptor, cholesterol, plays an important role in the oligomerization step as well as in membrane insertion and pore formation (Alouf and Geoffrey, 1991).

Crystallographic data are available only for the thiol-activated cytolysin (perfringolysin O; PFO; Fig. 1, panel 4) of *Clostridium perfringens* (Rossjohn et al., 1997). Nevertheless, given the high degree of sequence conservation (Fig. 10) detected within this class of protein toxins (ranging from the 43% identity of PFO and listeriolysin, to the 72% identity of PFO and alveolysin), this structure can be considered the prototype of the entire family (Fig. 11).

PFO is an unusually elongated rod-shaped molecule mainly composed of β-sheets; the monomer is made of four discontinuous domains, indicated with different colors in the picture. Domain 1 (green) has an α/β structure

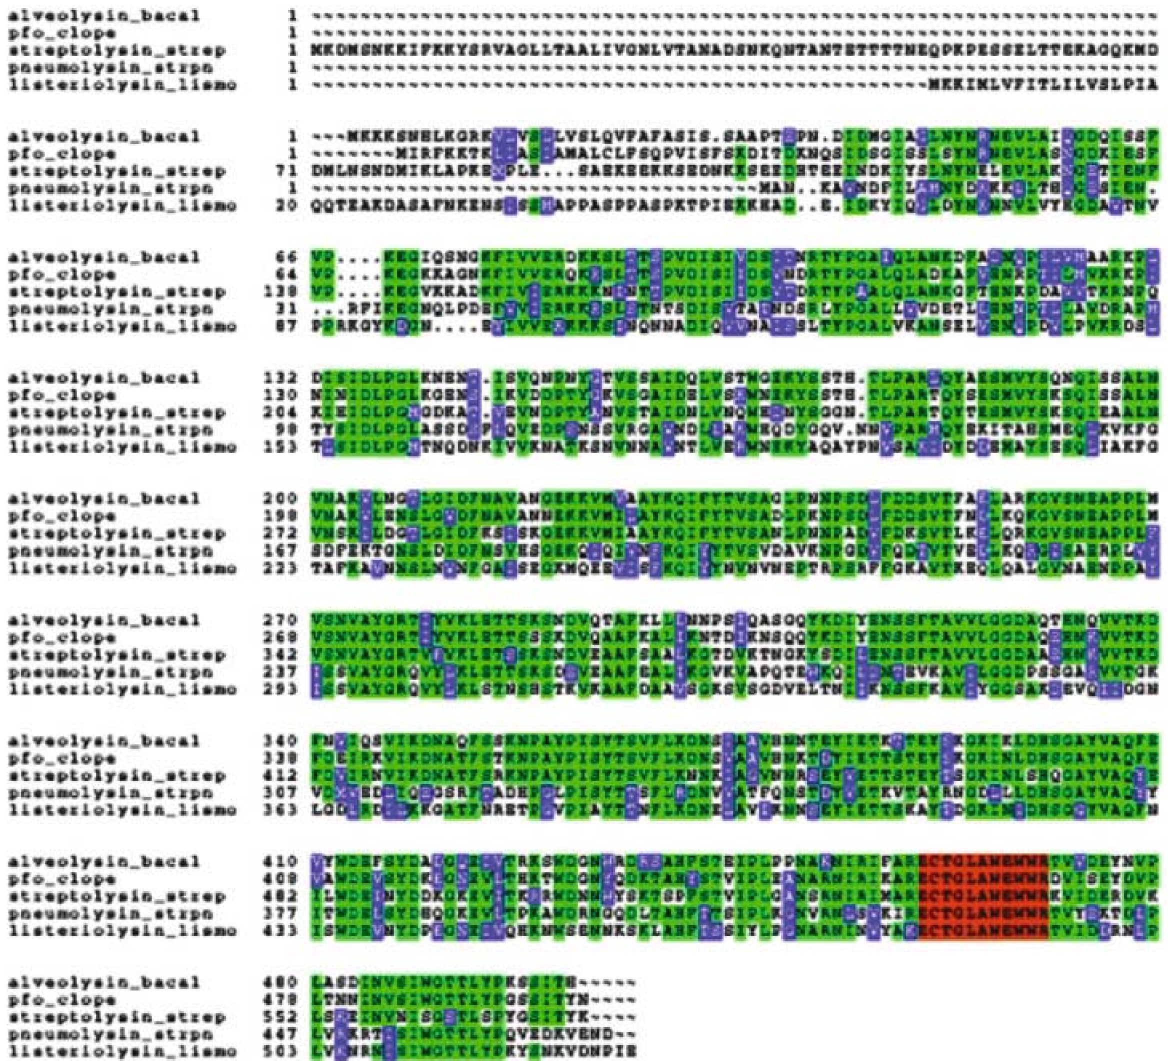

Fig. 10. Multiple sequence alignment of proteins belonging to the class of large-pore-forming toxins. Green indicates identity, whereas blue stands for amino acid similarity.

containing a seven-stranded antiparallel β-sheet. Domain 2 (blue) consists mainly of four β-strands, while domain 3 (yellow) is comprised of an α/β/a structure. Finally, domain 4 (red) is folded into a compact β-sandwich consisting of multiple-stranded sheets.

The mechanism of membrane insertion is not clear; in fact, no canonical transmembrane domains can be identified along the primary structure and no significant patches of hydrophobic residues can be mapped on the surface of the molecule. Nevertheless, a model of the membrane-bound state, which takes into account the interaction with the cholesterol receptor as the first step for penetration of the hydrophobic bilayer core, has been proposed on the basis of electron microscopy and other experimental data. Several chemical modifications and mutagenesis studies have suggested the cholesterol-binding site to be located at the tip of domain 4 (Fig. 12), and in particular, it has been mapped within the highly conserved, Trp-rich segment (Michel et al., 1990; Hill et al., 1994). Proteolysis studies have further demonstrated that domain 4 is also the membrane-spanning domain, although the distribution of charged and hydrophobic residues on the β-sheet of this region is not compatible with an insertion into the lipid bilayer. From these studies, it has emerged that only the tip of the β-barrel domain D4 is responsible for membrane insertion and that a major conformational rearrangement takes place during pore formation (Shepard et al., 1998; Shatursky et al., 1999).

Taken together, these observations suggest a model of oligomer insertion. After the toxin binds to the cholesterol molecule, the aliphatic side chains neutralize the charged resi-

dues present on the β-sheet (blue) of domain 4 and then trigger membrane penetration. Consistent with this model is the hypothesis that the highly hydrophobic Trp-rich loop

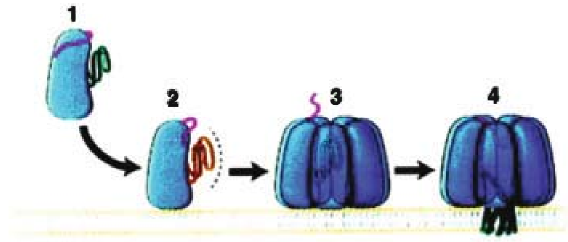

Fig. 13. General mechanism of assembly for small-pore-forming toxins: the stem region is initially folded against in the body of the water-soluble monomer; upon binding to the membranes and oligomerization, it subsequently undergoes conformational rearrangement and promotes insertion into the lipid bilayer.

could lead to and promote the final penetration step.

Furthermore, on the basis of recent data, a mechanism has been proposed whereby insertion into the bilayer occurs only after PFO monomers have assembled into a pre-pore state. Monomer-monomer interactions therefore not only promote insertion, but cooperative interactions between PFO monomers appear to be required to drive transmembrane insertion and β-barrel formation (Hotze et al., 2002). Recently, a protein belonging to this class of cytolysins has been identified in *Bacillus anthracis* and named "anthrolysin O" (ALO). This putative toxin is able to bind erythrocytes and could have a role in the virulence of anthrax (Shannon et al., 2003).

Small Pore-Forming Toxins

The family of small-pore-forming toxins acts by creating very small pores (1–1.5 nm of diameter) in the membrane of host cells, thus allowing their selective permeabilization to solutes with a molecular mass less than 2 kDa. Alpha toxin (α-hemolysin) is the prototype of a group of pore-forming toxins produced by most pathogenic strains of *Staphylococcus aureus* (Gray and Kehoe, 1984a; Song et al., 1996; Gouaux, 1998; Fig. 1, panel 5); other members of this family include leukotoxins, such as leukocidin F (LukF), leukocidin S (LukS), Panton-Valentine leukocidin (PVL) and γ-hemolysin (Prèvost et al., 1995; Tomita and Kamio, 1997; Olson et al., 1999; Pedelacq et al., 1999; Cooney et al., 1993) and the β-toxin of *Clostridium perfringens* (Steinthorsdottir et al., 2000; Tweten, 2001; Magahama et al., 2003). These staphylococcal and streptococcal proteins are secreted as water-soluble monomers and assemble on the surface of susceptible cells to form heptameric transmembrane channels of approximately 1 nm in diameter (Finck-Barbancon et al., 1993; Sugawara et al., 1997; Fig. 13).

Fig. 14. Multiple sequence alignment of proteins belonging to the family of small pore-forming toxins. Green and blue stand for amino acid identity and similarity, respectively.

The monomers have molecular weights of 33 kDa and are related in sequence and function (Fig. 14).

These toxins bind to human erythrocytes, monocytes, platelets, lymphocytes and endothelial cells, causing (at high concentrations) membrane rupture and cell lysis and death. Alpha-toxin has been recently shown to be the major mediator of caspase activation and apoptosis (Haslinger et al., 2003).

The structure of the transmembrane pore of staphylococcal α-toxin has been solved and has confirmed the heptameric structure of the oligomer (Song et al., 1996; Fig. 15). The complex is mushroom-shaped and measures 100 Å in height and up to 100 Å in diameter; the aqueous channel forms the transmembrane pore and spans the length of the entire complex ranging from 14 Å to 46 Å in diameter.

Each protomer (Fig. 16) is mainly composed of β-strand elements; two of these in particular constitute the stem domain, which contributes to the formation of the transmembrane pore in the heptameric form of the complex; a glycine-rich

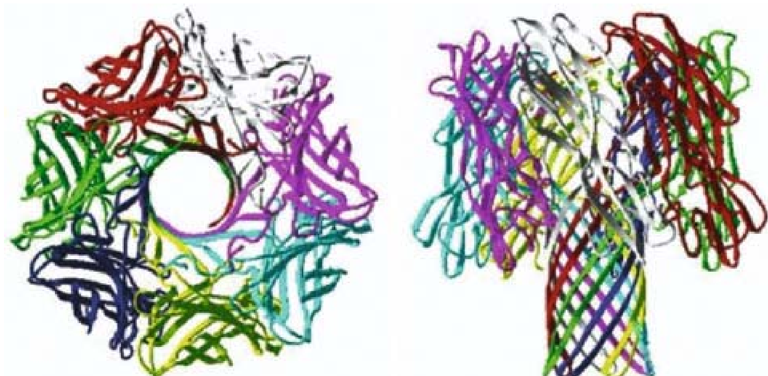

Fig. 15. Top and side views of the heptameric complex of a-toxin; each monomer is represented here with a different color (see Fig. 1, panel 5).

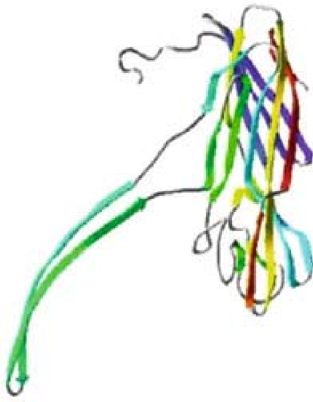

Fig. 16. Structure of the monomer of *S. aureus* α-toxin; the stem domain involved in pore formation protrudes outside of the core of the structure.

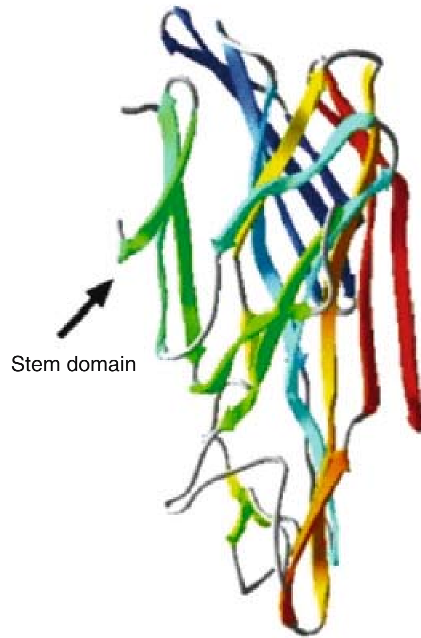

Fig. 17. Crystallographic structure determined for the protomer of toxin LukF; the glycine-rich, stem domain is in this case folded against the main body of the structure.

segment that is probably involved in solvent interaction characterizes this domain.

Leukotoxins and γ-hemolysin (HγII) should be grouped together, inasmuch as they form two types of bi-component complexes (LukF+LukS and LukF+HγII) that exhibit leukotoxic and hemolytic activity, respectively (Tomita and Kamio, 1997). Panton-Valentine leukocidin (PVL) is a closely related toxin carried by 2% of clinically isolated *S. aureus* strains and is also composed of type F and S components (Prèvost et al., 1995). The components of each protein class are produced as nonassociated, water-soluble proteins that undergo conformational changes and form oligomeric complexes after recognition of their cell targets, a process leading to transmembrane-pore formation and, ultimately, to cell death. The resultant transmembrane channels (estimated diameter 8 Å) are mainly permeable to divalent cations. Recently, fluorescence microscopy experiments have been performed to elucidate the mechanism of membrane insertion of the γ-hemolysin complex. This study shows that the three cooperative stages (dimer-dimer interaction, single pore assembly, and aggregation of pores) enhance the efficiency of assembly of oligomeric pores (Nguyen et al., 2003).

As representative of this class of bi-component toxins, consideration is given the X-ray structure of the Luk-F protomer (Olson et al., 1999; Fig. 17), which has been solved at a 1.90 Å resolution. The superposition of this monomer with that of α-toxin shows that the core structures are very similar despite the relatively low primary sequence identity (32%); nevertheless, a conformational change has affected the region of the glycine-rich stem domain, which appears in this case as a compact β-sheet folded against the body of the structure.

From a structural point of view, in contrast to a wide range of bacterial and insect toxins that utilize α-helices to perturb or penetrate the bilayer, these pore-forming toxins (members of an emerging family of proteins) can be defined by their use of bilayer-spanning antiparallel β-barrels instead.

Since the initial discovery of the first small pore-forming toxins, the number of these proteins has grown to include several members, among which are the recently identified hemolysin II (HlyII), and cytotoxin K (CytK) of *Bacillus cereus*, implicated in necrotic enteritis (Lund et al., 2000; Hardy et al., 2001; Miles et al., 2002).

RTX Toxins

Escherichia coli hemolysin (HlyA) is a 110-kDa protein, which can be considered as the prototype of a class of pore-forming toxins mainly produced by Gram-negative bacterial pathogens (Felmlee et al., 1985; Welch, 1991). This well-represented family includes a large number of calcium-dependent cytolysins known as RTX toxins, which are produced by different genera of Enterobacteriaceae and Pasteurellaceae. Characterized by the presence of a conserved repeated glycine- and aspartate-rich motif of nine amino acids, these cytolysins have multiple calcium-binding sites essential for function (Felmlee and Welch, 1988).

The toxin is encoded by four genes, one of which, *hlyA*, encodes the 110-kDa hemolysin.

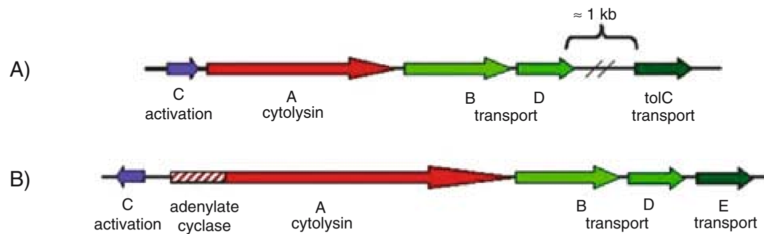

Fig. 18. Schematic representation of the genetic organization of RTX determinants; the genes encoding the Hly, Lkt, Aalt and Hpp proteins are organized in the same fashion, as illustrated in panel A, whereas the genes involved in synthesis and secretion of adenylate cyclase/hemolysin of *B. pertussis* display a somewhat different organization (panel B).

The other genes are required for its posttranslational modification (*hlyC*) and secretion (*hlyB* and *hlyD*). The four genes are found in a very limited number of *E. coli* clonal types, and can be sometimes located on transmittable plasmids (Smith and Halls, 1967). To give an idea of the level of toxicity associated with *hlyA* gene product, when non-hemolytic strains of *E. coli* are transformed with recombinant plasmids encoding the hemolysin, the transformants (in rodent models of peritonitis) are 10-fold to a 1000-fold more virulent than the parental strains. The receptor-binding domain of HlyA has been recently mapped (Cortajarena et al., 2003).

Other members of this class of RTX proteins include the adenylate cyclase/hemolysin of *Bordetella pertussis* (CyaA; Glaser et al., 1988), the ApxI-II and III hemolysins from Actinobacillus pleuropneumoniae (Maier et al., 1996), and the leukotoxins of *A. actinomycetemcomitans* (LtxA; Korostoff et al., 1998; Henderson et al., 2003) and of *Pasteurella haemolytica* (LktA; Chang et al., 1987; Wang et al., 1998).

Although a remarkable level of primary structure similarity can be detected among this group of toxins (20–60% identity), nevertheless they differ in host cell specificity and seem to adopt diverse mechanisms for cellular damage (Frey et al., 2002).

The synthesis and secretion of RTX toxins involve the participation of at least five different gene products; the organization of the five genes is very similar (Fig. 18, panel A), with the exception of B. pertussis bifunctional adenylate cyclase/hemolysin, where all five (*cyaC*, *A*, *B*, *D* and *E*) are found together (Glaser et al., 1988; Barry et al., 1991; Fig. 18, panel B); for the other family members, in fact, four of the genes are encoded within a single operon, whereas the fifth gene is located approximately 1 kb downstream (Welch and Pellett, 1988; Wandersman and Delepelaire, 1990).

The activation process performed by HlyC on HlyA ultimately results in the acquired capacity of HlyA to bind target cells; this activation involves proteolytic processing and posttranslational acylation, as well as binding of Ca^{+2} ions to the repeated domain.

Membrane-Perturbing Toxins

δ-Toxin or δ-hemolysin is secreted into the medium by *S. aureus* strains at the end of the exponential phase of growth. It is a 26-amino-acid peptide (MAQDIISTIGDLVKWIIDTVNKFTKK) that has the general structure of soap with a nonpolar segment followed by a strongly basic carboxy-terminal peptide. The peptide has no structure in aqueous buffers but acquires an a-helical structure in low-dielectric-constant organic solvents and membranes. The α-helix has a typical amphipathic structure, which is necessary for the toxin to interact with membranes. The toxin binds nonspecifically parallel to the surface of any membrane without forming transmembrane channels. At high concentration, the peptide self-associates and increases the perturbation of the lipid bilayer that eventually breaks into discoidal or micellar structures. Interestingly, mellitin, which is also a 26-amino-acid lytic peptide produced by *S. aureus*, has no sequence homology with δ-toxin but has identical distribution of charged and nonpolar amino acids. These toxins are active in most eukaryotic cells. Cells first become permeable to small solutes and eventually swell and lyse, releasing cell intracellular content.

Recent data have demonstrated that δ-hemolysin insertion is strongly dependent on the peptide-to-lipid ratio, suggesting that association of a critical number of monomers on the membrane is required for activity. The peptide appears to cross the membrane rapidly and reversibly and cause release of the lipid vesicle contents during this process.

Other Pore-Forming Toxins

Additional members of this class of β-barrel, channel-forming toxins include aerolysin of *Aer-*

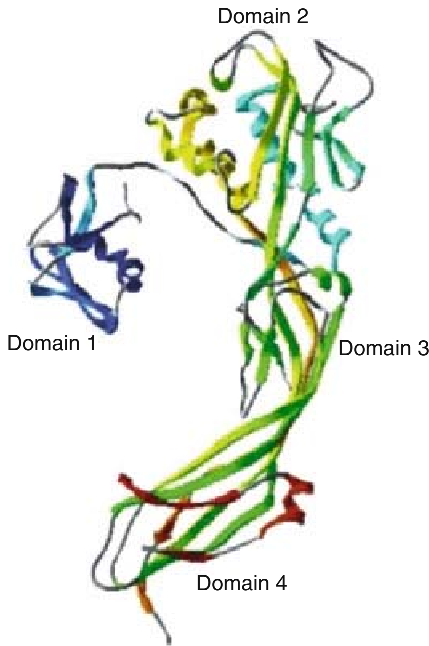

Fig. 19. X-ray structure of aerolysin toxin of *Aeromonas hydrophila*; the four domains are indicated; in particular, domain 1 clearly protrudes outside of the main body of the structure.

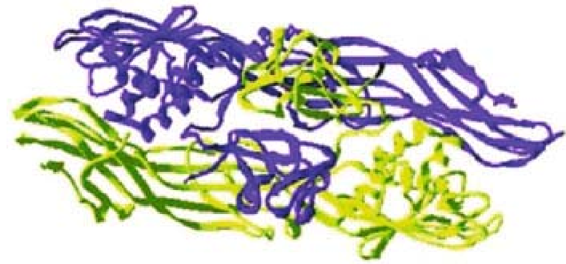

Fig. 20. Structure of the dimer of aerolysin and interaction between the two first domains.

omonas hydrophila (Parker et al., 1994; Rossjohn et al., 1998), and the closely related a-toxin of *Clostridium septicum* (Ballard et al., 1995), the anthrax toxin protective antigen PA of *Bacillus anthracis* (Petosa et al., 1997; Wesche et al., 1998), and the HlyE pore-forming toxin produced by pathogenic *E. coli*.

AEROLYSIN AND ALPHA-TOXIN (AT). Aerolysin (Fig. 1, panel 7) is mainly responsible for the pathogenicity of Aeromonas hydrophila, a bacterium associated with diarrheal diseases and wound infections (Altwegg and Geiss, 1989; Fivaz et al., 2001). It is secreted as a 52-kDa protoxin that is proteolytically cleaved into a 25-residue carboxy-terminal peptide and a 48-kDa active protein. Like other functionally related toxins, aerolysin changes its topology in a multistep process from a completely water-soluble form to a membrane-soluble heptameric transmembrane channel (ca. 1.5 nm in diameter) that destroys sensitive cells by breaking their permeability barriers.

Proaerolysin is a dimer in solution as well as in the crystal form (van der Goot et al., 1993; Parker et al., 1994); four structural domains characterize the monomer (Fig. 19).

In the structure of the dimer, the position of domain 1 appears to be stabilized by contacts with domain 1 of the other monomer, resulting in a very strict interaction of the two (Fig. 20).

Domain 4 is characterized by an amphipatic β-barrel structure, which is responsible for membrane insertion of the final complex. In fact, oligomerization is an essential step in channel formation and it seems to precede membrane insertion. A model has been suggested for the entire process; it assumes that proaerolysin approaches the target cell as a water-soluble, hydrophilic dimer which, once concentrated on the surface of the target cell, binds to the receptor; subsequent proteolytic cleavage would cause dimer dissociation and oligomerization. This would ultimately result in an exposure of the hydrophobic region of the toxin and thus in membrane penetration.

Clostridium septicum AT is a channel-forming protein that is an important contributor to the virulence of the organism. Recent data have proved that this toxin, like aerolysin, binds to glycosylphosphatidylinositol (GPI)-anchored protein receptors. Furthermore, AT is also active against *Toxoplasma gondii* tachyzoites. Toxin treatment causes swelling of the parasite endoplasmic reticulum thus providing the first direct evidence that α-toxin is a vacuolating toxin (Ballard et al., 1995; Gordon et al., 1999). Recently, based on the available crystal structure of aerolysin, a molecular model of the membrane spanning domain of AT has been generated (Melton et al., 2004).

ANTHRAX PROTECTIVE ANTIGEN (PA). Anthrax protective antigen (PA; Fig. 1, panel 17) is one of the three components of the anthrax toxin complex secreted by *Bacillus anthracis*, which also includes the edema factor (EF) and the lethal factor (LF; Brossier et al., 2000; Collier and Young, 2003). Whereas EF and LF are responsible for the toxic activity, PA can be considered as the receptor-binding domain for two distinct A subunits, which are in turn EF and LF. The three subunits are encoded on a plasmid and are synthesized and secreted independently. Once on the host cell surface, PA needs a proteolytic activation to form a membrane-inserting heptamer through which EF and LF can be translocated (Klimpel et al., 1992; Milne and Collier, 1993; Milne et al., 1994; see Fig. 37 for the mechanism of action). The monomer is mainly constituted by antiparallel

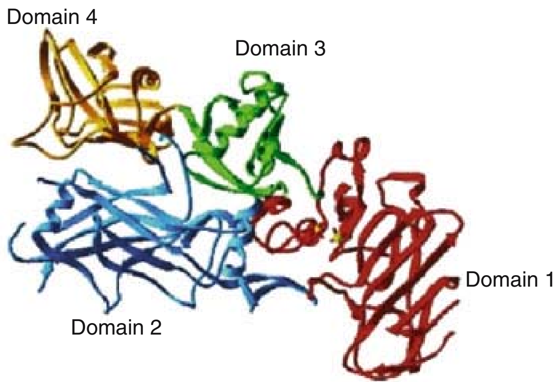

Fig. 21. X-ray structure of *Bacillus anthracis* protective antigen PA. The four structural domains are indicated by different colors. The two cysteines present in domain 1 are colored in yellow.

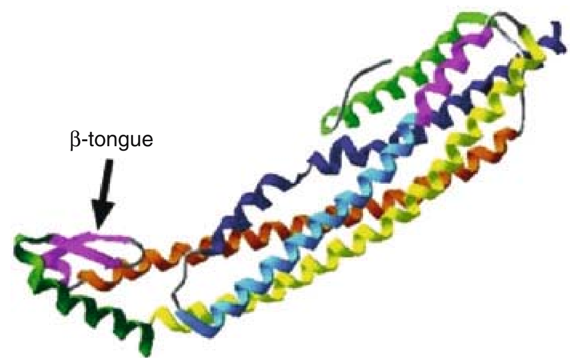

Fig. 22. X-ray structure of *E. coli* HlyE cytolysin. Two hydrophobic domains are present at the extremities of the α-helical bundle (colored in magenta).

β-sheets and contains four functional domains (Fig. 21). The crystallographic structure has revealed how PA can be assembled into heptamers and has suggested how some of the domains can undergo pH-driven conformational change.

Domain 1 (red) contains two Ca^{+2} ions (yellow) and the cleavage site for proteolytic activation; domain 2 (cyan) is the heptamerization domain and is implicated in membrane insertion; domain 3 (green) has an unknown function, whereas domain 4 (yellow) is for receptor-binding. Given its ability to promote the translocation of many heterologous proteins, PA is being evaluated as a general protein delivery system (Leppla et al., 1999).

ESCHERICHIA COLI HLYE. *Escherichia coli* produces a novel pore-forming toxin HlyE (Fig. 1, panel 8), which is completely unrelated to the *E. coli* hemolysin HlyA of the RTX family (Reingold et al., 1999; Wallace et al., 2000). Nevertheless, sequence comparison studies confirm the presence of highly homologous toxins in other pathogenic organisms such as *Salmonella typhi* and *Shigella flexneri* (these orthologs display 92–98% identity to HlyE). This observation suggests that HlyE could be the prototype of a new family of HlyE-like hemolysins specific for Gram-negative bacteria.

This new class of pore-forming toxins form cation-selective water-permeable pores (25–30 Å in diameter); the channel formation could be either part of a mechanism for iron acquisition by the bacterial cell, or it may promote bacterial infection by killing immune cells and causing tissue damage (Ludwig et al., 1999).

The crystal structure of HlyE has been solved (Wallace et al., 2000; Fig. 22).

The toxin has an elongated shape characterized by a four-helix (A–D) bundle topology with each helix approximately 70–80 Å long. Two predicted hydrophobic domains have been identified on the primary sequence: both are located at the extremities of the molecule, one being mainly composed of a short β-hairpin (β-tongue) folded between the third and fourth helices of the main bundle, and the other consisting of the C-terminal end (magenta) of helix B (cyan).

The precise mechanism of HlyE oligomerization to form the final transmembrane pore is at the moment unknown; nevertheless, the first step involves a process of dimerization of two HlyE molecules that pack in a head-to-tail fashion burying the two hydrophobic patches against each other. Electron microscopy experiments have led to a model of channel formation in which the possible oligomer topology is that of an octameric complex, and the β-tongue domain is primary responsible for interaction with the membrane.

Insecticidal Toxins

The class of insecticidal proteins, also known as δ-endotoxins, includes a number of toxins produced by species of *Bacillus thuringiensis*. These exert their toxic activity by making pores in the epithelial cell membrane of the insect midgut (Hofte and Whiteley, 1989; Knowles, 1994).

δ-Endotoxins form two multigenic families, *cry* and *cyt*; members of the cry family are toxic to insects of Lepidoptera, Diptera and Coleoptera orders (Hofmann et al., 1988), whereas members of the cyt family are lethal specifically to the larvae of Dipteran insects (Koni and Ellar, 1994). The insecticidal toxins of the cry family are synthesized by the bacterium as protoxins with molecular masses of 70–135 kDa; after ingestion by the susceptible insect, the protoxin is cleaved by gut proteases to release the active toxin of 60–70 kDa (Drobniewski and Ellar, 1989). In this form, they bind specifically and with high affinity to protein

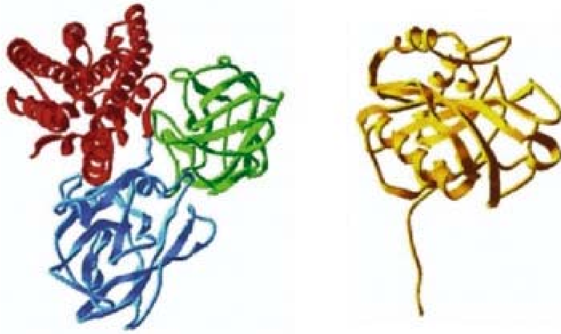

Fig. 23. Comparison of X-ray structures determined for representatives of the cry and cyt families of insecticidal δ-endotoxins: CryIA (left panel) is organized in three structural domains, whereas CytB (right panel) is a single-domain globular protein.

receptors and create channels 10–20 Å wide in the cell membrane. This subgroup includes several toxins (CryIA, CryIIIA, CryIV, CryV, etc.), whereas the only proteins so far characterized that belong to the cyt are CytA and CytB (Koni and Ellar, 1993; 1994).

Three-dimensional (3D) structures determined for members of the two families show that the folding of these toxins is entirely different. As representative of the two families, consideration is given to the structures of CryIA (Fig. 1, panel 9; Grochulski et al., 1995) and CytB (Li et al., 1996; Figs. 1 [panel 10] and 23), which share more than 39% sequence identity, suggesting an overall similar folding of the corresponding 3D structures.

The CryIA toxin is a globular protein composed of three distinct (but closely packed) domains connected by single linkers: domain 1 is totally α-helical, domain 2 consists of three antiparallel β-sheets and two short α-helices, and domain 3 is a β-sandwich. On the other hand, CytB (also a globular protein) is composed of a single domain with α/β architecture. The molecular mass of the protoxin is in this case only 30 kDa.

The region of CryIA, which has been associated with receptor–binding, maps within a loop of domain 2, whereas domain 1 has been shown to be responsible for membrane insertion and pore formation (Martens et al., 1995); this notion is strongly supported by the high structural similarity between the domain 1 of CryIA and that of CryIIIA to the pore-forming domains of colicin A and diphtheria toxin, both composed of helical bundles (Cabiaux et al., 1997; Duche et al., 1999). Conversely, in the case of the CytB/A, the model that has been proposed for the channel formation is based on a β-barrel structure.

Because they are toxic to several species of insects, δ-endotoxins have been formulated into commercial insecticides, and these insecticides have been used for more than three decades. Recently, Lepidoptera-specific toxin genes have also been used to engineer insect-resistant plants (Christov et al., 1999).

Very recently, a novel crystal protein produced by *B. thuringiensis* has been identified. This toxin (BT) is noninsecticidal and nonhemolytic, but has strong cytocidal activity against various human cells. Its amino acid sequence has little homology with the other known insecticidal toxins, suggesting that BT might belong to a new group of *Bacillus thuringiensis* crystal toxins (Ito et al., 2004).

Toxins Acting on Intracellular Targets

See Tables 1 and 2 for a summary of the principal features of toxins described in this section.

The group of toxins with an intracellular target (A/B toxins) contains many toxins with different structures that have only one general feature in common: they are composed of two domains generally identified as “A” and “B.” The A domain is the active portion of the toxin; it usually has enzymatic activity and can recognize and modify a target molecule within the cytosol of eukaryotic cells. The B domain is usually the carrier for the A subunit; it binds the receptor on the cell surface and facilitates the translocation of A across the cytoplasmic membrane (Fig. 2, panel 2). Depending on their target, these toxins can be divided into different groups that act on protein synthesis, signal transduction, actin polymerization, and vesicle trafficking within eukaryotic cells.

Toxins Acting on Protein Synthesis

These toxins are able to cause rapid cell death at extremely low concentrations. Two ADP-ribosylating bacterial proteins (see also the section ADP-Ribosyltransferases: A Family of Toxins Sharing the Same Enzymatic Activity) are actually known to belong to this class of toxins: diphtheria toxin (DT) of *Corynebacterium diphtheriae* (Pappenheimer, 1977; Collier et al., 1982) and *Pseudomonas aeruginosa* exotoxin A (PAETA; Gray et al., 1984b; Wick et al., 1990). Both display their toxic activity by transferring the ADP-ribose moiety to a posttranslationally modified histidine residue of the cytoplasmic elongation factor 2 (EF2) of eukaryotic cells (Brown and Bodley, 1979; Van Ness et al., 1980). This reaction leads to the formation of a completely inactive EF2-ADP-ribose complex, which ultimately results in inhibition of protein

synthesis and cell death. From the biochemical point of view, the two toxins have a similar size, a signal peptide and disulfide bridges, and both are produced in iron-depleted medium. Nevertheless, they show a completely different amino acid composition and bind different cell receptors. In addition, Shiga toxin is another protein that exerts its toxic activity by interfering with protein synthesis.

DIPHTHERIA TOXIN. This toxin (DT; Fig. 1, panel 11) is a 535-amino acid polypeptide that is secreted into the growth medium by strains of toxinogenic *Corynebacterium diphtheriae*, and the polypeptide sequence is encoded by a lysogenic bacteriophage. Biosynthesis is regulated by an iron-binding protein, and proceeds only in the absence of iron (Qiu et al., 1995; Ding et al., 1996). The toxin is synthesized as a single polypeptide chain that is subsequently cleaved into two fragments, A and B of 21 kDa and 37 kDa, respectively (Pappenheimer, 1977).

From the functional point of view, three separate domains (C, T and R) are seen in the crystallographic structure of DT. The catalytic domain (C) entirely corresponds to the A subunit, whereas the translocation domain (T) and the carboxy-terminal, receptor-binding domain (R) are contained in fragment B (Choe et al., 1992; Bennett and Eisenberg, 1994).

From the structural point of view, the C domain (residues 1–191) has an α+β structure, the receptor-binding domain is a flattened β-barrel with a jelly-roll-like topology, whereas the translocation domain T (residues 201–384) consists in nine helices, two of which may participate in the pH-triggered membrane insertion. The molecule contains four cysteines and two disulfide bridges: one joins fragment C to fragment T and the other is contained within fragment R (Fig. 24).

Although the toxicity of DT is entirely due to the enzymatic activity carried on by fragment A (Fig. 25), fragment B is absolutely required for the cell intoxication process.

After secretion from *Corynebacterium diphtheriae*, the toxin binds to the DT receptor and is internalized by receptor-mediated endocytosis. In the endosome, the acidic environment triggers a conformational change of the B subunit that exposes the hydrophobic regions of the T domain allowing the interaction with the endosomal membrane and the translocation of the amino-terminal catalytic domain C across the membrane to the cytosol. According to a recent model, the A subunit of DT is able to cross the endosomal membrane making use of a metastable transmembrane domain, which has also been identified (Wolff et al., 2004). The toxin receptor is the heparin-binding, epidermal growth factor (EGF)-like precursor (Naglich et al., 1992; Hooper and Eidels, 1995) that is present in most mammalian cells; nevertheless, the receptors of murine cells contain a few amino acid substitutions that make rodents insensitive to DT.

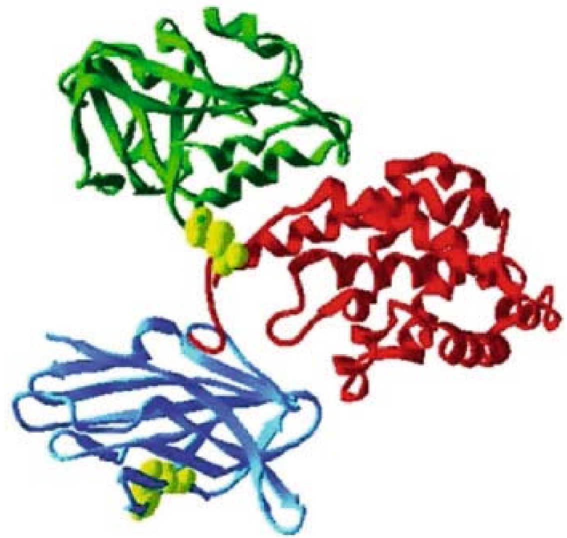

Fig. 24. X-ray structure of diphtheria toxin. The three functional domains are indicated with different colors: the catalytic domain C is green, the translocation domain T is red and the receptor-binding domain R is cyan. The two disulfide bridges are colored yellow.

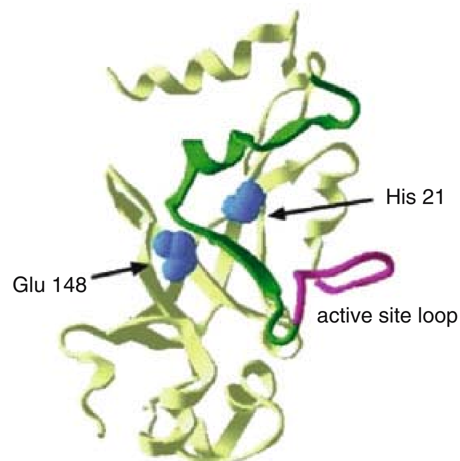

Fig. 25. Crystal structure of the isolated catalytic domain of diphtheria toxin. The scaffold of the enzymatic cleft is green, and the two described catalytic residues are blue. The "active-site loop" is represented here in the "closed" conformation.

Diphtheria toxin is one of the most potent bacterial toxins: in vitro experiments have shown that a single molecule of the enzymatically active fragment A is by itself able to kill one eukaryotic cell (Yamaizumi et al., 1978).

Biochemical and mutagenesis studies have greatly contributed to the understanding of structure-function relationships and to the mapping of the catalytic residues. In particular,

His-21 has been mutagenized with a number of different residues and has been found to be essential for catalysis (Papini et al., 1989; Blanke et al., 1994); in fact, some activity was maintained only when Asn replaced His. In a similar manner, Glu-148 was identified as an active-site residue by photoaffinity labeling experiments with nicotinamide adenine dinucleotide (NAD; Carroll et al., 1985) and subsequent site-directed mutagenesis studies; in this case, not even a conservative substitution with Asp could be possible without complete loss of activity (Tweten et al., 1985). Whereas the possible function for His-21 could be that of maintaining the integrity of the active-site pocket, Glu-148 is likely to be involved in the interaction with the upcoming substrate molecule. Later, crystallographic data confirmed and extended the experimental observations, and added a number of other important residues to the list of the catalytic ones.

A very important step in the elucidation of the mechanism of enzymatic activity has been the determination of the crystal structure for the complex of diphtheria toxin with NAD (Bell and Eisenberg, 1997). Upon the addition of NAD to nucleotide-free DT crystals, a significant structural change affects the region encompassing residues 39–46. This portion of the C domain constitutes a mobile loop that becomes disordered after the formation of the complex. The best hypothesis to explain this observation is that NAD enters the cavity upon displacement of the mobile loop, which is then made available for the recognition and binding of the acceptor substrate EF-2. This would explain why DT recognizes EF-2 only after NAD has bound (see the section A Common Structure of the Catalytic Site in this Chapter).

Detoxified diphtheria toxin has been used in the formulation of a vaccine against toxinogenic strains of *Corynebacterium diphtheriae* (Porro et al., 1980; Rappuoli, 1983).

PSEUDOMONAS AERUGINOSA EXOTOXIN A. This exotoxin (PAETA; Fig. 1, panel 12) is a 66-kDa single-chain protein that inhibits protein synthesis (by a mechanism of action identical to that of DT) in eukaryotic cells by catalyzing the transfer of the ADP-ribosyl moiety of oxidized NAD onto elongation factor 2 (Brown and Bodley, 1979; Van Ness et al., 1980; Gray et al., 1984b; Wick et al., 1990; see the section ADP-ribosylating Toxins in this Chapter). Exotoxin A is the most toxic of the proteins secreted by the opportunistic pathogen *Pseudomonas aeruginosa*, having an LD_{50} of 0.2 mg upon intraperitoneal injection into mice. Secreted in the supernatant as an enzymatically inactive proenzyme; this toxin must undergo structural alteration to be able to perform its ADP-ribosylating activity.

According to X-ray crystallography (Allured et al., 1986; Li et al., 1995; 1996b), the molecule can be divided into three functional domains. The receptor-binding domain I binds to the ubiquitous α2-macroglobulin receptor of eukaryotic cells, thus initiating receptor-mediated endocytosis. This domain is composed primarily of antiparallel β-structure and is arranged in two noncontiguous regions that encompass residues 1–252 (Ia) and 365–399 (Ib), respectively. Domain II maps within amino acids 253–364, is composed mostly of hydrophobic α-helices, and mediates the translocation of the enzymatically active carboxy-terminal domain III (residues 400–613) to the cytosol of infected cells. Furthermore, it has been shown that for domain III to be functional, a specific proteolytic cleavage at residue 280 of domain II is needed.

Genetic studies based on the expression of mutated forms of the exotoxin A gene in *E. coli* have confirmed these functional assignments. In fact, whereas deletion of domain Ia results in nontoxic, enzymatically active molecules that cannot bind the cells, deletions in domain II give rise to molecules that bind to the cells, are enzymatically active, but are not toxic; finally, deletions or mutations in domain III result in enzymatically inactive molecules (Siegall et al., 1989). To become active, the PAETA toxin requires an intracellular furin-mediated proteolytic cleavage to generate a 37-kDa C-terminal fragment that is then translocated to the cytoplasm to reach the EF2 target (Inocencio et al., 1994).

By using a fluorescence resonance energy transfer approach, the mechanism of interaction between ExoA and its substrate EF has been studied, showing that the binding is strongly dependent on the pH. Furthermore, the finding that EF-2 bound to GDP or GTP is still recognized by ExoA shows how adaptable this toxin is in ADP-ribosylating its substrate.

In particular, mutational analysis affecting the last five residues at the carboxy-terminus of the enzymatic domain resulted in complete loss of cytotoxicity; this segment (Arg-Glu-Asp-Leu-Lys, REDLK) closely resembles the KDEL motif that is a well-defined endoplasmic reticulum retention sequence and that has also been found at the C-terminus of other ADP-ribosyltransferases such as cholera toxin and heat-labile enterotoxin of *E. coli* (Chaudhary, 1990). It has been postulated that the sequence REDLK may be a recognition signal required for entry of the ADP-ribosylation domain of PAETA into the cytosol. Four disulfide bonds are present in the structure, but all of them are confined to the portion of exotoxin A that is not required for enzymatic activity.

Photoaffinity labeling experiments have identified Glu-553 as an active-site residue; substitu-

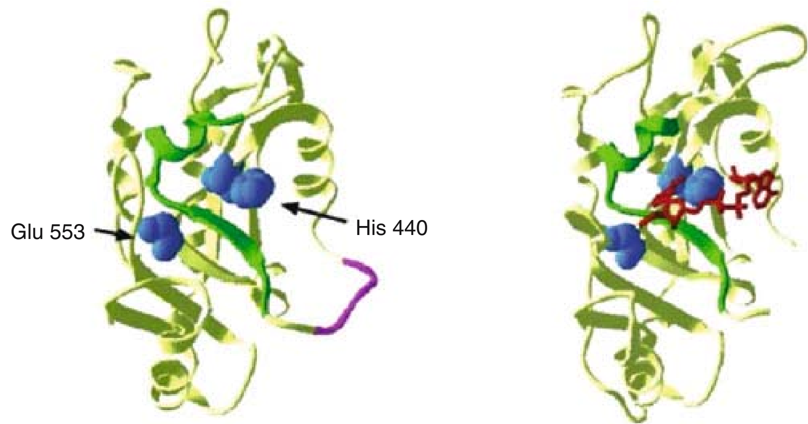

Fig. 26. Comparison of exotoxin A crystal structures in the absence (left panel) and in the presence (right panel) of the ligand (in red). The active site residues are shown in blue. The loop (when present) is colored in magenta (see Fig. 1, panel 12).

tion of this residue with any other amino acid, including the closely related Asp, decreased the enzymatic activity by a factor of 1000 (Douglas and Collier, 1990). In a similar manner, experiments of site-directed mutagenesis on His-440 led to molecules with a severely reduced cytotoxic activity, thus suggesting an important role for this residue in the reaction (Han and Galloway, 1995).

The crystal structure of the catalytic domain has been recently solved both in the isolated conformation and in the presence of an NAD analog (β-methylene thiazole-4-carboxamide adenine dinucleotide; β-TAD; Li et al., 1995; 1996b; Fig. 26). Comparison of the two structures shows that the major difference resides in the new conformation of the loop 458–463, which appears to be displaced by ligand binding; displacement of this loop from the active-site cleft could be an essential step allowing entrance and correct positioning of the NAD molecule during the enzymatic reaction.

Given the potent lethal activity, the catalytic domain of exotoxin A has been widely used for the construction of fusion proteins with cell-binding domains specific for tumor cells or other types of dangerous cells. So far, nucleotides encoding domain I have been replaced by sequences encoding interleukin (IL) 2, IL-6 and T-cell antigen CD4. These fusion molecules are promising candidates for the treatment of arthritis and allograft rejection (PAETA-IL2), acquired immune deficiency syndrome (PAETA-CD4), and other diseases (Chaudhary et al., 1987, 1988; Siegall et al., 1988; Ogata et al., 1989; Baldwin et al., 1996; Mori et al., 1997).

SHIGA TOXIN. This toxin (SHT; Fig. 1, panel 13), also known as "verotoxin," is the key virulence factor produced by *Shigella dysenteriae*, the pathogen responsible for the most severe forms of dysentery in humans (Kozlov et al., 1993). Shiga toxin is the prototype of a family of closely related bacterial protein toxins (Shiga-like toxins), also produced by certain strains of *E. coli* responsible for hemorrhagic colitis (Karmali et al., 1988).

From its 3D structure (Fraser et al., 1994), it is possible to recognize this protein as belonging to the class of A/B bacterial toxins, which consist of an enzymatic A subunit associated with a B domain binding to specific cell-surface receptors. The A subunit bears the enzymatic activity and is thus responsible for toxicity; like *Pseudomonas aeruginosa* exotoxin A and diphtheria toxin of *Corynebacterium diphtheriae*, SHT has an effect on protein synthesis, and in particular, by means of its *N*-glycosidase activity, it is able to depurinate a specific adenosine of ribosomal RNA and stop protein synthesis in the target cell (Endo et al., 1988). The catalytic subunit is composed of two regions, A1 and A2, and like many other bacterial protein toxins, it needs to be activated by proteolytic cleavage. Fragment A2 has an α-helical structure and is noncovalently linked to the B domain (Fig. 27). Interestingly, its primary structure displays a notable similarity to chain A of ricin, a plant toxin that also shares the same enzymatic function acting on the same substrate (Katzin et al., 1991).

This domain displays an overall organization which is very similar to that of the corresponding receptor-binding subunits of the ADP-ribosyltransferases cholera toxin and heat-labile enterotoxin LT of *E. coli*, all formed by five identical protomers which assemble into the final ring-like structure of the B oligomer (Fig. 28). The B-subunit of Shiga toxin has been demonstrated as a powerful vector for carrying attached peptides into cells for intracellular transport studies and for medical research (Hagnarelle et al., 2003).

Upon binding of verotoxin to its receptor (globotrialosylglyceramide, Gb) on the surface of a eukaryotic cell (Cohen et al., 2000), the toxin is internalized by receptor-mediated endocytosis and is transported to the Golgi and to the endoplasmic reticulum, from which the A subunit is

translocated to the cytoplasm, where it can gain access to the ribosomal target. Numerous recent studies have shown that Shiga toxins trigger programmed cell death signaling cascades in intoxicated cells. The mechanisms of apoptosis induction by these toxins are newly emerging, and the toxins may signal apoptosis in different cells types via different mechanisms (Cherla et al., 2003).

Toxins Acting on Signal Transduction

Signal transduction is an essential mechanism for the survival of any living organism. In eukaryotic cells, signals received from the outside stimulate receptors on the cell surface and are subsequently transmitted across the cell membrane mainly using two types of mechanism: 1) tyrosine phosphorylation of the cytoplasmic portion of the receptor which initiates a cascade of intracellular signaling events; and 2) modification of a receptor-coupled GTP-binding protein that transduces the signal to various enzymes which respond with the release of secondary messengers such as cyclic AMP (cAMP), inositol triphosphate, and diacylglycerol; accumulation of these products alter the normal equilibrium of the cell and thus provoke malfunction and death.

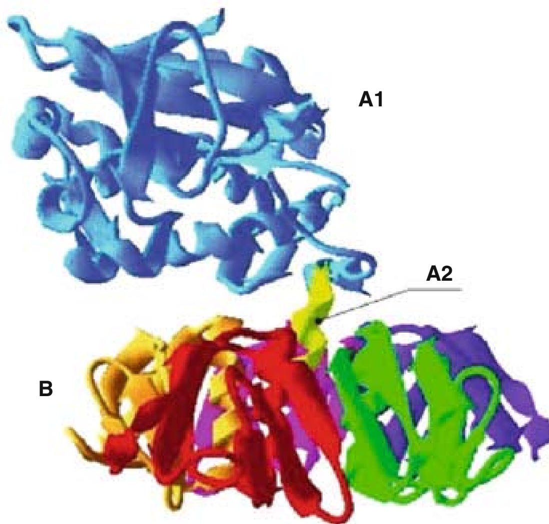

Fig. 27. Three-dimensional structure of Shiga holotoxin. The A subunit is distinguished between A1 (blue) and A2 (yellow), whereas the receptor-binding domain B has different colors for the five monomers.

Pertussis Toxin

This toxin (PT; Fig. 1, panel 14) is a protein of 105 kDa released into the extracellular medium by *Bordetella pertussis*, the etiological agent of whooping cough. It belongs to the A/B class of ADP-ribosylating toxins and is composed of five distinct subunits, named "S1" through "S5," where S4 is present in two copies in the final oligomer. The genes encoding for the five monomers of pertussis toxin are organized into an operon structure (Locht et al., 1986; Fig. 29) and contained within a chromosomic DNA fragment of approximately 3200 base pairs.

Interestingly, the genes coding for S2 and S3 share a 75% similarity (67%, if calculated from S2 and S3 gene products at the amino acid level), suggesting a common evolutionary origin for the two sequences, possibly because of gene duplication.

The five subunits are independently secreted into the periplasmic space, where the toxin is assembled and then released in the culture

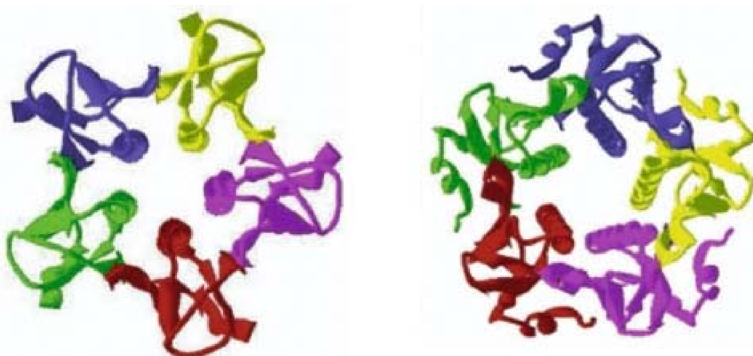

Fig. 28. Bottom view of the B subunit of Shiga toxin (left panel) in comparison to the B subunit of *E. coli* LT (right panel).

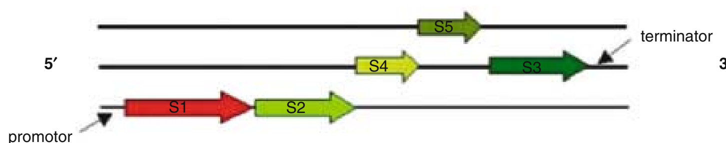

Fig. 29. Schematic representation of the genetic organization of the open reading frames (ORFs) coding for the five subunits of pertussis toxin.

medium by a specialized type IV secretion apparatus (Covacci and Rappuoli, 1993a; Weiss et al., 1995). Subunit S1 represents the enzymatically active domain A, which is totally responsible for the toxicity, whereas the pentamer S2-S3-$(S4)_2$-S5 constitutes the receptor-binding domain B (Fig. 30).

The A domain acts on eukaryotic cells by ADP-ribosylating their GTP-binding proteins, and specifically it transfers an ADP-ribose group to a cysteine residue located in the carboxy-terminal region of the α-subunit of many G proteins such as G_i, G_o and transducin (Katada et al., 1983; West et al., 1985); G_s which has a tyrosine residue in place of the cysteine is not a valid substrate for PT. The consequence of ADP-ribosylation is the uncoupling of G-proteins from their receptors which results in an alteration of the response of eukaryotic cells to exogenous stimuli and thus in a variety of in vivo phenotypes, such as leukocytosis, histamine sensitization, and increased insulin production (Sekura, 1985). Conversely, the most interesting activity displayed by PT in vitro is the observed change in cell morphology in Chinese hamster ovary (CHO) cells (Hewlett et al., 1983).

The B domain is a nontoxic oligomer that binds the receptors on the surface of eukaryotic cells and allows the toxic subunit S1 to reach its intracellular target proteins through a mechanism of receptor-mediated endocytosis, likely following a mechanism of retrograde transport through the Golgi apparatus. The importance of the Golgi localization of pertussis toxin for the S1-dependent ADP-ribosylation of G-proteins was investigated employing Brefeldin A (BFA) treatment to disrupt Golgi structures. This treatment completely blocked the pertussis toxin ADP-ribosylation activity of cellular G-proteins, therefore indicating that retrograde transport to the Golgi network is a necessary prerequisite for cellular intoxication (el Baya et al., 1997). In CHO cells, the PT receptor has been shown to be a high-molecular weight glycoprotein that binds the B oligomer through a branched-mannose core containing *N*-acetylglucosamine (Sekura, 1985). In contrast to the other ADP-ribosyltransferases, where the enzymatically active domain A mediates all the toxic activities, PT possesses other nonlethal activities (such as a mitogenic activity on T cells), which are mediated exclusively by the receptor-binding domain B (Tamura et al., 1983). The active site of pertussis toxin is structurally homologous to the active sites of other ADP-ribosylating toxins. This aspect will be described in the section ADP-Ribosyltransferases: A Family of Toxins Sharing the Same Enzymatic Activity in this Chapter.

Pertussis toxin plays a central role in the pathogenesis of whooping cough and in the development of protective immunity against reinfection. For this reason, the role of many residues of S1 has been tested by site-directed mutagenesis to produce nontoxic mutants of the toxin to be used as vaccines. The minimal region still enzymatically active is constituted by amino acids 4–179 of S1 subunit (Pizza et al., 1988; Cieplak et al., 1988; Fig. 31), and it is within this fragment that many mutations have been

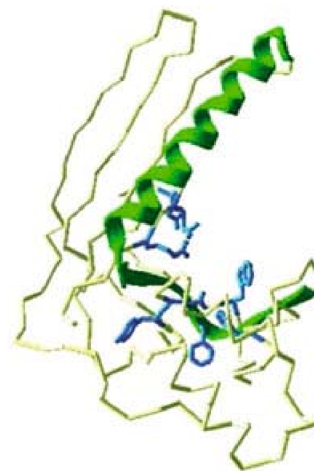

Fig. 31. Crystal structure of the wildtype S1 subunit of pertussis toxin. The scaffold of the enzymatic cleft is represented as a green ribbon, whereas the rest of the molecule is in pale yellow carbon trace representation. Residues proved to be essential for activity by means of site-directed mutagenesis are represented with side chains and are colored in blue.

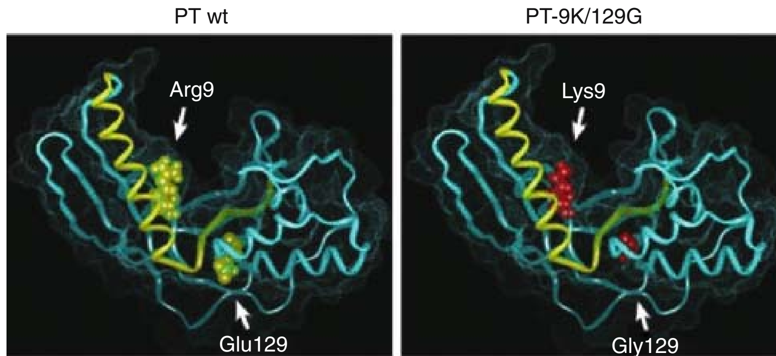

Fig. 32. X-ray representation of the wildtype pertussis toxin (left panel) and of the double mutant 9K/129G (right panel). The catalytic cleft is colored in yellow, whereas the mutated residues are in red.

designed and analyzed for activity. In particular, Arg-9, Asp-11, Arg-13, Trp-26, His-35, Phe-50, Glu-129 and Tyr-130 were found to be essential for enzymatic activity and, when replaced with other residues, the toxicity was reduced to levels of about 1%; nevertheless, none of the single-amino acid mutants were completely devoid of toxicity.

The most successful mutant contains in fact two amino acid substitutions: Arg-9/Lys and Glu-129/Gly (PT-9K/129G; Fig. 32). This mutant is structurally identical to the wildtype but is completely nontoxic and has been used for the construction of an acellular vaccine against pertussis. This vaccine has been extensively tested and has been shown to induce protection from disease (Pizza et al., 1989; Rappuoli, 1997).

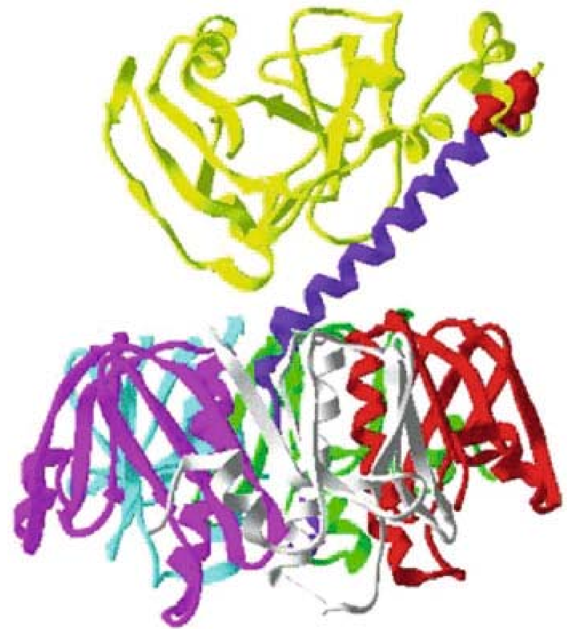

Fig. 33. X-ray structure of heat-labile enterotoxin LT of *E. coli*. The catalytic domain A1 is yellow, the linker domain A2 is blue, and the five monomers of the B subunit are all represented in different colors.

Cholera Toxin and Heat-Labile Enterotoxin

Cholera toxin (CT) and *E. coli* heat-labile enterotoxins (LT-I and LT-II) share an identical mechanism of action and homologous primary and 3D structures (Dallas and Falkow, 1980; Spicer et al., 1982; Sixma et al., 1991; Figs. 1 [panel 15] and 33). The CT is produced by *Vibrio cholerae* (the etiological agent of cholera), whereas LT-I and LT-II are produced by enterotoxigenic strains of *E. coli* (ETEC) isolated from humans with traveler's diarrhea, from pigs (LT-I), or from food (LT-II; Seriwatana et al., 1988). The two toxins belong to the class of ADP-ribosylating toxins and are organized in an AB_5 architecture, where the B domain is a pentamer which binds the receptor on the surface of eukaryotic cells, and domain A bears the enzymatic activity and is thus responsible for toxicity (Holmgren, 1981; Moss and Vaughan, 1988). Both the A and B subunits of CT and LT are synthesized intracellularly as precursor proteins which, after removal of the leader peptide and translocation across the cytoplasmic membrane, assemble in the periplasmic space to form the final AB_5 complex. While *V. cholerae* exports the CT toxin into the culture medium, LT remains associated to the outer membrane bound to lipopolysaccharide (LPS; Horstman et al., 2002). The corresponding genes of CT and LT are organized in a bicistronic operon and are located on a filamentous bacteriophage and on a plasmid, respectively (So et al., 1978).

The A subunit (Fig. 34, left panel) is a 27-kDa monomer composed of a globular structure and linked to the B domain by a trypsin-sensitive loop and a long α-helix, which inserts inside the core of the B pentamer thus anchoring the two subunits. For full activity, the A subunit needs to be proteolytically cleaved and reduced at the disulfide bridge between cysteines 187 and 199 to give two fragments: the enzymatic subunit A1 and the linker fragment A2 (Lai et al., 1981).

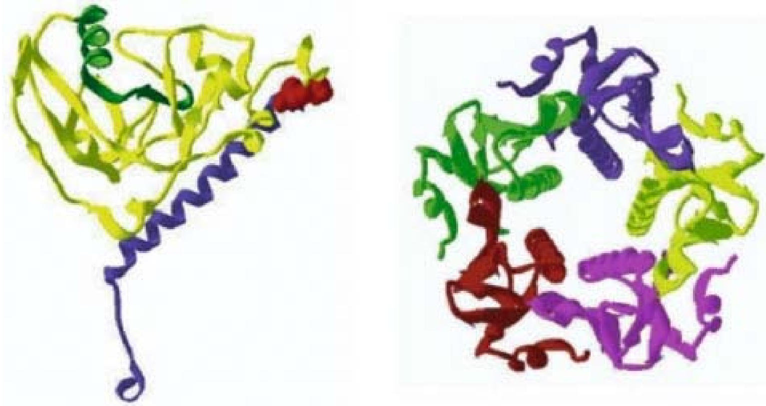

Fig. 34. Left side: front view of the catalytic A subunit, with the toxic moiety A1 in pale green and the linker domain A2 in violet; cysteines 187 and 199 involved in the disulfide bridge are red. Right side: bottom view of the pentameric receptor-binding domain B.

Whereas in cholera toxin the proteolytic process is performed during biosynthesis by an endoprotease (Booth et al., 1984), in the case of LT, it occurs by extracellular processes; in both cases, the reduction is thought to take place at the surface of the target cell.

The enzymatically active domain A binds NAD and transfers the ADP-ribose group to an Arg residue located within the central portion of several GTP-binding proteins such as G_s, G_t and G_{olf}. Upon ADP-ribosylation of G_s, in particular, the adenylate cyclase is permanently activated, causing an abnormal intracellular cAMP accumulation, which in turn alters ion transport and thus is the main reason for the toxic effects (Field et al., 1989a, 1989b).

A peculiar feature of CT and LT is that the basal ADP-ribosyltransferase activity is enhanced by interaction with 20-kDa guanine-nucleotide binding proteins, known as "ADP-ribosylation factors" (ARFs; Tsai et al., 1988; Moss and Vaughan, 1991). After receptor binding, the holotoxins are internalized and undergo retrograde transport through the Golgi to the endoplasmic reticulum (ER). Recent studies show that both A and B subunits move together from the cell surface into the ER, and this depends on the B-subunit binding to ganglioside GM1. The KDEL motif in the A2 chain does not appear to affect retrograde transport, but slows recycling of the B-subunit from ER to distal Golgi stacks. Specificity for GM1 in this trafficking pathway is shown by the failure of the *E. coli* type II toxin LTIIb that binds ganglioside GD1a to concentrate in lipid rafts, enter the ER, or induce toxicity. These results show that the B subunit carries the A1 chain from cell surface into the ER where they dissociate, and that a membrane lipid with strong affinity for lipid rafts provides the dominant sorting motif for this pathway (Fujinaga et al., 2003). In the ER, the A1-chain of the CT unfolds and enters the cytosol by a process termed "retro-translocation." Upon entering the cytosol, the A1-chain rapidly refolds, binds ARF and induces toxicity (Lencer et al., 1995). The B subunits persist in the Golgi and are subsequently degraded.

The exact localization of the ARF-binding site is still unknown, but it has emerged from recent studies that the two domains (the NAD-binding and ARF-binding) are independent and located in different regions of the A domain (Stevens et al., 1999).

When the toxins are released in the intestine during infection, the major consequence is intestinal fluid accumulation and watery diarrhea (also typical symptoms of the diseases; Holmgren, 1981).

The B domain (Fig. 34, right) is composed of five identical subunits (each 11.5 kDa) that are arranged in a symmetric shape around a central pore inside which the C-terminal portion of the catalytic domain (A2) is inserted (Sixma et al., 1991, 1993). Their secondary structure consists predominantly of two three-stranded antiparallel β-sheets, a short N-terminal helix, and a long central helix. Although still well conserved in terms of quaternary structure, CT and LT B domains have a lower degree of primary sequence homology than the corresponding A domains. Interestingly, the B subunit of LT-II, although maintaining a conserved structure, lacks any sequence homology with the corresponding B domains of CT and LT-I (Domenighini et al., 1995).

In addition to their function as receptor-binding domains and as carriers of the toxic moieties, the B subunits possess specific biological activities such as induction of apoptosis of CD8+ and CD4+ T cells (Truitt et al., 1998) and the property to function as potent mucosal adjuvants (Xu-Amano et al., 1994). This feature has been extensively used to develop mucosal vaccines against cholera and ETEC infection, and to induce a mucosal response also against the other antigens used.

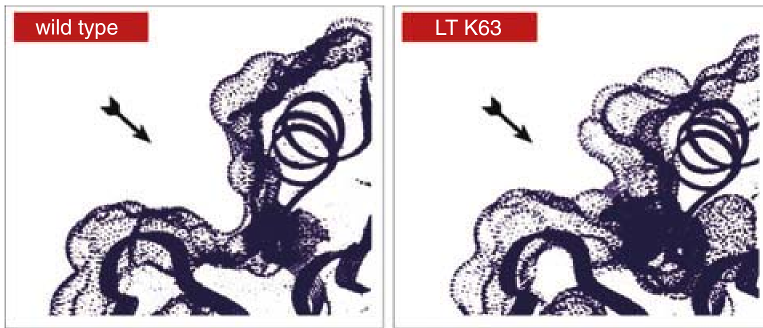

Fig. 35. Three-dimensional structure of the enzymatic cavity of the wildtype LT (left) and of the mutant LT-K63 (right). The arrows point out how much a single amino acid substitution can affect the dimension of the pocket and thus the entrance of NAD.

To produce molecules suitable for these pharmacological applications but completely devoid of toxic activity, more than fifty mutant derivatives have been constructed both for the A and B subunits. Among those which completely inactivate the toxin, the best characterized are LT-K63 (Fig. 35), LT-K97 and LT-K7, all in the vicinity of the catalytic domain, and for which the 3D structures have also been determined (Merritt et al., 1995; Van den Akker et al., 1995, 1997). In the case of LT-K63 (and the corresponding CT-K63), where the wildtype Ser in position 63 is substituted with a Lys, the mutated proteins are enzymatically inactive and nontoxic, either in vitro and in vivo, but are otherwise indistinguishable from the wildtype. In fact, they are still able to bind the receptor and the ARFs (Stevens et al., 1987), and the crystal structure and that of wildtype LT are almost perfectly superimposable except for the catalytic site, where the bulky side-chain of Lys-63 fills the catalytic pocket thus making it unsuitable for NAD entrance and binding (Giannelli et al., 1997; Douce et al., 1998).

Another interesting mutant is LT-K97, where the substitution Val/Lys introduces a salt bridge between Lys-97 and the carboxylate of Glu-112, thus making it unavailable to further interactions. This observation suggests a dominant role of this glutamic acid in the enzymatic reaction.

Mutations affecting the B domain lead often to products that can no longer bind to eukaryotic receptors, as is the case of LTB-D33, which contains a glycine-to-aspartic acid substitution in position 33. These types of mutants have been found to be almost completely nonimmunogenic at mucosal surfaces, suggesting that an intact receptor-binding site is necessary not only for binding but also for immunogenicity and adjuvanticity (Guidry et al., 1997).

Clostridium perfringens Alpha-Toxin

This toxin (Fig. 1, panel 16) is the most important toxin produced by *Clostridium perfringens* and is responsible for gas gangrene or clostridial myonecrosis (Stevens et al., 1987; Florez-Diaz et al., 2003). It plays a key role in the spread of the infection either by suppressing host immune responses, triggering the release of inflammatory mediators, or causing changes in intracellular calcium levels. Specific mutants of *C. perfringens* that do not produce the toxin are unable to cause disease, and vaccination with a genetically engineered toxoid has been shown to induce protection against gas gangrene (Williamson and Titball, 1993).

This virulence factor is a 370-amino acid zinc metalloenzyme that also displays phospholipase C (PLC) activity (Leslie et al., 1989); nevertheless, not all the bacterial PLCs act as virulence determinants, therefore this enzymatic activity is not sufficient for toxicity.

Alpha-toxin is capable of binding to mammalian cell membrane and cleaving membrane-bound phosphatidylcholine (or sphingomyelin) to produce phosphocholine and diacylglycerol (or ceramide). The reaction product diacylglycerol, which is a leukotriene precursor, is believed to be the responsible of the subsequent lethal effects.

The crystal structure of α-toxin has been recently solved (Naylor et al., 1998; Fig. 36), indicating the presence of two distinct domains in the molecule. Whereas the N-terminus is mainly organized as a globular α-helical domain that contains the active site, the β-sandwich C-terminal subunit is involved in membrane binding and shows strong structural analogy to eukaryotic calcium-binding C2 domains. A flexible linker containing a series of highly mobile residues connects the two domains.

In addition, the C-terminal subunit displays hemolytic and sphingomyelinase activities and primarily contributes to the toxin's lethal effect, even if it is completely devoid of toxic activity when used alone. Nevertheless, immunization with this domain affords full protection from disease in mouse models, thus indicating that the protective epitopes are located in this portion of the molecule (Titball et al., 1993; Nagahama et al., 2002).

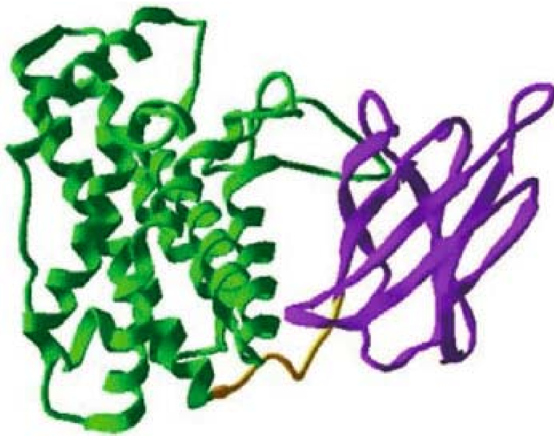

Fig. 36. Three-dimensional structure of *Clostridium perfringens* α-toxin. The N-terminal and C-terminal domains are green and violet, respectively, and the flexible linker is orange.

Recently, other bacterial PLCs, like those from *L. monocytogenes* and *Mycobacterium tuberculosis*, have been implicated in the pathogenesis of a number of diseases (Wadsworth et al., 1999; Raynaud et al., 2002).

Clostridium difficile Toxins A and B

Enterotoxin A (TcdA) and cytotoxin B (TcdB) of *Clostridium difficile* are the two virulence factors responsible for the induction of antibiotic-associated diarrhea. These toxins have molecular masses of 308 and 270 kDa, respectively, and belong to the class of large clostridial cytotoxins (Lyerly et al., 1986; Knoop et al., 1993).

The toxin genes *tcdA* and *tcdB* together with three accessory genes (*tcdC–E*) constitute the pathogenicity locus (PaLoc) of *C. difficile* (Cohen et al., 2000). Primary sequence homology between *tcdA* and *tcdB* gene products is higher than 60% identity (von Eichel-Streiber et al., 1994).

Upon binding to eukaryotic cells and translocation across membranes via receptor-mediated endocytosis, TcdA and TcdB monoglucosylate small GTP-binding proteins such as Rho, Rac and Cdc42 at a threonine residue (Just et al., 1995a, 1995b; Ciesla and Bobak, 1998). In most cells, *C. difficile* toxins induce depolymerization of the actin cytoskeleton, leading to a morphology similar to that induced by C3-like transferases. While toxin B has potent cytotoxic activity in vitro, the enterotoxic activity of *C. difficile* in animals has been mainly attributed to toxin A.

From the structural point of view, they are composed of two portions: the N-terminal nonrepetitive two thirds corresponding to the catalytic subunit, and the C-terminal third characterized by a highly repetitive domain called the "clostridial repetitive oligopeptide" (CROP), identified as the site of interaction with a carbohydrate structure as well as the ligand to which neutralizing antibodies bind (von Eichel-Streiber, 1994). A central hydrophobic region contains several predicted transmembrane segments and is believed to function as the translocation unit.

Bordetella pertussis Adenylate Cyclase

Adenylate cyclase (CyaA) is a toxin produced by *Bordetella pertussis*, *B. bronchiseptica* and *B. parapertussis* (Weiss and Hewlett, 1986). It is essential in the early stages of bacterial colonization of the respiratory tract and can induce apoptosis of lung alveolar macrophages (Goodwin and Weiss, 1990; Khelef et al., 1993).

Organized as a bifunctional protein, CyaA (177 kDa) is composed of an N-terminal cell-invasive and calmodulin-dependent adenylate cyclase domain (residues 1–400) fused to a pore-forming hemolysin (residues 401–1706; Glaser et al., 1988; Bejerano et al., 1999; see also the section Pore-Forming Toxins: RTX Hemolysins). Unlike most of the other members of the RTX family that are secreted into the supernatant, CyaA remains associated to the bacterial surface, through interactions with filamentous hemagglutinin (FHA). This toxin forms small cation-selective channels in lipid bilayer membranes and delivers into the cytosol of target cells the adenylate cyclase (AC) domain, which, upon binding to calmodulin, catalyzes an uncontrolled conversion of ATP to cAMP, thus causing intoxication and disruption of cellular functions (Ladant and Ullmann, 1999). Calcium has been shown to play a fundamental role in channel formation (Knapp et al., 2003). Furthermore, it was also demonstrated that the ability of the AC domain to form pores and translocate across the membrane is strictly linked to the correct folding of an amphipathic α-helix spanning residues 509–516. Substitution of Glu-509 with a helix-breaker proline residue, in fact, significantly reduced the capacity of the toxin to undergo translocation (Osickova et al., 1999).

A very similar function and mechanism of action is that of ExoY, an adenylate cyclase produced by *Pseudomonas aeruginosa* and injected into the cytoplasm of eukaryotic cells by the type III secretion apparatus (see Table 1, and the section Toxins Injected into Eukaryotic Cells in this Chapter). However, differently from CyaA, ExoY is not activated by calmodulin. In vivo, following infection with ExoY-expressing strains, CHO cells showed a rounded morphology, which correlated with increased cAMP levels (Yahr et al., 1998).

Anthrax Edema and Lethal Factors

Lethal factor (LF) and edema factor (EF) proteins, produced by *Bacillus anthracis*, combine with the protective antigen PA to give the lethal (PA+LF) and edema (PA+EF) toxins (Brossier et al., 2000; Collier and Young, 2003; Fig. 1, panel 17). In both complexes, the PA has the pore-forming, receptor-binding activity (see the section Pore-Forming Toxins in this Chapter), whereas EF and LF display, in turn, the toxic activities.

The EF and LF genes are located on a large plasmid (Mikesell et al., 1983) and encode precursors of approximately 800 residues. Cleavage of the N-terminal signal peptides yields mature EF and LF proteins with molecular masses of 88.8 kDa and 90.2 kDa, respectively. These virulence factors enter cells by binding to proteolytically activated, receptor-bound, oligomeric PA; following receptor-mediated endocytosis, the low pH causes a conformational change in PA, allowing the translocation of EF-LF across cell membrane (Collier, 1999). The EF-LF is then endocytosed and translocated from endosomes directly to the cytosol of cells, where both toxins perform their toxic activities (Fig. 37). The binding sites of EF and LF on PA have been recently mapped (Cunningham et al., 2002).

Once inside the cells, EF binds calmodulin and catalyzes an unregulated production of the second messenger cAMP, thereby perturbing the normal cell regulatory mechanisms (Goyard et al., 1989). Calcium influx is required for inducing cyclic AMP toxicity in target cells (Kumar et al., 2002).

Whereas the PA-binding domain displays a strong sequence homology to lethal factor LF, the catalytic domain is more similar to the other known adenylate cyclase CyaA toxin of *Bordetella pertussis* (Escuyer et al., 1988). On the other hand, LF cleaves the amino-terminus of the cellular mitogen-activated protein kinase kinases (MAPKK1 and MAPKK2), thus causing inhibition of the MAPK signal transduction pathway, which is key to cellular proliferation and signal transduction processes in the cell (Duesbery et al., 1998; Vitale et al., 1999).

Recently, the 3D structures of LF and EF have been solved (Fig. 38). LF comprises four domains: domain I binds the membrane-translocating component of anthrax toxin (PA); domain II resembles the ADP-ribosylating toxin from *Bacillus cereus*; domain III is inserted into domain II, and seems to have arisen from a repeated duplication of a structural element of domain II. Domain IV is distantly related to the zinc metalloprotease family, and contains the catalytic center (Pannifer et al., 2001). The catalytic portion of EF is made by three globular domains. The active site is located at the inter-

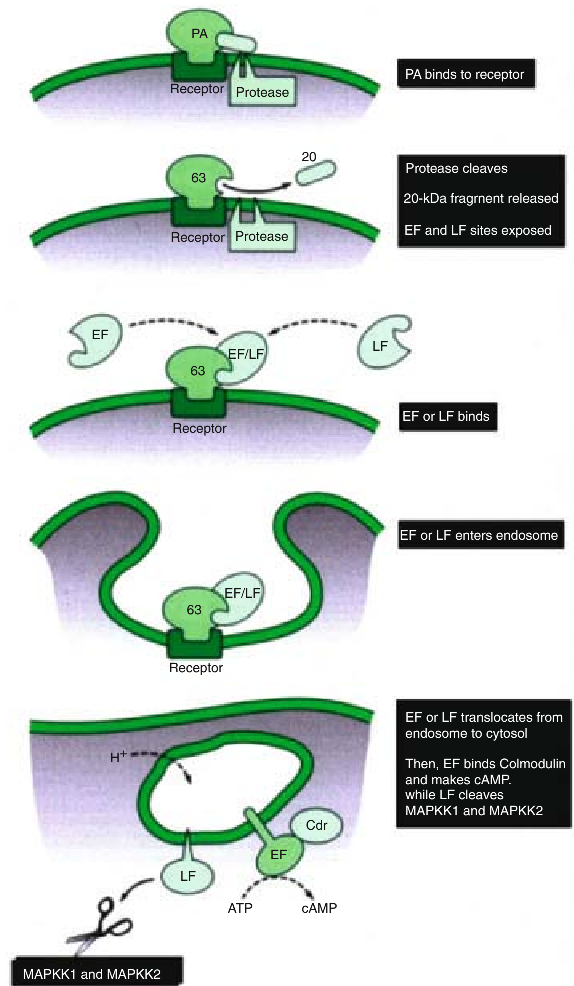

Fig. 37. Mechanism of PA-mediated entry and intoxication of anthrax LF and EF toxins.

face of two domains (C_A and C_B), which together form the catalytic core, containing the catalytic residue His351. EF has been crystallized both alone and in complex with calmodulin. The differences between the two forms are induced by calmodulin, which acts by stabilizing the conformation of the substrate-binding-site of EF (Drum et al., 2002). Interestingly, a remarkable level of primary sequence similarity can be detected between EF and the N-terminal, calmodulin-binding domain of *Bordetella* adenylate cyclase CyaA. In particular, His351 is conserved between the two proteins.

Once in the cytoplasm, LF acts as a zinc-metalloprotease disrupting normal homoeostatic functions. The macrophage is a uniquely sensitive cell type that seems to be a vital global mediator of toxin-induced pathologies. Removal of macrophages from mice renders them insensitive to LF challenge (Hanna, 1999).

In addition, LF, but not EF, is able to cause apoptosis in human endothelial cells. As a con-

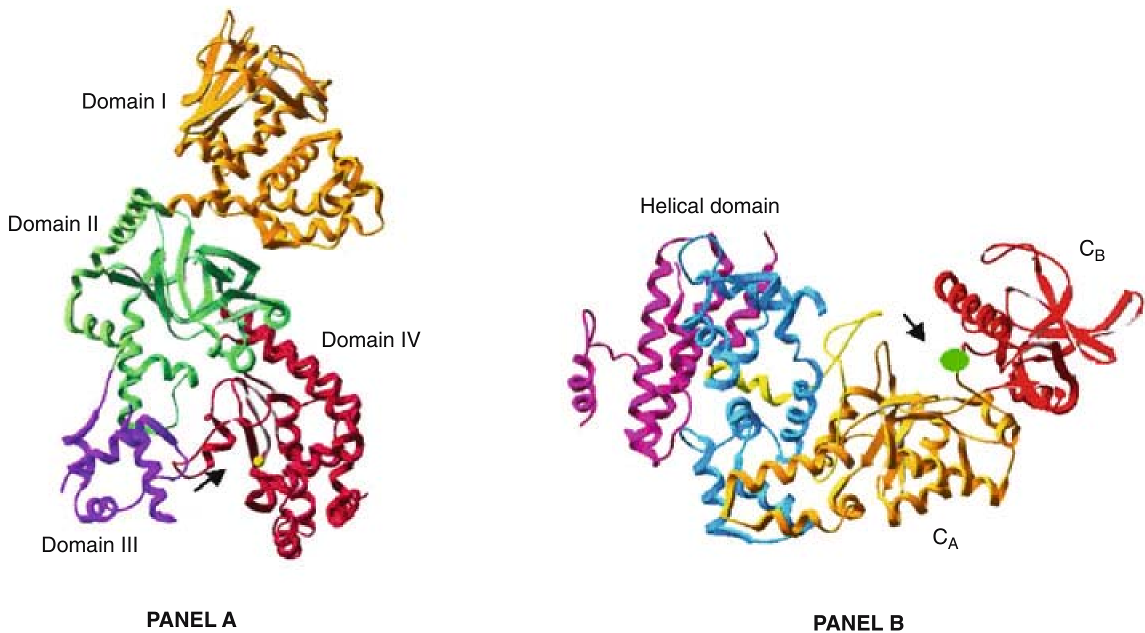

Fig. 38. Crystal structures of the catalytic portion of anthrax lethal factor (panel A) and edema factor in complex with calmodulin (panel B). Panel A. The four domains are in different colors. The zinc atom complexed by domain IV is indicated by an arrow.

sequence, the observed endothelial toxicity contributes to vascular pathology and hemorrhage during systemic anthrax (Kirby, 2004).

E. coli Cytotoxin Necrotizing Factors

Cytotoxin necrotizing factors (CNF1 [Fig. 1, panel 18] and CNF2), single-chain proteins of 115 kDa produced by a number of uropathogenic and neonatal meningitis-causing pathogenic *E. coli* strains (Caprioli et al., 1984; De Rycke et al., 1987), are immunologically related and share 85% identity. They also share some similarity with the dermonecrotic toxin of *Pasteurella multocida* and *Bordetella pertussis* (Schmidt et al., 1999). Both CNF1 and CNF2 toxins are encoded by a single structural gene with a low G+C content (35%). However, whereas *cnf1* is chromosomally encoded, cnf2 is carried on a large transmissible F-like plasmid called "Vir" (Oswald and De Rycke, 1990; Falbo et al., 1992).

These toxins induce ruffling, stress fiber formation, and cell spreading in cultured cells by activating the small GTP-binding proteins Rho, Rac and Cdc42, which control assembly of actin stress fibers (Oswald et al., 1994). CNF1 induces only a transient activation of Rho GTPase and a depletion of Rac by inducing the addition of an ubiquitin chain, which is known to drive to specific degradation by the proteasome. Reduction of Rac GTPase levels induces cell motility and cellular junction dynamics allowing efficient cell invasion by uropathogenic bacteria (Doye et al., 2002). The catalytic region of CNF1 has been crystallized (Buetow et al., 2001; Fig. 39). The active site contains a catalytic triad, which is positioned in a deep pocket, thus explaining the restricted access to unspecific substrates and therefore its specificity. Very likely, some type of conformational rearrangement is required also to accomodate Rho in this narrow cavity.

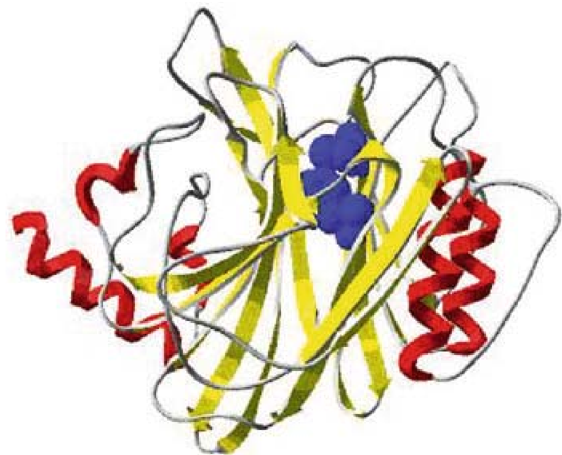

Fig. 39. Crystal structure of the active site of *E. coli* CNF1. The catalytic site composed by Cys866-His881 is colored in blue.

Recently, a CNF1-like toxin (CNFY) has been identified also in *Yersinia pseudotubercolosis* (Lockman et al., 2002). Differently from the *E. coli* CNFs, CNFY has been shown to selectively activate RhoA (Hoffman et al., 2004).

Bordetella Dermonecrotic Toxin

Dermonecrotic toxin (DNT) is produced by *Bordetella* species as a single-chain polypeptide chain of 1464 amino acids, which is composed of a C-terminal portion that contains the catalytic site, and of an N-terminal receptor-binding domain. DNT shares about 30% identical residues in the catalytic domain with *E. coli* CNF1, including the catalytic Cys and His residues. DNT is a transglutaminase, which catalyzes the deamidation or polyamination at Gln63 of Rho and of the corresponding residues of Rac and Cdc42 (Horiguchi, 2001). This activity causes alteration of cell morphology, reorganization of stress fibers, and focal adhesions on a variety of animal models. Recently, it has been demonstrated that the initial 54 amino acids of DNT are sufficient for cell surface recognition. However, the receptor is still unknown.

Cytolethal Distending Toxins

The cytolethal distending toxin (CDT) produced by *Haemophilus ducreyi* (HdCDT) is the prototype of a growing family of bacterial toxins that act by inducing cell enlargement followed by cell death (Cortes-Bratti et al., 1999; Frisan et al., 2003). HdCDT is a complex of three proteins (CdtA, CdtB and CdtC) encoded by three genes that are part of an operon. Members of this family have been identified in *E. coli*, *Shigella*, *Salmonella*, *Campylobacter*, *Actinobacillus* and *Helicobacter hepaticus* (Okuda et al., 1995; Lara-Tejero and Galan, 2001; Hoghjoo et al., 2004; Pickett et al., 2004; Shenker et al., 2004; Young et al., 2004). The overall sequence similarity varies among the different members of this family of toxins. HdCDT intoxicates eukaryotic cells by causing a three- to fivefold gradual distension and induces cell cycle arrest in the G_2 phase. It has also been shown to induce DNA double-strand breaks and formation of actin stress fibers via activation of the small GTPase RhoA. Recently it has been shown that CdtB is the active subunit of the CDT toxin and acts as a nuclease. All the amino acids predicted to be important for nuclease activity are conserved in the CdtB of different bacteria, suggesting that the mechanism of action is the same for all CDT toxins. On the other hand, CdtA and CdtC are able to bind to the surface of HeLa cells, therefore playing a role in the delivery of the active domain to target cells (Lee et al., 2003).

Toxins Acting on the Cytoskeleton Structure

The cytoskeleton is a cellular structure that consists of a fiber network composed of microfilaments, microtubules, and the intermediate filaments. It controls a number of essential functions in the eukaryotic cell and participates in all kinds of cellular movement and transport; furthermore, the cytoskeleton is involved in processes like exo- and endocytosis, vesicle transport, cell-cell contact, and mitosis (Kabsch and Vandekerckhove, 1992).

The group of cytoskeleton-affecting bacterial toxins comprises not only virulence factors that directly act on particular elements of the cytoskeleton, but also proteins that perform an indirect action by affecting regulatory components, which control its organization (Aktories, 1994; Richard et al., 1999). Most of them do it by modifying the regulatory, small G proteins, such as Ras, Rho, Rac and Cdc42, which control cell shape. These toxins, which have a dramatic but indirect effect on the cytoskeleton and are described in the section Toxins Acting on Signal Transduction, are *E. coli* CNF and *C. difficile* enterotoxins A and B. Other toxins acting on regulatory G proteins are exoenzyme S, C3 and YopE, which are described below as toxins that are directly injected into the eukaryotic cells. Other bacterial molecules that cannot be strictly considered toxins but that have a powerful ability to polymerize actin are ActA and IcsA of *Listeria* and *Shigella,* respectively. These are described elsewhere in this volume (see Listeria and Relatives in Volumn 4 and The Genus Shigella in Volumn 6). Another toxin acting indirectly on the cytoskeleton is the zonula occludens toxin (Zot) produced by *V. cholerae*, a toxin with an unknown mechanism of action that modifies the permeability of tight junctions (Zot is described in the paragraph Toxins with Unknown Mechanism of Action in this Chapter). In the following section we consider only toxins that have the cytoskeleton as a direct target. The only toxin shown to affect directly the cytoskeleton is the C2 toxin of *C. botulinum*, which ADP-ribosylates monomeric actin, making it unable to polymerize. A second protein that has recently been described as being able to bind actin and stabilize the fibers supporting the ruffles induced by the *Salmonella* type III secretion system is SipA (described in the section Toxins Injected into Eukaryotic Cells in this Chapter).

Representatives of both subgroups can be identified among the class of ADP-ribosylating factors that ultimately display their toxic effect on the cytoskeleton of eukaryotic cells. In fact, whereas the family of *Clostridium botulinum* toxin C2, clostridial toxin C3 (and related pro-

teins), and *Pseudomonas aeruginosa* exoenzyme S (Exo S) act on small GTP-binding proteins that regulate the correct functioning of the cytoskeleton, and thus have an indirect toxic effect (Coburn et al., 1999).

Clostridium botulinum Toxin C2 and Related Proteins

Clostridium botulinum toxin C2 is the main representative of a class of binary cytotoxins produced by clostridial species that predominantly act on polymerized actin microfilaments of 7–9 nm in diameter (Aktories et al., 1986; Aktories and Wegner, 1992). C2 ADP-ribosylate monomeric G-actin at an arginine residue (Aktories et al., 1986; see the section ADP-Ribosylating Toxins in this Chapter). Because this arginine (Arg-177) is a contact site between actin monomers, the binding of the ADP-ribose moiety prevents actin's polymerization.

Other members of this family are *C. perfringens* iota toxin (Stiles and Wilkins, 1986; Perelle et al., 1993) and the related *C. spiroforme* and *C. difficile* ADP-ribosylating toxins (Popoff and Boquet, 1988a; Just et al., 1994), which are generally classified as iota-like toxins. These binary toxins are constructed according to the A/B model architecture, but in this case the two domains reside in separate molecules that interact to cause the toxic effect. Therefore, these toxins have an enzymatically active and toxic domain (A) and a binding component (B), which is essential for the binding at the cell surface and for the translocation inside the cell.

Clostridium botulinum toxin C2 is an extremely toxic agent, which induces hypotension, increase in intestinal secretion, vascular permeability, and hemorrhaging in the lungs. In contrast to botulinum neurotoxins, C2 does not seem to display any neurotoxic effect. The two molecules that constitute its toxic moiety are classified as C2-II (for the binding component) and C2-I (for the enzymatic component). The C2-II is a 100-kDa protein that must be proteolytically cleaved to a 75-kDa fragment before it can bind to the surface receptor; upon this interaction, a binding site for the 50-kDa C2-I component is activated and the toxic domain is taken up by receptor-mediated endocytosis (Ohishi, 1987). Substrates of the C2-I toxin are β/γ-non-muscle actin and γ-smooth muscle actin, but not α-actin isoforms. Conversely, the related iota toxin of *Clostridium perfringens* has been found to ADP-ribosylate all actin isoforms (Mauss et al., 1990). The iota toxin is a binary toxin produced by *Clostridium perfringens* type E, which has been implicated in fatal calf, lamb and guinea pig enterotoxemias (Madden et al., 1970). Structurally, it has two independent domains: Ia, which is the ADP-ribosyltransferase, and Ib, which is involved in the binding and internalization of the toxin by the cell (Stiles and Wilkins, 1986). The crystallization of the C2-I component in complex with its substrate NADH has recently been achieved (Tsuge et al., 2003; Fig. 40), showing a close relationship of iota toxin with insecticidal protein VIP2 of *Bacillus cereus*.

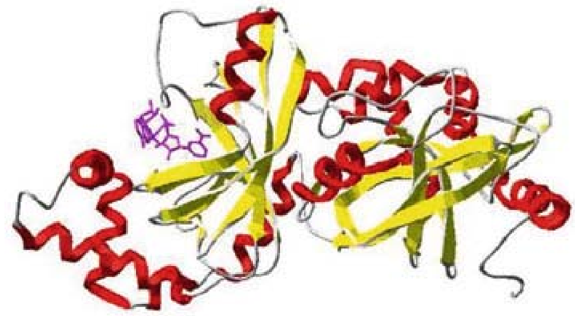

Fig. 40. Crystal structure of the catalytic domain C2I of *C. perfringens* C2 toxin (red and yellow) in complex with NADH (pink).

Clostridium difficile induces its pathogenic effects by secreting a number of potent cytotoxins; one, in particular, has been found to possess ADP-ribosyltransferase activity (CDT). CDT acts on the cytoskeleton structure by disaggregating actin filaments and thus provokes an increase of globular actin (G-actin; Popoff et al., 1988b; Gulke et al., 2001).

Another member of the group of iota-like toxins is the *Clostridium spiroforme* toxin, composed of a toxic subunit Sa and a binding subunit Sb (Popoff et al., 1989). The level of primary sequence homology detected among the enzymatic and binding components of this class of ADP-ribosylating toxin ranges from 32% to 80% identity, the binding domains being the better conserved. The C2 toxin is the one with the lower degree of sequence conservation, and this correlates with the fact that it does not appear to be crossreactive with the other iota-like toxins.

Experiments of site-directed mutagenesis have helped to define for these toxins an active site very similar to those described for the better studied members of the family of ADP-ribosyltransferases (Barth et al., 1998; see the section ADP-Ribosyltransferases: A Common Structure of the Catalytic Site in this Chapter).

Escherichia coli Lymphostatin

Lymphostatin is a very recently identified protein in enteropathogenic strains of *E. coli* (EPEC; Klapproth et al., 2000).

A leading cause of diarrhea among infants in developing countries, EPEC is also one of the few known bacterial causes of chronic diarrhea. These strains are characterized by their ability in host cells to induce cytoskeletal rearrangements that result in the formation of adhesion pedestals. This mechanism known as "the attaching and effacing effect" (Moon et al., 1983; Khoshoo et al., 1988) ultimately allows the bacterium to colonize the host for prolonged periods.

Lymphostatin also has been identified as one of the primary factors that selectively block the production of interleukin-2 (IL-2), IL-4, IL-5 and γ interferon by human peripheral cells and inhibit proliferation of these cells, thus interfering with the cellular immune response (Klapproth et al., 1995).

Lymphostatin, a very large toxin with a predicted molecular weight of 366 kDa, shares significant homology with the catalytic domain of the large clostridial cytotoxins, including toxins A and B of *Clostridium difficile*, lethal toxin of *C. sordelii*, and a toxin of *C. novyi*. Its corresponding gene, *lifA*, with 9669 bp, is the largest reported gene in *E. coli*. Some *lifA* mutants of EPEC have been constructed to verify the lymphocyte inhibitory factor (LIF) activity of its gene product; lysates of this mutant lacked the ability of wildtype EPEC lysates to inhibit expression of IL-2, IL-4 and γ interferon mRNA and protein in mitogen-stimulated lymphocytes, while the expression of IL-8 was unaffected (Klapproth et al., 2000). Experiments of colony hybridization performed using an internal fragment of the *lifA* gene identified a similar gene present in most of the EPEC and enterohemorrhagic *E. coli* (EHEC) strains able to produce the attaching and effacing lesions on host epithelial cells, but this gene was not found in other *E. coli* and related organisms (Klapproth et al., 2000).

Toxins Acting on Intracellular Trafficking

Vesicle structures are essential in the eukaryotic cell for a number of vital processes such as receptor-mediated endocytosis and exocytosis; these are used either to internalize portions of the plasma membrane and address them to the specialized compartment, or to transport to the cell surface molecules synthesized in the ER and modified in the Golgi apparatus.

One example of exocytic pathway is that involving the release of neurotransmitters that are contained within small synaptic vesicles packed at synaptic terminals; the majority of these vesicles are bound to the cytoskeleton and are not directly available for immediate release, but some of them are present at the cytosolic face of the presynaptic membrane and are ready to release their content. However, at low calcium concentrations, only an occasional vesicle fuses to the presynaptic membrane, giving rise to a depolarization event. This event leads to the opening of calcium channels and thus to an increase of calcium concentration, which finally triggers the fusion of the neurotransmitter vesicles with the plasma membrane.

Recently, this field was greatly advanced by the identification of the eukaryotic molecules responsible for vesicle docking and membrane fusion. Three of these proteins (namely vesicle-associated membrane protein [VAMP]/synaptobrevin, synaptosome-associated protein [SNAP-25], and syntaxin) are the specific targets of a number of neurotoxins produced by bacteria of the genus *Clostridium* (CNTs; Montecucco and Schiavo, 1994; Fig. 41).

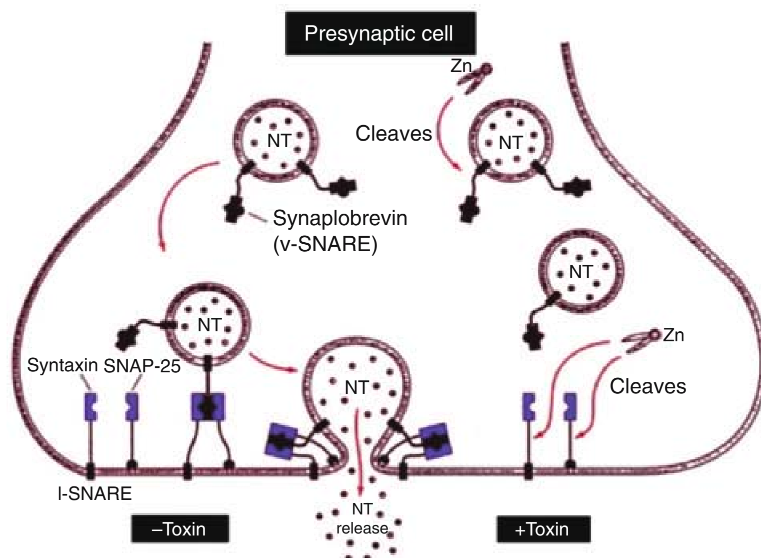

Fig. 41. Mechanism of action of clostridial neurotoxins.

The CNT family is composed of tetanus neurotoxin (TeNT) and seven serotypes of botulinum neurotoxins (BoNT/A–BoNT/G), which are specific zinc-dependent proteases whose action finally causes the block of neuroexocytosis (Schiavo et al., 1992; Pellizzari et al., 1999; Lalli et al., 2003). The degree of sequence homology detected among this group of toxins is high, ranging from 30% to more than 50% identity.

Clostridium tetanii Neurotoxin

Tetanus neurotoxin (TeNT; Fig. 1, panel 19) is the unique causal agent of the pathological condition of spastic paralysis known as tetanus. This is one of the most potent toxins known so far, with a 50% lethal dose (LD_{50}) in humans of 0.1–1.0 ng/kg.

The TeNT is produced by *Clostridium tetanii* as a single chain polypeptide of 150 kDa that, following proteolytic cleavage, is divided into fragments H (heavy) and L (light) held together by a disulfide bridge. Its overall structure is similar to that of A/B toxins, where the toxic subunit A is represented here by the light chain L, and subunit B is constituted by the H_C and H_N domains. The heavy chain is composed of fragments HC, which has recently been found to bind di- and trisialylgangliosides on neuronal cell membranes, and HN, which is involved in the transmembrane translocation of the L chain to the cytosol (Schiavo et al., 1990; Shapiro et al., 1997). The L chain is a 50-kDa fragment containing the –HExxH– motif typical of metalloproteases. It binds zinc and specifically cleaves VAMP/synaptobrevin, a eukaryotic factor essential for membrane fusion (Rossetto et al., 1995).

The first step of intoxication is the specific binding of domain H_C of TeNT to both high and low affinity receptors exposed on the presynaptic neuronal membrane at neuromuscular junctions (Montecucco, 1986); the second step is internalization of TeNT into the peripheral motoneuron and then retrograde axonal transport. The TeNT is released through the postsynaptic membrane into the synaptic space where it enters into the inhibitory interneurons of the central nervous system through receptor-mediated endocytosis (Halpern and Neale, 1995). At this point, while the H_C domain is in the vesicle, the translocation domain H_N helps the catalytic light chain L to cross the vesicle membrane and gain access to the cytosolic compartment where L performs its toxic activity on VAMP/synaptobrevin (Montal et al., 1992).

Interestingly, domain H_C retains the unique transport properties of the intact holotoxin and is capable of eliciting a protective immunological response against the full-length tetanus neurotoxin. A single zinc atom is bound to the L chain of TeNT and is essential for toxicity. This specific metallo-dependent proteolytic activity is common to the other clostridial toxins and to the lethal factor (LF) of *Bacillus anthracis*.

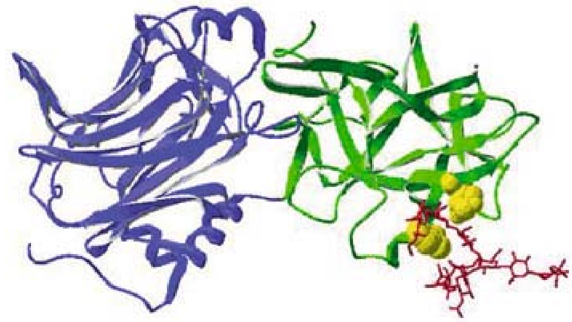

Fig. 42. Crystal structure of the receptor-binding domain HC of tetanus neurotoxin in complex with a ganglioside analogue (in red). The N-terminus and C-terminus are colored in blue and green, respectively. The residues probably involved in ganglioside binding are yellow (see Fig. 1, panel 18).

The crystal structure of the receptor-binding fragment HC of tetanus neurotoxin has been recently determined at 2.7 Å resolution (Umland et al., 1997; Fig. 42) revealing an N-terminal jellyroll domain and a C-terminal β-trefoil domain.

To determine which amino acids in tetanus toxin are involved in ganglioside binding, homology modeling was performed using recently resolved X-ray crystallographic structures of the tetanus toxin HC fragment. On the basis of these analyses, the amino acids tryptophan 1288, histidine 1270, and aspartate 1221 were found to be critical for binding of the HC fragment to ganglioside GT1b (Fotinou et al., 2001; Louch et al., 2002).

Although the overall sequence homology detected among clostridial neurotoxins is significant, this similarity weakens in the region encompassing the C-terminal domain (Murzin et al., 1992); the fact that each toxin possesses its own unique receptor and is immunologically distinct from the others has been attributed to sequence divergence of this domain which, therefore, could be responsible for receptor specificities (Lacy et al., 1999).

Clostridium botulinum Neurotoxins

These neurotoxins (BoNT/A-G; Fig. 1, panel 20) are the causative agents of the flaccid paralysis typical of clinical botulism intoxication (Hatheway, 1995). All of them are zinc-dependent proteases that show a strong tropism for the neuromuscular junction (Simpson, 1980; Rossetto et al., 1995), where they bind to still unidentified receptors in a strictly serotype-specific manner. This binding step is followed by the entry of the toxin into the cytoplasm of the motoneurons and

by specific proteolytic cleavage of intracellular targets belonging to the family of soluble *N*-ethylmaleimide-sensitive, fusion factor attachment protein receptors (SNARE). Four out of the seven botulinum neurotoxins (BoNT/B, D, F and G) cleave VAMP/synaptobrevin, another two act specifically on SNAP/25, whereas the last one, BoNT/C, cleaves both syntaxin and SNAP/25 substrates. In all cases, the ultimate effect is the total block of acetylcholine release (Montecucco and Schiavo, 1995).

These toxins are generally produced as large complexes of 300–900 kDa containing additional proteins such as hemagglutinin (300 kDa) and nontoxic peptides, which are believed to act as stabilizing agents of the neurotoxins in the gut environment (Sakaguchi, 1983).

The BoNTs are synthesized as inactive polypeptide chains of 150 kDa, which (following proteolytic cleavage) divide into two chains of 50 and 100 kDa that remain linked by a disulfide bridge. The catalytic function is carried by the 50-kDa fragment, the light chain L (residues 1–437), whereas the 100-kDa subunit (heavy chain, H) contains both the translocation (residues 448–872) and the receptor-binding domains (residues 873–1295; Krieglstein et al., 1994). The crystal structure determined for the full-length polypeptide of BoNT serotype A (Lacy et al., 1998; Fig. 43) reveals a number of remarkable features, particularly related to the peculiar structure of the translocation domain. This contains, in fact, a central pair of α-helices 105 Å long and a 50-residue loop that wraps around the catalytic domain in a belt-like fashion, partially occluding the active-site pocket. This unusual loop bears the site of the proteolytic cleavage, which is required for activation of the toxin; the fact that in the protoxin, the translocation domain shields the active site explains why the catalytic activity in test tube experiments is greatly enhanced by reduction of the disulfide bond. The fold of the translocation domain suggests a mechanism of pore formation different from that displayed by other pore-forming toxins. The helices are antiparallel and amphipathic and twist around each other in a coiled-coil-like structure. In addition, the domain has two strand-like segments that lie parallel to the helical axis and are predicted to be directly involved in membrane spanning. Very recently, the X-ray structure obtained for the recombinant form of chain L of BoNT-A has shed light on a possible novel mode of substrate binding and catalytic mechanism (Segelke et al., 2004).

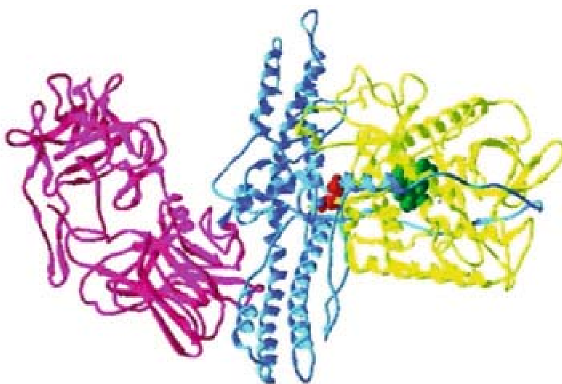

Fig. 43. X-ray structure of *Clostridium botulinum* neurotoxin serotype A. The 50-kDa catalytic domain (L) is colored in yellow, with the zinc-binding domain in green. The N-terminal portion of the 100-kDa subunit involved in translocation is blue, whereas the C-terminal receptor-binding moiety is in magenta. The disulfide bond linking the two 50- and 100-kDa fragments is colored in red (see Fig. 1, panel 20).

The highest degree of homology detected among this family of clostridial neurotoxins is concentrated in the light chain L (30–60% identity; particularly its N-terminus), probably involved in substrate recognition, and in the central portion that contains the catalytic zinc-binding motif –HexxH– characteristic of zinc endopeptidases. The zinc atom coordinated by this pocket is required for the in vivo toxicity of BoNTs.

Years ago, medical experiments demonstrated that injection of BoNT/A is very effective in strabismus; since then, the therapeutic applications of these neurotoxins have been extended to a variety of diseases which benefit from a functional paralysis of the neuromuscular junction, and all the BoNTs are under clinical testing (Jankovich and Hallett, 1994).

Helicobacter pylori Vacuolating Cytotoxin Vac A

Highly pathogenic strains of *Helicobacter pylori*, the etiological agent of peptic ulcer and gastritis (Cover and Blaser, 1992), produce vacuolating cytotoxin A (VacA; Papini et al., 1994; Fig. 1, panel 21). This toxin is responsible for massive growth of vacuoles within epithelial cells and, when administered to mice, VacA causes loss of gastric gland architecture, cell necrosis, and gastric ulceration (Telford et al., 1994). Synthesized as a 140-kDa precursor, VacA is secreted from the bacterium through its 45-kDa carboxy-terminal domain, using a mechanism similar to that of neisserial IgA proteases (Schmitt and Haas, 1994; Fiocca et al., 1999). When purified from the culture supernatant of Type I *H. pylori* strains, the protein has a molecular weight of approximately 600–700 kDa, suggesting the idea of a multimeric complex; electron microscopy studies have in fact demonstrated the flower-shaped structure of the toxin (Lupetti et al., 1996; Fig. 44) resulting from the aggregation of either six or seven monomers, each

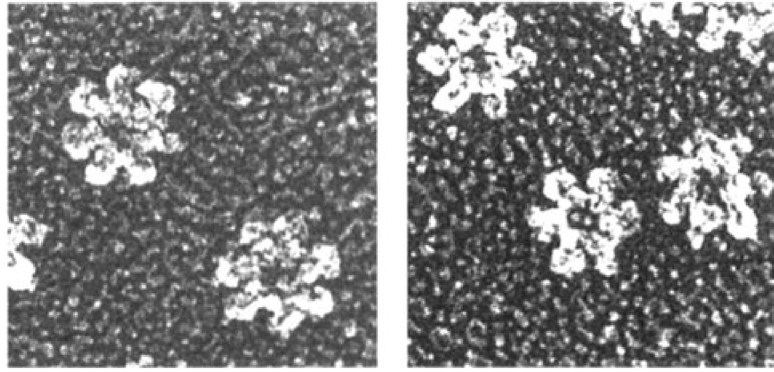

Fig. 44. Vacuolating cytotoxin structure: heptameric and hexameric forms of VacA as observed in electron micrographs of quick-freeze, deep-etched preparations. The oligomers are approximately 30 nm in diameter with a 10–12 nm central cavity.

comprising the 95-kDa amino-terminal region of the VacA precursor. Recently, a model has been proposed to show how VacA can insert into membranes forming hexameric, anion-selective pores (Kim et al., 2004).

Each monomer can be cleaved at a protease-sensitive site into two fragments of 37 kDa and 58 kDa (p37 and p58 moieties) that may represent the A and B moieties of AB-like bacterial toxins. The 37-kDa, amino-terminal portion is highly conserved at the sequence level and is able to induce vacuoles when the *vacA* gene is placed under the control of a strong eukaryotic promoter and transfected into epithelial cells. This evidence suggests that the active site could be located in this region of the molecule, whereas the carboxy-terminal portion is likely to be devoted to receptor recognition and binding. Although VacA is exported over the outer membrane and is released from the bacteria, recent data have been presented to show that a portion of the toxin remains associated with the bacterial surface. Surface-associated toxin is biologically active and organized into distinct toxin-rich domains on the bacterial surface. Upon bacterial contact with host cells, toxin clusters are transferred to the host cell surface via a contact-dependent mechanism, followed by uptake and intoxication (Ilver et al., 2004).

The mechanism of toxicity exploited by this virulence factor has not yet been completely elucidated. What is known is that VacA causes an alteration of the endocytic pathway, which results in the selective swelling of late endosomes or prelysosomal structures. The small GTP-binding protein Rab7 is necessary for vacuole formation (Papini et al., 1994, 1997). Even though it is unknown, the target of VacA action is strongly believed to be a fundamental effector in membrane trafficking.

Streptococcus pyogenes NAD$^+$ Glycohydrolase

NAD$^+$ glycohydrolase is an important virulence factor produced by group A streptococci (GAS), which is thought to enhance pathogenicity by facilitating the spread of the microorganism through host tissues. This enzyme catalyzes the hydrolysis of the nicotinamide-ribose bond of NAD to yield nicotinamide and ADP-ribose. Differently from ADP-ribosylating toxins, NAD$^+$ glycohydrolases possess a much higher rate of NADase activity and do not require an ADP-ribose acceptor. Interestingly this GAS virulence factor is functionally linked to streptolysin O (SLO), a pore-forming toxin, which has been shown to be required for efficient translocation of NAD$^+$ glycohydrolase into epithelial cells. In contrast to the wildtype GAS, isogenic mutants deficient in the expression of SLO, NAD$^+$ glycohydrolase, or both proteins resulted in reduced cytotoxicity and keratinocyte apoptosis. These results suggest that NAD$^+$ glycohydrolase modulates host cell signaling pathways and contributes to the enhancement of streptolysin O cytotoxicity (Bricker et al., 2002).

Toxins Injected into Eukaryotic Cells

See Tables 1 and 2 for a summary of the principal features of toxins described in this section.

In the classical view, toxins were believed to be molecules that cause intoxication when released by bacteria into the body fluids of multicellular organisms. This definition failed to explain the pathogenicity of many virulent bacteria such as *Salmonella*, *Shigella* and *Yersinia*, which did not release toxic proteins into the culture supernatant. Today we know that these bacteria also intoxicate their hosts by using proteinaceous weapons. These bacteria intoxicate individual eukaryotic cells by using a contact-dependent secretion system to inject or deliver toxic proteins into the cytoplasm of eukaryotic cells (Fig. 2, panel 3). This is done by using specialized secretion systems that in Gram-negative bacteria are called "type III" or "type IV," depending on whether they use a transmem-

brane structure similar to flagella or conjugative pili, respectively.

Mediators of Apoptosis

Pathogens use different mechanisms to induce or prevent apoptosis in host cells. Virulence factors produced by the pathogen can interact directly with effector molecules of apoptosis or interfere with factors involved in cell survival (Weinrauch and Zychlinsky, 1999).

They include: pore-forming toxins which induce cell death by altering host cell permeability, bacterial toxins (such as DT, PAETA, Shiga and Shiga-like toxins) which induce cell death by inhibition of host protein synthesis, and type III secreted proteins of *Shigella*, *Salmonella* and *Yersinia* which are directly delivered into host cell compartment and trigger apoptosis by altering the signal transduction pathway. This latter class of toxins will be described here in more detail.

IpaB

Shigella, the causative agent of bacillary dysentery produces IpaB. *Shigella* invades the epithelial cells by causing the cell cytoskeleton to reorganize during bacterial entry. The bacteria are phagocytosed by macrophages and rapidly escape from phagosomal compartment to the cytosol where they induce apoptosis of the macrophages. Invasion and cytotoxicity require *Shigella* invasion plasmid antigen (Ipa) proteins, which are secreted by a type III secretion apparatus. Invasion and escape from the phagosome are dependent upon the expression and secretion of the IpaB, IpaC and IpaD. Only IpaB is required to initiate cell death by interaction with the interleukin-1β converting enzyme, or caspase I, which is one of the effector molecules of apoptosis. The IpaB-induced apoptosis results in an inflammation that has the effect not only of clearing and possibly localizing the infection but also promoting bacterial spread in the intestinal epithelium (Hilbi et al., 1998). Protein domains directly involved in pathogenicity have recently been mapped (Guichon et al., 2001).

SipB

An analog of *Shigella* invasin IpaB, *Salmonella* invasion protein (SipB) is produced by *Salmonella* and is delivered to the host cells by a type III secretion system. In contrast to *Shigella*, *Salmonella* does not escape from the phagosome, but it survives and multiplies within the macrophages. *Salmonella* virulence genes responsible for invasion and killing of macrophages are encoded by a chromosomal operon named *sip* containing five genes (sipEBCDA; Hermant et al., 1995). The sip genes show high sequence homology with the *ipa* operon of *Shigella*, and the Sip proteins show functional similarities with Ipa proteins. Both proteins have a predominant alpha-helical structure and contain two helical transmembrane domains, which insert deeply into the bilayer (Hume et al., 2003). Similarly to IpaB, SipB also induces apoptosis by binding interleukin-1β-converting enzyme.

Necessary for *Salmonella*-induced macrophage apoptosis, SipB acts through a caspase-I-activating mechanism similar to that used by IpaB (Hersh et al., 1999). Also, SipB can complement IpaB mutants, enabling them to invade cells and escape macrophage phagosomes.

YopP, YopJ and Related Proteins

Yersinia enterocolitica and *Yersinia pestis* produce YopP and YopJ, respectively (Straley et al., 1986; Mills et al., 1997). Following contact with the host cell, *Yersiniae* deliver into the cytoplasm of eukaryotic cells, through a type-III secretion system, plasmid-encoded proteins named "*Yersinia*-outer-membrane proteins" (Yop). These proteins are able to induce alteration of cytoskeleton (YopE and YopT), inhibition of phagocytosis (YopH), and in the case of YopP and YopJ, induction of apoptosis.

The mechanism by which *Yersinia* induces apoptosis is probably different from that described for *Shigella*, inasmuch as *Yersinia* induces apoptosis from the outside of host cells. The binding of YopJ directly to the superfamily of MAPKKs blocks both their phosphorylation and subsequent activation. These activities of YopJ are responsible for the inhibition of extracellular signal-regulated kinase, downregulation of TNF-α and suppression of the nuclear factor kappa B (NF-κB) signaling pathways, preventing cytokine synthesis and promoting apoptosis (Orth et al., 1999). The YopJ-related proteins that are found in a number of bacterial pathogens of animals and plants, such as AvrRxv from *Xanthomonas campestris* (Whalen et al., 1993), AvrA from *Salmonella* (Hardt et al., 1997), and y410 from *Rhizobium* (Freiberg et al., 1997) may function to block MAPKKs so that host signaling responses can be modulated upon infection. Whereas no function is known for AvrA and y410, AvrRxv is a plant pathogen virulence protein involved in the programmed cell death pathway.

Toxins Interfering with Inositol Phosphate Metabolism: SopB and IpgD

The SopB protein, secreted by *Salmonella dublin*, is a virulence factor essential for

	Motif 1	Motif 2
SopB	VVTFNFGVNELALKM	AWNCKSGKDRTGMMSDE
IpgD	VAAFNVGVNELALKL	CWNCKSGKDRTGMQDAE
PTPaseI	PVLFNVGINEQQTLA	FTSCKSAKDRTAMSVTL
PTPaseII	PVLFNVGINEQQTLA	FTCCKSAKDRTSMSVTL

Fig. 45. Alignment of conserved motifs.

enteropathogenicity. The toxin hydrolyzes phosphatidylinositol triphosphate (PIP_3), which is a messenger molecule that inhibits chloride secretion, thus favoring fluid accumulation and diarrhea (Norris et al., 1998). Furthermore, SopB, mediates actin cytoskeleton rearrangements and bacterial entry in a Rac-1 and Cdc42-dependent manner. Consistent with an important role for inositol phosphate metabolism in *Salmonella*-induced cellular responses, a catalytically defective mutant of SopB failed to stimulate actin cytoskeleton rearrangements and bacterial entry (Zhou et al., 2001).

SopB is homologous to the *Shigella flexneri* virulence factor IpgD, suggesting that a similar mechanism of virulence is also present in *Shigella*. Both proteins contain two regions of sequence similarities (motifs 1 and 2, Fig. 45) with human inositol polyphosphatases types I and II. Motif 2 contains a consensus sequence (Cys-X5-Arg) characteristic of Mg^{+2}-independent phosphatases in which the cysteine is the residue essential for catalysis. Recent studies have shown that IpgD acts as a potent inositol 4-phosphatase and is responsible for dramatic morphological changes of the host cell, ultimately leading to consistent actin filament remodeling (Niebuhr et al., 2002).

Toxins Acting on the Cytoskeleton

PSEUDOMONAS AERUGINOSA EXOENZYME S. This toxin is one of several products of *Pseudomonas aeruginosa* that contributes to its pathogenicity (Woods et al., 1989; Kulich et al., 1993; Fig. 1, panel 22). It belongs to the group of ADP-ribosylating factors that lack both the receptor-binding and translocation domains, and are directly injected by bacteria into the cytoplasm of eukaryotic cells. In this case, bacteria intoxicate individual eukaryotic cells by means of a contact-dependent type III secretion system (Yahr et al., 1996).

The 49-kDa ExoS protein ADP-ribosylates the small GTP-binding protein Ras at multiple sites but preferably at Arg-41 (Ganesan et al., 1998; see the section ADP-Ribosyltransferases: A Family of Toxins Sharing the Same Enzymatic Activity in this Chapter). To become enzymatically active, ExoS requires the interaction with a cytoplasmic activator named "FAS" or "14.3.3" (Fu et al., 1993). When cells are transfected with the *exos* gene under the control of a eukaryotic cell promoter, a collapse of the cytoskeleton and a change of the morphology of the cells can be observed as primary consequences.

Pseudomonas aeruginosa ExoS is a bifunctional cytotoxin where the ADP-ribosyltransferase domain is located within its C-terminus portion. Recent studies showed, in fact, that when transfected or microinjected into eukaryotic cells, the N-terminus part of ExoS (amino acid residues 1–234) stimulates cell rounding. The N-terminus of ExoS (1–234) does not influence nucleotide exchange of Rho, Rac and Cdc42 but increases GTP hydrolysis. It has also been shown that Arg-146 of ExoS is essential for the stimulation of GTPase activity of Rho proteins (Goehring et al., 1999). The GTPase activating domain (GAP) of ExoS has been crystallized (Wurtele et al., 2001). In addition to these toxic effects performed on the cytoskeleton, other activities have been demonstrated for Exo S, such as the adhesive property on buccal cells (Baker et al., 1991) and the induction of human T lymphocyte proliferation (Mody et al., 1995). From sequence analysis, it has been possible to identify the regions of Exo S, which could be involved in NAD binding and thus constitute the common structure of the catalytic site.

CLOSTRIDIUM BOTULINUM EXOENZYME C3 AND RELATED PROTEINS. Produced by certain strains of *Clostridium botulinum* types C and D, exoenzyme C3 is a 251-amino acid protein that specifically ADP-ribosylates *rho* and *rac* gene products in eukaryotic cells (Moriishi et al., 1993; Fig. 1, panel 23). These substrates belong to the group of small GTP-binding proteins and seem to have a fundamental role in cell physiology and cell growth. The ADP-ribosylation process occurs at asparagine residues (Asn-41) located in the putative effector binding domains of *rho* and *rac* and thus alter their functions (Sekine et al., 1989). The enzymatic activity is identical to that of all ADP-ribosylating enzymes; however, the recently solved 3D structure has shown that the C3 exoenzyme structure can be distinguished by the absence of the elongated α-helix, which generally constitutes the ceiling of the active site cleft in the ADP-ribosylating toxins crystallized so far. Seemingly, this feature does not impair the ability of C3 either to accommodate the NAD substrate or to carry out the enzymatic reaction (Han et al., 2001; Fig. 46).

This exoenzyme is the prototype of the group of A-only toxins because it apparently lacks the receptor-binding B domain and thus is unable to enter the cells; for this reason, C3 cannot be considered a real virulence factor, and still unknown is whether C3 alone is able to intoxicate the cells.

Nevertheless, when microinjected into cells, it causes complete disruption of actin-stress fibers, rounding of the cell body, and formation of arborescent extensions.

Other members of this family of C3-related exoenzymes have been isolated from Gram-positive bacteria, such as certain strains of *Staphylococcus aureus* (Sugai et al., 1992), *Clostridium limosum* (Just et al., 1992) and *Bacillus cereus* (Just et al., 1995c). Whereas *C. botulinum* C3 and *C. limosum* exoenzyme are about 70% homologous and immunologically related, the epidermal cell differentiation inhibitor (EDIN) produced by *S. aureus* is only 35% homologous with C3 and shows no immunological crossreactivity (Fig. 47). However, crystal data recently obtained for *S. aureus* C3 exotoxin (EDIN-B) have disclosed a very similar structure (Evans et al., 2003). *Bacillus cereus* exoenzyme exhibits the same substrate specificity as the other C3-like transferases (it was found to act specifically on rho proteins). Nevertheless some differences can be observed for this toxin, such as the higher molecular weight (28 kDa) and, more importantly, the lack of immunological relationship to any other member of this family (Just et al., 1995a).

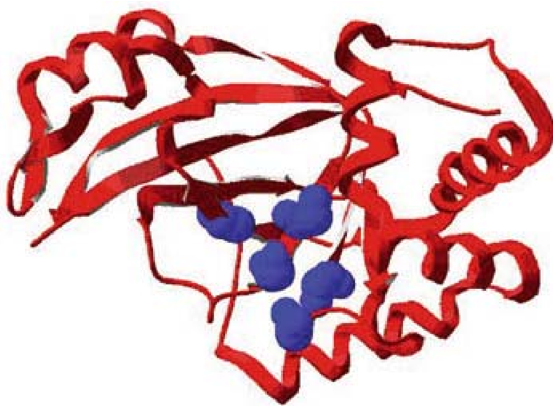

Fig.46. Crystal structure of exoenzyme C3 of *C. botulinum*. The residues which constitute the catalytic site are in blue.

SALMONELLA SOPE AND SIPA. *Salmonella typhimurium* achieves entry into cells by delivering effector proteins into the cytosol through a type III secretion system. These effectors stimulate signal pathways leading to reorganization of the cell's actin cytoskeleton, membrane ruffling and stimulation of nuclear response to promote efficient bacterial internalization. One of the proteins that stimulate the cellular response is SopE, which is able to activate signaling pathways through Rho GTPases by stimulating GTP/GDP nucleotide exchange on proteins such as Cdc42 and Rac (Hardt et al., 1998).

These signaling events lead to the recruitment of cellular proteins such as actin and T-plastin (an actin-binding protein that bundles actin), which finally induce actin cytoskeleton rearrangement and membrane ruffling. In addition, SopE stimulates nuclear responses that induce the synthesis of proinflammatory cytokines that contribute to the induction of diarrhea.

These cytoskeletal rearrangements are further modulated by SipA, which binds directly to actin, stabilizes actin filaments inhibiting depolymerization, and forms a complex with T-plastin thus increasing its actin-bundling activity (Zhou et al., 1999a, 1999b). SipA activities result in localized actin cytoskeleton reorganization and more pronounced extension of membrane ruffles, which facilitate bacterial uptake. The actin-cytoskeleton reorganization induced by *Salmonella* is reversible and infected cells are able to recover their normal architecture after bacterial internalization.

Crystal structures are available for SipA (Lilic et al., 2003) and for the catalytic fragment of SopE in complex with its host cellular target

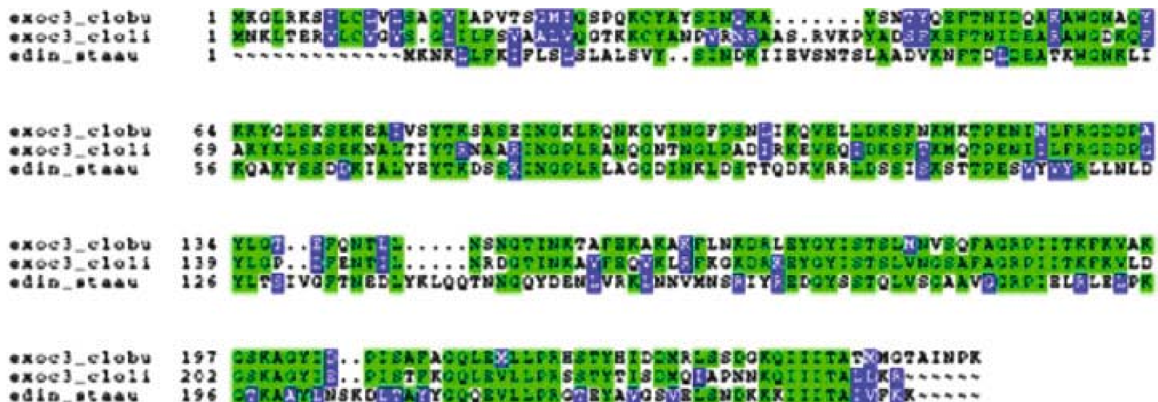

Fig. 47. Multiple sequence alignment of protein toxins belonging to the group of exoenzyme C3-like ADP-ribosyltransferases.

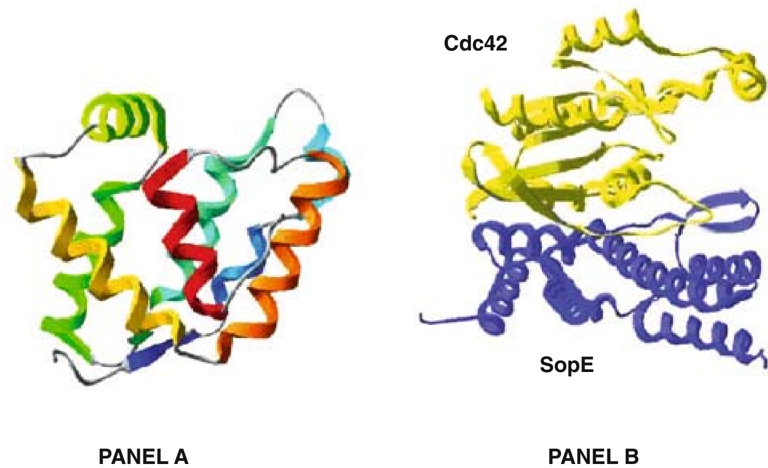
Fig. 48. Crystal structures of SipA (panel A) and of SopE in complex with Cdc42 (panel B).



Cdc42 (Buchwald et al., 2002; Figs. 1 [panels 24 and 25] and 48).

SHIGELLA IPAA. The entry of *Shigella* into epithelial cells requires the Ipa proteins, which are secreted upon cell contact by the type III apparatus and act in concert. The IpaB and IpaC proteins form a complex that binds B1 integrin and CD44 receptors and induces actin polymerization at the site of bacterium-cell contact, allowing the formation of membrane extension that probably requires also the action of Cdc42, Rac and Rho GTPases (Nhieu and Sansonetti, 1999).

The translocation of IpaA into the cell cytosol probably favors *Shigella* entry. The IpaA protein binds with high affinity to the N-terminal residues 1–265 of vinculin, a protein involved in linking actin filaments to the plasma membrane. The vinculin-IpaA complex interacts with F-actin inducing subsequent depolymerization of actin filaments. Presumably, these interactions further modulate the formation on the membrane of adhesion-like structures required for efficient invasion.

Shigella internalization still occurs at low levels in the absence of IpaA, suggesting that IpaA acts in concert with other bacterial effectors to promote cell entry. Binding of the *Shigella* protein IpaA to vinculin induces F-actin depolymerization (Bourdet-Sicard et al., 1999). The IpaA and vinculin rapidly associate during bacterial invasion. Although defective for cell entry, an *ipaA* mutant is still able to induce foci of actin polymerization but differs from wildtype *Shigella* in its ability to recruit vinculin and α-actinin. It has been postulated that IpaA-vinculin interaction initiates the formation of focal adhesion-like structures required for efficient invasion (Tran Van Nhieu et al., 1997).

YERSINIA YOPE. A protein secreted by *Yersinia* through a type III secretion system, YopE contributes to the ability of *Yersinia* to resist phagocytosis (Rosqvist et al., 1990). Following infection of epithelial cells with *Yersinia*, the microfilament structure of the cells changes leading to a complete disruption of the actin microfilaments, which finally results in cell rounding and detachment from the extracellular matrix (Rosqvist et al., 1991). The effector YopE was recently shown to possess GAP activity towards the Rho GTPases RhoA, Rac and CDC42 in vitro (Aili et al., 2003; Fig. 1, panel 26). Further experimentation has shown that in vivo YopE is able to inhibit Rac- but not Rho- or Cdc42-regulated actin structures. Furthermore, the structure of this toxin has recently been solved, showing a close relationship with the analogous ExoS Gap domain (Evdokimov et al., 2002).

YERSINIA YOPT. YopT is the prototype of a new family of 19 cysteine proteases with potent

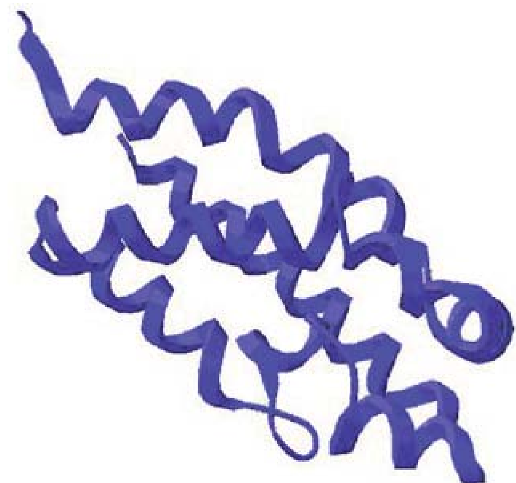


Fig. 49. Crystal structure of YopE catalytic domain.

effects on host cells. These include the AVr protein of the plant pathogen *Pseudomonas* and possibly Yop-J of *Yersinia*. YopT cleaves the posttranslationally modified cysteine located at the C-terminal end of Rho GTPases (DKG-CASS), causing the loss of the prenyl group from RhoA, Rac and cdc42, and releasing them from the membrane (Shao et al., 2003). The inability of Rho to be located to the membrane causes disruption of the cytoskeleton. While the C terminus of YopT is crucial for activity, the N terminus of YopT is crucial for substrate binding (Sorg et al., 2003).

SHIGELLA VIRA. The invasiveness of *Shigella* is an essential pathogenic step and a prerequisite of bacillary dysentery. VirA is a *Shigella* effector protein, which is delivered into the host cell by a specialized type III secretion system. This protein can interact with tubulin to promote microtubule destabilization and membrane ruffling (Yoshida et al., 2002). With this mechanism, *Shigella* is able to remodel the cell surface and thus promote its entry into the host. Recent data have shown that *VirA* deletion mutants displayed decreased invasiveness and were unable to stimulate Rac1.

Toxins Acting on Signal Transduction

YERSINIA YPKA AND YOPH. Phosphorylation is central to many regulatory functions associated with the growth and proliferation of eukaryotic cells. Bacteria have learned to interfere with these key functions in several ways. The best-known system is that of *Yersinia*, where a protein kinase (YpkA; Barz et al., 2000) and a protein tyrosine phosphatase (YopH; Zhang, 1995; Fig. 1, panel 27) are injected into the cytoplasm of eukaryotic cells by a type III secretion system to paralyze the macrophages before they can kill the bacterium.

YpkA is a Ser/Thr protein kinase that also displays autophosphorylating activity in vitro. In vivo experiments have shown that this protein is essential for virulence: in fact, challenge with a *YpkA* knockout mutant causes a nonlethal infection, whereas all mice challenged with wildtype *Y. pseudotuberculosis* die. Recently, natural eukaryotic substrates of YpkA have been identified by using a two-hybrid assay. These belong to the class of small GTPases and comprise RhoA and Rac-1, but not Cdc42.

YopH is a modular protein where the tyrosine phosphatase domain shows a structure and catalytic mechanism very similar to those of eukaryotic enzymes. YopH acts by dephosphorylating cytoskeletal proteins thus disrupting phosphotyrosine-dependent signaling pathways necessary for phagocytosis. Host protein targets include Crk-associated substrate, paxillin, and focal adhesion kinase. In vivo, YopH inhibits phagocytosis by polymorphonuclear leukocytes (PMNs) and macrophages (Fallman et al., 1995; Ruckdeschel et al., 1996). The protein has a molecular weight of 51 kDa and is composed of an N-terminal domain important for translocation and secretion (Sory et al., 1995) and a C-terminal domain homologous to eukaryotic PTPases (Guan and Dixon, 1990; Bliska, 1995).

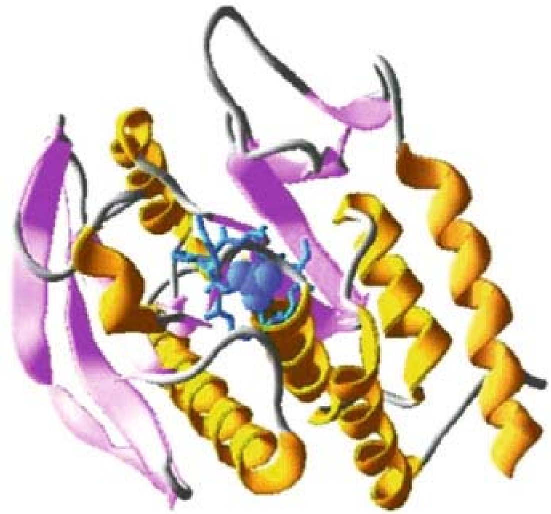

Fig. 50. X-ray structure of YopH. Colors have been assigned on the basis of secondary structure (yellow for helix and pink for β-sheet). The PTPase phosphate-binding loop and Cys-403 are in blue.

The three-dimensional structure of YopH has been solved (Stuckey et al., 1994; Su et al., 1994) revealing the presence of a catalytic domain which, despite its low level of sequence identity to the human PTP1B, still contains all of the invariant residues present in eukaryotic PTPases. Its tertiary fold is a highly twisted α/β structure with an eight-stranded β-sheet flanked by seven α-helices. Residues 403–410 form the PTPase phosphate-binding loop with the invariant Cys-403 thiol centered within the loop (Fig. 50).

EPEC TIR. A 78-kDa protein produced by enteropathogenic *E. coli* (EPEC) strains, Tir mediates the attachment of bacteria to eukaryotic cells and is essential for EPEC virulence. The Tir protein is tyrosine phosphorylated upon injection into eukaryotic cells by a type III secretion system. While in the host cell, it becomes an integral part of the eukaryotic cell membrane and functions as receptor for intimin, the major EPEC adhesin (Kenny et al., 1997). It is believed that, once in the host, Tir adopts a hairpin-like structure using its two putative transmembrane domains (TMDs) to span the host cell membrane. The region between the two TMDs constitutes the extracellular loop that functions as the intimin-binding domain. Following tyrosine

phosphorylation, the protein mediates actin nucleation, resulting in pedestal formation and triggering tyrosine phosphorylation of additional host proteins, including phospholipase C-γ. Tir is essential for EPEC virulence and was the first bacterial protein described to be tyrosine phosphorylated by host cells (Crawford and Kaper, 2002).

HELICOBACTER PYLORI CAGA. Cytotoxin-associated gene A (CagA) is an immunodominant protein produced by most virulent strains of *Helicobacter pylori*, with a size that can vary from 128 kDa to 146 kDa and which is commonly expressed in peptic ulcer disease (Covacci et al., 1993b). CagA is characterized by a central region containing an EPIYA motif, which can be repeated up to six times increasing the molecular weight of the protein. The gene is encoded within a pathogenicity island, which also encodes the type IV secretion system necessary to inject the protein into eukaryotic cells. Once injected into the host cell, the protein is tyrosine phosphorylated at the EPIYA motif by the kinase C-Src and Lyn. The signal is proportional to the number of EPIYA motives present (Stein et al., 2000). The tyrosine phosphorylated CagA (CagA-P) activates SHP-2, inactivates C-Src leading to cortactin dephosphorylation triggering a signal transduction cascade (which results in cellular scattering proliferation, a phenotype indistinguishable from that induced by the hepatocyte growth factor [HGF]).

The long-term chronic infection and the continuous stimulation increase the risk of cancer of people infected by CagA+ *H. pylori*. CagA is the first bacterial protein linked to cancer in humans and the *cagA* gene can be considered the first bacterial oncogene.

YERSINIA PESTIS YOPM. YopM is an effector protein delivered to the cytoplasm of infected cells by the type III secretion mechanism of *Yersinia pestis.* YopM is a highly acidic protein, which is essential for virulence, but whose mechanism of action is still elusive. Differently from other effectors, this toxin has been shown to accumulate not only in the cytoplasm but also in the nucleus of mammalian cells. Recently, McDonald and colleagues have found that YopM interacts with two kinases, protein kinase C-like 2 (PRK2) and ribosomal S6 protein kinase 1 (RSK1). These two kinases associate only when YopM is present, and expression of YopM in cells stimulates the activity of both kinases. These results indicate that PRK2 and RSK1 are the first intracellular targets of YopM (McDonald et al., 2003).

The X-ray structure determined for YopM has shown a modular architecture constituted by leucine-rich repeats, mainly organized in an extended β-sheet structure (Evdokimov et al., 2001; Figs. 1 [panel 28] and 51). This organization is very similar to that found for other important proteins, such as rab geranylgeranyltransferase and internalin B produced by *Listeria*.

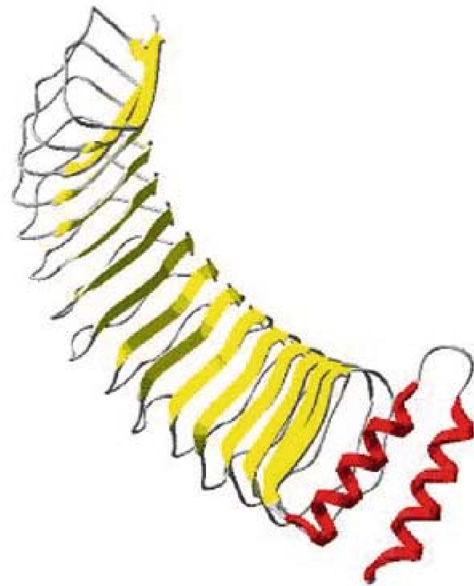

Fig. 51. Crystal structure of YopM effector protein of *Yersinia pestis*.

SALMONELLA SPTP. *Salmonella* protein tyrosine phosphatase (SptP) is an effector protein secreted by the type III secretion apparatus of *Salmonella enterica*. SptP is a modular protein composed of two functional domains, a C-terminal region with sequence similarity to *Yersinia* tyrosine phosphatase YopH, and an N-terminal domain showing homology to bacterial cytotoxins such as *Yersinia* YopE and *Pseudomonas* ExoS (Murli et al., 2001). Recently, it was demonstrated that this domain possesses strong GTPase activating domain protein (GAP) activity for Cdc42 and Rac1. The crystal structure of SptP-Rac1 complex has shown that SptP is strongly stabilized by this interaction (Stebbins and Galan, 2000; Fig. 52).

PSEUDOMONAS AERUGINOSA EXOU. Several extracellular products secreted by the *P. aeruginosa* type III secretion system are responsible for virulence. Among these, the 70-kDa protein, ExoU, is responsible for causing acute cytotoxicity in vitro and epithelial lung injury. Recent studies demonstrated that ExoU has lipase activity, and that the cytotoxicity of ExoU is dependent on its patatin-like phospholipase domain. The results suggest that ExoU requires the presence of a catalytically active site Ser(142) and that a yet unknown eukaryotic cell factor(s) is necessary for its activation (Tamura et al., 2004).

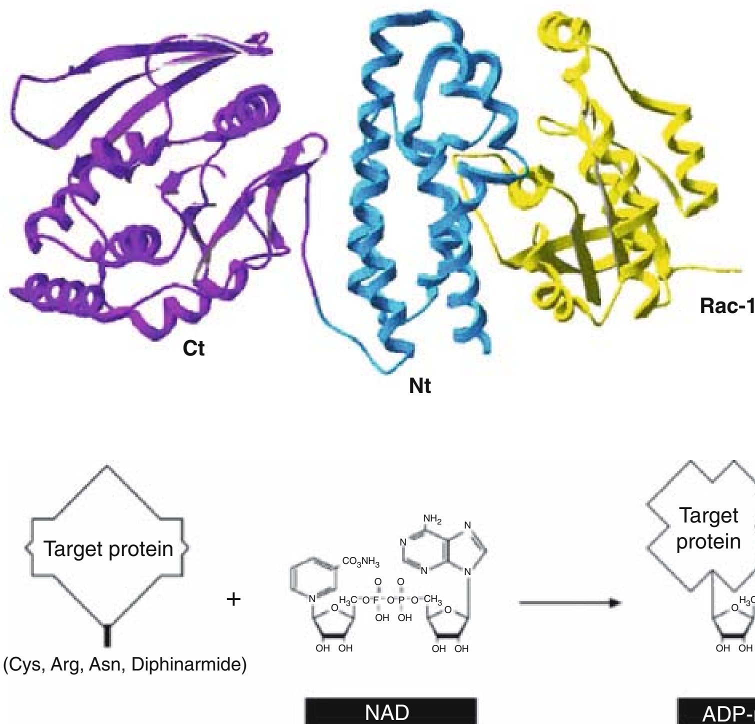

Fig. 52. Crystal structure of SptP in complex with Rac-1 (yellow). The N-term and C-term domains of SptP are colored in cyano and purple, respectively.

ADP-Ribosyltransferases: A Family of Toxins Sharing the Same Enzymatic Activity

ADP-Ribosylating Toxins: Main Features

The ADP-ribosylating toxins are a class of bacterial proteins that characterized by an enzymatic domain with ADP-ribosyltransferase activity (Ueda and Hayaishi, 1985; Althaus and Richter, 1987). During ADP-ribosylation (Fig. 53), these toxins bind NAD and transfer the ADP-ribose moiety to a specific substrate molecule, which is thus forced to undergo a dramatic functional modification. The toxic effect is totally dependent upon the enzymatic activity.

On the basis of their overall structure, ADP-ribosyltransferases can be separated into A/B toxins, binary toxins, and A-only toxins, where A is the subunit with the enzymatic activity, and B is the carrier domain involved in the recognition of the specific surface receptor and in the translocation of the toxic moiety into the eukaryotic cell. Most of the best characterized ADP-ribosylating toxins belong to the class with an A/B architecture: pertussis toxin (PT; Locht et al., 1986; Nicosia et al., 1986), cholera toxin (CT; Mekalanos et al., 1983), and *E. coli* heat-labile enterotoxin (LT; Spicer and Noble, 1982; Yamamoto et al., 1984) are typical examples of this family where the A domain (called "S1" in PT) bears the enzymatic core and the B domain is an oligomer that helps the translocation across the cell membrane; the two subunits are linked together by noncovalent bonds. The genes coding for CT and LT are highly homologous (Dallas and Falkow, 1980) and are organized into operons located on the chromosome of *Vibrio cholerae* and on a plasmid of *E. coli* (So et al., 1978).

Diphtheria toxin (DT; Pappenheimer, 1977; Collier et al., 1982) and *Pseudomonas aeruginosa* exotoxin A (PAETA; Gray et al., 1984b; Wick et al., 1990) are A/B toxins with a three-domain structure: the catalytic domain C, contained in fragment A, and the transmembrane domain T and receptor-binding domain R, both within the B subunit.

The binary (as opposed to the A/B) toxins have a fairly similar organization, but in this case the A and B domains are separately secreted in the culture supernatant where the B domain initially binds the receptor on the surface of the target cell and only then is able to bind the A subunit and help its translocation into the cytosol. Examples of this family of ADP-ribosyltransferases are the C2 toxin of *Clostridium botulinum* (Aktories et al., 1986), the iota toxin of *C. perfringens* (Perelle et al, 1995), the toxin of *C. spiroforme* (Popoff and Boquet, 1988a), the mosquitocidal toxin (MTX) of *Bacillus sphaeri-*

cus (Thanabalu et al., 1993), and the *C. difficile* transferase (Just et al., 1994).

Finally, the "A-only" toxins include Exo S of *Pseudomonas aeruginosa* (Kulich et al., 1994) and other toxins such as C3 of *Clostridium botulinum* (Nemoto et al., 1991), EDIN of *Staphylococcus aureus* (Sugai et al., 1990), and the toxins of *Bacillus cereus* (Just et al., 1995b) and of *Clostridium limosum* (Just et al., 1992). All the A-only toxins possess a still unknown mechanism of cell entry, with the notable exception of Exo S, which has been shown to be directly injected into eukaryotic cells by a specialized secretion system (Yahr et al., 1996).

With the exception of actin, all the eukaryotic proteins that are ADP-ribosylated by these toxins are GTP-binding proteins (G-proteins); these proteins are molecular switches involved in a number of essential cell functions including protein synthesis and translocation, signal transduction, cell proliferation, and vesicular trafficking (Hamm and Gilchrist, 1996).

ADP-Ribosylating Toxins: A Common Structure of the Catalytic Site

Bacterial enzymes with ADP-ribosyltransferase activity include a variety of toxins with different structural organizations; the better-represented class is that comprising proteins with an A/B structure (PAETA, DT, CT, LT and PT), where subunit A is responsible for enzymatic activity and subunit B is involved in receptor binding.

Other toxins, termed "binary toxins" (*Clostridium botulinum* toxin C2 and related proteins) are still composed of the two functional domains A and B. However, they reside on different molecules and need to interact to acquire activity. Finally, there is a group of ADP-ribosylating toxins that do not possess the receptor-binding domain B at all and are thus named "A-only toxins." This group includes *Clostridium botulinum* exoenzyme C3 and related proteins, which are unable to invade the cells, and toxins which are directly injected into eukaryotic cells (ExoS) by means of a specialized secretion apparatus.

From primary sequence analysis, it is possible to identify two main groups of homology (Fig. 54): the DT-like group, mainly composed of DT and PAETA, and the CT-like group comprising the remaining ADP-ribosyltransferases.

Although some homology is present among the members of the CT group, no overall significant and extended sequence similarity can be detected to justify the observed common mech-

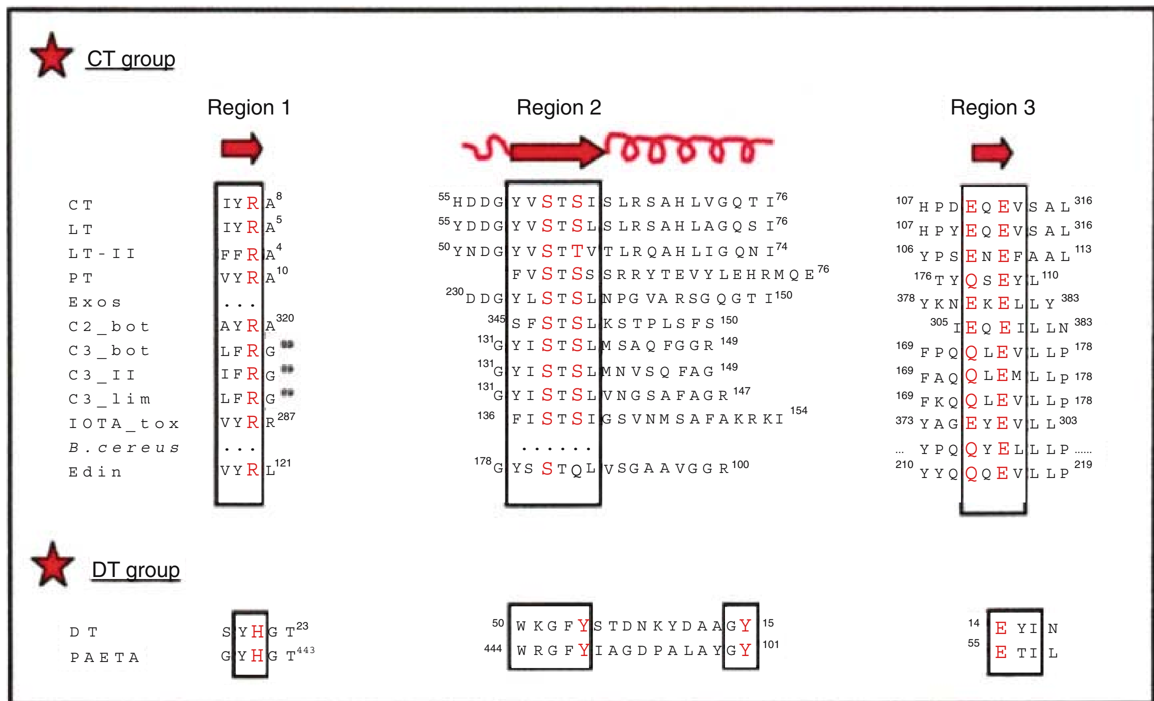

Fig. 54. Sequence alignment of protein segments containing Regions 1, 2 and 3 of bacterial ADP-ribosylating enzymes. The two groups of homology (DT-like and CT-like groups) are distinguished. Catalytic residues of Regions 1 and 3, and most relevant and conserved residues of Region 2 are colored in red; extended consensus sequences detected in the three regions are boxed, whereas other partially conserved residues are in boldface. Predicted and observed secondary structure folding is indicated for each region: Regions 1 and 3 are β-strands (arrows), while Region 2 is characterized by a short coil (solid line), followed by a β-strand and by an α-helix.

anism of catalysis; nevertheless, biochemical experiments of photoaffinity labeling and studies of site-directed mutagenesis had previously demonstrated for most of the toxins that the presence of a glutamic acid is so important for catalytic activity, even a conservative substitution with an aspartate could not be tolerated without loss or drastic decrease of toxicity (Douglas and Collier, 1987; Wilson et al., 1990; Lobet et al., 1991; Antoine et al., 1993).

On the basis of these experimental data and on the crystallographic structures which are now available for LT (Sixma et al., 1991), CT (Zhang et al., 1995), PT (Stein et al., 1994), DT (Choe et al., 1992) and PAETA (Allured et al., 1986), a common catalytic site could be identified which, despite the low level of sequence homology, is almost perfectly superimposable for all them (Domenighini et al., 1994).

In terms of tertiary structure, the active site is a cleft formed by a β-strand followed by a slanted α-helix that has a different length in the various toxins (spanning from 12 residues for DT, PAETA and LT, to 21 in the case of PT). The β-strand and the α-helix represent, respectively, the lower and upper face of the cavity in which the nicotinamide ring of NAD is anchored during the enzymatic reaction (Region 2 of Fig. 54).

Although all the toxins share this similar folding in the region of the active site, at the amino acid level, the only residue which is well conserved among all the representatives of the CT- and DT-groups is a glutamic acid (Glu-148 of DT, Glu-553 of PAETA, Glu-112 of CT and LT, and Glu-129 of PT), which corresponds to the core of Region 3 (Fig. 54). These residues retain an equivalent spatial position and orientation residing in a short β-strand flanking the external side of the cavity (Fig. 55). With the exception of the conserved glutamate, the consensus sequence generated for Region 3 differs between the two groups of toxins. In the DT family, in fact, it is composed of the catalytic Glu followed by an aromatic and a hydrophobic residue, whereas in the CT-group, the consensus can be extended to a few neighboring residues (Fig. 45). On the basis of alignment of C2-I with iota toxin and with the other ADP-ribosyltransferases, the catalytic glutamate was identified (Glu-389 of C2) and its function experimentally confirmed by site-directed mutagenesis (Barth et al., 1998). In the case of *Pseudomonas aeruginosa* Exo S, the equivalent Glu has been mapped at position 381 (Liu et al., 1996).

Another well-conserved residue is His-21 of DT that can be aligned to His-440 of PAETA, and with the conserved Arg-7 of CT and LT, and Arg-9 of PT (Burnette et al., 1988, 1991; Papini et al., 1990; Lobet et al., 1991; Han and Galloway, 1995). The segment comprising this residue is termed “Region 1” (Fig. 54). These amino acids are once again located in essentially identical positions within the active site, lying opposite to the glutamic acid on an antiparallel β-strand close to the internal face of the catalytic cleft.

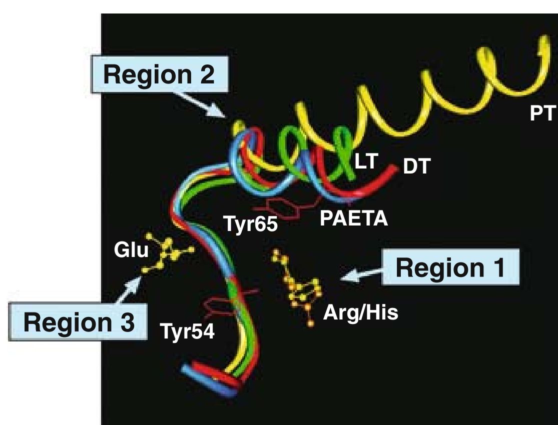

Fig. 55. Superimposition of the three-dimensional structures of the NAD-binding cavities (Region 2) of the bacterial toxins LT (green), PT (yellow), DT (red) and PAETA (blue). The catalytic residues carried by Region 1 (Arg/His) and by Region 3 (Glu) and common to the two regions of homology are shown. In addition, the two essential tyrosines of the DT group are colored in red.

Although several models have been proposed to explain the possible function of the conserved histidine/arginine of Region 1, that this residue does not play a direct role in catalysis seems now widely accepted; very likely it may have a function in maintaining the integrity of the active-site pocket upon formation of structurally stabilizing hydrogen bonds (Johnson and Nicholls, 1994). Nevertheless, mutations at the His-440 position of PAETA, though affecting the enzymatic activity, have little or no effect on NAD-binding (Han and Galloway, 1995); this suggests that His-440 may not be exactly homologous to His-21 of DT or to the arginines of the CT-group. In the case of the C2-I component of clostridial toxin C2, site-directed mutagenesis of Arg-299 induced a dramatic reduction of transferase activity, thus suggesting an equivalent role for this residue in the conformation of the active site (Perelle et al., 1995).

Region 2 includes a number of amino acids that, while maintaining the same secondary structure in both DT- and CT-families (Fig. 55), result in a major sequence difference (Fig. 54). This is mainly a structural region corresponding to the core of the active site cleft, which is devoted to the docking of NAD. The consensus sequence generated for the DT group is characterized by two conserved tyrosines spaced by ten amino acids, and located on the middle portion

of the β-strand and on the internal face of the α-helix, respectively. Tyr-54 and Tyr-65 of DT, and Tyr-470 and Tyr-481 of PAETA have been shown to play an important role in catalysis inasmuch as they anchor the nicotinamide ring during the reaction by creating a p pile of three aromatic rings which strengthen the overall binding of NAD and stabilize the complex (Carroll and Collier, 1984; Li et al., 1995). This consensus motif can be extended to four other residues which precede the first Tyr, and to a glycine residue which is located upstream of the second Tyr.

In PT, a similar role is likely to be played by Tyr-59 and Tyr-63, which have a similar spatial orientation and distance from each other. This observation is supported by the fact that in CT and LT, where the stacking interactions produced by the two tyrosines are lacking, the affinity for NAD is 1000-fold lower (Galloway and van Heyningen, 1987).

In the case of the CT-group, Region 2 is centered on a consensus core domain characterized by the motif Ser-Thr-Ser that is observed and predicted to fold in a β-strand representing the floor of the cavity. Experiments of site-directed mutagenesis have confirmed the importance of these residues in maintaining the shape of the cavity. Substitutions of Ser-61 and Ser-63 of LT with Phe and Lys, respectively, have been shown to produce nontoxic mutants (Harford et al., 1989; Fontana et al., 1995). The core sequence of Region 2 can be extended to give the more general consensus aromatic-hydrophobic-Ser-Thr-Ser-hydrophobic.

Another amino acid that has been proposed as being important in catalysis is His-35 of PT (Xu et al., 1994) located near the beginning of the β-strand which forms the floor of the cavity, in a position equivalent to that of His-44 of LT and CT (Yamashita et al., 1991); a functional homologue, His is also present in the mosquitocidal toxin SSII-1 from *Bacillus sphaericus* (Thanabalu et al., 1991) but is absent in DT and PAETA. In the 3D structure, this residue appears to be sufficiently close to the oxygen atom of the ribose ring of NAD to interact with it and increase the electrophilicity of the adjacent anomeric carbon atom. The absence of an equivalent residue in DT and PAETA again supports the idea that the two groups of toxins perform the same enzymatic activity in a slightly different fashion.

An additional feature that is common to all ADP-ribosylating toxins is the need for a conformational rearrangement to achieve enzymatic activity.

In the native structure, in fact, the NAD-binding site of LT and CT is obstructed by a loop (amino acids 47–56) that needs to be displaced to obtain a functional NAD-binding cavity. A functionally homologous region is also present in PT where the loop comprises residues 199–207. In the case of DT, where the crystallographic data of the complex are available, the observation that the active-site loop consisting of amino acids 39–46 changes structure upon NAD-binding, suggests that these residues may be important for the recognition of the ADP-ribose acceptor substrate, EF-2 (Weiss et al., 1995; Bell and Eisenberg, 1996).

The recent publication of the crystallographic data of the DT-NAD complex, and the presence of common features within all ADP-ribosylating toxins, permits speculation on a possible common mechanism of catalysis (Fig. 56). The best hypothesis is that NAD enters the cavity, which is then made available for the recognition of the

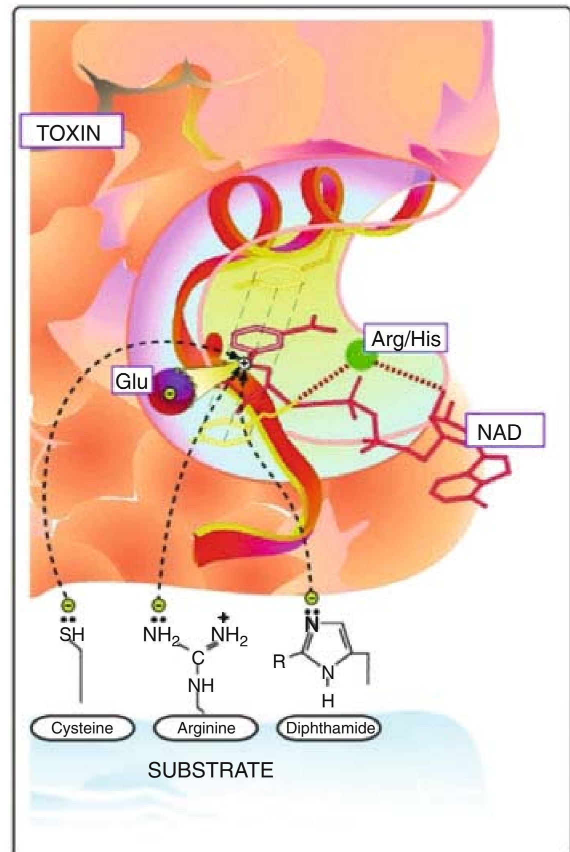

Fig. 56. Schematic representation of a possible common mechanism of catalysis: the nicotinamide adenine dinucleotide (NAD) molecule (red) is docked inside the cavity by means of stacking interactions provided by the two aromatic rings (yellow) that protrude from the scaffold of Region 2. The catalytic glutamic acid (purple) and its possible interactions with the acceptor residues of the various substrates are also reported. The Arg/His residue (green) provides stabilizing interactions with the backbone of the cavity and seems to be also responsible for the correct positioning of NAD inside the pocket.

substrate, upon displacement of the mobile loop. Then, NAD docks at the bottom of the pocket where a small residue (the conserved serine in Region 2 of the CT-group, the threonine-56 of DT, and the alanine-472 of PAETA) is required to allow good positioning. The nicotinamide moiety of NAD is then blocked in a suitable position by means of stacking interactions provided by a couple of aromatic rings (Tyr-54 and Tyr-65 of DT, Tyr-470 and Tyr-481 of PAETA, and possibly, Tyr-59 and Tyr-63 of PT). In this context the conserved arginine/histidine might display its key role in maintaining the correct shape of the active site pocket via hydrogen bonds formed with the backbone of the structure and possibly one with the ribose moiety. The enzymatic reaction is then catalyzed by the essential glutamic acid, which is likely to stabilize a positively charged oxocarbonium intermediate of NAD, to favor its subsequent interaction with the nucleophilic residue of the incoming substrate (diphthamide in the case of DT and PAETA, arginine in the case of LT and CT, and cysteine in the case of PT).

Novel ADP-Ribosylating Toxins Detected by Genome-Mining

With the advent of the Genomic Era, identification of bacterial factors possibly involved in virulence is an easier challenge. In fact, given the vast amount of information that we now possess on toxins—including sequence data—and thanks to the growing number of sequenced bacterial genomes, it is possible to proceed by homology criteria to predict novel members of important classes of bacterial toxins.

Several examples exist where computer-based methodologies have been instrumental to the identification of novel potential bacterial toxins in sequenced genomes. Among them, we will mention here the case of mono ADP-ribosyltransferases.

Mono-ADP-ribosyltransferases (mADPRTs) constitute a class of potent toxins in bacteria, which generally play an important role in the pathogenesis of related microorganisms. Despite the poor overall conservation at the primary structure level, the catalytic subunits of these toxins show a remarkable similarity within the enzymatic cavity, so that these portions of the proteins are quite well conserved.

For these reasons, and encouraged by the availability of a growing number of sequenced bacterial genomes, a series of studies have been directed towards the computer-based identification of novel members of this family of enzymes by means of sequence-homology criteria in finished and unfinished genome sequences. As a result, more than twenty novel putative ADP-ribosyltransferases have been identified both in Gram-positive and Gram-negative organisms, including five from *Pseudomonas syringae*, five from *Burkholderia cepacea*, two from *Enterococcus faecalis*, and one each from *Salmonella typhi*, *Streptococcus pyogenes*, *Mycoplasma pneumoniae*, *Streptomyces coelicolor*, *Bacillus halodurans* and *Vibrio parahaemolyticus* (Pallen et al., 2001). With the exception of the protein detected in *Salmonella*, which is adjacent to an ORF protein similar to the S2 subunit of pertussis toxin, all the other genome-derived putative ADPRTs lack a predicted translocation domain. So far, none of these bacterial proteins has been tested either for their ADP-ribosyltransferase activity or for the capability of entering eukaryotic cells; however, sequence data indicate a possible role of these proteins in the pathogenesis of the corresponding microorganisms. Very recently, a new protein has been added to the list of ADP-ribosyltransferases detected by computer analysis (Masignani et al., 2003). This novel factor has been identified by means of primary and secondary structure analysis in the genomic sequence of a virulent isolate of *Neisseria meningitidis* and has been named "NarE" (*Neisseria* ADP-ribosylating enzyme). As predicted by "in silico" studies, biochemical analysis has demonstrated that NarE is capable of transferring an ADP-ribose moiety to a synthetic substrate.

Toxins with Unknown Mechanism of Action

See Tables 1 and 2 for a summary of the principal features of toxins described in this section.

The zonula occludens toxin (Zot) is produced by bacteriophages present in toxinogenic strains of *Vibrio cholerae*. Zot is a single polypeptide chain of 44.8 kDa, which localizes in the outer membranes. After internal cleavage, a carboxy-terminal fragment of 12 kDa is excreted and this is probably responsible for the biologic effect. Zot has the ability to reversibly alter the tight junctions of intestinal epithelium, thus facilitating the passage of macromolecules through mucosal barriers (Di Pierro et al., 2001). Zot has also been shown to act as mucosal adjuvant and to induce protective immune response in the animal model (Marinaro et al., 2003).

Hemolysin BL (HBL) is an enterotoxin produced by *B. cereus*, which is composed of three proteins (B, L1 and L2), each with a molecular mass of 40 kDa, and whose corresponding genes are located on the same operon. HBL has hemolytic as well as dermonecrotic and vascular permeability activities and is able to cause fluid accumulation in ligated rabbit ileal loops (Beecher et al., 1997; Beecher and Wong, 2000).

The bile-salt hydrolase (BSH) is a protein elaborated by *Listeria monocytogenes*, which is absent from the genome of the nonpathogenic *L. innocua*. The *bsh* gene encodes an intracellular enzyme and is positively regulated by PrfA, the transcriptional activator of known *L. monocytogenes* virulence genes (Dussurget et al., 2002). Furthermore, *bsh* deletion mutants show reduced virulence and liver colonization, thus demonstrating that BSH is a toxin specifically involved in the intestinal and hepatic phases of listeriosis.

CHAPTER 1.29

The Metabolic Pathways of Biodegradation

LAWRENCE P. WACKETT

Introduction

History

The decay (biodegradation) of organic matter has been a part of life throughout human history. When the organic matter was a person's food, clothing or dwelling, biodegradation was no doubt very undesirable. In this context, humans have, through most of their history, sought to prevent or, more practically, slow down biodegradation. Animal hides were treated with tannins to crosslink proteins and prevent their degradation. Food was dried, salted or pickled to prevent microbial growth, and hence, spoilage.

Though solutions to biodegradation were found, the underlying causes of the phenomenon were less clear. But no doubt, correlations were made by direct observation of macroscopic microorganisms, typically fungi, on rotting material. People could see wood rot fungi on decaying wood or hyphal masses on bread. And, in fact, some of the foundations for the science of microbiology were established with macroscopic fungi. Micheli showed that fungi now known as *Mucor*, *Botrytis* and *Aspergillis* could be cultivated on the surfaces of fresh-cut melon, quince and pear (Bull and Slater, 1982). Micheli serially transferred the fungi, thus initiating the practice of isolating, maintaining and characterizing specific genera of microorganisms. He also observed that different fungal genera showed preferences for certain fruits used as the cultivating medium, thus establishing the idea of selective culture.

In fact, these observations became entwined with the controversy over spontaneous generation because macroscopic fungal growth derived from microscopic fungal spores. Many interpreted proliferation of microscopic life, biodegrading different organic material, as the spontaneous generation of life from non-life. Louis Pasteur is generally credited with demonstrating most convincingly that the elimination of all bacterial and fungal contamination would prevent spoilage (Clarke, 1985). It was recognized from the work of Pasteur, Tyndall and others that bacteria are ubiquitous and difficult to remove from any given environment.

In a broad sense, virtually all prokaryotes participate in biodegradation. Prokaryotes decompose (biodegrade) organic molecules as part of their need to derive chemical energy to make ATP or to produce metabolic intermediates. In the early twentieth century, Beijerinck (1901) and Winogradsky (1890) contributed to the current idea that prokaryotes are important in the recycling of carbon, nitrogen, sulfur and other elements on a global scale. For example, we now know that 10^{15} grams of methane gas are produced annually by anaerobic Archaea known as "methanogens" and most of the biogenic methane is oxidized by aerobic methanotrophic bacteria (Lipscomb, 1994). This constitutes one small part of the global carbon cycle. If one considers that over ten million organic compounds are known, many of which are theoretically biodegradable, the magnitude of these cycles is enormous.

Scope of Biodegradation in the Modern World

Although naturally occurring compounds biodegrade on a massive scale, the biodegradation of synthetic compounds attracts more interest. Over the last century, some synthetic, industrial chemicals have been shown to exert toxic or carcinogenic effects on humans. For example, factory workers in aniline dye (Bulbulyan et al., 1995) and vinyl chloride polymer industries (Langard et al., 2000) were developing certain cancers at relatively high rates and the epidemiological studies were confirmed in animals. From these observations has emerged the awareness that, with increasing world population, more effort must be expended to maintain clean water, air and soil.

Problems of human exposure to potentially harmful organic compounds can be handled in different ways. For example, certain chemicals may be banned, manufacturing processes can be made cleaner, or wastes can be treated at the

source or in the open environment. In fact, all of those are occurring. And prokaryotes are increasingly being exploited for treating wastes, either in the manufacturing facility or for remediation of chemical spills or releases. Some high profile applications have been published (Harkness et al., 1993; Roberts et al., 1993; Strong et al., 2000; Wagner-Dobler et al., 2000) but in fact, most of these applications are quietly in use at manufacturing facilities all around the globe.

The University of Minnesota Biocatalysis/Biodegradation Database

To facilitate the use of microbial catalysis, either for developing cleaner manufacturing or treating wastes, we have developed the University of Minnesota Biocatalysis/Biodegradation Database (UM-BBD) (umbbd.ahc.umn.edu).

The UM-BBD provides information on microbial biocatalytic non-intermediary metabolism (i.e., reactions generally associated with biodegradation of synthetic industrial chemicals; Ellis et al., 2000). This metabolism is considered non-intermediary because it is restricted to only a few prokaryotes. It is these non-intermediary metabolic reactions that biotransform compounds and funnel them into the central metabolism of most prokaryotes. For example, only a limited number of prokaryotes can catabolize nitrobenzene, as shown, but many organisms can metabolize the open chain carboxylic acid products of those initial catabolic, or biodegradative, reactions. Intermediary metabolism databases such as KEGG, the Kyoto Encyclopedia of Genes and Genomes, which includes the LIGAND database of enzymes and reactions (Goto et al., 2000), depict this process. For example, one of the metabolic pathways for nitrobenzene is shown on the UM-BBD to yield 2-aminomuconate semialdehyde and the metabolic fate of this latter compound is shown on KEGG (http://www.genome.ad.jp).

It is important to study the pathways of biodegradation to insure that more highly toxic compounds are not generated as the result of microbial metabolism. This concern was raised by the recent observation that the widely used industrial solvent trichloroethylene undergoes reductive dechlorination, generating vinyl chloride as an intermediate (Vogel and McCarty, 1985). See umbbd.ahc.umn.edu/tce2/tce2_map.html for more information about this pathway. Because it is a strong human carcinogen, vinyl chloride is a greater environmental problem than trichloroethylene (Maltoni and Cotti, 1988). So it is not enough to know that a pollutant is disappearing from a given environment; regulatory agencies increasingly need to account for its complete environmental fate.

Methodological Advances Relevant to Biodegradation

Enrichment Culture

In the late 1800s, microbiologists largely focused on the bacteria that cause disease in humans. Isolating the disease-causing bacteria directly from an infected tissue was relatively easy because the infection was largely a monoculture. Thus, plating onto a rich medium might well yield a single organism that could be studied for its disease-causing properties.

This contrasted with the situation in a natural soil or water where thousands of different bacteria might well be present in a gram of material. In this case, culturing on a nonselective laboratory medium would yield a complex mixture, difficult to analyze for one particular metabolic trait. Thus, one needed to enrich the mixture to obtain one or a few different types of bacteria. This would simplify the system so that it could be studied productively.

As pioneered by the Dutch microbiologist Beijerinck (1901), the enrichment culture technique allowed selective cultivation of one or more bacterial strains obtained from complex environmental mixtures. Assume that one wanted to study the ability of microorganisms in a particular soil to metabolize a given compound. The compound would then be added as the sole carbon, nitrogen or sulfur source to a liquid laboratory medium lacking one of those major elements but containing the others and trace nutrients. The medium would then be inoculated with soil or water, perhaps adding as many as 10^{11} bacteria. If only a few of the bacteria are able to metabolize the compound to meet their nutritional needs, they will reproduce, or be enriched, selectively. The numbers of these specific bacteria will increase markedly in comparison to what is present in the native soil or water where alternative carbon, nitrogen or sulfur sources are present. With repeated transfer of the enriched microbial mixture into fresh growth medium, the numbers of the preferred bacterium will sometimes increase to the extent that it can be readily isolated.

The preferred bacterium is one that can metabolize the given compound, utilize the trace nutrients provided, grow at the temperature used in the laboratory and reproduce quickly. In this context, one may not necessarily obtain the bacterium most prevalent in the original sampled environment. For this reason, some people have

criticized the practice of obtaining and characterizing prokaryotes in pure culture as unsuited to yielding insights into what occurs in nature. But think of the difficulties inherent in trying to learn the details of biodegradation in a complex milieu such as soil. The metabolism of a particular compound might be inferred if it is disappearing from soil, but one has to rule out abiotic reactions in soil and soil can be difficult to sterilize. If the compound is available in a radiolabelled form, an accumulating intermediate may be obtained if it is stable in soil. This may or may not yield insights into metabolic pathways. But one would be hard-pressed to learn about the other metabolites, the enzymes, genes and specific microorganisms involved. In short, without obtaining pure cultures, one could learn whether a compound is metabolized but little about the molecular details.

The use of prokaryote pure cultures, many of which have been obtained by enrichment culture, has been instrumental in the identification of the many novel enzymes catalyzing metabolic transformations that drive the carbon, nitrogen and sulfur cycles of Earth. In turn, the corresponding genes have been identified; at first these were identified singly, and now wholesale as the result of genome sequencing efforts, which focused initially on prokaryotes because of their relatively small genome size. Without the development of enrichment culture, we would know far less about the Earth's biological cycles, the catalytic diversity of the planet and microbial phylogenetic diversity.

Anaerobic Culturing Methods and Biodegradation

Most of our early knowledge on biodegradation derived from studies on aerobic or facultative bacteria. This reflected the comparative ease of studying aerobic versus anaerobic bacteria. Anaerobic conditions were fairly easy to maintain with mixed-cultures because facultative organisms would consume oxygen and thus allow strict anaerobes to survive. Obtaining strict anaerobes in pure culture, and elucidating the novel biochemical reactions they catalyze, required the development of specialized techniques (Barker, 1940; Hungate, 1985).

Several decades ago, microbiologists used such techniques as roll-tubes to cultivate strictly anaerobic prokaryotes such as methanogenic bacteria. More recently, people routinely began using crimp-sealed, septum-plugged bottles for liquid cultures and putting Petri plates into anaerobic chambers containing an inert gas such as helium or argon. The latter can routinely be maintained at oxygen levels of around one part per million when coupled with oxygen-scrubbers for the gas mixtures and catalyst cartridges inside the anaerobic chamber.

Anaerobic biodegradation is also difficult to study in another context. Anaerobic enrichment cultures may initially show very long lag phases, perhaps six months or one year, before significant biodegradation occurs. Upon repeated transfer, the lag phase often shortens continually. Still, many years may be required to achieve significantly rapid rates of biodegradation and those may never approach the rates of comparable aerobic biodegradation. In most cases, a definitive explanation for the lag phase phenomenon is lacking. It is these kinds of impediments which have skewed the focus of laboratory studies in biodegradation toward the fast-growing aerobic prokaryotes such as *Pseudomonas* species, which can be grown overnight with simple equipment and typically yield high cell densities.

Despite this, anaerobes offer rewards to those who persevere by providing for the discovery of the most novel biochemical reactions on Earth. Some of these reactions have recently been elucidated. For example, bacteria are now known to catabolize toluene anaerobically. They initiate attack on the benzylic carbon via a radical mechanism that generates a new carbon-carbon bond to form benzylsuccinate as the first metabolite (Leuthner et al., 1998). Others, such as the anaerobic formation of methane from long-chain alkanes (Zengler et al., 1999), remain obscure biochemically.

Analytical Chemistry

Chemical methods for analyzing organic compounds have improved enormously since the late 1800s when use of enrichment culture methods began. Thus, obtaining pure cultures has gone hand in hand with new methods for analyzing the intermediates and products of their metabolism. Thus, one might anticipate a biodegradative metabolic pathway based on chemical logic, obtain authentic chemical standards, and screen for the presence of such compounds in growth cultures of the microbial isolate. But how does one screen for the compound(s)?

Chromatography, coupled to the use of authentically synthesized standard compounds, has been a powerful method for studying biodegradation over the last century, and it remains so today. There have been big advances in the science of chromatographic separations. A century ago, thin-layer chromatography (TLC) was state of the art. Later, gas chromatography (GC) provided better resolution and most recently, high pressure liquid chromatography (HPLC) gives

excellent resolution and the ability to capture and further analyze compounds.

Identification of compounds in complex mixtures is being aided by new developments in mass spectrometry (MS), which may be coupled with isotopic labelling for additional power. Similarly, with high-field nuclear magnetic resonance (NMR) spectroscopy, and the use of specifically labelled ^{13}C-compounds becoming increasingly available, it is now feasible to monitor metabolism in situ (Sauer et al., 1999). This, in turn, may lead to a revolution in environmental microbiology, in which systems more resembling natural systems can be analyzed with respect to biodegradation.

Whole Genome Sequencing and Analysis

Biodegradative genes have been identified, usually by transferring the DNA containing a specific gene(s) from a pure culture environmental isolate into *Escherichia coli* for sequencing and functional expression. With a substantial set of genes available, it is becoming routine to screen soils for the presence of homologous genes that might be involved in identical or similar biodegradative reactions. This gives insights into the environmental prevalence of certain biodegradative genes.

In the last several years, DNA sequencing techniques have advanced to the point that we can readily sequence entire prokaryote genomes (Nelson et al., 2000). With appropriate annotation techniques, this can provide insight into the metabolic pathways encoded by the genes. Theoretically, an organism's entire network of metabolism can be deduced. In practice, deducing metabolism is an imperfect task. Consider that the complete genomic DNA sequence of *Escherichia coli*, the most intensely studied biochemical entity on Earth, yielded 38% of the coding regions having unknown function (Blattner et al., 1997). If there are gaps in the metabolic map of *E. coli*, there will be many more as we proceed to sequence the genomic DNA of soil isolates important in biodegradation. Despite this caveat, it is exciting to contemplate the explosive increase in obtaining complete genome sequences for an expanding array of prokaryotes. This will spur a resurgence of interest in comparative biochemistry, with an attendant interest in new "exotic" genes. I predict that a significant number of the newly discovered gene functions in soil Eubacteria will be involved in the biodegradation of organic compounds. This will enhance interest in biodegradation and microbial biocatalysis, in general, as the era of functional genomics comes into full swing.

The Prokaryotes of Biodegradation

Our current perspective on the microorganisms of biodegradation derives largely from enrichment culture methods, isolating pure cultures and studying the individual reactions of biodegradation. Table 1 shows the list of prokaryotes and compounds they degrade; the biodegradative pathways each of them initiate are depicted in the UM-BBD. An analogous microorganism index can be found at umbbd.ahc.umn.edu (UM-BBD).

The UM-BBD Microorganism Index has links for the entries containing both genus and species names to the corresponding entries on websites maintained by the American Type Culture Collection (ATCC) or the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ). Another excellent web resource that deals with microorganisms which are important in biodegradation is the Biodegradative Strain Database (BSD) bsd.cme.msu.edu maintained at Michigan State University by John Urbance, Jim Cole and Jim Tiedje.

The BSD microorganism listings, in turn, link to http://www.cme.msu.edu (Ribosomal RNA Database) and to biodegradative pathways maintained on the UM-BBD.

Several trends are apparent from perusing the data in Table 1. First, biodegradative capabilities are widespread phylogenically within the *Proteobacteria*, high G+C Gram-positive bacteria, and *Flavobacterium* in the *Cytophageles*-green sulfur bacteria. As discussed in the section above, this reflects the facile transfer of genes, especially those that might be contained on plasmids or flanked by transposable elements.

Second, there are several genera of bacteria, which have emerged repeatedly as having diverse catabolism, particularly with starting compounds we think of as metabolically unusual, such as synthetic industrially relevant organic compounds. The latter include herbicides, insecticides, industrial solvents and synthetic intermediates. As illustrated in Table 1, the following genera are particularly well represented: *Arthrobacter*, *Burkholderia*, *Pseudomonas* and *Rhodococcus*. The caveat to these observations is that we have largely depicted biodegradation pathways catalyzed by prokaryotes, which have been obtained in pure culture via enrichment culture. Thus, we have selectively depicted microorganisms that grow well under conditions typically used for enrichment culture and the maintenance of pure culture isolates in the laboratory. These microbial strains may only reflect some fraction, perhaps a small fraction, of the prokaryotes that actively carry out biodegradation in the soils and waters of the Earth. The complete genome sequencing of both pure culture bacteria

Table 1. Prokaryote genera identified in biodegradation and the compounds they metabolize.[a]

Prokaryote genus	Compound undergoing biodegradation
Acetobacterium	Triethanolamine
	Carbon tetrachloride
Achromobacter	2,4-Dichlorobenzoate
Acinetobacter	Cyclohexanol
	2-Chloro-*N*-isopropylacetanilide
Actinomycetes	2,4,6-Trinitrotoluene (TNT)
Aeromonas	Phenanthrene
Agrobacterium	Glyphosate
	1,2,3-Tribromopropane
	Atrazine
Alcaligenes	2,4-Dichlorobenzoate
	2,4-Dichlorophenoxyacetic acid (2,4-D)
	2,4-Dichlorobenzoate
	2-Aminobenzenesulfonate
	Toluene-4-sulfonate
	Atrazine
Ancylobacter	1,2-Dichloroethane
	2,4-Dichlorophenoxyacetic acid
	4-Nitrophenol
	1,3-Dichloro-2-propanol
	Tyrosine
	2,4-Dichlorobenzoate
	Glyphosate
	Parathion
Arthrobacter	2,4-Dichlorophenoxyacetic acid (2,4-D)
	4-Nitrophenol
	Octamethylcyclotetrasiloxane
	Iprodione
	1,3-Dichloro-2-propanol
	Fluorene
	Tyrosine
	2-4-Dichlorobenzoate
	Glyphosate
	Methyl *tert*-butyl ether
	Nicotine
	2-Aminobenzoate
	Phenanthrene
	Parathion
Azoarcus	Benzoate
	Toluene
Azotobacter	2,4-Dichlorophenoxyacetic acid (2,4-D)
	Thiocyanate
Bacillus	2,4,6-Trinitrotoluene
	2-Phenylacetaldoxime
Beijerinckia	Xylene
Brevibacterium	Dibenzofuran
	Nitrobenzene
Brevundimonas	Parathion
Burkholderia	2,4-Dichlorophenoxyacetic acid (2,4-D)
	1,2,4-Trichlorobenzene
	Phthalates
	Benzoate
	Pentachlorophenol
	2,4,5-Trichlorophenoxyacetic acid (2,4,5-T)
	3-Chloroacrylic acid
	Toluene
	Trichloroethylene
	o-Xylene
Clavibacter	2,4-Dichlorobenzoate
	Atrazine
Clostridium	2,4,6-Trirtotoluene (TNT)
	Phenol
Chelatobacter	Nitrilotriacetate

Table 1. *Continued*

Prokaryote genus	Compound undergoing biodegradation
Comamonas	Nirtobenzene
	3-Methylquinoline
	Phthalates
	Toluene-4-sulfonate
Corynebacterium	1,3-Dichloro-2-propanol
	2,4-Dichlorobenzoate
Dehalobacter	Tetrachloroethene
Dehalococcoides	Tetrachloroethene
Dehalospirillum	Tetrachloroethene
Desulfitobacterium	Tetrachloroethene
Desulfobacterium	Carbon tetrachloride
Desulfovibrio	2,4,6-Trinitrotoluene (TNT)
Enterobacter	Glyphosate
	1,1,1-Trichloro-2,2-*bis*-(4-chlorophenyl)ethane (DDT)
	Pentaerythritol tetranitrate
Escherichia	3-Phenylpropionate
	Arsonoacetate
	Phenylmercuric chloride
Eubacterium	Gallate
Exophiala	Styrene
Fiavobacterium	Bromoxynil
	2,4-Dichlorophenoxyacetic acid (2,4-D)
	Glyphosate
	Parathion
	Pentachlorophenol
Hydrogenophaga	4-Carboxy-4′-sulfoazobenzene
Hyphomicrobium	Dichloromethane
	Dimethyl sulfoxide
Klebsiella	Benzonitrile
	Bromoxynil
	Acetylene
	1,1,1-Trichloro-2,2-*bis*-(4′-chlorophenyl)ethane (DDT)
Lactobacillus	2,4,6-Trinitrotoluene (TNT)
Methanobacterium	Carbon tetrachloride
Methanosarcina	Tetrachloroethene
	Carbon tetrachloride
Methylobacterium	Dichloromethane
	Methyl *tert*-butyl ether
Methylococcus	Thiocyanate
Methylophilus	Dichloromethane
Methylosinus	Trichloroethylene
Methylosulfonomonas	Methanesulfonic Acid
Moorella	Carbon tetrachloride
Moraxella	4-Nitrophenol
	2-Chloro-*N*-isopropylacetanilide
	Naphthalenesulfonates
Mycobacterium	Methyl *tert*-butyl ether
Myrothecium	Cyanamide
Neurospora	2-Nitropropane
Nirtosomonas	Methyl fluoride
	Dimethyl ether
Nocaradia	Methyl *tert*-butyl ether
	Parathion
	Methyl ethyl ketone
Pelobacter	Acetylene
Proteus	1,1,1-Trichloro-2,2-*bis*-(4-chlorophenyl)ethane (DDT)
Pseudomonas	Acrylonitrile
	2-Aminobenzoate
	1,3-Dichloropropene
	Dichloromethane
	Dimethyl sulfoxide
	Carbazole

(continued)

and genomic DNA from soil, the so-called "soil metagenome" (Rondon et al., 2000), may help address this question by helping unveil what percentage of the total genome of a given organism functions in non-intermediary catabolic metabolism. In another example, culture-independent molecular methods were used to analyze microbial communities in an aquifer contaminated with hydrocarbons and chlorinated solvents in which active biodegradation was occurring (Dojka et al., 1998). In that study, 16S rRNA sequences were determined for 21 bacterial members of the consortium, belonging to four recently described divisions of bacteria for which there are no cultivated representatives. Moreover, two particularly abundant 16S rRNA sequence types were implicated in the overall hydrocarbon metabolism. They were members of the genera *Syntrophus* and *Methanosaeta*, both of which were proposed to participate in aceticlastic methanogenesis at the end of the catabolic food chain.

In parallel with molecular non-culture methods, the well-established methods of enrichment culture are more frequently being applied under anaerobic and other nonstandard conditions in an effort to obtain novel microbial types. This approach also suggests that biodegradative capabilities are more widespread in the microbial world than has been appreciated by some. For example, halophiles have been identified which metabolize nitroarenes, and members of the *Heliobacterium* group are known that catabolize polychlorinated biphenyls (PCBs) and chlorophenols (Table 2). These and other recent observations are expanding the taxonomic range of bacteria that catabolize environmental pollutants. Further experiments are likely to expand this further.

Themes in Biodegradation Pathways

Occurrence of Similar Pathways in Divergent Prokaryotes

Gene transfer amongst prokaryotes is quite facile, and our appreciation of this seems to be increasing all the time. The genes most prone to transfer are those conferring survival advantage only under specialized conditions, the so-called "dispensible genes." Principal among those

Table 2. Microbes recently identified as organic pollutant biodegraders, but falling outside of the prokaryotic groupings typically isolated for studies on biodegradation.

Prokaryote[a]	Taxonomic group	Substrate	Reference

[a]These bacteria do not belong to the following groups: Proteobacteria, and high and low G+C Gram-positive bacteria.

genes are ones conferring antibiotic resistance, heavy metal resistance or new catabolic activities. These genes are commonly found on plasmids. Many catabolic plasmids have been shown to have a broad host-range and transfer by conjugation in the absence of helper plasmids. Thus, the genes, and the metabolic functions they encode, can show up in diverse prokaryotes. An example will best serve to illustrate this point.

In 1995, a *Pseudomonas* species, denoted strain ADP, was isolated from an enrichment culture in which the herbicide atrazine was supplied as the sole source of nitrogen (Mandelbaum et al., 1995). Subsequent studies over the ensuing three years elucidated the atrazine catabolic pathway and yielded the DNA sequences of the genes encoding the first three metabolic steps (Fig. 1). During the same period, other laboratories isolated atrazine-catabolizing prokaryotes using different enrichment and isolation conditions (Bouquard et al., 1997; de Souza et al., 1998a; de Souza et al., 1998b; Radosevich et al., 1995; Struthers et al., 1998). The bacteria were subjected to taxonomic determination and found to be members of the following genera, respectively: *Rhizobium*, *Agrobacterium*, *Ralstonia* and *Clavibacteria*. In our laboratory, DNA from each of the distinct atrazine-catabolizing bacteria was prepared (de Souza et al., 1998b). They were each found to contain genes with more than 99% sequence identity to the atrazine genes from the original *Pseudomonas* sp. ADP isolate. This occurred despite the fact that the organisms were isolated independently in different regions of Earth, by different groups and under different conditions. These observations are consistent with a facile transfer of the atrazine-catabolic genes amongst soil prokaryotes.

In another example, illustrated by perusing the UM-BBD, the same organic compound is metabolized by different genera of bacteria via

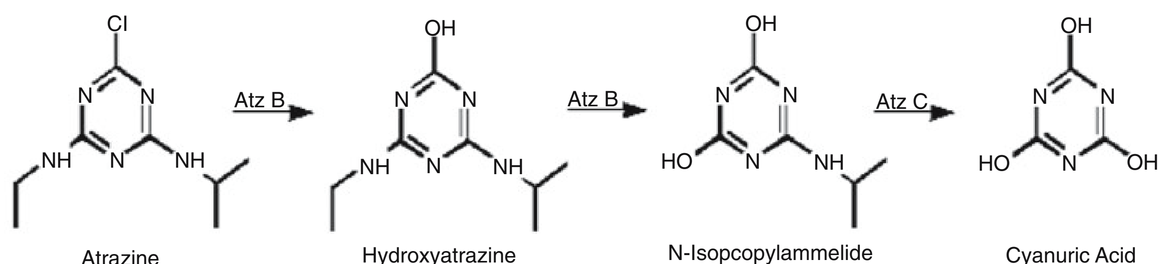

Fig. 1. Catabolic pathway for the catabolism of atrazine in *Pseudomonas* sp. ADP.

different intermediates. Examples of starting compounds are:

{atrazine
{fluorene
{glyphosate
{nitrobenzene
{4-nitrophenol
{parathion
{phenanthrene
{styrene
{toluene
{2,4,6-trinitrotoluene

Common Themes in Catabolic Pathways

Although some catabolic pathways are widespread, there are some correlations between certain types of metabolism and the prokaryotic group catalyzing those reactions. This can be attributed to the compatibility between the catabolic reactions and the core metabolic pathways that the catabolic intermediates feed into. This is particularly well illustrated for chemical compounds which are composed of a single carbon atom or which are readily metabolized to C-1 fragments.

Figure 2 shows the C-1 meta-pathway, which is also depicted in the [{umbbd.ahc.umn.edu/c1/c1_map.html}{UM-BBD}]. At the core of the map are the oxidative and reductive parts of the C-1 metabolic cycle, which is important on a global scale as discussed previously. Anaerobic Archaea (known as methanogens) catalyze the reductive reactions that transform carbon dioxide to methane. These organisms are important members of certain anaerobic consortia involved in the biodegradation of complex organic matter such as cellulosic wastes. Methanogens occupy the end of the anaerobic food chain in the overall biodegradative process.

A class of prokaryotes called “methanotrophs” (Fig. 2) carry out the oxidative reactions leading from methane, the most reduced C-1 compound, to carbon dioxide, the most oxidized. Some C-1 oxidizing organisms (known as “methylotrophs”) cannot oxidize methane to methanol, but can carry out the next three oxidative reactions. Methane is a common natural product; it is the main constituent of natural gas. Moreover, data suggests that a majority of the methane generated in lake sediments is oxidized in higher, aerobic levels of the lake by methanotrophs, and thus methane never enters the atmosphere.

Methanotrophic and methylotrophic metabolism may be expanded to include a set of oxidative, hydrolytic or thiolytic reactions whereby simple organic structures can be transformed to the methanotrophic intermediates methanol, formaldehyde or formate (Fig. 2). Some of these

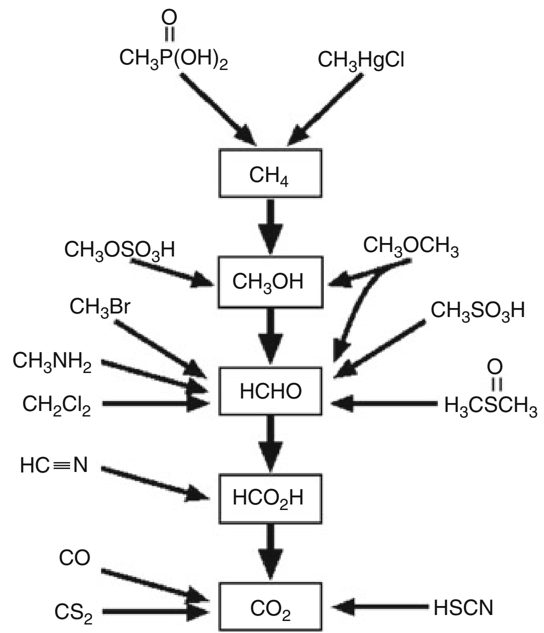

Fig. 2. Catabolism of organic compounds containing one carbon atom that funnel into the central intermediates of methanotrophy: methane, methanol, formaldehyde and formate.

compounds are natural products; for example dimethyl sulfide, methylamine and methyl chloride. Others are predominantly the products of organic synthesis: dichloromethane, dimethylether and methyl fluoride. Regardless of their origin, these compounds are readily transformable to methanotrophic metabolic intermediates and thus some methanotrophs will grow on them as their sole source of carbon and energy. This catabolic metabolism is not universal, however. Only some small subset of the total set of methanotrophs and methylotrophs will grow on a given compound shown at the periphery of Fig. 2. But methanotrophs and methylotrophs are common in nature and thus dichloromethane, dimethylether and methyl fluoride are generally thought of as being fairly biodegradable.

Another common theme is seen in the transformation of the commercially important BTEX compounds (i.e., benzene, toluene, ethylbenzene and xylenes). They are clustered because of their co-occurrence in environmental contamination stemming from spillage of petroleum materials. Because BTEX compounds are structurally analogous to each other, there are commonalities in their metabolism by prokaryotes. Anaerobic metabolism of BTEX compounds has been studied only more recently, and the biochemical basis of the biodegradation reactions is now being revealed. The aerobic metabolism of BTEX compounds is much better studied. For example, see Fig. 3 and (umbbd.ahc.umn.edu/BTEX/

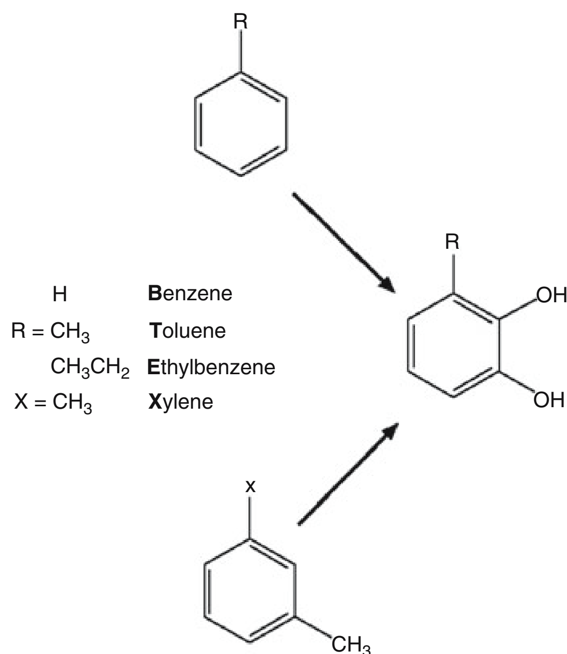

Fig. 3. Convergence of aerobic pathways for BTEX compounds leads to a catechol intermediate.

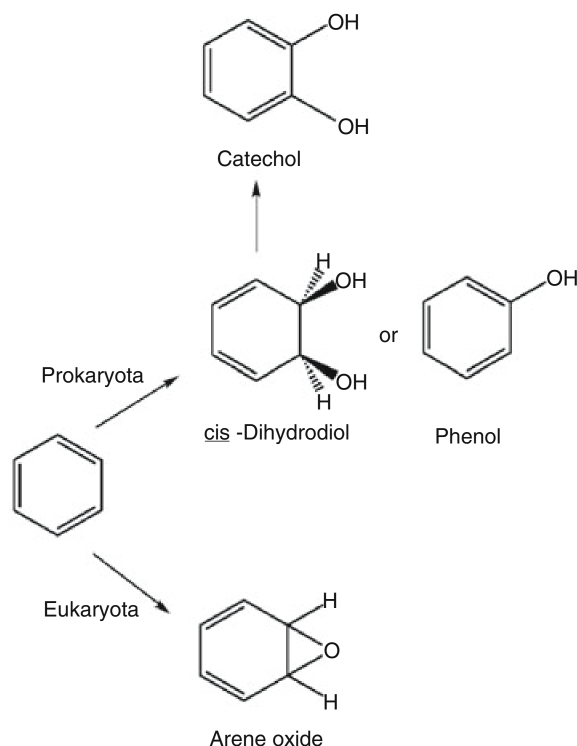

Fig. 4. Divergence in the catabolism of aromatic compounds by Prokaryota and Eukaryota.

BTEX_map.html#aerobic). Almost invariably, oxygenase enzymes initiate the metabolism to produce ring cis-dihydrodiols, phenols, benzyl alcohols and ultimately catechols, which undergo ring cleavage. These alcohol products are all more activated than their aromatic hydrocarbon starting compounds. There are multiple pathways possible but all of them produce catechol intermediates. To follow all known aerobic prokaryotic metabolic pathways for each of the BTEX compounds, follow the links:

{Benzene
{Toluene
{Ethylbenzene
{*o*-Xylene
{*m*-Xylene
{*p*-Xylene

The metabolic strategy for BTEX compounds used by aerobic prokaryotes differs from that used by aerobic eukaryotic organisms such as fungi (Cerniglia et al., 1978) and mammals (Jerina et al., 1968). The latter group also uses oxygenase enzymes to attack resonance-stabilized aromatic hydrocarbons. However, the initial products of the oxygenase-catalyzed reactions are often arene oxides (Fig. 4). Aromatic alcohols are detected but are shown to largely arise from spontaneous isomerization of the arene oxides and are not direct enzyme products. This contrasts with the prokaryote aromatic ring monooxygenation reactions in which the phenol product is detected directly. For example, with toluene catabolism by *Burkholderia cepacia* G4, the initial reaction product is 2-hydroxytoluene, or o-cresol, exclusively. There was no evidence for the intermediate formation of toluene 2,3-epoxide, which would have isomerized to a mixture of o-cresol and m-cresol. The data do not rule out that an epoxide is an enzyme-bound intermediate that undergoes a controlled isomerization on the enzyme surface. This would be advantageous to the organism, as epoxides are reactive electrophiles and can alkylate proteins and other molecules in the cell. So a high-flux metabolic pathway that produces such a reactive species might well be selected against during evolution. In contrast, the mammalian metabolism of BTEX compounds is largely low flux metabolism, to scavenge stray hydrocarbons that may enter the body. Other enzymes further metabolize the epoxide products to make intermediates that are excreted from the animal. A nonspecific detoxification metabolism such as this may work best when it proceeds through an initial arene oxide intermediate.

Acknowledgments. I thank the many talented colleagues with whom I have collaborated on metabolic pathways of biodegradation. Special thanks go to Professor Lynda Ellis for her meticulous work on the University of Minnesota Bio-

catalysis/Biodegradation Database, making it a resource that has been worth accessing millions of times by researchers around the world.

CHAPTER 1.30

Haloalkaliphilic Sulfur-Oxidizing Bacteria

DIMITRY YU. SOROKIN, HORIA BANCIU, LESLEY A. ROBERTSON AND J. GIJS KUENEN

Introduction

Chemolithoautotrophic sulfur-oxidizing bacteria (SOB) play an important role in the element cycling in natural and man-made environments because of their extremely high capacity to transform various sulfur compounds and their contribution to secondary production of organic matter. They are widely distributed in various habitats, associating primarily with sulfide-oxygen interface layers, where they successfully compete with chemical sulfide oxidation by oxygen. Energetically, the reaction of complete oxidation of sulfide or thiosulfate to sulfate (8 electrons) is among the most attractive for chemosynthesis, and not surprisingly, sulfur oxidizers can be found in many different groups of prokaryotes. Currently, lithoautotrophic sulfur bacteria are mostly found among the proteobacteria (alpha, beta, gamma and epsilon subdivision; The Colorless Sulfur Bacteria in the second edition; Kuenen and Robertson, 1992; Kelly and Wood, 2000). The currently known exceptions outside the proteobacteria are among the Gram-positive bacteria (*Sulfobacillus*), Crenarchae (*Sulfolobus*), and deep lineages (*Aquificalis*; The Chemolithotrophic Prokaryotes in this Volume).

According to their response to pH, the known sulfur-oxidizing species include acidophiles (optimum pH <6) and neutrophiles (optimum pH 7–8). The former have received much attention because of their important role in acidic metal leaching processes (Pronk et al., 1990). The neutrophiles are more common in natural environments, dominating in fresh and marine waters, and in waste treatment plants (Robertson and Kuenen, 1992). However, until recently, very little was known about the possibility of sulfur oxidation at pH above 9. Several years ago, the authors of this chapter became interested in alkaliphilic sulfur oxidation, as this would offer new options for removing H_2S from industrial wastes. An analysis of the literature available on bacterial life at high pH clearly pointed to soda lakes as the best possible natural habitat for such bacteria.

Soda Lakes as a Unique Habitat

Soda lakes represent a specific type of salt lake that contains an alkaline sodium carbonate-bicarbonate fraction among its dominant salts. Like most of the other inland salt lakes, the soda lakes are located in areas with dry climate conditions that facilitate gradual salt accumulation in depressions. The main mechanism of their genesis is the leaching of salt from sodium-rich rocks by high CO_2-containing groundwaters low in Ca and Mg content (Eugster, 1970; Jones et al., 1977). The presence of sodium carbonate creates a uniquely stable natural alkaline habitat, although the total salt content and the sodium carbonate fraction in the soda lakes vary within a broad range, depending on the local conditions. Although a high pH can occur in several other habitats, such as low-salt alkaline springs or microzones of ammonification in soils, the alkaline conditions in these habitats are not stable. For this a high buffering capacity (alkalinity) is necessary. In soda lakes, the presence of sodium carbonate ensures that the high-to-extremely high pH (usually around 9.5–10.5) is maintained. Thus, the soda lakes seem to be the only natural environment with appropriate conditions for the stable development of obligately alkaliphilic microorganisms, which usually grow optimally at a pH around 10. Indeed, as will be described later in the text, the alkaliphilic sulfur bacteria cannot be isolated from the neutral saline lakes or from alkaline, but not sufficiently buffered, freshwater springs.

The well-known hypersaline soda lakes are located in the East African Rift Valley in Kenya and Tanzania (Bogoria, Magadi, Natron), the Libyan Desert in Egypt (Wadi Natrun), California, and Nevada. These lakes were extensively studied by geologists because of their deposits of soda minerals. Another area where saline alkaline lakes are numerous is Central Asia, where the Transbaikal dry steppe stretches from southeast Siberia to northeast China. Here much smaller, shallow, and usually less saline lakes predominate, with a relatively unstable water regi-

Fig. 1. Typical small soda lake (Kulunda steppe, Altai, Russia).

men and a freezing winter period causing frequent and substantial fluctuations of the water salinity and temperature. A typical example of such a lake is presented in Fig. 1.

Recent microbiological analysis of the soda lakes by both traditional and culture-independent molecular techniques revealed the remarkable fact that, despite the doubly extreme conditions of salt and pH, fully structured and active microbial communities are present, even in saturated alkaline brines (Imhoff et al., 1979; Grant and Tindall, 1986; Jones et al., 1998; Zavarzin et al., 1999; Zavarzin and Zhilina, 2000; Humayoun et al., 2003; Sorokin et al., 2004a). Among them, the main functional groups of anaerobes, such as fermentative, acetogenic, methanogenic and sulfate-reducing bacteria, represented by unique haloalkaliphilic species, have recently been isolated and identified (Zavarzin et al., 1999). The microbial sulfur cycle seems to be one of the most active cycles observed in the soda lakes, with anaerobic phototrophic purple sulfur bacteria and sulfate-reducing alkaliphiles as the main participants (Isachenko, 1951; Imhoff et al., 1979; Zhilina et al., 1997; Gorlenko et al., 1999). However, no information is available regarding the presence of chemolithotrophic sulfur bacteria in soda lakes.

The Investigated Area and the Samples

Surface sediment samples from all the main areas of soda lakes, as described above, were obtained for the study of sulfur bacteria, either from colleagues or during our own expeditions. The main characteristics of the samples are given in Table 1. The sampled lakes can be divided into three categories: 1) low-saline, small and shallow steppe lakes of the Transbaikal area; 2) moderately saline soda lakes of the Kulunda steppe and Mono Lake in California; and 3) hypersaline alkaline brines of Africa and south Kulunda, in areas with significant deposits of the trona mineral $NaHCO_3{\cdot}Na_2CO_3{\cdot}2H_2O$). Most of the lakes belong to the carbonate-chloride-sulfate type. In a few, sodium chloride is the dominant salt, e.g., the hypersaline, alkaline Stamp Lake in the Kulunda steppe of Altai in Russia.

Enrichment, Isolation and Cultivation of Haloalkaliphilic Sulfur-Oxidizing Bacteria

Following the published examples (Tindall, 1988; Horikoshi, 1991), our first attempts to enrich for alkaliphilic SOB using soda lake sediments as the inoculum were made using medium containing 20 mM thiosulfate as energy source, 10 g liter^{-1} of sodium carbonate, 0–50 g liter^{-1} NaCl, 0.5 g liter^{-1} NH_4Cl, and 1 g liter^{-1} of K_2HPO_4. Sodium carbonate was added after sterilization and the pH was adjusted to 10 by HCl. Some growth was observed on this medium using inoculum from the Hadyn soda lake in Tuva (Table 1), but the resulting cultures were not stable and, in particular, a drop in pH below 9 was followed by heavy sulfur precipitation. An optimization study resulted in the formulation of a mineral base medium, containing 0.6–4.0 M Na^+ (Table 2). For the inocula from the hypersaline lakes where NaCl was the dominant salt (Wadi Natrun), the amount of sodium carbonate in the base medium was reduced by substituting NaCl. The medium contained a minimum amount of sodium carbonate and bicarbonate, equivalent to 0.5 M Na^+, and NaCl equivalent to 0.1–3.5 M Na^+. Such mineral bases provided sufficient alkalinity so that even when a dense sulfur-oxidizing culture producing high amounts of sulfuric acid from thiosulfate developed, the pH of the

medium remained at 9.5–10.2. Potassium nitrate provided the source of nitrogen and potassium. In addition, in some cases, ammonium chloride was added after sterilization at low concentration (<3 mM) to ensure enrichment of species unable to utilize nitrate. The low concentration is dictated by the almost complete conversion of ammonium to highly toxic, free ammonia at pH 10. After sterilization, the alkaline mineral base medium was supplied with 20–80 mM of thiosulfate, 1 ml per liter of trace elements solution (Pfennig and Lippert, 1966) and 1 mM $MgCl_2 \cdot 6H_2O$. The latter formed a soluble basic magnesium carbonate complex [$Mg_2(OH)_2CO_3$]. The use of this medium provided a basis for the successful enrichment and isolation of many strains of obligately alkaliphilic sulfur bacteria with varying degrees of salt tolerance. The preparation of solid alkaline media is complicated by the chemical instability of agar at high pH at temperatures above 50°C and by the low solubility of sodium carbonate. Therefore, the preparation of solid medium involves mixing equal volumes of sterile 4% agar and mineral base

medium in double strength at 50°C. Obviously, the maximum soda concentration in the final solid medium is then limited to 2 M Na^+.

The isolation strategy was based on the following procedure. Positive enrichment cultures were subcultured several times with 1:100 inocula to obtain a stable active culture. This stable culture was serially diluted and the successive dilutions were plated. Sometimes, especially when the low-salt medium (0.6 M Na^+) was used, it was necessary to make serial dilutions immediately without preliminary enrichment because of the high grazing activity of protozoa. This approach was also useful in combining enrichment, enumeration and isolation in a single procedure. Moreover, it later appeared that the efficiency of colony formation of many sulfur bacteria isolated from soda lakes was very low in comparison with their growth in liquid media. Therefore, in some cases the extinction dilution approach was used to isolate the dominant species growing in liquid culture. Growth was monitored by measuringthiosulfate consumption (iodimetric titration in presence of acetic acid) and by microscopy. Some variations in the selective enrichment strategy, such as the use of sulfide and thiocyanate instead of thiosulfate as substrate or nitrogen oxides instead of oxygen as electron acceptors will be discussed below.

Distribution and Diversity of Haloalkaliphilic Chemolithoautotrophic Sulfur-Oxidizing Bacteria

Enrichment on low-salt alkaline medium under fully aerobic conditions using inocula from the Siberian low-salt soda lakes gave the first indication of the presence of aerobic sulfur bacteria capable of stable growth at pH 10 (Sorokin et al., 2000). Two pure cultures, strains AL 2 and AL 3, isolated from lake Hadyn in Tuva (Russia) became the reference type strains for two different groups of the haloalkaliphilic SOB most often isolated from soda lakes. Subsequent investigation of the samples from different geographic locations (Table 1) resulted in the isolation of more than 100 strains of obligately alkaliphilic sulfur bacteria. Positive enrichment cultures were only obtained from the lakes with pH >9 and not from the neutral salt lakes with pH 7–8.5. Combining the enrichment and serial dilution procedures yielded sulfur bacteria (10^3–10^8 cells/cm^3 of sediment) capable of growth at pH 10 and a salt concentration of 0.5–4 M total Na^+. The cultivation and maintenance of the haloalkaliphilic sulfur bacteria is not complicated by acid production because of the extremely high buffering capacity of the soda-based medium. For example, full oxidation of 80 mM thiosulfate (20 g/liter) resulted in a pH drop from 10 to 9.2 even at the lowest buffering capacity used (0.6 M total Na^+). The dense liquid cultures of haloalkaliphilic sulfur bacteria obtained after utilization of 40–80 mM thiosulfate remained viable during storage at 4°C for 3–6 months. Most of the strains also survived freeze-drying and deep-freezing storage in 10% glycerol.

The soda lake isolates grouped into two distinct clusters and created a basis for the description of two new genera of Gammaproteobacteria—*Thioalkalimicrobium* and *Thioalkalivibrio* (Sorokin et al., 2001c; Sorokin et al., 2002a). The former is closely affiliated with the neutrophilic sulfur bacteria *Thiomicrospira*, while the genus *Thioalkalivibrio* is affiliated with the purple sulfur bacteria of the family Ectothiorhodospiraceae (Fig. 2), which includes both halophilic and haloalkaliphilic species (Imhoff and Süling, 1996).

In general, the *Thioalkalimicrobium* group dominated in enrichment cultures from the low-saline Siberian soda lakes. *Thioalkalimicrobium* also could be enriched from the more saline soda lakes in Central Asia and Africa, but only from fresh samples. *Thioalkalivibrio* dominated in enrichments from highly mineralized lakes and from old samples and was always dominant when the enrichment medium contained >1.5 M total Na^+. Therefore the most important selective force favoring survival of alkaliphilic sulfur bacteria in soda lakes appeared to be the salt concentration (Table 3).

Ecophysiology of Aerobic Haloalkaliphilic Sulfur-Oxidizing Bacteria

The main properties of the two groups of haloalkaliphilic sulfur bacteria are presented in Tables 4 and 5. The *Thioalkalimicrobium* group is represented by highly specialized, low-salt tolerant, fast-growing and low-yield strains with extremely high sulfide- and thiosulfate-oxidizing activity. In contrast, the *Thioalkalivibrio* group is more physiologically diverse and accommodates slowly growing organisms with more efficient substrate conversion. These are, in general, more salt-tolerant, with many strains able to grow in saturated soda brines. This group uniformly synthesized a membrane-bound yellow pigment not found in the low-salt tolerant *Thioalkalivibrio* strains. This pigment is a 23-carbon polyene compound with a structure unlike that of any known bacterial pigments (Takaichi et al., 2004). Although its complete formula and function is not yet completely understood, it is clearly

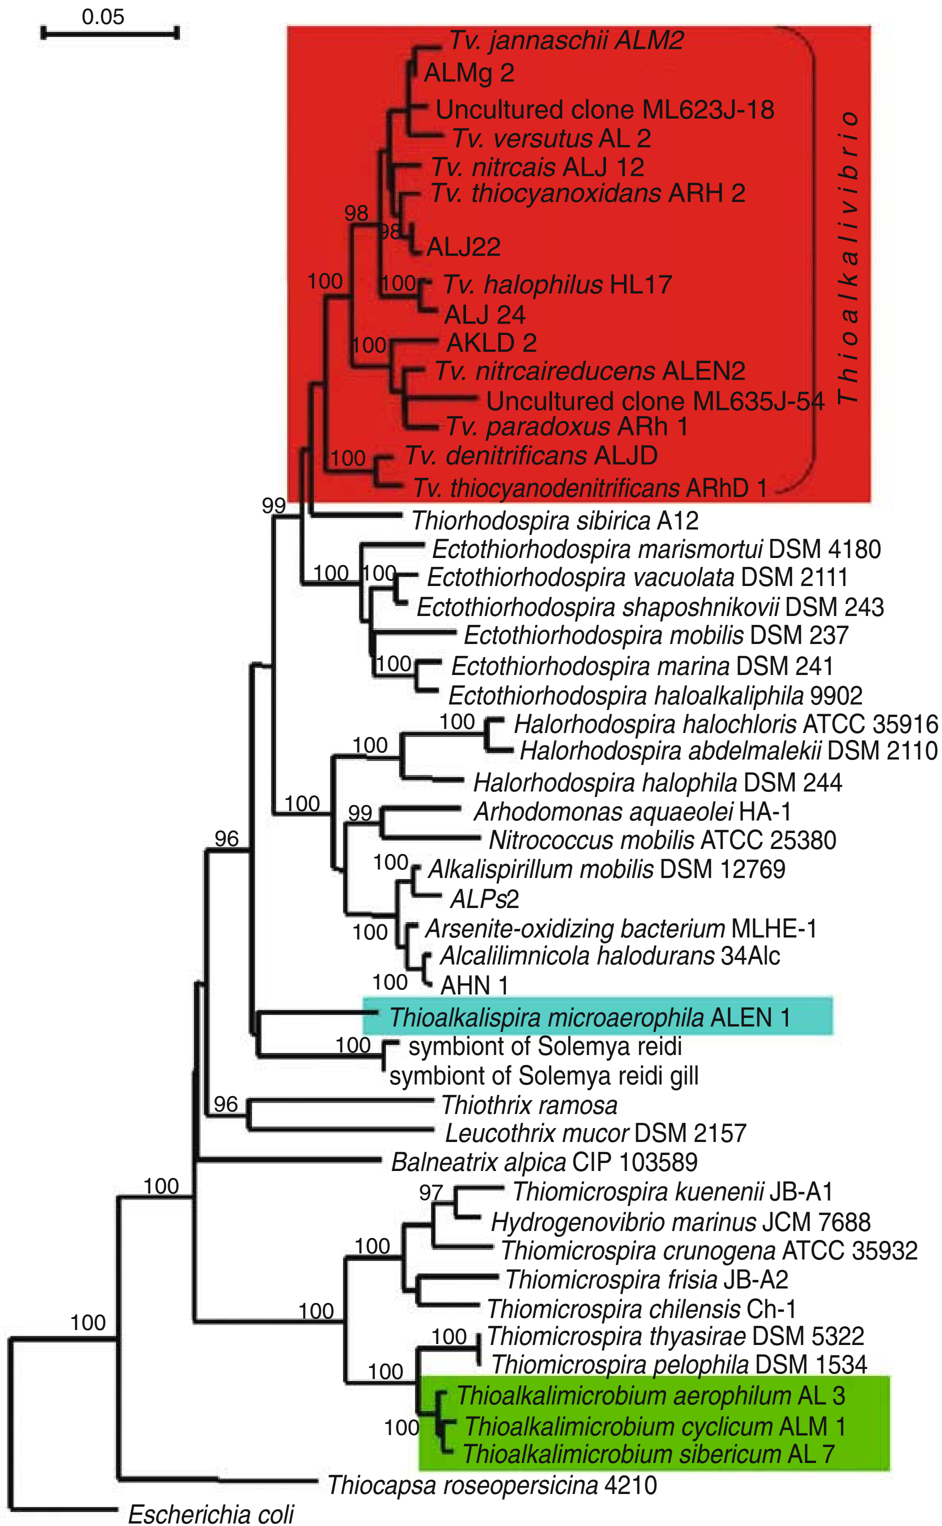

Fig. 2. Phylogenetic tree demonstrating position of the three new genera of haloalkaliphilic sulfur oxidizing bacteria isolated from the soda lakes. Numbers on the branches indicates bootstrap values (only the highest values are included). essential for the functioning of these bacteria at extremely high salt and high pH conditions. The typical cell morphology of these bacteria is shown in Figs. 3 and 4.

Soda lake sulfur oxidizers differ from all other known sulfur bacteria because of their ability to grow and oxidize sulfur compounds at pH >9. The sodium carbonate-bicarbonate buffer appears to be the most appropriate mineral environment for such bacteria, providing both stable alkalinity and a source of carbon. The buffering capacity of the carbonate system is maximal at pH 9.5–10.2. This pH range was suitable for batch cultivation. However, to explore a realistic pattern of the pH-dependence of growth, continuous cultivation under pH-controlled conditions was necessary (Sorokin et al., 2003b). This investigation confirmed the obligately alkaliphilic

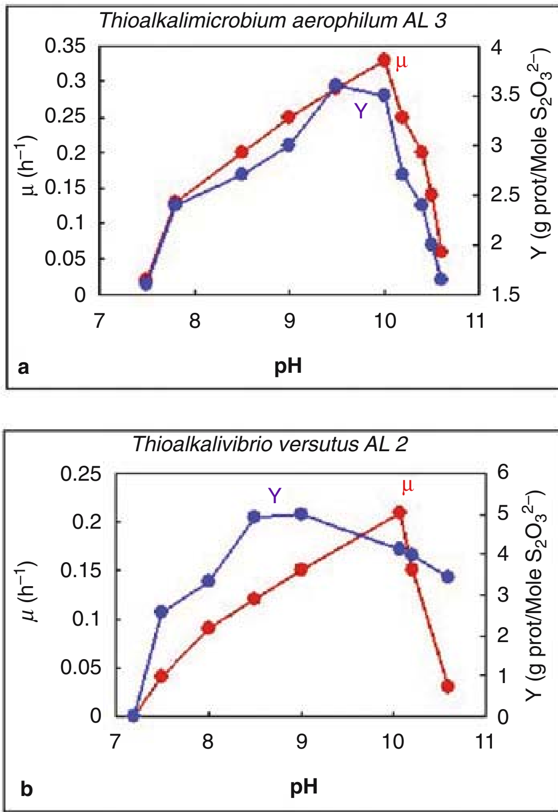

Fig. 5. pH profiles for growth rate (μ) and growth yield (Y) of alkaliphilic sulfur oxidizing bacteria measured in pH-controlled thiosulfate-limited continuous culture (0.6 M total Na^+).

The background Cl^- concentration in (a) was 0.1 M, the background carbonate concentration in (b) was 0.5 M of total Na^+. Tm, *Thioalkalimicrobium*; Tv_1, low-salt tolerant *Thioalkalivibrio*; Tv_2, extremely natronotolerant *Thioalkalivibrio*; Tv3, extremely natrono*philic Thioalkalivibrio*; ALJ 15, Kenyan natronophilic *Thioalkalivibrio* strain; and ALE 10, ALE 20 and ALE 28, haloalkaliphilic *Thioalkalivibrio* isolates from Wadi Natrun in Egypt.

nature of the representative strains of *Thioalkalimicrobium* and *Thioalkalivibrio* and, for the first time, demonstrated that chemolithoautotrophic bacteria are capable of stable growth at pH >10 (Fig. 5). Both the growth rate and the growth yield of the soda lake isolates were maximum at pH values around 10. The maximum pH for growth registered in chemostat cultures was 10.6. On the other hand, the pH for maximum respiratory activity was at least 11.0 (Fig. 6). The failure to grow at pH >10.6 might be explained by an anabolic constraint, most probably the unavailability of carbon in the form of CO_3^{-2}, as has been suggested previously for alkaliphilic cyanobacteria (Kaplan et al., 1982).

Another important environmental factor in the selection of a particular type of SOB is the total salt content. Although all strains isolated from the soda lakes belonged to the haloalkaliphiles, three different subgroups can be identified on the basis of their salt tolerance and requirement (Fig. 7a). 1) All *Thioalkalimicrobium* and some of the *Thioalkalivibrio* isolates

belong to a moderately salt tolerant type, being able to grow in up to 1.2–1.5 M total Na^+. They originated mostly from the hyposaline lakes and were isolated on medium containing a low salt concentration. 2) The biggest group of the *Thioalkalivibrio* isolates was extremely salt-tolerant and able to grow in saturated soda brines (4–4.5 M Na^+). However, most of them grew optimally at moderate salt concentrations (0.5–1 M Na^+). 3) The third type consisting of only a few isolates was the true extreme halophiles that cannot grow at salt concentrations below 1 M Na^+. All extremely salt tolerant *Thioalkalivibrio* strains were isolated from hypersaline soda lakes, mostly in Mongolia (Sorokin et al., 2004a) and Egypt (our unpublished results). The extreme halophiles were also the most thermotolerant, some being able to grow up to 50°C. Continuous culture experiments with one of these isolates, *Thioalkalivibrio versutus* ALJ 15, demonstrated its excellent adaptation to doubly extreme conditions (Banciu et al., 2004b). Its growth rate and growth yield in soda brine at pH 10 and 4 M Na^+ were only 3 and 2 times lower, respectively, than found at 0.6 M Na^+. Not only the total sodium concentration was important for optimal growth and activity, but also the anionic composition of the sodium salts. In particular, the ratio of carbonates to Cl^- was critical. Most of the extremely salt tolerant *Thioalkalivibrio* (isolates from Kenyan, Mongolian and Kulunda soda lakes) were able to grow in pure soda brines without Cl^-, but for maximum growth they required 0.1–0.5 M Cl^-. Higher concentrations of Cl^- inhibited growth, resulting in complete inhibition at >2 M Cl^-. In contrast, the strains isolated from the NaCl-dominated Wadi Natrun lakes, had an obligate requirement for 0.5 M Cl^-, grew optimally at 1–2 M Cl^- and still grew at 3–3.5 M NaCl in the presence of only 0.5 M Na^+ and carbonate to maintain an alkaline pH and provide the carbon source (Fig. 7b). The latter strains can be regarded as true haloalkaliphiles, while the dominant subgroup of the extremely salt-tolerant *Thioalkalivibrio* strains does not fit this term. We suggest calling such bacteria "natronophiles"—the soda-loving bacteria.

Under low-salt conditions, both *Thioalkalimicrobium* and *Thioalkalivibrio* representatives developed in some of the enrichment cultures. Competition experiments in thiosulfate-limited continuous culture at low salt and high pH conditions demonstrated that *Thioalkalivibrio* has a competitive advantage over *Thioalkalimicrobium* at extremely low dilution rates ($<0.02\ h^{-1}$), which in fact is close to starvation. This was confirmed in a direct starvation experiment, which proved that *Thioalkalivibrio* survives much better than *Thioalkalimicrobium* (Sorokin et al., 2003b). Furthermore, it was found that starvation induced the formation of thermotolerant cyst-like resting cells in both groups, but with different efficiency. *Thioalkalivibrio* formed several orders of magnitude more cyst-like cells as compared to *Thioalkalimicrobium* , but the cysts of the latter were of "higher quality," e.g., more resistant to stress conditions (Loiko et al., 2003).

Overall, the data suggest that the two groups of sulfur-oxidizing bacteria dominating in soda lakes exhibit different ecological strategies. The *Thioalkalimicrobium* group fits to the *r*-strategy—fast but inefficient growth, and advantage probably taken of short periods of substrate excess and wet weather. The *Thioalkalivibrio* group fits more the *K*-strategy—slow but efficient growth, relatively larger metabolic diversity, and broader adaptation to the extreme environment of saline soda lakes. Such organisms are usually more persistent in the environment. Recently, evidence from a culture-independent molecular ecology approach, including denaturing gradient gel electrophoresis and cloning, confirmed the ubiquitous presence of the *Thioalkalivibrio* group in various soda lakes (Baumgarte, 2003; Humayoun et al., 2003; Rees et al., 2004; G. Muyzer, unpublished results).

Sulfur Oxidation Mechanisms in Haloalkaliphilic Bacteria

Significant difference in the rates of oxidation of various sulfur compounds (Table 5) and production of different intermediates during thiosulfate oxidation suggest different pathways of sulfur metabolism in *Thioalkalimicrobium* and *Thioalkalivibrio*. The former never produced elemental sulfur during oxidation of thiosulfate, unless severe oxygen limitation was applied, while most of the *Thioalkalivibrio* strains formed extracellular or intracellular sulfur from thiosulfate during growth in liquid and solid culture media. Moreover, *Thioalkalimicrobium* was virtually unable to oxidize external elemental sulfur in contrast to *Thioalkalivibrio*, which converted it to sulfate. Another important difference between these two groups is sulfite metabolism. Sulfite is considered a key intermediate in sulfur oxidation pathways of many sulfur bacteria (Kappler and Dahl, 2001). The *Thioalkalimicrobium* strains released up to 3 mM sulfite into the medium during batch growth with thiosulfate (Sorokin et al., 2000), but it was never detected in the cultures of *Thioalkalivibrio*. Furthermore, neither of the *Thioalkalimicrobium* strains studied was able to oxidize external sulfite even at micromo-

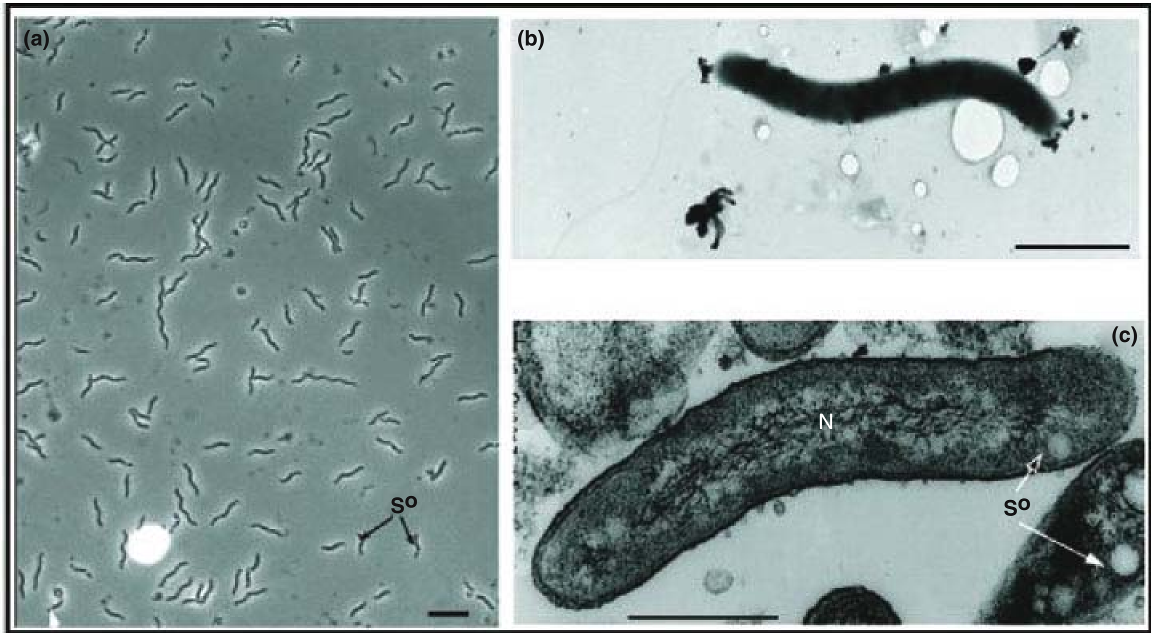

Fig. 8. Cell morphology of *Thioalkalispira microaerophila*. (a) – phase contrast, bar = 10 µm; (b) – total electron microphotograph, bar = 1 µm; (c) — thin section, bar = 0.5 µm; So — sulfur globules; N-nucleoide.

lar concentrations, while some of the *Thioalkalivibrio* isolates did. Sulfite oxidation correlated with the presence of sulfite dehydrogenase activity (AMP-independent type), which was uniformly detected in *Thioalkalivibrio* but not *Thioalkalimicrobium* (Sorokin et al., 2001c). Among the other activities, sulfide dehydrogenase (cytochrome *c*-dependent), SQR (sulfide-quinone reductase), and thiosulfate reductase activities have been detected in both groups. Cytochrome *c*-dependent sulfide dehydrogenase was purified from *Thioalkalimicrobium aerophilum* AL 3 (Sorokin et al., 1998). In contrast to the type of flavocytochrome *c*-containing enzymes found in chemotrophic sulfur bacteria (Visser et al., 1997), the enzyme from the alkaliphiles only contained cytochrome *c* as a cofactor. The presence of a second, quinone-dependent, sulfide dehydrogenase in alkaliphiles implies that more than one mechanism of sulfide oxidation in sulfur bacteria might exist in a single organism. Overall, the data so far suggest that in *Thioalkalimicrobium* the oxidation pathway of reduced sulfur is probably similar to the one proposed for facultatively autotrophic *Paracoccus* species, i.e., complete oxidation of the sulfane atom by a multienzyme complex without releasing free intermediates (Friedrich et al., 2001). In contrast, *Thioalkalivibrio* seems to employ different mechanism with formation and consumption of free sulfur intermediates, such as elemental sulfur and sulfite, more common for neutrophilic sulfur-oxidizing bacteria (Kelly et al., 1997).

Specific Physiological Subgroups of the Soda Lake Sulfur-Oxidizing Bacteria

Microaerophiles

Apart from the numerous aerobic alkaliphilic SOB discussed above, several different strains have been obtained from the soda lakes using specific enrichment conditions. Micro-oxic conditions with thiosulfate as substrate and a low salt content favored the enrichment and isolation of an obligately microaerophilic spirillum (Fig. 8). This has been described as a new genus and species *Thioalkalispira microaerophila* (Sorokin et al., 2002b)—another haloalkaliphilic gammaproteobacterium (Fig. 2). A micro-oxic enrichment with sulfide as substrate, using a gradient culture technique (Nelson et al., 1986) resulted in the isolation of five obligately microaerophilic *Thioalkalivibrio* strains, most of which had a relatively low DNA homology (<40%) with the aerobic strains. The common property of these species is the formation of multiple intracellular sulfur globules during growth with sulfide or thiosulfate.

Denitrification

Anoxic enrichments from the soda lake sediments, with thiosulfate or sulfide as the electron donor and nitrate as the electron acceptor, resulted in the domination of partial denitrifiers,

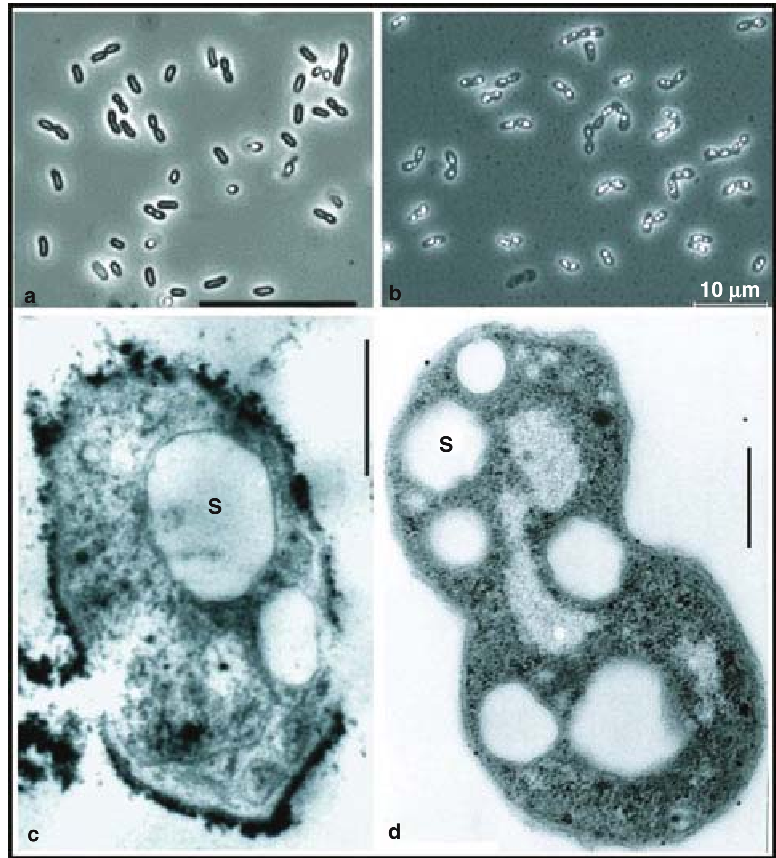

Fig. 9. Cell morphology of coccoid Thioalkalivibrio. (a,c) — *Tv. paradoxus*, (b,d) — *Tv. nitratireducens*; (a–b) — phase contrast, (c–d) — thin sections; S — intracellular sulfur globules; bars: a = 20 µm, b = 10 µm; c–d = 0.5 µm.

mostly reducing nitrate only to nitrite with copious sulfur formation. Only one enrichment culture from the hypersaline Lake Fazda in Wadi Natrun (Egypt) resulted in complete denitrification of nitrate, although with intermediate nitrite production (Sorokin et al., 2003a). Purification of this culture resulted in the selection of a stable coculture of two facultatively anaerobic alkaliphilic sulfur oxidizers. There was a numerically minor population of large nonmotile coccoid cells with intracellular sulfur globules. In pure culture, this bacterium reduced nitrate only to nitrite despite having a very active nitrite reductase (Antipov et al., 2003). Despite its obvious phenotypic difference from the known alkaliphilic SOB species (Fig. 9), the 16S rDNA sequenced-based phylogenetic analysis placed this unusual bacterium into the genus *Thioalkalivibrio*, and the strain ALEN 2 was described as a new species *Tv. nitratireducens* (Sorokin et al., 2003c). The second (numerically dominant) organism, strain ALED, was a thin motile rod, which reduced nitrite to dinitrogen gas, and could grow anaerobically with thiosulfate and nitrite or nitrous oxide (N_2O) but not nitrate. A similar organism, *Thioalkalivibrio denitrificans* ALJD, was isolated previously from a Kenyan soda lake using N_2O as electron acceptor (Sorokin et al., 2001a). One of the essential properties of this bacterium was its preference for N_2O as an electron acceptor. In pH controlled continuous culture, *Tv. denitrificans* was able to grow within the pH range 7.5–10.5 with an optimum at pH 9.0. Growth with N_2O as electron acceptor was more stable and faster than with O_2 at pH >10. Moreover, in the chemostat it grew well with N_2O and polysulfide—a form of autotrophic denitrification unique to alkaliphiles, since polysulfide is only chemically stable at highly alkaline pH.

Thiocyanate Oxidation

Thiocyanate ($N{\equiv}C\text{-}S^-$) represents a one-carbon reduced sulfur compound, which is produced both naturally and as an industrial waste product from cyanide. Thiocyanate is not an easy substrate to metabolize for bacteria. Only a few neutrophilic, autotrophic sulfur-oxidizing species can use it as a source of energy after first breaking it down to sulfide, ammonia and CO_2. Aerobic enrichment culturesin medium containing thiocyanate at pH 10 from various soda lake sediments resulted in the isolation of nine strains of haloalkaliphilic, obligately autotrophic SOB capable of growth on thiocyanate as energy and

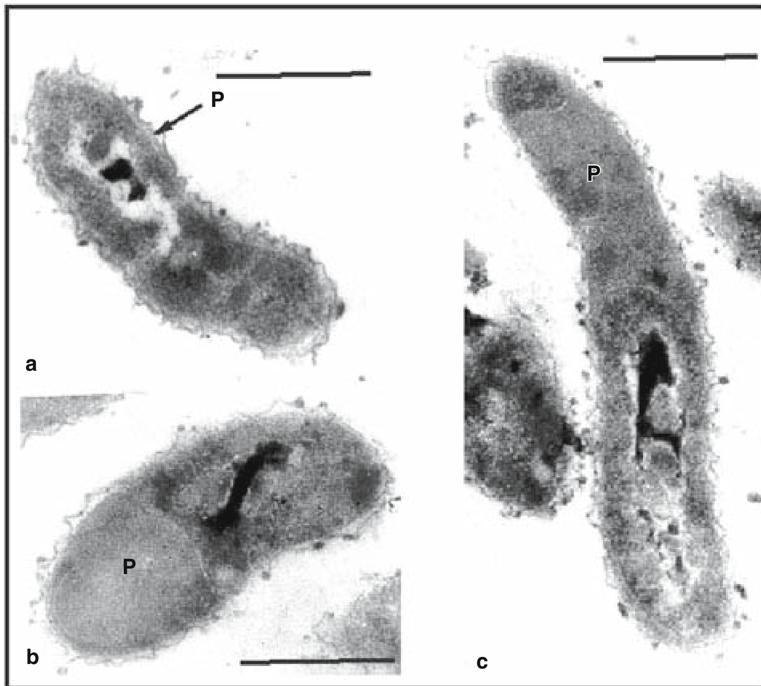

Fig. 10. Ultrastructure of the cells of *Thioalkalivibrio thiocyanoxidans* ARh 2 grown with thiosulfate (a) or thiocyanate (b, c) as electron donor at pH 10. P, periplasm. Bar = 0.5 μm.

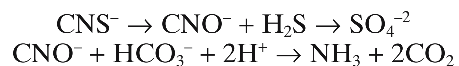
nitrogen source (Sorokin et al., 2001b). The isolates fell into two distinct groups. The four motile, vibrio-shaped strains were genetically closely related to the previously described sulfur-oxidizing alkaliphiles from the genus *Thioalkalivibrio*. They were described as a new species *Tv. thiocyanoxidans* (Sorokin et al., 2002c; Fig. 2). These strains had unusually extended periplasmic compartments when grown with thiocyanate but not thiosulfate as energy source (Fig. 10). The other five isolates had nonmotile barrel-shaped cells, accumulating large amounts of intracellular sulfur, and were able to oxidize carbon disulfide (Fig. 9). Despite their obvious phenotypic difference, these strains were also *Thioalkalivibrio* on the basis of 16S-rDNA sequence-based phylogenetic analysis and were described as a new species *Tv. paradoxus* (Sorokin et al., 2002c) clustering with another coccoid nonmotile member of the *Thioalkalivibrio*—*Tv. nitratireducens* (Fig. 2). Successful enrichments with thiocyanate as substrate at pH 10 were also obtained from the soda lake sediments under denitrifying conditions with nitrate as electron acceptor—a mode of chemolithoautotrophic metabolism suggested previously by De Kruyff et al. (1957) for the neutrophilic *Thiobacillus denitrificans* but never confirmed. Two closely related haloalkaliphilic SOB strains, ARhD 1 and ARhD 2, isolated from these enrichments were identified as members of the genus *Thioalkalivibrio* with closest relationship to *Tv. denitrificans*. They are described as a new species *Tv. thiocyanodenitrificans* (Sorokin et al., 2004b; Fig. 2). They were able to grow anoxically on thiocyanate and thiosulfate with nitrate or nitrite as the electron acceptor, representing, therefore, the first known complete denitrifiers among the sulfur-oxidizing haloalkaliphiles (D. Sorokin, unpublished results). All thiocyanate-utilizing soda lake isolates accumulated cyanate (($N{=}C{=}O^-$) as an intermediate of thiocyanate degradation. This was the first direct confirmation of the involvement of the "cyanate pathway" in the primary thiocyanate degradation in pure bacterial cultures:



$$CNS^- \rightarrow CNO^- + H_2S \rightarrow SO_4^{-2}$$
$$CNO^- + HCO_3^- + 2H^+ \rightarrow NH_3 + 2CO_2$$

However, in contrast to the mechanism of primary anaerobic hydrolysis of thiocyanate, resulting in the formation of cyanate and sulfide, as suggested previously (Youatt, 1954), the alkaliphiles appear to employ a different mechanism: direct oxidation of the sulfane atom of thiocyanate, producing cyanate and elemental sulfur, has been observed in cell-free preparations. The enzyme responsible for this action was produced in large amounts by thiocyanate-grown alkaliphilic strains and has recently been purified from the *Tv. thiocyanoxidans* ARh 4. A soluble monomer with an approximate molecular mass of 60 kDa, the enzyme oxidizes the sulfane atom of thiocyanate in the presence of cytochrome *c* as an electron acceptor (D. Sorokin, unpublished result).

Facultatively Alkaliphilic Sulfur-Oxidizing Bacteria

The numerous cultures enriched from the soda lakes using highly buffered sodium carbonate-based mineral medium invariably yielded obligately alkaliphilic isolates. On the other hand, nothing from the neutral salt lakes grew on such media. When NaCl-based medium was used with 0.1 M $NaHCO_3$ as a buffer and carbon source at pH 8.5, a halophilic strain was obtained from Stamp Lake (Table 1). It was able to grow both in neutral NaCl brines and at pH values above 9 in the presence of high sodium carbonate concentrations. Stamp Lake represents an intermediate lake type between soda and salt lakes, where NaCl dominates, but a small fraction of sodium carbonate provides the elevated pH. Strain HL 17 was identified as a member of the genus *Thioalkalivibrio* and will be described as a new species, *Tv. halophilus* (Fig. 2). It grew within the pH range 6.5–9.8, with a broad optimum range of 8.0–9.0. Being able to directly compare the biomass composition of this bacterium growing in NaCl- and sodium carbonate-based medium, it was possible to demonstrate that the specific content of its main compatible solute, glycine betaine, was twice as high in the NaCl-growing cells (Banciu et al., 2004a). This implies that the osmotic properties of the NaCl and sodium carbonate brines are substantially different. Direct measurements confirmed that the osmotic pressure of NaCl solutions was three times higher than that of the sodium carbonate media, which gives a certain energetic advantage to the natronophiles—the organisms preferring to live in the sodium carbonate brines.

Taxonomy of Haloalkaliphilic Sulfur-Oxidizing Bacteria

So far, the genus *Thioalkalivibrio* includes seven validly described species, and the genus *Thioalkalimicrobium* contains three species. Two more species in the genus *Thioalkalivibrio* are currently being described. The third genus, *Thioalkalispira*, contains a single species (Fig. 2). The most important properties of the type strains of these three genera are compared in Table 6. A large number of the isolates, especially those belonging to the high-salt tolerant *Thioalkalivibrio* subgroup from the Mongolian, Kulunda and Egyptian soda lakes, remain as yet undescribed. This is a common problem encountered when working with a wide range of genetically homologous strains. The more strains are isolated, the more it becomes clear that a bacterial group is represented by a continuous spectrum of organisms rather than a discrete number of distinct species. Despite their definite genetic difference (DNA-DNA hybridization), it is very difficult at this moment to find proper phenotypic descriptors sufficient to create an adequate taxonomy of all the soda lake isolates. As a rule, for a given geographic location, most of the isolates grouped together, with a DNA-DNA homology level typical for the single-species level (>60%). On the other hand,DNA homology between various "geographic species" was usually low (15–50%) despite their very similar phenotypes. At this moment, several molecular fingerprinting techniques are being employed to solve this problem.

Molecular techniques are now being used to improve detection of haloalkaliphilic sulfur bacteria in mixed populations in soda lake sediments and sulfide-removing bioreactors. So far, successful oligonucleotide probes have been designed forfluorescence in situ hybridization and polymerase chain reaction detection of the representatives of the *Thioalkalivibrio* (G. Muyzer and D. Sorokin, unpublished results).

Acknowledgments. We would like to thank our colleagues B.E. Jones and G.A. Zavarzin for making possible our work with their samples from the Kenyan soda lakes. We are also grateful to T.P. Tourova and A.M. Lysenko for help in genetic work, to M. Mityushina and K. Sjollema for electron microscopy and to E. Galinski and J. Sinninghe Damste for analyses of compatible solutes and fatty acids.

CHAPTER 1.31

The Colorless Sulfur Bacteria

LESLEY A. ROBERTSON AND J. GIJS KUENEN

The name "the colorless sulfur bacteria" has been used since the time of Winogradsky to designate prokaryotes that are either able, or believed to be able, to use reduced sulfur compounds (e.g., sulfide, sulfur and organic sulfides) as sources of energy for growth. Today, it is known that this group comprises a very heterogeneous collection of bacteria, many of which have little or no taxonomic relationship to each other. The colorless sulfur bacteria play an essential role in the oxidative side of the sulfur cycle (Fig. 1). Like all of the element cycles, the sulfur cycle has an oxidative and a reductive side, which, in most ecosystems, are in balance. However, this balance does not always exist, and accumulations of intermediates such as sulfur, iron sulfides, and hydrogen sulfide are often found. On the reductive side, sulfate (and sometimes elemental sulfur) functions as an electron acceptor in the metabolic pathways used by a wide range of anaerobic bacteria, leading to the production of sulfide. Conversely, on the oxidative side of the cycle, reduced sulfur compounds serve as electron donors for anaerobic, phototrophic bacteria or provide growth energy for the extremely diverse group of (generally) respiratory colorless sulfur bacteria. Common oxidation products of sulfide are elemental sulfur and sulfate (Fig. 1). The adjective "colorless" is used because of the lack of photopigments in these bacteria, although it should be noted that colonies and dense cultures can actually be pink or brown because of their high cytochrome content. This chapter will concentrate on the colorless sulfur bacteria, while the sulfate reducers and phototrophs will be discussed in 13 and 24.

There is a wide range of different types of colorless sulfur bacteria with very diverse morphological, physiological and ecological properties and with equally diverse environmental requirements. Table 1 lists the genera that have traditionally been regarded as colorless sulfur bacteria (part A), as well as genera containing species originally not classified as such that have now been shown to be able to obtain energy from the oxidation of reduced sulphur compounds (part B). As will be discussed later, the apparent similarity of the metabolic pathways for sulfur oxidation disguises a high level of variation in these pathways indicating that the diversity among the colorless sulfur bacteria is probably due to convergent rather than divergent evolution. In addition to inorganic sulfur compounds, some species can also gain energy from the oxidation of other inorganic compounds such as hydrogen or ferrous iron. As well as differences in substrate range, there is also some variation in electron acceptor usage. Although most colorless sulfur-oxidizing bacteria require oxygen, a few are able to grow anaerobically using nitrogen oxides (e.g., nitrate) as their terminal electron acceptor during denitrification. One or two species (of the genus *Acidianus*) are capable of anaerobic metabolism by the reduction of sulfur (Segerer and Stetter, 1989), during which organic compounds or hydrogen serve as electron donors. *Thiobacillus ferrooxidans* is known to be able to reduce ferric iron under anaerobic conditions (Sugio et al., 1985). A somewhat exotic example of a sulfate reducer that might also be considered to be a colorless sulfur bacterium is *Desulfovibrio sulfodismutans*, which can grow anaerobically by the disproportionation of thiosulfate to sulfate and sulfide (Bak and Pfennig, 1987). Some of the reactions that generate energy from inorganic reduced sulfur compounds using oxygen and nitrate as electron acceptors are shown in Table 2.

In the following sections, we will first discuss the physiology of the colorless sulfur bacteria, since physiology forms the basis of their present taxonomy, and then treat the taxonomy in the following section. This will be followed by a discussion of the habitats of the colorless sulfur bacteria, including artificial habitats, and finally some applications of their use. The chapter concludes with a brief section on the role of the colorless sulfur bacteria in the natural sulfur cycle, together with a description of the tech-

This chapter was taken unchanged from the second edition.

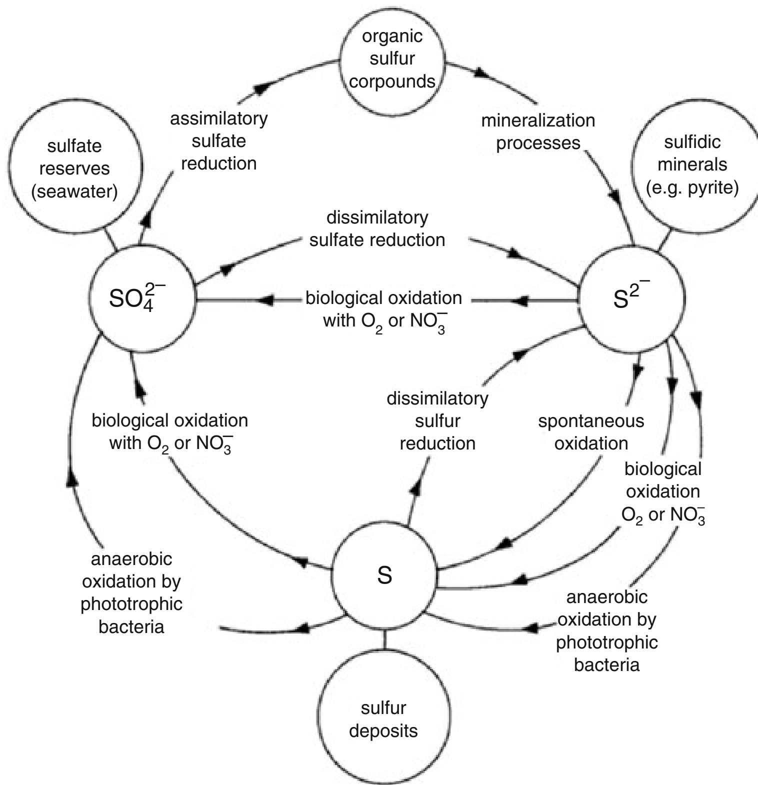

Fig. 1. The sulfur cycle. The colorless sulfur bacteria are involved primarily in those steps in which S^{2-} and S are oxidized with O_2 or NO_3^-. (Adapted from Bos and Kuenen, 1983).

Physiology

The great diversity of colorless sulfur bacteria is also reflected in their physiology. This will come as no surprise if we remember that the group encompasses archaebacteria as well as eubacteria, and that the latter group is also very diverse, including common pseudomonads and organisms that might be considered "colorless blue green bacteria," such as species of *Beggiatoa*.

Most of our knowledge of the physiology of these organisms comes from the study of the relatively limited number of bacteria, such as the thiobacilli, that can be grown relatively easily in the laboratory. This is particularly true of our understanding of the biochemistry of sulfur metabolism and, to a lesser extent, of carbon metabolism.

Although the biochemistry of the oxidation of sulfur compounds has received much attention over the last few decades, the pathways involved were not well understood. This was due, in particular, to the fact that the research was formulated around the hypothesis that there would be a single unifying enzymatic pathway for the oxidation of all reduced sulfur compounds. However, it is now clearly established that this is not the case. For example, the facultatively autotrophic *Thiobacillus versutus* and the obligately autotrophic *T. tepidarius* use two entirely different pathways (Fig. 2a and b). It should be noted that not only do the enzymes and electron carriers differ, but their localization in the membranes of the two species appears to be different. This is, of course, important for the mechanism behind the generation of a proton motive force (PMF) in these organisms. Little is known of the electron carriers involved in reverse electron transport for the production of reducing power during autotrophic growth, but all available evidence indicates that the PMF is the driving force for this process. For an extensive review of the state of the art, the reader is referred to Kelly (1988b).

In most obligate and facultative autotrophs, the Calvin cycle serves as the route for carbon dioxide fixation. This is true, for example, for species from the genera *Thiobacillus*, *Thiomicrospira*, *Thiosphaera*, and *Beggiatoa*. Some other species, including those from *Sulfolobus* and *Hydrogenobacter*, possess a carbon dioxide fixation pathway based on a reductive Calvin cycle (Segerer and Stetter, 1989).

Energy and Carbon Sources or Electron Donors

It has been common practice to subdivide the colorless sulfur bacteria in terms of their physiological type as defined mainly by their carbon metabolism. Table 3 defines these physiological types, which will be discussed briefly below. It should be remembered that some genera or species have not been studied in pure culture, and it is not yet known to which of the physiological groups they belong.

Obligate Chemolithotrophs. These highly specialized bacteria require an inorganic source of energy and obtain their cell carbon from the fixation of carbon dioxide. As mentioned above, except in the case of the archaebacteria (which use a reductive carboxylic cycle [König and Stetter, 1989]), the colorless sulfur bacteria do this by means of the Calvin cycle (e.g., Schlegel, 1981). The citric acid cycle in these bacteria seems to be incomplete, and its enzymes probably serve a purely biosynthetic function. Despite their label as "obligate" autotrophs, it has been shown that many of these species actually can use small amounts of exogenous carbon compounds as a supplementary carbon source (Kuenen and Veldkamp, 1973; Matin, 1978), or can even ferment endogenous organic storage compounds such as glycogen (Beudeker et al., 1981; Kuenen and Beudeker, 1982), but these are both secondary metabolic activities, the organisms being primarily dependent on a lithotrophic energy source and carbon dioxide for autotrophic growth. Many *Thiobacillus* species, at least one species each from *Sulfolobus* and *Hydrogenobacter*, and all of the known species of *Thiomicrospira* fall into this group.

Facultative Chemolithotrophs. These bacteria can grow either chemolithoautotrophically with an inorganic energy source and carbon dioxide, or heterotrophically with complex organic compounds providing both carbon and energy, or mixotrophically. Mixotrophy is the simultaneous use of two or more different metabolic pathways for energy and carbon (Gottschal and Kuenen, 1980). In the laboratory, mixotrophic growth is most easily observed

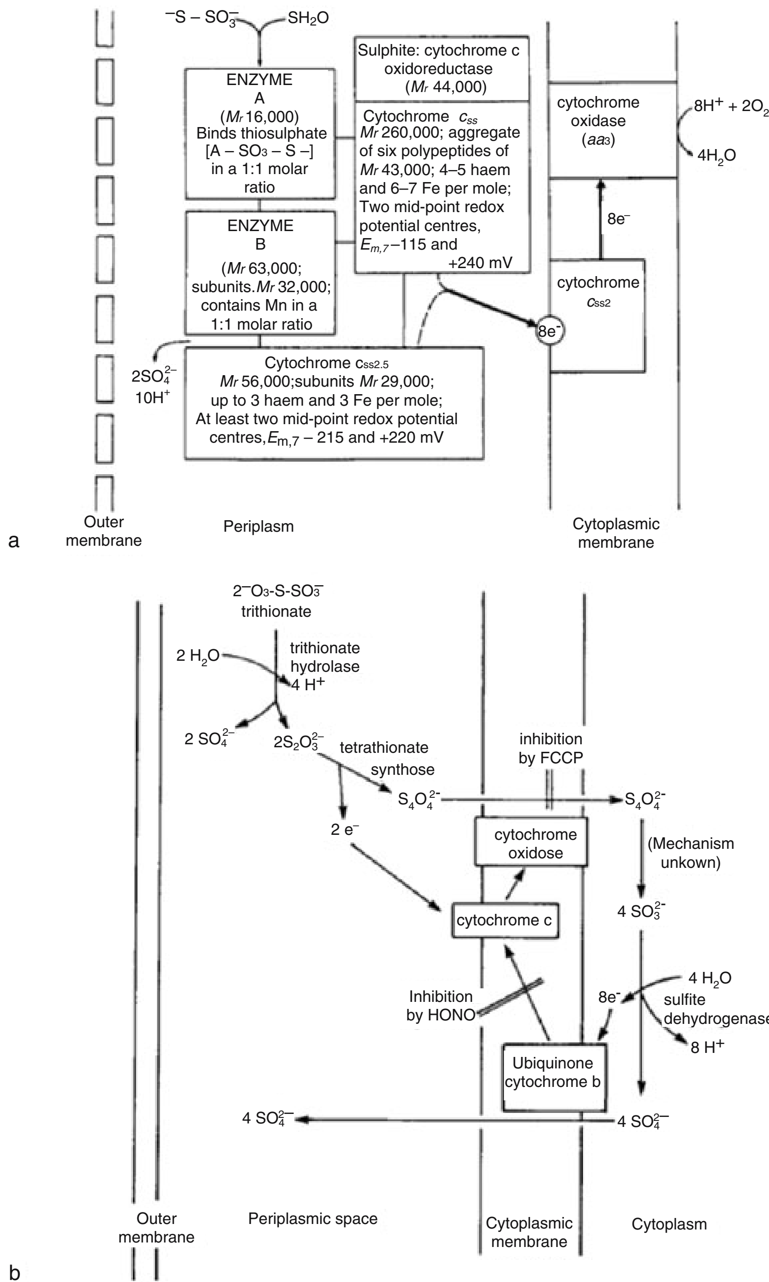

Fig. 2. Pathways of oxidation of reduced sulfur compounds in two different organisms. (a) The periplasmic thiosulfate-oxidizing system of *Thiobacillus versutus* as proposed by Kelly (1988a). The enzyme complex does not produce or metabolize polythionates such as tetrathionate. Thiosulfate is oxidized to sulfate without the formation of sulfur or other intermediates. Thiosulfate metabolism is initiated by its binding to enzyme A. In subsequent steps, sulfate is produced and released, while electrons are finally transferred to an aa_3-type of cytochrome oxidase. (b) The periplasmic and cytoplasmic metabolism of trithionate, thiosulfate, and tetrathionate by *Thiobacillus tepidarius* as proposed by Kelly (1988b). In contrast to the system shown in part a, tetrathionate appears to be an intermediate in the oxidation of both thiosulfate and trithionate. After an initial hydrolysis of trithionate, yielding thiosulfate and sulfate, the thiosulfate is oxidized to tetrathionate. Available evidence indicates a periplasmic location of these systems. Tetrathionate is believed to be transported into the cell and then oxidized to sulfite in the cytoplasm by an unknown mechanism. Sulfite dehydrogenase is responsible for the final oxidation to sulfate, in which cytochrome *b* may be involved. FCCP, carbonylcyanide-*p*-trifluoromethoxyphenylhydrazone; HQNO, 2-heptyl-4-quinolinol-1-oxide.

during continuous culture on limiting mixtures of substrates. The term mixotrophy usually designates simultaneous growth on a mixture of autotrophic and heterotrophic substrates (e.g., on thiosulfate and acetate). However, the simultaneous use of any mixture of substrates requiring (partially) separate metabolic pathways or enzymes, and thus might produce diauxie or biphasic growth in batch culture (e.g., glucose and lactose, succinate and glucose, iron and sulfur, hydrogen and sulfide, acetate and lactate), could be considered as mixotrophy.

Table 3. Classification of the different physiological types of colorless sulfur bacteria.[a]

	Carbon source		Energy source	
Physiological type	Inorganic	Organic	Inorganic	Organic
Obligate chemolithotroph	+[b]	–	+	–
Facultative chemolithotroph (mixotroph)	+	+	+	+
Chemolithoheterotroph	–	+	+	+
Chemoorganoheterotroph (heterotroph)	–	+	–	+

Commonly used synonyms for chemolithotroph include chemolithoautotroph, autotroph, chemoautotroph, and lithotroph.
+, used by the group; –, not used.

Some of the thiobacilli, *Thiosphaera pantotropha*, *Paracoccus denitrificans* (Friedrich and Mitrenga, 1981), and certain *Beggiatoa* species (Nelson and Jannasch, 1983) are typical examples of organisms able to grow on mixtures of reduced sulfur compounds and organic substrates. To some extent, the phototrophic sulfur-oxidizing bacteria might also be considered members of this group since most, if not all, of them are able to grow chemolithoautotrophically and mixotrophically on reduced sulfur compounds in the dark (Kuenen et al., 1985).

CHEMOLITHOHETEROTROPHS. This little-known group of bacteria is characterized by an ability to generate energy from the oxidation of reduced sulfur compounds, but which cannot fix carbon dioxide. Until recently, *Thiobacillus perometabolis* was considered to be a member of this group, but it is now known that under certain conditions, it can grow autotrophically (Katayama-Fujimura et al., 1984). However, unnamed chemolithoheterotrophic species have been isolated, and a few strains of *Thiobacillus* have been well characterized (Tuttle et al., 1974; Gommers and Kuenen, 1988). Some *Beggiatoa* strains may also belong in this group (Larkin and Strohl, 1983). As is clear from the example of *T. perometabolis*, careful testing under a variety of conditions is necessary in order to discriminate chemolithoheterotrophs from the facultative autotrophs as well as from the sulfur-oxidizing heterotrophs.

SULFUR-OXIDIZING CHEMOORGANOHETEROTROPHS. Some heterotrophic bacteria can oxidize reduced sulfur compounds, but do not appear to derive energy from them. However, they may benefit from the reaction by the detoxification of metabolically produced hydrogen peroxide (e.g., some species of *Beggiatoa*, *Macromonas*, *Thiobacterium*, and *Thiothrix*) (Larkin and Strohl, 1983; Dubinina and Grabovich, 1984). The oxidation of thiosulfate to tetrathionate by many heterotrophic bacteria that do not seem to gain energy from the reaction is well documented (Tuttle and Jannasch, 1972; Tuttle et al., 1974; Mason and Kelly, 1988).

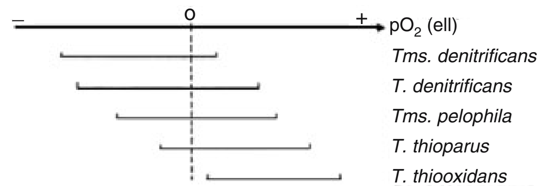

Fig. 3. A "spectrum" showing the response of five different species of colorless sulfur bacteria to redox. The position of each line indicates the range of conditions of redox under which the organism can grow. *T.*, *Thiobacillus*; *Tms.*, *Thiomicrospira*. (Based on Timmer ten Hoor, 1977.)

Electron Acceptors for Aerobic and Anaerobic Growth

Oxygen is universally used among the colorless sulfur bacteria, although the degree of aerobiosis that can be tolerated by different species varies. The response of some of the colorless sulfur bacteria to redox can be demonstrated by means of a "spectrum" as shown in Fig. 3.

Various colorless sulfur bacteria have different ways of growing or surviving anaerobically. One of the best studied is the use of nitrate or nitrite as a terminal electron acceptor, whereby the nitrogen oxides are reduced to nitrogen, a process termed denitrification. This will be discussed in detail in Chapter 23, but a brief consideration of the nitrate-reducing colorless sulfur bacteria is appropriate here.

The denitrifying species tend to be neutrophilic (Table 4), but not necessarily mesophilic,

Table 4. Examples of the neutrophilic, mesophilic species capable of autotrophic growth on reduced sulfur compounds.

	Autotrophy		Denitrification

Beggiatoa sp. (freshwater)	–	+	+	+

+, property present; –, property absent.

since at least one of the thermophiles (*Thermothrix thiopara*) can denitrify. A few (e.g., *Thiobacillus thioparus*) can only reduce nitrate to nitrite and require the presence of a nitrite-reducing bacterium for anaerobic growth (Table 4). Strictly speaking, of course, the latter reaction is not truly denitrification, but since the reaction still serves for electron acceptance and survival under anaerobic conditions, these species are appropriately included here.

There are two known obligately chemolithotrophic sulfur bacteria that carry out complete denitrification to nitrogen. *Thiobacillus denitrificans* is relatively versatile in being able to grow under fully aerobic conditions with oxygen, and under fully anaerobic conditions with nitrate or nitrite (Aminuddin and Nicholas, 1973; Ishaque and Aleem, 1973). *Thiomicrospira denitrificans* is more fastidious. It grows well anaerobically with nitrate or nitrite, but can only use oxygen for growth if its concentration is kept extremely low (i.e., below the detection level of normal oxygen electrodes) (Timmer ten Hoor, 1975). These obligate autotrophs are far more efficient at anaerobic (denitrifying) growth on reduced sulfur compounds than the facultative species. Of the latter, only *Thiosphaera pantotropha* has been, thus far, found to retain its sulfur-oxidizing potential under denitrifying conditions, but its μ^{max} while doing so is extremely low (approx. 0.015 h^{-1}) compared with those of *Thiobacillus denitrificans* and *Thiomicrospira denitrificans* (0.06 h^{-1}). Other facultatively autotrophic bacteria lose their sulfur-oxidizing capacity in anaerobic cultures, but are still able to denitrify using organic compounds, or even hydrogen. Among these are *Thiobacillus versutus* and *Paracoccus denitrificans* (Taylor and Hoare, 1969; Friedrich and Mitrenga, 1981). Sulfide-dependent reduction of nitrate to N_2 by *Beggiatoa* tufts has recently been shown using ^{15}N-labelled nitrate (Sweerts et al., 1990).

Of the two sulfur-oxidizing genera of archaebacteria, *Sulfolobus* species appear to be the more dependent on oxygen, although some have been shown to use ferric iron and molybdate as electron acceptors under microaerobic conditions (Brock and Gustafson, 1976; reference is not an exact matchBrierly, 1982). Members of the genus *Acidianus* are able to grow under anaerobic conditions, by using hydrogen as the electron donor and sulfur as the acceptor, thus making these bacteria both sulfur-oxidizing and sulfur-reducing, depending on the conditions (Segerer and Stetter, 1989). Nelson and Castenholz (1981) have reported that some *Beggiatoa* species carry out an anaerobic reduction of intracellularly stored sulfur, using organic compounds such as acetate as electron donors. The ability of these organisms to oxidize sulfide to sulfur under aerobic conditions and then to reverse this reaction anaerobically would permit them to optimally profit from their habitat, where aerobic and anaerobic conditions frequently alternate. They may also actively migrate between aerobic and anaerobic zones.

Even apparently obligately aerobic strains may have mechanisms allowing them to survive during anaerobiosis for a limited length of time. Thus, *Thiobacillus neapolitanus*, a species normally considered to be obligately respiratory, has been shown to be able to ferment internal reserves of polyglucose when confronted with anoxic conditions (Beudeker et al., 1981). As mentioned in the introduction, *T. ferrooxidans* can use ferric iron as an electron acceptor, although it is not yet clear whether this is linked to energy generation.

Ecophysiology as a Function of pH, Temperature and Nutrient Availability

Colorless sulfur bacteria have been found growing at pH 9.0 and pH 1.0, at 4°C and 95°C, and at dissolved oxygen concentrations ranging from air-saturation to anaerobic levels (Table 1). It is obvious that a combination of physical, chemical, and (eco)physiological factors will suit the ecological niche of the organism within a particular microbial community. A number of these will be considered here.

pH Range and Effects. The pH ranges of some of the colorless sulfur bacteria are surveyed in Table 1, and examples of neutrophilic and acidophilic species are listed in Tables 4 and 5. Within these ranges, of course, species often have different pH optima. The outcome of competition for a substrate at different pH values will therefore be dictated to a large extent by the pH optima of the competing bacteria. Thus, Kuenen et al. (1977) found that at pH values above 7.5, *Thiomicrospira pelophila* dominated

Table 5. Characteristics of acidophilic, mesophilic species capable of growth on reduced sulfur compounds and/or iron.

	Autotrophy		Utilization of	
Species	Obligate	Facultative	Sulfur	Iron

T. thiooxidans	+	−	+	−
T. albertis	+	−	+	−
T. acidophilus	−	+	+	−
Leptospirillum ferrooxidans	+	−	−[a]	+

Also negative on other sulfur compounds, can use the iron in pyrite.

thiosulfate-limited chemostat cultures, whereas when the pH was below 6.5, *Thiobacillus thioparus* was able to outcompete the other for thiosulfate. At intermediate pH values, the outcome of the experiments was not reproducible, with varying levels of the two populations. Apparently, the substrate affinities of the two species were so similar that other, less well-controlled variables (e.g., iron concentration, minor amounts of wall growth, etc.) became important for the outcome of the competition. Similar pH effects have been observed in the competition between *T. versutus* and *T. neapolitanus* (Smith and Kelly, 1979).

The colorless sulfur bacteria that grow at neutral to slightly alkaline pH values are found in marine and freshwater sediments, soils, and wastewater treatment systems, to name but a few sources. As can be seen from Table 4, representatives of almost all of the genera fall within this group. Many of them have specialized in growth in the gradients where (anaerobic) sulfide-containing zones come into contact with air or oxygen-containing water and will be discussed in the section on gradients. Some colorless sulfur bacteria are extreme acidophiles, able to grow at pH values as low as 1. As Table 5 shows, the group includes mesophilic obligate and facultative autotrophs (e.g., *T. ferrooxidans* and *T. acidophilus*, respectively). The acidophilic colorless sulfur bacteria are abundant in locations such as acid mine-drainage water, and it is therefore interesting that many of them are also able to oxidize (and gain energy from the oxidation of) metals such as iron. Thus, *T. ferrooxidans* is able to grow "mixotrophically" on the iron and sulfur components of pyrite (Arkestein, 1980) or on mixtures of ferrous iron and tetrathionate, gaining energy from the iron and sulfur oxidizing reactions (Hazeu et al., 1986, 1988). There have been a few reports of facultatively heterotrophic growth by *T. ferrooxidans* (e.g., Shafia and Wilkinson, 1969; Lundgren et al., 1964). However, it has since been shown that most of the *T. ferrooxidans* cultures available from culture collections were contaminated with acidophilic facultative autotrophs and heterotrophs (Harrison, 1984), including *T. acidophilus* and *Acidiphilium cryptum*, and it is now generally accepted that *T. ferrooxidans* is an obligate autotroph.

It has frequently been assumed that *T. ferrooxidans* is one of the key species active in pyrite oxidation. In order to assess its likely significance for pyrite oxidation during coal desulfurization, Muyzer et al. (1987) used antibodies raised against *T. ferrooxidans* for an immunofluorescent assay of slurries made from coal from different sources. Unsterilized and sterilized coal samples were inoculated with *T. ferrooxidans*, with a mixed culture of pyrite-oxidizing bacteria from a coal-washing installation, and a mixture of the two. Despite the fact that a DNA-fluorescent stain indicated abundant microbial life in all of the slurries, the only sample in which a significant *T. ferrooxidans* population was detected was the control, which had been sterilized and then inoculated with the pure culture of *T. ferrooxidans*. It appears that in all other cases, other strains (which might include such species as *T. thiooxidans*, *Leptospirillum ferrooxidans*, or *Acidiphilium cryptum*, to name but a few) were able to successfully out-compete *T. ferrooxidans* for a niche in the consortium.

Temperature As pointed out at the beginning of this section, colorless sulfur bacteria can be found growing at temperatures ranging from 4–95°C. However, the majority of the well-studied species are mesophilic. Although it is evident that the majority of natural environments are suitable for the growth of mesophiles, the diversity of the thermophilic organisms is likely to be much larger than suggested by Table 6, particularly in view of the recent discoveries of new thermophilic species among the colorless sulfur bacteria and other metabolic groups. Thus, it is clear that the species discussed in this section should be regarded as indicative rather than definitive. As most of the examples discussed elsewhere in this chapter will be taken from mesophilic bacteria, most of this section will be dedicated to consideration of the thermophiles.

Thermophilic bacteria are generally associated with waters that have been geothermally heated. These range from warm springs, used for bathing since Roman times, through solfataras to submarine hydrothermal vents (e.g., Caldwell et al., 1976; le Roux et al., 1977; Jannasch, 1985). As can be seen from Table 6, the bacteria in this group can be subdivided into two groups, the moderate thermophiles (generally eubacteria),

Table 6. Characteristics of moderately and extremely thermophilic species capable of growth on reduced sulfur compounds.

	Autotrophy		
Species	Obligate	Facultative	Temperature range (°C)
Thiobacillus tepidarius	+	–	20–52
T. aquaesulis	–	+	30–55
Thermothrix thiopara	–	+	72
Sulfolobus acidocaldarius	–	+	60–85
Sulfolobus sp. HVS	+	–	60–95
Acidianus infernus	+	–	60–95
A. brierleyi	–	+	60–95

which grow over the range 45–55°C, and the extreme thermophiles (generally archaebacteria), some of which can grow at temperatures approaching 100°C.

Neutrophilic species make up the moderately thermophilic group. One neutrophile, *Thermothrix (Tx.) thiopara* has a higher optimum growth temperature (72°C). This facultative autotroph was found in neutral (pH 7.0), hot (74°C) springs (Caldwell et al., 1976; Brannan and Caldwell, 1980), where it forms macroscopic streamers as well as microscopic mats on the tufa. The streamers occur at the sulfide: oxygen interface (Caldwell et al., 1983), and the key role that oxygen plays in their development was demonstrated by means of a very simple experiment during which the surface of the hot spring was covered by a sheet of plastic to restrict entry of oxygen from the air. As a result of this, the dissolved oxygen dropped to 0.1 mg l^{-1} from 3 mg l^{-1}, but other parameters such as pH and temperature were unaffected. The *Tx. thiopara* streamers then disappeared from their accustomed positions and reappeared at the edges of the sheet, where the sulfide:oxygen gradient had been reestablished.

The acidophilic archaebacteria of the genera *Sulfolobus* and *Acidianus* represent the colorless sulfur bacteria among the hyperthermophiles. These genera include both obligately and facultatively autotrophic species. They are frequently found in association with sulfidic ores such as pyrite, chalcopyrite, and sphalerite. It has been suggested that the failure to find *Sulfolobus* species around hydrothermal vents, where *Acidianus* does occur, is due to the low salt tolerance of *Sulfolobus* species. *Acidianus* species can tolerate NaCl concentrations of up to 4% (Stetter, 1988). Of course, with growth temperatures between 60–95°C, these strains seem almost "moderate" in comparison to the growth temperatures of the sulfur-reducing *Pyrobaculum* and *Pyrodictium* species (74–110°C).

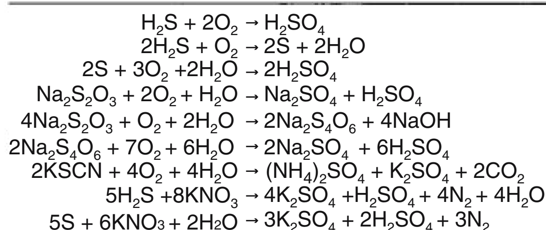

Fig. 4. A model to describe the selection of different physiological types by the ratio of inorganic to organic substrates supplied in the medium. This model may also hold for complex (semi-natural) systems, where the relative turnover rates of the inorganic and organic compounds (or the ratio between the fluxes of these compounds) would determine the selection of different physiological types. For definitions of the various terms, see Table 3.

Nutrient Availability and Ecological Niches. Of the physiological types shown in Table 3, the obligate and facultative chemolithotrophs are the best known, having been the most extensively studied in pure and mixed cultures (e.g., Kelly and Kuenen, 1984; Kuenen, 1989; Kelly and Harrison, 1989; Kuenen et al., 1985; Kuenen and Robertson, 1989a, 1989b). One of the most important environmental parameters affecting the selection of these bacteria in freshwater environments was found by Gottschal and Kuenen (1980) to be the relative turnover rates of inorganic and organic components in the available substrates (Fig. 4). Thus, if the available substrate in energy-limited systems is wholly or predominantly inorganic, obligate autotrophs such as *Thiobacillus neapolitanus* will normally tend to dominate a community. Similarly, abundant organic substrates will generate communities dominated by heterotrophs. On mixed substrates, facultative autotrophs such as *T. versutus* or chemolithoheterotrophs will appear, depending on the ratio between the two types of substrate. If the substrate supply is predominantly organic, the sulfide-oxidizing heterotrophs or other heterotrophs will appear. This model was put to the test by means of a number of competition experiments in two- and three-membered mixed cultures of representatives from the physiological groups. In addition, a number of enrichment cultures inoculated from natural samples containing representatives of all of the physiological types were obtained. All of the experiments essentially showed that the predicted metabolic type became dominant (for example, see Fig. 5a and b). Although mathematical modelling predicted that in some cases pure cultures of only one metabolic type should be obtained, in practice, satellite populations of the others remained (Fig. 6). Clearly, secondary environmental or experimental conditions (e.g., excretion products such as glycollate, fluctuations in substrate or oxygen concentrations, and growth on the wall of the vessel) can result in deviations from the idealized model. It is obvious that a well-mixed chemostat is a model system that is rather remote from the common natural habitats of colorless sulfur bacteria, such as the sulfide:oxygen gradient in a sediment, and the results obtained can only demonstrate the principle. Moreover, the relative turnover rate of the organic and inorganic substrates is only one of the environmental parameters that determines the success of a particular species. Nevertheless, the use of this model (Fig. 4) has now clarified the situation, a practical consequence

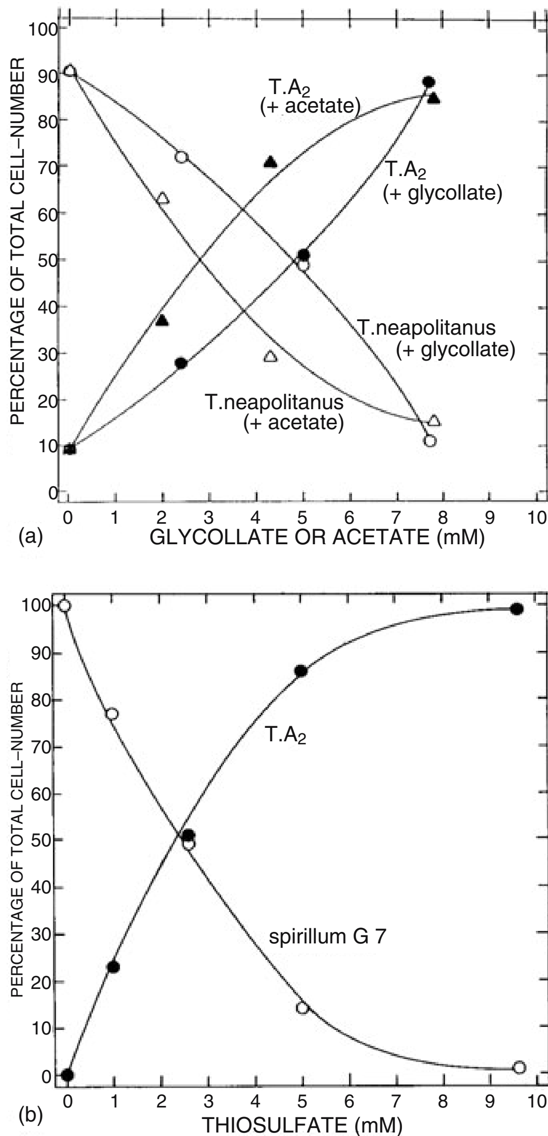

Fig. 5. The effect of organic or inorganic energy sources on competition. (a) The effect of different concentrations of organic substrates on the competition between *Thiobacillus versutus* (T. A_2) and *T. neapolitanus* for growth-limiting thiosulfate in a continuous culture. The influent medium contained 40mM thiosulfate. During growth limitation by thiosulfate, it and the organic additives (where present) were used simultaneously by the mixed culture, and their actual concentrations in the chemostat were below the detection level. The graph shows the ratios of the two species at steady state. Open symbols, *T. versutus*; closed symbols, *T. neapolitanus*; circles, glycollate supplied; triangles, acetate supplied. (b) The effect of thiosulfate on the competition for acetate (10 mM) between *T. versutus* (T. A_2) and a heterotrophic spirillum called G7. For experimental details, see (a). Open symbols, *Spirillum* G7; closed symbols, *T. versutus*. (Based on Gottschal et al., 1979.)

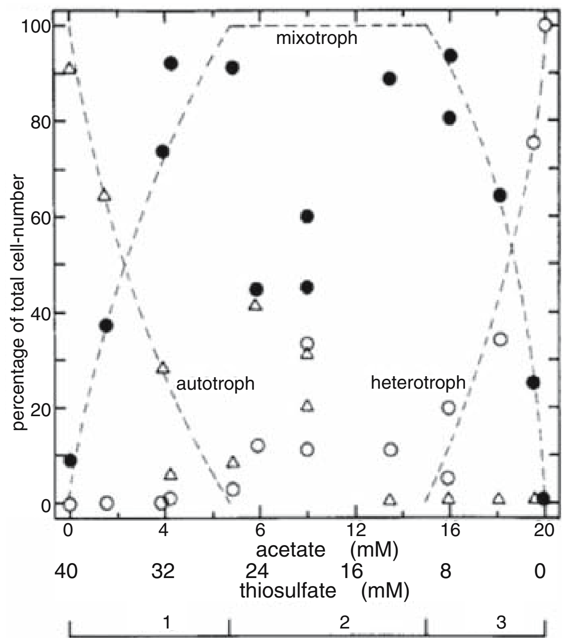

Fig. 6. Competition for acetate and thiosulfate in a chemostat between an autotroph, *T. neapolitanus* (open triangles); a mixotroph, *T. versutus* (closed circles); and a heterotroph, *Spirillum* G7 (open circles). The dotted lines indicate the results predicted from the model, the symbols indicate the actual results. The model held well for the extreme ratios of thiosulfate and acetate. However, although *T. versutus* dominated at intermediate ratios, as predicted, the other two types did not completely disappear. For the experimental details, see Fig. 5a. This model can be used for the selective enrichment of facultative autotrophs in chemostat cultures using an intermediate ratio of acetate and thiosulfate. (Based on Gottschal et al., 1982.)

being that it has shown the way for the selective enrichment of facultatively autotrophic sulfur bacteria from fresh water.

Steady-state conditions are more common in artificial environments than in nature, and therefore in order to test the effect of substrate fluctuations on the selection of the three representative species used in the experiments discussed above (Figs. 5a, 5b, and 6), Gottschal et al. (1981) ran chemostat cultures alternating feeds of acetate and thiosulfate. In two-membered cultures, the mixotrophic *T. versutus* was able to maintain itself on the substrate not used by whichever obligate species was involved, so that both species were subject to alternating periods of growth and starvation. However, in three-membered cultures, the two specialists were able to react more swiftly to the onset of substrate provision because of their constitutive enzymes, while the facultative species, which had to reinduce its autotrophic enzymes each time, disappeared. As with the steady-state experiments, when different mixtures of acetate and thiosulfate alternated, the outcome was deter-

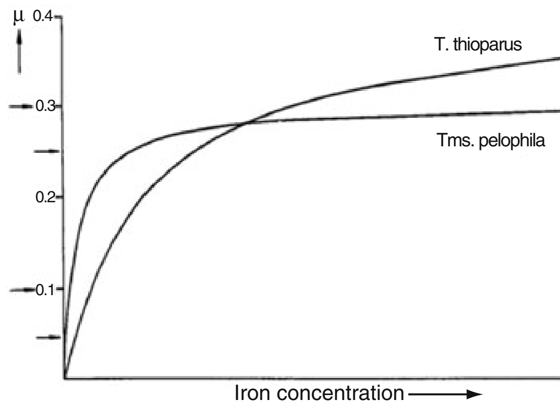

Fig. 7. The specific growth rates (μ) of *Thiomicrospira pelophila* and *Thiobacillus thioparus* as a function of the iron concentration in chemostat cultures at 25°C. The graph was constructed from the results of competition experiments (at the growth rates indicated by the arrows at the y axis). The actual iron concentrations were not determined. (From Kuenen et al., 1977.)

mined by the concentrations involved. Enrichment cultures under this regime yielded a facultative autotroph that was able to avoid the need to induce its carbon dioxide fixation system by accumulating large amounts of PHB during the heterotrophic period.

This work was carried out on aerobic, freshwater chemostat cultures and, as has been discussed in previous reviews (Kelly and Kuenen, 1984; Kuenen, 1989; Kelly and Harrison, 1989; Kuenen et al., 1985), marine enrichments are, for unknown reasons, generally less predictable. For example, mixotrophs did not form the dominant population in thiosulfate/acetate-limited marine cultures (Kuenen et al., 1985). That marine mixotrophs do exist has been shown by the isolation of a facultatively chemolithotrophic marine strain of *T. intermedius* from a thiosulfate-limited culture (Smith and Finazzo, 1981).

Of course, factors other than the availability of electron donors can determine the type of population to be found in any given environment. For example, Kuenen et al. (1977) studied the effect of iron limitation and pH on the outcome of competition between two marine obligate autotrophs, *Thiomicrospira* (*Tms.*) *pelophila* and *Thiobacillus* (*T.*) *thioparus*. As can be seen from Fig. 7, *Tms. pelophila* will dominate mixed cultures of the two species at low iron concentrations, whereas *T. thioparus* will do better when iron is more abundant. One of the characteristics of *Tms. pelophila* is its tolerance of sulfide concentrations high enough to inhibit *Thiobacillus* spp. It has been postulated that sulfide inhibition is caused by the reaction of the sulfide with available iron, forming insoluble ferrous sulfide and thus drastically reducing the concentration of iron available for microbial utilization. If this hypothesis is accurate, the ability of *Tms. pelophila* to grow well at very low iron concentrations would explain its sulfide tolerance.

Taxonomy

Many of the colorless sulfur bacteria were discovered in the early years of microbiology, at a time when scientists were relying mainly on morphological characteristics to identify their organisms, and this fact is still reflected in our approach to their taxonomy. Needless to say, this has caused a certain amount of confusion (see Table 1 for an overview of the genera involved). The problems associated with the identification of some colorless sulfur bacteria have been aggravated because many of the bacteria involved are very specialized (e.g., obligate autotrophs) and, as a consequence, the number of physiological traits that can be screened is limited. This has resulted in relatively trivial features being given undue weight during classification. Taxonomy is a way of establishing identities and relationships in an attempt to create a sense of order among the various forms of life on earth. In ecology, as in other applications of taxonomy, the precise identification of a particular species may not always be as relevant as an accurate description of its physiological characteristics, but the comparison and correlation of data from different sources becomes easier if one can be certain, or even reasonably sure, of the identities of the various bacteria involved. Changes in taxonomic practice largely reflect new developments in available technology as well as improvements in our understanding of which factors indicate relationships, and which are merely resemblances. Taxonomic research into the colorless sulfur bacteria can thus be separated into three distinct, if overlapping phases, which will be discussed sequentially here.

Morphology

The colorless sulfur bacteria, as a group, encompasses rods, spirals, cocci, filamentous cells and archaebacteria, and it comes as no surprise to find that the first of them to be described, *Beggiatoa* (Trevisan, 1842), is also one of the largest. The longest cells reported in the latest edition of *Bergey's Manual* are 50 μm long (Strohl, 1989), but a recent paper described the observation of a marine strain more than 100 μm long (Nelson et al., 1989). Another morphologically distinct genus, *Thiothrix,* was described by Winogradsky in 1888, but it was not until 1904 that Beijerinck described the first of the smaller colorless sulfur bacteria, *Thiobacillus thioparus*.

As may be seen from a survey of the relevant chapters in *Bergey's Manual* a few genera are still, today, based largely on morphological descriptions (e.g., *Thiospira*, *Macromonas*, *Thiovulum*) because pure cultures are either not available, or have only recently been achieved.

In addition to cell size and shape, other morphological details that have been considered important are the appearance of inclusion bodies such as sulfur or poly β-hydroxybutyrate (PHB), number and placement of flagella, colony size, colony form and colony color. One of the dangers associated with too strong a reliance on such features is that all of them can vary depending on the growth conditions. As a single example of this problem, the faculatively autotrophic *Thiosphaera pantotropha* might be considered. When grown autotrophically on thiosulfate, it occurs as small cocci (0.7×0.9 μm), which are generally found singly or in pairs (Fig. 8a). Cultivation in batch culture on rich media in which rapid growth will occur leads to a slightly larger, pleomorphic form (Fig. 8b). In chemostat cultures on mineral medium with acetate, chains of cocci appear. The internal structure of *Thiosphaera pantotropha* also changes with its growth conditions. Thus the normal appearance, with few inclusions, of a Gram-negative organism, which is found during substrate-limited chemostat culture (Fig. 8c), gives way to cells with PHB granules and complex membranous structures (Fig. 8d) when grown under oxygen or nitrogen-limited conditions, or in the presence of hydroxylamine. Cultivation on acetone or propan-2-ol results in the formation of large, crystalline structures (Fig. 8e), while denitrifying growth on sulfide can result in the accumulation of a fine deposit of sulfur in the periplasm (Fig. 8f). The colonial form of this species also varies, with off-white, translucent colonies being produced during growth on mineral medium with acetate or thiosulfate; and larger, thicker, browner colonies being generated during growth on rich media.

Even the obligate autotrophs, which with their more limited range of growth conditions might appear to have less scope for variation, can produce substantial morphological changes. Thus, the number of carboxysomes formed by *Thiobacillus neapolitanus* increases dramatically under CO_2 limitation (Beudeker et al., 1980), and polyglucose inclusions appear under nitrogen limitation (Beudeker et al., 1981).

From all of this, it is clear that while valuable information can be gained from morphological studies on cells or colonies grown under well-defined conditions, this information should be used cautiously and in conjunction with other data. In exceptional circumstances, very distinctive morphology (e.g., in the case of *Beggiatoa* or *Hyphomicrobium*) might be more reliable as an indicator of identity.

Physiological Screening

As more pure cultures became available, it became possible to determine the physiological capabilities of different bacteria, and physiological criteria gradually became an integral part of the taxonomists' armory. For the obligate autotrophs, these might include such tests as optimum pH, growth temperature, ability to denitrify, and (generally very limited) substrate range. In addition to these, the facultative autotrophs are generally subjected to the same range of tests used for heterotrophic bacteria including oxidase, catalase and urease reactions, and the ability to grow on or generate acid from a range of substrates. An extensive study of the *Thiobacillus* species then available resulted in a numerical taxonomy analysis of the genus (Hutchinson et al., 1969) that recognized that "species" such as *Ferrobacillus ferrooxidans* and *Thiobacillus thiocyanoxidans* were actually strains of existing species (*T. ferrooxidans* and *T. thioparus*, respectively). The tests recommended by Hutchinson et al. (1969) for the identification of new *Thiobacillus* species included growth on sulfide, sulfur, thiocyanate, citrate and nutrient broth, the amount of thiosulfate used, sulfur deposition, and the effect of inhibitors such as streptomycin, bacitracin and ampicillin.

In many respects, the range of substrates on which an isolate is tested is defined by the interests of the research group. The reduced sulfur compounds are not included in standard test batteries, and the sulfur-oxidizing abilities of many bacteria are only now being discovered. For example, Friedrich and Mitrenga (1981) tested a number of hydrogen-oxidizing bacteria and found that many of them, including *Paracoccus denitrificans* and some *Alcaligenes* species, were able to grow autotrophically on thiosulfate. Attempts to use thiosulfate as an inhibitor of heterotrophic nitrification by a "*Pseudomonas*" species gave anomalous results until it was realized that the culture was growing mixotrophically, using both the acetate supplied as the primary growth substrate and the thiosulfate added as a possible inhibitor. Subsequent experiments revealed that this "*Pseudomonas*" species was also able to grow autotrophically using reduced sulfur compounds (Robertson et al., 1989).

A problem associated with the use of substrate ranges for taxonomic purposes is that it is difficult to determine how closely related bacteria with the same enzyme system are. Thus, possession of the Calvin cycle enzymes for carbon dioxide fixation or the denitrification pathway enzymes is not considered sufficient grounds for

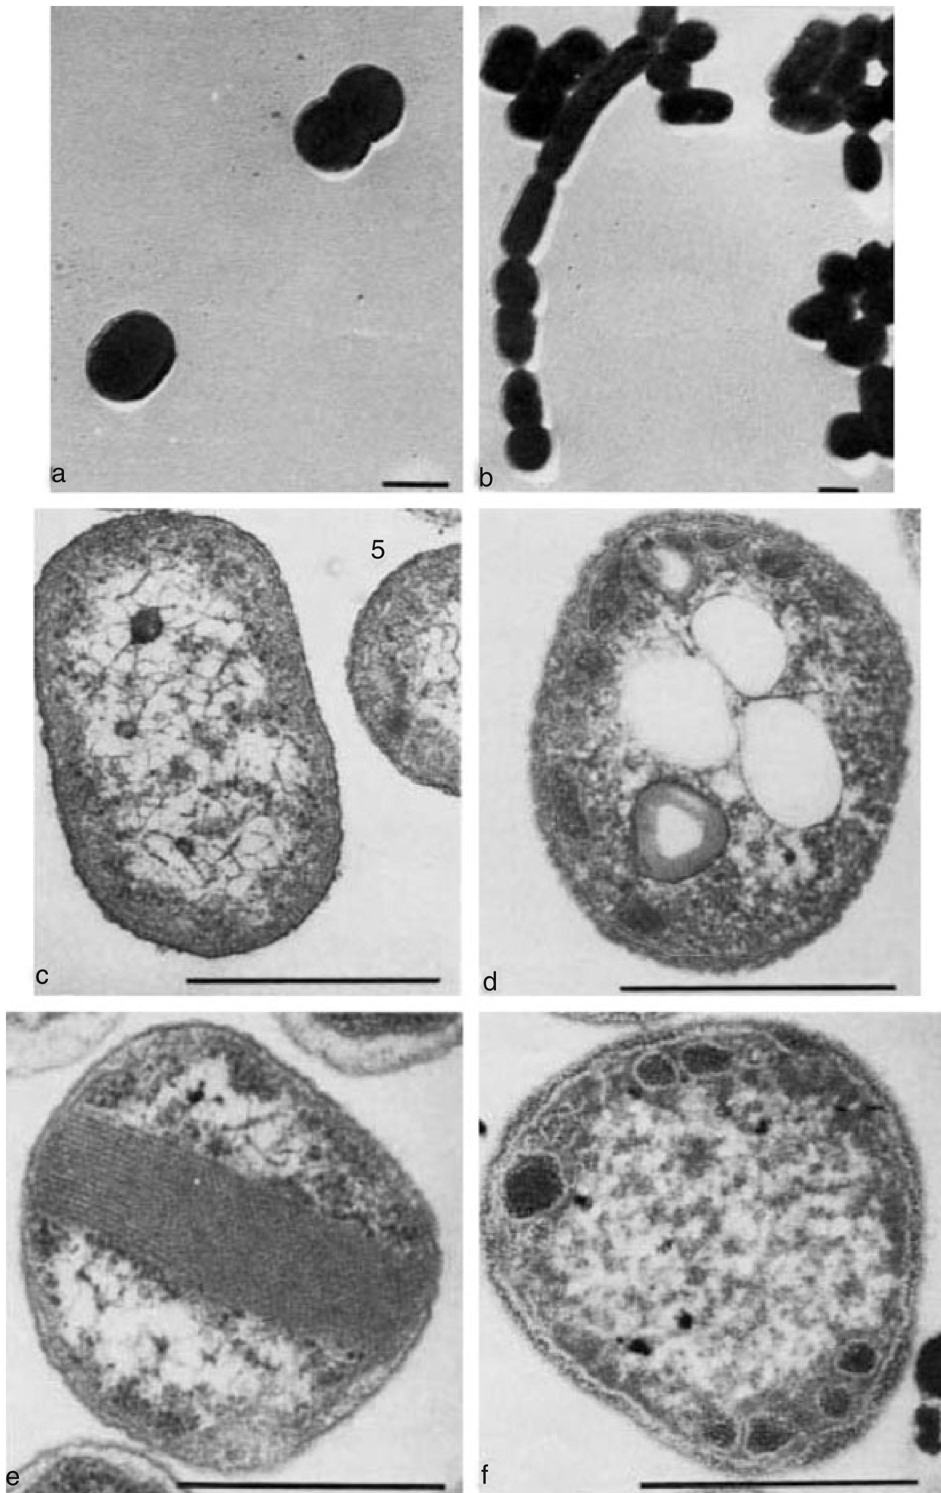

Fig. 8. Variations in the morphology of cells of *Thiosphaera pantotropha* in relation to growth conditions or substrates as seen under the electron microscope. (a) Aerobic, autotrophic growth on thiosulfate, Pt shadowed. (b) Aerobic, heterotrophic growth on a mixture of acetate, fructose, and yeast extract, Pt shadowed. (c) Thin section of cells from an acetate-limited, chemostat-grown culture, stained with ruthenium red to show the membrane structures. (d) Thin section of a cell from an aerobic, acetate-limited chemostat with hydroxylamine, stained with ruthenium red to show the membrane structures. The white bodies are PHB granules. (e) Thin section of an acetone-grown cell showing crystalline inclusions. (f) Thin section of an anaerobic (denitrifying) cell grown on sulfide and stained with silver to show the periplasmic deposits of sulfur. (Fig. 8b from Robertson and Kuenen, 1983b. Fig. 8c from Bonnet-Smits et al., 1988. Fig. 8f, courtesy of H. J. Nanninga. All electron microscopy courtesy of W. Batenberg.) All bars = 0.5 µm.

classifying the relevant bacteria into a single group, and it must be questioned whether the sulfur-oxidizing enzymes are a better indicator, especially since there appears to be several different pathways involved (Kelly, 1988a, 1988b) (see also Fig. 2, above). Certainly, it is recognized that at least one genus, *Thiobacillus*, is very heterogeneous (Kuenen, 1989; Kelly and Harrison, 1989) and will probably require subdivision. It has been suggested that this separation should be made between the obligate and the facultative autotrophs (thus, again on physiological grounds) but, as will be seen in the following section, this is probably not sufficient.

Analytical Techniques

The determination of the GC content of the DNA of bacterial isolates has been used for a long time to determine whether or not strains could be related. It is, to some extent, a negative test because, while widely differing GC values could confirm that two strains were not related, matching GC values do not guarantee that they are the same.

Cellular fatty acid analysis has been used in the taxonomy of the *Thiobacilli* (Agate and Vishniac, 1973; Katayama-Fujimura et al., 1982). Katayama-Fujimura et al. (1982) also included the analysis of ubiquinones and DNA base composition in their study. They initially subdivided the bacteria into groups based on whether they were obligately or facultatively autotrophic, and then on the basis of their possession of menaquinone 8 or 10, (MK-8 or MK-10) and then used the fatty acid analysis to further examine each group. This led to a proposal for the grouping of the different strains, which is shown in Table 7.

Some of the first publications to consider the *Thiobacilli* in relation to other colorless sulfur bacteria involved the phylogenetic analysis of the various species by comparison of their 5S rRNA sequences (Lane et al., 1985; Stahl et al., 1987). This work has now been extended by the use of 16S rRNA analysis (Lane et al., 1990; Oyaizu et al., 1990), and has revealed that there are closer matches between some sulfur-oxidizing bacteria and other apparently unrelated strains such as *Escherichia coli* than between these and other sulfur oxidizers. Table 8 summarizes some of the results from the 5S and 16S rRNA comparisons. The sulfur oxidizing genera *Sulfolobus* and *Acidianus* are archaebacteria and therefore not listed in Table 8.

If the initial separation into obligate and facultative autotrophs employed by Katayama-Fujimura et al. (1982) is removed, it can be seen that the results in Tables 7 and 8 support each other. Thus groups I.1 and I.2 from the menaquinone/fatty acid analysis correspond to group alpha from the 16S rRNA, groups II and III-1 with group beta-1, and groups III-2 and III-3 with beta-2. Of course, the range of bacteria subjected to the menaquinone/fatty analysis was much more limited than that in the 5S and 16S rRNA survey, and more data would be useful. However, such independent agreement must confer additional weight that chemotaxonomy and phylogeny may provide more reliable tools for the classification of these bacteria than physiological or morphological observations.

Habitats

As may be deduced from the range of physiological characteristics discussed above, the colorless sulfur bacteria, in one form or another, are to be found in almost every life-supporting environment where reduced sulfur compounds are found. Because the range of habitats is so wide, the principles underlying the selection of colorless sulfur bacteria in selected situations will be be discussed below. The following section will then deal more generally with the role of the

Table 7. Classification of the *Thiobacillus* species based on analysis of their menaquinone and fatty acid composition.

Autotrophy type	Menaquinone	Hydroxy fatty acid	Species	Group
Facultative	MK-10	None	*T. novellus*	I.1
Facultative	MK-10	3OH 10:0	*T. versutus*	I.1
Facultative	MK-10	3OH 14:0	*T. acidophilus*	I.2
Facultative	MK-8	3OH 10:0	*T. delicatus*	II
Facultative	MK-8	3OH 10:0, 3OH 12:0	*T. perometabolis*	II
Facultative	MK-8	3OH 10:0, 3OH 12:0	*T. intermedius*	II
Obligate	MK-8	3OH 10:0, 3OH 12:0	*T. denitrificans*	III.1
Obligate	MK-8	3OH 10:0, 3OH 12:0	*T. thioparus*	III.1
Obligate	MK-8	3OH 12:0	*T. neapolitanus*	III.2
Obligate	MK-8	3OH 14:0	*T. ferrooxidans*	III.3
Obligate	MK-8	3OH 14:0	*T. thiooxidans*	III.3

MK, menaquinone. The number indicates the number of isoprenoid units. Groupings are as proposed by Katayama-Fujimura et al. (1982).

Table 8. Classification of the colorless sulfur bacteria and examples of apparently related species (group "purple"), also termed *Proteobacteria* (Stackebrandt et al., 1988), as shown by 16S rRNA analysis.[a]

Main group	Subgroup	Species
Alpha	1	*Thiobacillus (T.) acidophilus*, *Acidiphilium rubrum*
	1	*A. cryptum*, *T. novellus*
	2	*Rhodobacter capsulatus*, *T. versutus*
	2	*Paracoccus denitrificans*
Beta	1	*T. denitrificans*, *T. thioparus*
	1	*T. intermedius*, *T. perometabolis*
	1	*Rhodocyclus gelatinosa*
	1	*Vitreoscilla*
	2	*T. tepidarius*, *T. ferrooxidans*
	2	*T. albertis*, *T. thiooxidans*
Borderline		*T. neapolitanus*, *Chromatium vinosum*
Gamma	1	*Thiothrix nivea*, *Riftia symbionts*
	1	*Thiomicrospira pelophila*, *Thiomicrospira* L-12
	1	*Bathymodicius* symbionts
	1	Other symbionts
	1	*Pseudomonas aeruginosa*, *P. putida*
	1	*Beggiatoa alba*, *Beggiatoa* sp.
	2	*Escherichia coli*, *Salmonella*, *Proteus*, *Vibrio*
Delta		*Thiovulum*, *Campylobacter*, *Wollinella*

Atypical strains have been omitted for the sake of simplicity.
Adapted from Lane et al., 1990; and Harrison (1989).

colorless sulfur-oxidizing bacteria in the sulfur cycle, and this discussion of habitats is not intended to be exhaustive.

In natural habitats, the reduced sulfur compounds available tend to be either sulfides (including metallic ores) or sulfur. Thanks to the activities of sulfate-reducing bacteria, especially in anoxic sediments, hydrogen sulfide is very commonly available, and some algal and cyanobacterial mats have been shown to generate organic sulphides (e.g., Andreae and Barnard, 1984). One of the main factors that bacteria growing on hydrogen sulfide have to contend with is the chemical reaction between sulfide and oxygen, and therefore the colorless sulfur bacteria are frequently found in the gradients at the interface between anoxic, sulfide-containing areas and aerobic waters and sediments where, at very low oxygen and sulfide concentrations, they can effectively compete with the spontaneous chemical oxidation reaction. Of course, the rate of chemical oxidation of metal sulfides with oxygen is very low at acid pH levels, so that the acidophilic bacteria need not, therefore, occur predominantly in gradients, as their neutrophilic counterparts must. The same holds for deposits of elemental sulfur, which does not react spontaneously with oxygen at a significant rate. Another habitat in which sulfide-oxidizing bacteria appear to be of some importance is in the complex communities of prokaryotes and eukaryotes around hydrothermal vents, where the sulfide is geologically rather than biologically generated. In the course of research into the life around these vents, it was shown that many invertebrates have symbiotic colorless sulfur bacteria, and this can itself be regarded as a distinct habitat (Cavanaugh et al., 1981). A third example of a type of habitat for these bacteria that is becoming steadily more common is that associated with human activities, largely in connection with waste treatment and industrial leaching of ores for (heavy) metal recovery.

Gradients in Aquatic Systems and Sediments

Sulfide:oxygen gradients occur in stratified water bodies, as well as in soils and sediments. Such gradients can range in size from a few hundred-micrometers-thick in a microbial mat or surface sediment to several meters in a stratified body of water (Sorokin, 1970, 1972; Jørgensen et al., 1979). These gradients can sometimes be distinguished with the naked eye. For example, *Thiovulum* grows as a fine white veil at the interface between sulfide and oxygen (Jørgensen, 1988). Wirsen and Jannasch (1978), studying the effect of the sulfide:oxygen gradient on the formation of these veils in continuous flow cultures, observed that the veils dispersed within minutes of the cessation of the flow of sea water through the culture vessel, and formed again once the flow was resumed, indicating chemotaxis of the swarming form of *Thiovulum* toward critical concentrations of oxygen and sulfide.

The genus *Beggiatoa* contains marine and freshwater species that are typical of life at the aerobic:anaerobic interface. Dense mats of

almost axenic cultures of *Beggiatoa* on sulfide-containing sediments are frequently observed, especially in marine sediments where sulfide production rates can be very high. These mats are characterized by very steep oxygen and sulfide gradients over a few mm (Jørgensen, 1982, 1988). Since *Beggiatoa* oxidizes the sulfide at a very high rate, the overlying aerobic water is effectively "protected" from diffusion of toxic sulfide. The typical conditions for growth in this type of mat have been very difficult to reproduce in the laboratory. Indeed, they are so specialized that it was only recently, when available techniques had improved sufficiently to allow in vitro cultivation on sulfide:oxygen gradients, that the autotrophic potential of marine strains was established unambiguously (Nelson and Jannasch, 1983; Nelson, 1988) (see also Chapter 166). The *Beggiatoa* cells were cultured in closed tubes using a layer of very soft (0.2%) agar over a sulfide-containing plug of harder (1.5%) agar, thus allowing the formation of an upward sulfide gradient. Diffusion from a headspace containing air contributed a downward oxygen gradient. The *Beggiatoa* colony grew as a "plate" that was less than 1 mm thick at the point where the two gradients overlapped. The very rapid oxidation of sulfide allowed the organisms to maintain an extremely low concentration of the two substrates. As a result, chemical oxidation of sulfide was insignificant. For example, the turnover time for sulfide and oxygen was only 3 seconds in *Beggiatoa* gradients, whereas the half life of these two substances in sterile controls was about 20 min. Enzyme analysis and the fixation of $^{14}CO_2$ by these cells confirmed that they were capable of autotrophic growth. The situation regarding freshwater strains is not so clearcut. Schmidt et al. (1987) showed sulfide oxidation rates for a freshwater strain comparable to those obtained with the marine strain discussed above, but further experimentation is necessary in order to establish whether energy for growth can be derived from the reaction.

Another well-known place where gradients occur is within phototrophic mats. Jørgensen and des Marais (1986) studied the zonation around a cyanobacterial mat growing in a hypersaline pond and found that a band of *Beggiatoa* occurred 1.5 mm below the cyanobacteria. The photosynthetic activity of the cyanobacteria generated sufficient oxygen to produce an oxygen peak with a maximum of 1mM at the cyanobacterial band. A steep downward gradient of oxygen overlapped a sulfide gradient at the point where the *Beggiatoa* were growing. In an earlier study, Jørgensen (1982) described the diurnal changes in the sulfide and oxygen gradients and the microbial community to be found in a sulfuretum (a microbial mat in which the total turnover of inorganic and organic compounds is heavily dominated by the sulfur cycle) on the surface of a sediment. It was observed that the mixture of cyanobacteria, phototrophic sulfur bacteria, and *Beggiatoa* was stratified, and that the relative positions of the the three populations among the strata were governed by the level of photosynthetically generated oxygen (Fig. 9). During the night, when the oxygen had been depleted and the oxygen boundary extended to the surface of the sediment, the phototrophic *Chromatium* was found at the surface. However, once photosynthesis began, with the onset of daylight, oxygen began to build up in the sediment, and the *Chromatium* followed the sulfide boundary down, remaining within the anaerobic part of the sediment. The *Beggiatoa* population tended to move with the sulfide:oxygen interface, except during the night when this was in the stagnant water above the surface of the sediment. As *Beggiatoa* is only motile by means of a gliding action, it is restricted to the solid phase.

Other conspicuous colorless sulfur bacteria such as *Thiothrix*, *Thioploca*, and *Archromatium* have all been encountered as typical organisms in such gradients. Furthermore, mixed cultures of *Thiobacillus*-like bacteria sampled from sulfide:oxygen gradients and showing active sulfide-dependent carbon dioxide fixation clearly exhibit chemotaxis toward the interface when transferred to artificial sulfide:oxygen gradients in the laboratory (J. G. Kuenen, unpublished observations).

Hydrothermal Vents

An interesting extension of the model for the selection of freshwater colorless sulfur bacteria discussed above is to be found in the results of research on the mesophilic bacterial communities found around the different hydrothermal vents (Jannasch, 1985, 1988). These vents are a result of the movements of the tectonic plates of the earth's crust. Seawater penetrates deep under the sea floor and is heated geothermally, reaching temperatures as high as 1,200°C. Under these conditions, it reacts with and dissolves various reduced chemicals before being forced to the surface again as hydrothermal fluid, which contains sulfide, CO_2, and methane, as well as various metals and hydrogen. The type of vent that occurs depends very much on the overlying geology, and can be at least partially separated into "bare lava" and "warm" systems. In the bare lava vents, the pressurized hydrothermal fluid reaches the surface of the sea floor at temperatures around 350°C. As it issues from the vents, it reacts with chemicals in the sea water, forming precipitates that often accumulate as "chim-

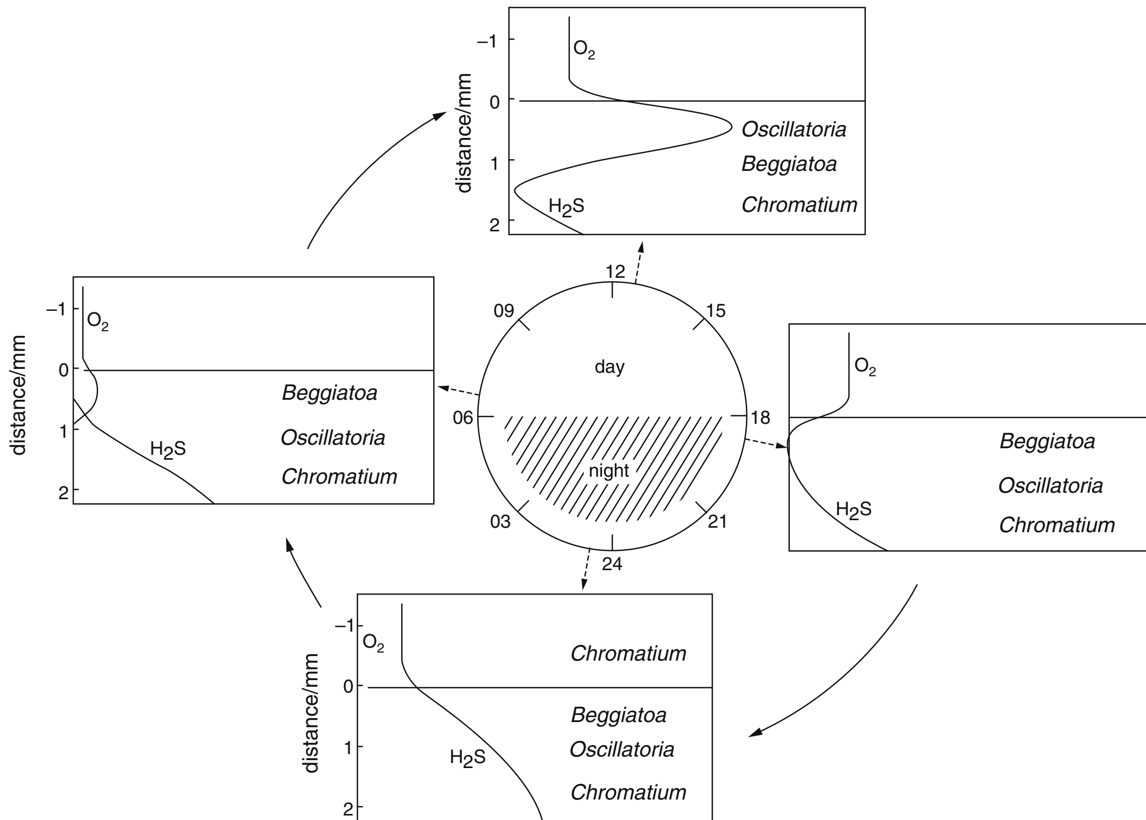

Fig. 9. Diurnal cycle of oxygen and sulfide distribution and of microbial zonation in a marine sulfuretum. The zero line in each box indicates the interface between the sediment and the overlaying water phase. The dominant genera at each stratum are indicated in each box. Diatoms were primarily seen among the *Oscillatoria.* In addition to diurnal changes in light, oxygen, and sulfide, another important factor was that the *Beggiatoa* which are gliding bacteria could not move out of the sediment, whereas *Chromatium,* which is also motile, was able to move into the water phase above. From Jørgensen (1982).

neys." Because the formation of metal sulfides gives the fluid issuing from these chimneys the appearance of smoke, they have become known as "black smokers." The "warm" vents, on the other hand, are the result of the hydrothermal fluid percolating through sediments on its way to the surface, and the solution tends to be much cooler (<25°C) and to have substantial organic content when it reaches the sea water. The waters around these vents support dense communities of bacteria able to grow on the geothermally generated reduced compounds. Thus far, obligately autotrophic sulfur bacteria, especially *Thiomicrospira* species (Ruby et al., 1981; Ruby and Jannasch, 1982), have been found associated with the areas around black smokers where the organic turnover is relatively low, while facultative autotrophs such as *Beggiatoa* appear to dominate around the sedimented vents where the organic turnover is much higher (Jannasch, 1988). Indeed, until recently, it was believed that *Beggiatoa* mats rarely exceeded 1 mm in thickness (Nelson, 1988). However, observations at the Guaymas Basin hydrothermal vents, where the hydrothermal fluid in some areas percolates though 400 m of sediment before reaching the surface, revealed mats of *Beggiatoa* up to 60 cm thick (Nelson et al., 1989). The communities around these vents appeared to be made up of three strains of *Beggiatoa* that had widely differing cell widths (115–122 µm, 40–42 µm, and 24–32 µm). The narrowest of these dominated, almost to the point of a monoculture, in the thickest layers, which were apparently associated with colonies of the vestimentiferan tube worms (see "Symbiosis," below). In addition to sulfide concentration and temperature, the authors suggest that organic excretion compounds from the worms may be an important factor in the development of these mats.

Symbiosis

Geologists studying areas of volcanic activity on the sea bed (1,800–3,700 meters below the surface) were surprised to find that not only were there dense, free-living bacterial populations associated with the vents, but that these perma-

nently dark areas were also occupied by an extensive community of invertebrates (and also, in some areas, fish), most of which were previously unknown (Corliss et al., 1979). Despite the density of the bacterial community, it was difficult to see how a food chain based entirely on suspended bacteria as a source of prey could support the considerable population of very large tube worms, clams and other invertebrates. Investigation of the anatomy of the tube worms (*Riftia pachyptilia*) revealed that they do not have an alimentary tract, but instead possess a large (more than half the weight of the worm) body of tissue, the trophosome, which is very rich in blood vessels. Examination of this tissue under the electron microscope revealed that it also contained a dense, intracellular community of bacteria (Cavanaugh et al., 1981; Cavanaugh, 1983a). The trophosome had already been shown to contain the enzymes necessary for chemoautotrophic growth on reduced sulfur compounds. These enzymes did not occur elsewhere in the tissues of the worm (Felbeck, 1981; Felbeck et al., 1981) and were presumably derived from the bacteria. It appears that this is an example of prokaryotic:eukaryotic symbiosis in which the tube worms rely on organic compounds excreted by the bacteria (see Chapter 215). The blood of the tube worms carries sulfide as well as oxygen from the gills to the trophosome, and has a special sulfide-binding protein that prevents sulfide toxicity. Endosymbionts have also been found in the giant white clams (*Calyptogena magnifica*), among other vent fauna and are not limited to sulfide-oxidizing bacteria, since methylotrophs have also been found (Jannasch, 1988) (see also Chapter 18). As yet, successful attempts to produce cultures of the symbiotic colourless sulphur bacteria have not been reported, but 5S and 16S rRNA analysis has indicated a relatively close relationship with members of the genus *Thiomicrospira* (Lane et al., 1985, 1990), which, as mentioned above, is one of the best-represented genera among the free-living bacterial community at the vents (Ruby et al., 1981; Ruby and Jannasch, 1982; Jannasch, 1988).

Once the occurrence of endosymbiotic bacteria in the animals of the hydrothermal vents had been accepted, many more occurrences were recognized in more mundane locations, including sewage outfalls and sulfide-rich sediments (Southward, 1986; Dando and Southward, 1986). Many of the animals associated with symbionts resemble *Riftia pachyptila* in that they completely lack a mouth and digestive system, whereas others may have only small guts and feeding appendages (Cavanaugh, 1983a, 1983b). Although not all of them have a specialized organ like the trophosome, many endosymbionts do appear to be associated with the gills of the eukaryotic host. For example, intracellular colorless sulfur bacteria have been found in the gill tissues of bivalves such as *Solemya velum* (Cavanaugh, 1983b) and *Thyasyris flexuosa* (Wood and Kelly, 1989). The recent description of a novel *Thiobacillus* species, *T. thyasiris*, (Wood and Kelly, 1989) from the gill tissue of *Thyasyris flexuosa* is probably the first report of the isolation of one of these symbionts. Whether all symbionts are capable of free-living growth (albeit with possible complex nutritional requirements), or whether some are so adapted to their symbiotic way of life that they are no longer capable of independent growth, remains to be seen.

A recent publication (Smith et al., 1989) has illustrated the effect that a localized deposit of organic material in an otherwise oligotrophic environment can have on the indigenous community. The skeleton of a 20 meter-long whale at a depth of 1,240 meters on the sea bed in the Santa Catalina basin was not only covered with mats of *Beggiatoa* resembling *Beggiatoa gigantea*, but it also supported six metazoan species, at least four of which are known in other locations to contain endosymbionts. As well as vent species (*Vesicomya gigas* and *Calyptogena pacifica*), others organisms known from anoxic sediments (*Lucinoma annulata*) and rotting wood (*Idasola washingtonia*) were also observed. None of these prokaryotic or eukaryotic species had been observed in this area before. It was found that the pore water under the skeleton contained around 20 μM sulfide, and the samples of whale bone that were recovered were found to be rich in oil and smelled strongly of sulfide. It would appear from the apparent ages of some of the molluscs present that a single whale carcass is sufficient to support these sulfide-dependent communities for several years.

Artificial Habitats and Application of Sulfur Bacteria

Artificial environments, such as the bioreactors used for industrial wastewater treatment, have provided habitats for bacteria that impose selective parameters not necessarily found in nature. Thus, substrates tend to be more abundant and conditions are generally more stable than in most natural situations. Two categories of artificial habitat where colorless sulfur bacteria are particularly important are wastewater treatment bioreactors and those associated with various leaching activities. Examples of other artificial habitats include industrial sulfur deposits or dumps, mining operations that expose sulfidic ores or sulfur to water or air, coal storage sites, and, last but not least, systems (including sewage

treatment plants) containing various amounts of reduced sulfur compounds.

Waste Treatment

Reduced sulfur compounds can occur in industrial wastes in a variety of forms and from a variety of sources. Thus, sulfide is an inevitable by-product of sulfate reduction associated with methanogenesis (if the effluent from which the methane is being generated contains significant amounts of sulfate) and the oil and gas industries. Thiosulfate and thiocyanate make up a substantial amount of the chemical content of photographic processing waste, and some papermaking processes generate both inorganic and organic sulfides. Of course, the amount of reduced sulfur compounds generated from industrial processes pales into insignificance when the quantity generated from animal wastes is considered, and research into methods of dealing with this is currently underway.

Reduced sulfur compounds present a problem both environmentally, because of their toxicity, and socially, because of their odor. If large amounts of sulfide are released into natural waters, this can result in oxygen depletion, either because of the oxygen demand for biological oxidation or, in the absence of suitable bacteria, by spontaneous chemical oxidation. Many water treatment plants impose surcharges for the treatment of such effluent, and there is obviously considerable pressure on companies to treat their effluent on the site. There are both chemical and physical methods of removing hydrogen sulfide from effluent; these include the use of ion-exchange resins, absorption with aqueous or organic solvents, and chemical oxidation (Gommers, 1988). Many of these simply transfer the problem to another waste stream or involve expensive or complex processes, and they are all expensive, especially for the removal of the last traces of sulfidic compounds.

Colorless sulfur bacteria occur in many sewage treatment systems and, in fact, are inadvertantly used to oxidize reduced sulfur compounds in the waste water. In some cases, this can lead to problems, such as the "bulking" caused by *Thiothrix*. The deliberate use of the biological treatment of sulfide-containing waste using colorless sulfur bacteria has attracted considerable attention of late. The end products (sulfur or sulfate) are not hazardous, and sulfate can be discharged directly into the sea or into brackish estuaries (which already are so high in sulfate that the discharge is insignificant). Moreover, biological treatment systems can be based on existing reactor designs (e.g., fluidized and packed bed reactors) and require very little in the way of new technology.

Another advantage of a biological process is that it can be combined with the treatment of other problems in an effluent. For example, the effluent of a methane reactor will contain ammonia in addition to sulfide. If the ammonia is then converted to nitrate or nitrite by aerobic, nitrifying bacteria, the resulting effluent can then be recycled to provide the electron acceptor for a sulfide-oxidizing reactor immediately after the methane reactor. The microbiological investigation of such a sulfide-oxidizing, denitritrifying reactor revealed the presence of large numbers of facultatively autotrophic colorless sulfur bacteria, which could oxidize sulfide to sulfate while reducing nitrate to nitrogen gas (Robertson and Kuenen, 1983a). In addition to the removal of nitrogen compounds, other advantages associated with the use of denitrifying bacteria rather than aerobic ones include lower production of both biomass and acid.

Combined Sulphide Oxidation and Denitrification. A denitrifying, sulfide-oxidizing reactor system was patented by a Dutch company, Gist brocades, for the post-treatment of effluent from methane-producing reactors (Patent number E.P.A.0051 888). Studies on a laboratory-scale model of this reactor, running on artificial waste water, revealed that sulfide (2–3 kg S/m^3·day), acetate (4–6 kg S/m^3·day) and nitrate (5 kg S/m^3·day) were all effectively removed (Gommers et al., 1988a). The rate-limiting step in the reactor proved to be the oxidation of sulfur to sulfate and, under most loads, the biomass had an overcapacity for both the oxidation of sulfide to sulfur and the conversion of acetate (Gommers et al., 1988b). During experiments in which nitrate depletion occurred, it became evident that in the absence of nitrate, at least one member of the bacterial community was able to reduce any available sulfur, thus illustrating the need for careful monitoring of the electron donor:electron acceptor ratios in such reactors (Gommers et al., 1988b).

The facultatively autotrophic species *Thiosphaera pantotropha* was isolated from a denitrifying, sulfide-oxidizing fluidized bed reactor that was supplied with approximately equivalent amounts of organic and inorganic substrates (Robertson and Kuenen, 1983b), and it initially appeared that the selection of a facultative bacterium would lend support to the model described for the ecological niches of aerobic, fresh-water sulfur-oxidizing bacteria (Fig. 4). However, subsequent attempts to isolate obligate autotrophs from a laboratory-scale model of this system that was being fed with an exclusively inorganic feed also resulted in the isolation of facultative autotrophs (M. Verbeek, W. Bijleveld, L. A.

Robertson, and J. G. Kuenen, unpublished observations). As yet, it is not clear whether obligate autotrophs were present in the inoculum, or the isolation techniques employed were inadequate for any obligate autotrophs present (although they were adequate for the cultivation of known obligate autotrophs), or whether growth in a biofilm in this type of reactor poses an additional selective pressure that favors facultatively autotrophic bacteria. Work has shown that a number of sulfide oxidizers from a wastewater system required cultivation on special membrane filters with sulfide gas before isolated colonies could be obtained (G. C. Stefess, R. de Schrijver, and J. C. de Bruyn, unpublished observations).

The same basic idea, that of using denitrifying colorless sulfur bacteria, was employed in a method proposed by Sublette and Sylvester (1987) for removing H_2S from gas streams by passing them through a reactor containing *Thiobacillus denitrificans*. The bacteria were first immobilized by co-culturing with floc-forming heterotrophs after the authors demonstrated that the presence of the heterotroph had no effect on the sulfide oxidation rate of *T. denitrificans*.

Removal of Sulfide as Elemental Sulfur. As already mentioned, sulfate-containing effluents can be discharged into the sea without significantly increasing the sulfur budget. However, the same is not true if the effluent is discharged into a body of fresh water. To overcome this problem, recovery as elemental sulfur, an intermediate in the oxidation of sulfide to sulfate, would be more appropriate. Research has shown that certain *Thiobacillus*-like bacteria are more inclined to produce sulfur than other species, and that both the dissolved oxygen and the sulfide concentration play an important part in determining whether sulfur or sulfate is the primary end product during sulfide oxidation. Both electron acceptor limitation and high sulfide loads favor sulfur production (Stefess and Kuenen, 1989). A pilot plant based on this principle, using a mixed bacterial biofilm reactor to treat the effluent from a paper mill, is being developed in the Netherlands (Buisman, 1989).

Removal of Organic Sulphides. A problem frequently encountered during the alkaline pulping of wood is the production of organic sulfides, such as methyl mercaptan and dimethyl sulfide. Alkaline pulping is done in order to improve the yield and quality of pulp derived from conifers to be used primarily in the manufacture of paper. Organic sulfides are toxic at even lower concentrations than hydrogen sulfide and have a very low threshold odor. Despite their toxicity, it has proved possible to grow bacteria on high concentrations of organic sulfides by using substrate-limited chemostats (Suylen et al., 1986; Kanagawa and Kelly, 1986; Smith and Kelly, 1988a, 1988b, 1988c). That the ability to oxidize these compounds may be widespread is suggested by the observation that the dominant organism in one set of experiments was a *Hyphomicrobium* species that was later shown to be able to grow as a facultative chemolithotroph on organic sulfur compounds in pure culture (Suylen and Kuenen, 1986; Suylen et al., 1986), whereas the key organism in the other series was a strain of *Thiobacillus thioparus*, an obligate autotroph (Kanagawa and Kelly, 1986). Immobilized cells of *T. thioparus* strain TK-m have now been successfully used on the laboratory scale to deodorize gases containing methyl mercaptan, dimethyl sulfide, dimethyl disulfide, and hydrogen sulfide (Kanagawa and Mikami, 1989; Tanji et al., 1989).

All of the colorless sulfur bacteria mentioned thus far are beneficial in wastewater treatment. However, in oxidation tanks fed with sulfide-containing waste water, the filamentous *Thiothrix* species can cause problems because they are associated with the phenomenon known as "bulking"; this occurs when bacterial aggregations that usually settle easily become loose and flocculent. This can result in blockages or loss of the biomass from the reactor.

Leaching-Associated Activities

Acidophilic bacteria are used in the recovery of metals from poor ores by leaching, and their potential use in the desulfurization of coal is currently being studied. To some extent, coal desulfurization and microbial leaching are the same process, in that in both cases sulfidic ores are oxidized, using similar organisms. However, the desired end products are different, and they are thus generally discussed separately. The aim of coal desulfurization is to produce a solid product (coal) that is as free of sulfur (including sulfur-containing precipitates) as possible, and it is therefore necessary to convert reduced sulfur compounds to soluble forms. In leaching, it is metal recovery that is important, and the presence of jarosite ($M{\cdot}Fe_3(SO_4)_2OH_5$, where M is a monovalent cation such as Na^+ or K^+) and other precipitates in the solid waste is not relevant (although it may constitute an environmental problem around the leaching heaps).

Bacterial Leaching. Bacterial leaching is used in the recovery of metals from ores that are too poor for conventional metallurgical extraction

methods (Tuovinen and Kelly, 1972; Brierley and Lockwood, 1977; Brierley, 1982). Combinations of *T. ferrooxidans* and either *T. thiooxidans* or *T. acidophilus* (previously called *T. organoparus*) and *Leptospirillum ferrooxidans* have been associated with the degradation of pyrite (FeS_2) and chalcopyrite ($CuFeS_2$). The leaching reactions may involve the direct bacterial oxidation of the sulfide ores with oxygen and/or an indirect process during which ferric ions produced by the bacterial oxidation of ferrous iron are used to chemically oxidize the sulfide ores. The ferric ions are thereby reduced to ferrous iron, which, in turn, can be recycled by the bacteria. During this process, other metallic ions such as cupric copper dissolve. Other metals that have been extracted using processes that involve bacteria include zinc, uranium, lead, gold, molybdenum, and, especially, copper.

Dump leaching operations, which are frequently used to extract copper, can be fairly primitive, involving the creation of ore dumps, often in valleys or old open pit mines. As water percolates through the heaped rocks, bacterial activity releases the metals into solution. This solution is then collected in catch basins, the metals recovered, and the liquids recycled to the top of the dump. A somewhat better controlled system is known as heap leaching. During this process, the ore-bearing rocks are crushed to promote contact with the acidified water, and the heaps are built on impermeable bases that prevent seepage into the soil beneath. Aeration systems can be built into the heaps. It is to be expected that as mineral reserves become depleted, and it becomes economically attractive to extract even small amounts of metals in poor ores and spoilage heaps, technological improvements will increase the efficiency of microbial leaching processes and, perhaps, lessen their environmental impact. For a full review of bacterial leaching, the reader is referred to reviews such as Brierley (1982) and the volume edited by Ehrlich and Brierley (1990).

Coal Desulfurization. Research into the use of the pyrite-oxidizing abilities of bacteria, such as *Thiobacillus ferrooxidans* and *Sulfolobus* species, for the removal of sulfur compounds from coal before it is burned, thus reducing sulfur emission into the atmosphere, has been carried out at a number of centers in the last decade. It has been shown that such a process could be effective, especially for low-sulfur coals, using consortia of mesophilic bacteria (Bos et al., 1988; Bos and Kuenen, 1990). Laboratory studies have shown that an optimal process requires two steps. First, a mixed-flow inoculation step, where a fairly dense population of bacteria already growing on pyrite can be brought into contact with fresh, finely ground coal at a pH suitable for growth (around pH 1.8). This inoculation step would then be followed by the use of plug-flow reactors, where the bulk of the pyrite oxidation would take place. At the end of the process, the process water can be recirculated, as can some of the biomass-bearing coal particles, to serve as the inoculum for the fresh coal. A plant design, involving a cascade of Pachuca tanks (Fig. 10), was devised for this type of system (Bos et al., 1988). Pachuca tanks (in their simplest form, an inverted cone with aeration at the narrowest point, at the bottom of the tank) are particularly suitable for this type of process because the upflow of air into the tanks not only provides the bacterial community with the oxygen and carbon

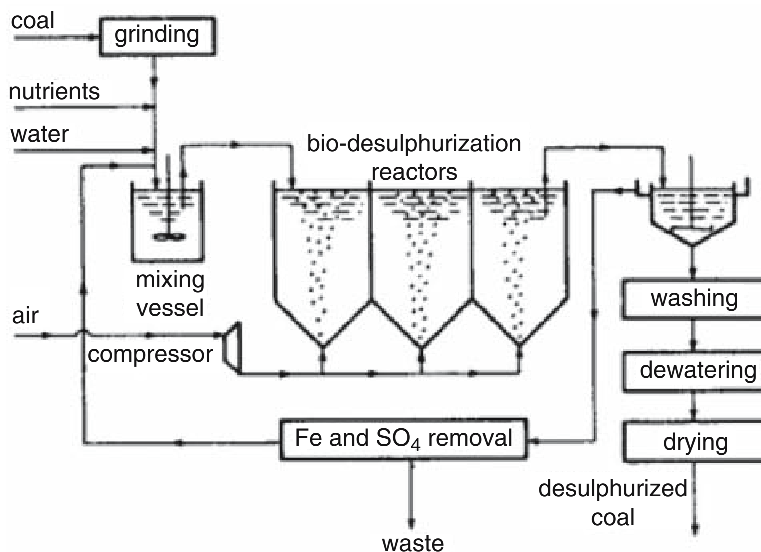

Fig. 10. Simplified scheme for the microbiological desulfurization of coal in Pachuca tanks (bio-desulfurization reactors). After grinding and mixing with water, the coal slurry contains particles less than 100 μm in diameter at a concentration of 20% (w/v). At this particle size, virtually all of the pyrite crystals become accessible to microbial leaching. The total leaching process requires about 10 days. More than 95% of the inorganic sulfur is removed, but little or no organic sulfur is degraded.

dioxide necessary, but it also keeps the slurry well mixed, without any need for complex and expensive stirring mechanisms.

Corrosion

Together with the sulfate-reducing bacteria, many of the sulfuric-acid-producing bacteria, and in particular the acidophiles, have been implicated in many corrosion problems. Indeed a strain of *T. thiooxidans* isolated from a corroding concrete pipe was originally known as *T. concretivorans* (i.e., concrete-eating). In sewage pipes with an aerobic headspace, sulfide may be produced in the anaerobic water phase and then be transferred to the film of water on the aerobic part of the pipe where it may be oxidized to sulfuric acid. In order to dissolve the carbonates in concrete, the pH need only be below 5.0–5.5 and such a pH can be generated by either neutrophilic or acidophilic bacteria. The activities of the acidophiles may also be responsible for steel pipe corrosion (Kuenen and Bos, 1988) as well as many of the pollution problems associated with the acid run-off from mine spoil heaps. These environmental problems are not only associated with the low pH of the water, but also with the toxic concentrations of heavy metals that they may contain. In addition, acidic water containing ferric sulfate may generate precipitates of jarosite, and these can block drainage pipes and cover stream and river sediments.

The Role of Colorless Sulfur-Oxidizing Bacteria in the Sulfur Cycle

Although much is known about the physiology and occurrence of colorless sulfur bacteria, less is known about the quantitative aspects of their activity in nature. Many of the reasons for this are difficulties commonly associated with field work (e.g., heterogeneous samples, unstable gradients, low concentrations of substrates), and are therefore outside the scope of this chapter, but a few difficulties are uniquely associated with the colorless sulfur bacteria.

Commonly used methods for estimating the activity of sulfur-oxidizing bacteria in the field include cell counts, oxidation of (radiolabelled) substrate (sulfide, thiosulfate, or sulfur), product formation (especially sulfuric acid, since this causes pH changes), and $^{14}CO_2$ fixation. Other, more specific techniques include the measurement of substrate-dependent respiration and immunofluorescent microscopy.

Cell Counts

With some of the more conspicuous bacteria (e.g., *Beggiatoa*, *Thiovulum*), it is possible to obtain a rough estimate of numbers based on direct cell counts. However, most of the colorless sulfur bacteria require cultivation before they can be counted. The choice of media and substrates for most-probable-number (MPN) estimates or direct plate counts is especially difficult for the colorless sulfur bacteria. The most obvious problem is that outside the chemostat there is no way of selectively growing facultative autotrophs or chemolithoheterotrophs. They must first be isolated on autotrophic or heterotrophic media, respectively, and then screened for sulfur oxidizing capacity. In addition, low recovery efficiency can be a problem with both plate counts and dilution series. Two other problems are associated with the obligate autotrophs: 1) thiosulfate is frequently used as an energy source in solid media, but this is not always the most suitable energy source. For some bacteria, agar plates containing colloidal sulfur (see Chapter 138) may be more appropriate, while other bacteria may require sulfide. The use of solid sulfide media can present technical problems with regard to toxicity and instability unless one of the less-soluble nontoxic sulfides (e.g., calcium sulfide) is used: 2) some autotrophic species do not give distinct colonies on agar, and moreover, the acidophiles may be inhibited by organic compounds resulting from chemical acid hydrolysis of the agar itself at their required growth pH values. To overcome these agar-associated problems, other techniques (such as the use of silica gel plates or floating filters [de Bruyn et al., 1990] may be more appropriate (G. C. Stefess, R. de Schrijver, and J. C. de Bruyn, unpublished observations). Some of the sulfur-oxidizers may have a requirement for an unidentified growth factor such as a vitamin or mineral.

Activity Measurements

Data on the rates of sulfide oxidation in natural systems are scattered and somewhat variable, possibly because of the difficulty of accurate sampling as well as the reactivity of the compounds involved.

Substrate Uptake and/or Transformation—Chemical and Radioassays. Once cell numbers have been estimated with a degree of confidence, they can only be used to provide an idea of the potential activity of colorless sulfur-oxidizing bacteria within that particular ecosystem. The measurement of substrate transformations (i.e, utilization or accumulation), preferably in situ, can be used as a measure of

actual activity. A major problem associated with the use and measurement of many reduced sulfur compounds, especially sulfide and sulfite, is that they are chemically very reactive and are readily oxidized spontaneously by oxygen. Appropriate controls can, to some extent, overcome this problem, but it must be remembered that in nature biological and chemical reactions compete, and equilibrium reactions causing the exchange of radiolabel in reduced sulfur compounds mean that extra caution must be used in the interpretation of results. Moreover, chemical oxidation rates are influenced by many of the environmental parameters that also affect biological activity (e.g., pH, temperature, chemical constitution of the solutions involved). In a few cases, where dominant populations of known colorless sulfur bacteria occur (e.g., *Sulfolobus* in solfataras, *Beggiatoa* mats), rough estimates have been made of the activity of these organisms. Mosser et al. (1973) found rates for sulfur oxidation to sulfate of 67 and 190 g $m^{-2}·day^{-1}$ for mats of *Sulfolobus acidocaldarius* growing in two hot pools (Moose Pool and Sulfur Cauldron, Yellowstone National Park, respectively). In the Black Sea, a maximum rate of 710 nmol $l^{-1}·day^{-1}$ was observed by Sorokin (1970). For an extended discussion of sulfur oxidation rates in nature, the reader is referred to Kuenen (1975) and to Jørgensen (1988).

Another problem is that the sulfur-oxidizing heterotrophs may also contribute to the turnover of reduced sulfur compounds at natural sites. In some cases, $^{14}CO_2$ fixation can be used to eliminate this but in many locations where mixotrophs or chemolithoheterotrophs are involved, CO_2 may not be the primary source of carbon. This type of experiment could, therefore, sometimes result in underestimates if it is not used in tandem with other measurements. An associated problem is that the specific activity of a given species can vary. For example, Beudeker et al. (1980) found that, when grown under carbon dioxide limitation, the ribulose bisphosphate carboxylase (Rubisco) activity in *T. neapolitanus* was 240 nmol $min^{-1}·mg$ $protein^{-1}$. If, however, thiosulfate was the limiting factor, the enzyme level fell to 72 nmol $min^{-1}·mg$ $protein^{-1}$. Other substrate conversion rates can also vary, especially among species. Thus, it has been found that *T. denitrificans* and *Thiomicrospira denitrificans* oxidize thiosulfate at rates of 0.86 and 2.9 mM thiosulfate g $C^{-1}·h^{-1}$ respectively (Timmer ten Hoor, 1977).

A combination of CO_2 fixation and oxygen and hydrogen sulfide analysis was used to measure microbial activity in Saelenvaan Lake, in Norway. As can be seen from Fig. 11, a peak of CO_2 fixation was found to coincide with the very narrow zone where oxygen and sulfide coexisted.

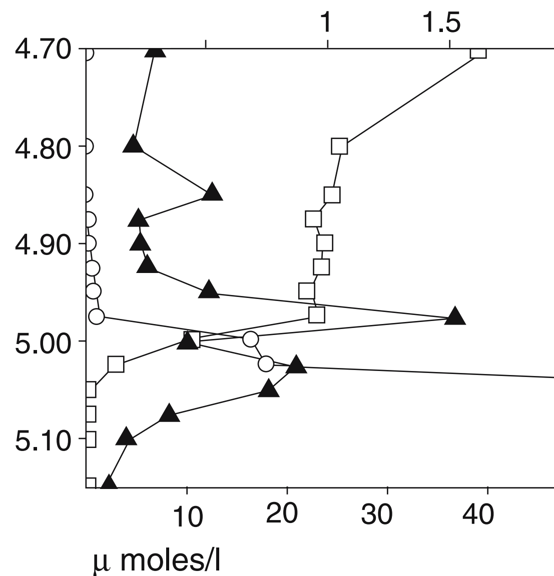

Fig. 11. Profiles of CO_2 fixation, dissolved oxygen, and dissolved hydrogen sulfide concentrations in Saelenvan Lake (Norway) sampled at 5 a.m. on 15 August 1978. The high resolution was due to the use of a special sampling device connected to a pump. CO_2 fixation rates (top horizontal axis) were obtained using $^{14}CO_2$ injected into dark bottles, which were incubated in situ. The left vertical axis is depth in m. The bottom horizontal axis is the concentration of dissolved gas in μmol $liter^{-2}$. Triangles, μmol CO_2 $liter^{-1}·h^{-1}$; squares μmol oxygen $liter^{-1}$; circles, μmol hydrogen sulfide $liter^{-1}$. (From Kelly and Kuenen, 1984.)

It should be noted that the sampling technique was critical for the success of these experiments. A special sampling device with an inlet that removes water from a horizontal area of the column at 1–2 cm intervals (Jørgensen et al., 1979) was necessary—if a less accurate device was used, the very narrow CO_2 fixation zone could not be seen because of dilution by the surrounding water.

Those working on the ecosystems around the hydrothermal vents have, of course, severe difficulties to overcome in making in situ measurements, especially since a new variable, pressure, must be considered (Jannasch, 1985). In order to measure the activity of autotrophic bacteria at these sites, $^{14}CO_2$ fixation was measured in syringes incubated on the sea bed (approximately 250 atmospheres, 3°C) and on board ship (1 atmosphere) at 3 and 23°C. Little or no difference was found between the two samples incubated at 3°C, and the bacteria responsible for the $^{14}CO_2$ fixation were thus obviously barotolerant rather than barophilic. Moreover, $^{14}CO_2$ fixation sharply increased if thiosulfate was added, or when the samples were incubated at 23°C, indicating that mesophilic colorless sulfur bacteria

were responsible (Tuttle et al., 1983; Wirsen et al., 1986).

MICROELECTRODES A technique that has been used with some success in the study of in situ bacterial biofilms and immobilization for biotechnology employs the use of microelectrodes that can be progressively moved through a biolayer, gradually registering the gradients present. The slope of the gradient, combined with data on the diffusion coefficient for the substrate measured, can provide direct information on the flux and turnover of substrates, and thus can give accurate information on in situ activities. These microelectrode systems are frequently linked to a computer that not only controls the rate of passage of the electrode tip through the biolayer, but also records and calculates the results (e.g., Revsbech et al., 1986). Among others, oxygen, pH, sulfide, carbon dioxide, and N_2O microelectrodes are available, but the use of some electrodes (e.g., sulfide, CO_2) is limited by their low sensitivity at commonly used pH values. However, the oxygen electrode has been extensively used, especially in systems where photosynthesis is involved and oxygen supply can easily be controlled by modifying the availability of light (e.g., Jensen and Revsbech, 1989; Revsbech and Ward, 1984). The construction of these electrodes, and their use in various ecosystems, was extensively reviewed by Revsbech and Jørgensen (1986). Their use, in conjunction with some of the other methods mentioned above, may at least provide a means of measuring actual activities in gradients, rather than potential activities in in vitro cultures.

Summary and Conclusion

The carbon metabolism of the colorless sulfur bacteria is the best-known facet of their physiology and biochemistry. New insights into their pathways of sulfur metabolism have done away with the old unifying concept of sulfur metabolism, as it is now clear that there are diverse pathways in the organisms investigated thus far.

With the use of new techniques for cultivating the more fastidious colorless sulfur bacteria (e.g., *Beggiatoa*) in gradient cultures, and with pure cultures of other strains (e.g., *Macromonas*) now available, the way is now open for further research into their (eco)physiology and biochemistry.

It is hoped that microelectrodes, in combination with improved isotope techniques, will also provide more detailed information about the activities of these bacteria in nature.

However, one important question remains—should the colorless sulfur bacteria still be considered a taxonomic group? As discussed throughout this paper, the use as a taxonomic criterion of the ability to gain energy from the oxidation of inorganic reduced sulfur compounds has resulted in the definition of a very heterogeneous group, collectively known as the colorless sulfur bacteria. It is possible that the possession of the relevant pathways for growth on reduced sulfur compounds is of no greater taxonomic relevance than the ability to use the Calvin cycle or to grow on hydrogen. Moreover, it seems likely, in view of the results obtained with 5S and 16S RNA analysis, that we are seeing the result of evolutionary convergence towards the (eco)physiological properties encountered in many of the colorless sulfur bacteria. The extreme heterogeneity of the group is further emphasized as other long-known bacteria are found to also possess the properties of colorless sulfur bacteria. Indeed, the common lack of a test for thiosulfate or sulfide oxidation in routine taxonomic screening has meant that the sulfur-oxidizing potential of species of genera such as *Paracoccus*, *Pseudomonas*, and *Alcaligenes* are only now being recognized.

Despite their morphological and phylogenetic diversity, the colorless sulfur bacteria present a coherent picture in physiological terms. As it is generally the physiological specifications of an organism that define its ecological significance, the reclassification of the colorless sulfur bacteria may present something of a microbiological dilemma because the relationships suggested by the rRNA analysis (Table 8) bear little relation to the ecophysiological activities of the organisms. Thus, in spite of the reallocation of species among different genera, research can only profit from the retaining of physiological, rather than taxonomic, groupings—such as the sulfate reducers, nitrogen fixers, denitrifiers, and colorless sulfur bacteria.

Acknowledgments. We thank Anke de Bruyn, Wim Hazeu, Don Kelly, David Lane, Hiroshi Oyaizu, and Jack Pronk for allowing us access to their results before publication, and to Piet Bos for his constructive comments on the manuscript.

CHAPTER 1.32

Bacterial Stress Response

ELIORA Z. RON

Introduction

Most bacteria live in a dynamic environment where temperature, availability of nutrients, and presence of various chemicals vary. Quick adaptation to these environmental changes is carried out by a series of global regulatory networks that control the simultaneous expression of a large number of genes. There are global regulatory systems that respond to change of temperature, pH, nutrients, salts and oxidation. The level of response by these regulatory networks is proportional to the extent of the change. Since the response level is highest under changes that constitute a stress condition, the control networks are labeled "stress response" systems.

The stress response systems show a high degree of similarity in prokaryotes, and some (e.g., the heat shock response) are also conserved in eukaryotes and archaea. However, the conditions under which the response systems are activated differ significantly from one organism to another. Clearly, the temperatures in which the heat shock response is activated will be much lower for a mesophile than for a thermophile, or the response to salt stress will be completely different in halophiles.

Global Regulatory Networks in Bacteria

The first attempts to study the extent of such regulatory networks were based on proteomic analysis, using O'Farrell two-dimensional (2D) gels, and resulted in the identification of the large group of *Escherichia coli* heat-shock proteins (O'Farrell, 1975; Neidhardt et al., 1981). Later, proteomic-based experiments followed by microarray studies of gene transcription (Hatfield et al., 2003) revealed the size and composition of the various-stress induced stimulons of *E. coli* (VanBogelen et al., 1987b). This induction of large groups of genes in response to a specific environment suggested the existence of global regulatory systems that control the expression of large regulons.

Gene expression can be regulated at the level of transcription or posttranscription. The level of transcription can be regulated by positive control elements—activators—or by negative control elements—repressors. Some of these control elements are specific for one gene, whereas others control a large group of genes, thus creating a regulon. In addition to transcriptional regulation, many posttranscriptional regulatory systems evolved affecting different steps along the way from the gene to the active protein. The posttranscriptional regulatory systems control the stability of the mRNA and the rate of translation initiation. In addition, they can determine the stability of the protein and its activity by carrying out posttranslational modifications. The existence of all of the control elements described here was demonstrated in the global regulatory systems that control the response to heat shock and other environmental and physiological conditions.

Transcriptional regulation is the primary mechanism that regulates gene expression. The process of RNA synthesis and its control was extensively studied in bacteria, especially in *E. coli* and *Bacillus subtilis* (Burgess and Anthony, 2001). The *E. coli* DNA-dependent RNA polymerase is the enzyme responsible for all cellular RNA synthesis. This enzyme consists of a core (subunits $a_2bb'w$) that is capable of elongation and termination of transcription, and an additional subunit (σ), which binds to the RNA polymerase to form the holoenzyme, increases the efficiency of transcription initiation, and determines specific promoter recognition (Burgess et al., 1969). In *E. coli* there are seven known sigma factors: σ^{70} and the vegetative sigma factors, σ^{S}, σ^{32}, σ^{F}, σ^{E}, σ*fecI* and σ^{54} (Helmann and Chamberlin, 1988; Lonetto et al., 1992; Burgess and Anthony, 2001). The sigma factors serve as master regulators mainly by competition for the core RNA polymerase, which is the limiting component of the transcription machinery (Ishihama, 2000). Additional regulation of transcription is exerted by repressors, transcriptional activators, sigma-binding anti-sigma factors, and even by small RNAs (Hughes and Mathee, 1998; Helmann, 1999; Vicente et al.,

1999; Ishihama, 2000; Severinov, 2000; Wassarman and Storz, 2000).

These various control elements regulate the expression of genes during environmental conditions such as starvation, sporulation and additional stress conditions. For example, the *E. coli* stationary phase is regulated by the master regulator σ^S (Lange and Hengge-Aronis, 1991). The levels of σ^S itself are affected by *cis* and *trans* elements—small molecules such as guanosine 5′-diphosphate 3′-diphosphate (ppGpp) and homoserine lactone, and the proteins that react to them, such as cAMP receptor protein (CRP)-cAMP (Hengge-Aronis, 2000). Sigma factor S regulates the induction of more than 50 genes (Hengge-Aronis, 2000). All of these elements create a complex regulatory network that enables the bacterial cell to adapt to the changing environment.

Stress Response, Stimulons and Regulons

In bacteria the stress responses are regulated by several control patterns: 1) Transcriptional control by alternative sigma factors is the most prevalent control pattern. Basically, genes or operons that belong to a specific response regulon contain a promoter that is recognized by a specific, alternative, sigma factor. The function of this sigma factor correlates with the conditions that bring about the response. As an example, in Gram-negative bacteria, the response to elevated temperatures is mediated by two alternative sigma factors (σ32 and σE) whose activities are temperature-dependent. 2) Transcription is controlled by repressor binding to a DNA control element. An example of this control is the HrcA repressor that binds to a conserved inverted repeat control element known as "CIRCE" (for "controlling inverted repeat of chaperone expression") present upstream of operons that code for heat shock proteins in Gram-positive and some Gram-negative bacteria. 3) Transcription is controlled by proteolysis. Well defined is the salt overly sensitive (SOS) response to genotoxic effects, which is mediated by a series of autoregulated proteases. Recently, control by proteolysis has emerged as one of the major systems regulating the availability of alternative sigma factors and other stress-related global processes (Hengge and Bukau, 2003). And 4) transcription is controlled by small RNAs. Recent findings indicate that small RNAs, about 50 of which are present in the *Escherichia coli* genome, control the cellular concentration of RpoS (sigma38), the alternative sigma factor of the starvation (or stationary) response. Small RNAs also control the response to oxidative stress.

A regulon is defined as all genes regulated by the same control pattern, while a stimulon is defined as all the genes whose expression responds to the same conditions. Stimulons are easily delineated by monitoring gene expression in a micro-array or on two-dimensional protein gels. Regulons can only be established following characterization of the molecular basis for the change in gene expression. Clearly, level of overlap between the various regulons and stimulons is high. Thus, the stimulon that responds to shifts to higher temperatures contains genes from at least two regulons (i.e., σ32 and σE). Yet, some of the genes of the σ32 regulon may also be controlled by the HrcA repressor, and so on.

Here, the focus is on two stress response networks—one responding to shifts to higher temperatures (heat shock response) and the other to limitation of carbon source and stationary phase (general stress response).

The Heat Shock Response

The heat shock response was the first global regulatory system to be discovered and is one of the most fundamental. This response is general, found in all living cells examined (Craig, 1985), and is a protective and homeostatic cellular process that increases thermotolerance. It has been studied in many cellular systems such as bacteria, yeast, insects (*Drosophila melanogaster*; Michaud et al., 1997), worms (*Caenorhabditis elegans*; Rose and Rankin, 2001), and mammals (Christians et al., 2002; Li et al., 2002; Srivastava, 2002). The heat shock response is characterized by the induction of a large set of proteins (heat shock proteins—HSPs) as a result of a rapid increase in the environmental temperature. Many of the HSPs are molecular chaperones (e.g., GroEL, GroES, DnaK and DnaJ) and ATP-dependent proteases (e.g., ClpP, Lon (La) and HslVU) that play a critical role in the restoration of protein folding and in protein degradation under normal and stress conditions. Proteins such as GroEL (the bacterial homolog of Hsp 60) and DnaK (the bacterial homolog of Hsp 70) are highly conserved in evolution all the way from bacteria to humans (Boorstein et al., 1994; Gupta, 1995). Although the major proteins in the heat shock response are highly conserved, the regulation of the response varies between different organisms and different bacterial species. Several regulatory systems evolved in bacteria and will be discussed here.

The Hsps are important for protection against environmental stress, and they produce tolerance against high temperature, high salt and

heavy metals (VanBogelen et al., 1987a; Inbar et al., 1993; Hecker and Volker, 1998). Heat-shock proteins also play critical roles in bacterial virulence and in protective systems such as the human immune system (Christians et al., 2002; Li et al., 2002). Several Hsps were found to protect against damage induced by temperature upshifts. Among the characterized proteins are the main cellular chaperone machineries GroE and DnaK, the ATP-dependent proteases Lon (La), HslVU, ClpP, DegP and FtsH (FhlB), and other proteins involved in protein folding, refolding, quality control, and degradation. GroE and DnaK are both multimeric complexes that have ATP-dependent activity (Sherman and Goldberg, 1992; Sherman and Goldberg, 1996; Kandror et al., 1994). The GroE catalytic complex involves GroEL and GroES in a ratio of 1 : 2, creating a football-shape molecular structure (Sparrer et al., 1997). This complex catalyzes protein refolding, and is involved in protein degradation by the ATP-dependent proteases (Sherman and Goldberg, 1992; Sherman and Goldberg, 1996; Kandror et al., 1994). These ATP-dependent proteases degrade abnormal proteins under stress and nonstress conditions, and in addition play major regulatory functions by controlling the degradation of specific proteins (Goldberg, 1972; Maurizi, 1992; Gottesman, 1996; Deuerling et al., 1997; Zhou et al., 2001). The role of these and other *E. coli* Hsps in protection against temperature-induced damage is summarized in Table 1.

Heat shock—a rapid up-shift in the environmental temperature—results in various physical and chemical changes in bacterial proteins and membranes. Presumably, these changes, such as protein unfolding, are detected by cellular systems, which induce the large set of heat shock proteins to cope with the changes and the potential damage. This heat shock response is regulated by several control elements, thus dividing the major stimulon of heat shock proteins into several regulatory groups (regulons).

The heat shock proteins are highly conserved, whereas the control of their expression is highly variable between organisms and even between various bacteria. One of the control elements found in Gram-negative bacteria is a heat shock σ factor that regulates the transcription of the major Hsps. The Gram-negative *E. coli* is a good example of this system because the synthesis of the major Hsps is regulated by the alternative sigma factor called "σ^{32}." In addition, there is a group of proteins induced under conditions of elevated temperature that is regulated by another heat shock sigma factor, σ^{E} (encoded by *rpoE*). In other Gram-negative bacteria, such as the *Agrobacterium tumefaciens* of the Alphaproteobacteria, the control systems are more

complicated. For example, the transcription of GroESL synthesis is stimulated during heat shock by a σ^{32}-like activator, but in non-heat shock conditions, transcription is repressed by the HrcA protein that binds to the CIRCE sequence upstream of the promoter region (Segal and Ron, 1993; Nakahigashi et al., 1999). The control system of HrcA-CIRCE was first described in the Gram-positive *Bacillus subtilis* (Zuber and Schumann, 1994).

The following sections will describe the specific control mechanisms in various bacterial groups. In short, the heat shock response in bacteria is controlled by one or a combination of both of the following control systems: 1) The first system involves alternative sigma factors that act as transcriptional activators by recognizing specific heat shock promoters upstream of heat shock genes. Among these are σ^{32} and σ^{E} of the Gram-negative bacteria, and σ^{B} of the Gram-positive bacteria. 2) The second system utilizes transcriptional repressors. The most conserved and the most ubiquitous among these repressors is HrcA (heat regulation at CIRCE), which binds to a conserved CIRCE present upstream of the heat shock operons. Heat shock operons controlled by HrcA-CIRCE are transcribed by the vegetative sigma factor σ^{A} (= σ^{70}) in Gram-positive bacteria and by the heat shock sigma factor s^{32} in Gram-negative bacteria.

Heat Shock Control Elements in Gram-Negative Bacteria

The first model organism for studying the heat shock response in Gram-negative bacteria was *E. coli*. Most of the heat shock genes of this bacterium are regulated by transcriptional activators, the alternative sigma factors (s^{32} or s^{E}).

Sigma-32-Controlled Genes

The heat shock response of Gram-negative bacteria is regulated mainly by the alternative sigma factors σ^{32} and σ^{E} (Morita et al., 2000). Sigma 32 is a master regulator encoded by the *rpoH* (*htpR* or *hin*) gene that was the first of a group of minor sigma factors discovered in *E. coli* (Grossman et al., 1984; Landick et al., 1984; Yura et al., 1984). This discovery of minor sigma factors led to the general concept of gene regulation by specific sigma factor-dependent transcription. In *E. coli*, at least 34 heat shock genes (out of 51 heat-shock induced loci) are regulated by σ^{32} (Richmond et al., 1999; Morita et al., 2000). The genes were identified by transcription analysis of specific genes, an examination of the synthesis rates of individual proteins, or proteomics and genomics approaches. This regulon includes all the major cytoplasmic Hsps of *E. coli*.

The σ^{32} regulon includes most of the proteins involved in protein folding, repair, and degradation. Such proteins are the heat-shock-induced molecular chaperones ClpB, DnaK, DnaJ, GroEL and GroES, which are involved in protein folding and prevention of protein aggregation (Neidhardt et al., 1981; Tilly et al., 1983b; Bardwell and Craig, 1984; Bardwell and Craig, 1986; Kitagawa et al., 1991; Tomoyasu et al., 2001). The regulon comprises also all of the important cytosolic proteases Lon (La), ClpP, ClpX, HslV (ClpY), and HslU (ClpQ; Goldberg, 1972; Gayda et al., 1985; Maurizi et al., 1990; Chuang et al., 1993b), and the membranal metaloprotease FtsH (HflB; Herman et al., 1995; Tomoyasu et al., 1995). Other important σ^{32}-regulated proteins are HTS (homoserine transsuccinylase), which is a key enzyme in methionine biosynthesis (Biran et al., 1995), proteins involved in protein isomerization (PpiD; Dartigalongue et al., 1998) and HtrM (Raina and Georgopoulos. 1991), and the vegetative sigma factor (σ^{70-}; Burton et al., 1981).

Homologs of *rpoH* were identified in more than twenty species of eubacteria from the alpha, beta and gamma subgroups of proteobacteria (Sahu et al., 1997; Andersson et al., 1998; Emetz et al., 1998; Huang et al., 1998; Karls et al., 1998; Nakahigashi et al., 1998; Nakahigashi et al., 1999; Nakahigashi et al., 2001). In some of these bacteria, the *rpoH* homologs demonstrates translational induction and stabilization upon heat shock, which are very similar to those found in *E. coli* (Nakahigashi et al., 1998).

The general function of the σ^{32} regulon was studied in several bacterial species by analysis of *rpoH* mutants. These mutants were usually found to be temperature sensitive (Zhou et al., 1988; Huang et al., 1998; Nakahigashi et al., 1999). As expected from their temperature-sensitive phenotype, some of the heat-shock proteins are essential at elevated temperature.

The levels of σ^{32} and its activity are temperature-regulated at several levels. At low temperature (30°C), when low amounts of heat-shock proteins are required, the intracellular concentration of σ^{32} is fewer than 50 molecules per cell (Straus et al., 1987; Craig et al., 1991). These low levels are maintained due to transcriptional repression and protein instability. Upon a rapid shift to 42°C, the level increases 15–20-fold within 5 min, and then declines to a new steady state level, 2–3-fold higher than the pre-shift level (Straus et al., 1987). The levels and the time-course of σ^{32} induction are sufficient for the necessary induction of heat-shock-gene expression upon temperature upshift. A relatively modest heat shock activates the translation of *rpoH* transcripts, and transiently stabilizes σ^{32} (Straus et al., 1987; Nagai et al., 1991), whereas a severe

heat shock (a rapid shift from 30 to 50°C) can also activate *rpoH* transcription (Morita et al., 2000). The decrease in the synthesis of heat-shock proteins upon temperature downshift is primarily a result of the decrease in σ^{32} activity (rather than its levels) caused mainly by an excess of the DnaK chaperone machinery (Straus et al., 1989; Taura et al., 1989).

The transcriptional regulation of the *rpoH* gene is very complex. It can be transcribed from at least four promoters, three of them (P1, P4 and P5) are recognized by the vegetative σ^{70}, and the fourth (P3) is recognized by σ^{E} (Erickson et al., 1987; Nagai et al., 1990). P3- and P4-transcription of *rpoH* is negatively regulated by DnaA (Wang and Kaguni, 1989), and P4-and P5-transcription is controlled by an additional negative control system—the cAMP-CRP/CytR nucleoprotein complex (Kallipolitis et al., 1998).

Several findings indicate that the heat shock induced σ^{32} levels are also regulated at the translational level. Expression of *rpoH-lacZ* translational fusion but not transcriptional fusion can be induced. Furthermore, heat induction of the fusion protein occurs even when RNA synthesis is inhibited (Nagai et al., 1991). Recent results based on extensive in vivo and in vitro experiments related to the secondary RNA structure have shown that the translation regulation of RpoH is mediated by the rpoH mRNA's secondary structure (Morita et al., 1999; Morita et al., 2000).

Sigma-32 level is regulated by not only its expression level but also the turnover of the protein. Although this protein is unstable during normal growth at 30°C (or even at 42°C), significant stabilization occurs immediately upon temperature upshift from 30°C to 42°C and continues for 4–5 minutes (Straus et al., 1987). The protein instability involves the DnaK chaperone machinery. Mutants in DnaK, DnaJ, or GrpE markedly stabilize σ^{32} under nonstress conditions (Tilly et al., 1983a; Tilly et al., 1989; Straus et al., 1990), indicating this involvement of these proteins in σ^{32} turnover. The initial studies suggested that the membrane-associated metalloprotease FtsH (HflB) is responsible for σ^{32} degradation (Herman et al., 1995; Tomoyasu et al., 1995). However, later studies were able to show that the cytosolic proteases Lon (La), HslVU and ClpP are also involved in σ^{32} degradation (Wawrzynow et al., 1995; Kanemori et al., 1997; Kanemori et al., 1999; Morita et al., 2000). Although the relative significance of each protease is difficult to determine in σ^{32} degradation, the latter three proteases seem to play a significant role in the degradation, possibly even equivalent to that of FtsH (Kanemori et al., 1997). Presumably during heat shock the DnaK machinery and the proteases become occupied by the misfolded and unfolded proteins that accumulate because of the denaturing effect of temperature increase. Consequently, levels of the proteolytic machinery are insufficient to bring about σ^{32} degradation and it accumulates and activates the transcription of the heat shock genes. Since the DnaK chaperones and the proteases have σ^{32} promoters, their synthesis is increased and therefore a few minutes after the temperature upshift, the level of the proteases and chaperones is high enough to destabilize σ^{32}, bringing the level of the heat shock proteins to a new steady state.

The final level of σ^{32} regulation is activity regulation (Morita et al., 2000). This regulation operates mainly by creating ternary complexes of (DnaK-ADP)-DnaJ-σ^{32} that sequester the σ^{32} that competes with the RNA polymerase core enzyme (Gamer et al., 1992; Gamer et al., 1996; Liberek et al., 1992; Liberek and Georgopoulos, 1993). Then, GrpE binds to the ternary complex and stimulates ADP release and complex dissociation by triphosphate (TP) binding. This cycle of binding and release appears to play an important role in σ^{32} activity (and possibly stability) in vivo (Gamer et al., 1992; Morita et al., 2000).

The σ^{32} control system has been well characterized in *E. coli* and other Gammaprotebacteria. However, σ^{32}-like heat shock transcriptional activators have recently been demonstrated in other bacteria, such as *Agrobacterium tumefaciens* of the Alphaprotebacteria (Nakahigashi et al., 1995; Nakahigashi et al., 1998; Nakahigashi et al., 1999; Segal and Ron, 1995a). The σ^{32} of the Alphaprotebacteria is different from that of *E. coli*, and the heat shock promoters are also different in the two groups of Gram-negative bacteria (Nakahigashi et al., 1999; Segal and Ron, 1995a; Fig. 1). The physiological difference of the two sigma factors may be more important: while the *E. coli* σ^{32} is unstable and tightly controlled by proteolysis carried out by the FtsH protease, the alphaprotebacterial σ^{32} is a stable protein, whose activity is affected mainly by a DnaK-mediated control (Nakahigashi et al., 2001).

Genes Controlled by σ^{E}

Another alternative sigma factor involved in the heat-shock response is σ^{E} (σ^{24}), which was found to be an essential gene in *E. coli* at all temperatures (De Las Penas et al., 1997). Presumably the σ^{E} regulon protects cells against extracytoplasmic stress-derived damage. Genes belonging to the σ^{E} regulon are important for bacterial pathogenesis: the mucoid phenotype of *Pseudomonas aeruginosa* in cystic fibrosis infections is controlled by AlgU, an analogue of σ^{E} (Yu et al., 1995), and *rpoE* mutants of *Salmonella typhimu-*

rium are defective in growth inside cells (Humphreys, 1999).

The *E. coli* σ^E controls the expression of genes encoding periplasmic folding catalysts, proteases, biosynthetic enzymes for the lipopolysaccharide component lipid A, and other proteins whose functions are involved with the cell envelope. Members of this regulon include periplasmic proteins that are involved in protein metabolism: the protease DegP (HtrA) and the periplasmic peptidyl prolyl isomerase FkpA (Erickson and Gross, 1989; Strauch et al., 1989; Dartigalongue and Raina, 1998).

As mentioned above, σ^E activates transcription of *rpoH* under conditions of severe heat shock, and because it has a σ^E promoter, it also regulates itself. The response is regulated by RseA (an inner membrane antagonist of σ^E), RseB (a periplasmic protein that binds to the periplasmic face of RseA), and the proteases DegS and YaeL. Envelope stress promotes RseA degradation, which occurs by a proteolytic cascade initiated by DegS. There is evidence that one σ^E-inducing stress (OmpC overexpression) directly activates DegS to cleave RseA (Alba and Gross, 2004).

HrcA-CIRCE-Controlled Genes

The HrcA-CIRCE repression system is the major system regulating the operons coding for chaperones in Gram-positive bacteria. This system is comprised of an inverted repeat *cis* element and a *trans* protein-repressor encoded by the *hrcA* gene. The first reported inverted repeat upstream to the *groE* operon was found in *Mycobacterium tuberculosis* in 1989 (Baird et al., 1989). Recognition of this element as a widespread heat-shock control element for the *groE* and *dnaK* operons took several years. Several lines of direct evidence for the role of CIRCE as a negative *cis* element were obtained (Narberhaus, 1999): 1) deletion of the inverted repeat relieved the repression of a reporter gene fusion (*amyS*; Van Asseldonk et al., 1993); 2) placement of CIRCE behind a foreign promoter reduced the expression of the downstream gene (Zuber and Schumann, 1994); and 3) site-directed mutation, or the removal of three or four nucleotides in one arm of the inverted repeat, resulted in an elevated transcription of the downstream genes at normal growth temperature (Zuber and Schumann, 1994; Babst et al., 1996). Transcription remained derepressed when the inverted repeat was restored by compensating mutations in the second arm of the inverted repeat. Therefore, the CIRCE is not only a potential stem and loop structure (because its sequence by itself is required for repression), but also a binding site for a sequence-specific repressor protein that binds to the CIRCE.

The elucidation of CIRCE as a potential repressor-binding site initiated a search for the

counterpart repressor. Major steps towards tracking the repressor were accomplished by two observations (Narberhaus, 1999): 1) a deletion of *orf39*—the first gene of the *dnaK* operon of *B. subtilis* resulted in an elevated levels of *groE* transcript (Schulz et al., 1995); and 2) *B. subtilis* mutants affected in the regulation of *groE* and *dnaK* operons were mapped to *orf39* (Yuan and Wong, 1995a). Moreover, production of Orf39 from a plasmid that carries a functional copy of *orf39* restored the repression activity in one of the mutants (Yuan and Wong, 1995a). The binding of Orf39 to CIRCE was shown by gel retardation (Narberhaus, 1999), and the name "HrcA" ("heat regulation at CIRCE") was given to this protein after disruption of the equivalent gene in *Caulobacter crescentus* (Roberts et al., 1996).

For several years, the HrcA-CIRCE system was found only in Gram-positive bacteria and was considered as a Gram-positive heat-shock control element. However, since the first discovery of the CIRCE element in the Gram-negative Alphaproteobacterium *A. tumefaciens* (Segal and Ron, 1993), many CIRCE elements were identified in other Gram-negative bacteria. The inverted repeat was detected in a large number of phylogenetically distant bacteria, including Gram-negative bacteria of the Alpha-, Beta-, and $Gamma_1$-purple proteobacteria. The only groups where it is probably not present at all are the $Gamma_2$ and $Gamma_3$ purple bacteria, which also include the Gram-negative model organism *E. coli* (Segal and Ron, 1998; Ron et al., 1999). The inverted repeat (TTAGCACTC-N9-GAGTGCTAA) is highly conserved in all of the studied genes (R. Segal and Ron, 1996; Segal and Ron, 1998).

In contrast to Gram-positive bacteria where CIRCE-regulated genes are transcribed with the vegetative sigma factor (σ^A), in *A. tumefaciens* the *groEL* operon is HrcA-CIRCE controlled, but is transcribed mainly by σ^{32} (Nakahigashi et al., 1999). In *A. tumefaciens*, it was possible to show, using 2D gels, that GroE proteins are the only proteins whose synthesis is repressed by the HrcA-CIRCE system (Rosen et al., 2002b). In *Bradyrhizobium japonicum*, two *groESL* operons were found: *groESL*$_1$ is σ^{32} regulated while *groESL*$_2$ is CIRCE-HrcA-σ^{96} dependent (σ^{96} recognizes the housekeeping promoter of *B. japonicum*; Munchbach et al., 1999a). The control of chaperone expression by the HrcA-CIRCE system seems to be more ancient than the σ^{32}-dependent transcription of heat-shock genes because it is found in all the bacteria except two small groups that lost it during evolution, whereas σ^{32}-dependent transcription is found only in Gram-negative bacteria (Ron et al., 1999).

Minor Regulatory Elements

Expression of at least ten genes in *B. japonicum*, seven of which code for small Hsps, is under the control of ROSE (repression of heat-shock gene expression; Narberhaus et al., 1998; Munchbach et al., 1999b). This negatively *cis*-acting DNA element confers temperature control to a s^{70}-type promoter. ROSE elements are not restricted to *B. japonicum* but are also present in *Bradyrhizobium* sp. (*Parasponia*), *Rhizobium* sp. strain NGR234, and *Mesorhizobium loti* (Nocker et al., 2001). The latest model for ROSE activity suggests that ROSE controls heat-shock protein expression by a temperature-dependent secondary structure of ROSE mRNA that controls the access of the ribosome to the ribosome binding site (Nocker et al., 2001).

Proteome analysis of *A. tumefaciens* and in its mutants deleted for *rpoH*, *hrcA* or in both, showed that the heat-shock induction of 32 (out of 56) heat shock proteins is independent of RpoH and HrcA. These results indicate the existence of additional regulatory factors in the *A. tumefaciens* heat-shock response (Rosen et al., 2001; Rosen et al., 2002b). These uncharacterized regulatory elements may also involve ROSE because *A. tumefaciens* belongs to the Rhizobiaceae group.

An additional unique posttranscriptional control mechanism demonstrated in *A. tumefaciens* involved a specific cleavage of the *groESL* operon transcript. The resulting *groES* transcript is rapidly degraded, whereas the *groEL* transcript is stable, leading to a differential expression of the two genes of the operon—as could be detected by quantitative analysis of the protein expression, using 2D-gels (Segal and Ron, 1995b; Rosen et al., 2002b). This mRNA processing is temperature dependent and constitutes the first example of a controlled processing of transcripts in bacteria.

The General Stress Response in *E. coli*

The "general stress response" is induced during carbon starvation or entry into stationary phase. In *E. coli* these conditions result in a variety of physiological and morphological changes that, presumably, ensure survival during periods of prolonged starvation. Although this general stress response was believed to involve the induction of 30–50 proteins (Lange and Hengge-Aronis, 1991), this stimulon now appears to be much larger and involve almost 500 genes, most of which are induced by osmotic shock. About half are induced by stationary phase or acidic stress, and many are induced by more than one, or all of

these stresses (R. Hengge, personal communication). The general stress response is also important in quorum sensing (Schuster et al., 2004).

The genes coding for the general stress response in *E. coli* are transcribed by an alternative sigma factor, σS (RpoS), which recognizes a consensus promoter upstream of the general stress genes. The promoter specificity of σS has been difficult to determine, as the promoter it recognizes appears quite similar to those recognized by the vegetative σ70. The specific σS promoter elements were recently characterized (Becker and Hengge-Aronis, 2001; Gaal et al., 2001; Hengge-Aronis, 2002; Lee and Gralla, 2002; A. Typas and R. Hengge-Aronis, personal communication) and the results suggest that the selectivity is provided by the K173 (the lysine in position 173 of the amino acid sequence) in σS (which is glutamate in σ70). σS binds to the C(-13) and the distal upstream (UP) element –35 of the promoter.

The *E. coli* RpoS is a highly unstable protein, whose degradation is inhibited by various stress signals, such as carbon starvation, high osmolarity and heat shock. As a consequence, these stresses result in the induction of σS-regulated stress-protective proteins (Bouche et al., 1998). Proteolysis of σS requires the response regulator RssB (a direct recognition factor with phosphorylation-dependent affinity for σS, which targets σS to the ClpXP protease; Zhou et al., 2001; Pruteanu and Hengge-Aronis, 2002). Recognition of σS by the RssB/ClpXP system involves two distinct regions—region 2.5 of RpoS is a long α-helix which binds phosphorylated RssB. This binding exposes a second region of RpoS, located in the N-terminal part, which is a binding site for the hexameric ring of the ClpX chaperone (Studemann et al., 2003).

Recent studies demonstrate the involvement of small, noncoding RNAs (Vogel et al., 2003) in the proteolysis of σS. These small noncoding RNA sequences are abundant—around 50 such sRNAs were described in *E. coli*. The levels of many of these sRNAs vary with changing environmental conditions, suggesting a potential regulatory function. At least three sRNAs were found to affect the regulation of RpoS translation (Repoila et al., 2003). DsrA and RprA stimulate RpoS translation in response to low temperature and cell surface stress, respectively, whereas OxyS represses RpoS translation in response to oxidative shock. However, in addition to regulating RpoS translation, DsrA represses the translation of HNS (a global regulator of gene expression), whereas OxyS represses the translation of FhlA (a transcriptional activator), allowing the cell to coordinate different pathways involved in cell adaptation.

Control of the Heat Shock Response and the General Stress Response in Gram-Positive Bacteria

Although the stress gene and proteins in Gram-negative and Gram-positive bacteria are highly conserved, regulation of these genes is very variable. The presence of HrcA-CIRCE control elements has been noted in only some Gram-negative bacteria, and a comparison of Gram-negative with Gram-positive bacteria reveals major differences. Table 2 shows the factors affecting regulation of major stress genes in Gram-positive bacteria and in two Gram-negative bacteria belonging to the Alphaproteobacteria and Gammaproteobacteria. The data indicate that the expression of a stress protein can be under the control of different regulons, and also show difference in control elements between the various bacteria.

Many of the genes that in Gram-negative bacteria belong to the heat shock regulon (as their expression is controlled by the heat shock tran-

Table 2. Regulation of major stress genes.

Gene	Function of gene product	Bacteria	Regulon	Transcription during stress	Control element	Stability of gene product
DnaK	Chaperone	Gram positive	Heat shock	σA (σ70)	CIRCE	
		Alphaproteobacteria	Heat shock	σ32		
		Gammaproteobacteria	Heat shock	σ32		
GroEL	Chaperone	Gram positive	Heat shock	σ70	CIRCE	
		Alphaproteobacteria	Heat shock	σ32	CIRCE	
		Gammaproteobacteria	Heat shock	σ32		
rpoH	Activator—σ32	Alphaproteobacteria	Heat shock	σ32		Stable
		Gammaproteobacteria	Heat shock	σ32, σE		Unstable
lon, clpP	Proteases	Gram negative	Heat shock	σ32		
		Gram positive	General stress	σB		

Abbreviation: CIRCE, a conserved inverted repeat control element or "controlling inverted repeat of chaperone expression."

scriptional activator σ32) constitute part of the general stress response in Gram-positive bacteria. The only genes that are truly "heat shock genes" in Gram-positive bacteria are the genes coding for the major chaperones—Hsp10 and Hsp60 (GroES and GroEL) and the Hsp70 group (DnaK, DnaJ and GrpE).

Heat Shock Response

The model organism for studying the heat shock response in Gram-positive bacteria is *B. subtilis*. In contrast to *E. coli*, where most heat shock proteins are exclusively under the control of the alternative sigma factor σ32, Gram-positive bacteria have no heat-shock specific sigma factor. Rather, the heat-shock response of these bacteria involves the induction of the major chaperones, which is regulated by the HrcA-CIRCE control elements (Zuber and Schumann, 1994; Hecker and Volker, 1998), and several groups of proteins regulated by specific control elements, all of which are discussed below. Another major difference is that some of the proteins, which are part of the heat shock regulon in *E. coli* (such as the Clp proteases), are part of general stress proteins (GSPs) in *B. subtilis*, whose induction is regulated by the alternative sigma factor σ^B.

HRCA-CIRCE CONTROLLED GENES. This system, consisting of the HrcA repressor which binds to the CIRCE inverted repeat, was already described in the section The Heat Shock Response and General Stress Response in Gram-Negative Bacteria. Though in Gram-negative bacteria this system controls only the *groESL* operon, its role in Gram-positive bacteria is much more central. In the Gram-positive bacteria, the genes coding for Hsp70 (DnaK) and the proteins functionally associated with it are also under the control of HrcA-CIRCE. Thus, this control element regulates the expression of the genes coding for all the major chaperones. Notably, in these bacteria, the genes coding for the group of Hsp70 chaperones are usually organized in one operon: *grpE-dnaK-dnaJ*. In the group of low G+C Gram-positive bacteria, such as *B. subtilis*, this operon also contains the gene coding for the HrcA repressor and is *hrcA-grpE-dnaK-dnaJ*(R. Segal and Ron, 1996).

In *B. subtilis*, the operons regulated by the HrcA-CIRCE system (*groESL* and *dnaK* operons) are always transcribed during heat shock by the vegetative sigma factor σ^A (Yuan and Wong, 1995b). This situation is different from the Gram-negative bacteria, in which all the heat shock operons, including the *groESL* operon (which contains the CIRCE element) are transcribed by the specific heat shock σ32. Recently GroE itself has been shown to autogenously regulate the transcription of the *groE* and *dnaK* operons by the finding that the GroE chaperonin machine modulates the activity of the HrcA repressor (Mogk et al., 1997).

GENES CONTROLLED BY ADDITIONAL REPRESSORS. In *Streptomyces coelicolor* and *Streptomyces albus*, the *groESL*$_1$ operon and the *groEL*$_2$ gene are regulated by tandem CIRCE elements, whereas the *dnaK* operon encodes its own autoregulatory repressor (Bucca et al., 1995; Bucca et al., 1997). Heat-inducible transcription of the *dnaK* operon (*dnaK*, *grpE*, *dnaJ* and *hspR*) initiates from the vegetative promoter. Disruption of *hspR* led to high and constitutive transcription levels of the *dnaK* operon but had no effect on the *groE* expression level (Bucca et al., 1997). Similar to the GroE modulation of HrcA activity, DnaK protein forms a specific ATP-independent complex with the *Streptomyces* HspR repressor, and this interaction is necessary for HspR to bind a dnaKp fragment in gel-shift assays (Bucca et al., 2000). The *dnaK* heat-induction model suggested by Bucca et al. suggests a decrease in the availability of DnaK because of the accumulation of heat-damaged proteins (Bucca et al., 2000). This model has many similarities to the heat induction of the σ^{32}-dependent transcription in *E. coli*, a model that will be discussed in detail below.

Another heat-shock control element found in *S. albus* is the RheA, which represses the transcription of *hsp18* (encoding a small heat-shock protein) by binding specifically to the *hsp18* promoter (Servant and Mazodier, 1996; Servant et al., 1999). Transcription analysis of *rheA* in the *S. albus* wildtype and in *rheA* mutant strains suggested that RheA represses transcription not only of *hsp18* but also of *rheA* itself (Servant et al., 1999).

The General Stress Response

SIGMA B-CONTROLLED GENES. Sigma B was found to control a stress-starvation regulon that comprises a very large set of general stress genes (for reviews, see Hecker et al. [1996] and Hecker and Volker [1998]). These σ^B-dependent genes are strongly induced by heat, ethanol, acid or salt stress, as well as by starvation for a carbon source, phosphate and oxygen (Bernhardt et al., 1997; Bernhardt et al., 1999; Hecker and Volker, 1998; Buttner et al., 2001). Recent experiments (Petersohn et al., 2001) using gene arrays containing all currently known open reading frames of *B. subtilis* suggest that as many as 125 genes are under the control of σ^B. At least 24 of these also seem to be subject to a second, σ^B-independent stress induction mechanism. Most of the σ^B-dependent general stress proteins are probably located in the cytoplasm, but 25 contain at least one membrane-spanning domain, and at

least 6 proteins appear to be secreted. This very large stress regulon seems to give a basal level of protection against a large variety of stress conditions.

Two groups of signals were found to trigger the induction of *sigB*, the gene that codes for σ^B. The first group contains extracellular signals (i.e., glucose, oxygen, or phosphate, but not amino acid, starvation) that result in a drop of the ATP level (Maul et al., 1995). (Amino acids trigger the induction of ppGpp and keep the ATP pool constant.) The second group of stimuli includes physical stress-factors, such as heat, salt and acid stress, but not oxidative stress (Hecker and Volker, 1998). This group of stimuli induces the synthesis of σ^B via a two-component system (RsbS and RsbT) that changes the balance of a complex network of anti-sigma (RsbW) factor and its agonist (nonphosphorylated RsbV) to activate σ^{B-} (Akbar and Price, 1996; Yang et al., 1996). For the expression of some genes, the involvement of σ^B is essential, whereas for others it seems to be nonessential because it can be replaced by alternative stress-induction mechanisms (Hecker and Volker, 1998).

Not much is known about many of the 125 GSP genes (Petersohn et al., 2001), and their physiological role in the complex general stress response is not understood. The identified GSPs can be assigned to five main groups (Hecker and Volker, 1998): 1) Group 1 is the σ^B-dependent genes that encode subunits of stress-inducible proteases. ClpP, ClpC, and ClpX are probably essential for the renaturation or degradation of misfolded or denatured proteins that accumulate in the cell upon exposure to stress conditions (Gottesman, 1996; Gerth et al., 1998). Null mutants of *clpC*, *clpP* and *clpX* are extremely sensitive to heat, salt or ethanol stress, and much more sensitive than mutants of *sigB* (Kruger et al., 1994; Msadek et al., 1994; Gerth et al., 1998). 2) Group 2 is the σ^B-dependent genes that encode general oxidative stress-protective proteins (such as *katE*, which encodes catalase; Engelmann et al., 1995) and the DNA-protecting protein Dps (Antelmann et al., 1997b). Other σ^B-dependent proteins (such as thioredoxin ClpC, ClpP and the fifth and sixth gene products of the *clpC* operon [*sms* and *yacK*]; Kaan et al., 1999) may also be involved in adaptation to oxidative stress (Hecker and Volker, 1998). 3) The third group is proteins with a putative role in the adaptation to salt or water stress. A proline-uptake system encoded by a functional copy of *opuE* is required by *B. subtilis* for the use of external proline as an osmoprotectant (Hecker and Volker, 1998). However, the physiological role of σ^B in the expression of *opuE* is still unclear because exogenously provided proline was used as an osmoprotectant in a *sigB* mutant (Von Blohn et al., 1997). YtxH and GsiB are homologous to plant-desiccation proteins, which are involved in water-stress protection, and YkzA is a homolog of the *E. coli* OsmC, which is involved in osmo-adaptation (Mueller et al., 1992; Volker et al., 1994; Maul et al., 1995; Varon et al., 1996). 4) Group 4 is a heterogeneous group of proteins: their role in adaptation to stress is yet to be determined. One of these proteins, GspA (Antelmann et al., 1995), is also induced upon amino acids starvation (Eymann and Hecker, 2001) and seems to be involved in the expression of *hag*, which encodes flagellin, or UDP-glucose pyrophosphorylase, which participates in cell-wall metabolism (Varon et al., 1993). Some proteins seem to participate in nicotinamide adenine dinucleotide (NAD) synthesis (e.g., *nadC* and *nadE* gene products) or might catalyze reduced NAD phosphate (NADP[H])-dependent reactions (Antelmann et al., 1997a; Antelmann et al., 1997b; Hecker and Volker, 1998; Scharf et al., 1998). And 5), the fifth group consists of a large number of proteins that, so far, show no significant similarity to known proteins (Petersohn et al., 2001).

Several of the general stress operons in Gram-positive bacteria were found to be regulated by more than one control element. The *B. subtilis clpC*, *clpP* and *trxA* operons are under the control of the vegetative sigma factor σ^A and the stress sigma factor σ^B (Kruger et al., 1996; Gerth et al., 1998; Scharf et al., 1998). Although both promoters were used under a number of stress conditions, the induction pattern of the genes varied for the different genes and the particular stress condition. A *cis* element that contains a heptameric tandem consensus sequence was found upstream of the *clpC*, *clpE*, and *clpP B. subtilis* operons and was shown to be the binding site of the CtsR repressor (Kruger and Hecker, 1998; Derre et al., 1999a; Derre et al., 1999b). CstR was lately found also in *Listeria monocytogenes* (Nair et al., 2000).

Complexity of the Stress Response Networks

Regulation of bacterial stress response involves various positive and negative control elements that often interact with each other. Some heat shock proteins are directly regulated by only one control element, but other genes and operons are regulated by several control elements (e.g., *E. coli pspABCE* [Jovanovic, 1996], *A. tumefaciens groESL* [Segal and Ron, 1995b; G. Segal and Ron, 1996; Nakahigashi et al., 1999], and *B. subtilis clpC* [Kruger et al., 1996; Gerth et al., 1998; Scharf et al., 1998]). However, the stress

response is always a complex response that regulates itself. As an example, the heat-shock response is induced by damaged proteins, whose cellular concentration increases with temperature. Yet, since the heat shock stimulon contains the genes coding for proteases and chaperones, their induction at increased temperatures reduces the concentration of the damage proteins, thus reducing the level of induction of the heat shock response.

Because the regulatory elements of these complex stress response networks are associated with each other, any impairment of the cellular steady state at one point may affect the whole network, directly or indirectly. Therefore, the study of these global regulatory networks requires global analysis methods (Rosen and Ron, 2002a). Such methods for transcriptome and proteome analysis are now available and have been implemented in this field. For comprehensive understanding, more than one method should be used. Analysis of mRNA levels is required to define all the genes whose transcription is affected by environmental conditions or regulatory genes. This analysis, however, is insufficient because the expression and activity of the stress genes are controlled at posttranscriptional, higher regulatory levels. Thus, global analysis at the protein level (i.e., proteomics studies) also must be performed. These studies define the final cellular level of the various proteins, as well as their modifications, some of which may be controlled by stress conditions. One important protein modification shown to play a role in global regulatory networks is protein phosphorylation, usually at one or a few amino acids. Recently, a new group of highly phosphorylated proteins has been identified. These proteins accumulated during several stress conditions and may be involved in the degradation process (Rosen et al., 2004). In eukaryotic systems, protein phosphorylations are known to be involved in protein labeling and in many signal transduction pathways. In bacteria, the number of known phosphorylated proteins is much lower. However, several phosphorylated proteins are involved in the heat shock response of various bacteria, as will be shown in the following examples. The heat shock transcriptional activation of the *lonD* gene of *Myxococcus xantus* is controlled by a two-component histidine-aspartate phosphorylation system (Ueki and Inouye, 2002). The general-stress sigma factor of *B. subtilis* (σ^B) is regulated by several regulatory kinases and phosphatases (the Rsb proteins), which catalyze the release of σ^B from an anti-σ^B factor (Akbar and Price, 1996; Yang et al., 1996; Akbar et al., 2001; Zhang et al., 2001). Another heat shock protein (Hsp70 of *Mycobacterium leprae*) was found to be phosphorylated at threonine-175 (Peake et al., 1998), which results in an increased affinity for a model polypeptide substrate. One of the best-studied examples of stress-controlled protein modification was already discussed above, in the section The General Stress Response of E. coli. The phosphorylated form of RssB (a stationary phase response regulator) targets the alternative transcriptional activator σ^S for degradation by ClpXP (Bouche et al., 1998; Zhou et al., 2001). In view of these examples, protein modification will probably be demonstrated as one of the important control elements in global regulatory networks.

CHAPTER 1.33

Anaerobic Biodegradation of Hydrocarbons Including Methane

FRIEDRICH WIDDEL, ANTJE BOETIUS AND RALF RABUS

Introduction

Hydrocarbons, by definition, are constituted only of the two elements, hydrogen and carbon, and thus do not contain functional groups. As a result, most hydrocarbons exhibit poor solubility in water and low chemical reactivity at room temperature (except for hydrocarbons with triple bonds). Nevertheless, relative to several electron acceptors, in particular oxygen, hydrocarbons are energy-rich, and they are exploited as growth substrates by numerous microorganisms. Whereas the aerobic microbial degradation of hydrocarbons was known since the beginning of the twentieth century and has been studied microbiologically and biochemically in much detail (see the chapter on Hydrocarbon-Oxidizing Bacteria in this Volume), first major insights into the anaerobic degradation of hydrocarbons have been achieved only in the 1990s.

Hydrocarbons are naturally widespread organic compounds that are formed either as metabolites by bacteria, archaea, plants and animals (Birch and Bachofen, 1988; Widdel and Rabus, 2001), or as abiotic (thermogenic) transformation products of dead buried biomass (Tissot and Welte, 1984). The conversion of the polar compounds of biological origin to hydrocarbons is a defunctionalization and reflects an overall thermodynamic principle. The eliminated inorganic compounds H_2O, CO_2 or NH_4^+ together with the pure C-H compounds are energetically more stable than the parental organic compounds with -OH, $-COO^-$, $-NH_3^+$ or other polar groups (Widdel and Rabus, 2001). The energetically final, most stable state of carbon is represented by CH_4 and CO_2. It is likely that many reactions leading to hydrocarbons already took place during the early history of life and that hydrocarbons therefore represent relatively "old" substrates from an evolutionary point of view. Hence, hydrocarbon-degrading bacteria and archaea with various pathways may have already evolved before oxygen became abundant as an electron acceptor in the biosphere. The study of anaerobic microorganisms that degrade hydrocarbons is of interest from various points of view: A) The long-term fate of hydrocarbons as globally abundant forms of organic carbon in anoxic sediments, gas hydrates, petroleum reservoirs and other subsurface environments is of geochemical interest. A process of high global relevance in this respect is the anaerobic oxidation of the most abundant hydrocarbon, methane, which is also a potential greenhouse gas. B) The exploitation of petroleum is always connected with its mobilization and an increased exposure to microbial degradation. It is likely that certain hydrocarbons serve as substrates for sulfate-reducing bacteria in oil field waters and lead to the production of undesired sulfide. Knowledge of the involved organisms and their growth conditions may be valuable for the development of measures against this process. C) If deep aquifers (groundwater) or the sea floor are contaminated by oil spills, aerobic hydrocarbon degradation is usually limited by the availability of dissolved oxygen. It is therefore of interest to determine the extent to which oil hydrocarbons, in particular those with noticeable water solubility, can be degraded with other electron acceptors of higher solubility such as sulfate or nitrate. D) Since biochemical reactions always occur at functional groups, a hydrocarbon has to be functionalized before it can be channeled into the metabolism. Such reactions overcome unusually high activation energies (usually those of apolar C-H bonds) and thus include very reactive intermediates, but nevertheless occur in a controlled, highly specific manner. They are, therefore, biochemically intriguing. Knowledge of reaction mechanisms and principles may, in the longer run, be of interest in the development of new chemical catalysts by biomimetic approaches.

Anaerobic oxidation of the smallest hydrocarbon, methane, is apparently performed by close relatives of methanogens; these relatives represent special lines of descent within the Euryarchaeota of the archaeal domain. In contrast,

the anaerobic utilization of non-methane hydrocarbons occurs in various Deltaproteobacteria of the bacterial domain that utilize nitrate, ferric iron or sulfate as electron acceptor. Principles of anaerobic hydrocarbon metabolism have been elucidated in a number of representative microorganisms. Whereas the aerobic activation of hydrocarbons always involves reactive oxygen species derived from O_2 to introduce hydroxyl groups, the anaerobic activation employs rather different mechanisms, depending on the chemical nature of the hydrocarbon. There is evidence for at least five principally different mechanisms for an anaerobic activation of hydrocarbons; these are 1) the assumed activation of methane in a "reverse methanogenesis," 2) the radical-catalyzed addition of alkanes and many alkylbenzenes to fumarate yielding substituted succinates, 3) the dehydrogenation of ethyl- and propylbenzene yielding aryl-substituted secondary alcohols, 4) the hypothesized addition of a carboxyl or methyl group to unsubstituted aromatic hydrocarbons, and 5) the hydration of double bonds (assumed) and triple bonds (demonstrated experimentally) in alkenes and acetylene, respectively. The anaerobic activation reactions are usually very sensitive towards oxygen. In comparison to the aerobic activation reactions, the anaerobic ones are relatively slow. Also anaerobic hydrocarbon degraders usually exhibit much slower growth than their aerobic counterparts.

For convenience, the following presentation of the anaerobic degradation of various hydrocarbons follows their chemical classification in textbooks and monographs, i.e., begins with methane and other alkanes and leads via alkenes and alkynes to aromatic hydrocarbons.

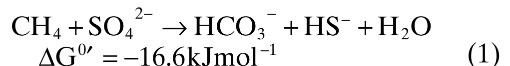
The focus of this chapter is on the presentation Microbiology and Biochemistry. Ecological aspects are presented in the case of the anaerobic oxidation of methane because the results from biogeochemical studies in various marine habitats are fundamental for our understanding of this process. Actually, the process has been discovered in situ rather than via microbiological experiments in vitro. Within the scope of this article, ecological aspects are not presented for the oxidation of various other hydrocarbons, except for some physiological aspects of anaerobic growth on crude oil. An important habitat-related topic in this context is contamination of aquifers and anaerobic in situ remediation. For information in this area, the reader is referred to other articles (for overview and recent articles, see Beller [2000a], Elshahed et al. [2001], Gieg and Suflita [2002], Hunkeler et al. [2002], Reusser et al. [2002], and Richnow et al. [2003], and Townsend et al. [2003]).

Anaerobic Degradation of Methane

Studies in the Habitat

Methane is of microbial or thermogenic origin and is the most abundant and chemically most stable hydrocarbon (Crabtree, 1995). Microbial origin is usually evident from low $^{13}C/^{12}C$ ratios and the absence of other gaseous hydrocarbons (ethane, propane, butane). Thermogenic methane (like other thermogenic hydrocarbons) either results from chemical transformation reactions (catagenesis, metagenesis; Tissot and Welte, 1984) of buried organic carbon, or from the interaction of water, iron(II)-containing rock, and carbon dioxide at several hundred degrees Centigrade (Holm and Charlou, 2001). Large reservoirs of methane hydrate with a mass exceeding that of conventional fossil fuel reservoirs by at least a factor of two lie buried in deep, sulfate-depleted zones of sea sediments (Kvenvolden, 1999). Despite permanent upward migration and new thermogenic or microbial production, little of the methane ever escapes into the hydrosphere. Most methane is scavenged by anaerobic microbial oxidation.

First evidence for an anaerobic oxidation of methane (AOM) came from geochemical studies in marine sediments (Martens and Berner, 1974; Barnes and Goldberg, 1976; Reeburgh, 1976). In these, methane diffusing upwards from deep sites often disappears nearly completely before any contact with oxygen is possible. The only electron acceptor that can account for the disappearance of methane is sulfate, resulting in the reaction



$$CH_4 + SO_4^{2-} \rightarrow HCO_3^- + HS^- + H_2O \quad \Delta G^{0\prime} = -16.6 \text{kJmol}^{-1} \qquad (1)$$

The zone of AOM in depth profiles of subsurface sediments is usually evident from a concave-up curvature of the methane concentration coinciding with an increased sulfate reduction rate (Alperin and Reeburgh, 1985; Iversen and Jørgensen, 1985). In zones where biogenic methane with its naturally low $^{13}C/^{12}C$ ratio disappears, isotopically light dissolved inorganic carbon and precipitated carbonates have been detected (Reeburgh, 1980; Ritger et al., 1987; Paull et al., 1992). This finding as well as the formation of radiolabeled CO_2 upon injection of ^{14}C-methane into samples from anoxic sediments further provided evidence for AOM (Reeburgh, 1980; Iversen and Jørgensen, 1985; Hansen et al., 1998).

Various habitats with intense AOM have been detected at submarine cold seeps. The most striking ones so far are surface sediments above methane hydrates at Hydrate Ridge (Cascadia Margin, Oregon) in the Northeast Pacific

(Boetius et al., 2000) and the gas seeps of the Northwestern Black Sea shelf (Michaelis et al., 2002). In these habitats, microbial life appears to be based exclusively on AOM. In Hydrate Ridge sediments, AOM occurs above gas hydrates lying a few centimeters below the sea floor. Sulfide produced by AOM nourishes chemolithotrophic sulfide-oxidizing aerobic bacteria, including those in symbioses with bivalves. In the Black Sea, AOM occurs in the anoxic part, far below the chemocline. Since AOM leads to a significant increase of inorganic carbon and alkalinity, calcium ions from seawater (usually near 10 mM) tend to be precipitated according to the net equation

$$CH_4 + SO_4^{2-} + Ca^{2+} \rightarrow CaCO_3 + H_2S + H_2O \quad (2)$$

The absence of a reoxidation of hydrogen sulfide to sulfuric acid in the direct vicinity may explain the massive deposition of carbonate plates and chimney-like structures in the anoxic part of the Black Sea (Figs. 1 and 2). Acidification by aerobic reoxidation of hydrogen sulfide would counteract such formation of precipitates.

Labeling studies with ^{14}C-methane in cultures of methanogenic archaea suggested that methanogenesis is reversible to a certain, small extent during net formation of methane (Zehnder and Brock, 1979; Harder, 1997). The occurrence of such "mini-reversibility" led to the view that a net AOM can be slowly catalyzed by methanogens themselves if an electron sink is available. Hoehler et al. (1994) proposed that AOM is performed by archaea and sulfate-reducing bacteria (SRB) in a consortium where the former produce a free, extracellular intermediate that is

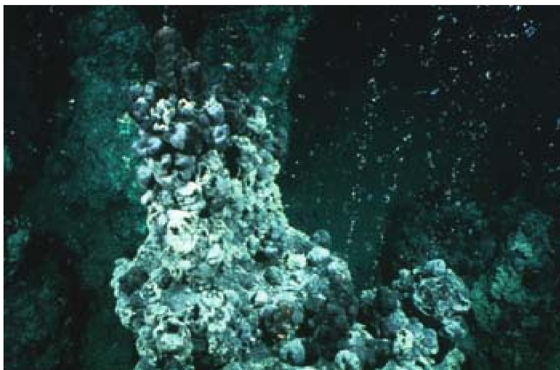


Fig. 1. Chimney-like structure at a cold methane seep on the northwestern Black Sea shelf (water depth, 250 m). The upper chimney-like structure (diameter approx. 0.3 m) consists of carbonate precipitates (presumably $CaCO_3$ and other alkaline earth carbonates) enclosed by massive biofilms that are partly dark due to precipitated ferrous sulfide. Bubbles of excess methane that has not been oxidized are rising from the chimneys. Courtesy of project GHOSTDABS, Walter Michaelis, University of Hamburg.

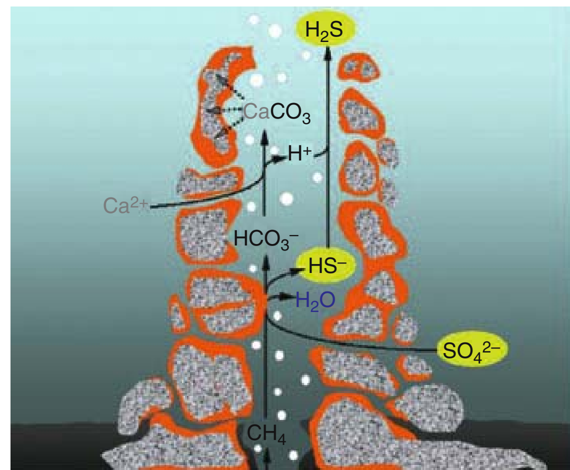

Fig. 2. Scheme of the anaerobic oxidation of methane showing the formation of calcified chimney-like structures as it occurs at the Northeastern Black Sea shelf. Methane-oxidizing mats are indicated in orange and precipitated carbonates in grey (grained).

scavenged by the latter. Molecular hydrogen has been most frequently supposed to function as such an intermediate. Further evidence for the existence of methanotrophic archaea was provided by the finding of strongly ^{13}C-depleted isoprenoid, presumably archaeal lipids and 16S rRNA gene sequences representing a distinct phylogenetic cluster related to the Methanosarcinales (Elvert and Suess, 1999; Hinrichs et al., 1999; Pancost et al., 2000; Hinrichs and Boetius, 2002). Microscopy of whole-cell hybridization assays with 16S rRNA-targeted fluorescent probes revealed consortia of archaeal and bacterial cells belonging to the Methanosarcinales and the *Desulfosarcina-Desulfococcus* branch of the Deltaproteobacteria, respectively (Boetius et al., 2000; Fig. 3). The incorporation of light (^{13}C-depleted) methane-derived carbon has subsequently been shown for each of the apparent partners, the archaea and the bacteria (Orphan et al., 2001; Orphan et al., 2002; Elvert et al., 2003). Presently, the two most abundant phylogenetic groups of methane-oxidizing archaea that have been distinguished by molecular probing in situ are the ANME-1 (Michaelis et al., 2002) and ANME-2 (Boetius et al., 2000) groups; the latter are more closely related to the Methanosarcinales than the former. Both groups are associated with apparently sulfate-reducing bacteria of the *Desulfosarcina*/*Desulfococcus* group (Knittel et al., 2003). A third phylogenetic group of archaea associated with sulfate-reducing bacteria of the *Desulfobulbus* group has been recently discovered at an Arctic mud volcano (T. Lösekann, personal communication). The associations between archaea and bacteria exhibit

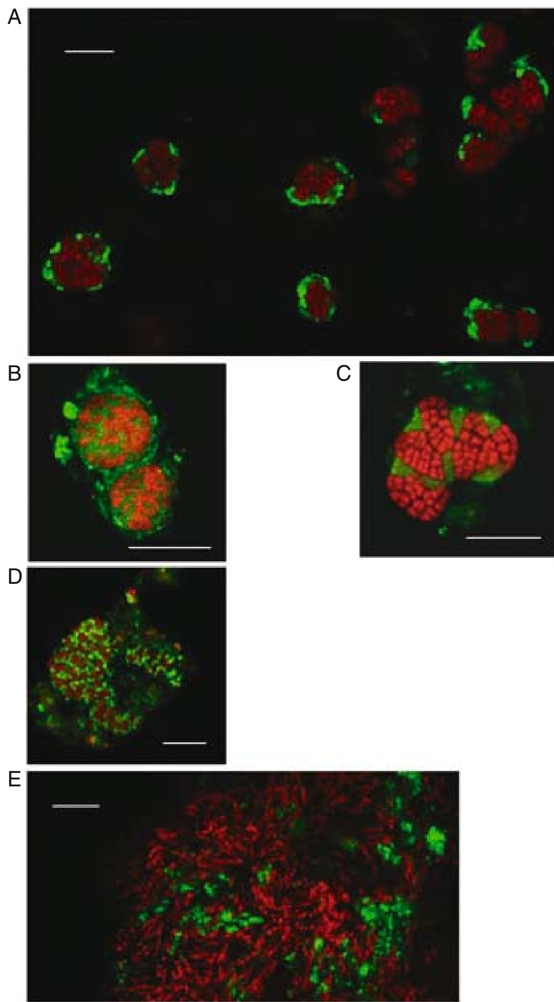

Fig. 3. Fluorescent in situ hybridization (16S rRNA-targeted) of methane-oxidizing archaea in association with sulfate-reducing bacteria. Probes for archaea exhibit red and probes for sulfate-reducing bacteria green fluorescence. (A), (B) Consortia grown as “shell-type.” (C), (D) Consortia grown as “mixed type”. (E) Consortia grown as “biofilm”. Origin: (A), (E) mat from a cold methane seep in the Black Sea (shown in Fig. 1); (B), (C), (D) sediment above methane hydrate of Hydrate Ridge (Cascadia Margin), NE Pacific. Scale bars, 10 μm. diverse structures (Fig. 3), but usually one type is dominant in a certain habitat. Three main structures of consortia may be distinguished: First, in a shell-type association, an inner core of densely packed archaeal cells is surrounded by the bacterial cells. Second, in a mixed type of association, archaeal and bacterial cells are more randomly or evenly throughout the consortia. And third, a biofilm-type of association is characterized by archae and bacteria growing seperately in dense microcolonies.

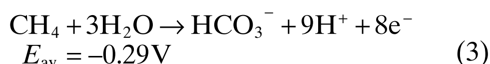
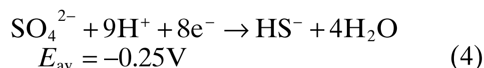
Physiological and Metabolic Studies

The reaction of AOM could be demonstrated in vitro with sediment samples from a marine gashydrate area that is naturally enriched with consortia of archaea and bacteria (Nauhaus et al., 2002). The measured substrate-product balance was in accordance with the above stoichiometric equation. This and the absence of sulfide formation in methane-free control experiments showed that electron donors other than methane were not relevant in the investigated sediment and that microbial communities are fueled merely by methane and sulfate. Furthermore, the measured molar ratio demonstrated that the portion of methane that is channeled into the synthesis of cell carbon (approximately according to $CH_4 + CO_2 \rightarrow 2\,[CH_2O]$) and not used for sulfate reduction must be very small and not quantifiable within the accuracy limits of the measurements, according to the relatively low free energy gain. For various in situ conditions, a free energy change between -10 kJ mol^{-1} and -40 kJ mol^{-1} was estimated, depending on the concentrations of substrates and products in their depth profiles. It is unclear whether AOM under the thermodynamically least favorable conditions can still be connected with growth. Results so far suggest that microorganisms performing AOM grow very slowly and have lower growth yields than, for instance, sulfate-reducing bacteria growing on conventional substrates such as acetate or lactate (which assimilate approx. 10% of their carbon substrate).

The intermediate channeled from methane oxidation into sulfate reduction is still a matter of discussion. In vitro feeding studies with the conventional methanogenic substrates, H_2, formate, acetate, or methanol, in the absence of methane suggested that none of these compounds is an intermediate during AOM (Nauhaus et al., 2002). Indeed, their functioning as an intermediate has been viewed critically also from a theoretical perspective on the basis of diffusion limits and kinetic predictions (Boetius et al., 2000; Valentine et al., 2000; Spormann and Widdel, 2000; Sørensen et al., 2001). Hence, the transfer of reducing equivalents from methane utilization into sulfate reduction probably does not occur via an intermediate that is a typical methanogenic growth substrate. Three principal possibilities for such a transfer can be envisaged. First, a syntrophic interaction may occur by a transfer only of reducing equivalents via electron shuttles (or hydrogen shuttles other than free H_2) that are associated with the cell surfaces. The formal half-reactions and their redox potentials (average of different steps) under in situ conditions (for sites with intense AOM) would be



$$CH_4 + 3H_2O \rightarrow HCO_3^- + 9H^+ + 8e^- \quad E_{av} = -0.29V \tag{3}$$



$$SO_4^{2-} + 9H^+ + 8e^- \rightarrow HS^- + 4H_2O \quad E_{av} = -0.25V \tag{4}$$

and a shuttle system with a midpoint potential in this range would be most favorable (Widdel and Rabus, 2001; Nauhaus et al., 2002). In this case, the archaeal partner would form the methane-derived CO_2 which may be assimilated by the sulfate-reducing bacterium in an autotrophic mode of growth. Second, a syntrophic interaction may occur by a transfer of a methane-derived carbon compound, which according to the experiments is not acetate or methanol. In this case, the bacterial partner (viz., the sulfate reducer) would form the methane-derived CO_2. And, third, methane oxidation as well as sulfate reduction may both take place in the archaeal cells. Growth of the sulfate-reducing partner could be explained by scavenging and utilization of a certain amount of reduced, so far unknown metabolites, i.e., as a kind of metabolic parasitism or commensalism. This model is favored by the finding that archaeal cells in some sediments with AOM are not closely associated with bacterial cells (Orphan et al., 2002) with bacterial cells (Orphan et al., 2002).

The hypothesis that AOM is biochemically in principle a reversal of methanogenesis was supported by the analysis of genes and biochemical components in samples from habitats where methane-oxidizing microbial communities are abundant (Hallam et al., 2003; Krüger et al., 2003). From these habitats, genes were retrieved that were very similar to those encoding the three subunits of methyl-coenzyme M reductase (MCR; composition, $\alpha_2\beta_2\gamma_2$), the terminal enzyme in methanogenesis; there were different types of evidence that these genes belong to the characteristic archaea (ANME-1 and ANME-2 groups) that are commonly associated *in situ* with AOM. The deduced proteins were phylogenetically related to MCR subunits of the Methanosarcinales, but clearly represented own lines of descent. Furthermore, from one of the analyzed habitats, a methane seep area of the Black Sea (Fig. 3), mat-like biomass with ANME-1 archaea was obtained that was sufficient for the purification of proteins. The dominant protein consisted of three subunits with N-terminal amino acid sequences matching those of the retrieved genes (Krüger et al., 2003). This protein harbored a nickel factor that was apparently a heavier (951 Da) variant of factor F_{430} (905 Da), the unique nickel porphinoid in MCR (two molecules F_{430} per molecule of MCR; Thauer, 1998). Hence, special archaea seem to catalyze the initial reaction of of AOM by an enzyme that shares an evolutionary origin with MCR in conventional methanogens, but has been optimized for "reverse methanogenesis."

In this context, the mechanism for the activation of methane as the least reactive hydrocarbon is of particular biochemical interest. A hypothetical activation mechanism may be derived from a reaction model of MCR (in methanogenesis) that is based on the crystal structure (Ermler et al., 1997) and theoretical considerations (Pelmenschikov, 2002; R. K. Thauer, personal communication). According to this model, methyl-coenzyme M (CoM-S-CH_3) in methanogens reacts with F_{430} in its Ni(I) state to yield a methyl radical (·CH_3) while the coenzyme moiety (i.e. the thiolate) is bound to F_{430}, now being in its Ni(II) state. The methyl radical subsequently yields free CH_4 via abstraction of an H-atom from the thiol group of coenzyme B (H-S-CoB), thus leaving a thiyl radical (·S-CoB). The latter scavenges the Ni(II)-bound coenzyme M to form the heterodisulfide (CoM-S-S-CoB). Vice versa, methane in AOM could first react with the coenzyme B thiyl radical yielding a methyl radical and coenzyme B, as depicted in the hypothetical reaction sequence in Fig. 4. Methane activation in this way would resemble, to certain extent, the anaerobic activation of other hydrocarbons which may also involve a thiyl radical for the initial attack (see the sections on Aerobic Degradation of Non-Methane Alkanes and Toluene in this Chapter). An alternative hypothetical mechanism is the direct reaction of methane at the nickel center yielding a Ni-CH_3 species as initial activation product.

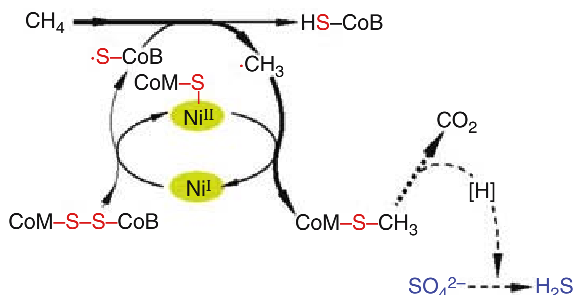


Fig. 4. Hypothesized reaction mechanism for the anaerobic activation of methane as a reversal of the final step in methanogenesis. The heterodisulfide (CoM-S-S-CoB) is reductively cleaved by Ni(I) as a strong reductant and forms a thiyl radical (·S-CoB) as a highly reactive intermediate; first, a short-lived disulfide radical anion (CoM-·S-S-CoB) may be formed (Pelmenschikov, 2002; R. K. Thauer, personal communication). Bold lines indicate the pathway of methane.

Anaerobic Degradation of Non-Methane Alkanes

Alkanes are major constituents of petroleum and natural gas. The possibility of an anaerobic oxidation of *n*-alkanes of various chain lengths has been repeatedly investigated since the 1940s (for references see, Aeckersberg et al., 1991) to understand the technically undesirable process of sulfide formation during oil production. Sulfide formation in oil field waters had been recognized in the 1920s as the activity of sulfate-reducing bacteria (Bastin et al., 1926). *n*-Alkanes as major oil constituents were suspected to serve as growth substrates for sulfate-reducing bacteria. Early reports of an anaerobic *n*-alkane degradation by bacteria that had been isolated with "conventional" polar substrates, for instance, sulfate-reducing *Desulfovibrio* or denitrifying *Pseudomonas* species, could not be repeated (for overview, see Aeckersberg et al. [1991] and Ehrenreich et al. [2000]). Definitely anaerobic degradation of *n*-alkanes with sulfate or nitrate was demonstrated first by quantitative measurement of degradation balances with novel isolates that differed from any of the previously known species of sulfate-reducing and denitrifying bacteria (Aeckersberg et al., 1991; Aeckersberg et al., 1998; Ehrenreich et al., 2000; Rueter et al., 1994; So and Young, 1999). Isolates are listed in Table 1. Furthermore, *n*-alkane degradation to methane and carbon dioxide in the absence of nitrate and sulfate was shown in methanogenic enrichment cultures with defined compounds (Zengler et al., 1999a; Anderson and Lovley, 2000) and with contaminated aquifer sediment enriched with petroleum (Townsend et al., 2003). Degradability of branched or cyclic alkanes under anoxic conditions has been studied to a lesser extent, but there is evidence that also these compounds can be activated and degraded (Bregnard et al., 1997; Rios-Hernandez et al., 2003; Wilkes et al., 2003).

The detection of succinates with alkane-derived alkyl chains in a sulfate-reducing enrichment culture (Kropp et al., 2000) and a denitrifying *Azoarcus* strain (Rabus et al., 2001) growing with *n*-dodecane or *n*-hexane, respectively, suggested that alkanes are activated by an addition to fumarate with formation of a new C-C bond. Hence, this was an analogy to the earlier elucidated activation reaction of toluene yielding benzylsuccinate (see the section on Toluene in this Chapter). Furthermore electron paramagnetic resonance (EPR) spectroscopy showed the presence of an organic radical in *n*-hexane-grown cells but not in *n*-hexanoate-grown cells (Rabus et al., 2001). This further supported the hypothesis that alkane activation resembles, in principle, anaerobic toluene activation, which most likely involves a glycyl radical (see the section on Toluene in this Chapter). A general scheme for such type of anaerobic hydrocarbon activation is shown in Fig. 5. However, in contrast to toluene, the alkanes are activated and added to fumarate at their secondary carbon atoms yielding methylalkylsuccinates. Interestingly, the alkylsuccinates occurred as two diastereomers. Formation of stereoisomers is exceptional among enzymatic reactions. Assuming that the reaction at fumarate is stereoselective, as in toluene activation (see the section on Toluene in this Chapter), the formation of the stereoisomers may be due to relaxed stereospecificity at the alkane carbon; this suggests that the diastereomers are nonracemic. An observation that cannot be explained mechanistically is the lack of a deuterium label at carbon-2 of the succinate moiety in (1-methylpentyl) succinate, if this is formed from *n*-hexane and 2,3-d_2-fumarate. If the addition were analogous to that of toluene (see the section on Toluene in this Chapter), this label should be retained. Also energetically, the activation of alkanes and toluene are not fully comparable. The energy to be overcome during activation of an alkane at the secondary carbon atom is by 33 kJ mol^{-1} higher than in the case of toluene. A hypothetical alkane activation at the primary carbon atom would be even by 51 kJ mol^{-1} higher than toluene activation. The net reaction of hydrocarbon addition to fumarate is exergonic (ΔG^0 between −35 kJ and −39 kJ mol^{-1}; Rabus et al., 2001). For the sulfate-

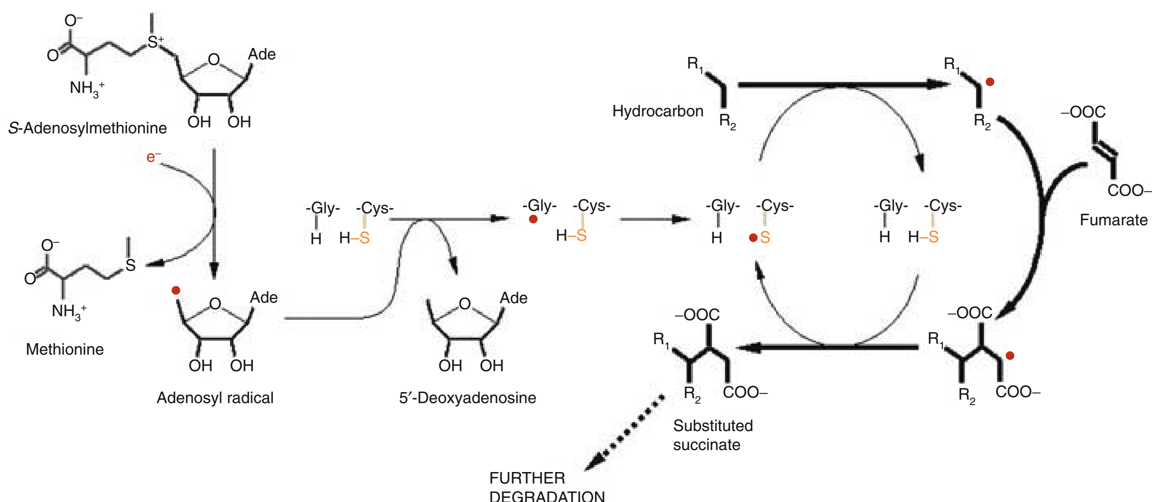

Fig. 5. Suggested general reaction scheme for the activation of saturated hydrocarbons and alkylbenzenes. The adenosyl radical is generated by an activating system in a reductive one-electron step that converts *S*-adenosylmethionine to methionine and the adenosyl-radical. By analogy to known glycyl radical enzymes in different metabolic reactions (Becker et al., 1999; Stubbe, 2000; Himo, 2002), the radical is first stored at a glycyl moiety in the polypeptide chain of the hydrocarbon-activating enzyme. The radical then abstracts a hydrogen atom from a cysteinyl moiety to generate a thiyl radical. The thiyl activates the hydrocarbon which adds to fumarate. The newly formed radicalic carbon compound recombines with the hydrogen atom thus leading to the free activation product (substituted succinate) and the reactive enzyme for the next round. R_1 = alkyl or aryl; R_2 = H or CH_3.

reducing bacterium, strain Hxd3 (Aeckersberg et al., 1991; Aeckersberg et al., 1998), the initial reactions of *n*-alkanes have been proposed to present a modified route with succinate addition at the third carbon position (Rabus et al., 2001), or an alternative, novel route (So et al., 2003).

The pathway for the further degradation of alkylsuccinates (Fig. 6) has been suggested on the basis of labelling studies and identified metabolites. The decisive finding that led to the proposition of the pathway was the observation that the deuterated 3-d_1-(methylpentyl)succinate formed in a labelling experiment yielded exclusively 3-d_1-4-methyloctanoate which was detected as further metabolite (Wilkes et al., 2002). This could be only explained by a deuterium/carboxyl-CoA exchange (opposite migration) followed by a loss of the other (free) carboxyl group. The exchange reaction would be analogous to the methylmalonyl-CoA mutase reaction involved in the formation or degradation of propionate. The assumed alkylmalonyl-CoA formed during anaerobic degradation of alkanes presents an acid with a β-carbonyl function and can easily undergo decarboxylation (or transcarboxylation) to yield the CoA derivative of a methyl-branched monocarboxylic acid. The position of the methyl branch does not interfere

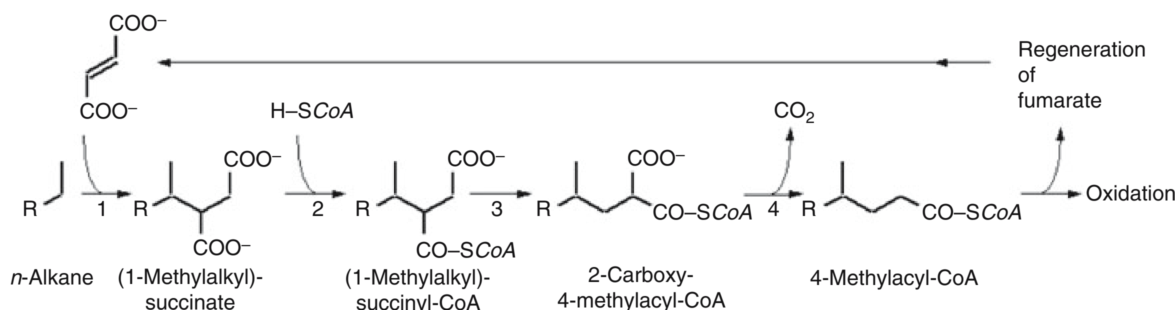

Fig. 6. Proposed reactions for the anaerobic activation and further metabolism of *n*-alkanes. (1-Methylalkyl)succinate generated by the radical-catalyzed reaction with fumarate (1) is presumably activated to become the coenzyme A thioester (2), which obviously undergoes carbon skeleton rearrangement (H/carboxyl-CoA exchange) (3). The resulting 3-ketoacid structure can undergo decarboxylation (or transcarboxylation) and lead to an activated fatty acid (4) that is oxidized by conventional β-oxidation. A propionyl fragment (not shown) from β-oxidation may be used for the regeneration of fumarate. (For details, see Wilkes et al., 2002.)

with conventional β-oxidation. The proposed pathway also offers a sequence for the regeneration of fumarate as the cosubstrate for the next round of alkane activation (Wilkes et al., 2002).

Anaerobic Degradation of Alkenes

Living organisms produce numerous alkenes, widespread compounds being the plant hormone ethene, carotenoids without functional groups, or the structurally large group of alkenoic terpenes that belong to the quantitatively most important secondary metabolites of plants. Alkenes are usually not present in petroleum and natural gas; they undergo saturation or aromatization during the long-term geochemical transformation processes (diagenesis and catagenesis).

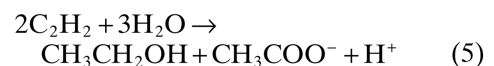
An anaerobic degradation of alkenes containing one or more double bonds has been repeatedly documented. A methanogenic coculture has been enriched on 1-*n*-hexadecene (Schink, 1985a), and a denitrifying bacterium has been isolated with 1-*n*-heptadecene as organic substrate (Gilewicz et al., 1991). Also, some of the denitrifying and sulfate-reducing bacteria originally isolated with *n*-alkanes are able to grow with 1-alkenes (see references in Table 1). Squalene, an isoprenoid alkene with six isolated double bonds, was slowly degraded in a methanogenic enrichment culture (Schink, 1985a). Strains of a nutritionally versatile denitrifying bacterium, *Alcaligenes defragrans*, have been isolated with the monounsaturated hydrocarbons *p*-menth-1-ene, α-pinene, 2-carene, and the diunsaturated hydrocarbon α-phellandrene (Foss et al., 1998). Two denitrifiers, strains pCyN1 and pCyN2, that were isolated with the aromatic monoterpene hydrocarbon *p*-cymene, also utilized several number of alkenoic monoterpenes (Harms et al., 1999a).

In contrast to monoterpenes, carotenoids appear to be very recalcitrant under anoxic conditions in the dark. Carotenoids (including those with functional groups) are preserved in anoxic sediments over thousands of years (Overmann et al., 1993). Strong adsorption to a matrix may contribute to this stability in sediments. Accordingly, β-carotene did not support growth of methanogenic enrichment cultures (Schink, 1985a).

The initial reactions of alkene activation are still unknown. Most anaerobes capable of degrading alkenes were directly enriched with these compounds and never were able to utilize saturated hydrocarbons (Schink, 1985a; Gilewicz et al., 1991; Foss et al., 1998). This suggests that there are specific alkene activating enzymes, and that the double bond is essential for the catalytic activation mechanism. Reactions appear in principle possible at the carbon atom next to the double bond, or at one of the double-bonded carbon atoms. In case of a reaction at the carbon adjacent to the double bond, hypothetical radical or cationic intermediates can be stabilized via delocalization. Comparative substrate tests with various menthadienes (monoterpene alkenes with two double bonds) suggested that sp^2-hybridization of the ring carbon atom next to the methyl group is a prerequisite for degradability of the hydrocarbon by *Alcaligenes defragrans* (Hylemon and Harder, 1999); however, there are no hints so far that the methyl group is the site of direct enzymatic attack. If a reaction (e.g., addition of a proton) occurred at an isolated double bond of an alkene, the intermediate (e.g., carbenium ion) would not be stabilized. Nevertheless, a bacterial enzyme has been purified and heterologously expressed that hydrates the isolated terminal double bond in the isopropyl side chain of limonene, an alkenoic monoterpene, yielding α-terpineol (Savithiry et al., 1997). In denitrifying *Alcaligenes defragrans*, a cometabolic conversion of the monoterpene isolimonene to isoterpinolene, viz., a shift of the terminal double bond to an energetically more stable position, has been observed (Heyen and Harder, 1998). The double bond involves a tertiary (branched) carbon atom such that a catalysis by protonation with formation of the relatively stable carbenium ion at a tertiary carbon is likely. (For more detailed aspects of reactions at double bonds, see Buckel [1992] and Spormann and Widdel [2000].)

Anaerobic Degradation of Alkynes (Acetylene)

Natural carbon compounds with triple bonds between carbon atoms (e.g., mycomycin) are rare: reactive secondary metabolites in some fungi and a few other organisms where such substances may sometimes function as deterrents. These compounds contain in addition polar groups; pure hydrocarbons with triple bonds have not been detected among the natural hydrocarbons. It is therefore remarkable that not only aerobic but also anaerobic bacteria such as *Pelobacter acetylenicus* can be readily enriched and isolated with acetylene (Schink, 1985b; Rosner and Schink, 1995). The anaerobic bacteria ferment acetylene to ethanol and acetate as end products according to



$$2C_2H_2 + 3H_2O \rightarrow CH_3CH_2OH + CH_3COO^- + H^+ \quad (5)$$

Growth on acetylene is fast (doubling time, 5–5.5 h). The natural significance of the capacity for acetylene degradation is unknown.

Acetylene is chemically reactive, and the fast metabolism of acetylene in *Pelobacter acetylenicus* indicates also substantial biochemical reactivity. Degradation of acetylene in *P. acetylenicus* occurs via hydratation to acetaldehyde, as observed in aerobic acetylene degrading bacteria (DeBont and Peck, 1980; Kanner and Bartha, 1982):

$$C_2H_2 + H_2O \rightarrow CH_3CHO \qquad (6)$$

One part of the acetaldehyde is then oxidized to acetate; the reducing equivalents are transferred to another part of the acetaldehyde (Schink, 1985b). Acetylene hydratase, which has been purified (Rosner and Schink, 1995), involves tungsten as a high-valent metal. It is part of tungstopterine-guanine dinucleotide (Meckenstock et al., 1999). The monomeric enzyme (molecular mass 83 kDa) contains in addition an Fe_4S_4 cluster. In a hypothesized model, acetylene binds to the tungsten(IV) site, followed by the addition of water to the triple bond. The reaction of the enzyme appeared to be independent of the redox state of the iron-sulfur cluster.

Anaerobic Degradation of Aromatic Hydrocarbons

Aromatic hydrocarbons are, besides or next to saturated ones, the main constituents of petroleum (Tissot and Welte, 1984). Many aromatic petroleum hydrocarbons are substituted by one or more alkyl chains of varying length and thus exhibit much structural diversity. Alkyl-substituted aromatic hydrocarbons may be regarded as chimeras of pure aromatic and aliphatic structures. So far known, the degradation of alkyl-substituted aromatic hydrocarbons makes use of the reactivity of the aliphatic carbon atom that is adjacent to the aromatic ring (in case of alkylbenzenes termed the benzyl carbon). Since this possibility does not exist for unsubstituted aromatic hydrocarbons (benzene, naphthalene, etc.), their degradation has to occur via different mechanisms.

Benzene

Evidence for anaerobic degradation of benzene, the most stable aromatic hydrocarbon, was first provided by studies with enriched populations in or from sediments with different electron acceptors (Grbić-Galić and Vogel, 1987; Edwards and Grbić-Galić, 1992; Phelps et al., 1998; Rooney-Varga et al., 1999; for overview, see Coates et al., 2002). A sediment-free sulfate-reducing consortium was analyzed on the basis of 16S rRNA gene sequences (Phelps et al., 1998); the bacterium supposed to be responsible for benzene degradation affiliates with purified strains of sulfate-reducing bacteria that degrade naphthalene, *m*-xylene, or ethylbenzene (Galushko et al., 1999; Kniemeyer et al., 2003). The first pure cultures shown to degrade benzoate anaerobically were two denitrifying *Dechloromonas* strains originally enriched and isolated with 4-chlorobenzoate and humic substances (Coates et al., 2001).

In the benzene-utilizing sulfate-reducing enrichment culture, benzoate was detected as an intermediate; however, isotope labeling showed that the carboxyl group was not derived from CO_2 in the medium. On the basis of substrate adaptation and inhibition studies, a coenzyme B_{12}-catalyzed methylation of benzene to toluene was suggested for *Dechloromonas* (Coates et al., 2002); toluene can indeed also serve as a growth substrate for this organism. Methylation of benzene, possibly with *S*-adenosylmethionine as the methyl donor, had been shown before as a biochemical reaction in human bone marrow (Flesher and Myers, 1991). Such a reaction can be envisioned as a biochemical analogue of a Friedel-Crafts type electrophilic substitution. An electrophilic enzymatic attack on benzene would circumvent an initiation of benzene activation by the energetically problematic radical cleavage of a C-H bond. In case of benzene (and naphthalene), the C-H bond is even more stable than that of methane (McMillen and Golden, 1982; March, 1992; Widdel and Rabus, 2001).

Naphthalene and Phenanthrene

Hints about anaerobic naphthalene degradation originally again came from studies with enriched communities under conditions of sulfate reduction (Coates et al., 1996; Zhang and Young, 1997). Complete degradation of naphthalene was demonstrated by quantitative growth experiments with a novel type of sulfate-reducing bacterium in pure culture (Galushko et al., 1999). Experiments with radiolabeled substrate revealed naphthalene oxidation by pure cultures of denitrifying bacteria (Rockne et al., 2000). Identification of 2-naphthoic acid as a metabolite in sulfate-reducing cultures enriched with naphthalene suggested an initial activation via carboxylation to 2-naphthoate (Zhang and Young, 1997; Meckenstock et al., 2000). This finding is in agreement with the observation that the sulfate-reducing isolate can utilize 2-naphthoate but not 1-naphthoate (Galushko et al., 1999). In principle, also a methylation as suggested in the case of benzene appears possible. Identification of other metabolites in a sulfate-reducing enrichment culture indicated further metabolism of 2-naphthoate (presumably as activated acid) via subsequent reduction of the two rings yielding

decahydro-2-naphthoate or an activated form (Meckenstock et al., 2000).

Degradation of the tricyclic aromatic hydrocarbon phenanthrene under anoxic conditions was demonstrated in sediment cultures with ^{14}C-labeled substrate (Coates et al., 1996; Zhang and Young, 1997). Mass spectrometric analysis indicated formation of a phenanthrene carboxylate isomer as initial product, again suggesting substrate carboxylation (Zhang and Young, 1997).

Toluene

Anaerobic biodegradation of hydrocarbons has been most intensely studied with toluene. Toluene-degrading anaerobes are apparently widespread and are relatively easily enriched from various aquatic sediments. Soon after the demonstration of anaerobic toluene degradation in various sediments and enrichment cultures (for references, see Widdel and Rabus, 2001), a steadily increasing number of pure cultures with the capacity for anaerobic toluene degradation was recognized or isolated de novo (Table 2). Most isolates are denitrifiers that belong to the genera *Azoarcus* and *Thauera*. Other isolates reduce iron(III), sulfate, or fumarate in a binary (syntrophic) culture. Furthermore, an anoxygenic phototroph utilized toluene together with CO_2 for the light-driven cell synthesis (Zengler et al., 1999b). Methanogenesis from toluene has been shown so far only in enrichment cultures (e.g., Grbić-Galić and Vogel, 1987; Beller and Edwards, 2000b). The apparent abundance of anaerobic bacteria with the capacity for toluene degradation may be explained by the occurence of toluene as a natural product in various habitats. Toluene does not only originate from petroleum and petroleum products, but also is formed by anaerobic microbial degradation of phenylacetate, a fermentation product of phenylalanine (Fischer-Romero et al., 1996). In comparison to other aromatic or saturated hydrocarbons, toluene allows relatively rapid growth (for denitrifiers, doubling time 6 h), which has been in favor of biochemical studies. Indeed, the study of anaerobic toluene degradation has provided important clues to help our understanding of anaerobic hydrocarbon metabolism.

The identification of benzylsuccinate in a toluene-degrading sulfate-reducing enrichment culture (Beller et al., 1992) and a denitrifying strain (Evans et al., 1992) was an important discovery and basis for the elucidation of the anaerobic metabolism of toluene (Biegert et al., 1996; Beller and Spormann, 1997; Heider et al., 1999; Spormann and Widdel, 2000; Boll et al., 2002) and other hydrocarbons. It could be shown that benzylsuccinate was not a by-product, but the direct initial intermediate formed from toluene and fumarate in a carbon-carbon addition reaction that does not require electron carriers or ATP as cosubstrates (Biegert et al., 1996). Activation by addition to fumarate was subsequently demonstrated in other metabolic types of anaerobic toluene-degrading bacteria (Zengler et al., 1999b; Beller and Edwards, 2000; Kane et al., 2002). Stereochemical analysis in denitrifying bacteria showed formation of *R*(+)-benzylsuccinate (Beller and Spormann, 1998; Leutwein and Heider, 1999). Experiments with deuterium-labeled toluene revealed that the hydrogen/deuterium atom that has to be removed before toluene can add to fumarate is retained in the product (Beller and Spormann, 1998).

Structural and mechanistic properties of the toluene-activating enzyme, benzylsuccinate synthase, have been elucidated by genetic (Coschigano et al., 1998; Leuthner et al., 1998b; Achong et al., 2001) and enzymatic (Leuthner et al., 1998b) approaches. One of the structural genes (*bbsA*; Fig. 7) revealed a region with high similarity to genes encoding pyruvate formate-lyase (PFL) and type III ribonucleotide reductase (RNR; Coschigano et al., 1998; Leuthner et al., 1998b); the latter two enzymes are known to involve glycyl radicals in the polypeptide chain. Benzylsuccinate synthase from *Thauera aromatica* (strain K172) is a heterohexamer ($\alpha_2\beta_2\gamma_2$) with a native molecular mass of 200 kDa (Leuthner et al., 1998b). The presence of a glycyl radical was further confirmed by protein fragmentation upon exposure to oxygen (Leuthner et al., 1998b), and by a characteristic EPR signal in *Thauera aromatica* strains (Krieger et al., 2001; Duboc-Toia et al., 2003). Furthermore, the gene encoding the putative activating (radical-generating) enzyme was detected on the basis of sequence similarities with the activator genes of PFL and RNR (Coschigano et al., 1998; Leuthner et al., 1998b).

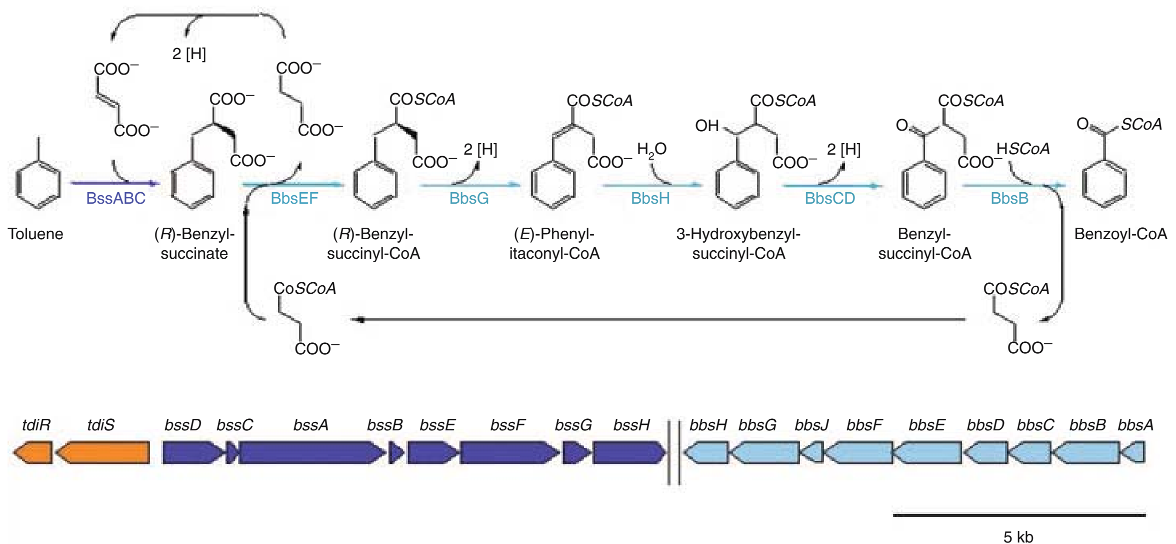

Fig. 7. Reactions and genes involved in anaerobic toluene degradation to the level of benzoyl-CoA in denitrifying *Azoarcus* strain EbN1. The biochemical reactions are supposed to be the same in other denitrifying, iron(III)-reducing, sulfate-reducing, syntrophic (associated with methanogens) and phototrophic bacteria. Fumarate as cosubstrate for toluene activation by benzylsuccinate synthase is recycled. Benzoyl-CoA is further oxidized via reductive dearomatization and ring cleavage (Haarwood et al., 1999) to carbon dioxide (not shown). Reducing equivalents ([H]) are used for the reduction of the electron acceptor. Enzyme names of gene products (in bold) are as follows: BssABC, benzylsuccinate synthase; BbsEF, succinyl-CoA:benzylsuccinate CoA-transferase; BbsG, benzylsuccinyl-CoA dehydrogenase; BbsH, phenylitaconyl-CoA hydratase; BbsCD, 3-hydroxyacyl-CoA dehydrogenase; and BbsB, benzylsuccinyl-CoA thiolase. Identified genes involved in this pathway are clustered into two groups. Dark blue: genes for benzylsuccinate synthase and associated proteins. Light blue: genes for enzymes involved in the β-oxidation-like reaction sequence leading from benzylsuccinate to benzoyl-CoA. Orange: genes for a toluene-specific two-component regulatory system which may mediate coordinated (simultaneous) expression of both gene clusters in response to toluene.

The occurrence of a glycyl radical in biochemical reactions was detected in pyruvate-formate lyase (Becker et al., 1999) and class III ribonucleotide reductase (Stubbe, 2000). Benzylsuccinate synthase presents a third class of glycyl radical enzymes. The activating enzymes of PFL and RNR generate the glycyl radical via cleavage of *S*-adenosylmethionine by one-electron reduction yielding methionine and an adenosyl radical; the latter abstracts an H atom from a glycyl residue leading to a glycyl radical (viz., -NH-·CH-CO- in the polypeptide chain); this is supposed to be a storage radical which then generates a thiyl radical (-*S*·) as the reactive form (Fig. 5). In a theoretical study, calculations of energy requirements of partial reactions suggested that formation of the benzyl radical is the rate-limiting step in the formation of benzylsuccinate (Himo, 2002).

RNA analysis demonstrated that expression of genes related to benzylsuccinate formation is induced by toluene and confirmed their previously observed arrangement in an operon (Leuthner et al., 1998b; Coschigano, 2000). In both strains of *Thauera aromatica*, genes were identified that exhibited significant sequence homology to sensor/regulator proteins of two-component systems and were suggested to function in regulation of toluene metabolism (Coschigano et al., 1997; Leuthner and Heider, 1998a).

Benzylsuccinate is further metabolized, somewhat in analogy to β-oxidation of fatty acids, to succinyl-CoA and benzoyl-CoA (Leutwein and Heider, 1999; Leuthner and Heider, 2000). The promotor controlling transcription of the operon for the enzymes of benzylsuccinate metabolism in *T. aromatica* (*bss* operon) was recently identified (Leuthner and Heider, 2000). A scheme is shown in Fig. 7. Benzoyl-CoA undergoes reductive dearomatization, ring cleavage, and reactions resembling those in β-oxidation of fatty acids (Haarwood et al., 1999).

A large DNA contig of *Azoarcus* strain EbN1 with the entire genetic blueprint for anaerobic toluene degradation has been elaborated (Kube et al., 2004; Fig. 7). Five genes of unknown function separate the predicted *bss* and *bss* operons. The absence of genes encoding for regulatory proteins in the proximity of the *bss* operon and the occurrence of similar sequence motifs in the promotor regions of the *bss* and *bss* operons suggest a coordinated regulation of both operons. The regulation in response to toluene is probably mediated by a two-component regulatory system (TdiSR).

Xylenes and *p*-Cymene

Among alkylbenzenes with two or more alkyl substituents, xylenes (dimethylbenzenes) are the most relevant ones in oil and as chemicals. Several strains that can degrade toluene can also grow with *m*-xylene (Spormann and Widdel, 2000; Widdel and Rabus, 2001). There is evidence that anaerobic degradation of *m*-xylene proceeds, in analogy to that of toluene, via *m*-methylbenzylsuccinate to *m*-methylbenzoyl-CoA (Spormann and Widdel, 2000). Further degradation of *m*-methylbenzoyl-CoA would be possible by reactions analogous to those of benzoyl-CoA because the methyl group does not interfere with reactions of a regular β-oxidation. Degradation of *o*- and *p*-xylene, which appear to be poorly and rarely utilized by anaerobic bacteria (Häner et al., 1995; Harms et al., 1999b), may be also initiated by reaction with fumarate which then leads to *o*- and *p*-methylbenzoyl-CoA, respectively. Upon ring cleavage, however, the methyl groups would prevent one round of regular β-oxidation and thus require additional mechanisms for complete substrate oxidation.

Furthermore, degradation of higher dialkylbenzenes has been observed, among which *p*-isopropyltoluene (*p*-cymene) as a plant hydrocarbon is probably the naturally most significant compound (Harms et al., 1999a). *p*-Isopropyltoluene was rapidly utilized by denitrifying strains, suggesting an effective mechanism to bypass the blockage (due to alkyl branching) of β-oxidation after dearomatization of the assumed intermediate *p*-isopropylbenzoyl-CoA and thiolytic ring cleavage. *p*-Isopropylbenzoate (*p*-cumate) has been detected as a metabolite, suggesting that the methyl group is the site of the initial enzymatic attack. One of the isolated strains, pCyN1, could also utilize toluene. However, the capacities for *p*-cymene and toluene degradation in strain pCyN1 were separately induced by the substrates, suggesting distinct enzymatic systems at least for parts of the metabolic pathways (Harms et al., 1999a).

Ethylbenzene and Propylbenzene

Pure cultures of anaerobes isolated with and shown to degrade ethylbenzene are denitrifying *Azoarcus* strains (Rabus and Widdel, 1995; Ball et al., 1996) and a gas-vesicle containing type of sulfate-reducing bacterium (Kniemeyer et al., 2003).

Ethylbenzene oxidation in the denitrifiers was shown to proceed via dehydrogenation to 1-phenylethanol and acetophenone, which is probably followed by carboxylation and activation yielding benzoylacetyl-CoA, and subsequently by thiolytic cleavage to acetyl-CoA and benzoyl CoA (Rabus and Widdel, 1995; Ball et al., 1996; Champion et al., 1999; Johnson and Spormann, 1999; Kniemeyer and Heider, 2001a; Kniemeyer and Heider, 2001b), as depicted in Fig. 8. Ethyl-

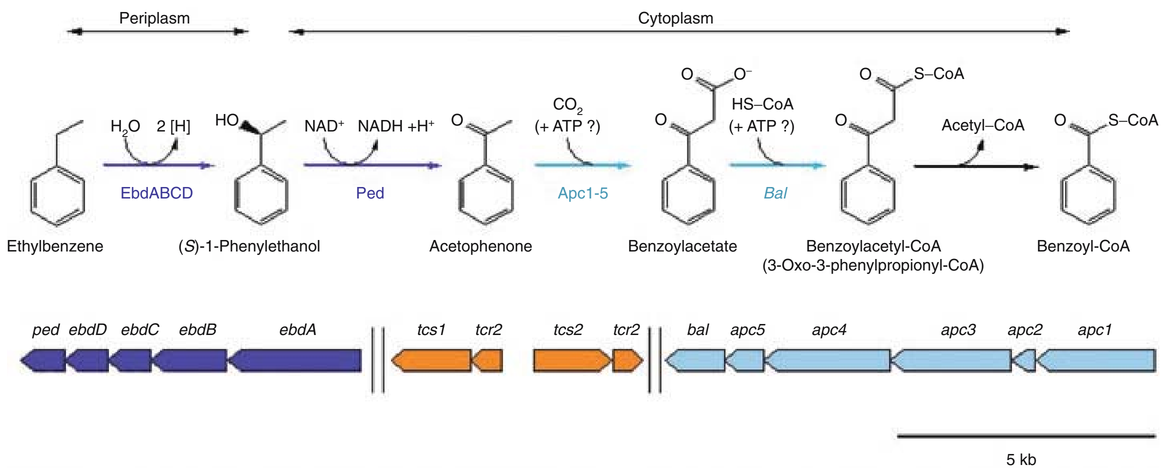

Fig. 8. Reactions and genes involved in anaerobic ethylbenzene degradation to the level of benzoyl-CoA in denitrifying strain EbN1. The biochemical reactions are supposed to be the same in other denitrifying bacteria. Benzoyl-CoA is further oxidized via reductive dearomatization and ring cleavage (Haarwood et al., 1999) to carbon dioxide (not shown). Reducing equivalents ([H]) are used for the reduction of nitrate to dinitrogen. Enzyme names of gene products (in bold) are as follows: EbdABCD, ethylbenzene dehydrogenase; Ped, (*S*)-1-phenylethanol dehydrogenase; Apc1-5, acetophenone carboxylase; and Bal, benzoylacetate CoA-ligase. The last reaction step is probably catalyzed by a benzoylacetyl-CoA thiolase. Identified genes involved in this pathway are clustered into two groups. Dark blue: genes for the upper part of the pathway from ethylbenzene to acetophenone. Light blue: genes for the lower part of the pathway from acetophenone to benzoyl-CoA. Orange: genes for two-component regulatory systems, one of which has been suggested to be specific for ethylbenzene degradation (Tcs2/Tcr2) and the other one for acetophenone (Tcs1/Tcr1) degradation; accordingly, both parts of the pathway may be regulated independently.

benzene dehydrogenase, which produces (*S*)-1-phenylethanol in *Azoarcus* strains (Johnson and Spormann, 1999; Johnson et al., 2001; Kniemeyer and Heider, 2001b), is a novel molybdenum/iron-sulfur/heme protein localized in the periplasm (Kniemeyer and Heider, 2001a). The natural electron acceptor is unknown. The capacity for ethylbenzene degradation was shown to be induced (Champion et al., 1999; Rabus and Heider, 1998). From the versatile alkylbenzene-utilizing *Azoarcus* strain EbN1, genes involved in anaerobic ethylbenzene metabolism have been identified on a large contig (Rabus et al., 2002). The genes for the “upper” pathway leading from ethylbenzene to acetophenone and for the “lower” pathway for the further metabolism of acetophenone are organized in two distinct operons. Two tentative two-component regulatory systems are encoded between these catabolic operons and are proposed to mediate the sequential, independent regulation of the pathways.

There is evidence from alkylbenzene-degrading communities (Elshahed et al., 2001) and a pure culture (Kniemeyer et al., 2003) that the initial anaerobic reaction of ethylbenzene in sulfate-reducing bacteria differs completely from the reaction in denitrifiers and is analogous to toluene activation. The formation of (1-phenylethyl)succinate and 4-phenylpentanoate indicated a radical-catalyzed addition of ethylbenzene to fumarate and subsequent carbon rearrangement and decarboxylation, in analogy to the anaerobic metabolism of alkanes (Fig. 6). In accordance with such a pathway for ethylbenzene instead of initial dehydrogenations, the sulfate-reducing strain was unable to oxidize 1-phenylethanol and acetophenone, which are intermediates and growth substrates in ethylbenzene-degrading denitrifiers. In the “low-potential” metabolism of sulfate-reducing bacteria, activation via a reductively generated radical (Fig. 5) is apparently easier to achieve than dehydrogenation (Fig. 8), which has a relatively high redox potential (1-phenylethanol/ethylbenzene, $E^{0\prime}$+0.03 V; estimated by analogy using thermodynamic data of other alcohols/hydrocarbons).

Azoarcus strain PbN1 utilizes *n*-propylbenzene in addition to ethylbenzene. The pathway of propylbenzene oxidation is assumed to proceed in analogy to that of ethylbenzene (Rabus and Widdel, 1995; Fig. 8) and may even involve the same enzymes for activation and subsequent steps (Kniemeyer and Heider, 2001a).

2-Methylnaphthalene

Alkylnaphthalenes (and higher polycyclic aromatic hydrocarbons) occur in great structural variety in crude oil, but little is known about degradation of these compounds. Alkylnaphtha-

lenes are expected to undergo activation easier than naphthalene (as alkylbenzenes are easier to activate than benzene) and to exhibit initial reactions comparable to those of alkylbenzenes. Indeed, identification of naphthyl-2-methylsuccinic acid as metabolite in a sulfate-reducing enrichment culture growing on 2-methylnaphthalene is in support of an activation mechanism analogous to that of toluene (Annweiler et al., 2000).

Anaerobic Microbial Growth with Crude Oil

As in the study of aerobic biodegradation of hydrocarbons (see the chapter on Hydrocarbon-Oxidizing Bacteria in this Volume), also the study of their anaerobic biodegradation is frequently connected with questions concerning microbial growth with and utilization of crude oil or derived industrial products such as fuels and organic solvents. A broad and relevant topic in this respect is the natural or stimulated in situ bioremediation of hydrocarbon-polluted environments. Even though aerobic hydrocarbon degradation is faster and probably includes a broader range of hydrocarbons than anaerobic degradation, the latter is of interest in subsurface environments where oxygen has no or limited access. Indeed, research of anaerobic in situ bioremediation of petroleum-derived hydrocarbons has developed into an own, vast area of research since the late 1980s. Coverage of this is beyond the scope of this chapter, and detailed information and references are given in other articles (e.g., Beller, 2000a, Elshahed et al., 2001; Gieg and Suflita, 2002; Reusser et al., 2002; Hunkeler et al., 2002; Richnow et al., 2003; Townsend et al., 2003). Here, we summarize some physiological aspects of anaerobic microbial growth with crude oil.

Crude oil (often also referred to as petroleum) is a highly complex mixture of saturated aliphatic and aromatic hydrocarbons as the main constituents (on the average 85% by weight; Tissot and Welte, 1984). Other constituents are aliphatic and aromatic compounds containing sulfur (e.g. alkylated thiophenes and benzothiophenes), monocarboxylic acids (so-called naphthenic acids), and resins and asphaltenes which are carbon- and hydrogen-rich polymeric substances with O- and S-atoms. Alkenes are usually absent; alkenes from biomass have been saturated or (in the case of appropriate structure) aromatized during the maturation of petroleum (Tissot and Welte, 1984).

Anaerobic enrichment cultures reducing sulfate (Rueter et al., 1994; Rabus et al., 1996) or nitrate (Rabus et al., 1999) and pure cultures reducing sulfate (Rueter et al., 1994; Wilkes et al., 2000) or nitrate (Rabus and Widdel, 1996; Wilkes et al., 2003) have been shown to grow with crude oil as the only source of organic substrates with simultaneous depletion of hydrocarbons. The enrichment cultures with crude oil (in freshwater medium) and nitrate favored the development of members of the Betaproteobacteria; crude oil and sulfate (in marine medium) enriched for sulfate-reducing Deltaproteobacteria related to genera with complete substrate oxidation and unrelated to *Desulfovibrio*. Of the saturated hydrocarbons, *n*-alkanes were consumed mostly in the C_6-C_{14} range. Of the aromatic hydrocarbons, toluene, xylenes and ethylbenzene were completely or largely consumed. Hence, in particular the lighter hydrocarbon fraction of crude oil seemed to be degraded under anoxic conditions. Estimations based on the amounts of oil added to cultures and sulfate or nitrate reduced by them suggested that up to about one tenth (wt/wt) of the crude oil was anaerobically degraded. However, the fraction that can be oxidized anaerobically may be higher since also hydrocarbons other than *n*-alkanes and alkylbenzenes can be also utilized anaerobically, especially by populations from highly contaminated sites (Bregnard et al., 1997; Lovley, 2000; Rabus and Widdel, 2001; Rios-Hernandez et al., 2003; Townsend et al., 2003; see also the section on Anaerobic Degradation of Aromatic Hydrocarbons). Nevertheless, anaerobic degradation of crude oil seems to occur to a lesser extent and at a much slower rate than aerobic degradation.

Anaerobic biodegradation of hydrocarbons, especially by sulfate-reducing bacteria, offers an explanation for the specific depletion of hydrocarbons in certain petroleum reservoirs despite the absence of oxygen (Connan et al., 1996). Nevertheless, petroleum in many reservoirs is still rich in the hydrocarbons that can be degraded anaerobically. This raises the question as for the circumstances that allow or prevent anaerobic hydrocarbon degradation in oil reservoirs (Rabus et al., 1996). First, microorganisms that were originally present in the sediments with biogenic carbon (that finally gave rise to petroleum) may have died off as the temperature increased with the depth of burial. But also reservoirs with temperatures favorable for bacterial growth (probably below 80°C) may harbor sterile oil if it has uplifted from deeper, hotter reservoirs (Wilhelms et al., 2001). Second, sulfate-reducing microorganisms as the apparently most significant anaerobic degraders of oil may be strongly limited by sulfate that may have been mostly depleted already before oil maturation. Third, diffusion of hydrocarbons from oil phases to water phases which are both in a rock matrix may be too slow for maintenance of microbial

life. In situ growth on petroleum hydrocarbons may be favoured only in connection with migration events and upon introduction of seawater and microorganisms from present marine habitats, for instance during oil production.

For the evaluation of the extent of an anaerobic biodegradation in contaminated deep aquifers or petroleum reservoirs, analyses of isotope ratios and polar metabolites are potentially useful. In cultures with crude oil (Fukui et al., 2000; Wilkes et al., 2000) or defined hydrocarbons (Meckenstock et al., 1999; Morasch et al., 2001), the residual portion of the degradable hydrocarbon became enriched in the heavier isotopes, ^{13}C (or ^{2}H), i.e. the lighter isotopomers were preferentially degraded. Isotope fractionations in hydrocarbon-contaminated aquifers can thus be taken as evidence for an anaerobic biodegradation in situ (Bolliger et al., 1999; Richnow et al., 2003). During anaerobic growth with crude oil in pure and enriched cultures (Wilkes et al., 2000, 2003) as well as during degradation of mixed hydrocarbons in contaminated subsurface sediment (Beller, 2000; Gieg and Suflita, 2002), formation of metabolites from the anaerobic degradation pathways was observed. However, metabolites such as alkyl- or arylsuccinates or alkylated benzoic acids may be also formed cometabolically, and the range of hydrocarbons activated in this way can be wider than the range that is definitely mineralized with coupling to growth (Wilkes et al., 2000, 2003).

Cultivation

The most commonly used electron acceptors for the study of the anaerobic degradation of hydrocarbons are sulfate and nitrate, and the following description of cultivation media and methods therefore focuses on these electron acceptors. However, the media can be modified for other purposes, for instance by omitting sulfate or nitrate to study methanogenesis from nonmethane hydrocarbons. The range of hydrocarbons utilized with sulfate as electron acceptor is apparently wider than the range utilized with nitrate. However, denitrifying anaerobic hydrocarbon degraders usually grow much faster, have higher growth yields, and are easier to handle in the laboratory. Denitrifying hydrocarbon degraders are, therefore, usually the first choice for enzymatic studies.

The use of defined, transparent media that do not contain organic nutrients other than the hydrocarbon substrate is recommended. An exception is the addition of ascorbate as a mild, compatible reductant (scavenger of traces of oxygen) to pure cultures of denitrifiers if this does not serve as a growth substrate (which is usually the case). Components that undergo chemical changes or volatilization in the heat are added from separately sterilized stock solutions after autoclaving and cooling of the main medium.

Oxygen is excluded as far as possible during preparation of the medium. An anoxic chamber is useful but not obligatory. With appropriate gassing devices and tubes with fitted stoppers and fixing caps (to avoid loss of stoppers) as described for the cultivation of sulfate-reducing bacteria (Widdel and Bak, 1992), all steps can be done at a normal laboratory bench.

Stock solutions are prepared as follows.

Trace Element Mixtures	A	B
Distilled water	987 ml	1000 ml
HCl (25% = 7.7 M)	13 ml	none
EDTA, disodium salt	none	5.2 g
H_3BO_3	10 mg	10 mg
$MnCl_2 \cdot 4H_2O$	5 mg	5 mg
$FeSO_4 \cdot 7H_2O$	4000 mg	2100 mg
$CoCl_2 \cdot 6H_2O$	190 mg	190 mg
$NiCl_2 \cdot 6H_2O$	24 mg	24 mg
$CuCl_2 \cdot 2H_2O$	2 mg	10 mg
$ZnSO_4 \cdot 7H_2O$	200 mg	144 mg
$Na_2MoO_4 \cdot 2H_2O$	36 mg	36 mg
pH adjustment	none	6.0

"A" is for sulfate-reducing bacteria; the mixture is kept acidic (by the added HCl). "B" is for nitrate-reducing bacteria; the indicated pH is adjusted with NaOH. Use only fresh, greenish crystals of $FeSO_4 \cdot 7H_2O$; brownish grains indicate weathering and oxidation. The trace element solutions are autoclaved (preferentially anoxically under N_2).

Bicarbonate Solution

Dissolve 84 g $NaHCO_3$ in distilled water to a final volume of 1000 ml. Saturate the solution with CO_2 (by shaking in a stoppered bottle under a head space of CO_2) and autoclave in closed tubes or bottles with fixed stoppers (butyl rubber or Viton) under a head space of CO_2 (1/4 of total volume).

Vitamin Mixture	
Sodium phosphate (10 mM; pH 7.1)	100 ml
4-Aminobenzoic acid	4 mg
D(+)-Biotin	1 mg
Nicotinic acid	10 mg
D(+)-Pantothenic acid, calcium salt	5 mg
Pyridoxine dihydrochloride	15 mg

Thiamine Solution	
Sodium phosphate (10 mM; pH 3.4)	100 ml
Thiamine chloride dihydrochloride	10 mg

Vitamin B12 Solution	
Distilled water	100 ml
Cyanocobalamin	5 mg

Filter-sterilize (pore size, 0.2 μm) all the above vitamin solutions and store in the dark (preferentially in brown glass bottles) at 4°C.

Sodium Sulfide Solution

Dissolve 48 g $Na_2S \cdot 9H_2O$ in 100 ml (final volume) of distilled water. Use only colorless, clear crystals of sodium sulfide. Sodium sulfide is autooxidizable. In the case of large crystals, opaque or milky surface layers (oxidation products) may be removed by brief rinsing with distilled water on a plastic sieve. Dissolve the sodium sulfide by stirring under an N_2 atmosphere and autoclave the solution in closed tubes or bottles with fixed stoppers (butyl rubber or Viton) under a head space of N_2 (≥1/4 of total volume).

Sodium Ascorbate Solution

Distilled water	40 ml
Ascorbic acid	9 g
NaOH (1.0 M)	40 ml

Add the NaOH solution slowly while stirring and cooling in an ice water bath, preferentially in a device that allows gassing with N_2 to avoid access of air. Add further NaOH dropwise so as to achieve a final pH of 8–9. Dilute with distilled H_2O to a final volume of 100 ml. Filter-sterilize and store anaerobically under a head space of N_2 in the dark at 4°C.

Preparation of Media

Depending on the physiological type of microorganisms to be cultivated and the salinity of the original source, one of the following basal mineral media is first prepared. For many marine isolates, the full marine medium can be replaced by the saltwater medium that tends to form less inorganic precipitates. For microorganisms from brackish habitats, also other concentrations of NaCl, $MgCl_2$ and $CaCl_2$ can be tested and applied.

Basal Salt Media	A	B	C
NaCl	0.5 g	20.0 g	26.0 g
$MgCl_2 \cdot 6H_2O$	0.5 g	3.0 g	5.0 g
$CaCl_2 \cdot 2H_2O$	0.1 g	0.15 g	1.4 g
NH_4Cl	0.3 g	0.3 g	0.3 g
KH_2PO_4	0.2 g	0.2 g	0.1 g
KCl	0.5 g	0.5 g	0.5 g
For sulfate-reducing bacteria:			
Na_2SO_4	3.0 g	3.0 g	4.0 g
For nitrate-reducing bacteria:			
$NaNO_3$	1.0 g	1.0 g	1.0 g

"A" (freshwater medium) is for microorganisms from freshwater habitats. "B" (saltwater medium) can be used for marine microorganisms that do not require high magnesium and calcium ion concentrations; the advantage of the relatively low concentration of these ions is that the pH can be increased without significant formation of precipitates. "C" (full marine medium) is used for marine microorganisms with unknown salt demands or which require high magnesium and calcium ion concentrations (as in natural seawater); a certain disadvantage is the formation of significant precipitates with increasing pH. Omit Na_2SO_4 and $NaNO_3$ in case of methanogenic cultures or growth tests with electron acceptors other than sulfate or nitrate. Prepare media in special flasks with tubes for anoxic sterile gassing and a closable outlet that allows distribution of the complete medium to smaller cultivation tubes or bottles (Widdel and Bak, 1992). Dissolve the salts in distilled water up to a final volume of 1000 ml and autoclave. Cool solution under an N_2-CO_2 mixture to prevent redissolution of oxygen. Then, add the following sterile stock solutions (amounts per liter of medium).

Trace element mixture	1.0 ml
$NaHCO_3$ solution	30.0 ml
Vitamin mixture	1.0 ml
Thiamine solution	1.0 ml
Vitamin B12 solution	1.0 ml

Reductant for sulfate-reducing bacteria:

Na_2S solution 5.0 ml

Reductant for nitrate-reducing bacteria:

Sodium ascorbate solution 3.0 ml

Do not use the sodium ascorbate solution in enrichment cultures. Adjust the pH to 7 with sterile 1 M Na_2CO_3 or H_2SO_4 solution. Distribute the completed medium in culture tubes and bottles and store anoxically under a small head space of an N_2-CO_2 mixture. Add the hydrocarbon of interest individually to each tube or bottle. Procedures are described in the following section.

Cultivation with Hydrocarbons

GASEOUS HYDROCARBONS. The gas is released from steel bottles via gauges. Aseptic addition is guaranteed by passing the hydrocarbon gas through a sterile cotton or membrane filter. The gaseous hydrocarbons may be injected through stoppers to the culture head space by means of syringes with hypodermic needles. The syringes should be preflushed with the gas to remove oxygen. The added amount is obvious from the added volume (at 25°C, a volume of 24 ml of the pure gas at ambient pressure [101 kPa] is approx. 1 mmol). The application of high overpressure to gaseous hydrocarbons (with the exception of methane) is usually not necessary. In the case of methane, an increased pressure clearly stimulates anaerobic methane-oxidizing communities (Nauhaus et al., 2002). A safe device has been described that allows application of high pressure to methane in glass tubes (Nauhaus et al., 2002).

LIQUID HYDROCARBONS. These can be sterilized by filtration through solvent-resistant cellulose filters (pore size, 0.2 μm) or be autoclaved in tightly closed bottles with a head space (approx. 1/2 of bottle volume); in the case of volatile hydrocarbons, the weight should be controlled to reveal the tightness of the closure. For storage (as well as for autoclaving), screw caps with Teflon-coated sealing disks are useful (Fig. 9A, B). A special glass flask has been used for sterilization and aseptic, anoxic storage of crude oil without loss of volatile components (Rabus and Widdel, 1996; Fig. 9B).

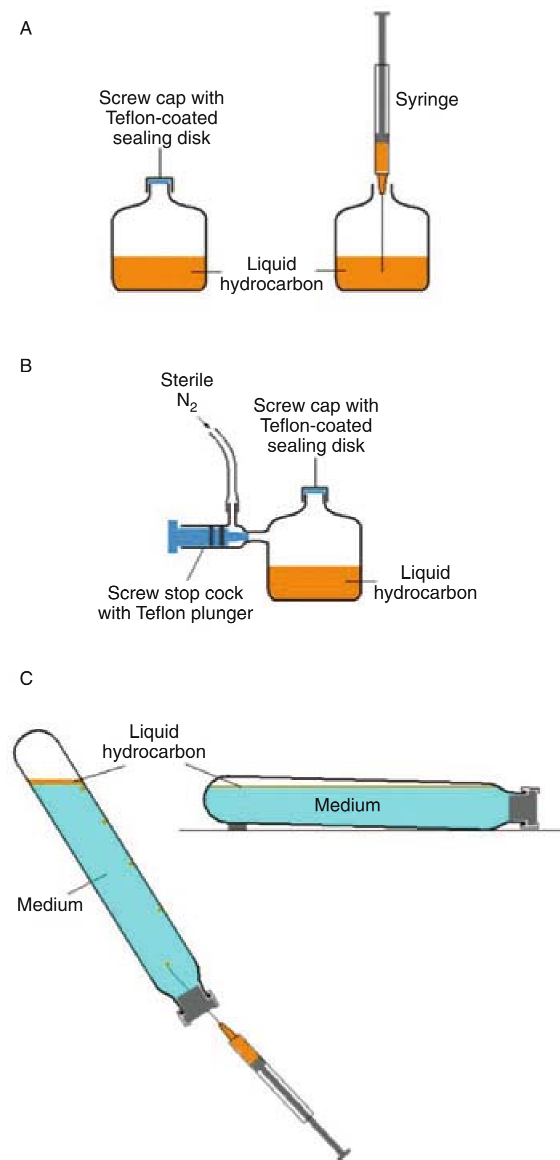

Fig. 9. Storage of (sterile) hydrocarbons and their addition to anoxic culture medium. (A) Use of a simple bottle. (B) Advanced method using a special bottle (with inner surfaces only of glass and Teflon) for anoxic autoclaving and storage. (C) Injection of hydrocarbon into culture tube while contact with the stopper is avoided, and incubation in near-horizontal position.

Hydrocarbons from stocks may be taken up with anoxic (N_2-gassed) syringes and added to the cultures, for instance by injection through the stoppers (Fig. 9A, C). The syringes should have plungers with plastic or Teflon sealing. Rubber-sealed plungers are affected by liquid hydrocarbons such that they stick to the syringe cylinder.

Cultivation with liquid hydrocarbons poses problems because of their poor solubility (viz., hydrocarbons usually float on the medium surface), their frequent toxicity, and their tendency to adsorb to stoppers or even to deteriorate stoppers gradually.

The low solubility problem can be minimized by providing a large contact area between the medium and the overlying hydrocarbon phase. For this purpose, tubes or bottles (preferentially flat bottles) are incubated horizontally (Fig. 9C). This enlarges the surface area and minimizes diffusion distances between the hydrocarbon phase and the bacteria in the medium.

The toxicity can in principle be minimized by adding extremely small amounts to keep the hydrocarbon concentration below saturation. However, such amounts are often below one milligram per liter and therefore yield only marginal cell densities. It is therefore much easier to provide such hydrocarbons from a dilute solution (often 1–15%, v/v) in an inert hydrophobic carrier. The overlying carrier phase then acts as a reservoir of the hydrocarbon substrate that is permanently provided at a nontoxic concentration. Mineral oil (pharmaceutical grade; not useful for cultures that degrade long-chain alkanes), 2,2,4,4,6,8,8-heptamethylnonane, or pristane have been applied as carriers.

Adsorption of hydrocarbons to stopper material can be minimized or prevented in several ways. Stocks of sterile hydrocarbons can be kept in bottles with screw caps with Teflon-coated sealing disks. For culture tubes and bottles, Teflon-coated stoppers may be used. Even if needles penetrate these stoppers, the areas exposed to the hydrocarbon remain relatively small and adsorption is much slower than at an unprotected stopper surface. In any case, stoppered culture tubes and bottles containing hydrocarbons should be kept in near-horizontal position so that the hydrocarbon phase is not in contact with the stopper. This is achieved by keeping the orifice always lower than the medium level (Fig. 9C). If the tube or bottle containing the hydrocarbon phase is initially in an upright position (which is usually the case), inversion to the horizontal position necessarily brings the hydrocarbon phase in contact with the stopper. Shaking the tube or bottle (causing a transient water-hydrocarbon emulsion) while it is being inverted can avoid adherence of large hydrocarbon droplets to the stopper. An elegant approach is to add the hydrocarbon to the horizontal bottle through the stopper by means of an anoxic syringe; this can be done in such way that the hydrocarbon ascends to the medium surface without coming into contact with the stopper (Fig. 9C).

CHAPTER 1.34

Physiology and Biochemistry of the Methane-Producing Archaea

REINER HEDDERICH AND WILLIAM B. WHITMAN

The methane-producing Archaea or methanoarchaea are distinguished by their ability to obtain all or most of their energy for growth from the process of methane biosynthesis or methanogenesis. To date, no methanogens have been identified that can grow without producing methane, and these Archaea are all obligate methane producers that are uniquely specialized for this lifestyle. Methanogenesis is an anaerobic respiration, but its complexity and commitment of resources far exceeds that found in other common respiratory processes. For instance, it requires the biosynthesis of six unusual coenzymes; a long, multistep pathway for methane; and a number of unique membrane-bound enzyme complexes for coupling to the proton motive force (see below).

Given the complexity of this process, it is not surprising that methanogens appear to be monophyletic. Hence, all modern methanoarchaea possess an ancient ancestor within the Euryarchaeota (Fig. 1). Although the branching order of the deep branches is not certain, several lineages of nonmethanogenic archaea appear within this clade, which argues for the antiquity of the methanogen group. Thus, the phylogeny suggests that the lineages represented by *Haloferax*, *Thermoplasma* and *Archaeoglobus* were derived from methanogenic ancestors. The sulfate-reducer *Archaeoglobus* also possesses many of the unusual coenzymes found in methanogens, providing further evidence of this hypothesis.

The methanoarchaea are also the only Archaea currently cultivated that are truly cosmopolitan, being found in a wide variety of the anaerobic environments on earth. Thus, in addition to many temperate habitats, methanogens are also common at extremes of temperature and salinity. As examples, psychrophilic and psychrotolerant species isolated from a meromictic lake in Antarctica grow well at 0–5°C (Franzmann et al., 1992; Franzmann et al., 1997), and hyperthermophilic species obtained from geothermal springs and submarine vents grow well up to 110°C (e.g., Jones et al., 1983; Kurr et al., 1991). While many methanogens grow well in fresh water, the extremely halophilic *Methanohalobium evestigatus* requires 4.3 M NaCl for optimal growth (Zhilina and Zavarin, 1987). The broad distribution of the methanogens is in contrast to the other cultivated archaea, which appear to be limited to extreme environments of high temperature, low pH, or high salinity. Presumably, archaea fair poorly in direct competition with temperate bacteria and eukaryotes and are limited to either extreme habitats or niches where they do not compete with bacteria or eukaryotes. This hypothesis implies that the currently uncultivated Crenarchaeota common in temperate soil and marine environments occupy a physiological niche unavailable to the Bacteria (for a review of these organisms, see Phylogenetic and Ecological Perspectives on Uncultured Crenarchaeota and Korarchaeota in Volume 3). It also poses an interesting physiological mystery as to why Bacteria might out-compete Archaea in many temperate environments.

Ecology of Methanogenesis

While the ecology of the methanoarchaea is discussed in detail in the chapters about specific groups, some generalities are appropriate here (for a more detailed review, see Zinder et al., 1993). The methanoarchaea flourish in anaerobic environments where sulfate, oxidized metals, and nitrate are absent. In these environments, the substrates for methanogenesis are readily available as the fermentation products of Bacteria and eukaryotes, and the methanoarchaea catalyze the terminal step in the anaerobic food chain where complex polymers are converted to methane and CO_2. In this food chain, polymers are first degraded by specialized microorganisms, like the cellulolytic Bacteria, to produce simple sugars (such as glucose), disaccharides (such as cellobiose), lactate, and volatile fatty acids (VFAs; such as acetate, propionate and butyrate) and alcohols (such as ethanol). These products are further metabolized by the intermetabolic group. These microorganisms convert simple sugars to VFAs and alcohols.

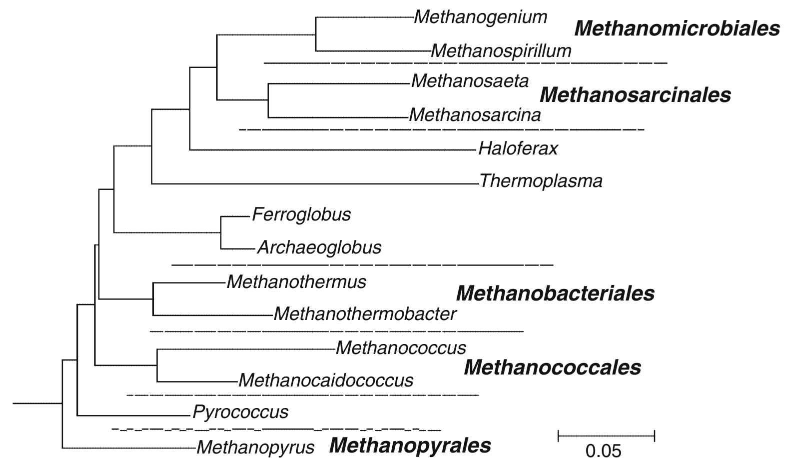

Fig. 1. Phylogeny of the methanoarchaea and related euryarchaeota. The gene tree of the 16S rRNA was calculated with the Fitch-Margoliash algorithm in PHYLIP and about 1260 bp of the small subunit rRNA sequences for representatives of each genus. The orders of methanogens are indicated on the right. The scale bar represents the Jukes-Cantor evolutionary distance.

They also convert VFAs and alcohols to acetate, H_2 and CO_2, which are major substrates for the methanoarchaea.

Molecular hydrogen (H_2) is a key intermediate in this process. Under standard conditions, when the H_2 partial pressure is 1 atmosphere, the fermentations of VFAs and alcohols to acetate and H_2 are thermodynamically unfavorable. Therefore, microorganisms that catalyze these reactions cannot grow, and toxic levels of the VFAs accumulate. However, if the methanoarchaea are present, H_2 is rapidly metabolized, and its partial pressure is maintained below 10^{-3}–10^{-4} atmospheres. Under these conditions, the fermentations of VFAs and alcohols are thermodynamically favorable, they are rapidly metabolized, and their concentrations are maintained below the toxic levels. This interaction between the H_2-producing intermetabolic organisms and the H_2-consuming methanogens is an example of interspecies hydrogen transfer (Syntrophism among Prokaryotes in this Volume). In many anaerobic environments, it is a key regulatory mechanism. Because the H_2-consuming methanogens play a critical role, they are said to "pull" the fermentation of complex organic polymers to methane and CO_2.

Interspecies hydrogen transfer is not limited to methanogenic food chains. In environments rich in sulfate, oxidized metals or nitrate, anaerobic Bacteria oxidize H_2, VFAs and alcohols. When sulfate is present, this activity is catalyzed by the sulfate-reducing bacteria. Because the oxidation of H_2 with sulfate as the electron acceptor is thermodynamically more favorable than when CO_2 is the electron acceptor (as in methanogenesis), the sulfate-reducing bacteria out-compete the methanogens for H_2. For similar reasons, the sulfate-reducing bacteria also out-compete the methanogens for other important substrates like acetate and formate. Therefore, methanogenesis is greatly limited in marine sediments that are rich in sulfate. The oxidation of H_2 with nitrate, Fe^{+3}, and Mn^{+4} as electron acceptors is also thermodynamically more favorable than methanogenesis. The denitrifying and iron- and magnesium-reducing bacteria also out-compete the methanogens when these electron acceptors are present. In conclusion, methanogenesis only dominates in habitats where CO_2 is the only abundant electron acceptor for anaerobic respiration.

Just as aerobic microorganisms rapidly deplete the O_2 in environments rich in organic matter to establish anaerobic conditions, sulfate-reducing bacteria, iron- and magnesium-reducing bacteria, and denitrifying bacteria frequently consume all the sulfate, Fe^{+3}, Mn^{+4} and nitrate in anaerobic environments and rapidly establish the conditions for methanogenesis. In these environments, CO_2 is seldom limiting because it is also a major fermentation product. Thus, methanogenesis is the dominant process in many anaerobic environments that contain large amounts of easily degradable organic matter. Especially important environments of this type include freshwater sediments found in lakes, ponds, marshes, and rice paddies.

Although methanoarchaea are most frequently found at the bottom of anaerobic food chains associated with the intermetabolic microorganisms, in some ecosystems they are the primary consumers of geochemically produced H_2 and CO_2. The submarine hydrothermal vents found on the ocean floor expel large volumes of very hot water containing H_2 and H_2S. As the water cools from several hundred degrees Celsius to the temperature of the ocean, zones suitable for the growth of thermophilic methanoarchaea are established. The methane produced escapes into the surrounding water where it is utilized by symbiotic methylotrophic bacteria living in marine invertebrates. In this ecosystem, the methanogens are at the top of the food chain.

Biogeochemistry of Methanogenesis

Methane is a major trace gas found in the earth's atmosphere, and most of the atmospheric methane is produced by the methanoarchaea (Conrad, 1996; Monson and Holland, 2001; Reeburgh, 2003). In the last several hundred years, the atmospheric concentration has more than doubled, to reach about 1.8 ppm in 1998. This increase in methane concentration is responsible for about 20% of the increased greenhouse effect observed for all radiatively important trace gases. Currently, methane emissions to the atmosphere are about 500–600 teragrams (Tg) of CH_4 year^{-1}. Once in the atmosphere, methane has a half-life of about 8.4 years, being removed primarily by reactions with hydroxyl radicals in the troposphere.

Major sources of atmospheric methane are shown in Table 1. The most important biogenic emissions are from habitats where gases formed anaerobically can exchange rapidly with the atmosphere, such as wetlands and rice paddies. Similarly, large amounts of methane are emitted from the rumen of livestock, which escapes directly to the atmosphere by eructation. However, large amounts of methane, probably about 700 Tg of CH_4 year^{-1}, are also consumed by aerobic and anaerobic methane-oxidizers without ever appearing in the atmosphere (Reeburgh et al., 1993; Valentine and Reeburgh, 2000; Reeburgh, 2003). Rice paddies are particularly active sites for methane oxidation, where oxygen is available in the root zone owing to transport through the plants. This allows for growth of the aerobic methane-oxidizing bacteria and consumption of 45–90% of the methane produced. Given that about 80% of the methane emitted to the atmosphere and nearly all of the methane oxidized prior to release to the atmosphere is microbially produced, an estimate of total microbial methane production is about 1100 Tg of CH_4 year^{-1}, which represents about 825 Tg of C year^{-1}. During the production of methane from carbohydrates, one mole of CO_2 is formed for every mole of CH_4. Thus, the total carbon processed in these systems is about 1650 Tg of C year^{-1}, or 1.65% of the C fixed by photosynthesis each year (Schlesinger, 1991). This estimate emphasizes the biogeochemical significance of this link in the carbon cycle.

Table 1. Sources of atmospheric methane.

Sources of methane	Methane evolved (Tg of CH_4/year)
Biogenic sources	
Natural wetlands	92
Rice paddies	88
Livestock	81
Manure decomposition	14
Termites	25–150
Landfills	15–81
Oceans	38–308
Tundra	42
Subtotal	395–856
Other sources

Systematics of the Methanoarchaea

Phylogenetic analyses of the rRNA and other genes indicate that the methanoarchaea are an ancient monophyletic lineage within the Euryarchaeota (Fig. 1). Although the branching orders of the deep groups of the Euryarchaeota are not known for certain, a number of nonmethanogenic organisms, such as the halobacteria and the sulfate-reducing *Archaeoglobus*, appear to have arisen within the methanogenic lineage. To produce descendants with very different phenotypic properties, the methanogenic lineage must be very ancient.

The current taxonomy for methanogens follows the general schema of Boone et al. (1993) and Whitman et al. (2001), which tried to form taxa of similar phylogenetic depth among groups of fairly unrelated organisms. This work attempted to deal with three major problems. First, because of their chemolithotrophic energy metabolism, it is often difficult to distinguish taxa on the basis of phenotype. Second, in spite of the phenotypic similarity, the methanogens are genetically, extremely diverse. The high genetic diversity suggests that, even though many of these organisms appear to do the same thing, the way they do these things are very different. Detailed studies of the physiology have tended to support this view, and large differences in cellular structure, metabolic pathways, and regulation have been observed. And third, on the basis of ribosomal RNA gene libraries of environmental DNA, many more taxa await to be isolated and characterized (see below). The cultured methanogens represent a very sparse sampling of the likely diversity in nature, and our knowledge

of this group is necessarily incomplete. Thus, the current taxonomy is best considered a work in progress with plenty of opportunities for improvement.

The methanoarchaea are a diverse group of organisms, containing five well-established orders and 31 genera (Table 2). For species, less than 70% DNA hybridization of the genomic DNAs is considered definitive evidence for novel species (Wayne et al., 1987). In the absence of DNA hybridization data, ribosomal RNA sequence similarity of less than 98% is considered equivalent evidence for novel species, even though this value is probably very conservative (Stackebrandt and Goebels, 1994; Keswani and Whitman, 2001). Less than 93–95% ribosomal RNA sequence similarity is evidence of novel genera, and less than 88–93% ribosomal RNA sequence similarity is evidence of novel families. The rank of order is then used to recognize deeper phylogenetic differences. In general, this taxonomy is supported by the chemotaxonomy of cellular lipids and distribution of other biological properties. Subsequently, three classes were also proposed: Methanobacteria (to include the Methanobacteriales), the Methanococci (to include the Methanococcales, Methanomicrobiales and Methanosarcinales), and the Methanopyri (to include the Methanopyrales; Boone, 2001). These classes were inferred from the deep phylogenetic relationships in the ribosomal RNA gene tree, which are imperfectly understood, and their biological significance remains to be further elucidated.

A summary of the major genera of methanoarchaea is given in Table 2. In prokaryotic nomenclature, the names of genera of methanoarchaea contain the prefix "methano-." This prefix distinguishes them from an unrelated group of aerobic Bacteria, the methylotrophic Bacteria, which consume methane and whose names contain the prefix "methylo-." More complete descriptions of the nutrition, growth properties, morphology, ecology and other general properties of these taxa are reviewed in other chapters of this volume (The Order Methanomicrobiales, The Order Methanobacteriales, and The Order Methanosarcinales in Volume 3) as well as *Bergey's Manual of Systematic Bacteriology* (Whitman et al., 2001). The descriptions of *Methanomethylovorans* and *Methanomicrococcus* and can be found in Lomans et al. (1999) and Sprenger et al. (2000).

Recent studies of the genus *Methanobrevibacter* serve to illustrate the incomplete nature of the current systematics of methanogens (Miller, 2001; The Order Methanobacteriales in Volume 3). This taxon is abundant in the gastrointestinal tracts of mammals, birds and termites as well as other habitats. It is particularly interesting because it illustrates the diversity of these organisms and some of the potential complexities of their lifestyle. In humans, methane is formed by the methanoarchaea in the anaerobic microflora of the large bowel. About one-third of healthy adults excrete methane gas. Some methane is also absorbed in the blood and excreted from the lungs. The most numerous methanogen in humans is *Methanobrevibacter smithii*. In people who excrete methane, it is found in numbers of 10^7–10^{10} cells per gram dry weight of feces, or between 0.001 and 12% of the total number of viable anaerobic prokaryotes (Miller and Wolin, 1982). Why the numbers of *M. smithii* fluctuates so greatly in apparently healthy individuals remains a mystery. Other species of *Methanobrevibacter* are encountered in the feces of other animals. *Methanobrevibacter gottschalkii* was isolated from horse and pig feces, *Methanobrevibacter thaueri* was isolated from cattle feces, *Methanobrevibacter wolinii* was isolated from sheep feces, and *Methanobrevibacter woesei* was isolated from goose feces (Miller and Lin, 2002). These characterized organisms apparently only represent a small fraction of the diversity present in nature.

The rumen is another major habitat for methanogens, and about 10–20% of the total methane emitted to the earth's atmosphere originates in the rumen of cows, sheep and other mammals. In this habitat, complex polymers from grass and other forages are degraded to acetate, volatile fatty acids, H_2 and CO_2 by the cellulolytic and intermetabolic groups of bacteria, fungi and protozoans (Miller, 1992). The acetate and VFAs are absorbed by the animal and are major energy sources. Thus, little methane is produced from acetate. The H_2 is used to reduce CO_2 to methane, which is emitted. Methanogenesis represents a significant energy loss to the animal, and up to 10% of the caloric content of the feed may be lost as methane. *Methanobrevibacter* species are also common in the rumen. For the bovine rumen, *M. ruminantium* is the predominant methanogen isolated. However, in a survey of rRNA genes in the rumen of sheep fed different diets, 62 phylotypes of *Methanobrevibacter* were recognized, many of which were not closely related to described species and were likely to represent members of at least four novel species (Wright et al., 2004). These results demonstrate the incomplete characterization of the methanoarchaea, even from a fairly well studied environment, and the substantial intraspecies diversity within these organisms. Similarly, an extensive analysis of 120 *Methanobrevibacter* sequences from cultures and clone libraries suggested the presence of at least ten deep lineages, many of which contained more than one described species (Dighe et al., 2004). Thus, this

Table 2. Taxonomy of the methane-producing Archaea.[a]

Order, family and genus	Morphology	Major energy substrates[b]	Temperature optimum (°C)	Cell wall[c]
Order Methanobacteriales				
Family Methanobacteriaceae				
Genus *Methanobacterium*	Rod	H_2, (formate, alcohols)	37–45	Pseudomurein
Methanothermobacter	Rod	H_2, (formate)	55–65	Pseudomurein
Methanobrevibacter	Short rod	H_2, (formate)	37–40	Pseudomurein
Methanosphaer[a]	Coccus	H_2 + methanol	37	Pseudomurein

Methanohalophilus	Irregular coccus	Methanol, $MeNH_2$	35–40	Protein
Methanohalobium	Flat polygons	Methanol, $MeNH_2$	40–55	ND
Methanolobus	Irregular coccus	Methanol, $MeNH_2$ (DMS)	37	Glycoprotein
Methanomethylovorans	coccus, packets	Methanol, $MeNH_2$ DMS, MT	34–37	ND
Methanomicrococcus	Flat polygons	H_2 + Methanol, H_2 + $MeNH_2$	39	ND
Methanosalsum	Irregular coccus	Methanol, MeH_2, DMS	35–45	ND
Family Methanosaetaceae				
Genus *Methanosaeta (Methanothrix)*	Rod	Ac	35–60	Protein + sheath
Order Methanopyrales				
Family Methanopyraceae				
Genus *Methanopyrus*	Rod	H_2	98	Pseudormurein

Abbreviations: $MeNH_2$, methylamines (monomethylamine, dimethylamine, and trimethylamine); DMS, dimethylsulfide; MT, methanethiol; Ac is acetate; HPS, heteropolysaccharide; and ND, not determined.
[a]All of the methanoarchaea are members of the phylum Euryarchaeota.
[b]Major energy substrates for methane synthesis. Alcohols are some or all of ethanol, isopropanol, isobutanol and cyclopentanol. Parentheses means utilized by some but not all species or strains.
[c]Cell wall components.
[d]Placement in higher taxon is tentative.

genus appears to be very deep, with a large amount of interspecies variation as well. Recognizing that only a small fraction of the organisms in even a single genus are in culture leads to the conclusion that the full extent of the diversity of these organisms is largely unknown.

Pathways of Methanogenesis—An Overview

Methanoarchaea derive their metabolic energy from the conversion of a restricted number of substrates to methane (Table 3; Fig. 2). Most

Table 3. Free energies for typical methanogenic reactions.

Reaction	)G^E (kJ/mol of CH_4)
Type 1	
$CO_2 + 4\ H_2 \rightarrow CH_4 + 2\ H_2O$	–130
$4\ HCOOH \rightarrow CH_4 + 3\ CO_2 + 2\ H_2O$	–120
CO_2 + 4 (isopropanol) → CH_4 + 4 (acetone) + 2 H_2O	–37
Type 2	
$CH_3OH + H_2 \rightarrow CH_4 + H_2O$	–113
$4\ CH_3OH \rightarrow 3CH_4 + CO_2 + 2\ H_2O$	–103
$4\ CH_3NH_3Cl + 2\ H_2O \rightarrow 3\ CH_4 + CO_2 + 4\ NH_4Cl$	–74
$2\ (CH_3)_2S + 2\ H_2O \rightarrow 3\ CH_4 + CO_2 + 2\ H_2S$	–49
Type 3	
$CH_3COOH \rightarrow CH_4 + CO_2$	–33

methanoarchaea can reduce CO_2 to CH_4. The major electron donors for this reduction are H_2 and formate. In addition, some methanoarchaea can use alcohols like 2-propanol, 2-butanol, cyclopentanol and ethanol as electron donors. For the secondary alcohols, a two-electron oxidation to the ketone is performed. For instance, 2-propanol is oxidized to acetone. Ethanol is somewhat different in that a four-electron oxidation to acetate is performed. Because eight electrons are required to reduce CO_2 to methane, four molecules of H_2, formate, or 2-propanol are consumed. Even though formate is a reduced C_1 compound, it is oxidized to CO_2 before reductionto methane. The reduction of CO_2 to CH_4 proceeds via carrier-bound one-carbon intermediates. Methanofuran (MFR), tetrahydromethanopterin (H_4MPT) or its derivatives, and 2-mercaptoethanesulfonate (coenzyme M, CoM-SH) are the three carriers involved (DiMarco et al., 1990; Gorris and van der Drift, 1994). These coenzymes were until recently thought to be unique for methanoarchaea but have now also been detected in nonmethanogenic bacteria and archaea (see below). The reaction sequence starts with a two-electron reduction of CO_2 and MFR to formyl-MFR where the formyl-group is bound to the amino-group of the coenzyme. The formyl-group is then transferred to the N5 of H_4MPT, the formyl-H_4MPT thus generated cyclizes to the methenyl-H_4MPT, which is reduced in two steps to the methyl-H_4MPT.

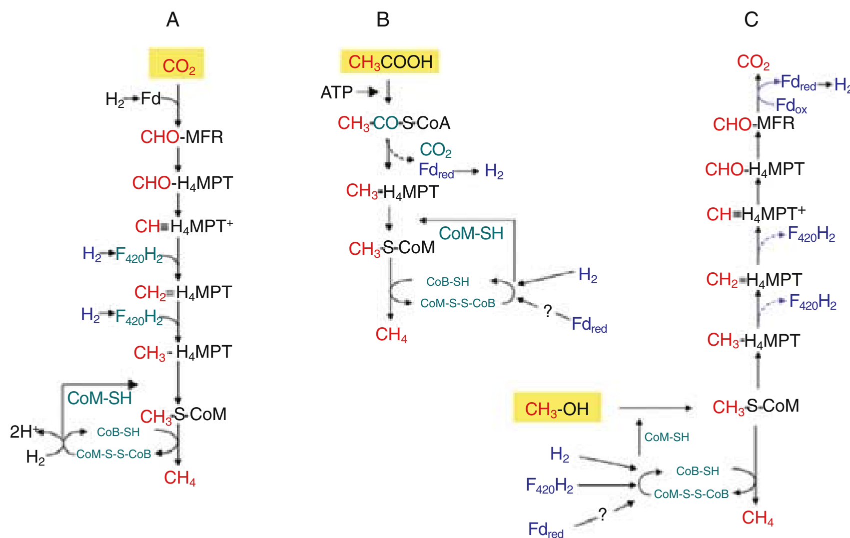

Fig. 2. Scheme of methanogenesis from H_2/CO_2 (A), acetate(B) and methanol (C). Methyl-coenzyme M (CH_3-S-CoM) is a central intermediate in all three pathways. It is converted to methane and the heterodisulfide of coenzyme M and coenzyme B (CoM-S-S-CoB). CoM-S-S-CoB thus generated functions as the terminal electron acceptor of different respiratory chains. H_2 and reduced coenzyme F_{420} ($F_{420}H_2$) have been identified as electron donors for the reduction of CoM-S-S-CoB. The unknown mechanism of electron transfer from the reduced ferredoxin ($Fd_{(red)}^-$) to CoM-S-S-CoB in acetate- and methanol metabolism is symbolized by a question mark. The role of H_2 as an intermediate of this reaction is discussed below (see Fig. 14). Abbreviations: CHO-FMR, *N*-formylmethanofuran; CHO-H_4MPT, N^5-formyltetrahydromethanopterin; CH=H_4MPT^+, N^5,N^{10}-methenyl-tetrahydromethanopterin; CH_2=H_4MPT, N^5,N^{10}-methylene-tetrahydromethanopterin; and CH_3-H_4MPT, N^5-methyl-tetrahydromethanopterin. For structures of the coenzymes, see Figs. 3, 7 and 9. For simplicity, only tetrahydromethanopterin (H_4MPT) is shown. For other methanopterin derivatives, see Fig. 9.

Finally, the methyl-group is transferred to the thiol group of coenzyme M. The methyl-thioether formed is reduced to CH_4 in the final step of the pathway.

The second type of substrate for methanogenesis includes C_1 compounds containing a methyl-group carbon bonded to O, N or S. Compounds of this type include methanol, monomethylamine, dimethylamine, trimethylamine, tetramethylammonium, dimethylsulfide and methane thiol. The methyl-group enters the C_1-pathway at the level of coenzyme M and is reduced to methane. The electrons for this reduction are obtained from the oxidation of an additional methyl group to CO_2 using the reverse of the steps of the reductive C_1-pathway. Because six electrons can be obtained from this oxidation and only two are required to reduce a methyl group to methane, the stoichiometry of this reaction is three molecules of methane formed for every molecule of CO_2 formed. In the presence of both a methyl-group donor and H_2, the methyl oxidation is inhibited and the methyl-groups are completely reduced to CH_4. An exception to this behavior is found in *Methanosphaera* and *Methanomicrococcus*, which lack the ability to oxidize methyl groups. These organisms only grow on methyl compounds when H_2 is also present. They are highly specialized for this activity and are unable to reduce CO_2 with H_2 or other electron donors.

The third type of substrate is acetate. In this reaction, the methyl (C-2) carbon of acetate is reduced to methane using electrons obtained from the oxidation of the carboxyl (C-1) carbon of acetate. This reaction is called the "aceticlastic reaction" because it results in the splitting of acetate into methane and CO_2. In this metabolism, the methyl group enters the C_1-pathway at the level of methyl-H_4MPT.

Key reactions of the different methanogenic pathways will be described below. For a detailed description of methanogenesis, the reader is referred to reviews (Thauer, 1998; Deppenmeier et al., 1999; Ferry, 1999; Deppenmeier, 2002a). For a historical overview on methanogenesis, see Wolfe (1991) and The Archaea: A Personal Overview of the Formative Years in Volume 3).

Key Reactions in Biological Methane Formation

The Final Step of Methanogenesis

Although every pathway starts out differently, they all end with the same step, the reaction of methyl-coenzyme M (CH_3-S-CoM) with a second thiol coenzyme, called "coenzyme B" (CoB-SH), to form methane and the mixed disulfide (also called "heterodisulfide," CoM-S-S-CoB) of coenzyme M and coenzyme B (Fig. 3). This reaction is catalyzed by methyl-coenzyme M reductase (Mcr), making Mcrthe key enzyme in methanogenesis (Thauer, 1998). In its active site, this enzyme contains a unique prosthetic group, which is a nickel (Ni) porphinoid called "coenzyme F_{430}" (Fig. 3). For the enzyme to be active, Ni has to be strongly reducing and in the Ni(I) state. From the crystal structure of various forms of the inactive Ni(II) state with the bound coenzymes, it is known that the enzyme has an active site channel which extends from the protein surface deeply into the interior of the protein complex (Ermler et al., 1997). Coenzyme F_{430} forms the bottom of this channel. Methyl-coenzyme M has to enter this channel before the channel is blocked by coenzyme B. Upon binding, coenzyme B fills the narrowest segment of the channel, with its thiol group facing coenzyme F_{430} (Fig. 4). The Mcr crystal structure reveals five modified amino acids near the active site. The side chains of specific histidine, arginine, glutamine and cysteine residues are methylated, and the carbonyl oxygen of a glycine residue is substituted by sulfur. Their high degree of con-

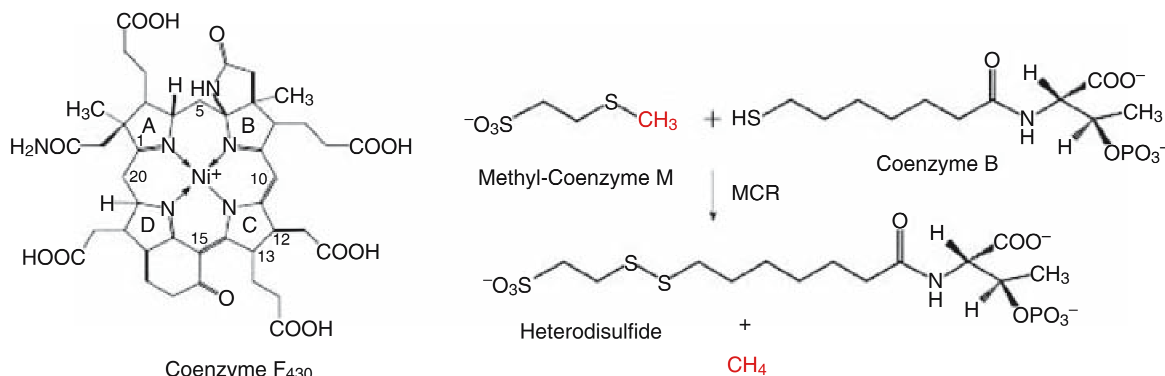

Fig. 3. Structure of coenzyme F_{430} and the reaction catalyzed by methyl-coenzyme M reductase.

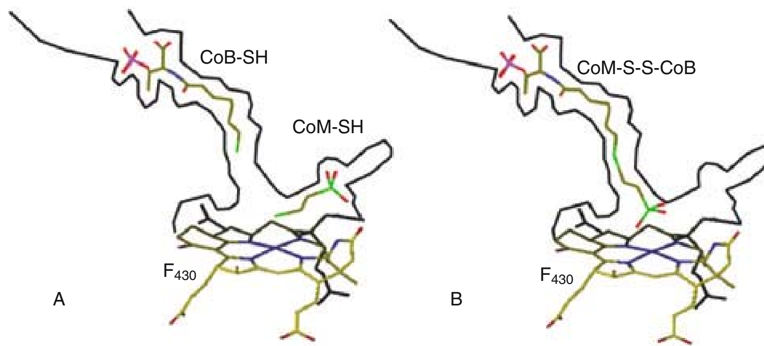

Fig. 4. Active-site of methyl-coenzyme M reductase with bound coenzymes. (A) Coenzyme B and coenzyme M are bound in the substrate channel. Note that coenzyme M is neither a substrate nor a product. In this structure, coenzyme M probably mimics the binding position of methyl-coenzyme M with respect to the binding of the sulfonate moiety but not with respect to the binding mode of the thiol group. A Ni-S-CoM species is not considered to be an intermediate in the catalytic cycle. (B) Heterodisulfide (CoM-S-S-CoB) product is bound in the active-site channel. The regions indicated with solid lines are the substrate channels near the active site.

servation and their location near the active site suggest an important function of these residues for the formation of the active site and catalysis. The reaction catalyzed by Mcr is rather unusual. Although the actual mechanism is still elusive, all of the proposed catalytic mechanisms involve radical chemistry (Goenrich et al., 2004). The closed hydrophobic environment of the substrate-binding pocket may be optimal for a mechanism employing unstable free radicals.

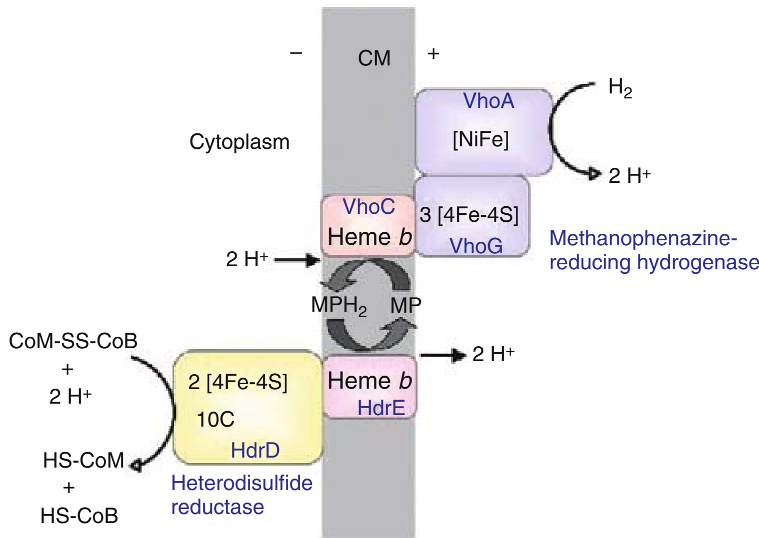
Energy Conservation via Disulfide Respiration

While the methane formed in the Mcr reaction can be regarded as a waste product, the heterodisulfide product is of central importance for the cell (Hedderich et al., 1998). Reduction of this disulfide is coupled with energy conservation (Deppenmeier et al., 1999; Deppenmeier, 2004). Hence, CoM-S-S-CoB can be regarded as the terminal electron acceptor of a respiratory chain in methanoarchaea. The electron donor can be either H_2 or coenzyme $F_{420}H_2$, depending on the growth substrate.

Evidence that heterodisulfide reduction is coupled to energy conservation comes from studies with *Methanosarcina* species. In Methanosarcina, all components of the respiratory chain are tightly membrane-bound, including a membrane-bound hydrogenase or $F_{420}H_2$ dehydrogenase, the lipophilic electron carrier methanophenazine, and a membrane-bound disulfide reductase (called "heterodisulfide reductase," Hdr). The latter enzyme functions as a terminal reductase and reduces CoM-S-S-CoB (Fig. 5). Methanophenazine is another novel coenzyme recently discovered in methanogens (Abken et al., 1998). Unlike the other methanogenic coenzymes, methanophenazine seems to be restricted to methanoarchaea belonging to the order Methanosarcinales. The function of this coenzyme is comparable with that of quinones in other respiratory chains.

Methanophenazine is reduced by one of the dehydrogenases, a membrane-bound [NiFe] hydrogenase or $F_{420}H_2$ dehydrogenase. For the [NiFe] hydrogenase, two isoenzymes are known. They are both anchored in the membrane via a β-type cytochrome (Deppenmeier et al., 1995b; Deppenmeier et al., 1999). The catalytic site is most probably facing the extracytoplasmic space, thus releasing two H^+ to the outside of the cell after H_2 oxidation. This enzyme, which in the past has been called "methylviologen-reducing hydrogenase" or "F_{420}-non-reducing hydrogenase," has now been designated "methanophenazine-reducing hydrogenase" (The H2-Metabolizing Prokaryotes in this Volume).

The $F_{420}H_2$ dehydrogenase (Fpo) is a multisubunit enzyme composed of six hydrophilic and seven integral membrane proteins (Bäumer et al., 2000; Fig. 6). The hydrophilic subunits are facing the cytoplasm. Eleven out of thirteen subunits of the enzyme reveal high sequence similarity to subunits of the energy-conserving reduced nicotinamide adenine dinucleotide (NADH):quinone oxidoreductase family (complex I), in particular to the bacterial enzyme which is formed by 14 subunits. Both enzymes differ with respect to the electron input module. In complex I, the electron input module (also called "NADH-dehydrogenase fragment") is formed by three subunits, which oxidize NADH and transfer the electrons to a central module. In Fpo, the NADH-dehydrogenase fragment is replaced by a single subunit, which oxidizes $F_{420}H_2$ (Brüggemann et al., 2000).



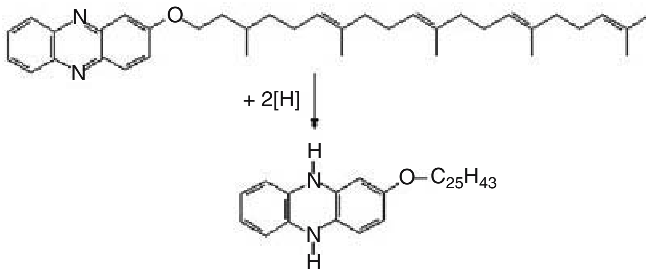


Fig. 5. Schematic representation of the respiratory chain catalyzing the reduction of CoM-S-S-CoB by H_2 in *Methanosarcina* species and structure of methanophenazine. Abbreviations: CM, cytoplasmic membrane; [NiFe], active site of the hydrogenases; [4Fe-4S], [4Fe-4S] clusters; heme b, subunits VhoC and HdrE each containing two heme β binding sites; 10C, ten highly conserved cysteinyl residues proposed to form one or two iron-sulfur clusters in the active site of Hdr; MP, oxidized methanophenazine; and MPH_2, reduced methanophenazine.

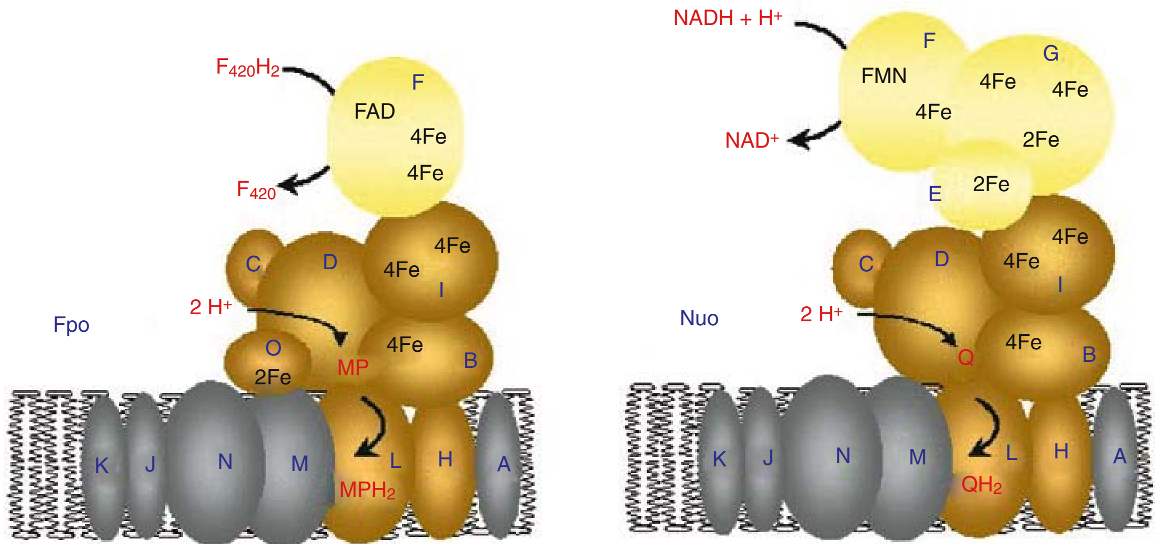

Fig. 6. Comparison of the structures of $F_{420}H_2$ dehydrogenase (Fpo) from *Methanosarcina mazei* and NADH:quinone oxidoreductase (Nuo) from *Escherichia coli*. Capital letters indicate subunits of the enzymes. Abbreviations: 4Fe: [4Fe-4S] cluster; 2Fe: [2Fe-2S] cluster; FMN: flavin mononucleotide; FAD, flavin dinucleotide; Q: ubiquinone or menaquinone; MP, oxidized methanophenazine; and MPH_2, reduced methanophenazine.FpoO has no counterpart in complex I, and its function is not known.

Reduced methanophenazine generated in the hydrogenase or $F_{420}H_2$ dehydrogenase reaction donates electrons to heterodisulfide reductase (Hdr), which catalyzes the reduction of CoM-S-S-CoB (Hedderich et al., 1998). In *Methanosarcina* species, this enzyme is formed by two subunits, a membrane-anchoring β-type cytochrome and a hydrophilic catalytic subunit, which is facing the cytoplasm. Unlike most other disulfide reductases, Hdr contains an iron-sulfur cluster in its active site which mediates the reductive cleavage of the disulfide substrate in two one-electron steps (Madadi-Kahkesh et al., 2001; Duin et al., 2003).

Using inverted membrane vesicles of *Ms. mazei*, both the H_2:CoM-S-S-CoB oxidoreductase and the $F_{420}H_2$:CoM-S-S-CoB oxidoreductase reactions were found to be coupled with the transfer of $4H^+/2e^-$ across the cytoplasmic membrane. More recent studies revealed that each partial reaction, the reduction of methanophenazine by H_2 or $F_{420}H_2$, and the reduction of CoM-S-S-CoB by reduced methanophenazine is coupled to the translocation of $2H^+/2e^-$ (Ide et al., 1999; Bäumer et al., 2000). As shown in Fig. 5, H^+-translocation in both the hydrogenase- and the heterodisulfide reductase reactions could function via a redox-loop mechanism. This mechanism cannot apply for the $F_{420}H_2$ dehydrogenase. Like complex I, this enzyme is thought to function as a proton pump (Bäumer et al., 2000).

In the hydrogenotrophic methanoarchaea belonging to the four other orders of methanoarchaea, the respiratory chain catalyzing the reduction of CoM-S-S-CoB differs significantly from that described above for *Methanosarcina*. These organisms do not contain heme. Thus β-type cytochromes can be excluded as membrane anchors and electron carriers of membrane bound dehydrogenases and reductases. Furthermore, methanophenazine has not been detected in these organisms (U. Deppenmeier, personal communication). As deduced from genome sequences, the membrane-bound $F_{420}H_2$-dehydrogenase (Fpo) is also lacking from these organisms.

Reduction of CoM-S-S-CoB in a non-*Methanosarcina* species has mainly been studied in *Methanothermobacter marburgensis*, which belongs to the order Methanobacteriales. In this organism heterodisulfide reductase, which is composed of three hydrophilic subunits, forms a tight and catalytically active complex with a [NiFe] hydrogenase (Setzke et al., 1994; Hedderich et al., 1998). This complex was designated as "H_2:heterodisulfide oxidoreductase complex." Hdr from this organism shares the catalytic subunit with the enzyme from *Methanosarcina* but is lacking a membrane anchor (Hedderich et al., 1998). The hydrogenase present in this complex is also lacking a membrane subunit and therefore is clearly different from the methanophenazine-reducing hydrogenase present in *Methanosarcina* species. Hence, the six subunits of the H_2:heterodisulfide oxidoreductase complex are all hydrophilic. The three transcriptional units encoding the different subunits of the complex do not contain additional open reading frames (ORFs) encoding potential integral membrane proteins, which might have been separated from the hydrophilic part during the purification. Hence, there is at present no conclusive answerhow this apparently cytoplasmic protein complex can couple the reduction of CoM-S-S-CoB by H_2 with the generation of a proton motive force.

Reductive Activation of CO_2 to Formylmethanofuran

The reduction of CO_2 to formylmethanofuran (CHO-MFR) is the first step of the methanogenic pathway from H_2/CO_2 (Fig. 7). This reaction is highly endergonic with H_2 as electron donor ($\Delta G^{\circ\prime}$ = +16 kJ·mol^{-1}). It becomes even more endergonic ($\Delta G'$ = +45 kJ·mol^{-1}) under the low hydrogen partial pressures prevailing in the natural habitats of methanoarchaea. In cell suspension experiments it was shown that this reduction is driven by reversed electron transport and requires an electrochemical ion gradient (Kaesler and Schönheit, 1989; Deppenmeier et al., 1996). A key enzyme involved in the catalysis of the reaction (Fig. 7) is formylmethanofuran dehydrogenase (Fmd; for a review, see Vorholt and Thauer, 2002). The enzyme catalyzes the reversible dehydrogenation of formylmethanofuran to CO_2 and methanofuran. In vitro this enzyme can be assayed with viologen dyes as artificial electron donors or acceptors. Fmd purified from *Methanosarcina barkeri* is a

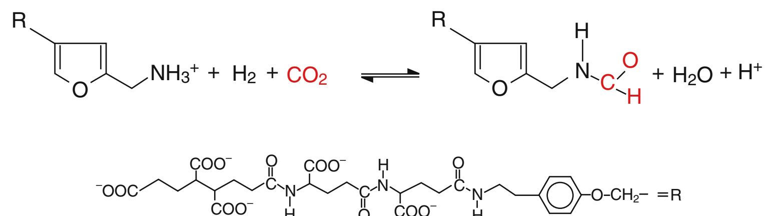

Fig. 7. Reaction catalyzed by formylmethanofuran dehydrogenase.

membrane-associated molybdenum iron-sulfur protein composed of six subunits. Other organisms, such as *Methanothermobacter* species, contain two Fmds, one enzyme containing molybdenum and the second enzyme containing tungsten bound to the molybdopterin cofactor.

The electron donor to Fmd and the hydrogenase participating in this reaction were unknown until recently. Upon identification of a novel membrane-bound [NiFe] hydrogenase in *Methanosarcina barkeri*, called the "*e*nergy-*c*onverting *h*ydrogenase" or Ech, it was suggested that this enzyme could play an essential role in driving this endergonic redox-reaction (Künkel et al., 1998; Meuer et al., 1999). Ech is a multisubunit membrane-bound [NiFe] hydrogenase. The six subunits of the enzyme exhibit high sequence similarity to subunits of the energy-conserving NADH:quinone oxidoreductase (complex I) of mitochondria and bacteria (Hedderich, 2004). In vitro, Ech catalyzes the reversible reduction of a special ferredoxin containing two [4Fe-4S] clusters by H_2 (Meuer et al., 1999). The oxidation of formylmethanofuran to CO_2 by the *M. barkeri* membrane fraction is also ferredoxin-dependent, and ferredoxin was therefore proposed to function as an electron carrier between Ech and Fmd in vivo. Support for this hypothesis came from the physiological characterization of a Δ*ech* mutant. This mutant was unable to make Ech and unable to form formylmethanofuran and reduce CO_2 to methane (Meuer et al., 2002). In addition, the Δ*ech* mutant was unable to biosynthesize acetyl-CoA and pyruvate via the acetyl-CoA synthase and pyruvate oxidoreductase reactions, respectively, using H_2 as the electron donor. Like the reaction catalyzed by Fmd, these reactions requirea strong reductant.

These data support the model depicted in Fig. 8. According to this scheme, Ech catalyzes the reduction of a low potential ferredoxin by H_2. Reduced ferredoxin can then function as the electron donor of Fmd but also of other oxidoreductases which require a low-potential electron donor. Since Ech is tightly membrane-bound via two integral membrane subunits and resembles the central part of complex I, it was suggested that ferredoxin reduction is driven by reversed electron transport. In contrast, the ferredoxin-dependent reduction of CO_2 to formylmethanofuran is not directly linked to an electrochemical ion gradient. This conclusion is supported by further experiments with the Δ*ech* mutant. In this mutant, CH_4 formation from H_2/CO_2 can be restored by CO or pyruvate, two strong electron donors which can couple to Fmd (Stojanowic and Hedderich, 2004). Moreover, when H_2 was replaced by CO as electron donor for the first step of methanogenesis, CH_4 formation was no longer dependent on an energized

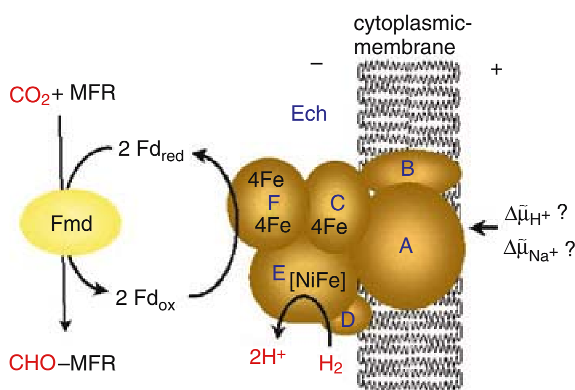

Fig. 8. Proposed function of Ech hydrogenase in the first step of methanogenesis from H_2/CO_2 in *Methanosarcina barkeri*. Whether Ech hydrogenase uses a H^+- or Na^+-motive force to drive the reduction of the ferredoxin by H_2 remains to be demonstrated. Abbreviations: Fmd, formylmethanofuran dehydrogenase; Fd, 2[4Fe-4S] ferredoxin; MFR, methanofuran; and CHO-MFR, formylmethanofuran.

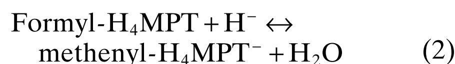
membrane. Thus, reduction of the electron carrier by H_2, which is catalyzed by Ech, and not the Fmd reaction per se, is dependent on an energized membrane.

Tetrahydromethanopterin Replaces Tetrahydrofolate in the C_1-Pathway of Methanoarchaea

Tetrahydromethanopterin (H_4MPT) carries the one-carbon unit at the oxidation level of formate, formaldehyde and methanol. In Methanococcales, Methanosarcinales and Methanomicrobiales, derivatives of H_4MPT such as tetrahydrosarcinapterin (H_4SPT) are used instead of H_4MPT (DiMarco et al., 1990; Gorris and van der Drift, 1994). H_4MPT is an analogue of tetrahydrofolate (H_4F), which is the C_1 carrier used by most other organisms (Fig. 9). The most important structural differences between the coenzymes are that H_4F has an electron-withdrawing carbonyl-group conjugated to the N10 via the aromatic ring, and H_4MPT has methyl groups at the ring carbons C7 and C11 (Maden, 2000). The entry into the H_4MPT-dependent reaction cascade is catalyzed by formyl-MFR:H_4MPT formyltransferase (Ftr), forming N^5-formyl-H_4MPT (reaction 1; Shima et al., 2002).

$$\text{Formyl-MFR} + H_4MPT \leftrightarrow \text{MFR} + \text{formyl-}H_4MPT \quad (1)$$

This is different from folate biochemistry where only N^{10}-formyl-H_4F is known. A cyclohydrolase then converts N^5-formyl-H_4MPT to N^5,N^{10}-methenyl-H_4MPT (reaction 2; Shima et al., 2002).



$$\text{Formyl-}H_4MPT + H^- \leftrightarrow \text{methenyl-}H_4MPT^- + H_2O \quad (2)$$

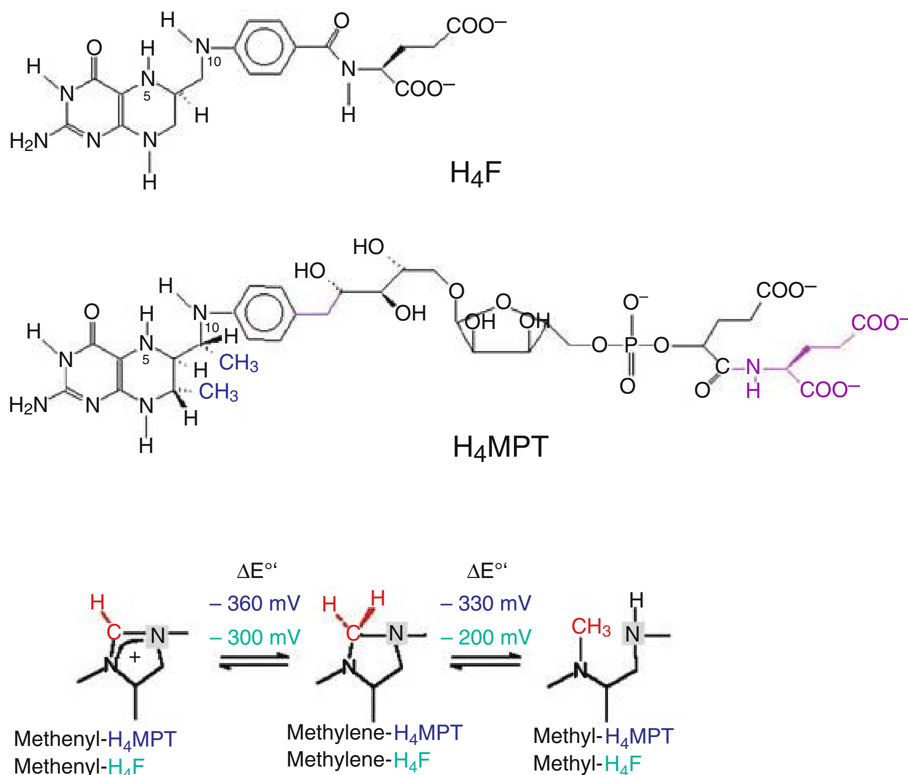


Fig. 9. Structure of tetrahydromethanopterin (H_4MPT), tetrahydrofolate (H_4F) and their C_1-derivatives. *Methanosarcina* species contain a H_4MPT analog called "tetrahydrosarcinapterin" (H_4SPT) in which the α carboxyl-group of the side chain is linked to a glutamate residue (highlighted in magenta).

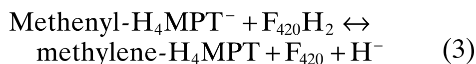
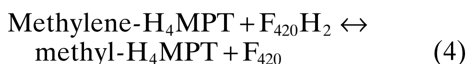
The following reduction to methylene-H_4MPT is catalyzed by N^5,N^{10}-methylene-H_4MPT-dehydrogenase using reduced coenzyme F_{420} ($F_{420}H_2$) as electron donor (reaction 3; Hagemeier et al., 2003).



$$\text{Methenyl-}H_4MPT^- + F_{420}H_2 \leftrightarrow \text{methylene-}H_4MPT + F_{420} + H^- \quad (3)$$

This reaction is analogous to the N^5, N^{10}-methylene-H_4F-dehydrogenase reaction, although the electron donor is different. As will be described below, some methanoarchaea have an alternative enzyme which catalyzes methenyl-H_4MPT reduction with H_2 as electron donor. N^5,N^{10}-methylene-H_4MPT is then reduced to N^5-methyl-H_4MPT by N^5,N^{10}-methylene-H_4MPT reductase using $F_{420}H_2$ as electron donor (reaction 4; Shima et al., 2002).



$$\text{Methylene-}H_4MPT + F_{420}H_2 \leftrightarrow \text{methyl-}H_4MPT + F_{420} \quad (4)$$

In contrast to the corresponding enzyme of the H_4F-dependent pathway, the reductase from methanoarchaea lacks a flavin.

In the H_4MPT pathway, the methylene-H_4MPT and methenyl-H_4MPT redox couples are substantially more negative than in the H_4F pathway (Fig. 9). This enables reversible coupling to

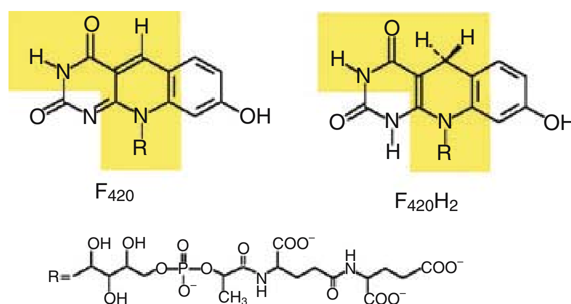


Fig. 10. Structure of coenzyme F_{420} in the oxidized and the reduced state. The structural similarity to pyridine nucleotides is indicated. *Methanothermobacter thermautotrophicus* and *Methanococcus voltae* F_{420} contain two glutamyl residues (F_{420}-2), and *Methanosarcina barkeri* contains F_{420} with four and five glutamyl residues (F_{420}-4,5).

the low redox-potential cofactor F_{420} (Fig. 10). This could be one reason why methanoarchaea utilize methanopterin instead of tetrahydrofolate in their C_1-pathway (Maden, 2000). F_{420} is a 5-deazaflavin, which is responsible for the blue-green fluorescence of methanoarchaea because of its high abundance in the cell. Unlike flavins, F_{420} only catalyzes hydride transfer reactions. Thus, it functions as a two-electron donor like $NAD(P)^+$. The $E^{\circ\prime}$ of the $F_{420}/F_{420}H_2$ couple is, however, about –360 mV, compared with

–320 mV for the $NAD(P)^+/NAD(P)H$ couple (Warkentin et al., 2001).

A Sodium Ion Pumping Methyltransferase

The last H_4MPT-dependent reaction in the methanogenic C_1-pathway is the transfer of the methyl-group from N^5-methyl-H_4MPT to coenzyme M (Fig. 11). This exergonic reaction ($\Delta G^{\circ\prime}$ = –30 kJ·mol^{-1}) is catalyzed by N^5-methyl-H_4MPT:CoM-SH methyltransferase (Mtr), a membrane-integral multienzyme complex composed of eight different subunits (MtrA-H; for a review, see Gottschalk and Thauer, 2001; Fig. 11). The enzyme is strictly dependent on sodium ions (Weiss et al., 1994). Subunit MtrA harbors a cob(I)amide prosthetic group (Gärtner et al., 1993), which is methylated and demethylated during the catalytic cycle. The demethylation reaction is Na^+-dependent. After reconstitution into proteoliposomes, the enzyme was shown to pump Na^+ (Lienard et al., 1996). A ratio of 1.7 mol of Na^+ translocated per mol of methyl-group transferred was determined. Thus, the enzyme appears to be a sodium pump that couples the methyl transfer to coenzyme M with formation of a sodium motive force.

The bound cobamide may play an important role in the enzyme mechanism. In aqueous solution, cob(II)amide and methylcob(III)amide contain axial ligands to the cobalt, whereas cob(I)amide does not (Kräutler, 1998). In unmethylated MtrA, the bound cob(I)amide should therefore have no axial ligand. Upon methylation of cob(I)amide to methylcob(III)amide, the methylcob(III)amide is expected to bind a histidine residue of the protein as an axial ligand (Harms and Thauer, 1997; Fig. 12). Binding of this axial ligand could therefore be associated with a conformational change of the protein. Upon demethylation of the cobamide, the axial ligand would be lost, and the conformational change would be reversed. Since demethylation is Na^+-dependent, the conformational change associated with this step can be coupled with the vectorial translocation of Na^+. The MtrH subunit can be separated from the MtrA-H-complex. The isolated MtrH subunit can catalyze the methylation of free cob(I)amide with methyl-H_4MPT (Hippler and Thauer, 1999).

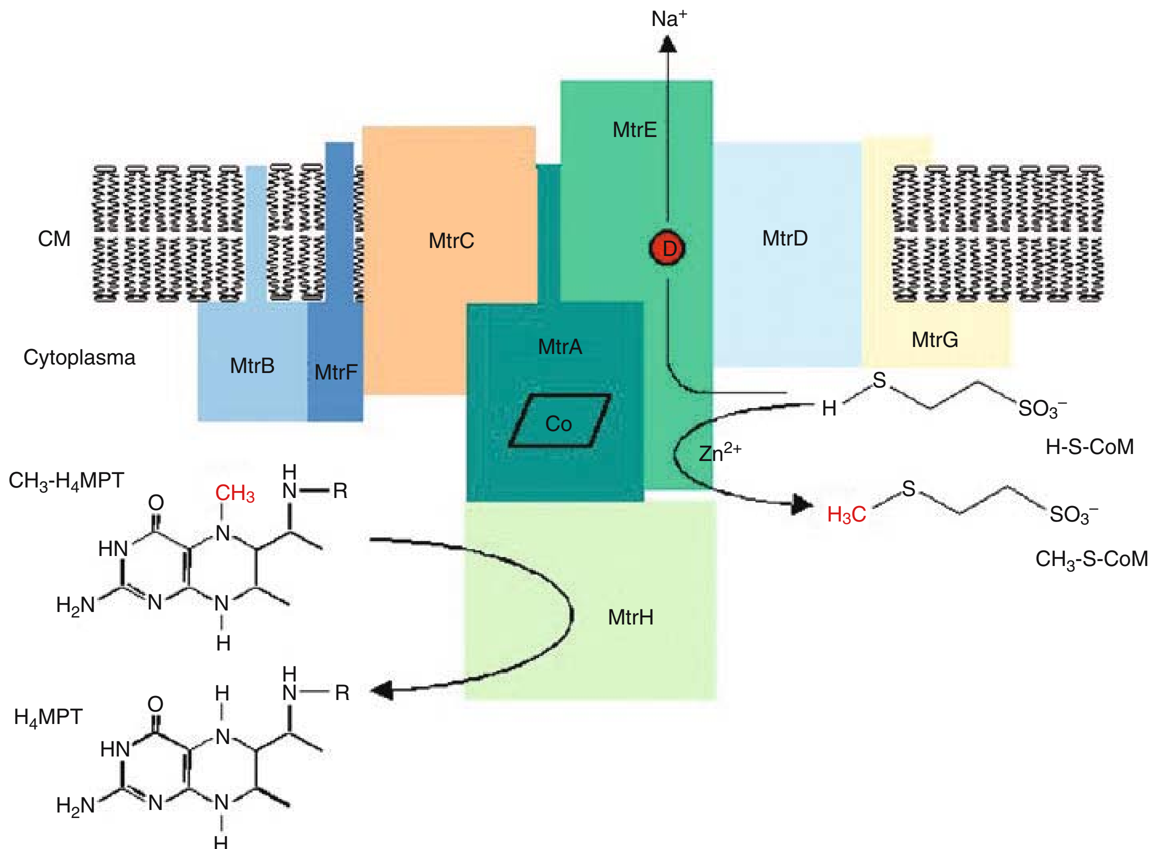

Fig. 11. Model of the methyl-H_4MPT:CoM-SH methyltransferase complex. A conserved aspartate residue (D) predicted to be located in a transmembrane helix of subunit MtrE is highlighted. This residue could be essential for sodium ion translocation. Modified from Gottschalk and Thauer (2001).

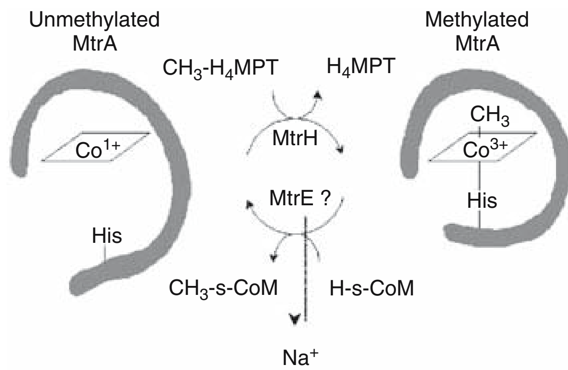

Fig. 12. Proposed conformational change of subunit MtrA of the methyl-H_4MPT:CoM-SH methyltransferase complex upon methylation and demethylation of its corrinoid prosthetic group. The MtrH subunit is proposed to catalyze the methylation of the cobamide bound to MtrA. The demethylation reaction is thought to be catalyzed by MtrE and coupled with vectorial sodium ion translocation since this reaction is sodium ion dependent. Modified from Gottschalk and Thauer (2001).

Therefore, MtrH is thought to catalyze the methylation of the corrinoid prosthetic group, which is bound to MtrA. Subunit MtrE is thought to transfer the methyl-group from the corrinoid prosthetic group of MtrA to coenzyme M, which is the Na^+-dependent reaction (Gottschalk and Thauer, 2001). MtrE is predicted to form six transmembrane spanning helixes and to have a large cytoplasmic domain containing a typical zinc-binding motif. All enzymes known to date that catalyze the alkylation of a thiol group are zinc proteins.

The reaction catalyzed by N^5-methyl-H_4MPT:CoM-SH methyltransferase is analogous to the formation of methionine from N^5-methyl-H_4F and homocysteine, which is catalyzed by methionine synthase (Banerjee et al., 1989). However, methionine synthase is a soluble enzyme containing only one type of subunit, reflecting the fact that the methyl transfer to homocysteine is not coupled to energy conservation.

Activation of Methanol and Methylamines

As shown in Fig. 13, methylotrophic methanogenesis begins with the transfer of the methyl-group from a variety of substrates to coenzyme M. For each substrate, there is a different methyltransferase system, specific for methanol (Mta), monomethylamine (Mtm), dimethylamine (Mtb), trimethylamine (Mtt), tetramethylammonium (Mtq), and methylthiols (Mts; Thauer and Sauer, 1999; Ferguson et al., 2000). Each system is composed of two methyltransferases, designated “MT1” (MtaB, MtmB, MtbB, MttB, and MtqB) and “MT2” (MtaA, MtbA, and MtqA), and a substrate-specific methylotrophic corrinoid protein (MtaC, MtmC, MtbC, MttC, and MtqC) containing a modified cobamide. MT1 in each system catalyzes the methylation of the reduced corrinoid protein, and MT2 catalyzes the transfer of the methyl group from the corrinoid protein to coenzyme M. Only in dimethylsulfide:coenzyme M methyltransferase are both methyl transfer reactions catalyzed by the same subunit (MtsA; Tallant et al., 2001). The MT2 proteins have high sequence similarity and contain zinc in the active site. Likewise, the sequences of the corrinoid proteins are related, all exhibiting a corrinoid-binding motif. In contrast, the substrate-activating MT1 enzymes are not phylogenetically related. For instance, MtaB, which activates methanol, is a zinc protein, but the other methylamine methyltransferases are not (Sauer and Thauer, 1997).

The genes encoding MtmB, MtbB, and MttB contain a single conserved in-frame amber codon (UAG) that is read through during translation (James et al., 2001). In the structure of MtmB, the UAG-encoded residue was identified as a lysine in amide-linkage to

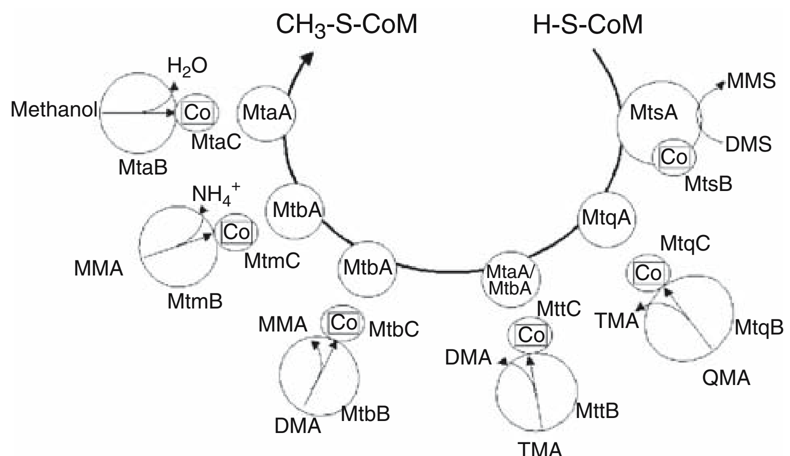

Fig. 13. Enzymes involved in the formation of methyl-coenzyme M from methanol, monomethylamine (MMA), dimethylamine (DMA), trimethylamine (TMA), tetramethylammonium (QMA) and dimethylsulfide (DMS). Except for DMS, the B subunits transfer the methyl groups from the substrates to the corrinoid prosthetic groups of the C subunits. The A subunits then transfer the methyl-groups from the corrinoid to CoM-SH. For DMS, the A subunit catalyzes both transfers. Abbreviations: MMS, methanethiol; and Co, corrinoid prosthetic group.

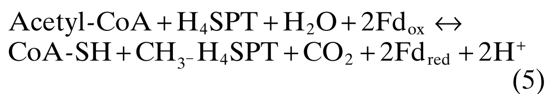
(*4R, 5R*)-4-substituted-pyrroline-5-carboxylate (called "pyrrolysine"; Hao et al., 2002). Furthermore, an amber decoding tRNA was identified (Srinivasan et al., 2002). Pyrrolysine can therefore be regarded as the twenty-second genetically encoded amino acid. Pyrrolysine is thought to position the methyl-group of methylamine for attack by the corrinoid protein (Hao et al., 2002).

The Aceticlastic Reaction

Species of *Methanosarcina*, as well as those of *Methanosaeta*, grow during the catabolism of acetate to CO_2 and CH_4 (Ferry, 1997). This is the acetate cleavage or aceticlastic reaction, where methane is formed without oxidation of the methyl group of acetate. Instead, after activation to acetyl-CoA, the acetyl C-C bond is cleaved by the multienzyme complex of acetyl-CoA synthase and carbon monoxide dehydrogenase (Acs/CODH), which in *Methanosarcina barkeri* and *Methanosarcina thermophila* is composed of five different subunits (α subunit, CdhA; β subunit, CdhC; γ subunit, CdhE; δ subunit, CdhD; and subunit, CdhB). The overall reaction catalyzed by the complex is the conversion of acetyl-CoA and tetrahydrosarcinapterin (H_4SPT) to CO_2, N^5-methyltetrahydrosarcinapterin (CH_3-H_4SPT), CoA-SH, and reducing equivalents (reaction 5). Tetrahydrosarcinapterin is similar in structure and function to tetrahydromethanopterin, which is common in the hydrogenotrophic methanogens.



$$\text{Acetyl-CoA} + H_4SPT + H_2O + 2Fd_{ox} \leftrightarrow \text{CoA-SH} + CH_3\text{-}H_4SPT + CO_2 + 2Fd_{red} + 2H^+ \quad (5)$$

A ferredoxin was identified as the physiological electron acceptor. In autotrophic methanoarchaea and the homoacetogenic bacteria like *Moorella thermoacetica*, a homologous enzyme system functions in the reverse direction for the biosynthesis of acetyl-CoA.

This overall reaction is made up of a series of partial reactions catalyzed by different protein subcomponents of the complex (Abbanat and Ferry, 1991; Grahame and DeMoll, 1996). The β subunit, the recombinant form of which can be produced in *Escherichia coli*, reacts with acetyl-CoA to form an acetyl-enzyme intermediate. Furthermore, this subunit catalyzes the formation of acetyl-CoA from CoA-SH, CO and methylcobalamin in the absence of other Acs/CODH subunits, demonstrating that this subunit catalyzes the reversible C-C bond activation (Gencic and Grahame, 2003). The β subunit also harbors the "A-cluster," which contains a Ni-Ni-[4Fe-4S] site, as deduced from the crystal structures of Acs/CODH from *Moorella thermoacetica* (Darnault et al., 2003; Seravalli et al., 2004) and *Carboxydothermus hydrogenoformans* (Svetlitchnyi et al., 2004).

The CO generated in the C-C cleavage reaction is transferred via a gas channel to the site of the CO dehydrogenase activity, which is on the α subcomplex. The isolated α subcomplex catalyzes the oxidation of CO to CO_2. Furthermore, the sequence of the α subunit is related to the sequences of the much simpler CO dehydrogenases from *Rhodospirillum rubrum* and *Carboxydothermus hydrogenoformans*. The active site of CO-dehydrogenase also contains a Ni-Fe/S center, which could be either a [Ni-Fe_4-S_4] or a [Ni-Fe_4-S_5] center, as deduced from the crystal structure of these enzymes (Dobbek et al., 2001; Drennan et al., 2001).

The methyl group generated in the β subunit is transferred to the corrinoid cofactor present in the γδ subcomplex, which catalyzes the subsequent methyl-transfer to the substrate H_4SPT. Here the methyl-group enters the general methanogenic pathway, which leads to the formation of CH_4 (Fig. 2). Reducing equivalents required for the reduction of the heterodisulfide are provided by reduced ferredoxin formed in the CO dehydrogenase reaction.

There might be alternative electron transport chains to couple ferredoxin oxidation to heterodisulfide reduction. In *Methanosarcina barkeri*, H_2 is thought to be an intermediate in this electron transfer reaction. This conclusion is based on several observations. First, H_2 accumulates during growth on acetate. Second, acetate-grown cells have high levels of the Ech hydrogenase and methanophenazine-reducing hydrogenase. Third, Ech hydrogenase is essential for growth of *M. barkeri* on acetate. It has therefore been proposed that this enzyme catalyzes H_2-formation from reduced ferredoxin (Meuer et al., 2002). H_2 thus formed could then diffuse to the extracytoplasmic side of the membrane, where it becomes oxidized by the methanophenazine-reducing hydrogenase. Reduced methanophenazine is then the electron donor for the heterodisulfide reductase (Fig. 14). On the other hand, *M. acetivorans* forms methane from acetate but lacks a functional Ech hydrogenase (Galagan et al., 2002). Hence, there must exist an alternative route to channel electrons from reduced ferredoxin into a membrane-bound electron transport chain that leads to heterodisulfide reduction.

The Hydrogenases of Methanoarchaea—A Summary

For most methanoarchaea, methanogenesis from H_2 and CO_2 is the only way to obtain energy for growth. Also growth on acetate could involve

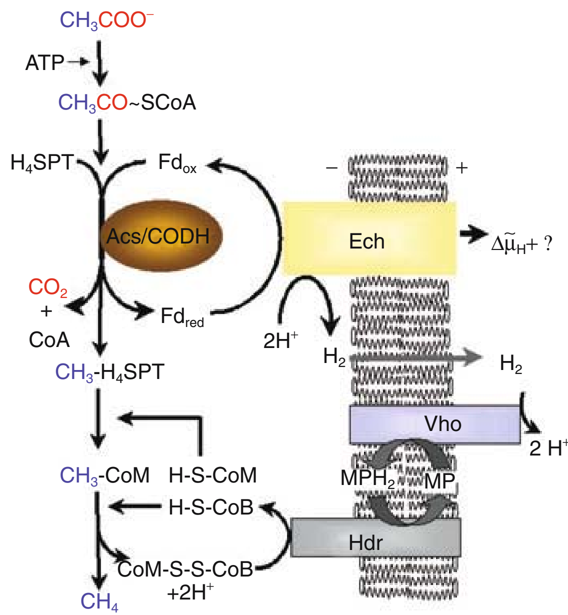


Fig. 14. Pathway of methanogenesis from acetate in *Methanosarcina barkeri*. Recent data indicate that the 2 [4Fe-4S] ferredoxin (Fd) from *M. barkeri* mediates electron transfer between acetyl-CoA synthase/CO dehydrogenase (Acs/CODH) and Ech hydrogenase. Abbreviations: CH_3-H_4SPT, methyl-tetrahydrosarcinapterin; MP, methanophenazine and MPH_2, reduced methanophenazine.

H_2-formation and H_2-consumption as discussed above. Therefore hydrogenases are essential enzymes for methanoarchaea, which is reflected by the presence of five different types of hydrogenases in these organisms. Four of these enzymes are [NiFe]-hydrogenases, and one enzyme is an iron-sulfur cluster-free hydrogenase that has only been found in methanoarchaea. Methanoarchaea seem to be lacking [FeFe] hydrogenases. For a more detailed description of hydrogenases including those from methanoarchaea, see The H2-Metabolizing Prokaryotes in this Volume.

F_{420}-Reducing Hydrogenase

This enzyme (Frh) is conserved in all methanoarchaea studied. Some organisms contain two closely related isoenzymes. The enzyme catalyzes the reduction of the deazaflavin coenzyme F_{420} and thus provides the reducing equivalents for the two intermediate reduction steps of the C_1-pathway. Frh is a soluble [NiFe] hydrogenase composed of three subunits, including the “hydrogenase large subunit” and the “hydrogenase small subunit” that form the basic module of all [NiFe] hydrogenases. The third subunit contains iron-sulfur clusters and FAD. It is assumed to harbor the F_{420}-binding site (Sorgenfrei et al., 1997).

H_2-Forming Methylene-H_4MPT Dehydrogenase

As outlined above, all hydrogenotrophic methanogens possess an F_{420}-dependent dehydrogenase for the reduction of methenyl-H_4MPT. Reduction of F_{420} to $F_{420}H_2$ by H_2 is catalyzed by Frh. Methanoarchaea belonging to the orders Methanobacteriales, Methanococcales and Methanopyrales also possess an enzyme that directly reduces methenyl-H_4MPT to methylene-H_4MPT using H_2 as the electron donor (Thauer et al., 1996; Fig. 15). Because this enzyme oxidizes H_2, it is a hydrogenase by definition. However, because this reaction is so unusual, it has been called the “H_2-forming methylene-H_4MPT dehydrogenase” (Hmd). In contrast to the well characterized [NiFe] hydrogenases and [FeFe] hydrogenases, Hmd does not contain Ni or iron-sulfur clusters. The primary sequence of Hmd does not possess similarity to known proteins. Furthermore, the enzyme is not inhibited by CO at concentrations known to inhibit other hydrogenases, and it does not catalyze the reduction of redox-dyes such as benzyl- or methylviologen. It does catalyze the exchange between H_2 and protons and the conversion of *para* H_2 to *ortho* H_2 but only in the presence of methenyl-H_4MPT. More detailed mechanistic studies have shown that the enzyme catalyzes the reversible reduction of methenyl-H_4MPT to methylene-H_4MPT in a ternary complex catalytic mechanism. In this reaction, a hydride is transferred from H_2 into the *pro*-R position at C^{14} of methenyl-H_4MPT.

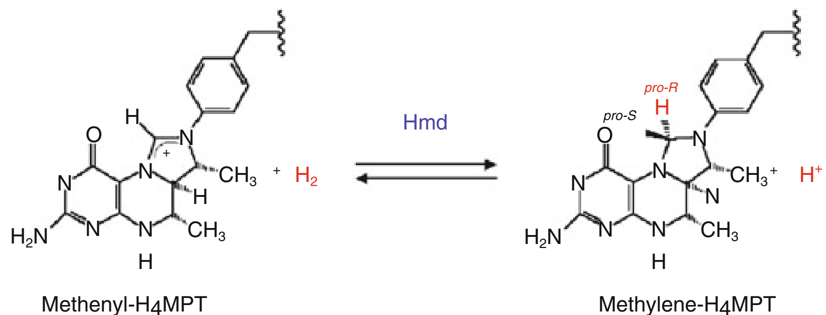

Fig. 15. Reaction catalyzed by H_2-forming methylene-H_4MPT dehydrogenase (Hmd). In the presence of H_2, methenyl-H_4MPT is reduced to methylene-H_4MPT.

Iron at concentrations up to 1 mol of Fe per mol of enzyme is the only metal that has been detected in Hmd. This iron was not redox-active and not considered to be functional. The enzyme was therefore called "metal-free" hydrogenase. Recently active enzyme was shown to contain a cofactor (Buurman et al., 2000). Addition of the purified cofactor to the apoprotein, which can be produced in *E. coli*, resulted in active enzyme. The structure of the active cofactor is not yet known. But upon illumination with ultraviolet (UV)-A/blue light, the cofactor is inactivated and Fe and CO are released (Lyon et al., 2004b). The remaining organic component could be cleaved by phosphodiesterase to GMP and a pyridone moiety, which is a new structure in biology (Shima et al., 2004). How this organic compound is involved in iron complexation in the active Hmd cofactor remains to be shown. There is experimental evidence that two CO are bound to the iron-center (Lyon et al., 2004a). Interestingly, CO is also a ligand to the iron center in [NiFe]- and [FeFe]-hydrogenases.

In cells cultivated under Ni-limiting conditions, the [NiFe] hydrogenase Frh is barely detectable, while the concentration of Hmd in the cell increases (Afting et al., 1998). Hmd in combination with F_{420}-dependent methylene-H_4MPT dehydrogenase (Mtd) mediates the reduction of coenzyme F_{420} by H_2 and thus provides an alternative source for reduced coenzyme F_{420}. This allows the cell to spare Ni. In contrast to the [NiFe] hydrogenase Frh, Hmd and Mtd are not oxygen sensitive. This becomes important in the context of the recent finding that methanoarchaea contain an $F_{420}H_2$ oxidase, which catalyzes the reduction of O_2 to H_2O with $F_{420}H_2$ as the electron donor (Seedorf et al., 2004). The reduction of O_2 with H_2 in methanoarchaea is not coupled with energy conservation. The function of this oxidase is most probably to reduce the intracellular O_2 concentration to a level that allows growth and methanogenesis. There is evidence that the O_2 concentration has to be lowered well below 5 μM in order for a "nanaerobe" to grow (Baughn and Malamy, 2004). The function of $F_{420}H_2$ oxidase is, therefore, O_2 detoxification.

F_{420}-Non-Reducing Hydrogenase

F_{420}-non-reducing hydrogenase (Mvh) is a soluble [NiFe] hydrogenase. In addition to the basic hydrogenase module of two subunits, the enzyme contains a third subunit, a 17-kDa protein that carries a [2Fe-2S] cluster. In *M. marburgensis*, Mvh forms an enzyme complex with heterodisulfide reductase (Hdr). There is indirect evidence that the hydrogenase interacts via its 17-kDa subunit with Hdr (Stojanowic et al., 2003). This type of hydrogenase is not found in *Methanosarcina* species.

Methanophenazine-Reducing Hydrogenases

Methanosarcina species form two closely related [NiFe] hydrogenases, encoded by the *vho* and the *vht* transcriptional units. In addition to the basic hydrogenase module, these enzymes contain a membrane-anchoring β-type cytochrome, which easily becomes separated from the hydrogenase module during purification. These enzymes possess the highest similarity to the membrane-bound, periplasmically oriented uptake hydrogenases of bacteria (Vignais et al., 2001). Vho and Vht also contain a twin-arginine leader peptide in their hydrogenase small subunit, indicating that the hydrophilic subunits of these enzymes are translocated across the membrane by twin arginine translocation (TAT) machinery. This type of hydrogenase has only been found in *Methanosarcina* species where it is part of the H_2:CoM-S-S-CoB oxidoreductase system (Deppenmeier et al., 1999; Fig. 5). The *vhoGAC* operon is expressed during growth on H_2/CO_2, methanol or acetate. The *vhtGAC* operon is only expressed during growth on H_2/CO_2 and methanol but not during growth on acetate (Deppenmeier, 1995a). Whether this pattern of expression reflects a different metabolic function is not known.

Energy-Converting [NiFe] Hydrogenases

Energy-converting [NiFe] hydrogenase (Ech) is an integral membrane protein, which, when purified, is composed of six subunits, corresponding to the products of the *echABCDEF* operon (Künkel et al., 1998; Meuer et al., 1999). Ech hydrogenase is only distantly related to the other [NiFe] hydrogenases found in methanoarchaea. The subunits of this enzyme are closely related to members of a small group of membrane-bound [NiFe] hydrogenases, such as hydrogenase 3 from *E. coli* and the CO-induced hydrogenase from *Rhodospirillum rubrum*. The sequences of the six subunits conserved in these enzymes are closely related to subunits present in the central part of complex I from mitochondria and bacteria (Hedderich, 2004). The EchA and EchB subunits of the enzyme are predicted to be membrane-spanning proteins, while the other four subunits are expected to extrude into the cytoplasm. A low-potential, soluble two [4Fe-4S] ferredoxin ($E_0' = -420$ mV) isolated from *M. barkeri* was identified as the electron donor/acceptor of Ech. As outlined above, this enzyme provides the cell with reduced ferredoxin required for the first step of methanogenesis and for certain anabolic reactions. In vivo the reduc-

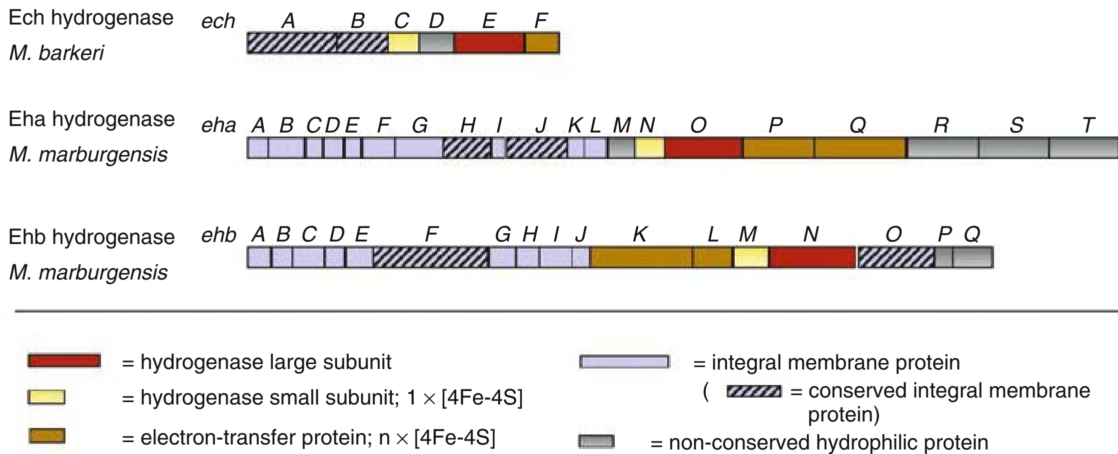

Fig. 16. Organization of the *Methanosarcina barkeri ech* operon and the *Methanothermobacter marburgensis eha* and *ehb* operons. Abbreviations: [4Fe-4S] iron-sulfur cluster; and n x [4Fe-4S], polyferredoxin encoded by the operon.

tion of the ferredoxin by H_2 is thought to be driven by reversed electron transport.

In aceticlastic methanogenesis, Ech was proposed to catalyze the reverse reaction (i.e., the production of H_2 with reduced ferredoxin as electron donor). This has been concluded from experiments with intact cells. Cell suspensions of wild-type *M. barkeri* convert CO quantitatively to CO_2 and H_2. Cell suspensions of the Δ*ech* mutant catalyzed the oxidative half of the aceticlastic pathway (conversion of CO to CO_2 and H_2) at a significantly lower rate than the wild type, indicating that Ech is the hydrogenase involved in this reaction (Meuer et al., 2002). Importantly, the conversion of CO to CO_2 and H_2 in wild-type *M. barkeri* was found to be coupled to the generation of a proton motive force. This is consistent with the putative ion-translocating activity of Ech.

Ech hydrogenase thus far has only been purified from *Methanosarcina* species. The genomes of *Methanothermobacter thermoautotrophicus*, *Methanococcus jannaschii* and *Methanopyrus kandleri* do not encode a homologue of the six-subunit Ech-hydrogenase present in *Methanosarcina*. However, these organisms encode related enzymes, which are predicted to have a much more complex subunit architecture (Fig. 16). *Methanothermobacter thermoautotrophicus*, *M. marburgensis* and *M. jannaschii* each encode two hydrogenases of this type, designated "Eha" and "Ehb" (Tersteegen and Hedderich, 1999). *Methanopyrus kandleri* only encodes for one of these hydrogenases (Slesarev et al., 2002). In *M. marburgensis* the length of the transcription units was determined. The *eha* operon (12.5 kb) and the *ehb* operon (9.6 kb) were found to be composed of 20 and 17 ORFs, respectively. Sequence analysis of the deduced proteins indicated that the *eha* and *ehb* operons each encode a [NiFe] hydrogenase large subunit, a [NiFe] hydrogenase small subunit, and two conserved integral membrane proteins. These proteins show high sequence similarity to subunits of Ech hydrogenase from *Methanosarcina barkeri*. In addition to these four subunits, the *eha* operon encodes a 6[4Fe-4S] polyferredoxin, a 10[4F-4S] polyferredoxin, four nonconserved hydrophilic subunits, and ten nonconserved integral membrane proteins; the *ehb* operon encodes a 2[4Fe-4S] ferredoxin, a 14[4Fe-4S] polyferredoxin, two nonconserved hydrophilic subunits, and nine nonconserved integral membrane proteins. Since *Methanothermobacter* species only grow with H_2/CO_2 as energy substrates, it has been proposed that these membrane-bound [NiFe] hydrogenases catalyze the reduction of a low-potential ferredoxin or polyferredoxins by H_2 in a reaction driven by reversed electron transport, in analogy to the function of Ech hydrogenase in *M. barkeri* when the organism is cultivated on H_2/CO_2. A purification of these enzymes has not been achieved thus far.

Methanogenic Coenzymes and Enzymes in Nonmethanogenic Archaea and Bacteria

Sulfate-Reducing Archaea Use Three Methanogenic Coenzymes for the Oxidation of Reduced C_1-Compounds to CO_2

So far, all isolated archaeal sulfate reducers belong to the genus *Archaeoglobus*. The best-studied species is *A. fulgidus*, for which the genome sequence is also known (Klenk et al.,

1997). *Archaeoglobus fulgidus* couples the oxidation of lactate to CO_2 with the reduction of sulfate to H_2S. Lactate is first oxidized to pyruvate, which is subsequently converted to acetyl-CoA, CO_2 and 2[H]. Cleavage of the C-C-bond of acetyl-CoA is catalyzed by the Acs/CODH complex, which has the same subunit architecture and high sequence similarity to the enzyme from methanoarchaea (Dai et al., 1998). This reaction generates enzyme-bound CO, which is oxidized to CO_2, and an enzyme-bound methyl group. For the oxidation of the methyl-group to CO_2, *A. fulgidus* uses three coenzymes characteristic of the methanoarchaea: tetrahydromethanopterin, methanofuran and coenzyme F_{420} (Möller-Zinkhan et al., 1989; Gorris et al., 1991). The methyl-group is first transferred to H_4MPT and then stepwise oxidized to CO_2 by the same reactions and enzymes found in methanoarchaea (Fig. 2). The $F_{420}H_2$ formed in this oxidative pathway is reoxidized by a membrane-bound $F_{420}H_2$ dehydrogenase, which closely resembles the enzyme from *Methanosarcina* species (Kunow et al., 1994; Klenk et al., 1997). *Archaeoglobus fulgidus* contains a modified menaquinone, which probably functions as the electron acceptor of this dehydrogenase. It is not yet clear how electrons are transferred from the menaquinone pool to the enzymes of sulfate reduction. Recently a membrane-bound menaquinol-acceptor oxidoreductase that might mediate the electron transfer from the menaquinone pool to an as yet unidentified electron carrier in the cytoplasm has been isolated (Mander et al., 2002). The sequences of two of the subunits of this enzyme are related to those of the heterodisulfide reductase from *Methanosarcina* species, including the catalytic subunit of Hdr. However, *Archaeoglobus* lacks coenzymes M and B. Therefore this heterodisulfide-reductase-like enzyme has been proposed to catalyze the reduction of an unidentified disulfide substrate, which in turn could function as an electron donor of the enzymes of sulfate reduction, such as APS reductase and sulfite reductase.

Tetrahydromethanopterin-Dependent Formaldehyde Oxidation in Methylotrophic Bacteria

In the metabolism of aerobic methylotrophic bacteria, formaldehyde is formed as a central intermediate from various C_1-substrates. Different pathways of formaldehyde oxidation to CO_2 are known, one being tetrahydromethanopterin-dependent. The H_4MPT-dependent pathway was first discovered in *Methylobacterium extorquens*. This organism, in addition to the tetrahydrofolate-dependent pathway, has an H_4MPT-dependent route for formaldehyde oxidation, which is now believed to be the main catabolic route in this organism (Chistoserdova et al., 1998). The pathway involves three H_4MPT-dependent steps, which are catalyzed by an NADH-dependent methylene-H_4MPT dehydrogenase, a methenyl-H_4MPT cyclohydrolase, and a formyltransferase/hydrolase complex. H_4MPT-dependent enzymes have also been detected in many other methylotrophic proteobacteria. For a more detailed review, see Aerobic Methylotrophic Prokaryotes in this Volume.

F_{420} in Nonmethanogenic Organisms

Coenzyme F_{420} was first discovered in methanogenic archaea. Later, coenzyme F_{420} was also identified in *Archaeoglobus*, *Mycobacterium*, *Nocardia*, *Streptomyces*, cyanobacteria and some eukaryotes (Choi et al. [2001] and literature cited therein). The role of F_{420} in *Archaeoglobus* is similar to that in methanogens. Coenzyme F_{420} is used by *Streptomyces* species for tetracycline and lincomycin biosynthesis and may be used in mitomycin C biosynthesis. In *Mycobacterium* and *Nocardia* species, coenzyme F_{420} is used by a coenzyme F_{420}-dependent glucose-6-phosphate dehydrogenase. Enzymes belonging to the deazaflavin class of photolyases, which are found in the green alga *Scenedesmus* and the cyanobacterium *Synechocystis*, contain 8-hydroxyazoriboflavin (also called "coenzyme F_0"). Coenzyme F_{420} is a derivative of coenzyme F_0.

CoM-SH in Bacterial Aliphatic Epoxide Carboxylationtc "CoM-SH in Bacterial Aliphatic Epoxide Carboxylation"

Until 1999, methanoarchaea were the only organisms known to possess coenzyme M, which is the smallest organic cofactor found in nature. It was then discovered that coenzyme M also plays an essential role in the bacterial metabolism of short chain epoxyalkanes, as revealed by initial studies with *Xanthobacter autotrophicus* and *Rhodococcus rhodochrous* (Allen et al., 1999). These organisms use coenzyme M as the nucleophile for the epoxide ring opening, which results in the formation of the thioether bond between CoM-SH and a 2-hydroxyalkyl residue. After oxidation to the corresponding 2-ketoalkyl-CoM intermediate, the thioether bond is attacked by a cysteine residue present in the active site of one of the key enzymes of the pathway. This results in the formation of a mixed disulfide between CoM-SH and the active-site cysteine and a carbanion, which becomes carboxylated. Reduction of the mixed disulfide in a NADH-dependent step regenerates coenzyme M. Coenzyme M seems to be ideally suited as a

nucleophile and carrier molecule in this pathway (reviewed in Ensign and Allen, 2003).

Do Anaerobic Methane Oxidizers Use the Methanogenic Pathway in Reverse?

Although the elucidation of the pathway of CO_2 reduction in methanogens required the discovery of a large number of novel coenzymes and enzymatic reactions, many of these catalysts were subsequently found in other organisms. For many years, the reaction catalyzed by methyl-coenzyme M reductase seemed to be the only step of the pathway that was truly unique to the methanoarchaea. However, very recently genes encoding a methyl-coenzyme M reductase-like enzyme were identified in habitats where methane-oxidizing microbial communities are abundant (Hallam et al., 2003). From the biomass of one of these habitats, a methyl-coenzyme M reductase-like enzyme was isolated (Krüger et al., 2003). This protein harbored a nickel-containing prosthetic group that was identified as a heavier (mass of 951 Da) variant of coenzyme F_{430} (mass of 905 Da), the unique nickel porphinoid in Mcr. These studies led to the proposal that anaerobic methane oxidation biochemically, in principle, is a reversal of methanogenesis. For more details on anaerobic methane oxidation, see the chapter Anaerobic Biodegradation of Hydrocarbons Including Methane in this Volume.

Regulation of Gene Expression

Regulation of Catabolic Enzymes by Substrate Availability

Many methanoarchaea use only one or two energy substrates, so that one may not expect extensive metabolic regulation. Nevertheless, it was found that even organisms using H_2/CO_2 as the sole growth substrate regulate the formation of some key catabolic enzymes in response to the availability of H_2. One example is the differential expression of two methyl-coenzyme M reductase isoenzymes in the Methanobacteriales and the Methanococcales (Thauer, 1998). In *Methanothermobacter* species isoenzyme I is encoded by the *mcrBDCGA* operon, and isoenzyme II is encoded by the *mrtBDGA* operon. The two isoenzymes differ in their catalytic properties. Isoenzyme I has a lower V_{max} as compared to isoenzyme II but displays lower K_M values for its substrates, CoB-SH and methyl-coenzyme M (Bonacker et al., 1993). Expression of the two isoenzymes is differently regulated by the availability of hydrogen. Isoenzyme I is predominantly formed when growth is limited by the H_2 supply whereas isoenzyme II predominates when the H_2 supply is not growth-rate limiting (Bonacker et al., 1992; Morgan et al., 1997). In the latter case, the methylcoenzyme M reductase reaction might be a bottleneck of the pathway. Therefore, it could be of physiological relevance to synthesize an enzyme with a higher V_{max}.

There are conflicting results with respect to the regulation of other methanogenic enzymes in response to the H_2 availability. Two groups found that the formation of Hmd in *Methanothermobacter* species parallels that of isoenzyme II of Mcr (encoded by the *mrt* operon), while the formation of Frh and Mtd parallel that of isoenzyme I of Mcr (encoded by the *mcr* operon; Morgan et al., 1997; Vermeij et al., 1997). Two other groups did not observe a formation of these enzymes in response to H_2 availability with their systems (Afting et al., 2000; Luo et al., 2002). But all groups observed the same pattern of formation of McrI and McrII.

The formation of flagella in *Methanocaldococcus jannaschii* is another example of regulation in response to H_2-availibility. Although flagella are not directly involved in catabolic processes, they are essential for finding optimal substrate conditions. Under H_2-excess conditions, *M. jannaschii* cells are devoid of flagella and have almost undetectable levels of four flagella-related proteins. Flagella synthesis occurs when H_2 becomes limiting (Mukhopadhyay et al., 2000).

Many species of hydrogenotrophic methanogens use formate in place of H_2 as the electron donor for CO_2 reduction. The ability to use formate is attributed to formate dehydrogenase (Fdh), which in methanoarchaea catalyzes the formate-dependent reduction of coenzyme F_{420}. The *Methanococcus maripaludis* genome contains two formate dehydrogenase gene clusters. The transcription of both gene clusters was found to be controlled by the availability of H_2. Only in the absence of H_2 was maximal expression of both *fdh* gene clusters observed. In contrast, formate had no marked effect on the expression (Wood et al., 2003). In contrast, expression of formate dehydrogenase in *Methanobacterium formicicum* seems not to be regulated (Schauer and Ferry, 1980).

Methanogenium thermophillum can use 2-propanol as sole electron donor for CO_2 reduction. The secondary alcohol dehydrogenase responsible for 2-propanol oxidation was only formed when H_2 became limiting, irrespective of the presence of the alcohol. In other methanoarchaea able to grow with secondary alcohols, formation of alcohol dehydrogenase was dependent on the availability of an alcohol irrespective of the presence of H_2 (Widdel and Wolfe, 1989).

Another response to H_2-limitation is the synthesis of an autolytic enzyme by *Methanobacterium wolfei* (Kiener et al., 1987). The physiological role of this suicidal process is not known. It may be related to the induction of a defective bacteriophage (Stettler et al., 1995).

The regulation of the genes encoding methanogenesis from acetate in *Methanosarcina* species is also well studied. Early work had already shown that acetate is only used as energy substrate when none of the higher energy-yielding substrates methanol, methylamines or H_2/CO_2 are available, indicating that acetate catabolism is repressed by these other substrates (reviewed in Zinder, 1993). This is consistent with the observation that the key enzymes of acetate metabolism (i.e., acetate kinase, phosphotransacetylase, acetyl-CoA synthase/carbon monoxide dehydrogenase complex, and carbonic anhydrase) are formed at a lower level in cells grown on methanol as compared to acetate-grown cells (Jablonski et al., 1990). Regulation was shown to be at the mRNA level (Sowers et al., 1993; Singh-Wissmann and Ferry, 1995). On the other hand, most of the enzymes necessary for the reversible reduction of CO_2 to the level of methyl-tetrahydromethanopterin are present at a much lower level in acetate-grown cells (Jablonski et al., 1990; Mukhopadhyay et al., 1993). When *Methanosarcina* spp. are cultivated on methanol in the presence of H_2/CO_2, the oxidative branch of the methylotrophic pathway is repressed. This result is consistent with the observation that several enzymes of this pathway are formed at a lower level under these conditions (Mukhopadhyay et al., 1993). In conclusion, catabolic gene expression in *Methanosarcina* appears similar to systems in bacteria, which are regulated for preferential utilization of the most energetically favorable substrate.

For none of the regulatory systems described above has the primary sensor and the signal transduction cascade been elucidated. However, in *Methanothermobacter thermoautotrophicus*, studies have been performed which led to the proposal that coenzyme F_{390} could function as a reporter compound for H_2 limitation. Coenzyme F_{390} is formed from coenzyme F_{420} by adenylation or guanylation at its 8-hydroxy-group. This reaction is catalyzed by coenzyme F_{390} synthetase (Vermeij et al., 1994). This enzyme specifically uses oxidized coenzyme F_{420} as substrate, while reduced coenzyme F_{420} ($F_{420}H_2$) acts as a competitive inhibitor. Coenzyme F_{390} can be hydrolyzed to coenzyme F_{420} and AMP or GMP in a reaction catalyzed by coenzyme F_{390} hydrolase (Vermeij et al., 1995). This latter enzyme is redox-sensitive and is inactivated by O_2. Furthermore, this enzyme is activated by CoM-SH but inactivated by CoM-S-S-CoB. On the basis of the biochemical properties of these two enzymes, it has been predicted that the level of coenzyme F_{390} should be low when cells receive sufficient H_2 (which leads to a high coenzyme $F_{420}H_2$ to coenzyme F_{420} ratio and high CoM-SH to CoM-S-S-CoB ratio). Conversely, the coenzyme F_{390} concentration in the cell should increase when H_2 becomes limiting. This prediction was confirmed experimentally (Vermeij et al., 1997). In further studies a *Methanothermobacter thermoautotrophicus* mutant was isolated that was unable to grow under H_2-deprived conditions. This mutant was also unable to form coenzyme F_{390}. It also lacked the ability to synthesize isoenzyme I of Mcr, which is the enzyme preferentially synthesized under H_2-limiting conditions (Pennings et al., 1998). This gives further evidence for an important role of coenzyme F_{390} in the response of the cell to varying H_2-concentrations.

Regulation of Catabolic Enzymes by Trace Element Availability

In the methanogenic pathways, enzymes containing transition metals in their active site play an essential role. Therefore, not surprisingly, these organisms have developed strategies to cope with limitations on the availability of these metal ions. One example is the synthesis of different isoenzymes of formylmethanofuran dehydrogenase (Fmd; reviewed in Vorholt and Thauer, 2002). *Methanothermobacter marburgensis* and *Methanothermobacter wolfei* form two different isoenzymes, one containing tungsten bound to the molybdopterin cofactor (Fmd-W) and a second containing molybdenum bound to the molybdopterin cofactor (Fmd-M). Whereas Fmd-W is formed constitutively, Fmd-M is only formed when molybdenum is available (Hochheimer et al., 1996). A DNA binding protein, called "Tfx," was found to specifically bind to a DNA region downstream of the promoter of the *fmdECB* operon, which encodes Fmd-M. Therefore, Tfx may be a transcriptional regulator of the *fmdECB* operon (Hochheimer et al., 1999). A different set of Fmd enzymes is found in *Methanopyrus kandleri*. This organism forms two tungsten-containing Fmd isoenzymes (Vorholt et al., 1997). One isoenzyme (called "Fwu") contains selenium, whereas the second (called "Fwc") does not. In general, Fmd contains a conserved cysteine residue, which is also conserved in other molybdopterin-containing enzymes. From the crystal structure of other molybdopterin-containing enzymes, for example dimethylsulfoxide reductase, this residue is known to provide a ligand to the molybdenum center. In Fwu, this cysteine residue is replaced by selenocysteine. The gene encoding the catalytic subunit FwuB is in the polycistronic operon *fwuGDB*. The gene

encoding FwcB, the catalytic subunit of Fwc, is transcribed monocistronically. During growth of the organism on medium supplemented with selenium, only the *fwuGDB* operon is transcribed. During growth under selenium limitation, both *fwuGDB* and *fwcB* are transcribed.

Selenium-dependent gene expression has also been observed in *Methanococcus voltae*. In this organism, two isoenzymes of the coenzyme F_{420}-reducing hydrogenase (called "Fru" and "Frc"), and two isoenzymes of the coenzyme F_{420}-nonreducing hydrogenase (called "Vhu" and "Vhc") are encoded in the genome (Sorgenfrei et al., 1997). One enzyme of each type, Fru and Vhu, contains selenocysteine in the hydrogen activating reactive site. The corresponding isoenzymes, Frc and Vhc, have a cysteinyl residue in the homologous positions. The two selenium-containing hydrogenases are constitutively expressed. The operons *vhc* and *frc* encoding the selenium-free enzymes are only transcribed under selenium limitation. They are connected by a common intergenic region comprising both promoters and positive and negative regulatory sequence elements, which were defined by mutational analyses employing a reporter gene system (Noll et al., 1999). A putative activator protein has been identified but not yet further characterized (Müller and Klein, 2001). A protein binding to a negative regulatory element involved in the regulation of the two operons was purified. Through the identification of the corresponding gene, the protein was found to be a LysR-type regulator. It was named "HrsM" (*h*ydrogenase gene *r*egulator, *s*elenium dependent in *M. voltae*). Also, *hrsM* knockout mutants constitutively transcribed the *vhc* and *frc* operons in the presence of selenium (Sun and Klein, 2004).

Nickel is an essential trace element for methanoarchaea. Studies with *Methanothermobacter marburgensis* have shown that this organism has developed a strategy to spare nickel under nickel-limitation. As outlined above, coenzyme F_{420}-reducing hydrogenase (Frh), which is a [NiFe] hydrogenase, can be functionally replaced by the combined action of Hmd and Mtd. These two latter enzymes do not contain Ni. When *M. marburgensis* was cultivated under nickel-limited conditions, the specific activity of Hmd and Mtd was 6- and 4-fold higher and that of Frh up to 180-fold lower than in cells grown on nickel-sufficient medium. The *frh* transcripts were no longer detectable in cells grown under Ni-limitation, whereas the relative abundance of the *hmd* and *mtd* transcripts increased (Afting et al., 1998; Afting et al., 2000).

Regulation of Nitrogen Assimilation

Nitrogen assimilation by *Methanococcus maripaludis* is highly regulated. This organism fixes N_2 but can also use ammonia or alanine as sole nitrogen sources. In the presence of ammonia or alanine, N_2 fixation is highly repressed (Cohen-Kupiec et al., 1997; Lie and Leigh, 2002). The repressor has been isolated and is very unusual for this class of proteins. Called "NrpR," it possesses very low sequence similarity to previously described DNA-binding proteins in the prokaryotes (Lie and Leigh, 2003). NrpR also regulates the expression of *glnA* in *M. maripaludis*. In addition to transcriptional regulation, N_2 fixation is also regulated by a switch-off mechanism. Upon the addition of ammonia or alanine, nitrogen fixation ceases immediately (Kessler et al., 2001; Lie and Leigh, 2002). This regulation requires the participation of two GlnB homologs encoded by *nifI*$_1$ and *nifI*$_2$. Although this system acts very similarly to the bacterial system for the posttranslational ADP-ribosylation of the nitrogenase reductase, its mechanism of action is not currently known.

Bioenergetics of Growth

Coupling Sites in Methanogenesis

Energy-conservation by methanoarchaea is via electron transport phosphorylation as outlined above. The H_2/CO_2 pathway contains two energy-coupling sites: the H_4MPT:coenzyme M methyltransferase reaction and the reduction of the heterodisulfide. While the methyl-transferase reaction is coupled to the primary extrusion of Na^+, the heterodisulfide reductase reaction is coupled to the extrusion of H^+. Experimental proof that the latter reaction is coupled to energy-conservation is, however, only available for *Methanosarcina* species. Via a Na^+/H^+ antiporter, $\Delta{:}\mu_{Na+}$ and $\Delta{:}\mu_{H+}$ are interconvertible (Kaesler and Schönheit, 1989). Part of the energy conserved in these ion gradients is used to drive the reduction of CO_2 to formylmethanofuran by reversed electron transport, while the remaining part of the energy is used for the synthesis of ATP via ATP synthase. Methanoarchaea contain A_1A_0 ATP synthases characteristic for archaea (Müller, 2004). In *M. thermoautotrophicus* and *M. mazei*, this is the only ATP synthase encoded in the genome sequences. In contrast, the genomes of *M. barkeri* and *M. acetivorans* encode both (an A_1A_0 ATP synthase and a F_1F_0 ATP synthase). Expression of the latter enzyme in *M. barkeri* could, however, not be demonstrated (Müller, 2004). The ion specificity of A_1A_0 ATP synthases is not yet established. In silico analysis of the proteolipid of some A_1A_0 ATP synthases reveal the presence of a Na^+ binding motif and suggest that these enzymes use Na^+ as coupling ion (Müller, 2004).

In aceticlastic methanogenesis, the methyltransferase and the heterodisulfide reductase reactions are also sites of energy conservation. Formation of H_2 from reduced ferredoxin, catalyzed by Ech hydrogenase, might represent an additional energy-coupling site (Fig. 14). On the other hand, activation of acetate to acetyl-CoA requires at least one ATP in *Methanosarcina* spp. and two ATP in *Methanosaeta* spp. Thus, cells must recover the high cost of acetate activation.

When methanol or methylamines are used as energy substrates, the heterodisulfide reductase reaction is also a site of energy conservation. However, the H_4MPT:coenzyme M methyltransferase and the formylmethanofuran dehydrogenase reactions now operate in reverse. Thus, the methyltransferase reaction becomes energy consuming while the oxidation of formylmethanofuran to CO_2 and methanofuran is coupled to energy conservation.

Table 4. Bioenergetic requirements for monomer biosynthesis during growth of methanogens in mineral and rich media.

Growth conditions	Requirement (mmol/g of cell dry wt.) ~P[a]	[2H][b]	Total [2H][c]
Autotrophic growth in mineral	89	97	451
medium + acetate	89	34	388
Rich medium[d]	63	25	276
E. coli minimal medium	21	18	—

[a]ATP equivalents required.
[b]Reductant as NADH or H_2 equivalents required for anabolism.
[c]Includes the H_2 necessary for methanogenesis to make ATP with a stoichiometry of 1 ATP/CH_4.
[d]Includes acetate + the volatile fatty acids for branched chain amino acid biosynthesis + aryl acids for aromatic amino acid biosynthesis + the nucleobases (guanine, adenine and uracil) commonly taken up by the salvage pathway.

Growth Yields

Methanoarchaea possess specialized systems to generate the energy needed for growth from the process of methanogenesis, and they have only a limited capacity to metabolize complex carbon compounds. Even the secondary alcohols, which can serve as electron donors for CO_2 reduction in some species, are only partially oxidized to ketones. About half of the described species of methanogens are capable of autotrophic growth and obtain all of their cellular carbon from CO_2. While the remainder may require organic compounds for growth, these compounds are assimilated into cellular carbon and not extensively metabolized. Compounds typically assimilated include acetate and the volatile fatty acids like isovalerate, 2-methylbutyrate, isobutyrate, and propionate, which are common in anaerobic environments, as well as amino acids.

The inability to assimilate complex organic compounds has profound effects on the energy requirements for growth. On the basis of biosynthetic pathways known and inferred from the genomic sequence, *Methanococcus maripaludis*, a typical hydrogenotrophic methanogen, must expend 89 mmol of ATP equivalents and 97 mmol of [2H] for the biosynthesis of a gram of cells from CO_2 (Table 4). Given that 50% of the cell is carbon, the amount of reductant required is close to 84 mmol of [2H], or the theoretical amount necessary to reduce 42 mmol of CO_2 to the oxidation state of carbon in the cell. Presumably, the difference is due to oxidations that occur during biosynthesis and the approximation of the cell composition. The ATP requirement greatly exceeds that of a typical heterotroph such as *E. coli* growing in a minimal medium. It is also much larger than the approximately 36 mmol ATP (gram of cells)$^{-1}$ required for polymerization reactions, which includes protein, DNA and RNA biosynthesis (Forrest and Walker, 1971; Ingraham et al., 1983). Thus, monomer biosynthesis is the major energy demand for growth of a hydrogenotrophic methanogen, and the assimilation of organic carbon sources may have large effects on their growth.

Many methanogens assimilate exogenous acetate, which is frequently abundant in anaerobic habitats. From the biosynthetic pathways, about 16 mmol of acetyl-CoA are utilized in the biosynthesis of one gram of cells; hence acetate has the potential of providing about 75% of the cellular carbon. Assuming that two ATPs are consumed to active acetate via the high affinity acetyl-CoA synthetase reaction, there is no savings in the ATP requirement for growth when compared with CO_2 fixation (Table 4). If only one ATP is utilized to activate acetate via the low affinity acetate kinase reaction, about 16 mmol of ATP is spared, which is about 18% of the total ATP requirement for monomer biosynthesis. Similarly, methanogens frequently assimilate the branched-chain volatile fatty acids as sources of branched-chain amino acids and aryl acids as a source of aromatic amino acids. Together, these amino acids account for about 25% of the cellular carbon. Assuming that the carboxylic acids are assimilated by an acyl-CoA synthetase reaction requiring two ATP equivalents, followed by ferredoxin-dependent oxidoreductase requiring one ATP equivalent to activate the reductant and one [2H], and an aminotransferase (which requires one ATP and one [2H] to make glutamate), four ATP equivalents and two [2H] are required for each amino acid biosynthesized. Even then, this pathway results in a large reduction in the energy requirements for growth (Table 4).

The maximum cell yields can be estimated. For a hydrogenotrophic methanogen fixing CO_2 as its major carbon source, about 89 and 36 mmol of ATP per gram of cells are required for monomer biosynthesis and polymerization reactions, respectively. Thus, the maximal cell yield is expected to be about 8.0 g of cell dry weight per mol of ATP. For a hydrogenotrophic methanogen obtaining carbon from acetate, the volatile fatty acids and aryl acids, the yield is about 10 g of cell dry weight per mol of ATP. In contrast, for a heterotroph, the maximal cell yield is 28 g of cell dry weight per mol of ATP. For an autotroph using the Calvin cycle of CO_2 fixation, the maximal cell yield is 4.75 g of cell dry weight per mol of ATP (Forrest and Walker, 1971). Thus, while the cell yield of an autotrophic methanogen is considerably less than that of a heterotroph, it theoretically could be nearly twice that of a chemolithotroph using the Calvin cycle.

For comparison, the observed cell yield for methanogens are usually in the range of 1–6 grams of cells per mol of methane, and the measured maximal cell yields are 3–6 grams of cells per mol of methane (Vogels et al., 1988; Tsao et al., 1994; Schill et al., 1996). In the literature, the *Methanosarcina* species appear to have higher growth yields on H_2/CO_2 than *Methanothermobacter* species and others, but these results are from different laboratories and observed under different growth conditions. Following cultivation of two mesophiles, *Methanosarcina barkeri* and *Methanobrevibacter aboriphilus*, under the similar conditions on H_2/CO_2, the cell yields were 4.2 g and 1.4 g of dry cells per mol of CH_4, respectively (R. Hedderich, unpublished data). These results confirmed the lower cell yield among the Methanobacteriales. Possibly, the lower cell yield might result from a different mechanism of coupling methanogenesis to the proton motive force or from higher maintenance energy during growth.

Genomes of the Methanoarchaea

The complete genomes have been sequenced in a representative of every order of the methanoarchaea except the Methanomicrobiales, where only a partial sequence is available (Table 5). The sizes of the genomes vary from 1.6–5.8 Mbp, reflecting the great diversity in this group of organisms (Table 5). In general, the genomes of the hydrogenotrophic methanogens are smaller, in the range of 1.6–1.8 Mbp. Even among these small genomes, the gene content is not highly conserved, and only about two-thirds of the genes in any one organism are likely to be conserved within the methanoarchaea (W. B. Whitman, unpublished observation). The genomes of the methylotrophic methanogens are much larger, in the range of 2.7–5.8 Mbp. In the *Methanosarcina* spp., the large genome seems to have followed the acquisition of a large number of genes from the anaerobic *Firmicutes* (Deppenmeier et al., 2002b) and may be responsible in part for the wide substrate specificity of these organisms (Galagan et al., 2002).

The growth temperature optima of those methanoarchaea whose genomic sequences have been determined are 15–98°C. Thus, it has been possible to make detailed correlations of certain structural features in proteins and nucleic acids with growth temperature (Saunders et al., 2003). The amino acid leucine was highly enriched in

Table 5. Genomic sequences of methanoarchaea.

Organism	Genome size (kbp)	Number of ORFs	Comments	Reference(s)
Methanothermobacter thermautotrophicus)H	1751	1855	Thermophilic hydrogenotroph	Smith et al., 1997

the proteins from organisms with high growth temperatures, while the amino acids glutamine and threonine were highly enriched at low growth temperatures. In addition, the proteins of organisms with high growth temperatures were enriched in the mean fraction of charged residues in the solvent accessible as well as solvent inaccessible areas. Likewise, the contribution of hydrophobic residues to the solvent accessible area decreased with growth temperature. The tRNAs of organisms with high growth temperatures also possessed higher mol% G+C contents, especially in the stem regions (Saunders et al., 2003).

  in sulfite reduction, 680–83
Thiosulfate oxidation, pathway of, 987
Thiosulfate reducers. *See* Dissimilatory thiosulfate reducing bacteria
Thiothrix, 444, 994, 999, 1002–3
Thiothrix ramosa, 444
Thiovulum, 998
Threonine, syntrophic fermentation of, 314
Thylakoids, 48
Tin oxidation, 451
Tindallia magadii, 286
Tissues, bacterial adhesion to, 20–21
T_m. *See* Melting temperature
TM helices. *See* Transmembrane helices
Toxic shock syndrome toxin-1, 900, 903
δ-Toxin, 911
Toxins, bacterial, 893–943
  cell surface activity, 893, 900–914
    cell membrane, 905–6
    immune system, 893, 900–905
    large pore-forming, 906–8
    membrane-perturbing toxins, 911
    other pore-forming toxins, 911–13
    RTX toxins, 910–11

small pore-forming, 908–10
surface molecules, 905
classes and properties of, 894–99, 901
injected into cells, 931–37
apoptosis mediators, 932
cytoskeleton, 933
inositol phosphate metabolism interference, 932–33
signal transduction, 936–37
intracellular activity, 914–31
cytoskeleton structure, 926–27
intracellular trafficking, 928–31
protein synthesis, 914–18
signal transduction, 918–26
release of, 128
structural features of, 899–900
unknown mechanisms, 942–43
Transmembrane (TM) helices, 112
Transmembrane signaling, 112
Transport processes, of planktonic prokaryotes, 3
Transport proteins, 119
Treponema, 365, 375
Treponema denticola, 355
Treponema pallidum, 106, 795
Treponema primitia, 373, 397
Trg, 111, 115–16
Tricarboxylic acid cycle, 62, 65, 447
Trichodesmium, 40, 44–45, 61
Trichomonas vaginalis, 524
Trifolium, 71
Trimethylamine oxidation, 622
Trithionate oxidation, pathway of, 987
tRNA molecules
under low temperature conditions, 234
stabilization of, 185–87
Trophic interactions, 393, 395
True differentiation, life cycles with, 157–63
True phototaxis. *See* Phototaxis
Tsr, 111, 114–16, 123
TTSS. *See* Type III secretion system
Tumbling, 103–4, 105
Tumor-inducing (Ti) plasmid, 342
Twitching, 109–10, 125
Two-component signaling
AHL integration with, 345–48
transduction of, 343–45
Two-state assumption, of protein stability, 178–79
Type III effectors
function of, 427–29
identification of, 426–27
Type III secretion system (TTSS), 128
in pathogenesis, 425–29
structure and components of, 426
Type IV pili, 109–10, 125

U

Universal phylogenetic tree, 198
Unsaturated fatty acids (UFA), biosynthesis of, 231
Upstream box, 216
Uranium, as electron acceptors, 689–90
Uranium oxidation, 451
Uranium reduction, 637–40, 649
Urinary tract
colonization of, 21, 127
prevention of infections of, 25–26
Urine, 21
Uronic acid polymers, 291–92
Uropathogenic bacteria, 21

V

Vaccine
for diphtheria toxin (DT), 916
for pertussis toxin, 919–20
Vacuolating cytotoxin A (VacA), 930–31
Vampirococcus, 71, 72
van der Waals interactions, for protein stability, 181–82
Variable control, by sessile bacteria, 10–11
Vascular wilts, 421
VBNC state. *See* Viable but not culturable state
Verotoxin, 917–18
Vertical migration, 59, 60
flagella v. gas vesicle advantages for, 61–62
in response to light changes, 55
Viable but not culturable (VBNC) state, 237
Vibrio, 8, 9, 234, 237
cold-adapted ammonium uptake system of, 237–38
luminous bacteria, 863, 865–67
Vibrio alginolyticus, 103, 105, 127, 129
Vibrio anguillarum, 127
Vibrio cholerae, 111, 127–28, 213, 865–67, 869–70, 920
Zot, 942
Vibrio fischeri, 347, 865–67, 871–79, 881
LuxI/LuxR system of, 337–38
quorum sensing in, 336–38
Vibrio harveyi, 868, 870, 873–79, 881
multiple systems of, 346–47
quorum sensing in, 345–48
Vibrio logei, 868, 871–72
Vibrio mimicus, 19
Vibrio parahaemolyticus, 219
Vibrio parahaemolyticus, 10–11, 105, 347
Vibrio salmonicida, 243, 865–67, 870, 881
Vibrio splendidus, 868
Vibrio vulnificus, 348, 870
Vibrio yasakii, 869
Vibrionaceae, luminous bacteria, 865–67
VirA, 936
Virulence genes
Erwinia carotovora regulation of, 343
induction of, 21
Pseudomonas aeruginosa regulation of, 339–42
Staphylococcus aureus regulation of, 345
temperature regulation of, 243–45
Viscosity, bacterial behavior influenced by, 102
Viscotaxis, 125

W

Wastewater treatment, with psychrophiles, 242
Water, 169–74
dissociation of, 171
hydration by, 171–72
properties of, 169–71
as solvent, 169–71, 171–74
temperature dependence of, 171
Water environment. *See* Aquatic ecosystems; Freshwater environments; Marine environments
Water quality, influence of iron reducers, 636–37
Wautersia taiwanensis, 799
Whooping cough, 919
Wolinella, 672
Wolinella succinogenes, 108, 319, 322, 513, 519, 529, 646, 665, 725–29, 737–38, 770, 773, 779
anaerobic respiration in, 87–88
Wood, Harland G., 354–55
Wood-Ljungdahl pathway, 354–59, 379
resolution of, 357–59

X

Xanthan gum, 431
Xanthobacter, 619
Xanthomonas, 126
hydrocarbon oxidizers, 570
NLSs, 427
Xanthomonas campestris, 421, 426–31, 433–34
X-ray crystallography
of solutions, 172–74, 177
of thermostable proteins, 193
Xylan
enzymes degrading, 584
as hemicellulose, 580–81
side chains of, 585
Xylanases, 597–98, 608
β-D-Xylosidases, enzymes degrading, 584

Y

Y-box motifs, 213–14, 217
Yersinia, 23, 105, 128
effector proteins of, 427
YopE, 935
YopH, 936

YopT, 935–36
YpkA, 936
Yersinia enterocolitica, 212, 217, 220–21, 243, 427
YopP, 932
Yersinia enterolitica, 24–25
Yersinia pestis, 108
producing YopJ, 932
YopM, 937
Yersinia pseudotuberculosis, 903–4
YopE, 935
YopH, 936
YopJ, 932
YopM, 937
YopP, 932
YopT, 935–36
YpkA, 936

Z

Zonula occludens toxin (Zot), 942
Zooplankton, 10
Zoospores, of Actinoplanetes, 147–48
