Activity	Compounds
	ribalinine, rutacridone, skimmianine, tryptanthrin, 1-Methyl-2-undecyl-4-quinolone, dihydroevocarpine, evodiamine, rutaecarpine [25–30, 32, 35–39, 41, 50, 53, 54, 69, 155, 158, 160, 162].
Antiplatelet activity	2-Phenylquinolin-4(1*H*)-one, 4methoxy-1-methylquinolin-2-one, atanine, confusadine, confusameline, dictamnine, dutadrupine, evolitrine, γ-fagarine, graveoline [1-methyl-2-(3,4-methylenedioxyphenyl)quinolin-4(1*H*)-one], graveolinine [4-methoxy-2-(3,4-methylenedioxyphenyl) quinoline], haplopine, kokusaginine, robustine, skimmianine [28, 33, 34, 37, 41].
Insecticide, antifeedant, nematicide activities	1-Hydroxy-3-methoxy-*N*-methylacridone, *rel*-(3*R*,4*R*)-(-)-3-Methoxy-4,5-dihydroxy-4-(4-methoxyphenyl)-3,4-dihydroquinolin-2-one, *rel*-(3*R*,4*R*)-(-)-3-Methoxy-4-hydroxy-4-(4-methoxyphenyl)-3,4-dihydroquinolin-2-one, arborinine, atanine, dictamnine, evolitrine, leiokinine A and B, *N*-methylquinolinium-2-carboxylate, penigequinolone A and B, (-)-peniprequinolone, quinolactacide, vasicine, vasicinol, vasicinone, xanthoxoline [22, 25, 29, 33–36, 39, 41].
Miscellaneous biological activities	
Inhibitory effect on germination	2-(Pent-1-enyl)quinoline, 2-*n*-pentylquinoline, 2-*n*-propylquinoline, graveoline [38, 41].
Anti-HIV activity	1-Hydroxy-*N*-methylacridone, 2-(pent-1-enyl)quinoline, 2-(pent-2-en) quinolin, 2-acetyl-4(3H)-quinazolinone, 2-*n*-pentylquinoline, 3-prenyl-4-prenyloxyquinolin-2-one, 4-methoxy-1-methylquinolin-2-one, *N*-methyl-3,3-diprenylquinoline-2,4-dione, buchapine, γ-fagarine, haplopine, (+)-platydesmine, uranidine [28, 30, 34, 38, 40, 41].
Muscle relaxant	Eduline, japonine [41, 43].
Estrogenic activity	1-Methyl-2-phenylquinolin-4(1*H*)-one, acutine [41].
Anti-inflammatory activity	Toddaliopsins A–D, tryptanthrin [40, 155].
Neurodegenerative diseases	Dictyoquinazols A–C [37].
Phtotoxicity (anti-psoriasis activity)	7-Desmethylskimmianine, 8-methoxypsoralen, dictamnine, isodictamnine, maculine, maculosidine [152].
Potassium channel blockers	Dictamnine, γ-fagarine, kokusaginine, *ent*-(-)-platydesmine, robustine, skimmianine [35].
Antiarrythmic activity	Acrophyllidine [34].
Vasorelaxing activity	Atanine, vasicinone [33, 91].
Pollen-growth inhibitors	Penigequinolones A and B [31].
Anti-inflammatory and antihypertensive	2-(2-Hydroxy-4-methoxyphenyl)-5,8-dimethoxy-3-propylquinoline-4(1*H*)-one, 5,6-Dimethoxy-2-(2,5,6-trimethoxyphenil)-1*H*-quinoline-4(1*H*)-one, 5,8-Dimethoxy-2-(2,3-dimethoxyphenil)-3-propylquinoline-4(1*H*)-one, 5,8-dimethoxy-2-(3-methoxyphenyl)-3-propylquinoline-4(1*H*)-one, (−)-Benzomalvin A, quinazoline-2,4-dione [28, 31, 88].
Endotoxic to limulus amoebocyte lysate test	3-(2-Carboxyphenyl)-4(3*H*)-quinazolinone [31].

(*continued*)

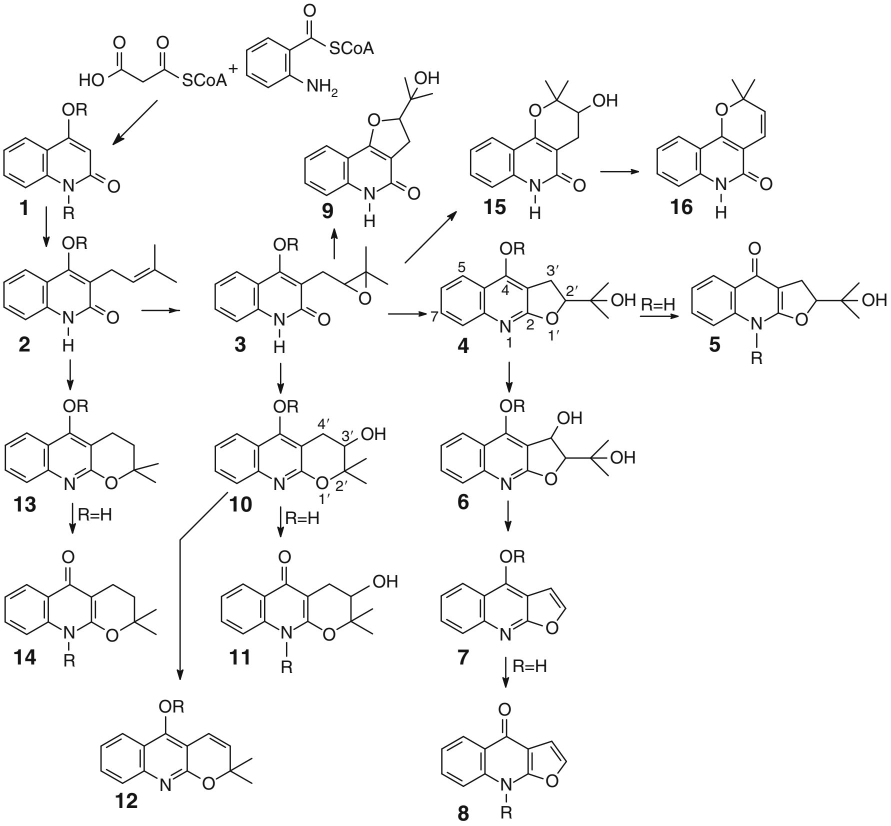
Table 24.32 (continued)

Activity	Compounds
Tremor and paralysis effects	27-*Epi*-nortryptoquivaline, 27-*epi*-tryptoquivaline, tryptoquivaline [31].
Pharmacokinetic	Dihydroevocarpine, evocarpine [26].
Raising body temperature	Evocarpine, evodiamine [25].
Anticoccidial	*Cis* and *trans* febrifugine [25].
Oxytocin effect and stimulation of muscular contraction	Vasicine [24].
Antispasmodic activity	Citracridone-I [22].
Antioxidant activity	4-Amino-6-hydroxyquinoline-8-carboxylic acid, 6-hydroxyquinoline-8-carboxylic acid, 7-hydroxy-1-oxo-1,2-dihydroisoquinoline-5-carboxylic acid, kokusaginine, Ophiuroidine (4,8,9-trihydroxyindolo[2,1-b] quinazoline-6,12-dione), quinosuaveoline B, skimmianine, tecleaverdoornine [57, 58, 63, 85].
Antiviral activity	5-Methoxydictamnine, dictamnine, glycofolinine, glycosparvarine [60,76].
Antiallergic activity	Buxifoliadine-E, citrusinine-I, *N*-methylcyclo-atalaphylline-A [72].
Phagocyte oxidative burst	Balsacridone A, balsacridone B, citracridone I, citracridone III, 5-hydroxynoracronycine [81].

A group of polycyclic quinoline alkaloids formally incorporating a geranyl group at C-3 form a tetracyclic skeleton by acid-catalyzed reaction (Scheme 24.9). Four of these compounds were isolated from *Halfordia kendak* (Rutaceae), *trans*-erioaustralasine (**31**, R = CH_2OAc), *trans*-deacetoxyerioaustralasine (**31**, R = Me), *trans*-deacetoxyerioaustralasine hydrate (**32**, α-tertiary hydroxyl, R = Me), *trans*-erioaustralasine hydrate (**32**, α-tertiary hydroxyl, R = CH_2OAc), *trans*-epideacetoxyerioaustralasine hydrate (**32**, β-tertiary hydroxyl, R = Me) (Table 24.8).

Acridone alkaloids are unique metabolites of the Rutaceae plant family (Table 24.11), with only few exceptions reported from single genera of the Asteraceae (Table 24.12), Simaroubaceae (Sapindales, Table 24.12), Piperaceae (Table 24.14), and Apocynaceae (Table 24.16). *Ruta graveolens* accumulates *N*-methylated acridones exclusively (Tables 24.11 and 24.13), whereas *N*-acetoxymethyl- and *N*-methoxymethylacridones were isolated recently from the south-central African plant *Toddaliopsis bremekampii* (Table 24.11), and a few unmethylated acridones have been reported from other genera (Tables 24.11, 24.13, and 24.15). The latter compounds conceivably derive from *N*-methylacridones, analogous to the formation of nornicotine from nicotine [113, 114].

An acridone synthase responsible for the conversion of *N*-methylanthraniloyl CoA and malonyl CoA into 1,3-dihydroxy-*N*-methylacridone (**33**, Scheme 24.10) has been purified from cell suspension cultures of *Ruta graveolens* and characterized [115, 116]. The essential *N*-methylation of the starter substrate was supported also by the anthranilate *N*-methyltransferase activity detected in crude extracts of *R*. *graveolens* cells [117].



Scheme 24.1 Biosynthesis (for **4** and **7**) and biogenesis of the quinolin/one alkaloids

These data have firmly established that, in *R. graveolens* at least, *N*-methylation of anthranilate prior to CoA ligation is crucial for acridone alkaloid formation. Thus, acridones arise from condensation of the starter substrate *N*-methylanthraniloyl CoA with three units of malonyl CoA, which are modified further by prenylation and cyclization reactions to more complex furo- or pyranoacridones (Scheme 24.10). The biosynthesis of rutacridone (**34**, 1″,2″-dehydro) in cell suspension cultures of *R. graveolens* from 1,3-dihydroxy-*N*-methylacridone and hemiterpenoid pyrophosphates via glycocitrine II (**33**, 1,3-diOH, 4-$CH_2CH = CMe_2$, 10-Me) has been investigated [118, 119]. The enzyme acridone synthase catalyzes all these steps and belongs to the family of plant type III polyketide synthases (PKSs) [120]. A group of acridone alkaloids formally incorporating a geranyl group at C-2 form a 2′-(4-methyl-3-penteneyl) pyranoacridone (**41**, Scheme 24.10).

No data is available on the biosynthesis of dimeric acridone alkaloids, which have been found in Rutaceae. Acridone-coumarin/xanthone/lignin dimers have also been found in Rutaceae (Table 24.17). The bark of the New Caledonia tree *Sarcomelicope megistophylla* (Rutaceae) have yielded an intriguing range of

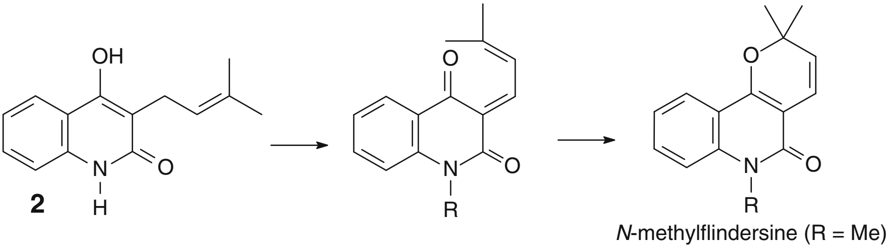
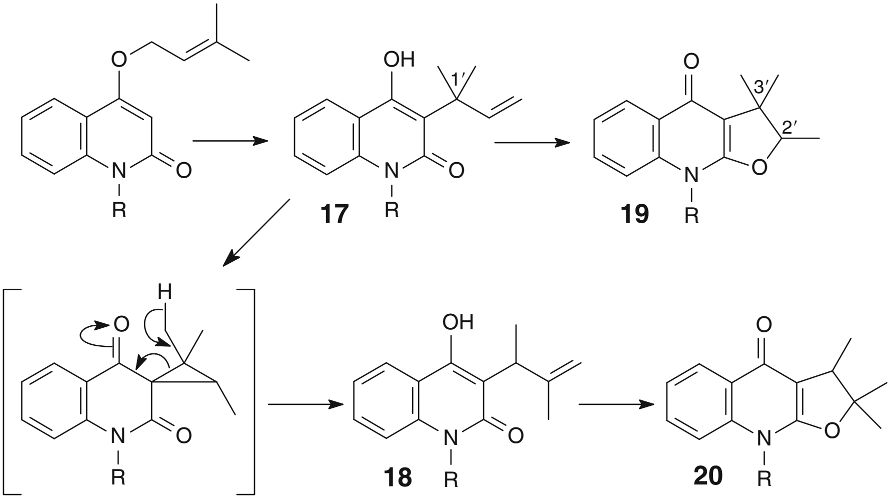
Mechanism as proposed by Fersht and coworker [141], in which pyridine catalysis involves initial formation of an acyl pyridinium ion, which then reacts with the alcohol



Scheme 24.3 Synthesis of piranoquinolin-2-one

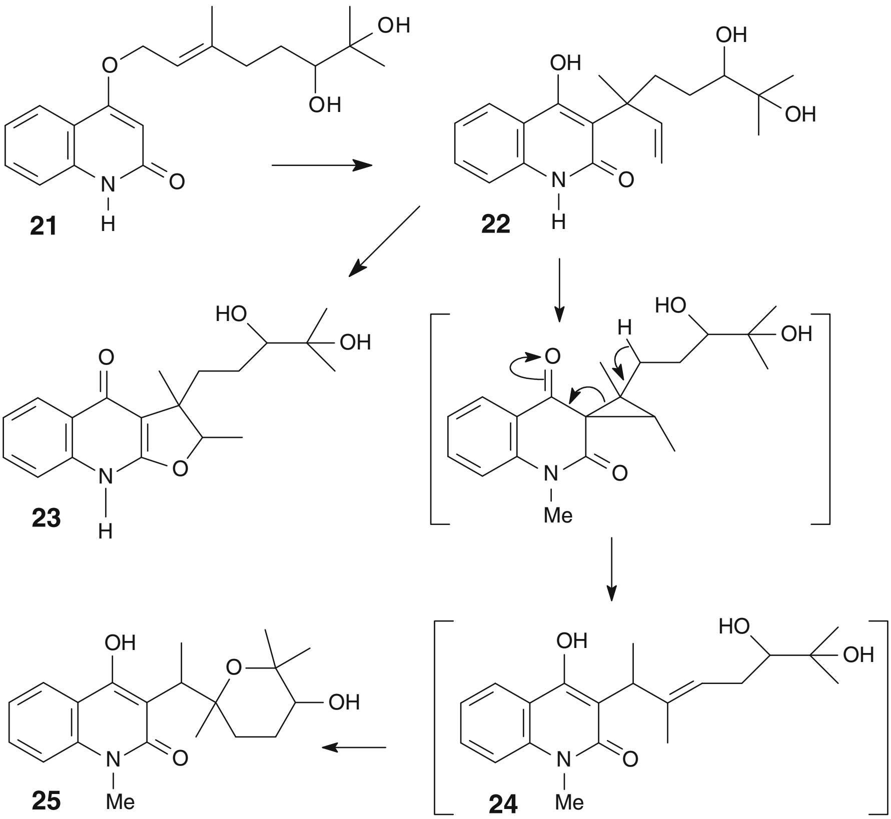


Scheme 24.4 Biogenetic pathway for the formation of quinolin-2(1*H*)-/4(1*H*)-one alkaloids by Claisen rearrangement of the prenyl ether

unprecedented acridone alkaloids, all of which are conceivably formed from highly oxygenated acridones such as melicopicine (**45**) by oxidative cleavage of ring B (Scheme 24.11). The structural similarity are clearly apparent in the (+)-sarcomejine (**47**), (−)-megistolactone (**46**), and cyclomegistine (**48**) [41]. The biosynthetic origins of megistonine I [**49**, R, R_1, R_2 = Me, R_3 = H, R_4 = 3,3-dimethylallyl] and II [**49**, R, R_1, R_2 = Me, R_3 = H, R_4 = OMe] are less obviously ascribable to acridone oxidation [41].

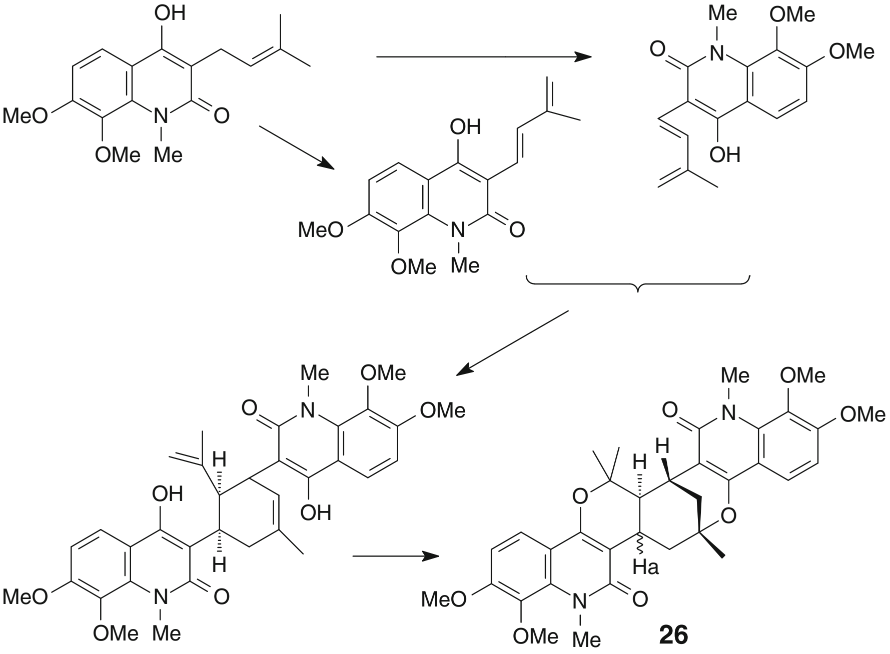
2.2 Alkyl, Aryl, Alkylarylquinoline Alkaloids

Many 2-alkylquinolin/4(1*H*)-one alkaloids bear the trivial names pseudans because of their occurrence in bacteria of the genus *Pseudomonas*. For example, *P. aeruginosa* is a ubiquitous gram-negative bacterial pathogen that causes infections not only in human hosts but also in animals and even plants.

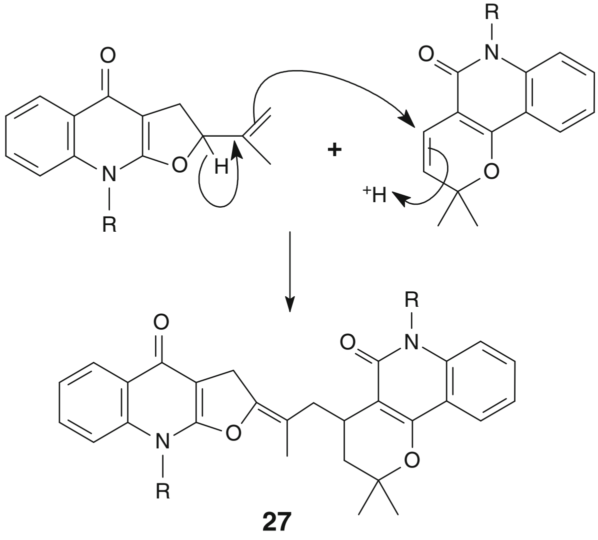


Scheme 24.5 Biogenetic pathway for the formation of quinolin-2(1*H*)-/4(1*H*)-one alkaloids by Claisen rearrangement of the geranyl ether

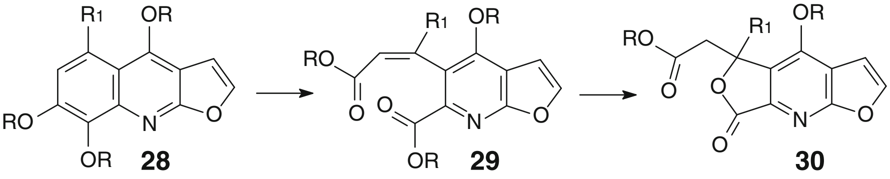
This pathogen has been identified as one of the leading causes of nosocomial infections and is responsible for fatal chronic lung infections in patients with cystic fibrosis (CF). *P. aeruginosa* coordinates its population behavior, such as biofilm formation and virulence factor production, by means of small extracellular signal molecules, so-called autoinducers, that are released into the environment under appropriate conditions. Since intercellular communication leads to cooperative and coordinated bacterial behavior in a cell density-dependent manner, it is referred to as quorum sensing. A common feature of intercellular communication is the transcriptional activation of quorum-sensing-controlled genes when the bacterial signal molecules reach a certain threshold. *P. aeruginosa* produces two major cell-to-cell signals that are members of the *N*-acyl-homoserine lactones and 4-hydroxy-2-alkylquinolines. The latter include in addition to N oxides, 3,4-hydroxy-2-heptylquinoline and 4-hydroxy-2-heptylquinoline. The latter two molecules have been shown to be involved in intracellular communication. Analysis of the underlying metabolic events of intercellular bacterial communication and elucidation of the biosynthesis of the signal molecules might contribute to the understanding and



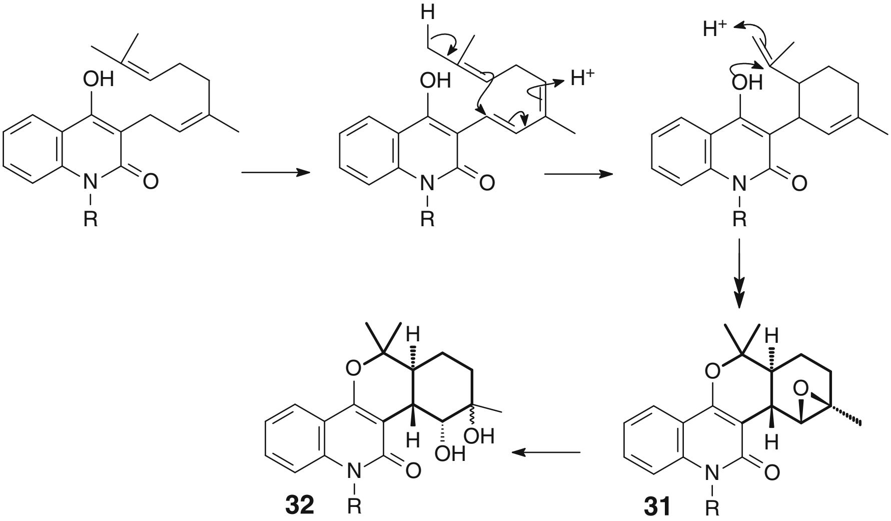
Scheme 24.6 Biogenetic pathway for the formation of dimeric quinolin-2(1*H*)-one alkaloids by Diels-Alder addition of prenyl dienes



Scheme 24.7 Biogenetic pathway for the formation of dimeric quinolin-2(1*H*)-/4(1*H*)-one alkaloids by acid-catalyzed reaction

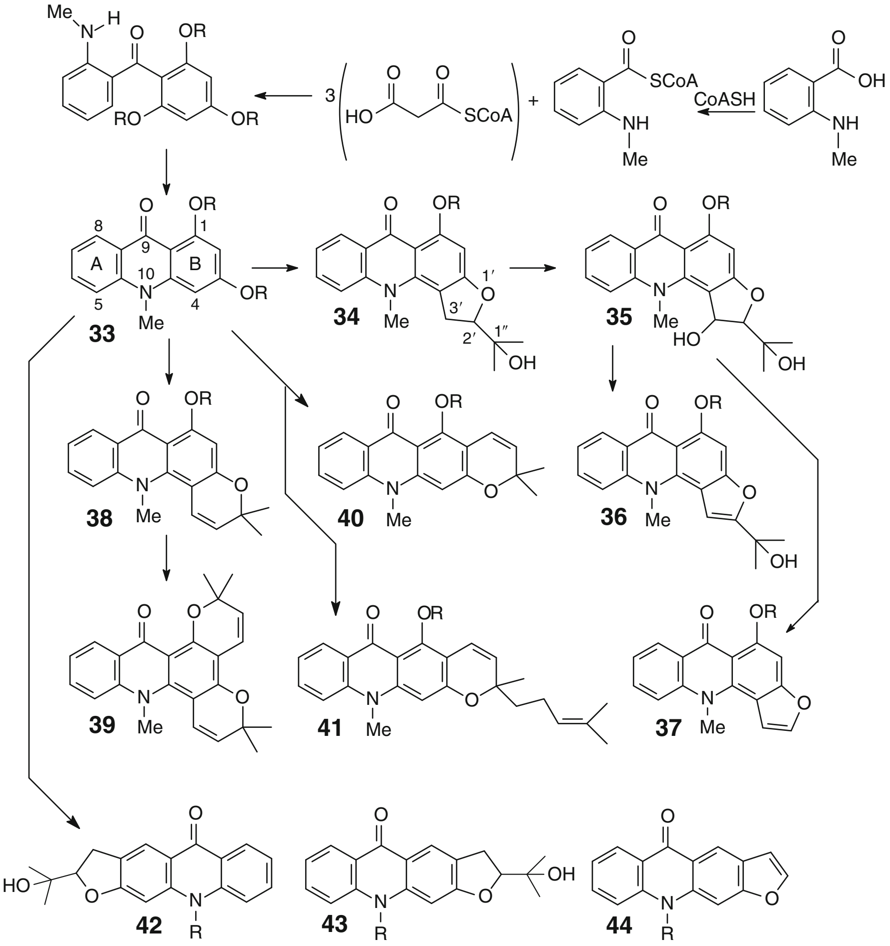


Scheme 24.8 Biogenesis of *seco*-furoquinoline alkaloids



Scheme 24.9 Biogenetic pathway for the formation of polycyclic quinolin-2(1*H*)-one alkaloids by acid-catalyzed reaction

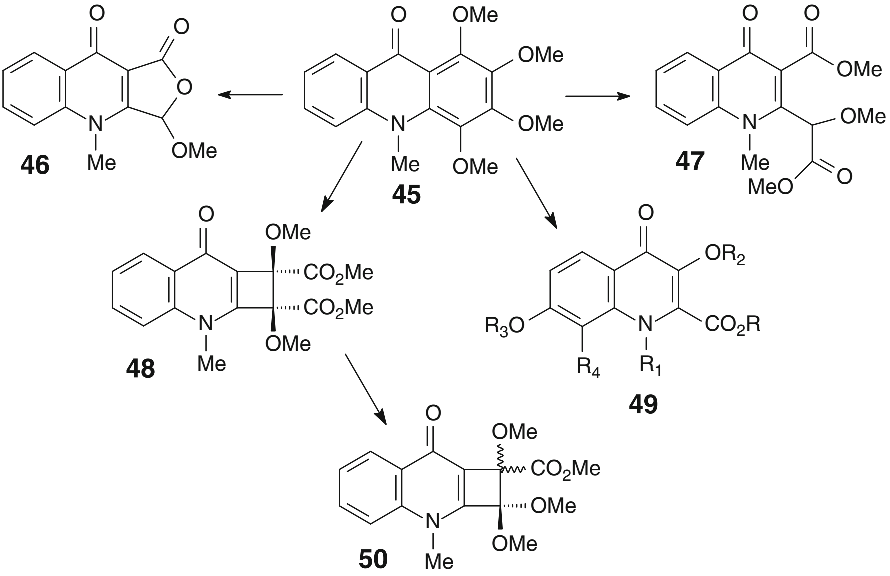
provide an opportunity to interfere with the control of virulence factor production. Moreover, a 2-heptyl-3-hydroxyquinolin-4(1*H*)-one biosynthetic gene cluster has been identified. This *pqsABCDE* operon codes for a putative coenzyme A ligase (*pqsA*), two β-keto-acyl-acyl carrier protein synthases (*pqsB*, *pqsC*), and a FabH1 homologous transacetylase (*pqsD*), whereas *pqsE* seems to encode a response effectors protein which itself is not involved in the biosynthesis of 2-heptyl-3-hydroxyquinolin-4(1*H*)-one. Although, it has clearly been demonstrated that the *pqsABCD* genes are essential for 2-heptyl-3-hydroxyquinolin-4(1*H*)-one biosynthesis, their enzymatic function remains to be elucidated [121–123]. Previous studies strongly suggested that anthranilic acid and a β-keto-acid are precursors of 2-alkylquinolin-4(1*H*)-ones [124, 125]. Further studies using feeding experiments with labeled isotopes, confirmed by gas chromatography (GC)-mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy that *P. aeruginosa* synthesizes 2-alkylquinolin-4(1*H*)-ones via a common biosynthetic pathway involving the "head-to-head" condensation of anthranilic acid and β-keto fatty acids (Scheme 24.12). Moreover, 2-heptyl-3-hydroxyquinolin-4(1*H*)-one biosynthesis



Scheme 24.10 Biosynthesis (for **33** and **34**, 1″,2″-dehydro) and biogenesis of the acridone alkaloids

seems to be dependent not only on an intact *pqsABCD* operon but also on the availability of β-keto acids. Interestingly, at least some of these acids seem to be derived from a common pool of β-hydroxy-keto acids involved in rhamnolipid biosynthesis [123].

A search of completed and uncompleted microbial genomes revealed that several species belonging to the genera *Pseudomonas* and *Burkholderia* as well as the plant pathogen *Ralstonia* contain putative homologs of the *P. aeruginosa* pqs biosynthetic genes pqsA, pqsC, and pqsD, respectively. However, apart from *P. aeruginosa*, only strains of the primary human pathogen, *B. pseudomallei* and the serologically and genetically related *B. thailandensis* were found to contain a

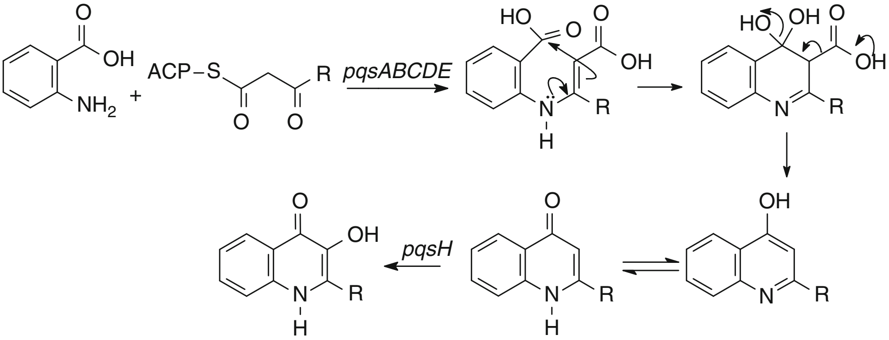


Scheme 24.11 Biogenesis of the *seco*-acridone alkaloids

complete, putative pqsABCDE operon located on chromosome 2. Interestingly, neither *B. pseudomallei* nor *B. thailandensis* possess a homolog of the *P. aeruginosa* pqsH gene. This gene facilitates the conversion of 2-heptylquinolin-4(1*H*)-one to 2-heptyl-3-hydroxyquinolin-4(1*H*)-one (Schemes 24.12 and 24.13) in *P. aeruginosa*, and its absence from *B. pseudomallei* would suggest that production of 3,4-hydroxy-2-heptylquinoline was unlikely in this organism [126].

No data is available on the biosynthesis of 2-alkylquinoline/4(1*H*)-one alkaloids from anthranilic acid in plant. However, the structures of many alkaloids isolated, especially from the Rutaceae (Tables 24.18, 24.23, and 24.24), have provided much indirect evidence for the route proposed at Scheme 24.13.

Aurachins (A-I, K, L, P) from *Stigmatella aurantiaca* strain Sg a15 are classified as A-type aurachins (A, B, F, P), which are C-3 oxygen-substituted quinolines carrying a farnesyl residue on C-4, C-type aurachins (C, D, G, H, I, K, L) are C-4 oxygen-substituted quinolines carrying a farnesyl residue on C-3, and C-type aurachin E has a [1,1a,8,d]imidazoloquinoline structure (Schemes 24.14, 24.15). Feeding of ^{13}C-labeled precursors showed that the quinoline ring is constructed from anthranilic acid and acetate, and the farnesyl residue from acetate by both the mevalonate and nonmevalonate pathways [84]. Further, feeding of labeled aurachin C indicated the A-type aurachins are derived by a novel intramolecular 3,4-migration of the farnesyl residue that is induced by a 2,3-epoxidation and terminated by a reduction step. ^{18}O-Labeling experiments indicated the new oxygen substituents originate from atomospheric oxygen [84]. On the basis of these results a biosynthetic scheme covering all aurachins is proposed (Schemes 24.14, 24.15). Insight into the loading process of anthranilate into the biosynthetic pathway for the



Scheme 24.12 Biosynthesis of a pseudan [41]

quinoline alkaloids aurachins has been provided by the sequencing of a partial biosynthetic gene cluster in the myxobacterium *Stigmatella aurantiaca*. The cluster encodes a predicted aryl: CoA ligase AuaE that was hypothesized to activate and transfer anthranilate to the acyl carrier protein AuaB [127, 128]. However, gene inactivation and in vitro experiments described by Pistorius and coworkers [129] contradicted this model. Aided by the genome sequence of *S. aurantiaca*, they identified an additional aryl:CoA ligase homologue, AuaEII, encoded in a different gene operon, which is additionally required for anthranilate priming. They report the characterization of both enzymes and the elucidation of a novel non-acetate priming strategy in thio-templated biosynthetic machineries (Scheme 24.14).

2-Geranylquinolin-4(1*H*)-ones were isolated from bacterium *Pseudonocardia sp.* (CL38489; Table 24.28) [41] and their biogenesis may involve direct reaction between a quinoline or quinolin-4(1*H*)-one and geranyl diphosphate, but chemical reactions do not justify this route, because quinoline and quinolin-4(1*H*)-one are insufficiently nucleophilic at C-2 for that reaction to occur readily. Another reasonable biogenesis for them may involve direct reaction between a quinolin-4(1*H*)-one and linalyl diphosphate (LPP) by Michael addition at C-2 to give 1-methyl-2-(3-hydroxy-3,7-dimethyl-octa-1,6-dienyl)quinolin-4(1*H*)-one of naturally occurring (**60**, **61**; Scheme 24.13, Table 24.28) [41]. Therefore, they are of uncertain biogenetic origin, it is not known whether they are formed via a biosynthetic pathway involving the condensation of anthranilic acid and β-keto intermediate with one acetate unit attached to the geranyl group (**60**, **61**; Scheme 24.13) [41]. Höfle and Kunze [84] based in Aurachins experiments proposed that 2-geranylquinolin-4(1*H*)-ones are formed by rearrangement mechanisms similar to that for A-type aurachins (Scheme 24.16).

3-Phenylquinolines (**62**), previously unknown as natural products, are surprising new metabolites of the Chinese medicinal plant *Peganum nigellastrum* (Zygophyllaceae; Table 24.21) [41]. The same plant source also yielded unusual mixed alkaloids 3-(1*H*-indol-3-yl)quinoline (**63**) and quinoline-quinazoline (**64**) (Scheme 24.17). The biogenesis of the latter was plausibly suggested to be from pegamine, a quinazoline alkaloid found in *P. nigellastrum* [41]. Oxidation

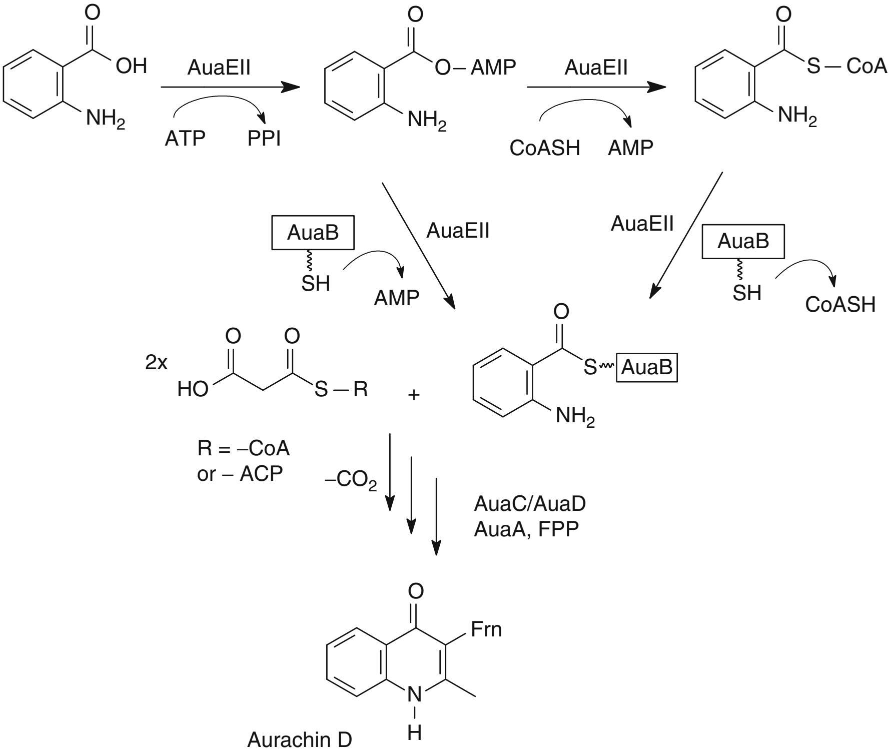
Scheme 24.13 Biogenesis of the quinolin and alkylquinolin/4(1*H*)-one alkaloids



Scheme 24.14 Biosynthesis for Aurachin D alkaloid [129]

of pegamine to the corresponding aldehyde followed by imine formation with anthranilic acid was suggested to produce an intermediate imine, cyclisation and further elaboration of which leads to the luotonin F (**64**) (Scheme 24.17). Thus, it seems likely that quinoline-3-carboxamide (**65**) is a product of oxidative cleavage of luotonin F (Table 24.21). Therefore, these compounds do not have the same biogenetic origin observed in other 3-substituted quinolines. Phenylquinolines and 3-(1*H*-indol-3-yl)quinoline likely are derived from quinoline, however a mechanism for the formation of them is not clear. They may be produced by the coupling of two phenolic or phenolic and indol systems, by means of free radical reactions, as occur in lignans found in Zygophyllaceae [130].

Blaschke-Cobet and coworkers [131] have shown that the non-anthranilate portion of the 2-arylquinolin-4(1*H*)-one of graveoline of *Ruta graveolens* is derived from the decarboxylation and deamination of phenylalanine. Feeding experiments with labeled isotopes in *R. graveolens* indicated that the hydroxylation to the aromatic ring precede cyclization to the quinolin-4(1*H*)-one system. A β-keto ester and a 3-carboxyquinolin-4(1*H*)-one are probable intermediates in the biosynthesis of graveoline (**66**) (Scheme 24.18).

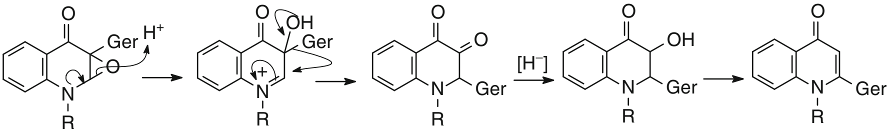
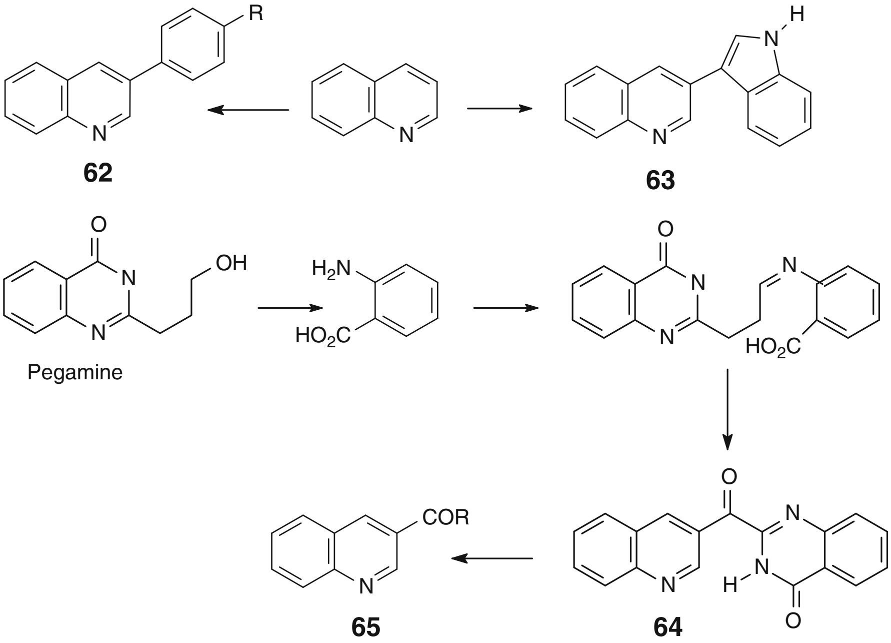
Scheme 24.15 Biosynthesis (for Aurachin A–D) and biogenesis of the Aurachin alkaloids



Scheme 24.16 Biogenesis of the 2-geranylquinolin-4(1*H*)-one alkaloids [84]

No data is available on the biosynthesis of alkaloids of rutaverine type found in *R. graveolens* (Table 24.26), in which quinolin-4(1*H*)-one and phenyl ring systems are separated by a multiple carbon chain (2-alkylarylquinolin-4(1*H*)-ones). A similar pathway to that leading to graveoline (**66**), but involving condensation of β-keto intermediate with more than one acetate unit to give a polyketide chain attached to the carboxylic acyl group of the amino acid can be proposed.

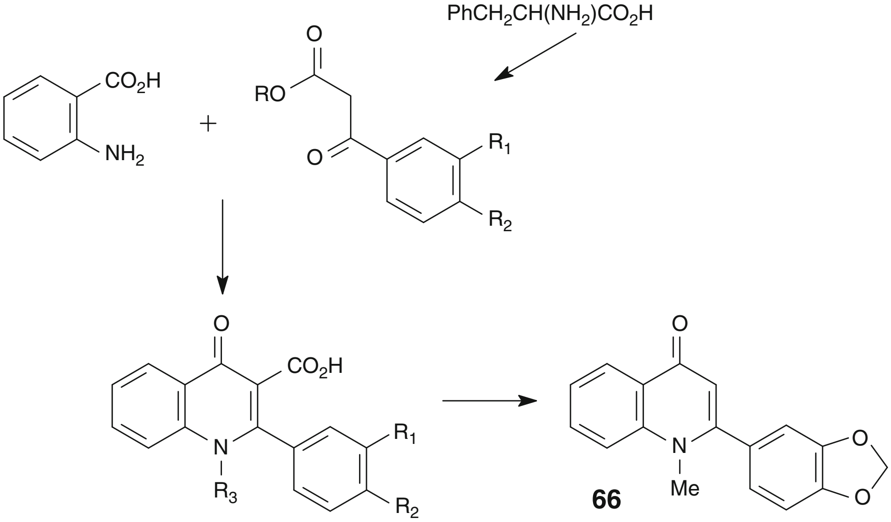


Scheme 24.17 Biogenesis of 3-substituted quinolines

It condenses with anthranilate to form the 2-alkylarylquinolin-4(1*H*)-ones. Direct supports for biogenetic ideas through the appropriate labeling studies are little from Rutaceae, but the structures of many aryl- and alkylaryquinolin/ones isolated from the rutaceous genus (Tables 24.19, 24.20, 24.26), have provided much indirect evidence for the route proposed at Schemes 24.19 and 24.20.

The coexistence of the NH-quinolin-4(1*H*)-one and 4-hydroxyquinoline isomers has been confirmed by spectrometric analysis. However, the exclusive NH-4-oxo nature of these compounds in solution phase (NMR) and solid state (IR and X-ray) have been corroborated [132]. For example, galipoline, isolated from *Angostura trifoliata* (Table 24.20), has a potential to exist in the tautomeric equilibrium (Scheme 24.21), explaining a number of reports which have appeared showing the structure of galipoline [1, 44] as 2-(3,4-dimethoxyphenylethyl)-4-hydroxyquinoline or 2-(3,4-dimethoxyphenylethyl)quinolin-4(1*H*)-one [44]. A number of reports have been confirmed the carbonyl nature by ^{13}C NMR of NH-2-alkylquinolin-4-one, indicating the predominance of the NH-oxo forms, which are widely distributed in rutaceous genus and *Pseudomonas* species (Tables 24.23, 24.28).

Novel quinolone antibiotics, quinolactacins A-C (Schemes 24.22 and 24.23; Table 24.28) were first discovered from the cultured broth of *Penicillium* sp. EPF-6, which was isolated from the larvae of the mulberry pyralid (*Margaronia pyloalis* Welker) [41]. More recently, the two quinolactacin A diastereomers were isolated from solid-state fermentation of *Penicillium citrinum* 90648 and named



Scheme 24.18 Biosynthesis of graveoline in *Ruta graveolens* L [131]

quinolactacin A1 and quinolactacin A2. The relative configuration of quinolactacin A2 is assumed to be the same as that of the originally assigned quinolactacin A from the cultured broth of *Penicillium* sp. EPF-6 on the basis of spectroscopic analysis. Quinolactacin A1 is the C-1′ diastereomer of A2 [41]. Further studies with *Penicillium citrinum* VKM FW-800 obtained from the permafrost region of Northern Russia, led to the isolation of the (+)-quinocitrinine A and (−)-quinocitrinine B, which are diastereomers at the C-1′ and C-9 stereocentres [41]. These compounds are the first pyrrolo[3,4-*b*]quinoline-types isolated from microbial metabolites. The structures are unique in that a quinolone skeleton is conjugated with a γ-lactam ring. A biomimetic total synthesis of quinolactacin B has been reported by Tatsuta's group [133]. A new enantioselective synthesis of quinolactacins A2 and B, via skeletal rearrangement of a β-carboline to the pyrrolo[3,4-*b*]quinolin-4(1*H*)-one system by an oxidative process, confirmed the absolute configuration of quinolactacin B as assigned by the literature, (S)-(−)-quinolactacin B [134]. It also established both absolute configurations of quinolactacins A1 and A2, which have not been clearly determined. Quinolactacin A2 was obtained as a single enantiomer and C-9 and C-1′ stereochemistry were established as the *S* configuration (9S, 1'S). Via the same synthetic route a pair of C-1′ diastereomers were obtained. Chiral HPLC was used for separation of these two diastereomers. From ^{1}H NMR of the diastereomeric mixture, the C-1′ diastereomer of quinolactacin A2 could be differentiated by comparison of the spectrum of A2. The spectrum was in agreement with the data of quinolactacin A1 [41, 134]. This result confirmed quinolactacin A1 is the C-1′ diastereomer of A2 (9S, 1'R) [134]. The first synthesis suggested that these compounds might be biologically synthesized from three components, amino acids L-valine and L-isoleucine, anthranilic acid, and acetic acid [133] (Schemes 24.22, 24.23).

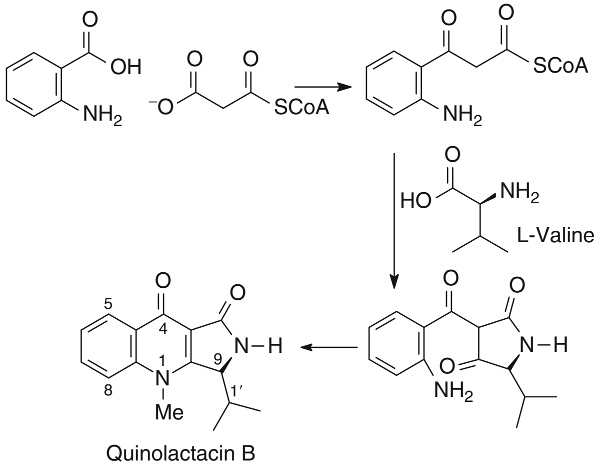
Scheme 24.22 Biogenesis of quinolactacin B from anthranilic acid



Quinolactacin A1 does not appear to have the same biogenetic origin observed in quinolactacin A2, since other possible isoleucine stereoisomer is not generally found in living organisms. In addition, the β-carbon is insulated from the amino and carboxy groups which by electron-withdrawing effects and resonance stabilization promote epimerization at the α-position. Thus, the β-epimerization rates of the isoleucine are predicted to be extremely slow in comparison to their α-epimerization rates. Quinolactacin C was also found in *Penicilliun* genus, leading to the hypothesis that the quinolactacin A1 is not derived from β-epimerization, but perhaps from the former by elimination of H_2O and subsequent hydrogenation producing the C-1′ diastereomer of A2 (Scheme 24.23). However, the stereochemistry at the two stereogenic centers in quinolactacin C was not elucidated. A new quinolactacin with a pyrrole ring (quinolactacide) was isolated from *Penicillium citrinum* Thom F 1539 [41]. The additional ring could be formed from quinolactanin C by oxidation of methyl group at C-1′, decarboxylative elimination ($-CO_2$ and $-H_2O$) and subsequent oxidative cyclization (Scheme 24.23).

The second synthesis, which suggested pyrrolo[3,4-*b*]quinolin-4(1*H*)-one system to derive from tryptamine [134], is other alternative pathway (Scheme 24.24). This route using the keto acid derived from amino acid L-leucine (or L-valine) by transamination and tryptamine, under some stereochemical control, can also form quinolactacins stereospecifically as C-9 (*S*)-diastereomer (Scheme 24.24). Biological oxidation of indol ring by tryptophan 2,3-dioxygenase could form the 3-hydroperoxy-β-carboline, subsequent intramolecular addition of 3-hydroperoxy to iminium ion at C-2 followed by heterolytic cleavage of the peroxide bond would give the dione intermediate, which rearrange to quinolin-4(1*H*)-one. For convenience the first proposals were codified. Therefore, any proposal cannot yet be regarded as the main pathway, proofs are required.

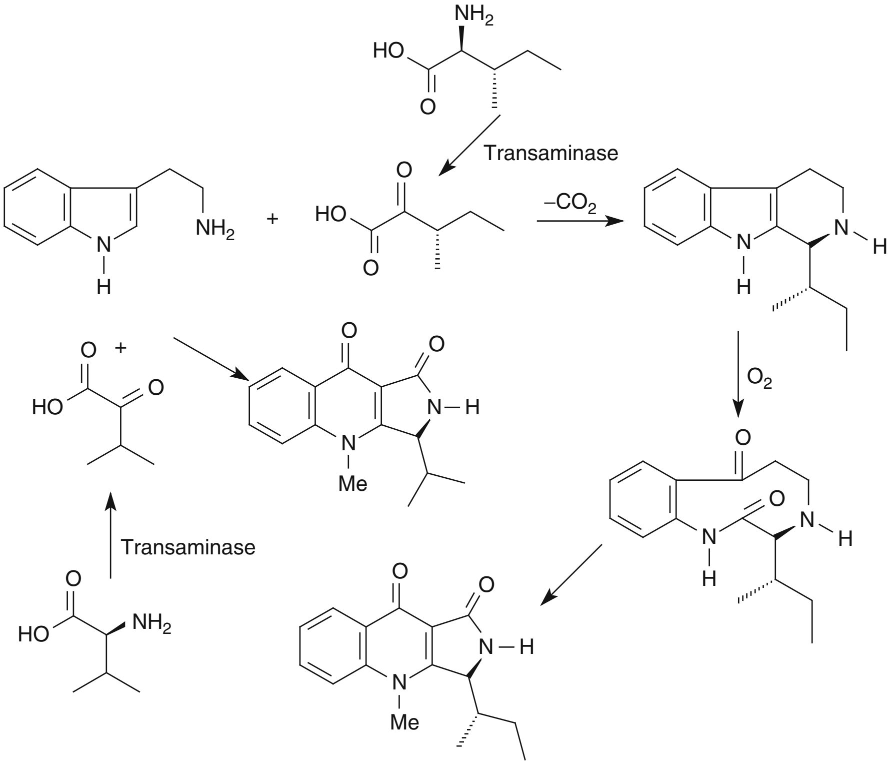
2.3 Quinazoline Alkaloids

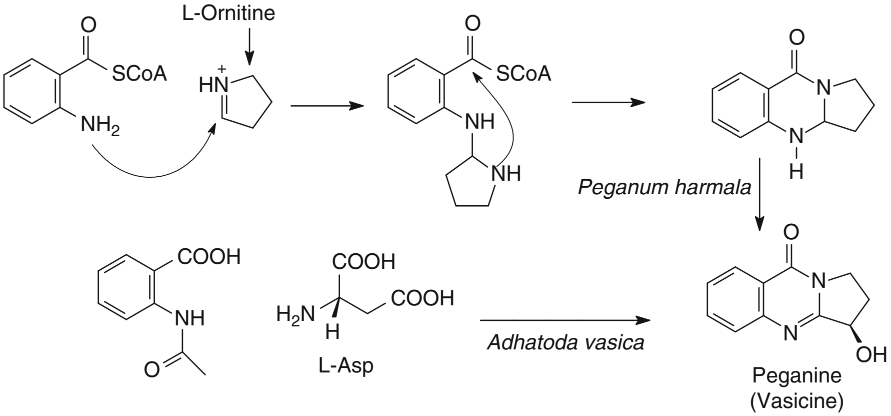
Quinazolinone is a building block for naturally occurring alkaloids isolated to date from a few of families of the plant kingdom, from animals, and from microorganisms (Tables 24.29–24.31). The first known quinazoline alkaloid was vasicine isolated from *Adhatoda vasica* (Acanthaceae). The alternative name peganine is also used for vasicine, which is found in *Peganum harmala* (Zygophyllaceae). Few data are available on the biosynthesis of these alkaloids, studies in *Peganum harmala* have clearly demonstrated peganine to be derived from anthranilic acid, the remaining part of the structure being a pyrrolidine ring supplied by ornithine (Scheme 24.25). Remarkably, this pathway is not operative in *Adhatoda vasica*



Scheme 24.24 Biogenesis of quinolactacins A2 and B from tryptamine

(*Justicia adhatoda*), and a much less predictable sequence from *N*-acetylanthranilic acid and aspartic acid is observed (Scheme 24.25) [135–140].

Aspergillus fumigatus Af293 is a known producer of quinazoline natural products, including the antitumor fumiquinazolines, of which the simplest member is fumiquinazoline F with a 6-6-6 tricyclic core derived from anthranilic acid, tryptophan, and alanine (Scheme 24.26). Fumiquinazoline F is the proposed biological precursor to fumiquinazoline A in which the pendant indole side chain has been modified via oxidative coupling of an additional molecule of alanine, yielding a fused 6-5-5 imidazoindolone. Ames and coworkers [94] identified fungal anthranilate-activating nonribosomal peptide synthetase (NRPS) domains through bioinformatics approaches. One domain previously identified is part of the trimodular NRPS Af12080, which the authors predict is responsible for fumiquinazoline F formation. They also show that two adjacent *A. fumigatus* ORFs, a monomodular NRPS Af12050 and a flavoprotein Af12060, are necessary and sufficient to convert fumiquinazoline F to fumiquinazoline A. Af12060 oxidizes the 2′,3′-double bond of the indole side chain of fumiquinazoline F, and the three-domain NRPS Af12050 activates L-Ala as the adenylate, installs it as the pantetheinyl thioester on its carrier protein domain, and acylates the oxidized indole



Scheme 24.25 Biosynthesis of Peganine

for subsequent intramolecular cyclization to create the 6-5-5 imidazolindolone of fumiquinazoline A (Scheme 24.26). This work provides experimental validation of the fumiquinazoline biosynthetic cluster of *A. fumigatus* Af293 and describes an oxidative annulation biosynthetic strategy likely shared among several classes of polycyclic fungal alkaloids.

Ames and Walsh [96] validated that the first module of the acetylaszonalenin synthetase of *Neosartorya fischeri* NRRL 181 activates anthranilate to anthranilyl-AMP. With this as a starting point, they then used bioinformatic predictions about fungal adenylation domain selectivities to identify and confirm an anthranilate-activating module in the fumiquinazoline A producer *Aspergillus fumigatus* Af293 as well as a second anthranilate-activating NRPS in *N. fischeri*. This establishes an anthranilate adenylation domain code for fungal NRPS and should facilitate detection and cloning of gene clusters for benzodiazepine and quinazoline-containing polycyclic alkaloids with a wide range of biological activities (Scheme 24.27).

The biosynthesis of the bioactive compound tryptoquivaline, which are characterized by an acetylated quinazoline ring connected to a 6-5-5 imidazoindolone ring system via a five-membered spirolactone, has remained uncharacterized. Gao and coworkers [95] recently reported the identification of a gene cluster (tqa) from *Penicillium aethiopicum* that is involved in the biosynthesis of tryptoquialanine. The pathway has been confirmed to go through an intermediate common to the fumiquinazoline pathway, fumiquinazoline F, which originates from a fungal trimodular nonribosomal peptide synthetase (NRPS), as showed above. By systematically inactivating every biosynthetic gene in the cluster, followed by isolation and characterization of the intermediates, Gao and coworkers [95] were able to establish the biosynthetic sequence of the pathway. An unusual oxidative opening of the pyrazinone ring by an FAD-dependent berberine bridge enzyme-like oxidoreductase has been proposed based on genetic knockout studies. Notably, a 2-aminoisobutyric acid (AIB)-utilizing NRPS module has been identified and

reconstituted in vitro, along with two putative enzymes of unknown functions that are involved in the synthesis of the unnatural amino acid by genetic analysis. This work provides new genetic and biochemical insights into the biosynthesis of this group of fungal alkaloids, including other related to tryptoquialanine (Scheme 24.28).

Similar biosynthetic logic is likely involved in the formation a number of fungal quinazoline alkaloids (Table 24.31), some examples are showed in Scheme 24.29.

The biosynthesis of the main groups of quinoline, acridone, and quinazoline alkaloids is established. However, a great deal of more detailed work remains to be done. The topics included here have been selected to stimulated further experimental biosynthetic research in the area.

3 Biological Activity

Interest in the 2-substituted quinolin/ones, quinazolines and acridones alkaloids has accelerated rapidly with the finding that these compounds display marked biological activities, such as leishmanicidal, antimicrobial, anticancer activities.

3.1 Antiprotozoal Activity

The need for novel and more selective agents to treat protozoal diseases remains. The classic examples of these diseases are Chagas, sleeping sickness, leishmaniasis, and malaria.

3.1.1 Leishmaniasis

Leishmaniasis is a group of tropical diseases caused by a number of species of protozoan parasites belonging to the genus *Leishmania*. In humans, *Leishmania* spp. causes a variety of clinical diseases, which have been used by the World Health Organization as the basis to classify leishmaniasis in four clinical forms: visceral, mucocutaneous, cutaneous diffuse or disseminated, and cutaneous. Certain species of the parasite have been associated with the different clinical forms of the diseases; *Leishmania donovani* complex causes visceral leishmaniasis, while the *Leishmania tropical* complex is known to induce cutaneous and cutaneous diffuse leishmaniasis in several countries of Latin America. During its biological cycle, parasites of the *Leishmania* genus exist in two forms that develop in a different host, a flagellated extracellular form known as promastigote and an intracellular one designated as amastigote. The form that infects both man and other vertebrate hosts is the promastigote. The vertebrate host is infected with the promastigote form of the parasite as a result of a sting by the vector insect (*Phlebotomus* and *Lutzomyia*). After this, the promastigotes are quickly phagocytized by the macrophages of the host and inside of them the promastigotes change to the amastigote form. The clinical manifestation of the disease is a consequence of the multiplication of the amastigotes inside the macrophages. Drugs currently used to cure leishmaniasis are derivatives of pentavalent antimony, which are potentially toxic and generally administered via the parenteral route in a hospital setting for relatively long periods. In many endemic regions, the classic treatments are too expensive or unavailable to the population suffering from cutaneous leishmaniasis [143]. Most of the studies directed toward the detections of plant secondary metabolites with leishmanicidal activity have been done using the promastigote form of the parasite because it is easier to maintain under in vitro conditions. However, since the promastigote is not the infective form of the parasite in vertebrate hosts, evaluations done with theme have only an indicative value of the possible leishmanicidal activity of the metabolite tested. The study must be complemented with an evaluation using intracellular amastigotes in macrophages. Interest in the 2-substituted quinolines has accelerated rapidly with the finding of Fournet and his colleagues in the early 1990s [41, 144–146] that these compounds display marked leishmanicidal activity (Table 24.32).

3.1.2 Chagas

Chagas disease is a protozoosis caused by the flagellate protozoan *Trypanosoma cruzi*, which belongs to the Kinetoplastida order and the Trypanosomatidae family. Four main evolutionary forms can be identified during the *T. cruzi* life cycle. The trypomastigote is the infective flagellate form of the parasite found in the blood of the mammalian host (blood trypomastigote) and in the terminal part of the digestive and urinary tracts of vectors (metacyclic trypomastigote). Metacyclic trypomastigotes are more infective than blood trypomastigotes. The epimastigote is the replicative form of the parasite in the insect vector and in the acellular culture medium. The amastigote is the intracellular replicative form of the parasite in the vertebrate host. The spheromastigote is found in the stomach of the vector [147]. Besides low efficacy, the drugs currently available, nifurtimox and benznidazole have strong side effects. A number of 2-substituted quinoline and acridone alkaloids were found to display antitrypanosomal activity (Table 24.32).

3.1.3 Malaria

Human malaria is caused mainly by four species of *Plasmodium*, *P. vivax*, *P. malariae*, *P. ovale*, and *P. falciparum*. Of these four species *P. falciparum* is responsible for the vast majority of the 300–500 million episodes of malaria worldwide and accounts for 0.7–2.7 million annual deaths. *P. vinckei* was first isolated in 1952 although it was not recognized as an independent species until 1975. Four subspecies are recognized, *P. vinckei vinckei*, *P. vinckei petteri*, *P. vinckei lentum*, and *P. vinckei brucechwatti*. The parasite is readily grown in mice and laboratory-reared thicket rats, where it shows a preference for mature red blood cells. Infections are synchronous with a periodicity of 24 h. Malaria parasites are transmitted by female *Anopheles* mosquitoes. *A. gambiae* is one of the best known, because of its predominant role in the transmission of the most dangerous *P. falciparum*. *P. vinckei* may be transmitted by *Anopheles stephensi* mosquitoes over a wide temperature range. The parasites multiply within red blood cells, causing symptoms that include anemia (light headedness, shortness of breath, tachycardia, etc.), as well as other general symptoms such as fever, chills, flu-like illness, and in severe cases, coma and death. Malaria infections are treated through the use of antimalarial drugs, such as chloroquine or pyrimthamine, although drug resistance is increasingly common [148, 149]. These factors increase the urgency of the search for novel antimalarials. Many of the reviewed alkaloids possessed antimalarial activity (Table 24.32).

3.2 Molluscicidal Activity

Schistosomiasis or bilharzia is a disease affecting many people in developing countries. The most common way of getting schistosomiasis in developing countries is by wading or swimming in lakes, ponds, and other bodies of water which are infested with the snails (usually of the *Biomphalaria*, Bulinus, or *Oncomelania* genus) that are the natural reservoir of the *Schistosoma* pathogen. *Schistosoma mansoni* is found in parts of South America and the Caribbean, Africa, and the Middle East; *S. haematobium* in Africa and the Middle East; *S. japonicum* in the Far East; and *S. mekongi* and *S. intercalatum* focally in Southeast Asia and central West Africa, respectively. Freshwater snails of the genus *Biomphalaria* are intermediate snail hosts for the transmission of the medically important *S. mansoni*; of the seven species of *Biomphalaria* transmitting schistosomiasis in the Western Hemisphere, *B. glabrata* is the most important and the best studied experimentally. It is found mostly in South America and the Greater and Lesser Antilles, where the snails occupy habitats that are often temporary due to frequent floods and droughts. They are dispersed to new habitats during times of flooding. A few countries have eradicated the disease, and many more are working toward it. Snail control by means of molluscicides is today considered an auxiliary method within integrated control of schistosomiasis [150]. Many of the reviewed alkaloids possessed antimolluscicidal activity (Table 24.32).

3.3 Antimicrobial Activity

Discovery of new antimicrobial substances is an important research objective, due to the continuing evolution of microbial resistance in medicine and agriculture (Antimicrobial activity against plant pathogens; Activity against fungus, symbiotic fungus and algicide). A number of plant 2-substituted quinolin/ones, quinazoline and acridones alkaloids have been shown potent antimicrobial activity: (a) Bacteria: *Arthrobacter aurescens*, *Bacillus cereus*, *B. circulans*, *B. licheniformis*, *B. sphaericus*, *B. subtilis*, *Brevibacterium ammoniagenes*, *Corynebacterium fascians*, *Enterobacter cloacae*, *Enterococcus faecalis*, *Escherichia coli*, *Helicobacter pylori*, *Klebsiella pneumonia*, *Kurthia zopfii*, *Listeria monocytogenes*, *L. innocua*, *L. seeligeri*, *L. welshimeri*, *Micrococcus luteus*, *Mycobacterium fortuitum*, *M. phlei*, *M. tuberculosis*, *M. smegamatis*, *Proteus mirabilis*, *Pseudomanas aeruginosa*, *Salmonella typhi*, *S. setubal*, *Sarcina lutea*, *Staphylococcus aureus*, *S. epidermidis*, *Streptomyces viridochromogenes*, *Streptococcus epidermidis*, *Vibrio harveyi*, *V. anguillarum*; (b) Bacterial plant pathogens: *Agrobacterium tumefaciens*, *Corynebacterium michiganense*, *Erwinia carotovora*, *Pseudomonas solanacearum*, *Xanthomonas campestris* pv *oryzae*; (c) Fungus: *Aspergillus niger*, *A. fumigatus*, *Candida albicans*, *C. neoformans*, *Mucor hiemalis*, *M. miehei*, *Penicillim* sp., *Saccharomyces cerevisiae*, *Sporobolomyces almonicolor*, *Trichophyton interdigitale*; (d) Fungal plant pathogens: *Botrytis cinerea*, *Cochliobolus miyabeanus*, *Colletotrichum acutatum*, *C. fragariae*, *C. gloeosporioides*, *Fusarium oxysporum*, *Gaeumannomyces graminis*, *Phomopsis obscurans*, *P. viticola*, *Pyricularia oryzae*, *Pythium ultimum*, *Rhizoconia solani*, *Verticillium dahlia*; (e) Yeasts: *Debaryomyces hansenii*, *Rhodotorula acuta*, *Schizosacharomyces pombe*, *Cryptococcus* sp.; (f) Soil-borne pathogen: *Fungo*: *Phytophthora capsici*, B*acteria*: *Pseudomonas cepacia*; (g) Symbiotic fungus: *Leucoagaricus gongylophorus*; (h) Micro-algae: *Chlorella vulgaris*, *C. sorokiniana*, *Scenedesmus subspicatus* (Table 24.32).

3.4 Antitumor Activity

According with WHO (World Health Organization 2011) cancer will be the main cause of death in the world population and it will supplant the cardiovascular disease [163]. In Brazil, it is estimated that 520,000 people will develop cancer until 2013 (INCA 2011) [164].

Cancer is the main cause of death in developed country and research in this field with quinoline, quinazoline, and acridone alkalois has showed high potential use of these compounds in the cancer treatment. These compounds were bioassayed for these activities in several models (Toxicity in the brine shrimp; Inhibitory effect on tumor necrosis factor (TNF) production; Antitumour activity; Nuclear Factor of Activated T Cells – NFAT Inhibitor; Cytotoxic activity; Antimutagenic). Many of the reviewed alkaloids were found to display anticancer activity (Table 24.32).

3.5 Enzyme Inhibitors

Enzymes are frequently chosen as targets for drug design and discovery. For example, a potential strategy for the treatment of diseases caused by parasites is the design of compounds which selectively inhibit enzymes that are pivotal for survival of the parasite within the host that are part of biochemical pathways that are specific to the parasite. In recent years, a number of the reviewed alkaloids have been found to be inhibitors of enzymes which are involved in many important biological processes: (a) Inhibitory activity on CYP3A4 and CYP2D6: Cytochrome P450 enzymes are essential for the metabolism of many medications, the two most significant enzymes being CYP3A4 and CYP2D6, they can be inhibited or induced by drugs, resulting in clinically significant drug-drug interactions that can cause unanticipated adverse reactions or therapeutic failures, knowledge of the most important drugs metabolized by cytochrome P450 enzymes, as well as the most potent inhibiting and inducing drugs, can help minimize the possibility of adverse drug reactions and interactions; (b) Cytochromes *bo* and *bd* – two terminal respiratory oxidases found in *E. coli* and many other bacteria; (c) Lipoxygenase; (d) NADH oxidation; (e) Angiotensin II receptor binding; (f) Diacylglycerol acyltransferase; (g) Type B monoamine oxidase – potential value in the treatment of neurological disorders such as Parkinson’s and Alzheimer’s diseases and Huntington’s chorea; (h) Screening of acetylcholinesterase and butyrylcholinesterase inhibition – Alzheimer’s diseases; (i) Leukotrienes such as LTB_4 are highly potent mediators of inflammation and allergic reactions, they are formed in human neutrophils by 5-lipoxigenase (5-LOX) which catalyzes the first step in the conversion of arachidonic acid – leukotriene biosynthesis inhibitory activity; (j) Cathepsin V enzyme has been considered as a potential diagnostic marker for colon tumors (Table 24.32).

3.6 Antiplatelet Activity

Platelets are a type of blood cell. They play a key role in normal blood clotting. During the clotting process, platelets clump together to plug small holes in damaged blood vessels. The purpose of clotting is to stop bleeding. The number of platelets in blood can be affected by many diseases. Platelets may be counted to monitor or diagnose diseases or identify the cause of excess bleeding. If the number is higher than normal (thrombocytosis), this may be associated with: Polycythemia vera, post-splenectomy syndrome, primary thrombocytosis, certain malignancies, early chronic myelogenous leukemia (CML), and anemia. Theoretically, antiplatelet agents can be developed that target each step in the platelet activation or inhibition mechanisms. For example, the antiplatelet activity of aspirin was discovered while studying cyclooxygenase inhibitors. Numerous new antiplatelet agents were developed based on their inhibitory effects on platelet activation. Nonetheless, the number of antiplatelet agents ready for clinical is still insufficient, and deleterious side effects are also associated with most of the existing agents [151]. Therefore, the search for an ideal antiplatelet agent is still an important goal for the medical and pharmaceutical industries. Antiplatelet activity has been found in a number of the reviewed alkaloids (Table 24.32).

3.7 Insecticide Activity

Insects compete with the men by feed and control them with natural products is a method that can avoid contaminating the environments. The quinoline, quinazoline, and acridone alkaloids were found to display insecticide activity (Table 24.32).

3.8 Miscellaneous Biological Activities

Quinoline, quinazoline, and acridone alkaloids were found to display several other activities such as:

- Inhibitory effect on germination
- Anti-HIV activity
- Muscle Relaxant
- Estrogenic activity
- Anti-inflammatory activity
- Neurodegenerative diseases
- Phtotoxicity (anti-psoriasis activity)
- Potassium channel blockers
- Antiarrythmic activity
- Vasorelaxing activity
- Pollen-growth inhibitors
- Anti-inflammatory and antihypertensive
- Endotoxic to limulus amoebocyte lysate test
- Tremor and paralysis effects
- Pharmacokinetic
- Raising body temperature
- Anticoccidial
- Oxytocin effect and stimulation of muscular contraction
- Antispasmodic activity
- Antioxidant activity
- Antiviral activity
- Antiallergic activity
- Phagocyte oxidative burst (Table 24.32)

4 Conclusions

Alkaloids derived from anthranilic acid undoubtedly occur in greatest abundance in plants from the Rutaceae family. Particularly well represented are alkaloids based on quinoline (633 derivatives) and acridone skeletons (256 derivatives). The furoquinoline alkaloids of the dictamnine group (117 compounds) are the most widespread in the Rutaceae. The simplest representative is dictamnine and the most common is skimmianine (Table 24.5). Traditionally, the Rutaceae has been subdivided into six subfamilies of which three, the Rutoideae, Toddalioideae, and Aurantioideae, are large [41]. The furoquinolines occur widely in genera of Rutoideae, Toddalioideae, and Flindersioideae, and only to a limited extent among the Aurantioideae. They appear to be absent in the smaller subfamily Dictyolomatoideae and Spathelioideae. Of the 633 quinoline derivatives 28 % are dihydro- and furoquinolines, followed by quinolin-2(1*H*)-ones (22 %), alkyl-, aryl-, and alkylarylquinolin-4(1*H*)-ones (18 %), dihydro- and pyranoquinolines (12 %), simple quinolones (11 %), quinolin-4(1*H*)-ones (5 %), and dimeric quinolin-2(1*H*)-one/4(1*H*)-ones (4 %).

Acridones have been recorded in genera of the three large subfamilies Rutoideae, Toddalioideae, and Aurantioideae. Simple, dimeric, pyrano- (including dihydro) and furoacridones (including dihydro) are also known in order decreasing of their derivatives 53 %, 18 %, 17 %, and 12 %, respectively. The literature registers the occurrence of two simple acridones in Simaroubaceae and one in Asteraceae, one furoacridone in Piperaceae, and one pyranoacridone in Apocynaceae. The first case is not surprising since Simaroubaceae also belong to the order Sapindales. The other cases are more interesting since the families Asteraceae, Piperaceae, and Apocynaceae do not even belong to the Sapindales. It can of course be argued that the plant specimens were wrongly identified. Indeed the sporadic occurrence of particular micromolecular types in unrelated taxa is a general phenomenon. A few quinoline derivatives (43 compounds) occur sporadically in other families of Sapindales (Simaroubaceae, Meliaceae, Zygophylaceae) and in other unrelated families (Acanthaceae, Annonaceae, Apocynaceae, Araliaceae, Asteraceae, Brassicaceae, Elaeocarpaceae, Euphorbiaceae, Fabaceae, Fagaceae, Loganiaceae, Menispermaceae, Nitrareaceae, Poaceae, Periplocaceae, Ranunculaceae, Rubiaceae, Santalaceae, Sterculiaceae, Zingiberaceae).

The 2-alkylquinolin/4(1*H*)-one alkaloids isolated from some bacteria are typical of the Rutaceae. From the systematic standpoint the co-occurrence of 2-*n*-nonylquinolin-4(1*H*)-one in *Ruta graveolens*, *Raulinoa echinata*, *Boronia bowmanii*, 2-*n*-undecylquinolin-4(1*H*)-one in the former, *Ptelea trifoliate* (Rutaceae), and both in *Pseudomonas* (Proteobacteria) is astonishing. In addition, it is noteworthy that many of these alkaloids in bacteria were firmly established as derived from anthranilic acid, while the Rutaceae were less biosynthetically investigated. The analysis of distribution of alkylquinolin/ones among five genera of Proteobacteria division showed that *Pseudomonas* (Pseudomonadaceae) is the major sources of 2-alkylquinolin/4(1*H*)-ones. There is a much less proliferation of this alkaloid type in *Alteromonas* (Alteromonadaceae). Both produce these alkaloids with variation only in the aliphatic chains at C-2. These two families are included in the orders Pseudomonadales and Alteromonadales, respectively, and in the same class Gammaproteobacteria [41]. *Stigmatella*, which form part of Cystobacteraceae family (Myxococcales order and Deltaproteobacteria class), explore 2-alkylquinolin/4(1*H*)-ones chemistry along several different biosynthetic pathways, which leads to compounds containing farnesyl as substituent (Scheme 24.15). Of the four genera from Actinobacteria division examined, notably *Pseudonocardia* yield 2-alkylquinolin-4(1*H*)-ones with an uncommon substitution pattern, containing a geranyl group at C-2 (Scheme 24.13) instead of an aliphatic chain derived from β-keto fatty acids (Scheme 24.13). These genera are included in the Actinomycetales order and the quinolin/ones are of sporadic occurrence in the three remaining genera. *Arthrobacter* (Micrococcaceae) contain 2-alkylquinolin-4(1*H*)-one with a methyl group at C-3 (Scheme 24.13, Table 24.28), while in *Janibacter* (Intransporangiaceae) alkylation in a quinoline skeleton appear in position C-8 as oxidized methyl group (Table 24.22).

The quinolin/4(1*H*)-one alkaloids with a linear aliphatic side chain at C-2 appear to be absent in fungi. Fungus *Penicillium* (Ascomycota phylum, Ascomycetes class, and Eurotiales order) has yielded a novel class of quinolin/ones [41]. They are based on the combination of amino acids L-valine and L-isoleucine, anthranilic acid, and acetic acid [41] (Schemes 24.22, 24.23), or these amino acids and tryptamine [41] (Scheme 24.24). They constitute two small groups which can be considered as 2-substituted quinolin-4(1*H*)-ones: quinolactacins A1, A2, B, and C, quinolactacide; and 2-substitued quinolines: quinocitrinines A and B. Both are alkaloid types at present unknown from any other source. Thus, clearly fungi from Ascomycetes class deserve more attention in order to find new quinolactacins, since they showed interesting biological effect on tumor necrosis factor (TNF) [41].

Quinazoline derivatives are less common (11 compounds) in Rutaceae. Interestingly, these alkaloids (50 derivatives) occur in the following taxonomically unrelated plant families: Acanthaceae, Apocynaceae, Araliaceae, Asteraceae, Brassicaceae, Fabaceae, Hydrangeaceae, Malvaceae, Orchidaceae, Polygonaceae, Ranunculaceae, Rubiaceae, Saxifragaceae, Scrophulariaceae, and Zygophylaceae. A variety of quinazoline (62 derivatives) are also produced by bacteria, fungi, and marine animals.

The alkaloids reported in the Rutaceae can help to confirm the affinity between subfamilies because there is greater chemical diversity. On the other hand, the bacteria and fungi are needed for more substantial chemical studies. When more data become available, it is likely that useful systematic correlations will emerge. More detailed studies regarding the biosynthetic pathways of quinolines and quinazolines in the Rutaceae are needed. Such studies would clarify the differences in the pathways based on their derivation from anthranilic acid in bacteria and in rutaceous plants.

Finally, this survey indicates that the Rutaceae, and various bacterial and fungal species offer considerable potential for the discovery of new or known alkaloids with significant and possibly valuable biological activities.

Acknowledgments The authors thank the Brazilian agencies: Institutos Nacionais de Ciência e Tecnologia, do Conselho Nacional de Desenvolvimento Cientifico e Tecnológico (CNPq/MCT, INCT, 573742/2008-1), Fundação de Amparo a Pesquisa do Estado de São Paulo (FAPESP, INCT, 08/57859-5), Coordenação de Aperfeiçoamento de Pessoal de Ensino Superior (CAPES), and Financiadora de Estudos e Projetos (FINEP) for their financial support.

Abstract

This chapter will cover the alkaloids containing the imidazole nucleus which is the smallest group of alkaloids in terms of number of compounds known. This class of alkaloids is synthesized by precursors derived directly from the amino acid, L-histidine. The known structures can be divided in those derived from histamine as a precursor and the other ones called *Pilocarpus* alkaloids that

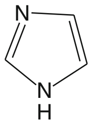
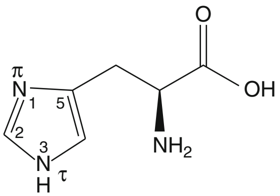
1 Introduction

Alkaloids form a large group of secondary metabolites with a structural diversity comparable to that of terpenoids, representing ca. 20% of all known natural substances [1]. In spite of this abundance, proportionally few alkaloids contain the imidazole group (**1**).



1



2

In general, the nitrogen atom in alkaloids, normally forms a heterocyclic ring, is derived from amino acids. L-Histidine (**2**) is the only amino acid that contains an imidazole ring (glyoxaline) (**1**), an aromatic heterocyclic group with one nitrogen atom hybridized as in pyridine and the other one hybridized as in pyrrole. These two nitrogen atoms confer a relatively high basicity to the imidazole ring because the protonated species can be stabilized by resonance. This amino acid is considered the precursor of all alkaloids containing this ring system because of their close structural relationship [2].

About the nomenclature of histidine and its derivatives, there has been some confusion for a considerable time, mainly concerning the numbering of atoms in the imidazole ring. Biochemists generally numbered the nitrogen atom adjacent to the side chain as 1 and organic chemists designating it as 3. In this chapter, we followed the IUPAC recommendation for numbering the nitrogen atoms in the imidazole ring of histidine. The nitrogen nearest the alanine side chain is called *pros* ("near," abbreviated π) and the farthest one, *tele* ("far," abbreviated τ). This means that the pros-nitrogen atom (N^{π}) has position 1 and the *tele*-nitrogen (N^{τ}), position 3. Consequently, the carbon atom between the two-ring nitrogen atoms is numbered 2 (as in imidazole), and the carbon atom next to the τ nitrogen is numbered 5. The carbon atoms of the aliphatic chain are designated α and β. This numbering is also used for the decarboxylation product histamine and for substituted histidine derivatives [3].

Battersby and Openshaw [4] wrote one of the first reviews on imidazole alkaloids. At that time, this group was even smaller, and the discussion dealt mainly with pilocarpine and related alkaloids. Since the 1980s, the number of alkaloids containing the imidazole ring has increased mainly from marine organisms such as mussels, sea urchins, and sponges and in smaller number from plants [5]. These marine alkaloids will be discussed in a specific chapter in this handbook (▶ Chap. 9, "Marine Pyrroloiminoquinone Alkaloids, Makaluvamines and Discorhabdins, and Marine Pyrrole-Imidazole Alkaloids").

On the other hand, their occurrence in plants is restricted to some specific genera or even species from different families without a distribution pattern. The only exception is *Pilocarpus* Vahl (Rutaceae) in which all the species are known to accumulate imidazole alkaloids. No new sources from these alkaloids from higher plant have been reported since 1990.

In this chapter, we will only discuss about nonmarine alkaloids which are originated directly from histidine and are not simple peptide alkaloids. The alkaloids here discussed were classified, accordingly to their biosynthetic origin, in simple histamine derivatives and the so-called *Pilocarpus* alkaloids which are originated directly from histidine but from different precursors.

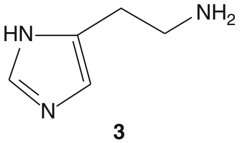
2 Histidine-Derived Alkaloids

Few imidazole alkaloids can undoubtedly be associated to L-histidine as biogenetic precursor. Nevertheless, some of these are closely related to this amino acid despite lack of biosynthetic experimental data. In this chapter, imidazole alkaloids were divided according to their chemical features as histamine and derivatives, simple histamine amides, and *Pilocarpus* alkaloids. Plant species, isolation, and detection are highlighted in this topic.

2.1 Alkaloids Formed from Histamine and Derivatives

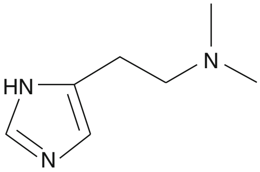
2.1.1 Histamine and Simple Amines

Histamine is a biogenic amine formed by L-histidine decarboxylation mediated by HDC (histidine decarboxylase) (EC EC 4.1.1.22) and naturally occurs in some fungi, marine, and plant species [6, 7]. It was isolated from aerial parts of *Capsella bursa-pastoris* (L.) Medik. (Brassicaceae), *Lolium perenne* L. (Poaceae) [8], and *Spinacea oleracea* L. (Chenopodiaceae) [7, 9]. This amine may act as an intermediate in many imidazole derivatives biosynthesis such as amides.



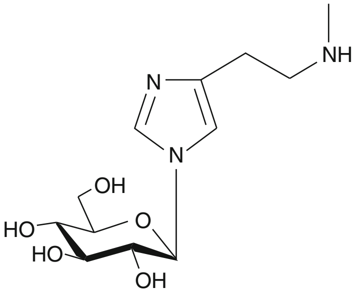
3

S. oleracea [7], *Echinocereus blanckii* Palm. and *E. triglochidiatus* Engelm. var. *paucispinus Engelm.* ex W.T. Marshall (Cactaceae) [10] provide N^{α},N^{α}-dimethylhistamine (4) in addition to other alkaloids. Extraction and isolation procedures were performed accordingly to classical phytochemical techniques, using partition, column, and thin layer chromatography. *E. triglochidiatus* var. *neomexicanus* yielded 0.11% of this alkaloid with the following major mass fragment: 139 (8%) M^+, 95 (10%), and 58 (100%).

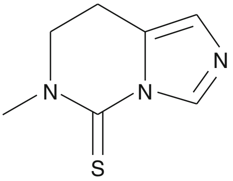


4

This imidazole alkaloid is also present in *Casimiroa edulis* Llave et Lex (Rutaceae), which also produces a glycosylated derivative of N^{α}-methylhistamine, casimidine (**5**), and the unusual alkaloid containing a sulfur atom, zapotidine (**6**) [8, 11–13].



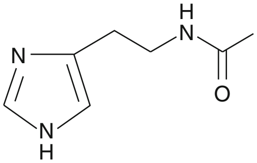
5



6

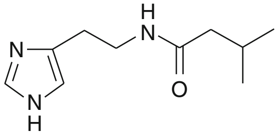
2.1.2 Simple Histamine Amides

The simplest histamine derivative from this group, N^{α}-acetylhistamine (**7**), was firstly identified by Appel and Werle in *S. oleracea* [7] crude alkaloid extract.



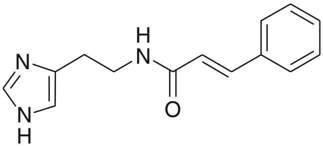
7

Also in this group, dolichotheline (*N*-isovalerylhistamine) (**8**) was isolated, in 1969, from a small cactus named *Dolichothele sphaerica* (Dietrich) Br. and R. [14, 15]. The alkaloid was obtained from crystallization from nonphenolic fraction with a benzene-acetone mixture. Identification was carried out by thin layer chromatography using chromogenic Pauly's reagent (for histidine and tyrosine metabolites) and spectroscopy methods. Structural identity of dolichotheline was provided by means of mass spectral data with molecular ion at *m*/*z* 195 and an *m*/*z* 85 and *m*/*z* 111 fragments due to the loss of the isovaleryl and histamine moieties, respectively [14]. This was the first imidazole alkaloid reported to a Cactaceae plant and out of jaborandi species.



8

N^{α}-cinnamoylhistamine (**9**) was isolated from several plant species such as *Argyrodendron peralatum* (Bailey) Edlin ex J.H. Boas (Sterculiaceae), *Acacia* spp. (Fabaceae), and *Glochidion philippicum* (Cav.) C.B.Rob. (Euphorbiaceae) [8, 16]. Using current analytical methods, this alkaloid was isolated as colorless crystals (m.p. 178–179 °C) and characterized as the *trans* isomer due to high coupling constant for the olefinic protons signs [16].



9

The *cis* isomeric form (**9a**) was not previously reported in former species, but it was isolated from aerial parts of *Lycium cestroides* Schltdl. (Solanaceae) [17, 18]. By means of ^{1}H NMR spectroscopy the *cis*-*trans* isomers of N^{α}-cinnamoylhistamine were characterized as two quasi-bicyclic forms with a hydrogen bond between the carbonyl amidic group and the N^{π}-H imidazolic ring [17]. According to the authors, these isomers spontaneously undergo to lineal form especially the *trans* isomer (**9b**). Methyl derivatives were also isolated from crude ethanolic extract (**10a** and **10b**). The Rutaceae species *C. edulis* affords casimiroedine (**11**) [11, 12], a glycosylated derivative of N^{α}-cinnamoyl-N_{π}-methylhistamine from *L. cestroides*.

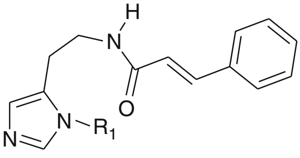
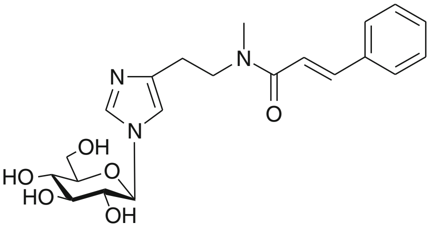
10a R_1= $-CH_3$

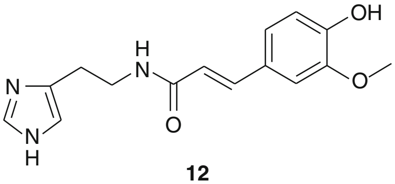


9b R_1= H
10b R_1= $-CH_3$



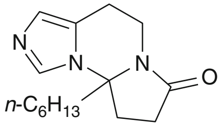
11

Ephedra spp. roots are known as major source of ephedrine and derivatives alkaloids, but this plant species also contains an imidazole derivative, feruloylhistamine (**12**), which was identified in methanolic extract of the drug in 1983 [19, 20]. After column chromatography and crystallization procedures, feruloylhistamine was characterized by ^{1}H and ^{13}C NMR and mass spectroscopy. A molecular ion peak was observed at *m*/*z* 287 consistent to a $C_{15}H_{17}N_3O_3$ fragment, and the ^{13}C NMR spectrum revealed signals for aliphatic and aromatic carbons and also one carbonyl group. The synthetic derivative was also obtained and afforded the same physical data as the natural compound [19].

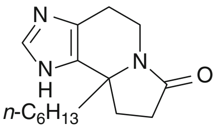


12

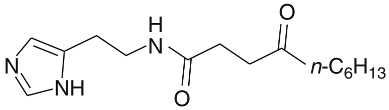
The isomers glochidine (**13**) and glochidicine (**14**) (both with a lactam ring) and *N*-(4-oxodecanoyl) histamine (**15**) were isolated from *G. philippicum*. Structure elucidation was performed by elementary analysis, ^{1}H and ^{13}C NMR and mass spectroscopy. The *m*/*z* 176 fragment, which corresponds to *n*-hexyl loss from C-12, was present in both isomeric forms [21].



13



14



15

Other examples of histamine amides that also contain a lactam portion are the alkaloids from *Cynometra* spp. (Fabaceae). Structurally, they are very similar to that one found in *Pilocarpus* species. *C. hankei* Harms, *C. ananta* Hutch. & Dalziel, and *C. lujae* De Wild. and are indigenous to west tropical Africa, which contain lactams derivatives, in which occur isomerization at imidazole ring level, such as anantine(**16**)/isoanantine (**19**) and cynodine (**18**)/isocynodine (**19**) [22]. As these alkaloids are only found in *Cynometra* species, possibly, they have a chemotaxonomic importance to this genus.

26 $R_1 = R_2 = -CH_3$

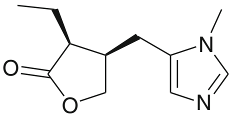
2.2 *Pilocarpus* Alkaloids

This is undoubtedly the most important class of L-histidine derivatives only because of pilocarpine's (**27**) therapeutic uses [8, 23, 24]. Since Byasson's first report of jaborandi alkaloids isolation from the leaves of *Pilocarpus* spp. (Rutaceae) [8], in 1875, several other imidazole alkaloids have been reported in this genus. The identification of these was facilitated due to recent advances in hyphenated chromatographic techniques such as HPLC–ESI–MS/MS (high performance liquid chromatography with electrospray ionization tandem mass spectrometry).

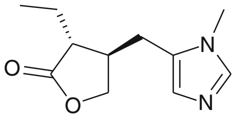
Chemically, the majority of *Pilocarpus* alkaloids hold simultaneously an imidazole and a γ-lactone ring. Epimerization at C2 and C3 carbons of the lactone moiety is commonly observed, and this change in absolute configuration gives rise to some compounds that can naturally occur in *Pilocarpus* species or are generated during extraction procedures [23, 25].

Pilocarpine (**27**) was first isolated, in 1875, by Hardy and by Gerrard, in distinct works, as colorless crystalline salts from the leaves of *P. jaborandi* Holmes [8, 23]. This alkaloid is also found in several other species such as *P. microphyllus* Stapf., *P. pennatifolius* Lemmaire, *P. racemosus* Vahl, *P. trachyllophus* Holmes, and *P. carajaensis* Skorupa, where total pilocarpine content ranges from *ca.* 3.0% to

70% of total alkaloids. Isopilocarpine (**28**) is the epimerization product of pilocarpine produced by enolization pathway, accordingly to Döpke and d'Heureuse [26].



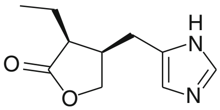
27



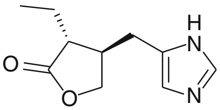
28

Initially, pilocarpine structure was incorrectly attributed as a betaine derivative of a pyridine-lactic acid compound. Further research, based on chemical degradation, synthesis, and X-ray analysis, provided pilocarpine structure as (2*S*,3*R*)-2-ethyl-3-[(1-methylimidazol-5-yl)methyl]-4-butanolide, as extensively described in previous reviews [8].

Pilocarpidine (**29**) and isopilocarpine (**30**) are the non-N^{π} derivatives of this series of compounds [8, 23, 24]. They were isolated in 1900, by means of classical phytochemical procedures, from *P. jaborandi*, which was confirmed as the only source of these alkaloids by HPLC–ESI–MS/MS [27–29].

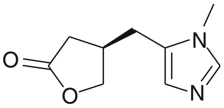


29

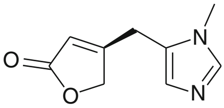


30

Pilosinine (**31**) is a naturally occurring alkaloid in *P. microphyllus*, structurally, it resembles pilocarpine (**27**) since it lacks the ethyl substituent at C2 [8]. This substance plays an important role in pilocarpine synthesis as a key intermediate as indicated by recent works [30, 31]. Tandem mass spectroscopy studies indicated that *P. carajaensis*, *P. spicatus* A. St. Hil., *P. trachyllophus*, *P. pennatifolius*, *P. jaborandi*, and *P. racemosus* accumulated 2,3-dehydropilosinine (**32**). Confirmatory fragmentation pattern was made by comparison with that described to the synthetic derivative.

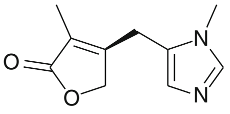


31



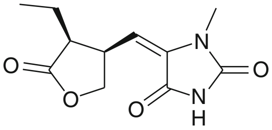
32

The alkaloid 13-*nor*-7(11)-dehydro-pilocarpine (**33**) was firstly isolated from *P. trachyllophus* [32] as a nitrate salt. Recently afforded, as mentioned before, by chromatographic techniques improvements, this substance was identified in five other species, namely, *P. microphyllus*, *P. carajaensis*, *P. spicatus*, *P. racemosus*, and *P. pennatifolius* [29]. As it was found in this genus and could possibly participate in different biosynthetic routes.



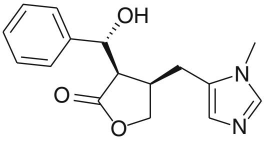
33

The imidazole alkaloid 4,6-dehydro-1,2,4,5-tetrahydro-2,5-dioxopilocarpine (**34**) was isolated from *P. grandiflorus* Engl. stems, as a yellowish oil. Its structure was determined by high-resolution mass spectroscopy (*m*/*z* 238) and ^{1}H and ^{13}C NMR that indicated a change in the structure of pilocarpine due to the signals at 177.7, 162.4, 152.4, 132.2, and 112.3 ppm, associated to two additional carbonyl groups and a double bond [33].

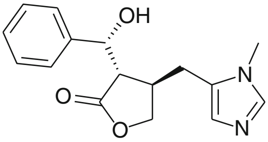


34

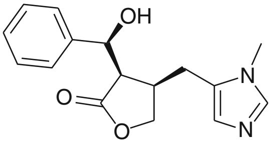
Seven isomers of molecular formula $C_{16}H_{18}N_2O_3$ are reported to *Pilocarpus* species, six out of them have proposed structures: pilosine (**35**), isopilosine (**36**), epipilosine (**37**), epiisopilosine (**38**), and the N^{τ}-methyl derivatives piloturine (**39**) and epiisopiloturine (**40**) [29, 34, 35]. All they have is an α-hydroxylbenzyl group instead of the ethyl substituent at C-2 in the lactone ring. Except for epipilosine (**34**), all these alkaloids were identified in *P. microphyllus*, *P. jaborandi*, and *P. carajaensis* species [29].



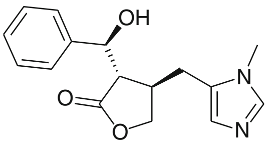
35



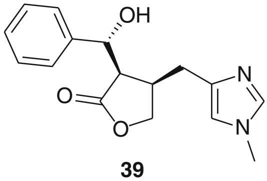
36



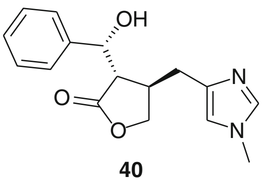
37



38

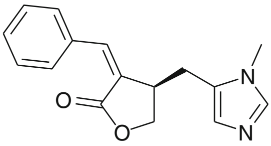


39



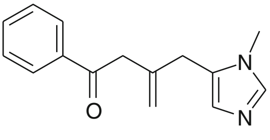
40

High-resolution mass spectrometry of the total alkaloids of *Pilocarpus* species (*P. microphyllus*, *P. spicatus*, and *P. carajaensis*) indicated the presence of three isomers of m/z 269. The fragmentation pattern was consistent of that from anhydropilosine (**41**) [28, 29].

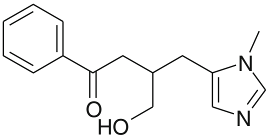


41

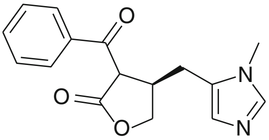
As previously mentioned, HPLC advances improved *Pilocarpus* alkaloids' identification, and several new derivatives of this class were characterized. Three protonated molecules (**42**) (*m*/*z* 241), (**43**) (*m*/*z* 259), and (**44**) (*m*/*z* 285) were identified in *P. microphyllus* ESI-MS fingerprints, whose structures are shown below. These new compounds display a common and characteristic fragment of the benzoyl ion, $C_6H_5CO^+$ (ion of *m*/*z* 105). Screening studies in other *Pilocaprus* species showed (**42**) (and an isomer) were also present in *P. carajaensis*, *P spicatus*, *P. trachyllophus*, and *P. racemosus* [27–29].



42



43



44

Some of these new *Pilocarpus* derivatives were found specifically in *P. pennatifolius* and *P. microphyllus* samples. Following compounds occur as isomeric forms in which absolute configuration was not elucidated [29].

3 Imidazole Alkaloids Biosynthesis

Alkaloids are important secondary metabolites with marked physiological effects and some of them with unmeasured pharmacological interest [23, 36]. It is a general belief that, in plants, alkaloids may be associated with protection against predators or as nitrogen storage/transport and even be involved in physiological balance of the plant [23]. The biosynthesis of these nitrogen derivatives depends on the presence of amino acid precursors (such as ornithine, nicotinic acid, tyrosine, anthranilic acid, and histidine), carbon units, and also key enzymes that conjugate them [23, 36, 37].

Biosynthetic studies have experienced great development since initial works on imidazole alkaloids biogenesis [36]. The use of isotopic labeled precursors, in the 1950s, is the first boundary in secondary metabolite biosynthesis. Cell cultures were also extensively used as tool to track active enzymes involved in alkaloid production. Advances in molecular biology have led biosynthetic researches to gene level, successfully used in genetic engineering studies guiding alkaloids or other secondary metabolites accumulation in plants [36–38]. Despite these recent improvements in biosynthetic approaches, biogenesis of imidazole alkaloids remains obscure.

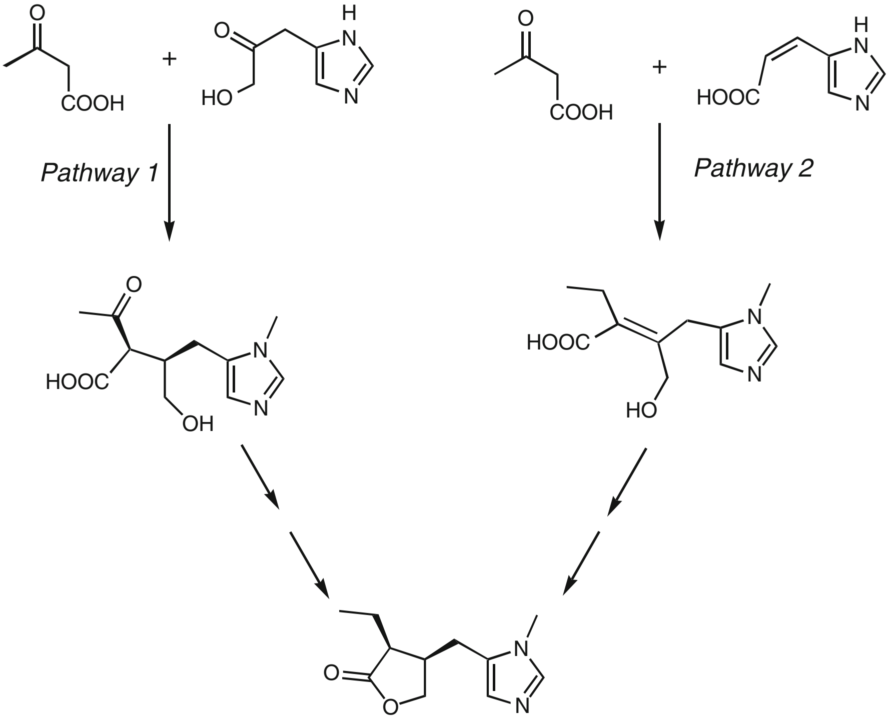
Only the biosynthesis of *Pilocarpus* alkaloids and dolichotheline, from *Dolichothele sphaerica*, were reported in literature as described below.

3.1 *Pilocarpus* Alkaloids Biosynthesis

The amino acid L-histidine is the assumed building block in the biosynthesis of pilocarpine (**27**) and other imidazolic alkaloids due to the presence of glyoxaline ring [8, 23]. First attempts to clarify this pathway were proposed by Boit and Leete that considered the phosphate derivative of 2-oxo-3-(5-imidazolyl)-propanol, also known as imidazole pyruvic acid, as imidazole ring precursor (Scheme 25.1- Pathway 1) [8]. This initial biosynthesis proposal was improved detailing the lactone ring formation by aldol condensation. Another biosynthetic approach suggested condensation of 2-oxobutyric acid (lactone moiety) with urocanic acid (imidazole moiety) (Scheme 25.1- Pathway 2) [8, 39].

Isotopic studies with labeled potential precursors such as sodium acetate-^{14}C, threonine-^{14}C, histidine-^{14}C, histidinol-^{14}C, and L-methionine-(*S*-methyl-^{14}C) were carried out with *P. pennatifolius* in an attempt to prove the proposed pathways [8, 39]. Only the methylation of pilocarpidine, last step in both mechanisms, was attested by significant incorporation of radioactivity in the methyl group attached to the imidazole nucleus. This data confirmed an important assumption, the one that considers methionine the biological source of the *N*-methyl group of pilocarpine. Also, one should consider that these radiolabeled studies were carried out with stems, no other parts of the plant were analyzed, and thus some other site involved in biosynthesis was not considered in this study.

The presence of the enzyme histidine aminotransferase, (HT) (EC 2.6.1.38) was reported in *P. pennatifolius* roots [40], which could link L-histidine to imidazole alkaloids biosynthesis and reinforce the hypothesis of a specific site for pilocarpine production. The enzyme activity was estimated in 46.09 nKat.mg^{-1} of protein and optimal reaction at pH 8–9. HPLC data from enzymatic reaction indicated the formation of a product with the same retention time of the imidazole pyruvic acid standard obtained by synthesis. Such an enzyme activity could not be detected in *P. pennatifolius* leaves, reinforcing these organs could be involved only in the later steps of the biosynthesis, such as *N*-methylation, or could play a role as accumulation site and not in the production.



Scheme 25.1 Hypothetical pathways for the pilocarpine biosynthesis

A cell suspension study with *P. microphyllus* recorded after several subcultures a stable cell line in pilocarpine and other imidazole alkaloids production and the same alkaloid profile found in leaves [41]. This study also characterized three new alkaloids with imidazole ring in this plant species for the first time, by means of ESI-MS. Posterior studies using the same technique in leaves of several samples of *Pilocarpus* suggested three different pathways may occur in imidazole alkaloids biosynthesis [27, 41].

Identification of the genes involved in imidazole alkaloids biosynthesis could be the next and final boundary in pilocarpine production in plants. Nevertheless, isolation from natural sources is still a feasible way to obtain this alkaloid.

3.2 Dolichotheline Biosynthesis

Dolichotheline is an amide derivative from histamine of *Dolichothele sphaerica* (Cactaceae) whose structure suggests the condensation of the imidazole unit with isovaleric acid [14, 15]. Its biosynthesis was evaluated by means of radiolabeled tracers such as DL-[2-^{14}C]histidine, DL-[2-^{14}C]leucine, DL-[2-^{14}C]mevalonic acid lactone, and sodium [1-^{14}C]isovalerate [42]. The extension of radioactivity incorporation indicated that histidine was involved in dolichotheline biosynthesis and also that leucine or mevalonic acid could be the carbon unit donor, since both of them can be reputed as isovaleric acid precursor [43].

The enzymatic system that promotes the amide linkage between L-histamine and isovaleric acid in *D. sphaerica* is not specific, so aberrant or unnatural alkaloids (derivatives produced in the absence of natural precursors) can be produced. Different aberrant alkaloids were produced in labeled studies; one could infer that this system is suitable to prepare biologically active natural products that are difficult to synthesize [44–46].

4 Biotechnological Approaches

Plant tissue culture was initially used for growing isolated plant cells, tissues, and organs under controlled conditions aiming regeneration or propagation of entire plants. This technique relies on cell totipotency, which means that single cells undergo differentiation and thus regenerate an entire plant [47].

Large-scale production of secondary metabolites by plant cell culture seems to be feasible and attractive to industrial production. It has two major advantages over traditional monoculture methods [48]: (1) controlled production of fine natural chemicals independent of climatic, edaphic, and political conditions and (2) higher quality and yield of the final product in well-defined systems. In recent years, metabolic engineering has opened a new promising perspective for improved secondary metabolites production. This approach can be used to improve production not only in cell culture but also in the plant itself or in other plant species or even other organisms.

Biotechnological approaches in imidazole alkaloids production are not so developed as other classes of secondary metabolites, and the studies deal exclusively with pilocarpine production. Nevertheless, the reported results do not lead to a profitable accumulation of this alkaloid but are interesting approaches considering that *Pilocarpus* species are threatened plants.

4.1 Biotechnology in Pilocarpine Production

Despite pilocarpine pharmaceutical importance and structural simplicity, synthetic approaches available for large-scale production are time consuming and do not achieve high yields. Even under ideal storage conditions, *Pilocarpus* spp. leaves can lose at least half of their alkaloid content after 1 year via regular degradation routes [25, 49]. Alternative methodologies aiming increased production of this secondary metabolite are thus a major objective to fine chemicals industries.

First attempts to obtain pilocarpine in cell cultures were performed during the 1990s. Seedlings and cell suspension cultures obtained from *P. microphyllus* species accumulate pilocarpine in a content of 1/5th to 1/20th of the amount of naturally growing plant [50]. Hairy roots, obtained from genetic transformation by *Agrobacterium rhizogenes*, exhibit about the same or greater biosynthetic capacity for secondary metabolite production compared to their mother plants. Thus, a hairy root culture of *P. microphyllus* was established in a Murashige and Skoog medium supplemented with 2,4-D and kinetin as growth regulators. Pilocarpine was accumulated in cells and also excreted to the medium in which the amount of alkaloid varied from 300 to 500 μg/g and were equivalent of the original plant [51].

Micropropagation of *P. microphyllus* seedlings were carried out in absence of GA_3 resulted in a higher percentage of germination and a lower rate of contamination [52]. The apical segment was the best explant for shoot formation grown on medium with different combinations and concentrations of BAP, zeatin, and kinetin.

P. microphyllus seedlings were subjugated to different stressing factors and elicitors, such as hypoxia, salt stress, wounding, nutrient (nitrogen/potassium) omission, salicylic acid, and methyl jasmonate [53]. A time of exposure/concentration relationship of salicylic acid and methyl jasmonate treatments increased pilocarpine accumulation over control in a fourfold factor. Further conditions on the other hand reduced pilocarpine production.

In *P. microphyllus* model, callus were also subjected to conditions and elicitors in an MS-liquid medium supplemented with 2,4-D as growth regulator [54]. Different nutrient concentration, pH value, type/concentration of elicitors (histidine, threonine and methyl jasmonic acid), and osmotic and salt stress (PEG and NaCl) were evaluated. Light incidence influence was also analyzed. Pilocarpine was released in the liquid medium from callus kept in the dark. Detection was carried out using HPLC-MS/MS techniques, and pilocarpine quantification was performed by HPLC. Elicitors induced highest accumulation of the alkaloid in a time/concentration relationship. Light incidence and methyl jasmonic acid inhibited pilocarpine release to the medium.

This model was also used in the evaluation of stable cell lineages with the same alkaloid profile than that of *Pilocarpus* leaves [55]. After 12 subcultures, imidazole alkaloids' composition of the cell cultures was similar to that of the leaves; thus, one can infer that imidazole alkaloid metabolism in *P. microphyllus* cells is similar to that found in leaves. After 24 subcultures, the overall alkaloid distribution remained the same indicating that cell cultures can be cultivated for long periods, and identification of three new imidazole derivatives suggested that this is a suitable model to biosynthesis studies. The effect of pH variations (from 4.8 to 9.8) on stable cell lineages changed pilocarpine/pilosine distribution between the cell and the medium, and highest pilocarpine accumulation was reached at pH 8.8–9.8 [56].

Callus and cell suspension culture of *P. pennatifolius* was established using young leaves on an MS medium (pH 5.7) supplemented with 2,4-D and kinetin as growth regulators [49]. Light-green- to yellowish-colored friable callus was obtained after six subcultures in solid media, and cell suspension culture was obtained (same growth regulators composition) and afforded 35 g/L of biomass after 20 days of maintenance. The callus cultures and suspended cells accumulated, respectively, 1.01 and 0.045 μg/g dry weight of pilocarpine.

5 Biological Activity

Some authors do not consider histamine, (2-[5-imidazolyl] ethylamine) as an alkaloid because it is a universal compound, mostly it is regarded as a biogenic amine. However, histamine is the simplest derivative from histidine presenting a remarkable biological activity. Histamine is formed in living cells by the 1 rate-limiting step exothermic decarboxylation of L-histidine, catalyzed by HDC [6, 7, 57]. This compound was discovered in 1910 by Dale and Laidlaw, as an isolate from the mold ergot capable of not only stimulating smooth muscle contraction but also inducing a shock-like syndrome when injected into mammals [58].

Nowadays, histamine is classified as a natural body constituent and a mediator on anaphylactic reactions, and it is implicated in several physiological functions, being one of the most extensively studied chemical compounds playing a central role in inflammation processes, gastric acid secretion, and neurotransmission. The research with histamine receptors allowed the development of drug therapies specifically targeted for allergies, gastric ulcers, asthma, and anaphylaxis. The control of histamine receptors has also some applications in sepsis control, hemorrhagic shock, anesthesia, surgery, cardiovascular disease, cancer, CNS disorders, and immune-mediated diseases [59–61].

Some histamine amides that have been isolated from some cactus species also showed pharmacological properties. In general, cactus alkaloids belong to β-phenethylamines or to the related tetrahydroisoquinolines that are potentially psychoactive compounds. The studies with *Dolichothele sphaerica* started due to its ethnobotanical relationship with the hallucinogenic *Lophophora williamsii* (Lem.) Coult., commonly known as peyote [62]. The chemical investigation of this cactus resulted in the isolation of the unusual imidazole alkaloid dolichotheline (*N*-isovalerylhistamine) [14], but no pharmacological studies were carried out with the isolated alkaloid.

Feruloylhistamine has also been isolated from the underground part of *Ephedra* plants, which was considered the hypotensive principle of the crude drug “maō-kon” [19]. Based on this finding, some feruloylhistamine analogues were prepared and their hypotensive and some other potential pharmacological properties were examined. The feruloyl group in the amide was changed by a caffeoyl, cinnamoyl, *p*-coumaroyl, and synapoyl substituent maintaining some hypotensive activity but much lower than that of histamine itself. Among the analogues, *p*-coumaroylhistamine presented a remarkable histidine decarboxylase inhibitory activity which was comparable with that of α-fluoromethylhistidine, a reference inhibitor for this enzyme. Consequently, it was expected that this analogue might decrease the gastric acid release, leading to new antiulcer drugs. However, *p*-coumaroylhistamine exerted no antiulcer activity either in the antistress ulcer formation assay or in the antiacid secretion test. All the feruloylhistamine analogues also exhibited some antihepatotoxic activity. Caffeoylhistamine was the analogue that presented the most significant antihepatotoxic activity in the two model assays [20].

The most important pharmaceutical alkaloids in this group are the so-called *Pilocarpus* alkaloids, mainly pilocarpine, which is used as an ophthalmic cholinergic drug. Pilocarpine and other related alkaloids were isolated from several *Pilocarpus* species which are popularly known by the name of "jaborandi" which was derived from the Tupi-Guarani language, *ya-mbor-endi* (the one who causes slobbering). The first record in Europe on the use of these species was made in 1570 by Gabriel Soares de Souza, a Portuguese explorer who traveled through Bahia, describing that the indigenous population used these plants to treat mouth ulcers. Adolf Weber was responsible for introducing pilocarpine as a medical treatment for glaucoma in 1877, soon after its isolation by Hardy and Gerrard in 1875 [63].

Pilocarpine is a parasympathomimetic agent that binds selectively to muscarinic receptors and exerts a broad spectrum of pharmacological effects, which include stimulation of bladder, tear ducts, and sudoriferous and salivary glands. These effects make this alkaloid the drug of choice in glaucoma treatment, because it increases the intraocular aqueous outflow through the trabecular meshwork by contracting the ciliary muscle and a mechanical pull on the trabecular meshwork [64]. Pilocarpine is also used as a cholinergic sialogogue to treat xerostomia, a subjective feeling of a dry mouth, which is relatively common in patients on chronic hemodialysis and after radiotherapy treatment of head and neck cancers. The beneficial effect of pilocarpine on xerostomia probably can be attributed to the stimulation of the salivary glands function [65, 66].

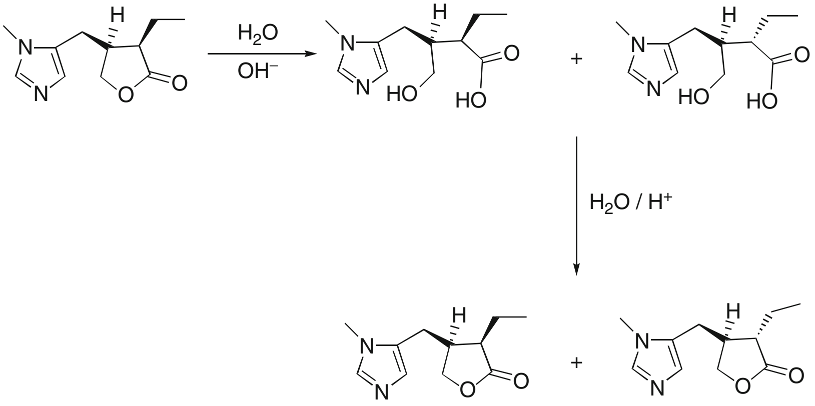
Sjögren's syndrome is a systematic autoimmune disease characterized by dysfunction of the lacrimal and salivary glands, its therapy remains largely empirical and symptomatic targeting, mainly the alleviation of the dryness symptoms. The stimulation of muscarinic M3 receptors to increase aqueous secretions by pilocarpine is the cornerstone of the current therapy [67, 68].

Systemic or intracerebral administration of pilocarpine hydrochloride in high doses induces seizures in rodents. These seizures are characterized by a sequential development of behavioral patterns and electrographic activity [69]. The pilocarpine seizure induces *status epilepticus* like in humans mimicking the pathogenesis and progression of mesial temporal lobe epilepsy [70]. It can be useful to exploit these model properties to design new therapeutic approaches for treating refractory epilepsies.

Isopilocarpine coexists with pilocarpine in nature; in aqueous solutions, pilocarpine can hydrolyze to both pilocarpinic and isopilocarpinic acids. The latter, in acidic pH, can recyclize to isopilocarpine (Scheme 25.2). The contrary does not happen, because the isopilocarpine hydrolysis yields only isopilocarpinic acid [25]. This change in the spatial structure decreases the binding affinity of isopilocarpine to approximately one-tenth to that of pilocarpine in bovine muscarinic cholinergic receptors [71].

Epiisopiloturine (**40**) was found in the leaves of *P. microphyllus* and presented an effect against *Schistosoma mansoni*, causing death on schistosomes from several ages at doses from 150 to 300 μg/mL and was also able to inhibit in 100% worm eggs laying at 100 μg/mL with no cytotoxicity to mammalian cells [72].

Although more than a dozen alkaloids have been isolated from *Pilocarpus* spp., the majority has not been screened for biological activities. Besides their structural resemblance, several are epimers, only pilocarpine possesses a relevant CNS activity.



Scheme 25.2 Epimerization of pilocarpine into isopilocarpine

6 Conclusions

Imidazole alkaloids are one of the smallest groups within alkaloids. This group does not have a defined distribution pattern among the plant species as observed for other groups, the only genus where all species accumulate imidazole alkaloids is *Pilocarpus*. Although the medicinal value of pilocarpine is widely recognized and the fact that the control of histamine receptors might have an important role in several therapies, the majority of the imidazole alkaloids have not yet received a thorough investigation.

The biosynthetic route leading to imidazole alkaloids is a puzzle to be solved. These alkaloids are most likely formed from L-histidine, either by its decarboxylation or deamination. The biosynthesis of those alkaloids derived from histamine, decarboxylation route, is already well established. On the other hand, the biosynthesis of *Pilocarpus* alkaloids is not yet completely elucidated. These alkaloids are thought to be formed by the deamination route having either imidazole pyruvic acid or urocanic acid as precursors. The hypothesis that the former acid is in fact the initial precursor in pilocarpine biosynthesis was supported when only HAT activity was detected in *P. pennatifolius* roots. However, the identification of new alkaloids in *P. microphyllus* cultures suggested that other biosynthetic pathways might be involved, making this an interesting field to be explored.

these alkaloids are described. The acetate-derived alkaloids (coniine) contained mainly in the plant poison hemlock (*Conium maculatum*); therefore, some of the botanical characteristics of this plant are mentioned.

It is, however, pertinent to mention at this juncture that the enormous volume of authentic information accumulated so far with regard to the isolation of alkaloids from a variety of plant species and their subsequent characterization by the help of latest analytical techniques they may be classified as alkaloids derived from amination reactions. These include:

(a) Acetate-derived alkaloids
(b) Phenylalanine-derived alkaloids
(c) Terpenoid alkaloids
(d) Steroidal alkaloids

Keywords
Acetate-derived alkaloids • biological activities • biosynthesis • coniine • phytochemistry

1 Introduction

It has been duly established that the larger section of alkaloids is virtually derived from amino acid precursors with the help of certain specific processes that essentially introduce into the final structure not only an N-atom but also an amino acid carbon skeleton or a major part of it. However, a good number of alkaloids do not essentially conform with this analogy. They are usually synthesized primarily from non-amino acid precursors having the N-atom inserted into the structure at a comparatively latter stage. Interestingly, such structures are predominantly based on both steroidal and terpenoid skeletons. Besides, a few comparatively simpler alkaloids also appear to be derived exclusively with the help of similar late amination processes. In extensive and intensive studies on certain alkaloids, it has been observed that the N-atom is specifically donated from an amino acid source through a transamination reaction using an appropriate ketone or aldehyde.

The taste of the hemlock potion offered to Socrates to induce his “suicide” should have been very bitter, but no comments about this are reported by Plato in the last chapter of *Fedone*, describing Socrates death, where he is reported to drink the poison “peacefully,” maybe thanks to his interior consciousness. If the bitter taste is indeed a poorly relevant feature of poisons used for suicide, it is a very negative and undesirable characteristic for poisons used in homicides. Thus, the poison present in it is really too dangerous for herbal administration by the uninitiated.

The coniine is the most important alkaloid of the hemlock plants. Coniine, one of the major toxic alkaloids present in poison hemlock (*Conium maculatum*), occurs in two optically active forms [36, 45].

1.1 Habitat

The poison hemlock (*Conium maculatum*) is a very common and worldwide plant species. It is one of the most toxic plants known [12, 18, 34, 38, 70, 85]. Poison hemlock is native to Europe and western Asia and has been brought in America and Oceania as an ornamental plant [12–14, 18, 43, 51, 53], although in other countries the plant has been introduced through the transport of seeds [14].

1.2 Botanical Characterization

Conium maculatum L., a member of *Apiaceae* (formerly *Umbelliferae*) of rhizomal plants, the carrot family [52], is an annual, biennial, or in favorable conditions perennial plant, usually 120–180 cm high. During the first year of growth, *Conium maculatum* reaches 45 cm height forming dense stands around the parent plants. The second year new plants grow from rosettes, with larger leaves which are dark green, bisected, triangular, and glabrous [12, 35, 85]. The root is long, forked, tuberous, pale yellow and reminds about a carrot. The stem is mottled with irregular purple spots, is erect, bright green and slightly ridged, much branched above and hollow. The leaves are fern-like [38], numerous, alternate, long-stalked, and tripinnate (which means that they are divided along the midrib into opposite pairs of leaflets which in turn are divided and subdivided) [85]. Its flowers are white, grouped in umbels, which are small and numerous and have a terminal position, with 12–16 rays per umbel. It produces a large number of green fruits, 2–3 mm long and about 2 mm wide [69, 70], grayish at maturity, and formed by two closed mericarps [51, 52]. The fruit is a broadly ovoid and is composed of two grayish-brown seeds with five wavy, longitudinal ridges. The petals of the small flowers are white, and the stamens of the flowers are longer than the petals and have white anthers. The inflorescence is produced mainly from June to September. At germination, the cotyledons are narrow and lanceolate; the first true leaves have two or more leaflets along an axis and are hairless. The plant has a bitter taste, and the odor reminds about a mouse. Where plants are numerous, the odor can be very pervasive. The seeds or fruits do not have a very marked odor, but if crushed or mixed with an alkali as potassium hydroxide solution, the same characteristic, odor of mouse urine is produced [38, 52, 70, 85].

The poison hemlock grows in ground, hedgerows, roadsides and woodland, pastures, banks of streams and rivers, meadows and waste grounds modified soils, along fences, roadsides and ditches, around windmills, abandoned constructions, and around woods, under which it can vegetate during the winter [38]. The poison hemlock is a nitrophile plant which means that it prefers moist soils with high nitrogen level. Since it belongs to a group of very common, wide-spreaded weed species, its germination is an important target of investigations. Poison hemlock can be a persistent weed species particularly in moist habitats. A single plant may produce 35,000–40,000 seeds, which usually fall near the parent plant, but can be spread by water and animals [35, 85].

1.3 Alkaloids

The *Conium maculatum* produces alkaloids, linear furanocoumarins have been isolated from the plant, and synthesis and accumulation sites have not yet been clearly identified [19]. All tissues of *Conium maculatum* were very rich in alkaloids [1, 3, 4, 12, 14, 20, 28, 31, 84]. The alkaloid synthesis in *Conium maculatum* took place more readily in tissues of the shoot than the root [4, 20].

There are eight known piperidine alkaloids in poison hemlock [3, 4, 12, 20, 30, 35, 44, 46, 54, 67–70, 85, 88] (Fig. 26.1).

Conium maculatum plants have typically a mousy odor when bruised due to the presence of piperidine alkaloids. One of the chief components was identified long ago as coniine, 2-propyl-piperidine, although this is sometimes replaced by γ-coniceine, accompanied by six minor ones [36].

Two of them, coniine and γ-coniceine, are frequently found in largest amounts. Coniine is reported to be eight times more toxic than γ-coniceine [3, 4, 20, 30, 67, 85].

A large width in the outcome regarding the alkaloid content, both qualitatively and quantitatively, has been found, depending on that different researchers have not used exactly the same method, which stage one study and which organ [1, 20, 51, 52]. Other parameters which had an effect on the alkaloid concentration were rain (gives an increase of γ-coniceine level in fruits and flowers) and temperature [19, 81]; even the diurnal concentration varied in the alkaloids [20]. The quantity of alkaloid was twice during the sunny seasons compared to cloudy seasons. As the fruits ripen, the alkaloid content increase, and this also depends upon the soil moisture and its exposure to the sun. Since green fruits contain more alkaloids than mature fruits and seeds, the level of alkaloids in fruits reaches its peak while ripening but reduces near maturity. The concentrations of coniine and coniceine are found in similar degrees in cloudy summers, while coniine is most prevalent during dry summers [1, 4]. A significant increase is detected in the alkaloid concentration of *Conium maculatum* on nitrogen-fertilized soils [36, 70, 85]. Coniine (2-propylpiperidine) and *N*-methylconiine progressively increase in flowers and fruits, while γ-coniceine decreases during plant development. Highest concentration of alkaloids is in seeds which can contaminate poultry and swine cereal grains. The coniine is derived from acetic acid [30, 33, 48, 55, 70, 78, 88], formed from an eight-carbon poly-β-keto acid. Obviously, γ-coniceine is a precursor of coniine and the other hemlock substances, but the knowledge of the eight-carbon compound which is converted to the former alkaloid is still like a black box [13, 19, 35, 51–53, 78].

At least eight piperidine alkaloids have been found in various parts of the plant [13, 14, 52]. The two predominant toxic alkaloids are coniine (mature plant and seeds) and γ-coniceine (young growing plant) [20, 30]. The leaves and stems prior to the development of seed heads are the most toxic part of the plant. The seeds themselves are highly toxic and can be a source of poisoning when they contaminate cereal grains fed to livestock. Alkaloid content varies with stage of

development and stage of reproduction of plant. Young plants in the first year of growth are less toxic than mature plants, and those growing in the warmer southern states appear to be more toxic than those in the northern areas. Plants in the second year have alkaloid contents of approximately 1 % in all plant parts [4–6, 14, 18, 79] (Table 26.1).

2 Phytochemistry and Isolation of Some Hemlock Plant Alkaloids

2.1 Isolation of the Alkaloids

Of the total alkaloids of hemlock isolated by the method of Chemnitius and fractionally distilled, the portion boiling up to 190 C contains most of the coniine, γ-coniceine, and *N*-methylconiine, while conhydrine and ψ-conhydrine remain in the higher boiling residues. For the separation of coniine from coniceine, recommends conversion into hydrochlorides. These are dried and extracted with acetone, which dissolves coniceine hydrochloride, leaving the coniine salt, from which the base may then be regenerated. For final purification, the coniine is converted into the ᴅ-hydrogen tartrate. It is sometimes necessary to start crystallization by adding a crystal of the desired salt. The crude-mixed alkaloids distill until the temperature rises to 190 C, benzoylate the distillate, extract the tertiary bases by shaking an ethereal solution with dilute acid, pour the concentrated ethereal solution into light petroleum to precipitate most of the benzoyl-δ-aminobutyl propyl ketone formed by the action of benzoyl chloride on coniceine, distill the solvent from the filtrate, and collect from the residue the fraction boiling at 200–210 °C/16 mmHg, which is nearly pure benzoylconiine (bp. 203–4 C/16 mmHg). From this a mixture of D- and L-coniines is obtained by hydrolysis, the former predominating.

2.2 Phytochemistry of the Alkaloids

These piperidine alkaloids have the simplest structures for alkaloids so far described. The hemlock plants are comprised of several potent alkaloids, such as *coniine, γ-coniceine, conhydrine, N-methylconiine, and pseudoconhydrine*. These alkaloids shall now be discussed as follows.

2.2.1 Coniine

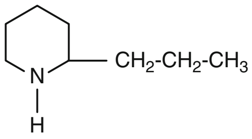
Coniine (2-propylpiperidine) can occur in two optically active forms according to configuration at C2, the (*S*) and (*R*) forms of which the former is the naturally occurring one. It is liquid at room temperature (melting point, −2 °C) and boils at 166 °C. Because of its volatility, it is best isolated as the hydrochloride (melting point, 220 °C), which crystallizes easily. Many synthetic routes have been-described in the literature, the earliest ones being a condensation between α-picoline and acetaldehyde or reduction of 2-allylpyridine by sodium in ethanol and the latest using modern, sophisticated reactions [55, 69, 70].

Synonyms: Cicutine, Conicine.

Biological sources: It is obtained from the unripe, fully grown dried fruits of *Conium maculatum* L. (*Umbelliferae*).

It also occurs in the plant *Aethusa cynapium L.* (*Apiaceae*) (Fool's Parsley), *Cicuta maculata* L. (*Apiaceae*) (water hemlock).

Chemical structure:



Coniine
(S)-2-Propylpiperidine.

It occurs naturally as the (S)-(+)- isomer.

Isolation. Coniine may be isolated by adopting the various following steps, namely:

(a) The powdered unripe, fully grown dried fruits of hemlock are mixed with a dilute solution of KOH and then subjected to stream distillation. The distillate is collected and neutralized carefully with dilute HCl and evaporated to dryness preferably under vacuum.

(b) The residue obtained as stated in (a) above is extracted with alcohol, filtered, and the alcohol evaporated to dryness under vacuum. The alcohol helps in extracting the alkaloidal salts that are dissolved in water; it is then rendered alkaline either with diluted KOH solution or with dilute NH_4OH and finally extracted with ether successively.

(c) The ether from the combined ethereal layer is evaporated completely, when an oily liquid consisting of the free bases remains in the residue.

(d) Finally, the residue is subjected to fractional distillation in a current of H_2 gas when the alkaloids could be broadly separated, and a mixture containing *coniine* and *γ-coniceine* shall pars over as the first fraction at 171–172 °C. These two alkaloids are consequently made to their corresponding hydrochloride salts, evaporated to dryness, and extracted with acetone. Thus, coniine hydrochloride would be separated as an insoluble product, while the *γ-coniceine* may be recovered by evaporating acetone under vacuum.

Coniine enjoys the unique distinction of being the first alkaloid produced synthetically.

Characteristic features:

- It is a colorless alkaline liquid.
- It darkens and polymerizes on being exposed to air and light.
- It has a mousy odor.
- Its physical parameters are as follows: bp 166–166.5 °C; $d\frac{20}{4}$ 0844–0848; $n\frac{23}{D}$ 1.4505.
- It is steam volatile.

Solubility: 1 ml dissolves in 90 ml of water, less soluble in hot water. The base dissolves in about 25 % water at room temperature. It is found to be soluble in alcohol, ether, acetone, benzene, amyl alcohol, and slightly soluble in chloroform.

Identification tests:

(a) It readily forms the corresponding hydrobromide ($C_8H_{17}N.HBr$), obtained as prisms, mp 211 °C, 1 g dissolves in 2 ml water, 3 ml alcohol, and is soluble freely in ether and chloroform.

(b) Its hydrochloride ($C_8H_{17}N.HCl$) forms rhomboids, mp 221 °C, freely soluble in water, alcohol and chloroform.

(c) It gives a red coloration with sodium nitroprusside slowly, which on addition of acetaldehyde changes to violet or blue.

Caution. It exhibits potential symptoms of overexposure as weakness, drowsiness, paresthesias, ataxia, nausea, excessive salivation, and bradycardia followed by tachycardia.

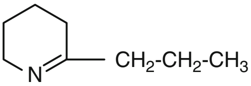
Uses. Externally, the coniine salts are used as ointments and infrequently employed for their local analgesic action in the symptomatic relief of pruritus, hemorrhoids, and fissures [45, 48, 74].

2.2.2 γ-Coniceine

γ-Coniceine (2,3,4,5-tetrahydro-6-propylpyridine) often accompanies coniine, sometimes occurring in greater quantities and is more toxic. As the free base is liquid (boiling point, 171 °C) at room temperature, it was better isolated as the hydrochloride (melting point 143 °C). The alkaloid was first synthesized by alkylation of phthalimide [70].

Biological source: It is obtained from the seeds of *Conium maculatum* L. (*Umbelliferae*).

Chemical structure:



γ-Coniceine
2, 3, 4, 5-Tetrahydro-6-propylpyridine.

Characteristic features:

- It is a colorless liquid alkaloid.
- It possesses a distinct mousy odor.
- It is steam volatile.
- Its physical parameters are bp 171 °C; d_{4}^{15} 0.8753; n_{D}^{16} 1.4661.
- It is slightly soluble in water, but freely soluble in ethanol, chloroform, and ether.

Identification test:

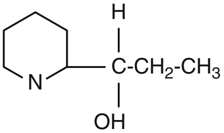
- γ-Coniceine when subjected to reduction, it gives rise to a racemic mixture of dl-coniine.
- It forms γ-coniceine hydrochloride ($C_8H_{15}N.HCl$) which gives hygroscopic crystals from ether mp 143 °C [21, 45, 46, 50, 70, 72, 75, 77].

2.2.3 Conhydrine

Conhydrine (2-(1-hydroxypropyl)piperidine) was recognized from early days as a minor, poisonous component of hemlock, where it occurs in the (+) form and could be separated by fractional distillation or crystallization. It is more soluble in water than coniine and crystallizes readily from ether (melting point, 121 °C). It was separated on a large scale from coniine [70].

Biological source: It is obtained from the seeds of *Conium maculatum* L. (*Umbelliferae*).

Chemical structure:



Conhydrine
[R-(R, S*)-a-Ethyl-2-piperidine methanol.*

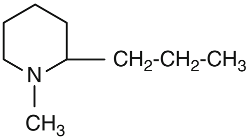
Characteristic features:

- The crystals obtained from ether have mp 121 °C, bp 226 °C, and $[\acute{\alpha}]_D$ + 10 °C.
- It is slightly soluble in water, but easily soluble in ethanol, ether, and chloroform [3, 45].

2.2.4 *N*-Methylconiine

Biological source: It is same as for conhydrine above.

Chemical structure:



N-Methylconiine

1-Methyl-2-propylpiperidine.

Isolation. The d-form is stated to occur in hemlock in small quantities, while thel-form may be isolated from residues left in the preparation of coniine by crystallization of the hydrobromides.

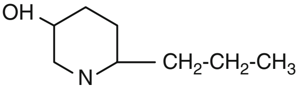
Characteristic features: The physical characteristic features of d-, l-, and dl-forms are given below (Table 26.2).

2.2.5 Pseudoconhydrine

Pseudoconhydrine (ψ-conhydrine, 6-propyl-3-piperidinol) is an isomer of conhydrine with the hydroxyl group on C5 (melting point, 105 °C), present in *Conium* usually as a minor component but reported unexpectedly as a major component in a certain American strain, growing in a greenhouse in early autumn, where it is formed from γ-coniceine [70].

Biological source: Its biological source is same as for coniine, through *N*-methylconiine above.

Chemical structure:



Pseudoconhydrine

(3S-trans)-6-Propyl-3-piperidinol.

Characteristic features:

(a) It gives hygroscopic needles from absolute ether.

(b) Its mp stands at 106 °C, whereas its monohydrate, scales, gives mp 60 °C from moist ether.

(c) Its physical parameters are bp 236 °C; $[\acute{\alpha}]^{20}_{D}$ +11° (c = 10 in alcohol); pK (18 °C): 3.70.

(d) It is soluble in water.

Table 26.2 The physical characteristic features of d-, l-, and dl-forms of the *N*-methylconiine [45]

Form	Nature	bp (°C)	d^{24}	$[\acute{\alpha}]_{D}^{24}$	n_{D}^{13}	Solubility
d-	Oily liquid	173–174	0.8318	+81°	1.4538	Slightly in water, soluble in organic solvents
l-	–	–	0.8318	–84°	1.4538	Slightly in water, soluble in organic solvents
dl-	–	10.5–56.6	–	–	–	–

Identification tests: It readily forms the hydrochloride salt ($C_8H_{17}NO.HCl$) as the crystals from ethanol having mp 213 °C [45].

Leaves and stems of a South African *Conium* species growing at high altitudes were found to contain *N*-methylpseudoconhydrine as a major component along with conhydrine. It occurred as only a minor alkaloid in plants growing at low altitudes. The free base is a liquid and is best prepared as its hydrochloride (melting point 157 °C).

Oxidation of the secondary alcoholic group of conhydrine yields conhydrinone, isolated from the plant as the crystalline hydrochloride (melting point, 249 °C) [3, 50, 70].

3 Biosynthesis of γ-Coniceine and Coniine

The γ-coniceine and coniine are generally the most abundant, and they account for most of the plant's acute and chronic toxicity. These alkaloids are synthesized by the plant from eight acetate units from the metabolic pool, forming a polyketoacid which cyclizes through an aminotransferase and forms gamma-coniceine as the parent alkaloid via reduction by an NADPH-dependent reductase.

A fatty acid precursor octanoic acid (capric acid) is employed, which is subsequently transformed into the ketoaldehyde through successive oxidation and reduction steps (Fig. 26.2). The resulting ketoaldehyde acts as a substrate for a transamination reaction; the amino moiety is derived from L-alanine [1, 8, 21, 30, 33, 45, 47, 49, 50, 55, 68, 70, 72, 74, 75]. The ultimate transformation leads to the formation of imine, giving the heterocyclic ring present in γ-coniceine, and then reduction of the coniine, as shown in Fig. 26.2.

4 Biosynthesis of *C. maculatum* Alkaloids

For a long time, secondary plant metabolites were considered as waste substances, accumulating during the plant life. Actually, they have a dynamic interaction with the primary metabolism and are involved in turnover and catabolic processes, fully participating in the whole scheme of the plant metabolism [3, 5, 44, 51, 52]. *C. maculatum* alkaloids are no exception. Their concentrations can undergo

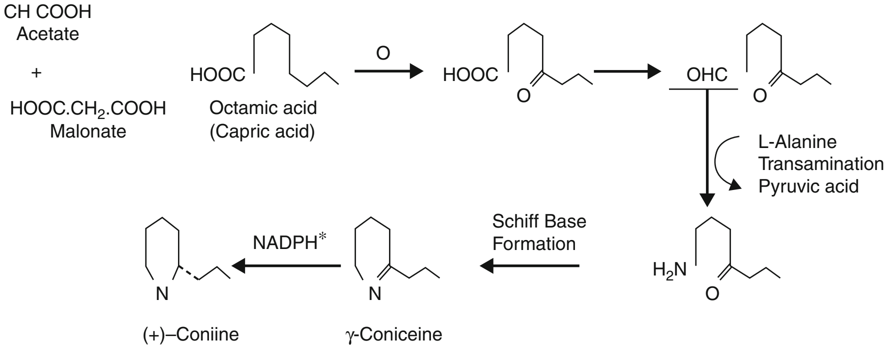


Fig. 26.2 Biosynthesis of γ-Coniceine and Coniine

frequent changes during the plant growth. It is remarkable that seeds present a high alkaloid content, while during the early stages of growth, a much lower alkaloid content is found in the foliage. Rapid changes in the alkaloid concentration are observed in different circumstances: wet or dry weather, different seasons, and degree of herbivory.

In early experiments related to changes of the concentrations of the two major alkaloids found in *C. maculatum* (coniine and γ-coniceine, the latter in much lower concentrations), it was noticed that coniine reached a maximum of about 6 μg/fruit at 4–5 weeks of growth depending on the year of collection, while γ-coniceine simultaneously, although not stoichiometrically, decreased to a minimum. Diurnal, large changes were also noticed in the concentrations of both alkaloids, the increase in one corresponding to a decrease in the other. According to these authors, minor quantities of other alkaloids were noticed: when coniine was at its maximum, *N*-methylconiine cooccurred, while conhydrine occurred in small amounts when coniceine predominated, but in this case *N*-methylconiine was absent [33, 52].

Biosynthesis of these compounds proceeds through a completely different route from that of the other piperidine alkaloids (Fig. 26.3). Early work pointed to γ-coniceine as the first alkaloid to be formed, followed by transformation to coniine, conhydrine, and *N*-methylconiine. Levels of these compounds varied greatly within the plant and under different environmental conditions and between varieties. Variations were even found between 2- or 4-h periods of a day and between days. This can be surprising, when, for instance, Leete and coworkers usually found coniine and conhydrine in equal amounts in their plants but on a subsequent occasion when the plants were grown in a greenhouse in the early autumn, coniine and pseudoconhydrine were the major components [44, 50–52, 68, 88].

It was proposed that the piperidine ring of *C. maculatum* alkaloids is produced by cyclization of lysine. However, attempts to demonstrate that lysine is a precursor of the piperidine ring in coniine by feeding D,L-lysine-2-^{14}C to the stems of *C. maculatum* plants, failed in producing labeled coniine.

Fig. 26.3 Biosynthesis of *C. maculatum* Alkaloids

Uniformly labeled L-lysine-^{14}C administered to hemlock plants afforded radioactive coniine, but no degradative studies were produced by these authors to prove that labeling was present in the piperidine ring. Instead, feeding sodium acetate-1-^{14}C to 2-year-old *C. maculatum* plants indicated that alkaloids obtained from the plant (coniine, γ-coniceine, and conhydrine) presented labeling. Chemical degradation of the obtained coniine showed that activity was mostly and evenly distributed in even-numbered C-atoms, which allowed to speculate that hemlock alkaloids are derived from an 8-C aliphatic polyketo chain produced by the linear attachment of four acetate units probably through the condensation of 4 molecules of acetyl-CoA. The results of may be due to metabolization of lysine-^{14}C to radioactive acetate units, then incorporated to coniine.

Feeding γ-coniceine-1′-^{14}C to *C. maculatum* plants showed that all the activity was transferred to the C-1′ of the propyl side chains of coniine and pseudoconhydrine indicating that γ-coniceine can be the precursor of the former. It is interesting to note that similar feeding experiments conducted in a greenhouse and outdoors produced conhydrine and pseudoconhydrine, respectively, suggesting that changes in the environment can induce changes in the alkaloid composition of *C. maculatum.*

Later experimental work provided evidence that the 8-carbon polyketoacid intermediate in the synthesis of γ-coniceine is derived from octanoic acid since this acid was shown to be readily incorporated into coniine. Further work indicated that 5-keto-octanoic acid and 5-keto-octanal were produced during the biosynthesis of γ-coniceine. A transaminase (L-alanine: 5-keto-octanal aminotransferase) was obtained from *C. maculatum*. This transaminase catalyzes the reaction between 5-keto-octanal with L-alanine as the amino group donor to form the piperidine ring and the propyl side chain. Another *C. maculatum* alkaloid, *N*-methylconiine, was shown to be produced by another enzyme from the plant: a coniine methyltransferase which acts as a transmethylator utilizing *S*-adenosyl-L-methionine as a methyl group donor.

The production of coniine is catalyzed by an NADPH-dependent γ-coniceine reductase in a reversible reaction, since earlier experiments showed a fast interconversion between both substances, even in an hourly basis.

Glutamate-oxaloacetate aminotransferase (GOT) and GPT, possible aliphatic aminotransferases in the amination of 5-keto-octanal instead of L-alanine:5-keto-octanal aminotransferase, were excluded from that function by further work which separated the activities of the former from that of the latter, in turn shown to be composed of two isozymes, although no individual function was described.

γ-Coniceine has also been proposed as the source of pseudoconhydrine. Tautomerization of the double bond between N and C2 of the piperidine ring could produce the shift of the double bond to N and C6, yielding an allylic C5 which in turn could be oxidized to produce a hydroxy C5. It has been proposed that conhydrine is produced by oxidation of γ-coniceine to conhydrinone and its subsequent reduction to conhydrine [1, 3, 4, 8, 21, 30, 33, 44–50, 55, 68–70, 72–78, 88].

The d-stereoisomer of the *N*-methylconiine was separated from coniine, from which it was distinguished by its rotary power, in a plant extract provided by the Merck factory, and the l-stereoisomer separated as the hydrobromide, again from coniine, in a plant extract also from the Merck factory [15].

Five unidentified polar compounds from Conium fruits and leaves were recognized chromatographically and distinguished by their differing solubilities in aqueous ethanol. On hydrolysis, they yielded coniine or related alkaloids. It is postulated that the alkaloid moiety may be part of a molecule resembling NAD, replacing the nicotinamide portion. Furthermore, other activities for NAD and NADP have been described, especially those involving signaling [8], and, who knows, maybe coniine is involved in these.

5 Biological Activities

Despite its poisonous nature, *Conium* is included in several herbals as Succus conii, described as a narcotic, sedative, analgesic, spasmolytic, antiaphrodisiac, and anticancer agent. It was even listed at one time (up to 1934) in the British

Pharmacopoeia and the British Pharmaceutical Codex as a sedative and antispasmodic, the latter property leading it to be recommended as an antidote to strychnine [32]. More recently, it was speculated that by modifying the structure to remove some of the toxic properties, notably the teratogenic effects [52], a substitute for curare could be obtained for surgical purposes. The coniine alkaloids are neurotoxins, and death results from respiratory failure. Problems arise with livestock eating the plants which may grow in fields adjoining watercourses, or dried material inadvertently becoming included in hay.

The biological activities of the poison hemlock (*Conium maculatum*) are due to the content of piperidine alkaloids – coniine (2-propylpiperidine), γ-coniceine (2n-propyl-1γ-piperidine), conhydrine (2-(1- hydroxypropyl)-piperidine), *N*-methylconiine (1-methyl-2- propylpiperidine), pseudoconhydrine ((5-hydroxypropyl)-piperidine), conhydrinone ((1-oxo-propyl)-piperidine), *N*-methylpseudoconhydrine (5-hydroxy-1-methyl-2-propyl-piperidine), and 2-methylpiperidine. The poisoning effect of hemlock supplements by the presence of poly-β-keto acid (2,5,7-tri-oxo-octanoic acid), quercetin, kaempferol, and glycoside dioxymid [4, 12, 13, 20, 52, 85, 87].

5.1 Mechanism of Action

The mechanism of action of the conium alkaloids is complex because they have a profound effect in blocking spinal cord reflexes. After an initial stimulatory effect, the autonomic nervous system ganglia become depressed [6, 26, 56, 87]. Large doses of alkaloid cause skeletal muscle stimulation followed by neuromuscular blockade and paralysis similar to that caused by nicotine on the central and peripheral nervous systems [52]. In small quantities, the alkaloids cause skeletal defects in the fetal calf if poison hemlock is grazed by pregnant cows. Hemlock alkaloids have been found to have an action on spinal cord reflexes and depress autonomic activity and in large quantities cause neuromuscular blockade [6, 7, 13, 28, 56, 57, 61, 62, 87]. This action may lead to respiratory depression [9] and anoxic brain injury, with eventual death following within 24 h of ingestion [17]. Despite rhabdomyolysis and associated acute renal failure have been recorded regarding hemlock poisoning, no direct toxic effects have been described concerning the liver or kidneys [29, 71, 79].

The action of poison hemlock of the central nervous system seems to play a minor role, as the senses seemingly remain intact in humans and in animals. Since stimulation of the sensory cells does not result in muscle contraction, there is an increased resistance in the sensory cells [7, 13, 26, 56, 87]. The influence the hemlock alkaloids have on the heart is of minor importance. After preliminary stimulation the sympathetic and parasympathetic ganglia become paralyzed, the same reaction takes place with the respiratory medullary center, which results in a respiratory arrest and asphyctic agonal convulsions [9, 17].

5.2 Species-Related Sensitivity

In the literature, spontaneous cases and experimentally induced intoxications with poison hemlock (*Conium maculatum*) in cattle [10, 11, 37, 56–58, 61, 65, 66, 85, 87], pigs [16, 23, 24, 37, 59, 60, 85, 86], sheep [10, 62], goats [10, 63, 64], horses [10, 52], donkeys [10], elk [39], rats [2, 25, 26], rabbits [25], birds [27], and humans [9, 17, 22, 71, 79, 85, 87] are reported.

These investigations show that in animals, poison hemlock intoxication occurs in two clinical forms – acute and chronic [52, 85]. For the acute form, the sensitivity of animal species in descending order is as follows: cattle, sheep, goats, and swine whereas for the chronic form – cattle, swine, and sheep [52]. Our data [10, 11] for the sensitivity to acute intoxication showed that cattle were the most sensitive, followed by horses, sheep, and goats. Cattle have been fatally poisoned by eating as little 0.5% of their body weight of green hemlock [37, 56, 61].

Experimental hemlock poisoning in cattle, pigs, and sheep has been produced by a wide range of doses, suggesting that there is considerable variation in the toxic alkaloid content of the plant [37]. Cattle dosed with 1 mg/kg developed clinical signs, while 5.3 mg/kg of green plant was lethal [66]. In sheep, repeated poison hemlock doses of 10 mg/kg body weight were lethal [62]. Cattle were most susceptible to pure coniine administered by stomach tube, requiring 3.3 mg/kg body weight to induce severe poisoning. Mares required 15.5 mg/kg and sheep 44.0 mg/kg of the alkaloid to induce severe poisoning [66]. The lethal dose following ingestion of poison hemlock seeds in swine is 1 g/kg [59–61], and in men – 2 g/kg [29, 38, 52, 85, 87]. People are usually poisoned when they mistakenly eat hemlock for plants [70, 85]. A tea made from poison hemlock was reportedly used to kill Socrates [70].

Toxic incidents in men, after consumption of milk from cows having ingested poison hemlock in minimal toxic doses, have been reported [38]. Lethal doses of fresh *C. maculatum* are given below (Table 26.3).

There is information concerning the acute toxicity of pure coniine, γ-coniceine, and *N*-methylconiine. The oral LD50s in mice are 12 mg/kg for coniceine, 100 mg/kg for coniine, and 204.5 mg/kg for *N*-methylconiine [15, 83]. The single oral doses of pure coniine inducing acute toxic effects in some domestic animals are indicated in Table 26.4.

Livestock seldom eat hemlock because of its strong odor, but they will do so if no other forage is available or if it is incorporated in hay or silage [52].

5.3 Acute Poisoning

The most important and toxic of these is coniine, which has a chemical structure similar to nicotine [13, 14, 80]. Coniine is a neurotoxin, which disrupts the workings of the central nervous system and is toxic to humans and all classes of livestock [85]. Ingestion in any quantity can result in respiratory collapse and death.

Table 26.3 Acute lethal oral doses of fresh *Conium maculatum* in some domestic animals [52]

Animal species	Lethal dose (g/kg LW)	Alcaloid content (%)	γ-Coniceine (%)	γ-Coniceine doses (g/kg LW)
Sows	8.0	0.023	98	1.8
Cows	5.3	0.40	98	21
Sheep	10.0	0.40	98	39

Table 26.4 Acute effects of single oral doses of coniine in different domestic animals [52]

Species	Dose (mg/kg)	Degree of symptoms
Cows[a]	3.3	Severe
Mares[a]	15.3	Severe
Ewes[a]	44.0	Moderate
Quails[b]	25.0	Severe
Chicks[b]	50.0	Severe
Turkey chicks[b]	100.0	Severe

[a] Adult animals (maximum nonlethal doses)
[b] Three- to six-week-old animals (lethal to some individuals)

Coniine causes death by blocking the neuromuscular junction in a manner similar to curare; this results in an ascending muscular paralysis with eventual paralysis of the respiratory muscles which results in death due to lack of oxygen to the heart and brain [80]. Death can be prevented by artificial ventilation until the effects have worn off 48–72 h later. For an adult, the ingestion of more than 100 mg of coniine (approximately 6–8 fresh leaves, or a smaller dose of the seeds or root) may be fatal [70, 85].

When this group of piperidine alkaloid-containing plants is involved, the symptoms of poisoning are similar in all livestock production. The initial symptoms include nervousness, depression, grinding of the teeth, frothing around the mouth, relaxation of the nictitating membrane of the eye, frequent urination and defecation, and lethargy. Then eventually follows muscular weakness, tremors and fasciculations, ataxia, collapse, respiratory failure, and death [17, 38, 85]. Signs of toxicosis may appear as early as 1 h after ingestion and get worse the next 24–48 h even if further ingestion does not occur [9, 38, 70].

The poison hemlock intoxications in men are accompanied with ataxia, vibration, convulsions, nausea, vomiting, general indisposition, muscle weakness, slow movements and speech, loss of skin sensitivity, arrhythmia, and mydriasis. Prior to the death, paralysis of limbs, eyelid collapse, and mental sluggishness [22, 43, 67, 79, 87] occur.

Our studies [10, 11] upon the acute form of poison hemlock intoxications in cattle showed that the body temperature was elevated but in the course of the intoxication, prior to the lethal issue, it falls under the reference values. These data could be used for determination of the prognosis and the outcome of this type of intoxication in cattle. The heart rate is accelerated and the pulse – weak, soft, and arrhythmic. The respiration is accelerated, labored, and accompanied with stridors. In cattle, a high-grade frothy bloat with alkaline pH of rumen liquid is observed. Apart these alterations, refusal of feed, lack of defecation and urination, hypersalivation, lack of thirst, diffusely reddened conjunctivae and mydriasis, eyelid collapse, gasping and moaning, teeth grinding, disturbances in locomotion, muscle cramps, ataxia, hyporeflexia, dermal anesthesia, and convulsions were also observed.

In goats and sheep, the bloat is remitting and transient. In sheep having ingested poison hemlock when grazing, a profuse, bad-odored greenish diarrhea was observed by us. In donkeys, a bilateral abdominal distention, arexia, lack of defecation, weak and brief episodes of colic alternating with long painless pauses have been observed. During rectal examination, intestinal meteorism is determined. In horses, the episodes of colic are stronger and prolonged, as a result of acute ventricular dilatation [10].

5.4 Chronic (Teratogenic) Toxicity

Since the piperidines behave in a specific way and are teratogenic, they also fulfill specific criteria for teratogenesis [23, 24, 38, 70, 85]. The structural characteristics of these piperidines need to be determined and their main differences outlined to be able to find out their mechanism of action, as fetal movement and malpositioning. The birth defects caused by *Conium maculatum* are the same, and their biological activities occur by a similar mechanism of action [16, 52, 65, 66, 70]. As usual with biological active compounds one use to characterize the toxicity into acute and chronic forms. The peripheral actions of coniine are similar to those of nicotine, but it produces more pronounced paralysis of the central nervous system and of the skeletal muscle nerve [65, 70].

The molecular structure determines the teratogenicity (chronic toxicity) of *C. maculatum* alkaloids (no information has been found relating the acute toxicity and the structure of these alkaloids). The side chain must be a propyl group or larger. For instance, 2-ethylpiperidine has been shown to be nonteratogenic. Partial unsaturation seems to increase toxicity since coniceine is more toxic than coniine, while 2-propylpyridine is nonteratogenic, i.e., aromatization of the ring suppresses toxicity.

The related malformations caused by poison hemlock have been described in calves, piglets, kits, and lambs: at birth they show arthrogryposis, scoliosis, torticollis, cleft palate, and excessive flexure of the carpal joints (Fig. 26.4).

These injuries were reproduced experimentally to cows during the 55–75 days and sows during the 30–45 days of pregnancy [38, 40–42, 70, 85]. The piperidine toxins from poison hemlock induce in livestock reduction of fetal movement and fetal malpositioning [24, 40, 41, 59, 60, 62–66, 70, 82] and produce a similar sedative and anesthetic effect on the fetus as on the dam [16]. The fetal mandibular movements (particularly, the downward movement of the lower jaw) and tongue retraction are required for palatal shelves to become closer, allowing a normal closure of the

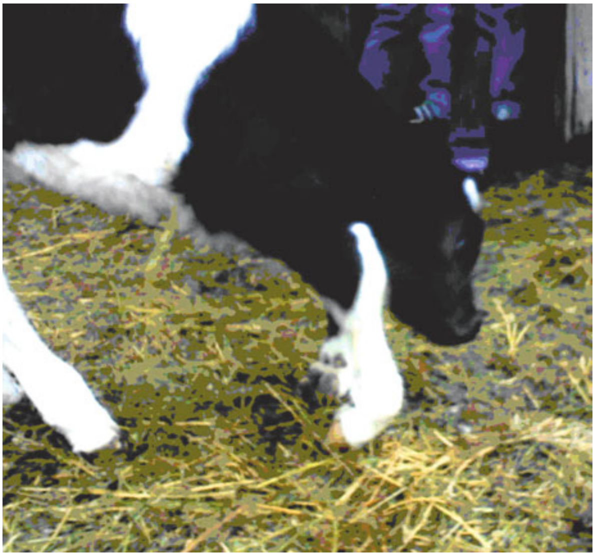

Fig. 26.4 Malformations caused by Poison Hemlock in calves: At birth they show arthrogryposis, scoliosis, torticollis, cleft palate and excessive flexure of the carpal joints

upper jaw. The absence of these movements can produce palatoschisis, since the tongue occupies the place where the palatal shelves must fuse.

Arthrogryposis has been questioned as an accurate name for the malformation, and it has been proposed to be replaced by multiple congenital contracture (MCC) [82]. These authors found that MCC is caused by loss of muscle mass with imbalance of muscle power at the joints which provokes a collagenic response consisting of partial replacement of muscle volume and collagenous thickening of the joint capsules, the latter leading to joint fixation.

It is possible that the known anesthetic effect of the alkaloids of *C. maculatum* inhibits the mentioned fetal movements. In consequence, the tongue obstructs the place where the shelves fuse together. Furthermore, the closure of the palatal shelves also depends on the separation of the fetal inferior jaw from the breast bone, which in turn depends on the fetal movements. If these movements are impaired, the lower jaw compresses the tongue against the upper part of the oral cavity, which impedes the mutual approaching of both palatal shelves [24].

Seeds and fresh *C. maculatum* administered orally to goats twice daily during 30–60 days of gestation produced malformations in the offspring (palatoschisis and arthrogryposis). Ultrasonic control of fetal movement was performed during 12 h at 45, 51, 55, and 60 days of pregnancy. *C. maculatum* seeds produced almost total fetal immobility, while the fresh plant produced the same effect, but lasting only 5h. Goat kids born to dams dosed with seeds showed palatoschisis and arthrogryposis, while those born to dams fed with the fresh plant showed minor flexures of forelimbs, which receded a few weeks after birth [63, 64]. This lack of fetal movement caused by *C. maculatum* had been also observed in pigs [23, 24, 59, 60, 82] and in sheep [62]. In the latter, only slight front limb abnormalities were found, which

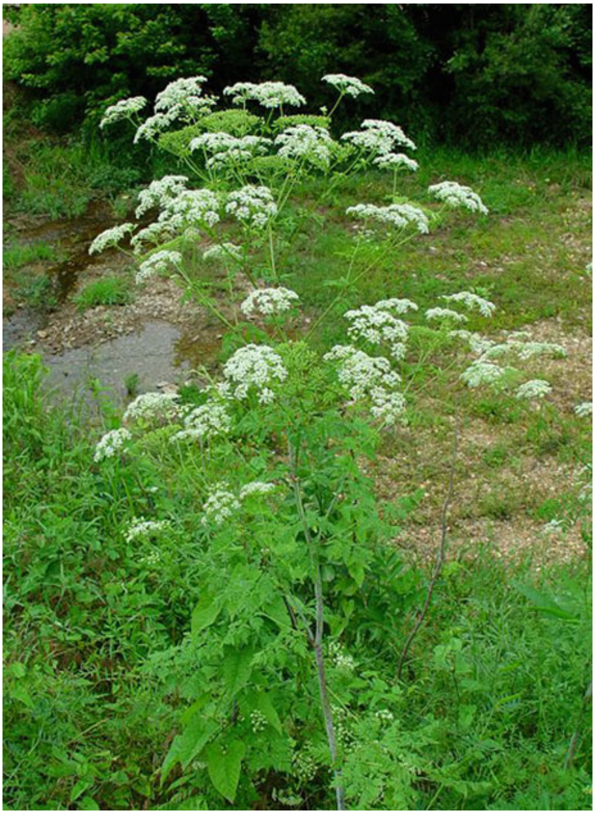

Fig. 26.5 Poison Hemlock (*Conium maculatum*)

receded in about 8 weeks, this being consistent with the already mentioned lower chronic toxicity produced by *C. maculatum* in sheep.

The four main alkaloids are coniine, γ-coniceine, *N*-methylconiine, and conhydrine. Conhydrine occurs in the smallest proportions and has the weakest pharmacological action [3, 4, 19, 20, 31, 67, 85, 87]. The most distinctive action of the three other hemlock alkaloids plus nicotine is their ability, provided the dose is small, to inhibit the crossed extensor reflex and the so-called knee-jerk by an action potential in the spinal cord. Since neurons in the spinal cord may both be inhibited and activated by the action of hemlock, the mechanisms involved are a bit complicated. If the alkaloids initially stimulate inhibitory neurons rather than blocking excitatory ones, the antagonistic relationship of the two substances may be explained. There is evidence that its central synapse is controlled by polysynaptic inhibitory pathways, although the patellar reflex is monosynaptic [3, 19, 67]. It is possible that the *C. maculatum* piperidine alkaloids may act upon the mechanism that regulates the amniotic liquid, adding to the production of malformations. Finally, lack of fetal movement, whatever its origin, can also cause limb malformations.

5.5 Medicinal Uses

Poison hemlock has been used as a sedative and for its antispasmodic properties. It was also used by Greek and Persian physicians for a variety of problems, such as arthritis. It was not always effective, however, as the difference between a therapeutic and a toxic amount (the therapeutic index) is very slight. Overdoses can produce paralysis and loss of speech, followed by depression of the respiratory function, and then death.

6 Conclusion

The study and use of alkaloids over the past 200 years is a success story. The acetate-derived alkaloids contained mainly in the plant poison hemlock (*Conium maculatum*) which is a very common and worldwide plant species, and it is one of the most toxic plants known. Levels of the various alkaloids are fluid with formation and interconversions being strongly influenced by plant variety, plant part, age, season, and growing conditions. Toxicity is due to a group of alkaloids of which the representative members are coniine and γ-coniceine. It has been suggested that the compounds are involved in an oxidation–reduction system of metabolic significance in the plant. The acetate-derived alkaloids derive biosynthetically from acetate units via the polyketide pathway in contrast to other piperidine alkaloids which derive from lysine. Coniine stimulates and then depresses autonomic ganglia and motor end plates in skeletal muscle. Large doses can cause neuromuscular block. Both acute and chronic symptoms have been described. The compounds are neurotoxins, and death results from respiratory failure. Chronic nonlethal ingestion by pregnant livestock leads to fetal malformation.

My purpose was to compose a beneficial text for an academic and professional audience that could also serve as a source of knowledge for anyone who is interested in the fascinating subject of alkaloids.

Abstract

Ephedrine is an alkaloid derived from various plants in the genus *Ephedra* (family Ephedraceae). The alkaloid is comparable in actions to adrenaline. It has many medicinal and pharmaceutical applications; it is a bronchodilator to relieve shortness of breath, chest tightness, wheezing, and cough associated with bronchial asthma. Amino acids such as phenylalanine and tyrosine serve as the precursors for a large number of alkaloids, including ephedrine, capsaicin, and colchicines. Although ephedrine is produced by chemical synthesis or enzymatic methods, it is also obtained from *Ephedra* species. This chapter provides general information about *Ephedra*, ephedrine, and its derivatives, discusses methods to analyze them, and finally presents achievements in this area of science.

1 Introduction

In today’s world, some plant-derived secondary metabolites play a great role in pharmaceutical production, among them nitrogen-containing natural compounds called alkaloids. Some alkaloids are produced by synthesis or enzymatic methods and others are obtained from plants. Unfortunately, overexploitation of these plants has made them endangered species. Therefore, appropriate technologies for sustainable use and sufficient focus on the biosynthetic routes and methods of isolation of these secondary metabolites derived from the plants are required.

Ephedrine, an alkaloid with an amphetamine-like structure, is currently used in pharmaceuticals, with potentials to affect nerves, muscle, blood pressure, and heart rate. In 2004, the US Food and Drug Administration (FDA) banned ephedrine alkaloids marketed for reasons other than asthma, colds, allergies, other disease, or traditional Asian use. Ephedrine and its derivatives (stereoisomers and diastereomers) are naturally found in varied proportions in different plant species such as *Catha edulis* [12], *Roemeria refracta* [48], *Taxus baccata* [20], *Sida cordifolia* [7], *Pinellia ternata* [24], *Aconitum napellus* [8], and *Ephedra* species [22, 29, 32, 37].

This chapter describes *Ephedra* alkaloids, their biosynthetic pathway, methods to analyze them, and biotechnological methods for their production.

2 *Ephedra*

Ephedra is a leafless evergreen plant, the only genus in the family of Ephedraceae and order of Gnetales, and a genus of gymnosperm that is introduced as a medicinal plant. This plant grows in dry climates in Central Asia, North America, the southern part of Europe, and the northern part of Africa. It reaches to about 60–100 cm high [23]. The Chinese have used *Ephedra sinica* (*má huáng*) for thousands of years to treat allergies, bronchial asthma, chills, colds, coughs, edema, fever, flu, headaches, and nasal congestion. There are more than forty species recognized in the literature,

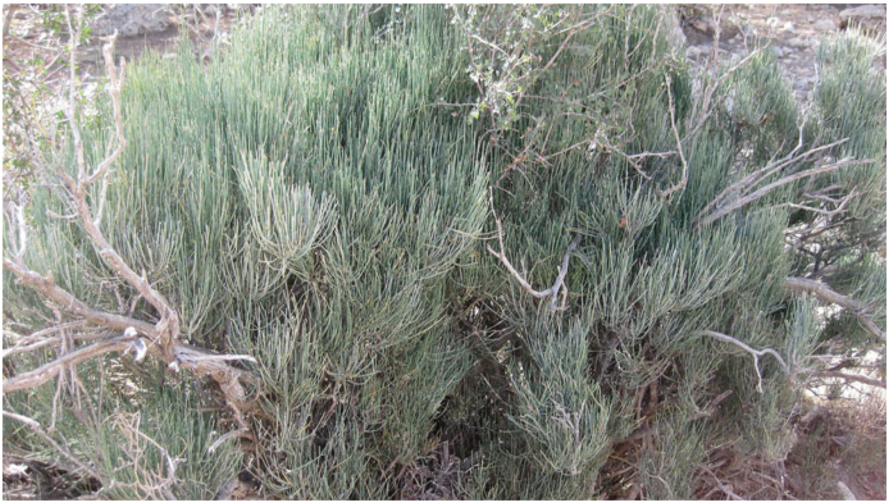

Fig. 27.1 Habitat of *Ephedra strobilacea*

however, the primary species of *Ephedra* are *E. sinica* Stapf, *E. major* Host, *E. gerardiana* Wall, *E. equisetina* Bunge, and *E. intermedia* Schrenk & Meyer [9]. Generally, the plant is a small woody bush, as shown in Fig. 27.1.

Ephedra is a strong stimulant and acrid-tasting herb. According to legends, the bodyguards of Genghis Khan, who were threatened with beheading if they fell asleep on sentry duty, used to drink a tea containing *Ephedra* to stay alert [3]. *Ephedra* has been a natural source of alkaloids such as ephedrine, pseudoephedrine, norpseudoephedrine, and other related compounds that are highly correlated with stimulatory actions. The total alkaloid content of *Ephedra* is approximately 1–2.5 %, and ephedrine and pseudoephedrine are more than 80 % of the alkaloid content of dried plant. Generally, extraction of ephedrine-type alkaloids from crude plant material involves an acid/base extraction procedure [4, 27, 35, 40].

There have been significant developments in the isolation of the other pharmacological compounds from different species of *Ephedra* besides ephedrine and its derivatives, such as kynurenic acid derivatives, methanoproline amino acids, flavones, tannins, carboxylic acids, volatile terpenes, and other compounds such as *cis*-3, 4-methanoproline, and a cyclopropyl analogue of proline or quinaldic acid known as an antimicroorganism agent [10, 19, 21, 44]. In this regard, researchers have reported the antimicrobial activity of *Ephedra* extracts against such microorganisms as *Vibrio parahaemolyticus*, *Clostridium perfringens*, *Bacillus subtilis*, and *Staphylococcus aureus*. Furthermore, there are significant reports on the presence of antioxidants in *Ephedra* species. Using a FRAP method (ferric reducing antioxidant power) on *Ephedra strobilacea*, an amount of 1.61 ± 0.08 mmol eq quercetin g^{-1} extract was recorded [32]. The antioxidant activity of *Ephedra* extract is perhaps correlated with the existence of reported phenolic compounds such as benzoic, p-hydroxybenzoic, cinnamic, p-coumaric, vanillic, and protocatechuic [10].

Another outstanding aspect of *Ephedra* lays behind its antimutagenic activity. The extracts of in vitro culture of *Ephedra* were tested against benzo[a]pyrene, 1, 6-dinitropyrene and 3, 9-dinitrofluoranthene and showed a remarkable inhibition against benzo[a]pyrene, whereas that inhibition against 1, 6-diNP and 3, 9-diNF was varied from 20 % to 86 %. Researchers concluded that the differences in inhibition might be due to inactivation of metabolic enzymes [12].

Recently, many dietary supplements containing *Ephedra* powder have received increasing attention for their use in aiding weight control and boosting performance and energy. However, there is also evidence that dietary supplements containing ephedrine alkaloids pose a risk of serious adverse events including heart attack, stroke, and death. Due to these results, the FDA has prohibited the sale of some dietary supplements containing *Ephedra* alkaloid, excluding its use in decongestants and medicines for colds and the treatment asthma [4, 25].

2.1 Ephedrine, its Derivatives, and their Pharmacological Uses

Ephedrine is an alkaloid, a sympathomimetic amine with molecular formula C_{10} H_{15} NO_1, a molecular mass of 165.2, and the structural name (1*R*, 2*S*)-2-methylamino-1-phenylpropan-1-ol. This bitter colorless or white solid-crystal is completely soluble in water, alcohol, chloroform, ether, and glycerol. Ephedrine is also produced by chemical synthesis and there is significant documentation of commercial ephedrine production using microbial biotransformation techniques [42]. Ephedrine has a structure close to methamphetamines, and its stimulant actions are comparable to epinephrine (adrenaline), a hormone produces by the adrenal glands that enhances heart rate and constriction of blood vessels in high-stress situations. Medicinal use of ephedrine began around 3000 B.C with the Chinese from *má huáng*, but its isolation was first reported in 1855 and its pharmaceutical application started in 1930 [22]. Studies on ephedrine's molecular structure show that two asymmetric carbon atoms are involved in ephedrine's molecular skeleton; therefore, four optically active stereoisomers forms naturally occur as follows: (1*R*, 2*S*)-(−)-ephedrine, (1*S*, 2*R*)-(+)-ephedrine, (1*R*, 2*R*)-(−)-pseudoephedrine, (1*S*, 2*S*)-(+)-pseudoephedrine (Fig. 27.2).

Notably, pseudoephedrine is a diastereomer of ephedrine and considerably racemic ephedrine (dl-ephedrine) has not been found naturally, however, it is prepared synthetically and is inactive for commercial purposes. Ephedrine and pseudoephedrine are completely stable compounds under changing temperature conditions, but they are quite unstable when exposed to sunlight or in the presence of oxygen pressure [2]. The unique molecular structure of ephedrine causes its different stereoisomers to be valuable for pharmaceutical applications such as nasal decongestant, pupil dilator, bronchodilator, and central nervous system stimulant. Ephedrine is a sympathomimetic substance and the principle mechanism of ephedrine activity is its influence, by enhancing the activity of noradrenalin, on post-synaptic α- and β-receptors in the nervous system. Stimulation of α 1-adrenergic receptors produces contraction of vascular smooth muscle,

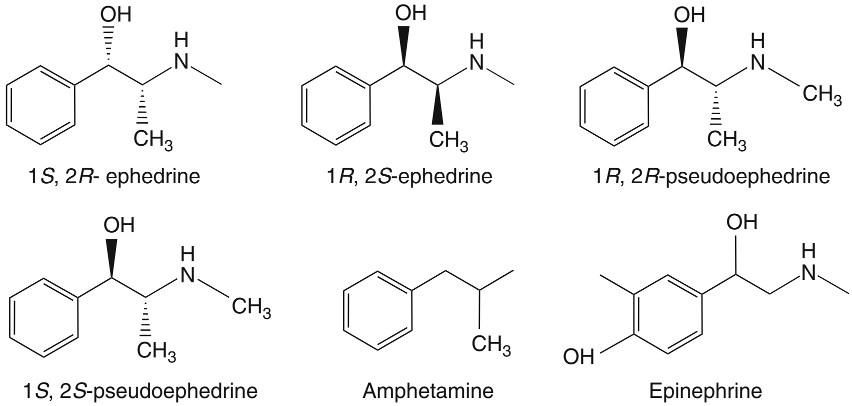

Fig. 27.2 Comparison of ephedrine and its derivatives with Amphetamine and Epinephrine

increased contractile force of the heart and arrhythmias, glycogenolysis, gluconeogenesis, hyperpolarization, and relaxation of intestinal smooth muscle. Stimulation of β_2-adrenergic receptors decreases insulin secretion, platelet aggregation, and the release of norepinephrine from the nerve terminals, and causes contraction of vascular smooth muscle [9]. It is also reported that ephedrine has the ability to metabolize to norephedrine (phenylpropanolamine), which may be responsible for the central nervous system stimulant effects that lead to weight lose; it seems that the mechanism for loss appears to be by increasing the metabolic rate of adipose tissue [6, 26]. Unfortunately, ephedrine has been correlated with toxic psychosis and based on this result the demand is increasing for d-pseudoephedrine, the ephedrine diastereomer that has fewer side effects compared with ephedrine; it also has a weaker, longer-lasting influence on the central nervous and cardiac system [43, 47].

2.2 The Biosynthesis Pathway and Expression of Ephedrine in *Ephedra*

About 5,000 different alkaloids are known and most of them are derived from amino acids. Typically, amino acids such as phenylalanine, tyrosine, and their corresponding decarboxylation products serve as the precursor for a large number of alkaloids, including ephedrine, capsaicin, colchicines, and even opium alkaloids. The class of phenylalkylamines in *Ephedra*, such as ephedrine, is originally derived from phenylalanine [15, 16, 41]. Evidently, the production of ephedrine and its derivatives in *Ephedra* starts via the biosynthetic pathway of shikimic acid by transformation of phenylalanine in to benzaldehyde (C_6H_5CHO) that consequently leads to a reaction to synthesize cathinone (benzoylethanamine), a monoamine alkaloid molecule from which ephedrine and pseudoephedrine are

derived (Fig. 27.3). Using ^{13}C nuclear magnetic resonance spectroscopy, researchers reported that the labeled C_2 fragment of [2, 3-$^{13}C_2$] pyruvic acid is transferred intact into the *C*-methyl group of the adjacent carbon atom of the *Ephedra* alkaloids. This observation lead to identification of pyruvate as the elusive precursor of the aliphatic C_2 terminus of the skeleton of ephedrine. In other words, the carbon skeleton of ephedrine is generated from pyruvate and either benzaldehyde or benzoic acid by a reaction analogous to the formation of acetoin or diacetyl from pyruvate and acetaldehyde or acetic acid, respectively [11].

2.3 Methods of Analysis for Ephedrine and its Derivatives

Secondary metabolites include a wide variety of compounds with different structures and chemical properties. Typically, isolation and estimation of secondary metabolites are carried out by extraction followed by quantification and separation using thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), gas chromatography (GC) and mass spectrometry (MS), nuclear magnetic resonance (NMR), or absorption spectroscopy.

Choosing the right solvent system and extraction method leads to reliable and reproducible results. Sonication and microwave extraction methods are frequently used to optimize the yield of the target compound. Currently, different methods are reported by different groups to extract ephedrine and its derivatives, and solvents such as dichloroethane, benzene, chloroform, toluene, chlorobenzene, amyl-, ethyl- and isopropyl- alcohol, and aqueous solutions have been widely tested [10]. The most frequently used method is the extraction by methanol-water (5:5) under the influence of sonication for 15–25 min, followed by centrifugation at 5,400–7,000 rpm for 7–10 min, and subsequently the supernatants of the samples are quantitatively and qualitatively explored by TLC, HPLC, or GC/MS devices [31, 33, 34, 45, 46].

To determine the presence of ephedrine and its derivatives using TLC, a solution of butanol, glacial acetic acid, and water (4:1:1) as the mobile phase and ninhydrin (2,2-Dihydroxyindane-1,3-dione) for localizations has typically been used [28, 29, 34]. O'Dowd and colleagues reported that ethanol extract of in vivo or in vitro grown plants often contains compounds that show a positive test for ephedrine and pseudoephedrine with ninhydrin in TLC, but such compounds were absent in HPLC analysis. Therefore, TLC cannot be used as a sufficient and reliable method and, in parallel, a more confirmative method must be conducted [28].

A simple method developed for the quantitative determination of ephedrine in *Ephedra* callus was reported using a HPLC device. In this method, a Tris–NaOH–H_3PO_4 ($pH = 3.2$) run buffer was used; the detector was adjusted to 185 nm. In order to increase the solubility of hydrophobic analyses and improve the separation efficiency, 15 % acetonitrile was used in the buffer as a modifier [22]. Sheu and Huang have presented two methods for ephedrine and its derivatives determinations. As a Cosmosil 5C18-MS column was used in their experiment with a gradient solvent system consisting of a phosphate buffer and acetonitrile, the detector was adjusted at 210 nm with a retention time of 50 min. Alternatively, an isocratic solvent system of a sodium dodecylsulfate-acetonitrile solution was also tried with a retention time of 35 min [45].

Quantitative analysis of *Ephedra* alkaloids using a GC or GC/MS devices is difficult considering their retention time and the task of distinguishing them from diastereomers. Cui et al. analyzed 12 species of Chinese *Ephedra* by trimethylsilyl (TMS) derivatization of *Ephedra* alkaloids using a GC/MS device equipped a nitrogen phosphorous detector and helium as the carrier gas with a flow rate of 0.9 mL min^{-1}; the smallest quantity detected by this method was less than 2 ng [5].

Another reliable quantitative analysis of ephedrine alkaloids using an H-NMR was also described by Kim et al. A certain amount of sample was mixed with 0.5 M H_2SO_4 solution and sonicated for 1 h, then centrifuged for 20 min at 3,000 rpm. Subsequently, the supernatant layer was transferred to a tube containing 5 M KOH solution, NaCl and diethyl ether. Samples were centrifuged again and the diethyl ether layers were combined into a flask and evaporated after addition of an internal standard. Finally, dried samples were dissolved in $CDCl_3$ (deuterated chloroform) and used for H-NMR measurement. The peak of each *Ephedra* alkaloid was quite well separated from the others. The H-NMR method was also found to be highly accurate with low standard deviation (5–10 %). This result was similar to that of HPLC and all four alkaloids can be detected without any derivatization [17].

3 Percentage of Ephedrine in Different *Ephedra* Species

A wide variation exists in alkaloid content among different species of *Ephedra* in different parts of the world, with the highest total alkaloid content of 2.5 % in *Ephedra equisetina*. In fact, the yield of ephedrine in the extract of different species of *Ephedra* varies from 55 % to 83 % [10, 13]. Cui and colleagues reported that the highest amount of ephedrine among different species analyzed was in *Ephedra monosperma* Gmel. Ex Mey (1.401 %), while the highest amount of pseudoephedrine was in *Ephedra intermedia* Schrenk ex (0.912 %) [5] (Table 27.1).

Parsaeimehr et al., using a HPLC gradient method, reported the presence of ephedrine and pseudoephedrine in three species of *Ephedra* and observed that the content of ephedrine and pseudoephedrine varied from species to species. The highest amount of ephedrine was recorded in *E. strobilacea* (2.7 mg g^{-1} dry weight), while the highest amount of pseudoephedrine was recorded in *Ephedra procera* (3.7 mg g^{-1} dry weight) [33] (Table 27.2).

Ephedra alkaloids content were determined by O'Dowd and colleagues, who reported the highest amount of ephedrine and pseudoephedrine in *E. equisetina*, while the lowest amount was recorded in *Ephedra andina* [28] (Table 27.3).

Using an H-NMR device, Kim and colleagues reported that the content of the four analyzed ephedrine alkaloids in their samples was quite different, varying from 1 % to 2 % of dry weight. Among two species, *E. intermedia* had a lower amount of total alkaloids (0.94 %) and ephedrine content compared with pseudoephedrine than *E. sinica* (Table 27.4) [17].

Molecular analysis combined with chemical assessments on collected *s*pecies of *Ephedra* from Mongolia revealed that the *Ephedra* plants were divided into nine genotypes based on the nucleotide sequences of 18S ribosomal RNA (rRNA) gene and *trn*K gene. The chemical analysis showed that the amount of ephedrine and its derivatives vary from genotype to genotype or even in similar genotypes. The *E. sinica* genotype Si-II showed the highest ephedrine accumulation; the lowest accumulation ephedrine and its derivatives was recorded in *Ephedra przewalskii* irrespective of its different genotypes [18].

Table 27.1 Alkaloid content (% dry weight) of different species of *Ephedra* (After Ref. [5])

Species	NPE	NE	E	PE	ME	MPE
E. equisetina	0.155	0.198	1.250	0.580	0.025	ND
E. intermedia	0.111	0.075	0.550	0.912	0.026	ND
E. likiangensis	0.170	0.051	0.630	0.606	0.027	Trace

NPE norpseudoephedrine, *NE* norephedrine, *E* ephedrine, *PE* pseudoephedrine, *ME* methylephedrine, *MPE* methylpseudoephedrine, *ND* Not detected

Table 27.2 Alkaloid content (µg/g dry weigh) of different species of *Ephedra* (After Ref. [33])

Alkaloids	*E. procera*	*E. pachyclada*	*E. strobilacea*
Ephedrine	884.42 ± 59.85	821.01 ± 81.42	2670.68 ± 10.15
Pseudoepehdrine	3679 ± 69.75	948 ± 75.40	1575.17 ± 62.09

Table 27.3 Alkaloid content (% dry weight) of different species of *Ephedra* (After Refs. [28, 29])

Alkaloids	*E. andina*	*E. equisetina*	*E. intermedia*	*E. major*	*E. minima*
Ephedrine	Trace	0.80	0.06	0.27	0.50
Pseudoepehdrine	0.13	0.50	0.15	0.75	1.04

Table 27.4 Alkaloid content (mg/g dry weight) of different species of *Ephedra* using H-NMR (After Ref. [17])

Species	E	PE	ME	MPE	Total alkaloids (%)
E. sinica	8.98 ± 1.23	3.92 ± 0.44	1.30 ±0.18	0.75 ±0.10	1.49
E. intermedia	2.15 ± 0.31	6.29 ± 0.87	0.22 ± 0.04	0.76 ± 0.14	0.94

Age of the plant, altitude, season of collection, and the sample tissue (primary or secondary shoots) on all have a significant influence on alkaloid content of *Ephedra*. However, the highest amount of ephedrine accumulates in older green stems at the mid-internodes [1, 14, 28, 29] (Table 27.5).

4 Biotechnological Methods for Ephedrine Production

4.1 In Vitro Culture of *Ephedra* and Ephedrine Production

Plant cell and tissue cultures are excellent systems for the production of secondary metabolites. O'Dowd and colleagues examined the influence of different types of plant growth regulators on alkaloid content of callus derived from different species

Table 27.5 Alkaloid content (% dry weight) of different species of *Ephedra* grown in Mongolia (After Ref. [18])

Species	Genotype	E	PE	NE	NEP	ME
E. sinica	Si-II	2.14	0.22	Trace	0.07	0.32
E. sinica	Si-I	0.99	0.84	0.15	0.29	Trace
E. equisetina	E-I	0.14	4.45	0.12	0.12	0.07

E. regeliana	Rg-II	0.41	1.44	Trace	Trace	0.10

of *Ephedra*. All *Ephedra* species were grown on MS medium supplement with 0.25 μM kinetin and 5.0 μM 2,4 dichlorophenoxy acetic or 1-naphtaleneacetic acid as callus cultures, and trace amounts of ephedrine and 0.01 % of pseudoephedrine on a dry weight basis were recorded. In comparison, 0.8 % and 0.5 % of ephedrine and pseudoephedrine, respectively, on a dry weight basis were recorded in the stem of *Ephedra equistina* [28, 29].

Many factors influence callus growth and secondary metabolite content, but the major ones are genotype, physiological status of the plant, tissue source, chemical composition and physical state of the culture medium, and the culture conditions of callus growth. Callus cultures of *Ephedra foliata* and *Ephedra gerardiana* were grown on MS medium supplemented with 2.3 μM Kin and 54 μM NAA. *E. foliata* callus contained no alkaloids whereas that of *E. gerardiana* contained 0.17 % ephedrine after 8 weeks growth. The authors recorded one tenth the ephedrine content in the callus of *E. gerardiana* compared with the stem. 2, 4-D reduced the yield of ephedrine content to 0.13 %, but by replacing NAA with IBA, the maximum level of ephedrine (0.3 % of dry weight) was recorded [37–39].

Different plant growth regulators had a significant impact on growth of in vitro cultures of *E. monosperma* and accumulation of alkaloids in callus [36]. In our laboratory, we recorded a significant influence of NAA 2.0 mgl^{-1} and Kin 1.0 mgl^{-1} incorporated in the medium on ephedrine and pseudoephedrine production. They also recorded superiority of kinetin over BAP for ephedrine production in callus cultures (Table 27.6) [34].

O'Dowd and Richardson reported for the first time the transformation in *Ephedra* by *Agrobacterium rhizogenes* producing in vivo and in vitro roots and tumors. Two-year-old in vivo tumor tissues of *Ephedra fragilis* and *Ephedra minima* contained up to 0.3 % ephedrine on a dry weight basis, and slow-growing in vitro cultured tumor tissues of *E. fragilis* contained up to 0.01 % ephedrine; alkaloid was not detected in faster-growing isolates [30].

When L-phenylalanine was used as precursor for ephedrine and pseudoephedrine production in *Ephedra* suspension culture, the maximum production of

Table 27.6 Effect of plant growth regulators on fresh weight and alkaloids content in *E. procera* (After Ref. [34])

Auxin (mg l^{-1})	Cytokinin (mg l^{-1})	FW (g/explant)	Ephedrine (μg g^{-1} DW)	Pseudoephedrine (μg g^{-1} DW)
NAA	BAP			
2.0	0.5	1.970 ± 0.20	37.4 ± 0.1	274.2 ± 1.9
1.0	1.0	0.970 ± 0.13	45.9 ± 0.5	320.8 ± 0.4
1.5	1.0	1.517 ± 0.16	64.5 ± 1.5	355.4 ± 0.3
2.0	1.0	2.421 ± 0.25	83.9 ± 1.3	466.2 ± 0.5
NAA	Kin			
2.0	0.5	2.670 ± 0.19	47.4 ± 0.9	322.2 ± 0.1
1.0	1.0	2.487 ± 0.27	62.4 ± 1.4	356.3 ± 0.6
1.5	1.0	3.766 ± 0.27	65.1 ± 0.5	356.9 ± 0.6
2.0	1.0	6.657 ± 0.26	108.1 ± 0.6	730.3 ± 1

Nd not detectable, *Ns* callus didn't survive, *Nr* not recorded, ——— No callus induction observed in the medium, *RGR* relative growing rate (g g^{-1} day^{-1}). The following formula was used to record RGR

RGR = $3(\mathrm{Wf}^{1/3}–\mathrm{Wi}^{1/3})/\mathrm{tf}–\mathrm{ti}$, where: *Wi* callus initial mass (at ti), *Wf* final callus mass (at tf), t = time, *tf*–ti = 28 days of subculture period

ephedrine and pseudoephedrine was recorded with 7.5 mM L-phenylalanine after the 12th day: 1.1 mg g^{-1} dry weight and 5.9 mg g^{-1} dry weight for ephedrine and pseudo-ephedrine, respectively [31]. Suspension cultures are excellent systems for isolating the suitable cell lines to be used in bioreactors through medium optimization by selection of correct precursors, elicitors, and growth regulators, appropriate design of a bioreactor, and selection of a suitable matrix for cell immobilization.

4.2 Biotransformation Techniques for Ephedrine Production

Significant progress has been made in the field of microbial biotransformation, and valuable compounds such as antibiotics, pigments, glycosides, terpenoids, and alkaloids have been successfully produced by biotransformation. Yeasts such as *Candida utilis*, *Saccharomyces cerevisiae*, and *Hansenula* spp. have been used for commercial production of ephedrine. The microbial biotransformation process starts with condensation of an active benzaldehyde (from pyruvic acid). This benzaldehyde (by enzyme pyruvate decarboxylase) leads to production of L-phenylacetylcarbinol, a precursor for the biosynthesis of ephedrine and its derivatives (Fig. 27.4). Other strategies using yeasts for the production of ephedrine and its derivatives include fed-batch culture, continuous culture, biotransformation methods using yeasts' immobilized cells, and biotransformation methods using purified pyruvate decarboxylase free enzyme [42].

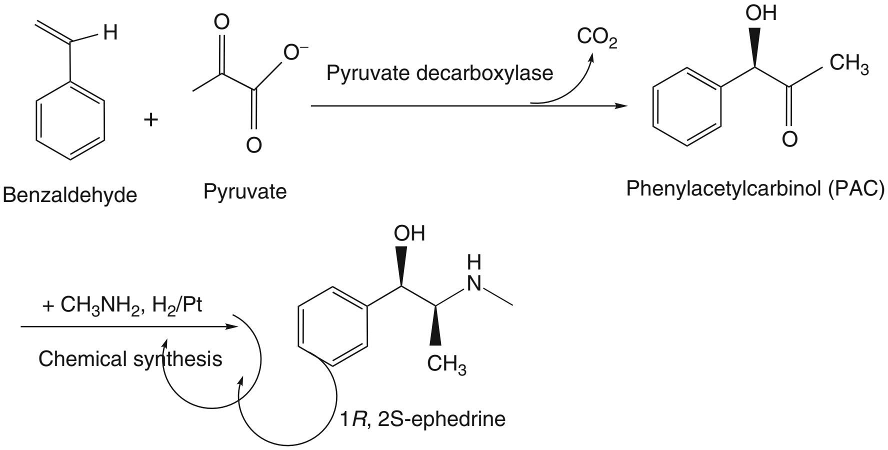

Fig. 27.4 The biotransformation process for ephedrine production

5 Perspective

Traditional uses of *Ephedra* have been known for thousands of years, however, the plant still needs proper phytochemical evaluation for antimutagen, anticarcinogen, antioxidant, antimicrobial, and anti-inflammatory agents. Proper evaluation of plant extract of this age-old drug may provide new clues. The mystery of somras (a drink of the gods in Hindu mythology) has yet to be revealed, though Ephedra is considered a potent candidate for its preparation. Biotechnological methods such as tissue culture, biotransformation, and gene manipulation techniques can produce secondary metabolites like ephedrine and its derivatives.

Abstract

Terpenoid alkaloids are a class of *pseudoalkaloids*, in which a nitrogen atom is inserted in the skeleton on a late biosynthetic stage. This class of compounds, sharing structural diversity, interesting chemistry, and promising pharmacological properties, has for a long time stimulated the interest of the scientific community and is covered in this chapter. The occurrence, phytochemistry with classification, and biological activities of monoterpenoid alkaloids reported between 2000 and Feb. 2012 and that of diterpenoid alkaloids reported between 2009 and Feb. 2012 are presented together with the biosynthetic approaches.

Key Words

Aconitum • amination reaction • *Delphinium* • diterpenoid alkaloids • incarvillea • monoterpenoid alkaloids • Ranunculaceae • Terpenoid alkaloids

Abbreviations

6T-CEM	Human acute T lymphocyte leukemia cell line
AChBP	Acetylcholine-binding protein
ED_{50}	Effective dose fifty percent
ent-CPP	Ent-copalyl diphosphate
GA–MLRs	Genetic algorithm–multiple linear regressions
GA–PLS	Genetic algorithm–partial least squares
GGPP	Geranylgeranyl pyrophosphate
hERG	Human ether-*á-go-go*-related gene

NTI	Naltrindole
QSAR	Quantitative structure–activity relationship
SRB	Sulforhodamine B
β-FNA	*β*-funaltrexamine

1 Introduction

Terpenoid alkaloids are an ever-growing class of plant natural products possessing various chemical structures and interesting biological activities.

Based upon biogenesis, the alkaloids are broadly classified as the *true alkaloids* and the *pseudoalkaloids*. The majority of alkaloids are *true alkaloids* which are derived from α-amino acid precursors. Other alkaloids such as terpenes and steroids are named *pseudoalkaloids* because a relatively late amination process occurs in a transamination reaction by donating a nitrogen atom of an amino acid source [1]. A large number of alkaloids based on mono- and diterpenoid skeleton produced in an amination reaction have been isolated from natural sources and characterized. Several book chapters and review papers have been published to describe the mono- and diterpenoid class of alkaloids, with an intriguing chemistry and numerous varied bioactivities which constitute the largest and the most complicated group of terpenoid alkaloids [2–7].

Terpenoid alkaloid-producing plants have been utilized for centuries as traditional medicines in China, Japan, Mongolia, Russia, India, Pakistan, and Nepal [5, 8]. For instance, the plants of genus *Aconitum* have for a long time been used in Asia, Alaska, and Europe [9] in traditional medicine for the treatment of traumatic injury [10], as febrifuge and bitter tonic [11], and as ingredients in intoxicating liquor [12]. The most popular use of this species is described in Chinese traditional medicine as an analgesic and cardiotonic herbal medicine [13] and for the treatment of some inflammations like gastritis, hepatitis, nephritis, etc. [14, pp. 186–187]. These plants have also been used as poisons for hunting since ancient times and, later, in homicides [7, 15]. Similarly, the species of genus *Delphinium* have been used as a traditional medicine in China since ancient time for the treatment of ringworm, scabies, other skin diseases, and inflammation [14, p. 365], whereas in Nepal, it is used for the treatment of jaundice and fever [8]. In general, the terpenoid alkaloids exhibit different actions varying from poisonous (e.g., aconitine) to therapeutic (e.g., lappaconitine), even though they share similar molecular skeletons [16].

2 Occurrence

Terpenoid alkaloids are nonuniformly distributed in the plant kingdom. Monoterpenoid alkaloids are mostly found in the plant family Gentianaceae, whereas diterpenoid alkaloids are mainly located in the family Ranunculaceae. Gentianaceae, a rich source of monoterpenoid alkaloids, is a family of flowering plants comprising approximately 70–80 genera and 900–1,200 species [17]. Most of the monoterpenoid alkaloids have been isolated from the genus *Incarvillea* of Gentianaceae. Similarly, the majority of the diterpenoid alkaloids have been isolated from the species of *Aconitum* and *Delphinium* of Ranunculaceae family that consists of more than 300 and 400 species, respectively, distributed throughout the Northern hemisphere including Asia, Europe, and North America. Out of those, more than 113 species of *Delphinium* [18] and more than 200 species of *Aconitum* [19] are endemic to China.

Table 28.1 Monoterpenoid alkaloids (compound **1–9**: actinidine-type and **10–18**: skytanthine-type monoterpenoid alkaloids)

3 Phytochemistry

Terpenoid alkaloids comprise a large number of compounds biosynthetically derived from pathways that lead to the various groups of terpenes such as monoterpenoids and diterpenoids. Due to structural diversity, these alkaloids are of great interest of study with respect to the phytochemistry, synthesis, and pharmacological activities.

3.1 Monoterpenoid Alkaloids

A number of important alkaloids are derived from monoterpenes. Monoterpenoid alkaloids are comparably simple compounds formed by addition of nitrogen atom to an existing monoterpene, mainly of the secologanin type. Several monoterpenoid alkaloids have been isolated and characterized and classified based upon their structural characteristics. The more common and pharmaceutically important types such as actinidine, skytanthine, and gentianine are discussed herein.

3.1.1 Actinidine-Type Alkaloids

Actinidine, one of the rare types of monoterpenoid alkaloid [49], is a steam-volatile methylcyclopentane pyridine derivative found mainly in the essential oils of the species of *Actinidia* and *Incarvillea* [20]. Nine new actinidine-type monoterpenoid alkaloids (**1**–**9**) have been isolated in the period of 2000 to Feb. 2012 [20–24]. Two novel actinidine-type monoterpene alkaloids, delavayine B (**1**) and delavayine C (**2**), were isolated from aerial part of *I. delavayi* [20]. Phytochemical investigation on *I. arguta* yielded incargutosine C (**3**) and incargutosine D (**4**). The absolute configurations of both **3** and **4** were determined by a synthetic method [21]. Compound **5** obtained from *A. radiate* contains a 10-acetoxy moiety [22]. Two novel monoterpenoid alkaloid dimers named argutane A (**6**) and argutane B (**7**) were obtained from the roots of *I. arguta* [23]. Similarly, two new compounds argutine A (**8**) and argutine B (**9**) having an *α*,*β*-unsaturated carbonyl moiety and an amide moiety, respectively, were reported from *I. arguta* [24].

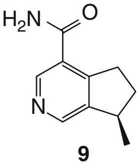
8



9

3.1.2 Skytanthine-Type Alkaloids

A 4-nor-7,8-dehydro-10-hydroxy-skytanthine (**10**) has been obtained from *A. radiata* [22]. Compound **10** and actinidine-type compound **5** are the alkaloid compounds that have been isolated from this plant species for the first time, and it is a reasonable hypothesis that the monoterpenoid structures of **10** and **5** should be derived from the previously isolated iridoids in this plant, which are known to be the biogenetic precursors of this type of alkaloids [50]. A novel skytanthine-type alkaloid named delavayine A (**11**) that comprises a benzoate ester has been isolated from *I. delavayi* [25]. Similarly, another novel skytanthine-type alkaloid, incarvillateine E (**12**), possessing three incarvilline moieties has been isolated and characterized from the aerial parts of *I. sinensis* [26]. Incarvine E (**13**) and incarvine F (**14**) [27] isolated from *I. sinensis* and isoincarvilline (**15**) [28] and mairines A–C (**16**–**18**) [29] from *I. mairei* are other new skytanthine-type monoterpenoid alkaloids. Compounds **16** and **18** contain a rare *δ*-skytanthine *N*-oxide in the structure [29].

18

3.1.3 Gentianine-Type Alkaloids

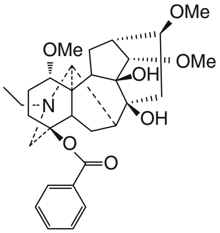
Gentianine-type monoterpenoid alkaloids are widely distributed in plants of the family Gentianaceae. Several studies were carried out on this type in the late 1950s. Gentianine is a bitter, crystalline monoterpenoid alkaloid possessing varying pharmacological activities [17]. This compound has been isolated from a number of plant genus including *Anthocleista* [51], *Gentiana* [52], *Fagraea* [53], and *Swertia* [54]. There is no report of isolation of new gentianine-type monoterpenoid alkaloid in the period of 2000 to Feb. 2012.

3.2 Diterpenoid Alkaloids

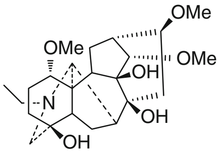
Plant species of the genera *Aconitum*, *Delphinium*, and *Consolida* of Ranunculaceae family are rich sources of diterpenoid alkaloids of pharmacological and economic importance [4]. Several review papers and chapter in books have been published in this class of alkaloids mainly by the research group of Wang from China and Atta-ur-Rahman from Pakistan [3–7]. The diterpenoid alkaloids are broadly classified into three categories: the C_{18}-, C_{19}-, and C_{20}-diterpenoid alkaloids. All these classes of alkaloids have been reviewed until the end of 2008 by Wang and coworkers [3]. The diterpenoid alkaloids reported from 2009 to Feb. 2012 will be discussed here. The chemical structures displayed in this chapter are predominantly those of new alkaloids. However, some of the known structures are also presented whenever necessary. During this period, the new diterpenoid alkaloids were isolated only from the genera *Aconitum* and *Delphinium* of Ranunculaceae family.

3.2.1 C_{18}-Diterpenoid Alkaloids

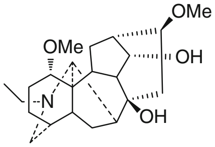
The C_{18}-diterpenoid alkaloids are a member of small groups within the diterpenoid alkaloids. The first C_{18}-diterpenoid alkaloid named lappaconitine was isolated from the plant *Aconitum septentrionale* [55], and its structure was confirmed after several years by extensive chemical studies [56]. In the beginning of the 1970s, three more C_{18}-diterpenoid alkaloids named lappaconidine [57], aconosine [58], and excelsine [59] were isolated and characterized which advanced this class of diterpenoid alkaloids. Until today, over 100 compounds of this class have been isolated from around 40 plant species mainly from *Aconitum* followed by *Delphinium*.



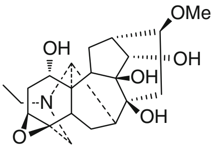
Lappaconitine



Lappaconidine



Aconosine

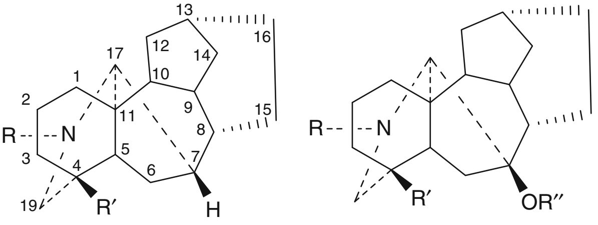


Excelsine

For a long time, lappaconitine and other C_{18}-diterpenoid alkaloids were classified as belonging to the C_{19}-diterpenoid class. Wang and Fang suggested a new class "C_{18}-diterpenoid alkaloids" in 1983 [60]. This was further classified as norditerpenoid alkaloids [61] or bisnorditerpenoid alkaloids [62]. However, the class "C_{18}-diterpenoid alkaloids" is common, and recent literature papers classified the compounds accordingly. Ichinohe et al. in 2004 divided the C_{18}-diterpenoid alkaloids into two categories as the lappaconitine type (A-1) and the ranaconitine type (A-2) (Fig. 28.1) based on presence or absence of an oxygen functionality attached at C-7 [63].

Lappaconitine-Type Alkaloids

The lappaconitine-type C_{18}-diterpenoid alkaloids are structurally classified by lack of an oxygen functionality and presence of a methine unit at C-7 [6]. This is a fairly



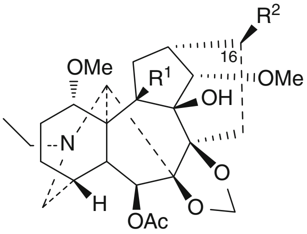
Lappaconitines (A–1)

Ranaconitines (A–2)

Fig. 28.1 C_{18} types of diterpenoid alkaloid: R and R″ can be hydrogen, acyl, or alkyl groups, and R′ can be hydrogen, hydroxyl, alkoxy, or acyloxy groups small class of compounds so far isolated. Only 16 compounds were reported in the period from 1998 to 2008 [3], and there is no report of isolation of this class of compounds since then.

Ranaconitine-Type Alkaloids

The ranaconitine-type C_{18}-diterpenoid alkaloids possess an oxygen functionality at C-7. This class also contains a small number of diterpenoid alkaloids. Only two new compounds anthriscifolcines F (**19**) and G (**20**) isolated from *D. anthriscifolium* between 2009 and Feb. 2012 are added in this series [30].



19 $R^1 = R^2 = OH$ **19a** $R^1 = OH$ $R^2 = OAc$

20 $R^1 = H$ $R^2 = OH$ **20a** $R^1 = H$ $R^2 = OAc$

Compounds **19** and **20** represent ranaconitine-type C_{18}-diterpenoid alkaloids having hydroxyl group at C-16 position. Initially, the orientation of the 16-OH group in **19** and **20** was ambiguous since no evident NOE correlation could be found when H-16 was irradiated. To accomplish this, the acetylated derivatives **19a** and **20a** were prepared where NOE correlations could be observed between 16-OAc and 14-OCH_3 and H-16 and H-17 in both **19a** and **20a**. The configuration of carbon atom 16 in **19** and **20** therefore was unambiguously established as *β*. The conformation of the D-ring in **19a** and **20a** was suggested as a boat, which would enable the 16-OAc substituent to remain in an equatorial position [30].

3.2.2 C_{19}-Diterpenoid Alkaloids

The C_{19}-diterpenoid alkaloids are the largest class of naturally occurring diterpenoid alkaloids with more than 700 compounds so far isolated and characterized from around 315 species of plants mainly from the genera *Aconitum* and *Delphinium*. This class of alkaloids is divided into six types: aconitine type (B-1), lycoctonine type (B-2), pyro type (B-3), lactone type (B-4), 7,17-*seco* type (B-5), and rearranged type (B-6) (Fig. 28.2). The order of types from B-1 to B-6 is based upon the higher to lower number of alkaloids obtained so far. In between 2009 and Feb. 2012, only aconitine, lycoctonine, and rearranged-type C_{19}-diterpenoid alkaloids have been isolated and are discussed herein.

Aconitine-Type Alkaloids

The main feature of aconitine-type C_{19}-diterpenoid alkaloid is the lack of an oxygen-containing functionality at C-7. The characteristic functionalities in this type include an amine, an imine, an amide, and the *N*,*O*-mixed acetal. A majority of the compounds bear oxygen functionalities at C-1, C-6, C-8, C-14, and C-16. In a very small number, alkaloids of this class including ouvrardianine B (**21**) possess the formyl moiety that is attached to the nitrogen [31]. 1,15-Dimethoxy-3-hydroxy-14-benzoyl-16-ketoneoline (**23**), isolated from *A. ouvrardianum*, is the first member of amine group that contains carbonyl group at C-16 [13]. *N*-Deethylaconine (**26**) is a rare aconitine with a secondary amine, while in most cases, a tertiary amine with ethyl or methyl groups is found [34]. Interestingly, beiwutinine (**27**) is the first aconitine-type C_{19}-diterpenoid alkaloid that has seven hydroxyl groups attached to the skeleton [34].

The aconitine-type C_{19}-diterpenoid alkaloids, namely, macrorhynine (**28**) and ouvrardianine A (**29**), with a rare C-19 imino unit, were isolated from *A. macrorhynchum* and *A. ouvrardianum*, respectively. The group at C-19 in both compounds **28** and **29** was determined on the basis of its 1D and 2D NMR and other spectroscopic data analysis [31, 35].

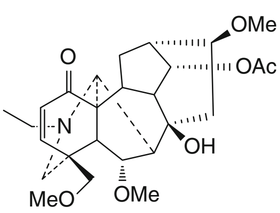
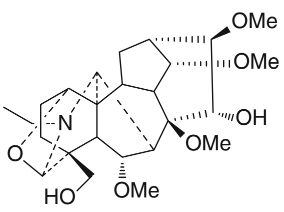
Liangshantine (**30**) features an *α*,*β*-unsaturated carbonyl group at ring A [36]. A novel aconitine-type C_{19}-diterpenoid alkaloid named aconitorientaline (**31**) was isolated from the roots of *A. orientale* [37]. This compound contains an epoxy group between C-1 and C-19.



30



31

Lycoctonine-Type Alkaloids

The characteristic feature of this type of C_{19}-diterpenoid alkaloids is the presence of an oxygenated functionality at C-7. Like that of aconitine type, these alkaloids are also subdivided into amines, imines, amides, and *N*,*O*-mixed acetals based upon the substitution pattern of the nitrogen. A total of 11 lycoctonine-type C_{19}-diterpenoid alkaloids (**32**–**42**) have been obtained between 2009 and Feb. 2012. Compounds **32**–**35** possess a benzoyl ester moiety at C-18 with a variety of amide groups in the *ortho* position. Anthriscifoldine A (**36**) [30] and delphidenine (**37**) [39] are identical compounds reported by different research groups almost at the same time from *D. anthriscifolium* and *D. densiflorum*, respectively.

Compound **39–41** bears a common methylenedioxy group at C-7 and C-8 [16, 30], whereas compound **42** is the first natural diterpene alkaloid with a nitrone functionality [40]. Biogenetically, compound **42** might be derived from lycoctonine by formation of *N*-oxide followed by *N*-deethylation followed by conversion into a hydroxylamine derivative.

42

C_{19}-Rearranged-Type Alkaloids

Some of the C_{19}-diterpenoid alkaloids have a rearranged skeleton in which either the bridge between C-8 and C-17 is formed instead of common bond between C-7 and C-17 or an additional bond formed between C-8 and C-10. Only one compound named yunnanenseine A (**43**) of this type having a bridge between C-8 and C-17 [41] was isolated between 2009 and Feb. 2012.

3.2.3 C_{20}-Diterpenoid Alkaloids

The C_{20}-diterpenoid alkaloids are the second largest group of diterpenoid alkaloids after C_{19}-diterpenoid alkaloids and are mainly obtained from the genera of *Aconitum* and *Delphinium*. The classification of C_{20}-diterpenoid alkaloids has not been very clear. Different group suggested different classifications [5]. Wang et al. [3] classified it as atisines, denudatines, hetidines, hetisines, vakognavines, napellines, kusnezolines and omeielines, racemulosines, arcutines, and tricalysiamides. During the period of 2009–Feb. 2012, compounds only from the types atisine (C-1), hetidine (C-2), hitisine (C-3), denudatine (C-4), and vakognavine (C-5) have been isolated (Fig. 28.3). Additionally, one more new class of C_{20}-diterpenoid alkaloid, atisine–denudatine type, has been isolated recently from the roots of *A. piepunense* [48].

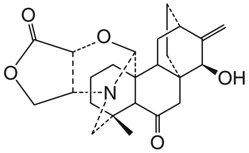
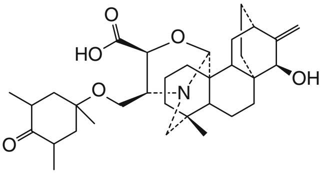
Atisine-Type Alkaloids

This type of comparatively simpler C_{20}-diterpenoid alkaloids bears a pentacyclic core in the structure. Only two new compounds named delphatisine C (**44**) from *D. chrysotrichum* [42] and honatisine (**45**) from *D. honanense* [43] have been isolated between the periods of 2009 and Feb. 2012. Compound **44** contains a five-membered lactone ring connecting to the oxazolidine ring. Extensive NOESY experiments were required to elucidate the relative configuration. Compound **45** is a novel C_{20}-diterpenoid alkaloid containing an unique 1′,3′,5′-trimethyl-4′-oxocyclohexyloxy unit attached to C-24.



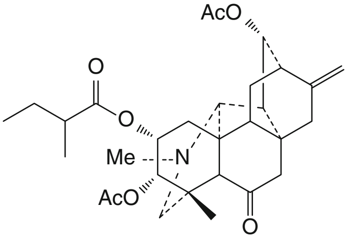
44



45

Hetidine-Type Alkaloids

This type of alkaloids has a hexacyclic core with an additional bond at C-20–C-14. They are more complex than the atisine alkaloids. One new hetidine-type C_{20}-diterpenoid alkaloid named anthriscifolmine I (**46**) was reported between 2009 and Feb. 2012 from *D. anthriscifolium* [44].



46

Hetisine-Type Alkaloids

This type is one of the most complex groups derived from the atisine skeleton having a heptacyclic system with an additional N-C-6 bond. A total of eight hetisine-type C_{20}-diterpenoid alkaloids (**47**–**54**) were isolated in the period of 2009 to Feb. 2012 [16, 41, 44–46]. Besides the complexity of the skeleton, acetyl, benzoyl, tertiary methyl, hydroxyl, *O*-formyl groups as well as an exocyclic double bond and a ketone make this skeleton a unique structure.

Denudatine-Type Alkaloids

This type of alkaloids is similar to the atisine type except of an additional bond between C-20 and C-7. Five new compounds, two of them, namely, anthriscifolmines A (**55**) and B (**56**) from *D. anthriscifolium* [41] and liangshantines A–C (**57**–**59**) from *A. liangshanicum* [36], have been isolated from 2009 to Feb. 2012. Compound **56** is a rare C_{20}-diterpenoid alkaloid bearing a CH_2OH-18 moiety attached to C-4.

Vakognavine-Type Alkaloids

This type of alkaloid have an *N*,19-*seco* hetisine skeleton in addition to a C-4 aldehyde moiety. This type is named after the first compound vakognavine [64, 65]. Ten new vakognavine C_{20}-diterpenoid alkaloids have been isolated between 2009 and Feb. 2012. Five new alkaloids of this type, anthriscifolmines D–H (**60–64**), were isolated from *D. anthriscifolium* [47]. Anthriscifolmines G (**63**) and H (**64**) are exceptional cases of this type having double bond in C-15 and C-16 [47]. Other compounds of this type are tatsienenseine A (**65**) isolated from *D. tatsienense* [46] and majusimines A–D (**66–69**) from *D. majus* [16].

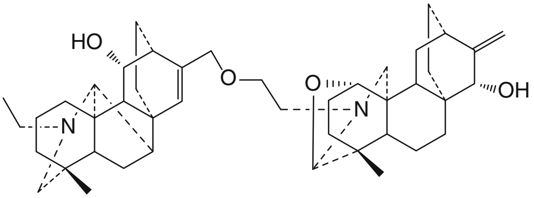
69

Atisine–Denudatine-Type Alkaloids

In the year 2010, a novel C_{20}-diterpenoid alkaloid named piepunine (**70**) has been isolated from *A. piepunense* containing both atisine and denudatine skeletons [48]. Compound **70** represents the first example of this type.



70

4 Chemotaxonomic Studies

During the review period of monoterpenoid and diterpenoid alkaloids, only one paper on the chemotaxonomic studies of diterpenoid alkaloids was published [18].

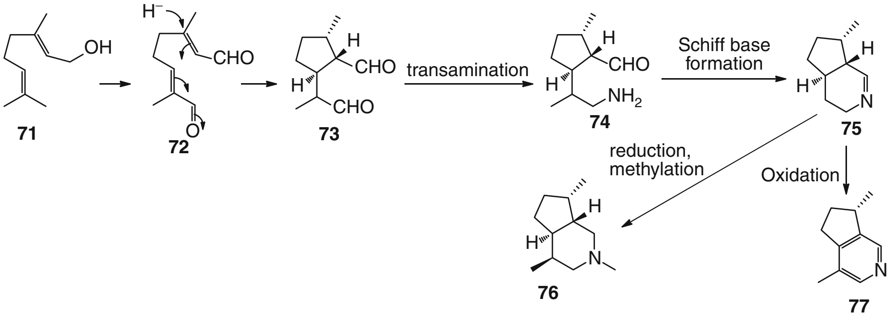
This paper described the chemotaxonomy characteristics of two C_{20}-diterpenoid alkaloids and five C_{19}-diterpenoid alkaloids from *Delphinium albocoeruleum* Maxim of Chinese origin. The study indicated that the compound delelatine may be considered as a chemotaxonomic marker for the *Delphinium* genus as it occurs in *Delphinium elatum*, *Delphinium barbeyi*, *D. tatsinenense* [66], and *Delphinium giraldii* [67]. Delphinine, a major compound, may possibly be utilized for identification of *D. albocoeruleum* Maxim.

5 Biosynthesis

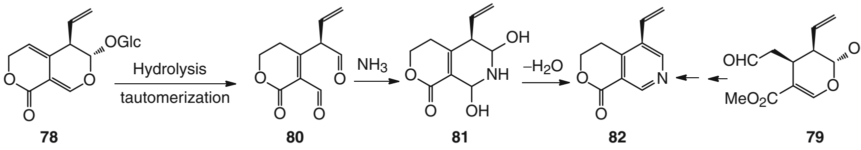
The majority of the alkaloids are derived from amino acid precursors through enzymatic processes. In most cases, the nitrogen atom is donated from an amino acid source through enzymatic transamination. Terpenoid alkaloids are most simplistically described as aminated terpenes [68]. The outcome of this unique biosynthesis is the formation of natural products containing unprecedented structures. A variety of mono- or diterpenoid alkaloid skeletons has been isolated and characterized, but the exact information about their biosynthesis in nature is still somewhat sparse [1]. It is considered that like in terpene biosynthesis, prenyl units are first linked together to form geranyl-, farnesyl-, or geranylgeranyl pyrophosphates, which then undergo enzyme-mediated cyclizations and Wagner–Meerwein rearrangements followed by oxidation and in some cases further rearrangement. Nitrogen incorporation can occur either before, during, or after the cyclase phase and thus convert terpene to terpenoid alkaloid.

5.1 Biosynthesis of Monoterpenoid Alkaloids

Monoterpenoid alkaloids are structurally related to iridoid compounds, the oxygen heterocycle being replaced by a nitrogen-containing ring [1]. A possible biosynthesis of actinidine and *β*-skytanthine starting from geraniol is proposed in Scheme 28.1.



Scheme 28.1 Possible biosynthesis of *β*-skytanthine (**76**) and actinidine (**77**) alkaloids from geraniol (**71**)



Scheme 28.2 Possible biosynthetic pathways of gentianine (**82**) from gentiopicroside (**78**) and secologanin (**79**)

The amination via an amino acid of an iridodial diastereomer (**73**), which was obtained from geraniol (**71**) after forming a dialdehyde intermediate (**72**), yielded compound **74** and its cyclization product **75**. Compound **75** upon reduction and methylation yielded β-skytanthine, (**76**) whereas oxidation produces actinidine (**77**).

Gentianine, one of the most common monoterpenoid alkaloids, might be formed from iridoid compounds such as gentiopicroside (**78**) or secologanin (**79**) [1] (Scheme 28.2). Compound **78** undergoes enzymatic hydrolysis of the β-glucoside followed by tautomerization to produce **80**, which upon hemiaminal formation and subsequent dehydration gives gentianine (**82**). Likewise, compound **79** reacts with ammonia followed by cyclization to give **82**.

5.2 Biosynthesis of Diterpenoid Alkaloids

Investigations on the biosynthesis of diterpenoid alkaloids have been scarcely reported [1, 5, 7, 68]. Specific details of the biosynthetic processes are yet unclear. Recent biosynthetic studies showed that the diterpenoid alkaloids are derived from *ent*-kaurene and *ent*-atisane diterpenoid alkaloid families via enzyme-mediated carbocationic rearrangements [69]. Geranylgeranyl pyrophosphate (GGPP, **83**) is cyclized enzymatically to give *ent*-CPP (**84**), which after loss of pyrophosphate further cyclizes to give the pimarenyl carbocation (**85**) (Scheme 28.3). The pimarenyl carbocation (**85**) is generally proposed to first undergo cation–alkene cyclization to form a secondary carbocation, the beyeranyl cation (**86**). Beyeranyl cation (**86**) is a key branch point in the reaction pathways leading to *ent*-kaurenes (**88**) and *ent*-atisanes (**92**). An alkyl shift (C12 migrating from C16 to C13) in beyeranyl cation (**86**) leads to the kauranyl cation (**87**), the precursor to *ent*-kaurenes (**88**). A 1,3-hydride shift in beyeranyl cation (**86**) leads to another secondary cation (**90**), which can form *ent*-atisanes (**92**) via a subsequent alkyl shift (C13 migrating from C16 to C12) to form cation (**91**) followed by deprotonation. The veatchine-type (**89**) and atisane-type (**93**) C_{20}-diterpenoid alkaloids are derived from the amination of the *ent*-kaurane-type (**88**) and *ent*-atisane-type (**92**) diterpenoids, respectively [70]. Zhao et al. [71] confirmed that the aminoethanol moiety in C_{20}-diterpenoid alkaloids was derived biosynthetically from L-serine, which was consistent with the biogenetic hypothesis of Benn [72]. Subsequently, further oxidations can occur, and more complex C_{20}-diterpenoid alkaloids skeleton can form. Similarly, loss of carbon atom(s) from C_{20}-diterpenoid alkaloids forms C_{19}- and C_{18}-diterpenoid alkaloids [68].

Scheme 28.4 Possible biosynthetic pathways of aconitine-type (**94**) and lycoctonine-type (**97**) C_{19}-diterpenoid alkaloids

The aconitine-type alkaloid (**96**) is most probably formed from the atisine skeleton through different modifications as indicated in Scheme 28.4. The intermediate **94** after a Wagner–Meerwein rearrangement process converts two fused six-membered rings into a (7 + 5)-membered bicyclic system in which C-17 exocyclic double bond is lost in the presence of a specific enzyme to produce **95**. Compound **95** undergoes internal rearrangement to give aconitine-type C_{19}-diterpenoid alkaloid **96**. Similarly, formation of lycoctonine-type C_{19}-diterpenoid alkaloid **99** from atisine alkaloids takes place via formation of the (7 + 5)-membered bicyclic intermediates **97** and **98** [7].

6 Biological Activities

Alkaloid-containing plants have been used by humans since ancient times for therapeutic and recreational purposes. The terpenoid alkaloids possess a diverse array of pharmacological properties, which has been studied for a century. Cordell reviewed the pharmacology of monoterpene alkaloids of the family Gentianaceae with focus on gentianine and skytanthine in 1977 [73]. Gentianine was found to exhibit central muscle-weakening action, inhibition of provoked aggression, and analgesic potentiating effects, whereas skytanthine exhibits no curare-like action but does induce tremor. More study is so far focused on biological activities of diterpenoid alkaloids obtained from Ranunculaceae [3].

6.1 Cardiovascular Activity

Liu and coworkers performed bioassay-guided fractionation of an *n*-BuOH extract of the lateral roots of *A. carmichaeli* that yielded five cardioactive C_{19}-diterpenoid alkaloids [34]. Among them, mesaconine, hypaconitine, and beiwutinine showed the strongest cardiac actions on the isolated perfused bullfrog heart. Also, the compound mesaconine is found to have protective effects, including improved inotropic effect and left ventricular diastolic function, on myocardial ischemia–reperfusion injury in rat at a dose of nM concentration and has almost no effect on heart rate.

Allapinine (lappaconitine hydrobromide) has passed clinical trials and was commercially available as a drug since 1987. Cardiologists believe that allapinine is the first-line drug for the treatment of certain types of cardiac arrhythmia [74]. The investigation of the structure–activity relationship of more than 200 diterpenoid alkaloids and their derivatives revealed that the structural elements are responsible for the arrhythmogenic and antiarrhythmic properties [75]. It is also noted that diterpenoid alkaloids containing the same skeletal and similar functionalities exhibited both arrhythmogenic and antiarrhythmic properties.

Mesaconitine, an aconite-type C_{19}-diterpenoid alkaloid, inhibited phenylephrine-induced contraction in the endothelium-intact but not endothelium-denuded, aortic rings [76]. Compounds named sharwuphinine A, lycoctonine, and deoxymethylenelycoctonine were tested when phenylephrine (PE) 3×10^{-7} M was applied to thoracic aortic rings with endothelium after achieving a maximal response. Only sharwuphinine A showed a moderate vasorelaxant activity (40% relaxation at 10^{-4} M) and that vasodilation may be influenced by the hydrophobicity of a nitrogen atom [40].

Forgo and coworkers studied 24 C_{19}- and C_{20}-diterpene alkaloids representing the structural diversity of *Aconitum* alkaloids for the human ether-à-go-go-related gene (hERG) channel activity by the whole-cell patch clamp technique, using the QPatch-16 automated patch clamp system [32]. At 10 μM, aconitine, 14-benzoylaconine-8-*O*-palmitate, songoramine, gigactonine, and neolinine demonstrated significant hERG K^+ channel inhibition; all other compounds exerted only low (6–21%) inhibitory activity. The study revealed that some structurally and functionally unrelated C_{19}- and C_{20}-diterpene alkaloids may block the hERG K^+ channel and may therefore act in cardiac action potential repolarization, with prolongation of the QT interval and increase of the risk of potentially fatal ventricular arrhythmias.

6.2 Cytotoxic Activity

A large number of diterpenoid alkaloids isolated from *Delphinium* and *Aconitum* exhibited significant cytotoxic activities [3]. The four compounds, delphatisine, delpheline, delbrunine, and delectinine, isolated from *Delphinium chrysotrichum* were determined by SRB assay for their cytotoxicity in which delphatisine showed significant cytotoxic activities (IC_{50} = 2.36 μM) against the A549 cell line [42]. A novel diterpenoid alkaloid named honatisine together with six other compounds of same series obtained from *D. honanense* were evaluated by a SRB assay for their cytotoxicity in which honatisine showed a significant cytotoxic activity (IC_{50} = 3.16 μM) against the MCF-7 cell line [43]. Similarly, six diterpenoid alkaloids isolated from a Tibetan medicinal plant *Aconitum richardsonianum* were also evaluated for their cytotoxicity activity in which a compound named delelatine showed cytotoxic activities ($IC_{50} = 4.36\ \mu$M) against the human cell line P388 [77]. An actinidine-type monoterpenoid named argutine A isolated from *I. arguta* was evaluated for cytotoxicity using four tumor cell lines, A549, LoVo, 6T-CEM, and MDA-MB-435 (MDA), in the MTT assay found to show modest cytotoxicity against these four cell lines with IC_{50} values in the range of 55.4–289.4 μM [21].

6.3 Antinociceptive Activity

Nakamura and coworker reported that the extract of *I. delavayi* moderately decreased the number of writhings and stretchings in the model of acetic acid-induced writhing test in mice in a dose-dependent manner [25]. While testing the pure compounds, orally administered 8-epodeoxyloganic acid (100 mg/kg) showed a weak antinociceptive activity. Similarly, subcutaneous injection of delavayine A (50 mg/kg), a novel monoterpene alkaloid, showed a more significant level of antinociceptive activity. The same group further studied the structure-antinociceptive activity of incarvillateine, a monoterpenoid alkaloid from *I. sinensis*, found to show significant antinociceptive activity in a formalin-induced pain model in mice [78]. Chie et al. in 2005 found that incarvillateine produced graded inhibition of both the neurogenic (early phase) and inflammatory (late phase) phases in a dose-related manner [79]. Comparing the antinociceptive effects of different doses of incarvillateine and morphine, the ED_{50} values of incarvillateine were *ca.* 1.06 (early phase) and 1.33 (late phase) times lower than those of morphine. The same research group further determined the antinociceptive mechanism of incarvillateine, which was antagonized by nor-BNI (κ-receptor antagonist) and β-FNA (μ-receptor antagonist), while NTI (δ-receptor antagonist) did not influence the effect. Furthermore, the antinociceptive effect of incarvillateine was blocked by theophylline, an adenosine-receptor antagonist. These results suggested that the antinociceptive effect arose from the activation of μ- and κ-opioid receptors and adenosine receptor [79].

6.4 Toxicity

Plants of the genus *Aconitum* are highly toxic and have been used for centuries as poisons for spears and arrows and later in homicides. Many C_{19}-diterpenoid alkaloids can cause arrhythmia [75]. The diterpenoid alkaloid aconitine is used by pharmacologists for the development of a cardiac arrhythmia model (the so-called aconitine model). It is one of the strongest plant toxins with potency comparable to the cobra venom [80]. Aconitine poisoning mainly occurs either by confusion with edible plants or accidental ingestion by children [81]. Similarly, larkspurs (*Delphinium* spp.) are responsible for more than 15% of cattle death in North America where larkspurs are abundant. The lycoctonine and the 7,8-methylenedioxylycoctonine-type of C_{19}-diterpenoid alkaloids are the major constituents of poisonous in larkspurs [3]. The highest levels of cardio- and neurotoxicity are expressed by the C_{19}-diterpenoid alkaloids and particularly those which contain two ester groups such as aconitine, mesaconitine, and hypaconitine [82].

6.5 Mode of Action

Ameri summarized the biological activities and mechanism of action of several diterpenoid alkaloids [83], and Wang and coworkers reviewed the mode of action of a number of alkaloids of this class [3]. Turabekova et al. studied 19 diterpenoid alkaloids with curare-like activity obtained from *Aconitum* and *Delphinium* and perform QSAR analysis and molecular docking into AChBP [84]. In this study, GA–MLRA and GA–PLS approaches have been used to build QSAR models to predict *N*-cholinolytic activity measured in vivo (blockade of neuromuscular conductivity, BNMC, and third eyelid relaxing activity, TYRA) and in vitro (suppression of frog's abdominal straight muscles on acetylcholine, SAM) for all 19 diterpenoid alkaloids. The H-bond interactions are revealed to be the prevalent factors modulating *N*-cholinolytic activity by both QSAR analysis and docking studies with additional contribution of steric and reactivity features as identified for TYRA and SAM data, respectively. The alkaloid–receptor complexes were further analyzed by means of the docking software using the binding site of MLA (an α7-type nAChR subtype selective antagonist) complexed with AChBP (homolog of the ligand-binding domain of nAChRs) as template. All compounds fitted in the binding pocket of native MLA. An additional docking on lappaconitine and aconite alkaloids revealed that they are known to bind to voltage-gated Na^+ channel but not to nAChRs.

6.6 Other Activities

A brine shrimp bioassay of the crude extract and the pure compounds gentianine and gentianadine obtained from *Gentiana olivieri* was found to be nontoxic [49].

7 Conclusion

Terpenoid alkaloids derived from a late-stage amination reaction, the so-called *pseudoalkaloids*, have for a long time been in the focus of investigation because of their intriguing structure, interesting chemistry, and ethnomedicinal and pharmaceutical importance. The majority of monoterpenoid alkaloids including some novel structure have been isolated from the genus *Incarvillea* of Gentianaceae family, while the majority of the diterpenoid alkaloids have been obtained from the genus *Aconitum* and *Delphinium* of Ranunculaceae family. The skeletal arrangement of monoterpenoid alkaloids is simple compared to the diterpenoid alkaloids. However, the structural peculiarities equally attract scientists to investigate monoterpenoid alkaloids. The diterpenoid alkaloids, on the other hand, are characterized by complicated but interesting structural features with a large number of stereocenters. Because of the structural diversity, diterpenoid alkaloids are classified into C_{18}-, C_{19}-, and C_{20}-diterpenoid alkaloids with many types.

The terpenoid alkaloids are considered to be derived from prenyl units that undergo enzymatic cyclization, while the nitrogen atom is inserted in the skeleton on a late stage in the biosynthesis. Some of the terpenoid alkaloids exhibit potent cardiovascular, cytotoxic, and antinociceptive activity, while others show extreme toxicity. The mode of action of some diterpenoid alkaloids including curare-like activity has also been studied. More investigations are needed on this type of alkaloids to provide a detailed understanding of the interdependence between structure, activity, and mode of action in order to develop future drug candidates.

Abstract

Purine alkaloids, such as caffeine, theobromine, theophylline, 7-methylxanthosine, and theacrine, are produced in several plant species including tea, coffee, cacao, and maté. The major route of caffeine biosynthesis is the xanthosine → 7-methylxanthosine → 7-methylxanthine → theobromine → caffeine pathway. Two hypotheses concerning the ecological roles of caffeine in plants, chemical defense and allelopathic function theories, have been proposed. Genetically modified plants of agriculturally important plant species have been obtained. One is construction of coffee plants in which caffeine production is suppressed, and the others are caffeine-producing tobacco and chrysanthemum plants which resist infection by fungal and insect pests. The impact of caffeine on human health is discussed, and, in addition to purine alkaloids, cytokinins, adenine-derived phytohormones, and the neurotoxin alkaloids, saxitoxin and tetrodotoxin are also described briefly.

Keywords

Caffeine • theobromine • methylxanthine • methyluric acid • *trans*-zeatin • phytohormone • neurotoxin • tea • coffee • cacao

1 Introduction

In a narrow sense, purine alkaloids comprise methylxanthines and methyluric acids [1]. This chapter, however, also includes information on cytokinins, which are purine ring-containing phytohormones, and the purine-like neurotoxin alkaloids, saxitoxin and tetrodotoxin.

The most well-known purine alkaloid is caffeine (1,3,7-trimethylxanthine) **1** which, along with theobromine (3,7-dimethylxanthine) **2**, accumulates in leaves of tea and maté and beans of coffee and cacao, which are popular components of nonalcoholic beverages and/or chocolate products [2]. The pharmacological effects of purine alkaloids in animals, such as stimulation of the central nervous system, have been investigated extensively [3]. Caffeine is also often utilized in cytological studies to induce the formation of binucleate cells and is, therefore, used to measure the duration of the mitotic cycle [4].

Caffeine was first isolated from coffee in 1820 by the German chemist Friedlieb Ferdinand Runge and, independently, in 1821 by French chemists, Pierre Jean Robiquet, Pierre Joseph Pelletier, and Joseph Bienaimé Caventou. The biosynthesis and catabolism of caffeine were not fully elucidated until the 1990s [1]. Highly purified caffeine synthase, a key enzyme in the caffeine biosynthetic pathway, was obtained from tea leaves in 1999 [5], and the first isolation of a caffeine synthase gene from tea leaves was reported in 2000 [6]. Other methylxanthines, such as theophylline (1,3-dimethylxanthine), paraxanthine (1,7-dimethylxanthine), 1-methylxanthine, 3-methylxanthine, 7-methylxanthine, and 7-methylxanthosine (**3–8**), are intermediates in the caffeine biosynthetic pathway as well as being catabolites of caffeine. Methyluric acids include structures **9–12**. Cytokinins, such as N^6-(Δ^2-isopentenyl)adenine (iP) **13**, *trans*-zeatin **14**, and *cis*-zeatin **15**, are hormones that promote cell division in plant tissues. Saxitoxin **16** and tetrodotoxin **17** are purine-like alkaloids responsible for shellfish and puffer fish poisoning, and these neurotoxins are also discussed briefly in this chapter.

2 Occurrence

2.1 Caffeine

Methylxanthines such as caffeine and theobromine have been found in nearly 100 species in 13 orders of the plant kingdom [7, 8]. Compared with other plant alkaloids, such as nicotine, morphine, and strychnine, purine alkaloids are distributed widely in plant species. The phylogenetic relationship between caffeine-synthesizing plant orders was shown in a review by Ashihara and Crozier [8] using Takhtajan's phylogenetic tree for angiosperms [9].

The accumulation of high concentrations of methylxanthines is restricted to a limited number of species belonging to the genera *Camellia*, *Coffea*, *Cola*, *Paullinia*, *Ilex*, and *Theobroma* [8]. The caffeine content of young leaves of first flush shoots of the teas *Camellia sinensis*, *Camellia assamica*, and *Camellia taliensis* is 2–3 % of dry weight, while the level in *Camellia kissi* is less than 0.02 %. The caffeine content of seeds of different *Coffea* species varies from 0.4 % to 2.4 % dry weight [10]. Green coffee beans (as opposed to roasted beans, which are used to prepare the beverage) of commercially cultivated species contain substantial quantities of caffeine; arabica coffee (*Coffea arabica*) beans typically contain 1.2–1.4 % caffeine [11], while robusta coffee (*Coffea canephora*) contains 1.2–3.3 % [10, 11]. There are also several wild coffee species where the green beans contain either no caffeine or extremely low levels. Such coffees include *Coffea eugenioides* and 30 species in the six subsections of *Mascarocoffea* [10, 12–14].

Young leaves of maté (*Ilex paraguariensis*) are a further source of caffeine (0.8–0.9 %) [15] as are seeds of guarana where caffeine is located mainly in the cotyledons (4.3 %) and testa (1.6 %) [16]. Citrus flowers can accumulate up to 0.17 % methylxanthines on a fresh weight basis with caffeine being the main component. Trace quantities of caffeine have also been found in the nectar of citrus flowers [17].

2.2 Theobromine and Other Methylxanthines

Theobromine **2** is an intermediate of caffeine biosynthesis and is often found as a minor methylxanthine in tissues that are actively synthesizing caffeine, such as young flush tea shoots and immature coffee seeds. However, it is the major methylxanthine in mature seeds of *Theobroma cacao* (cacao). The cotyledons of cacao beans contain 2.2–2.7 % theobromine on a dry weight basis and 0.6–0.8 % caffeine [18]. Analysis of several cacao genotypes representing the three horticultural races Criollo, Forastero, and Trinitario revealed considerable variations in the purine alkaloid content of the seed, with slightly higher levels found within the Criollo types [19]. Theobromine is also found as a predominant purine alkaloid (5.0–6.8 %) in young leaves of *Camellia ptilophylla* (cocoa tea) [20] and *Camellia irrawadiensis* (~0.8 %) [21]. Theophylline is a minor purine alkaloid in tea, coffee, maté, and guaraná [8].

2.3 Methyluric Acids

Methyluric acids are found in a very limited number of plant species. Theacrine (1,3,7,9-tetramethyluric acid) **10**, accompanied by caffeine, is a major purine alkaloid in the leaves of a Chinese tea called "kucha" (*Camellia assamica* var. kucha) [22]. The endogenous levels of theacrine and caffeine in expanding buds and young leaves of kucha can be up to 2.8 % of dry weight [23]. Mature leaves of wild coffee species, *Coffea liberica*, *Coffea dewevrei*, and *Coffea abeokutae*, contain different types of methyluric acids, namely theacrine along with liberine [*O*(2),1,9-trimethyluric acid] **11**, and methylliberine [*O*(2),1,7,9-tetramethyluric acid] **12** [24, 25]. Theacrine is the principal purine alkaloid in seeds of 11 species of *Theobroma* and nine species of *Herrania* [19]. *Theobroma grandiflorum* (cupu) contains 0.25 % liberine in cotyledons and 0.08 % in the nutshells [26].

2.4 Cytokinins

Naturally occurring cytokinins are adenine-type compounds synthesized in plant tissues. Major sites of cytokinin biosynthesis are roots, cambium, and other actively dividing tissues. Transport of *trans*-zeatin-type cytokinins **14** is via the xylem, while that of N^6-(Δ^2-isopentenyl)adenine-type cytokinins **13** occurs in the phloem. In addition to acting as local signals, cytokinins communicate acropetal and systemic long-distance signals, and structural side-chain variations mediate different biological messages [27].

2.5 Saxitoxin and Tetrodotoxin

Saxitoxin **16** is produced by certain marine dinoflagellates and cyanobacteria [28]. Ingestion of saxitoxin, usually through shellfish contaminated by toxic algal blooms, is responsible for the human illness known as paralytic shellfish poisoning. The term saxitoxin originates from the name of the butter clam (*Saxidomus giganteus*) [29]. Like saxitoxin, tetrodotoxin **17** is produced by symbiotic bacteria, such as species of *Pseudomonas* and *Vibrio*, which reside within globefish, and other aquatic animals. The name of tetrodotoxin derives from *Tetraodontiformes*, the order that includes the globefish and related species which carry this toxin [30].

3 Phytochemistry

3.1 Purine Alkaloids

Purine is a heterocyclic aromatic organic compound, consisting of a pyrimidine ring fused to an imidazole ring. Purines, including substituted purines and their tautomers, are the most widely distributed nitrogen-containing heterocycle in nature [31]. Methylxanthines and methyluric acids **1–12** are classified as purine alkaloids, and their respective structures are based on xanthine and uric acid skeletons. Methyl groups originating from *S*-adenosyl-L-methionine are attached to nitrogen atoms at positions 1, 3, 7, and 9 or an oxygen at position 2.

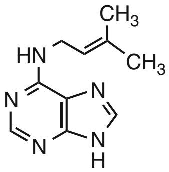
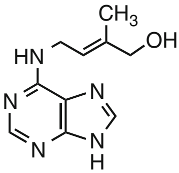
Methylliberine **12**

3.2 Cytokinins

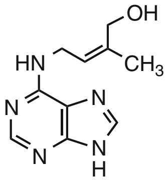
Structurally, cytokinins are classified into two groups, namely, adenine-type cytokinins represented by zeatin, kinetin, and 6-benzylaminopurine, and phenylurea-type cytokinins which include diphenylurea and thidiazuron. The naturally occurring cytokinins N^6-(Δ^2-isopentenyl)adenine **13**, *trans*-zeatin **14**, and *cis*-zeatin **15** differ in the stereoisomeric hydroxylation at the isoprenoid side chain. *trans*-Zeatin and N^6-(Δ^2-isopentenyl)adenine are physiologically the most important cytokinins in plants [27].



N^6-(Δ^2-Isopentenyl)adenine **13**



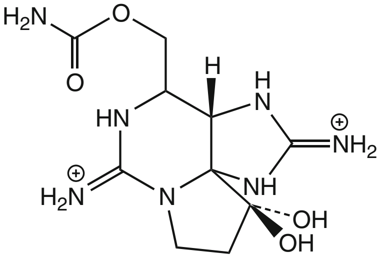
trans-Zeatin **14**



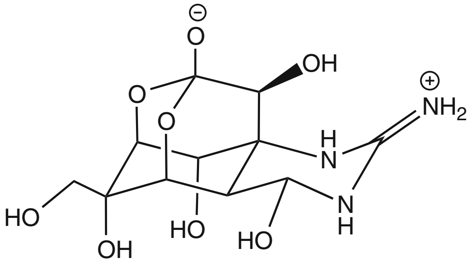
cis-Zeatin **15**

3.3 Saxitoxin and Tetrodotoxin

Chemical formula of saxitoxin **16** is $C_{10}H_{17}N_7O_4$ and that of tetrodotoxin **17** is $C_{11}H_{17}N_3O_8$. Both compounds are water soluble because of their ionic structures. There are many saxitoxin-related compounds which contain additional sulfate ester and/or sulfocarbamoyl moieties. In the case of tetrodotoxin, numerous analogues have been isolated from a variety of aquatic animals including puffer fish, newts, frog, and octopus [32].



Saxitoxin **16**



Tetrodotoxin **17**

4 Biosynthesis

4.1 Theobromine and Caffeine

Methylxanthines are formed from purine nucleotides in plants. Results from studies on in situ metabolism of ^{14}C- and ^{15}N-labeled precursors and from identification of enzymes and genes have established that the main caffeine biosynthetic pathway is a four-step sequence consisting of three methylations and one nucleosidase reaction with xanthosine acting as the initial substrate (Fig. 29.1). Although the information has been obtained mainly from coffee (*Coffea arabica* and *Coffea canephora*) and tea (*Camellia sinensis*), the available evidence suggests that the pathway is essentially the same in other methylxanthine-forming plants [8, 33, 34]. The formation of monomethylxanthine in the main caffeine biosynthetic pathway is initiated by the conversion of xanthosine to 7-methylxanthosine. This reaction is catalyzed by 7-methylxanthosine synthase (EC 2.1.1.158). The second step involves a nucleosidase which catalyzes the hydrolysis of 7-methylxanthosine. It was considered that *N*-methyl nucleosidase (EC 3.2.2.25), which occurs in tea leaves, participates in this reaction [35], but recent structural studies on coffee 7-methylxanthosine synthase suggested that both the methyl transfer and nucleoside cleavage are coupled and catalyzed by a single enzyme [36]. The third step in the caffeine biosynthesis is also catalyzed by a SAM-dependent *N*-methyltransferase.

Highly purified caffeine synthase (EC 2.1.1.160) obtained from young tea leaves has a broad substrate specificity and catalyzes the two-step conversion of 7-methylxanthine to caffeine via theobromine [5]. This enzyme is distinct from the *N*-methyltransferase that catalyzes the first methylation step in the caffeine pathway. Plural genes encoding *N*-methyltransferases have been cloned (Table 29.1). The recombinant enzymes obtained from these genes show different substrate specificities. The recombinant coffee caffeine synthase (EC 2.1.1.160) can utilize paraxanthine, theobromine, and 7-methylxanthine as substrates. The activity of the recombinant theobromine synthase (EC 2.1.1.159) is specific for the conversion of 7-methylxanthine to theobromine. Theobromine synthase, but not the dual-functional caffeine synthase, appears to participate principally in theobromine synthesis in theobromine-accumulating plants, such as *Theobroma cacao*, *Camellia ptilophylla*, and *Camellia irrawadiensis* [37]. Conversion of theobromine to caffeine is performed by the dual-functional caffeine synthase (EC 2.1.1.160). The methylation of *N*1 of 7-methylxanthine by caffeine synthase is much slower than that of *N*3, and, as a consequence, there is only transient accumulation of theobromine in caffeine-synthesizing tissues (Fig. 29.1). In addition to the main caffeine biosynthetic pathway, various minor routes may also operate (Fig. 29.1). Presence of these alternative pathways appears to be a consequence of the broad specificities of the *N*-methyltransferases. For example, caffeine synthase catalyzes *N*3- and *N*1-methylations; thus, 3-methylxanthine and paraxanthine are synthesized, respectively, from xanthine and 7-methylxanthine [5]. However, only restricted accumulation of these

Fig. 29.1 The biosynthetic pathways of caffeine from xanthosine. The major pathway that consists of four steps is shown with *solid arrows*. Conversion of 7-methylxanthosine to 7-methylxanthine is catalyzed by nucleosidase activity involved in 7-methylxanthosine synthase or a specific *N*-methyl nucleosidase. Minor pathways, shown with *dotted arrows*, are theoretically possible. They may occur because of the broad substrate specificity of caffeine synthase or other *N*-methyltransferases. Enzymes: *7mXS* 7-methylxanthosine synthase, *CS* caffeine synthase, *TS* theobromine synthase, *SAM S*-adenosyl-L-methionine, *SAH S*-adenosyl-L-homocysteine

compounds occurs: 3-methylxanthine can be catabolized to xanthine, and paraxanthine appears to be immediately converted to caffeine. Paraxanthine is the most active substrate of caffeine synthase [5], but only limited amounts of the dimethylxanthine appear to be produced in plant tissues because *N*1-methylation of 7-methylxanthine is very slow [1].

Xanthosine, the initial substrate of purine alkaloid synthesis, is supplied by at least four different pathways: *de novo* purine biosynthesis (*de novo* route), degradation of adenine nucleotides (AMP route), the SAM cycle (SAM route), and guanine nucleotides (GMP route) [1, 38]. The pathways leading to xanthosine formation are illustrated in Fig. 29.2.

4.2 1-Methylxanthine, 3-Methylxanthine, and Theophylline

Production of 1-methylxanthine **5**, 3-methylxanthine **6**, and theophylline **3** is carried out by minor branches of the caffeine biosynthetic pathway as described in Sect. 4.1; however, they are also involved in the degradation of caffeine [1, 34]. In contrast to theobromine, which is the immediate precursor of caffeine, theophylline, which is also a dimethylxanthine, is the first intermediate of caffeine catabolism. Caffeine accumulates in mature plant tissues, principally as a consequence of being degraded very slowly with the sequential removal of the methyl groups, resulting in the conversion of theophylline to xanthine, with 1- and 3-methylxanthine serving as intermediates. Xanthine is further degraded by the conventional purine catabolic pathway in higher plants [39–41] (Fig. 29.3).

4.3 Methyluric Acids

Little is known on the biosynthetic pathways of methyluric acids. Radiolabeled feeding experiments indicate that theacrine **10** is synthesized from caffeine.

Conversion of caffeine to theacrine in kucha probably occurs by successive oxidation and methylation steps with 1,3,7-trimethyluric acid **9** acting as the intermediate [23]. Leaves of *Coffea dewevrei*, *Coffea liberica*, and *Coffea abeokutae* converted caffeine **1** to liberine **11** probably via theacrine **10** and methylliberine **12** [25] (Fig. 29.4).

4.4 Cytokinins

Biosynthetic pathways of naturally occurring cytokinins are illustrated in Fig. 29.5. The first step of cytokinin biosynthesis is the formation of N^6-(Δ^2-isopentenyl) adenine nucleotides catalyzed by adenylate isopentenyltransferase (EC 2.5.1.27). In higher plants, N^6-(Δ^2-isopentenyl)adenine riboside 5′-triphosphate or N^6-(Δ^2-isopentenyl)adenine riboside 5′-diphosphate are formed preferentially. In Arabidopsis, N^6-(Δ^2-isopentenyl)adenine nucleotides are converted into *trans*-zeatin nucleotides by cytochrome P450 monooxygenases. Bioactive cytokinins are base forms. Cytokinin nucleotides are converted to nucleobases by 5′-nucleotidase and nucleosidase as shown in the conventional purine nucleotide catabolism pathway. However, a novel enzyme, cytokinin nucleoside 5′-monophosphate phosphoribohydrolase, named LOG, has recently been identified. Therefore, it is likely that at least two pathways convert inactive nucleotide forms of cytokinin to the active freebase forms that occur in plants [27, 42]. The reverse reactions, the conversion of the active to inactive structures, seem to be catalyzed by adenine phosphoribosyltransferase [43] and/or adenosine kinase [44]. In addition, biosynthesis of *cis*-zeatin from tRNAs in plants has been demonstrated using Arabidopsis mutants with defective tRNA isopentenyltransferases [45].

4.5 Saxitoxin

The biosynthetic pathway of saxitoxin **16** was originally proposed by Shimizu et al. [46]. Recently, Kellmann et al. [47] described a candidate paralytic shellfish poisoning toxin biosynthetic gene cluster (*sxt*) from *Cylindrospermopsis raciborskii* T3. The saxitoxin biosynthetic pathway is encoded by a more than 35-kb gene cluster, and comparative sequence analysis has assigned 30 catalytic functions to 26 encoded proteins. Saxitoxin biosynthesis is initiated by Claisen condensation-based acylation of arginine by propionyl-ACP produced from *S*-adenosylmethionine and acetyl-ACP by a new type of polyketide synthase. Further steps are catalyzed by enzymes responsible for heterocyclizations and various tailoring reactions that produce saxitoxin **16** (Fig. 29.6) and numerous isoforms of saxitoxin.

4.6 Tetrodotoxin

Based on the structures of tetrodotoxin **17** and its analogues, Yasumoto et al. [48] proposed that the biosynthetic pathway proceeds via condensation of arginine

and isoprene. Later, Yotsu-Yamashita et al. [49] suggested another possible pathway via condensation of guanidine, a pentose sugar and isoprene. The pathways are illustrated in Fig. 29.7, but as yet there are no firm data to support these proposals. Due to its unique structure, several plausible routes and many possible enzymes could potentially be involved in tetrodotoxin biosynthesis. Possible reactions involved in the putative pathways were discussed by Chau et al. [50].

5 Biological Activities

5.1 The Role of Purine Alkaloids *in Planta*

The physiological role of purine alkaloids, and in particular caffeine, *in planta* is largely unknown. They appear not to act as a nitrogen reserve since they are not transported to young developing organs and considerable amounts remain in senescing tissues. There are two hypotheses concerning the ecological roles of caffeine **1** in plants. The chemical defense theory proposes that the high concentrations of caffeine in young leaves, fruits, and flower buds of species such as tea and coffee act as a defense to protect young, delicate tissues from pathogens and herbivores [51]. The allelopathic or autotoxic function theory proposes that caffeine in seed coats and falling leaves is released into the soil to inhibit germination of seeds around the parent plants [52]. Inhibition of germination and growth of seeds by caffeine was recognized as long ago as 1912 by Ransom [53]. In caffeine-synthesizing plant species, caffeine is probably sequestered in special organelles or organs, such as vacuoles and seed coats, and as a result, no inhibition occurs. However, even in caffeine-producing plants, exogenously supplied caffeine inhibits the growth [54]. It is unclear to what extent caffeine is involved in allelopathy in natural ecosystems, especially as soil bacteria such as *Pseudomonas putida* can degrade methylxanthines [40].

5.2 Biological Activity of Purine Alkaloids in Humans

There are many publications on caffeine and human health [3, 55, 56]. The main effects of moderate consumption of caffeine by humans are an increase in attention,

Fig. 29.3 3-Methylxanthine, 1-methylxanthine, and theophylline are synthesized from caffeine as part of the caffeine degradation pathway that produces xanthine which is further degraded to CO_2 and NH_3 by the conventional oxidative purine catabolism pathway. The conversion of caffeine to theophylline is the rate-limiting step in caffeine-accumulating species such as *Coffea arabica* and *Camellia sinensis*. *Solid arrows* indicate major routes and *dotted arrow* minor conversions. The pathway was elucidated from data obtained in feeding experiments. *N*-Demethylase enzymes involved in caffeine degradation have not yet been characterized in plants. memory performance, physical performance, muscle recovery and intraocular pressure, and a possible decrease in risk of heart disease.

The attraction of tea and coffee to many consumers results from the ability of caffeine to increase alertness and a capacity to remain alert for longer periods without sleep. The biochemical mechanism underlying this effect is a synergistic interaction with catecholamines (adrenaline and noradrenaline – the major signals in the sympathetic nervous system) and antagonism of the actions of adenosine, which elevates another neurotransmitter in the brain, dopamine. Elevation of dopamine concentration in the brain is responsible for many of the central nervous system stimulants and indeed addictive properties of caffeine. Dopamine also enhances the action of serotonin on raising mood. Caffeine increases sympathetic activity and nor/adrenaline levels, and if catecholamines are elevated for any reason, such as stress, then the biological actions of caffeine are exaggerated. An important catecholamine action augmented by caffeine is inhibition of the enzyme cyclic AMP-phosphodiesterase, which results in the accumulation of cyclic AMP in cells, and promotes glucose synthesis. It also leads to excessive gastric acid secretion, which can cause symptoms of heartburn and indigestion [57]. This is one of a range of adverse effects of caffeine which includes anxiety, tremors, and other gastrointestinal problems to which some people are all but immune while

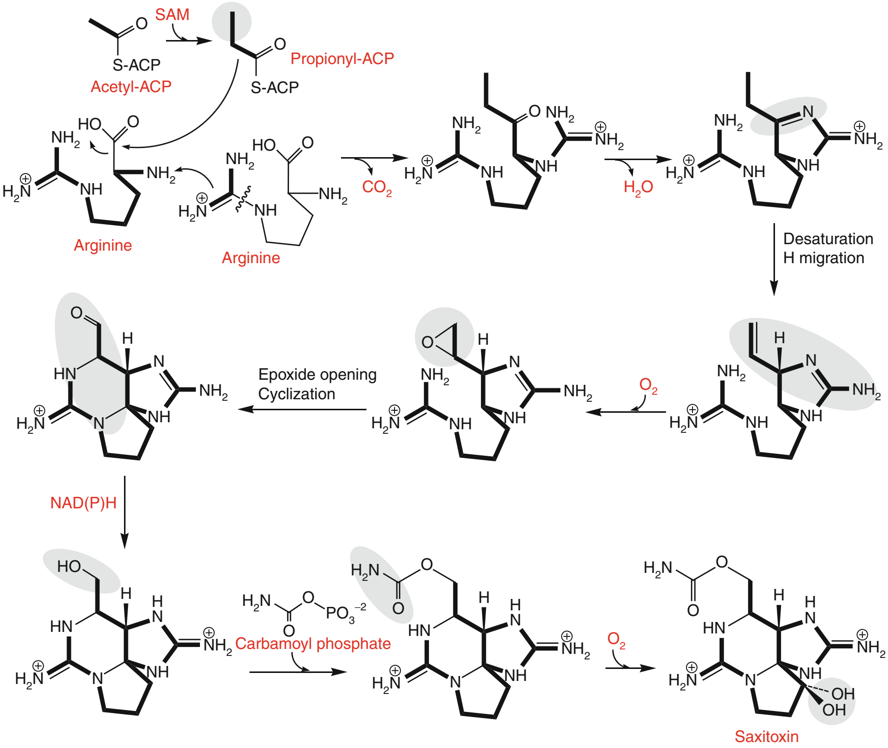

Fig. 29.6 Proposed biosynthesis of saxitoxin [47]. Pathways were envisaged by the analysis of a saxitoxin biosynthesis gene cluster in cyanobacteria. Moieties resulting from reactions are highlighted by *gray shading*

others are extremely sensitive and experience such effects after drinking of one cup of coffee [3].

After consuming tea or coffee, caffeine is rapidly absorbed in the upper gastrointestinal tract of humans and can be detected in the bloodstream within 5 min, reaching peak concentrations after ca. 30 min. It readily crosses the blood–brain barrier and enters all body fluids including serum, saliva, milk, and semen. Caffeine is metabolized in the liver by microsomal enzymes and xanthine oxidase, which together mediate demethylations and oxidations yielding products that include di- and monomethylxanthines, methylated uric acids, and uracil derivatives [3]. The half-life of caffeine is typically 2.5–4.5 h, and the elimination rate can be increased by exercise. Excretion is slower in the grossly obese and those suffering from liver disease. Oral contraceptives delay clearance by one third. Smoking, in contrast, enhances clearance by inducing the caffeine-metabolizing enzymes in the liver. Caffeine metabolism is slower, and the half-life extended up to 10 h, in pregnancy and is much longer in the developing fetus. Newborn children, especially premature infants, can have a greatly extended half-life for caffeine (>100 h) because of incomplete development of the hepatic

metabolizing enzymes. The occurrence of unwanted and unpleasant side effect of caffeine is, therefore, more likely in pregnancy, in young children, and those with liver disease, and for this reason, intake of caffeine-containing beverages by these groups should be limited [3].

5.3 Toxicity of Purine Alkaloids in Animals

Several species, including dogs, foxes, badgers, horses, and the New Zealand kea (an alpine parrot), have a very limited capacity to metabolize theobromine **2** which tends to accumulate and become toxic with potentially fatal consequences [58, 59]. Depending upon the size of the dog, as little as 100–200 mg of theobromine, which can be the content of ~100 g of milk chocolate or ~10 g of dark chocolate [60], can be fatal. Caffeine consumption by horses leads to theophylline accumulation and hyperactivity [61].

5.4 The Role of Cytokinins in Planta

Cytokinins are a group of mobile phytohormones that play a critical role in plant growth and development by regulating leaf senescence, apical dominance, root proliferation, phyllotaxis, reproductive competence, and nutritional signaling [27]. Cytokinins also participate in the maintenance of meristem function [42] and in the modulation of metabolism and morphogenesis in response to environmental stimuli [62].

5.5 Biological Activity of Saxitoxin and Tetrodotoxin

The ingestion of saxitoxin **16** causes paralytic shellfish poisoning. The medical importance of saxitoxin originates from its production by certain dinoflagellates which are abundant in algal blooms known as red tides. The toxin is released into the surrounding water and ingested by bivalve filter feeders such as oysters, clams, and mussels which sequester saxitoxin in their tissues. Saxitoxin is water soluble and heat resistant so is not destroyed by cooking and passes on readily into humans who consume contaminated seafood. The blocking of neuronal sodium channels which occurs in paralytic shellfish poisoning produces a flaccid paralysis that leaves its victim calm and conscious as the symptoms develop with death typically occurring from respiratory failure.

Tetrodotoxin **17**, produced by a number of marine organisms, including puffer fish and other members of Tetraodontiformes, is a potent neurotoxin that is approximately ten times more poisonous than potassium cyanide. It too blocks the action potential in nerves by binding to the voltage-gated, fast sodium channels in nerve cell membranes thereby preventing the nerve cells from firing.

The flesh of puffer fish (fugu) is considered a delicacy in Japan. The fish is prepared by specially trained chefs who are certified by the government to prepare the flesh free of the toxic, liver, skin, and gonads. Despite these precautions, many cases of tetrodotoxin poisoning are reported every year after eating fugu. The toxic dose, caused by paralysis of the diaphragm and subsequent respiratory failure, is unclear because different puffer fish contain varying levels of tetrodotoxin. A dose of 1–2 mg of purified tetrodotoxin can be lethal, and reported cases have documented poisoning after ingestion of as little as ~40 g of puffer fish [63, 64].

6 Biotechnology Approaches

Since genes of enzymes of caffeine biosynthesis have been cloned, genetically modified (GM) plants of several plant species have been obtained; one is construction of GM coffee plants in which caffeine production is suppressed, and the other is introduction of caffeine biosynthesis into what are normally non-caffeine-producing species [34]. The first approach involves introducing antisense or the double-stranded RNA interference (RNAi) constructs for enzymes of caffeine biosynthesis into *Coffea canephora* and *Coffea arabica* [65, 66]. Although transgenic coffee beans have not yet obtained, decaffeinated coffee beans are likely to be produced in the near future. The use of such genetic engineering to make full-flavored caffeine-deficient coffee and tea will be of interest to the increasing numbers of consumers who are concerned about the potentially adverse effects of caffeine consumption on their health.

The second approach was to construct caffeine-producing transgenic tobacco (*Nicotiana tobacum*) plants, which naturally do not synthesize the purine alkaloid. This idea was based on a report that exogenously applied caffeine markedly increased the resistance of plants against several pests, and thereby enhanced their growth and survival [67]. The study has been achieved using a multigene transfer system, involving cDNAs for all three *N*-methyltransferases, and the resulting transgenic tobacco plants successfully accumulated caffeine in leaves in amounts that proved unpalatable to tobacco cutworms [34, 68, 69]. Recently, Sano and coworkers reported the simultaneous activation of salicylate production and fungal resistance in transgenic caffeine-producing chrysanthemum plants [70]. The transgenic chrysanthemum, which produced an equivalent level of caffeine as the tobacco plants at ~3 μg per g fresh weight, exhibited resistance against gray mold fungal attack. Transcripts of *PR-2* gene, a marker for pathogen response, were constitutively accumulated in mature leaves without pathogen attack. The levels of salicylic acid and its glucoside conjugate in mature leaves of the transgenic lines were found to be 2.5-fold higher than in the wild-type control. These findings suggest that stimulation of endogenous caffeine production and/or deposition of salicylates may activate a series of defense reactions even under nonstressed conditions. The caffeine-producing transgenic chrysanthemum plants have also been shown to have resistance against herbivores, lepidoptera caterpillars, and aphids [71].

7 Conclusion/Prospects

It is over decade since the first report on the cloning of *N*-methyltransferases involved in caffeine biosynthesis from tea and coffee plants [1]. Much of the widespread interest in this research has been fuelled by the possibilities of using genetic engineering to obtain transgenic, low-caffeine coffee and tea that could be used to produce “natural” decaffeinated beverages. However, as yet, there are no reports on the caffeine content of coffee beans produced by such plants. The recent report of Kim and Sano [72] that tobacco plants genetically engineered to produce caffeine repel insect pests and exhibit resistance to viral and bacterial infections is potentially of major importance and likewise the resistance to fungal infection of transgenic chrysanthemum plants that accumulate caffeine and salicylic acid [70]. Almost 40 % of world agricultural production is lost because of herbivores and diseases, and a practical and economic means of pest control is one of the most urgent measures required to obtain a reliable and increasing supply of foodstuffs for the world’s expanding population. The production of low-level caffeine by agriculturally important crops may have the potential to offer protection against both insect pests and pathogens, and from an environmental prospective, it would certainly be cheaper and more environmentally friendly than treatment of crops with pesticides and fungicides.

Information on cellular metabolic organization of caffeine biosynthesis and catabolism links to purine nucleotide metabolism, intercellular translocation, and accumulation mechanisms at specific cellular sites, such as chloroplasts and vacuoles, have yet to be fully revealed. Cell-, tissue-, and organ-specific synthesis and possibly catabolism of purine alkaloids may be regulated by unique and unknown developmental- and environmental-specific control mechanisms. A great deal of fascinating purine alkaloid biology in plants still remained to be discovered.

Compared with purine alkaloids, an extensive number of studies have investigated cytokinins, and many reviews have been published. Readers interested in this topic are directed to a number of recent, excellent reviews [27, 62, 73]. The studies on paralytic shellfish toxin metabolism in the cyanobacteria suggested that saxitoxin and derivatives are converted into xanthine, urea, and further to CO_2 and NH_4^+ or recycled via primary metabolism through the purine degradation pathway [74]. Details on the current status of saxitoxin **16** and tetrodotoxin **17** can be found in recent reviews [28, 46, 47, 50, 75].

Abstract

This chapter describes research on natural aziridine alkaloids isolated from both terrestrial and marine species, as well as their lipophilic semisynthetic and/or synthetic analogues. Over 100 biologically active aziridine-containing compounds demonstrate confirmed pharmacological activity including antitumor, antimicrobial, and antibacterial effects. The structures, origin, and biological activities of aziridine alkaloids are reviewed. Consequently, this

1 Introduction

Several groups of rare natural alkaloidal metabolites incorporating the cyclobutane [1], aziridine [2, 3], and azetidine moieties [4] and/or their synthetic counterparts possess a broad spectrum of biological activities.

Aziridine alkaloids also belong to a rare and somewhat neglected group of natural products which are known to play a seminal role in the secondary metabolism of some microorganisms, plants, and various marine organisms [5]. The aziridine-containing compounds have been of interest as both immunomodulatory and anticancer agents since the late 1950s [6]. Aziridines are inherently strained making them attractive for study in terms of reactivity and pharmacodynamic action. Ethylenimine (or aziridine, **1**) and some of its simple derivatives are commercial products in different fields of applied chemistry [7]. Observations of the toxic action of aziridines have prompted extensive investigations involving their synthesis and pharmacological activity, allowing selection and advancement of suitable substances as putative cancer chemotherapeutic agents. Notably, a few are enjoying regular clinical use [8]. Bayer strain encourages ring-opening reactions of aziridines in the presence of nucleophiles, imparting useful alkylating properties, despite their powerful mutagenic and toxic activities [9].

Aziridines are highly valuable heterocyclic compounds and are widely used during the synthesis of numerous drugs and biologically active natural products (and their derivatives) [10–15]. Many aziridine alkaloids have anticancer, antibacterial, and/or antimicrobial activity against selected cancer cell lines, pathogenic bacteria, and/or microorganisms strongly indicating that the presence of the aziridine ring in natural as well as synthetic compounds is essential for such activities [16–19].

This chapter reviews natural aziridine alkaloids, with high antitumor, antimicrobial, and antibacterial activities, and also highlights those semisynthetic derivatives and analogues which possess therapeutic promise.

2 Natural Aziridine Alkaloids

The simple alkaloid, ethylenimine (aziridine, azacyclo-propane, or aziran, **1**) was detected in various foodstuffs including baker's yeast (*Saccharomyces cerevisiae*) autolyzate [20], in the volatile flavoring constituents of cooked chicken, beef and pork [21], and beef flavor [22]. Two metabolites (**1**) and aziridine-2-carboxylic acid (**2**) were isolated from mushrooms *Agaricus silvaticus* (class Basidiomycetes), both of which have been synthesized [23]. Aziridine-2-carboxylic acid (**2**) as well as aziridine-containing peptides are vital intermediates in the synthesis of various amino acid and peptide derivatives [24]. Furthermore, (**2**) and related compounds represent interesting substrates for clarifying enzyme mechanisms but also as the warhead of novel irreversible protease inhibitors with a number of potential therapeutic applications [25, 26].

More complex aziridines are found in various plant sources. For instance, 1-methyl-aziridine (**3**) was detected using GC-MS within onion bulbs (*Allium cepa*, class Liliopsida, order Asparagales, family Alliaceae) [27]. Flue-cured tobacco (*Nicotiana tabacum*, family Solanaceae) contains 4-(1-aziridinyl)-3-buten-2-one (**4**) [28]. Natural aziridine alkaloids (**2**,**5**–**11**) were detected and isolated from distillate, and residue in extractions of dried matter of *Petasites japonicus* (family Asteraceae, Japanese name Fuki) [29] is also known as bog rhubarb or giant butterbur. It is native to Japan, where the spring growth is relished as a vegetable. Consequently, its pharmacological properties are of considerable importance.

11

Since the 1950s, polymerization products of ethylenimine, their polymerizable homologs, as well as substitution products were considered useful for disinfecting and preserving textiles, leather, skins, meat, glands, blood, glue, casein (and other albuminous substances), starch, size, dressings, fruits, and vegetables. Their utility in disinfecting floors, walls, stock and portable water vessels, and medical instruments has improved health and safety [30–32].

The azirinomycin (**12**), 3-methyl-2H-azirine-2-carboxylic acid, was isolated from a strain of *Streptomyces aureus*. Its methyl ester (**13**) exhibited broad spectrum antibiotic activity in vitro against both Gram-positive and Gram-negative bacteria [33, 34]. The carboxylic acid (**12**) is most active against *Staphylococcus aureus* followed by *Proteus vulgaris*, *Bacillus subtilis*, and *Streptococcus faecalis*. In contrast, the methyl ester shows its lowest activities against one of the *Staphylococcus aureus* cultures and *Streptococcus faecalis*.

(2*S*,3*S*)-Aziridine-2,3-dicarboxylic acid (also known as *S*,*S*-2,3-dicarboxyaziridine, **14**), which demonstrates antibacterial activity toward *Aeromonas salmonecida*, was isolated from the cultured broth of a *Streptomycetes* MD 398-Al (FERM-P 3217) [35]. The compound (**14**) was effective against *Pellicularia sasaki* and *Pythium debaryanum* [36]. It is a potent competitive inhibitor of various enzymes including fumarase isolated from pig heart ($K_i = 0.08\ \mu M$) [37] and aspartase of *Escherichia coli* ($K_i = 55\ \mu M$). It also shows antibacterial activity against *Aeromonas salmonicida* [38]. Ethyl esters of aziridine-2,3-dicarboxylic acid inhibited the cysteine proteinase papain [39], whereas peptides containing the aziridine-2,3-dicarboxylic acid building block are inhibitors of several cysteine proteases such as the papain-like mammalian proteases [40].

The alkaloidal antibiotic, U-47,929 (also known as ficellomycin, **15**), was isolated from *Streptomyces ficellus* [41]. Interestingly, it inhibited the growth of Gram-positive bacteria in vitro and is effective in the treatment of experimental *Staphylococcus aureus* infections in mice [42]. Structural elucidation of (**15**) [43] was eventually achieved by a combination of NMR, mass spectrometry, and formation of derivatives. The 1-azabicyclo[3.1.0]hexane moiety in (**15**) represents an unusual ring system making ficellomycin a unique natural product [43].

The unique cytotoxic azacyclopropene, *R*-dysidazirine (**16**), was isolated from the marine sponge *Dysidea fragilis* (Fiji) just over 20 years ago [44]. More recently, both the (*Z*) and (*E*) geometrical isomers of *S*-dysidazirine (**17a**) and (**17b**) were isolated and were also found to possess cytotoxicity. The dibrominated analogues, *S*-antazirine (**18a**) and (**18b**), were also detected within the same marine sponge *D. fragilis* collected in Pohnpei, Micronesia [45]. Three new ω-halogenated long-chain 2*H*-azirines (**19a,b** and **20**) have recently been isolated from the marine sponge *Dysidea fragilis*, two of them containing a terminal (*Z*)-1-bromo-1-chlorovinyl group, the first such example from a marine invertebrate [46]. Cytotoxic activity of (**17b** and **18b**) and new compounds (**19a**,**b**, and **20**) is shown in Table 30.1.

The antitumor antibiotic FR-900482 (**21**) was isolated from *Streptomyces sandaensis* 6897 as a mixture of the two hydroxylamine hemiketal isomers (**22**) and (**23**) [47]. FR-900482 exhibits potent cytotoxic activity against various tumor cells in vitro. Furthermore, it possessed a weak antimicrobial activity against some Gram-positive and Gram-negative bacteria [48]. Activity against human LX-1, MX-1, SC-6, and LC-6 tumor cells has been identified [49]. Quite a number of FR-900482 derivatives were synthesized, and some of them showed antileukemic activity [50].

Additionally, FR-900482 inhibited DNA, RNA, and protein synthesis in cell culture of murine L1210 leukemia cells. Whereas FR 900482 did not induce DNA single-strand breaks either in the leukemia cells or in plasmid pBR322, it promoted interstrand DNA-DNA cross-links in leukemia cells. An activation of FR 900482 was required prior to induction of interstrand DNA-DNA cross-linking required for cytotoxic action [51]. FK317 (**24**), an analogue of FR-900482, had stronger cytotoxic effects against in vitro cultured B16, P388, HeLa S3, and KB tumor cell lines. In vivo experiments revealed an equivalent antitumor activity of FK317 against P388, M5076, and MX-1 and a more potent antitumor activity against L1210, Colon 38, and LX-1 cell lines as compared with FK973 (**26**) [52]. Both FR900482 (**21**) and FR66979 (**27**) are structurally novel natural products isolated by Fujisawa Pharmaceutical Co. (Japan) in 1987 and have been shown to be highly potent antitumor antibiotics structurally related to the mitomycins [5]. The N-O substructure is bioisosteric with peroxides, and the activity of natural products containing this functional group may generate free radicals, especially upon reductive activation. Not surprisingly, studies on the mode of action have established that these new agents form covalent DNA interstrand cross-links both in vitro and in vivo as a result of the reactive mitosene intermediate generated upon bioreductive activation [for details, see Refs. 53–55].

Semisynthetic analogues, such as FK317 (**24**) and FK973 (**26**), have been shown to be a potent cytotoxic compound; to date, no direct evidence of DNA interstrand cross-link sequence specificity has been reported. In one study, DNA interstrand cross-links were generated by treatment of a synthetic duplex DNA substrate with FK317 and its deacetylated metabolites FR70496 (**25**) and FR157471 [56]. FK973 and all its deacetylated metabolites showed strong cytotoxicity on in vitro cultured murine L1210 leukemia cells; however, FK973 remained the most potent cytotoxic agent of this series [57]. Synthesis and other biological activities of FR900482 and its analogues have been reviewed [58–60].

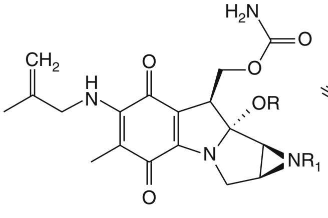
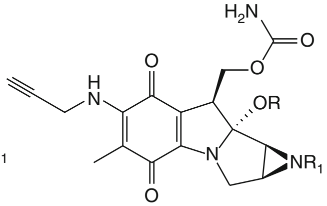
The mitomycins are potent antibiotics that belong to the family of antitumor quinones. In 1956, mitomycin A (**28**) and B (**34**) were isolated from *Streptomyces caespitosus*, and shortly thereafter, mitomycin C (**30**) was discovered within the same strain [61, 62]. The *N*-methyl derivative of (**31**), porfiromycin, was isolated in 1960 from *Streptomyces ardus*, which was followed by the discovery of mitiromycin from *Streptomyces verticillatus* [63, 64]. Among all these different mitomycins, (**31**) enjoyed early widespread clinical use as a consequence of its uniquely superior activity against solid tumors. Secondly, it possessed reduced toxicity when compared to the natural counterparts (**28**) and (**34**). Mitomycin A, B, and C and porfiromycin also were produced by a *Micromonospora* species KY 11084 [65]. Mitomycins A and C showed antimicrobial activity against *Bacillus subtilis* and *Klebsiella pneumoniae* [66].

Effects of mitomycin A (1–10 μg/mL), mitomycin B (1–50 μg/mL), mitomycin C (10–30 μg/mL), *N*-methyl-mitomycin (1–40 μg/mL), and porfiromycin (1–60 μg/mL) on the *Euglena gracilis* chloroplast system were reported. However, only *N*-methyl-mitomycin (20–40 μg/mL), porfiromycin (40–60 μg/mL), and mitomycin B (40–50 μg/mL) were effective bleaching agents.

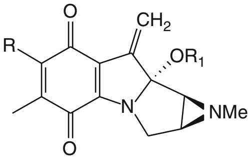


44 R = Me, R$_1$ = H
45 R = H, R$_1$ = Me



46 R = Me, R$_1$ = H
47 R = H, R$_1$ = Me

Thus, only mitomycin derivatives containing an alkyl group on the aziridine nitrogen are effective bleaching agents. The sensitivity of the *Euglena* chloroplast to small structural differences in the active centers of antibiotics demonstrates the usefulness of this organism in finding a relationship between biological activity and chemical structure [67]. Mitomycin A and C were manufactured by fermentation with mitomycin-producing *Streptomyces* and *Micromonospora* or by catalytic isomerization of mitomycin A and mitomycin C, respectively. Both isomers showed antibiotic activities against various bacteria, including *Streptococcus, Staphylococcus, Bacillus, Proteus*, and *Salmonella* [68].



48 Mitomycin H, R = OMe, R$_1$ = H
49 Mitomycin G, R = OMe, R$_1$ = Me
50 Mitomycin K, R = NH$_2$, R$_1$ = Me
51 Mitomycin Z, R = NH$_2$, R$_1$ = H

Molecular genetic manipulation of the mitomycin pathway can elucidate the sequence of reactions involved in mitomycin biosynthesis, as well as provide access to novel mitomycin natural products. Thus, 9α-demethyl mitomycin A (**32**), 9-epi-mitomycin B (**33**), and *N*-methylmitomycin A (mitomycin F, **29**) have been obtained using mitomycin B as starting material [69]. Mitomycin J (**35**) and mitomycin D (**36**) were isolated as minor antibiotics from *Streptomyces fradiae* SCF5 [70], and mitomycin E (**37**) was obtained from *S. lavendulae* [71]. Mitomycin C, A, and F showed anthelmintic activity against gastrointestinal parasites *Hymenolepis microstoma* and *H. nana* developing in *Tribolium confusum* (Coleoptera, Tenebrionidae) [72].

Several neoplasm inhibitor analogues (**38–47**) of mitomycin B and C were produced by *Streptomyces caespitosus*. Upon supplementation of the normal fermentation medium for the production of mitomycin C with *S. caespitosus* with a number of primary amines, two new types of mitomycin analogues, described as Type I and Type II, were produced. Type I analogues were related to mitomycin C with the amine substitution at position C7 on the mitosane ring. Type II analogues also contain the same substitutions at C7, but the conformation of the mitosane ring was related to mitomycin B, by possessing an OH at positions C9a and a Me-substituted aziridine [73]. In all cases, the Type I analogues are more active in a prophage induction test and against L1210 lymphatic leukemia in mice [73].

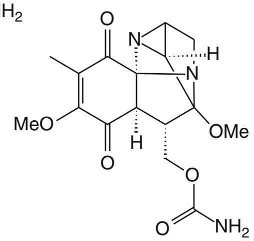
54 Albomitomycin A (AX-1), R = OMe
55 CX-1, R = NH_2



56 Albomitomycin C

Mitomycins H (**48**), G (**49**), and K (**50**) were produced by culturing a strain of *S. caespitosus* ATCC 29422 [74]. Mitomycins H, G, K, and Z (**51**) were also prepared from mitomycin B by cultivating *S. caespitosus* ATCC 27422 [72]. Four isolated antibiotics (**48–51**) possessed antibacterial activity [75]. Anticancer activity of some mitomycines against Sarcoma 180 cell line is shown in Table 30.2.

The neoplasm inhibitors, isomitomycin A (**52**) and albomitomycin A (**54**) and (**56**), were isolated, together with mitomycin A from *S. caespitosus* culture broth. Both antibiotics were obtained by intramolecular rearrangement of mitomycin A [76]. Anticancer antibiotics AX-2 (**53**) and CX-1 (**55**) were isolated from the culture broth of *S. caespitosus* and obtained from mitomycin C [77]. Other biological activities of different mitomycines, their mechanisms of action, and therapeutic utility have been described in various reviews [5, 9, 77–83].

Table 30.2 Anticancer activity of some mitomycines against sarcoma 180 cell line[a]

No.	Δ 9	LD_{50}	ED_{50}
28	β	2.1	1.1
29	β	5.0	1.3
30	β	8.4	4.4

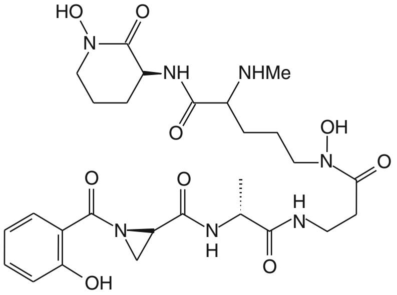
51	γ	210.0	82.0

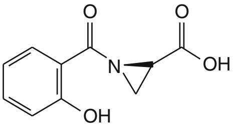
[a] Substituent at 9 position, a (carbamoyloxy) methyl group with α and β configurations and a vinyl group were taken into account. LD_{50} and ED_{50} were used as measures of biological activity. LD_{50} values of administration of an i.p. route were measured in male ddY mice by probit analysis. ED_{60} doses that gave 50% inhibition of tumor growth were calculated from the dose-response curve. Sarcoma 180 cells (5 × 106/mouse) were inoculated s.c. into ddY mice on day 0, and drugs were injected i.p. on day 1. Tumor volume was measured on day 7

A few naturally occurring peptides containing an aziridine ring have been discovered in living organisms. For instance, peptide madurastatin A1 (**57**) and madurastatin B1 (**58**), consisting of Ser and salicylic acid moieties, were isolated from the culture broth of a pathogenic *Actinomadura madurae* IFM 0745 strain. Both metabolites showed antibacterial activity against *Micrococcus luteus*, indicating that the presence of the aziridine ring is essential for such activity. Since (**57**) has a strong affinity with ferric ion attributed to the presence of two hydroxamic acids and a salicylic acid, this low molecular weight chelator is considered a siderophore [84].

Miraziridine A (**59**) isolated from the marine sponge *Theonella* aff. *mirabilis* unifies within one molecule three structurally privileged elements: (a) (2*R*,3*R*)-aziridine-2,3-dicarboxylic acid, (b) (3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid (statine), and (c) (E)-(*S*)-4-amino-7-guanidino-hept-2-enoic acid (vinylogous arginine).



57 Madurastatin A1



58 Madurastatin B1

The alignment of them realized in the tetrapetide allows for a simultaneous inhibition of the proteolytic activity of trypsin-like serine proteases, papain-like cysteine proteases, and pepsin-like aspartyl proteases. Therefore, this unique compound represents a blueprint for the design of protease class-spanning inhibitors [85, 86]. The capability of (**59**) to inhibit proteases belonging to different classes for trypsin, cathepsin B, cathepsin L, and papain was reported (see Table 30.3). Miraziridine A [85] also inhibited cathepsin B with an IC_{50} value of 1.4 μg/mL. Aziridine-2,3-dicarboxylic acid (**14**) is a rare natural product, reported from a *Streptomyces* [36], and vArg has never before reported as a natural product.

59 Miraziridine A

Miraziridine A (**59**) isolated from the marine sponge *Theonella* aff. *mirabilis* unifies within one molecule three structurally privileged elements: (a) (2*R*,3*R*)-aziridine-2,3-dicarboxylic acid, (b) (3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid (statine), and (c) (E)-(*S*)-4-amino-7-guanidino-hept-2-enoic acid (vinylogous arginine). The alignment of them realized in the tetrapetide allows for a simultaneous inhibition of the proteolytic activity of trypsin-like serine proteases, papain-like cysteine proteases, and pepsin-like aspartyl proteases. Therefore, this unique compound represents a blueprint for the design of protease class-spanning inhibitors [85, 86]. The capability of (**59**) to inhibit proteases belonging to different classes for trypsin, cathepsin B, cathepsin L, and papain was reported (see Table 30.3). Miraziridine A [85] also inhibited cathepsin B with an IC_{50} value of 1.4 μg/mL. Aziridine-2,3-dicarboxylic acid (**14**) is a rare natural product, reported from a *Streptomyces* [36], and vArg has never before reported as a natural product.

Anticancer antibiotics, azinomycin A (**60**) and B (**61**), were isolated from the culture broth of *Streptomyces griseofuscus* S-42227 [87, 88]. Azinomycin A and

Table 30.3 Inhibitory properties of miraziridine A [60]

Aspartyl protease	Pepsin	1.4×10^{-8} M

B expressed antitumor activities against P388 leukemia, P815 mastocytoma, B-16 melanoma, Ehrlich carcinoma, Lewis lung carcinoma, and Meth A fibrosarcoma, and it was markedly effective against i.p. inoculated tumors such as P388 leukemia, B-16 melanoma, and Ehrlich carcinoma [89]. Both compounds were active against Gram-positive and Gram-negative bacteria and L5178Y cells in tissue culture [87]. Azicemicin A (**62**) and B (**63**) were isolated from *Amycolatopsis sulphurea*, and its physicochemical properties and antimicrobial activity were defined [90]. It was also isolated from *Amycolatopsis* sp. (MJ126-NF4) cultures and showed MIC of 50 μg/mL against *Escherichia coli* NIHJ in vitro [91, 92]. Antimicrobial activities of azicemicin A and B were shown in Tables 30.4 and 30.5.

A carboxylic acid antibiotic, carzinophilin, active against Gram-positive bacteria and tumor cells, was isolated from the broth filtrate of *Streptomyces sahachiroi* in 1954 [93, 94]. The structure of carzinophyllin (or carzinophilin) was similar to azinomycin B, whose partial structure was previously reported [95]. Lown and Hanstock reported the complete structure (**64**) [96]. It has a twofold symmetry axis and consists of a dimer of a substituted 1-naphthoic acid attached to a 4-amino-hydroxyvaline linked to an *N*-methyl-aminohexose moiety. It is the first naturally occurring *bis*-intercalative (macrocyclic polyoxide) bisalkylator (aziridine), and the mode of its antitumor antibiotic activity is attributed to the reactive moiety (**64**) [96].

Maduropeptin (**65**) is a chromoprotein antitumor antibiotic isolated from the fermentation broth of *Actinomadura madurae* [97]. Maduropeptin consists of a 1:1 complex of an acidic, water-soluble carrier protein (32 kD) and a 9-membered ring enediyne chromophore possessing potent antibacterial and antitumor properties [97]. It exhibits potent inhibitory activity against Gram-positive bacteria and tumor cells and strong in vivo antitumor activity in P388 leukemia and B16 melanoma implanted mice [98]. The biosynthetic gene cluster for the enediyne antitumor antibiotic maduropeptin (MDP) from *Actinomadura madurae* ATCC 39144 was cloned and sequenced. Cloning of the mdp gene cluster was confirmed by heterologous

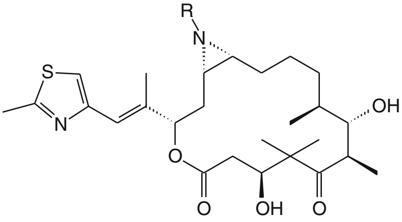
3 Selected Semisynthetic and Synthetic Aziridine Alkaloids as Analogues of Natural Products

The epothilones are a relatively new class of cytotoxic molecules identified as potential chemotherapeutic drugs which were originally identified as metabolites produced by the myxobacterium *Sorangium cellulosum* and/or *Streptomyces coelicolor* CH999 [100]. These compounds inhibited the growth of a broad range of human cancer cell lines in vitro with low nM or sub-nM IC_{50}s. A series of 12α,13α-aziridinyl epothilone derivatives as anticancer agents (**66**–**70**) were synthesized in an efficient manner from epothilone A. The final semisynthetic route involved a formal double inversion of stereochemistry at both the C12 and C13 positions. All aziridine analogues were showed cytotoxicity against cancer cell lines. Thus, (**67**) had IC_{50} value of 4.3 nM against KB cells. The obtained results indicate that the aziridine moiety is a viable isosteric replacement for the epoxide in the case of epothilones [101].

Several derivatives (**71–76**) of amide aziridine-2-carboxylic acid (also known as leacadine, **71**) were prepared as neoplasm inhibitors [102]. Leacadine has been used for treatment of multiple sclerosis [103]. The antitumor efficacy of azimexon (**72**) in experimental animals and humans was described with respect to its various immunological parameters [104]. Two synthetic aziridine-2-carboxylic acid (**2**) (**71** and **76**) showed antitumor activity against a mammary gland tumor in rats [105].

Treatment of (**77**) with KOH in MeOH at 50°C resulted in a 60% yield of an isomerization product (putative structures **78**,**79–81**) which in physiological saline solution converts to *N*-carboxyisoserine. This compound has which had cancerostatic and immunostimulating properties [106].



66 R = H
67 R = CH_2CH_2OH

69 R = COPh
70 R = CH_2Ph

Imexon (**78**) is an immunosuppressant which selectively suppresses B-lymphocyte activation and can be used in the treatment of B-cell or plasma cell leukemias or neoplasias. Thus, imexon inhibited the proliferation of stimulated human B-lymphocytes in vitro and inhibited the growth of methylcholanthrene-induced fibrosarcoma cells in vitro. It was also active against certain autoimmune disorders and infection with Rauscher leukemia virus [107], and also, imexon perturbs cellular thiols and induces oxidative stress leading to apoptosis in human myeloma cells (human 8226) [108]. More recently, (5*R*) and (5*S*) imexons (**78a** and **78b**) have been prepared and used in the treatment of cancer [109]. More details about activity of imexon, and their derivatives, have recently been reviewed [110]. Injection of 10–100 mg BM 06 002 (**78**) increased immune responses, as indicated by delayed cutaneous hypersensitivity and lymphocyte blastogenesis tests in vitro and also in cancer patients participating in clinical experiments [111].

Two isomeric aziridine-containing analogues of the polyamine spermidine were synthesized and evaluated for cytotoxic activity against cancer cell lines. Replacement of one of the primary amino groups of spermidine with an aziridinyl functionality yielded either (**82**) or (**83**). N^1-Aziridinylspermidine (**82**) was cytotoxic in vitro against L1210 murine leukemia cells (IC_{50} 0.15 μM) and HL60 human leukemia cells (IC_{50} 0.11 μM). N^8-Aziridinylspermidine (**83**) was slightly less potent against L1210 (IC_{50} 0.31 μM) and HL60 (IC_{50} 0.30 μM) cells. Both compounds inhibited incorporation of radiolabeled thymidine, uridine, and valine into tricholoracetic acid-precipitable material by L1210 cells [112].

Neoplasms inhibitor, 3,5-bis(1-aziridinylmethyl)-2,6-dimethyl-pyridine (**84**), was prepared and showed antitumor activity against spindle cell sarcoma 45 and Ehrlich muscle tumor in white rats [113]. Markofane (**85**), an oncostatic agent, was synthesized, and its properties and effect on hepatic lipids of rats with sarcoma M-1 were investigated [114]. The body weight of rats with sarcoma M-1 and given a 20% LD_{50} dose of markofane was slightly higher than that of non-treated, sarcomatous rats. Markofane proved quite toxic, and a daily dose of 40% LD_{50} resulted in 25% mortality. It exerted insignificant tumor-inhibiting effect on sarcoma M-1 in daily doses of 20% and 40% LD_{50}. Neither sarcoma M-1 nor markofane had any statistical significance on the content of lipids in dry liver. Markofane, 20% LD_{50}, administered to rats with sarcoma

M-1, increased the liver content of phosphatides. Preparations of (**86**) were less toxic, had a lower cumulative index, and did not produce profound leukopenia in treated animals and showed more antitumor activity than known aziridine derivatives. When tested clinically on 80 patients with chronic myeloleukemia, leukocyte counts decreased 30–80% on administration of between 60 and 80 mg daily doses of A95 [115].

All four prepared compounds (**87**–**90**) of the paramagnetic urethane phosphoric acid diethyl-enimides inhibited growth of the ascitic form of sarcoma 180 in rats 93–100%, and the three (**87**–**89**) inhibited Ehrlich ascites tumor growth by 90–98%. Two compounds (**87**,**88**) inhibited growth of erythromyelosis and Walker carcinosarcoma 100%, while (**89** and **90**) were essentially ineffective. Only compound (**87**) prolonged the survival of animals with leukemia La [116].

Several bioactive phospholipids (**91**–**96**) have been synthesized. Putative neoplasm inhibitors (**91**–**94**) showed significant activities in the Walker carcinosarcoma 256 and leukemia L1210 assay systems [117]. The low-melting cytotoxic phospholipids with aziridine groups (**95** and **96**) capable of forming stable dispersions in aquatic glycerol solutions containing 1% egg lecithin were prepared [118].

Fatty acid derivatives (**97–101**) containing an internal aziridine group were prepared by reaction of base with Me iodocarbamates obtained by addition of INCO to a natural fatty acid derivatives followed by treatment with MeOH [119]. Preparation of epimino-stearates (**97**) has also been reported [120].

Synthetic monoglycerides (**102**) with epimino fatty acids showed antimicrobial activity against Gram-positive bacteria and yeasts [121]. Laboratory preparations of 2-ethyl-*1*-oleoyl-aziridine (**103**) showed a wide spectrum of antifungal and antimicrobial activity [122].

Certain arachidonate aziridines such as 13-(3-pentyl-2-aziridinyl)-5,8,11-trideca-trienoic acid (**104**) and its methyl ester (**105**) have been synthesized [123] which are inhibitors of arachidonate epoxygenase [124]. Preparation of the fatty acid aziridines (**106–115**) has been described [125]. Bis(aziridine) Me *cis*-9,10;*cis*-12,13-diepiminooctadecanoate, derived from linoleic acid, and tris (aziridine) and Me *cis*-9,10;*cis*-12,13;*cis*-15,16-triepimino-octadecanoate, both derived from linolenic acid, showed cytotoxic and antimicrobial activity as well as remarkable antitumor-promoting and useful neuroprotective effects [126].

24(*RS*),25-epiminolanosterol (**116**) was a potent noncompetitive inhibitor ($K_i = 3.0$ nM) of the *S*-adenosyl-L-methionine-C-24 Me transferase from sunflower embryos [127]. Cholesteryl ester of 1-aziridine acetic acid (**117**) showed excellent inhibition of a dimethyl-benzanthrene induced and transplantable mammary adenocarcinoma [128].

Four steroidal alkylating agents (**118–121**) with an aziridine grouping at the C-16 position were synthesized. They were shown anticarcinogenic (oncolytic) activity against implanted mammary carcinoma (milk factor) in C3H/An mice. The steroids 16-(1-aziridinyl)-3β-hydroxy-pregn-5-en-20-one (**118**), 16-(1-aziridinyl)-3-methoxyestra-1,3,5(10)-trien-17-one (**119**), 16-(1-aziridinylmethyl)-3β-hydroxy-androst-5-en-17-one acetate (ester) (**120**), and 16-(1-aziridinyl)pregn-4-ene-3,20-dione (**121**), each injected (intraperitioneal, i.p.) at 0.5 mg/mouse/day for 14 days, inhibited tumor growth by 61%, 17%, 32%, and 55%, respectively. None of the compounds were toxic to the host [129].

Potentially cytotoxic estrogen derivatives (**122** and **123**) were prepared [130]. Aziridine derivatives demonstrated a high binding affinity for receptors but substitution of a bromoacetate group for the aziridine moiety in the same position decreased the binding affinity. Growth of MCF-7 and Evans-T cells from human breast cancer was inhibited by the nitrogen mustards, the mono-nitrogen derivative being the more potent analogue. This inhibitory action was unaffected by estradiol or 11 β-chloromethylestra-1,3,5(10)-trien-3,17-β-diol (ORG 4333). Aziridine derivatives either stimulated or inhibited cell growth depending on the concentration. Apparently, the antitumor action of cytotoxic-linked estrogens may be mediated through a mechanism involving estrogen receptors.

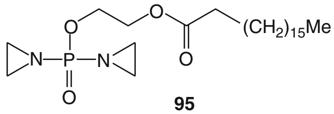
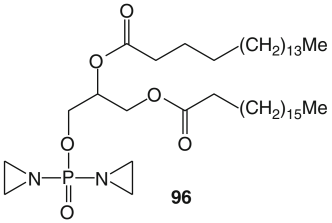
92 R = n-Pr **94** R = $C_{12}H_{25}$



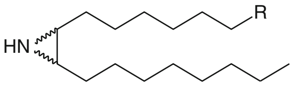
95



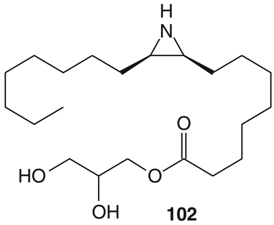
96

Mitomycin C is used extensively to treat various neoplasms and has led to the discovery of two aminoethylene disulfides: KW-2149 (**124**) and BMS-181174 (**125**). These new compounds differ from mitomycin C only in the C(7) substituent. Novel mechanisms for BMS-181174 and KW-2149 differ from the bioreductive activation pathway commonly accepted for mitomycin C, in that the C(7) aminoethylene disulfide unit undergoes thiol-mediated disulfide exchange to give a mitomycin C thiol derivatives [131].

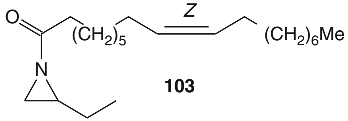
The cell growth inhibitory activity, antitumor activity, and toxicity of M-16 and M-18, the major metabolites of a new mitomycin C (MMC) derivative, KW-2149 (**124**), in both mice and humans were compared with those of KW-2149 and MMC in vitro and in vivo. The growth inhibitory activity of M-18, a symmetric disulfide dimer, active against human uterine cervix carcinoma HeLa S3 cells was almost equivalent to that of KW-2149, and their IC_{50} values were about tenfold smaller than that of MMC. The activity of M-16, a Me sulfide form, was almost equivalent to that of MMC.



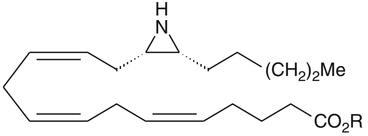
97 R = *cis*-COOH
98 R = *cis*-CH_2OH
99 R = *trans*-CH_2OH
100 R = *cis*-Me
101 R = *trans*-Me



102



103



104 R = H
105 R = Me

The cell-killing activity of MMC and M-16 was augmented under hypoxic conditions, whereas that of KW-2149 and M-18 was reduced. M-16 also exhibited almost equipotent activities to MMC in vivo in terms of various biological parameters, i.e., antitumor activity against murine P388 leukemia, ascitic or solid B16 melanoma or human lung carcinoma xenograft L-27, and bone marrow toxicity in mice.

These results in vitro and in vivo indicate that the antitumor activity and toxicity of KW-2149 might not be mediated by M-16 in mice. On the other hand, M-18 exhibited almost equivalence activities to KW-2149 in this respect, implicating the involvement of M-18 in the biological activities of KW-2149 [132]. Introducing the mercaptoethyl group at the N-7 position of mitomycin C led to the formation of N7, N′7′-dithio-diethylene-dimitomycin C (**126**). It showed excellent antitumor activity against sarcoma 180 and leukemia P388 in mice. Among the various synthetic compounds, the water-soluble conjugate with Et γ-L-glutamyl-L-cysteinyl-glycinate side chain was far more effective against sarcoma 180 and leukemia P388 than mitomycin C [133].

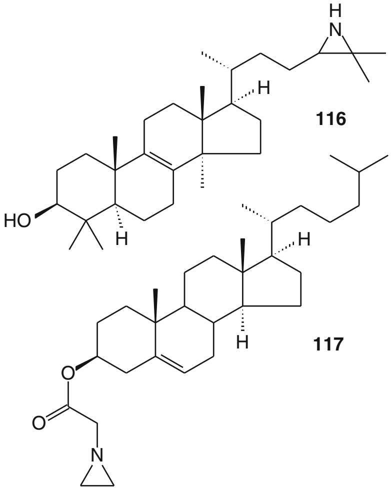
The three dimers (**127**, **128**, and **129**) of mitomycin C (MC), of the aforementioned natural antibiotic and cancer chemotherapeutic agent, were synthesized in which two MC molecules were linked with -$(CH_2)_4$-, -$(CH_2)_{12}$-, and -$(CH_2)_3N(CH_3)(CH_2)_3$- tethers, respectively [134]. The dimeric mitomycins were designed to react as polyfunctional DNA alkylators, generating novel types of DNA damage. To test this design strategy, their in vitro DNA alkylating and interstrand cross-linking (ICL) activities were studied using MC, which is itself an ICL agent. Evidence was presented that (**127**–**129**) multifunctionally alkylate and cross-link extracellular DNA and form DNA ICLs more efficiently than MC.



116

117

Biological activity depends upon reductive activation which is catalyzed by the same reductases and chemical reductants that activate MC. Dimer 5, but not MC, cross-linked DNA underwent activation by low pH environments. Sequence specificities of cross-linking of a 162-bp DNA fragment (tyrT DNA) by MC, (**128**), and (**129**) were detected using DPAGE.

The dimers and MC cross-linked DNA with the same apparent CpG sequence specificity, but (**129**) exhibited much greater cross-linking efficacy than MC. Greatly enhanced region selectivity of cross-linking to GC-rich regions by (**129**) relative to MC was observed, for which a mechanism unique to dimeric MCs was proposed. Covalent dG adducts of (**129**) with DNA were isolated and characterized by their UV and mass spectra. Tri- and tetrafunctional DNA adducts of (**129**) were also detected. Although the dimers were generally less cytotoxic than MC, dimer (**129**) was highly and uniformly cytotoxic to all 60 human tumor cell cultures of the NCI screen [134]. Its cytotoxicity to EMT6 tumor cells was enhanced under hypoxic conditions. These findings together verify the expected features of the MC dimers and warrant further study of the biological effects of dimer (**129**).

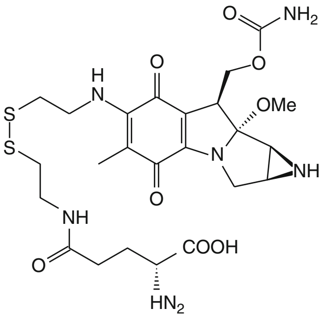
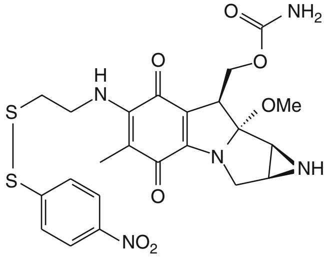
PNU-159548 (4-demethoxy-3′-deamino-3′aziridinyl-4′-methyl-sulfo-nyldaunorubicin, **130**), a synthetic derivative of the anticancer idarubicin, has a broad spectrum of antitumor activity both in vitro and in vivo attributable to its DNA intercalating and alkylating properties [135]. This study was designed to determine the cardiotoxic activity of PNU-159548 relative to doxorubicin in a chronic rat model sensitive to anthracycline-induced cardiomyopathy. PNU-159548 caused a dose-dependent myelotoxicity, with the dose of 0.5 mg/kg per week being equimyelotoxic to 1.0 mg/kg per week doxorubicin. PNU-159548 also caused an increase in liver weight that was reversible. However, it caused a nonreversible testicular atrophy but, unlike doxorubicin, had no effect on kidney weight. The cytotoxic antitumor derivative, PNU-159548, was significantly less cardiotoxic than doxorubicin at equimyelo-suppressive doses. The combination of intercalating and alkylating activities within the same molecule without the cardiotoxic side effects of anthracyclines makes PNU-159548 an excellent candidate for clinic development in oncology. It also showed an $IC_{50} = 2.7$ ng/mL against LoVo colon adenocarcinoma cells [136]. A synthetic preparation of (**131**) showed an IC_{50} of 9.0 μg/mL against mouse L 5178Y tumor cells, and compound (**132**) had IC_{50} of 0.004 mM against 12 ovarian tumors in the tumor Salmon colony formation test [137].

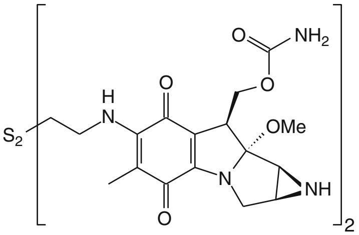
Semisynthetic aziridine derivative of colchicine (**133**) have been synthesized by the direct interaction of colchicine with chloroethylamine hydrochloride and also via the mono- and diethanolamine derivatives. These compounds had an increased radiomodifying and antitumoral activity and a decreased toxicity compared with the initial colchicine.



124 KW 2149



125 BMS 181174



126

Results obtained in the National Cancer Institute of the USA from the study of the cytostatic activity of the (**133**) and bis(chloroethyl)amino derivatives on 60 tumor lines were reported [138]. Originally colchicine a soluble alkaloid was extracted from *Colchicum autumnale* also known as autumn crocus, meadow saffron or itkuchala in Uzbekistan which means "dog poison" [138].

Neoplasm inhibitors at C-4 aziridine-bearing paclitaxel (taxol) analogues (**134–136**) were synthesized. The key step in the synthesis is the aziridine ring formation at the C-4 position via an intramolecular Mitsunobu reaction [139]. Biological activity of paclitaxel analogues is shown in Table 30.6.

4 Conclusion

Aziridine alkaloids comprise a rare group of natural products. They are mainly isolated from either microorganisms or plants. They have also been detected in some marine species. Reported activities for purified alkaloids have shown strong antitumor, antibacterial, antimicrobial, and other activities. A wide spectrum of pharmacological activities is associated with this type of alkaloid which extends to selected synthetic derivatives.

A priori, one should avoid rash conclusions that any of the reported effects of hundreds aziridines are due to their alkylating activity. Quite complex compounds (**21**–**65**) may display additional antioxidant properties; some of them would serve better substances for proteins assuring multidrug resistance, such as P-glycoprotein (MDR-1). It is generally accepted that this protein binds its substrates directly from the lipid bilayer rather than from the aqueous cytoplasmic phase. Binding sites of this protein thus in cancer cells characterized by increased expression of the gene mdr-1, these hydrophobic compounds would be more readily exported than such hydrophilic molecules as **1**–**20**.

Natural and/or synthesized aziridine-containing compounds, lipids, steroids, amino acids, as well as their peptide derivatives have shown to be promising candidates for the development of new drugs toward several diseases, especially neoplasms. No doubt incorporation of an aziridine warhead will allow development of interesting new synthetic and semisynthetic compounds with clinical utility.

Abstract

Tropane alkaloids are natural compounds with a prominent impact in medicine since ancient times. Due to their importance in chemotaxonomy, physiology, phytochemistry, toxicology, and forensic on the one hand, and the tremendous development of analytical technologies on the other hand, numerous articles have been published in the field of tropane alkaloid analysis in the recent years. In this chapter, we review the latest achievements in sample preparation (extraction and purification), separation sciences (thin-layer chromatography, gas chromatography, high-performance liquid chromatography, and capillary electrophoresis), and hyphenation with different detectors (ultraviolet, evaporative light scattering, mass spectrometry) for the analyses of this class of compounds in various biological matrices. Emerging non-chromatographic methods such as immunoassays, optical sensors, as well as standalone nuclear magnetic resonance and mass spectrometry have also been reviewed as powerful complementary alternatives.

Keywords

Chromatography • Hyphenation • Sample preparation • Separation and detection techniques • Tropane alkaloids

VMAE	Vacuum Microwave-Assisted Extraction

1 Introduction

1.1 Occurrence, Numbering, and Chirality

Among the oldest medicinal plants known to man are those containing tropane alkaloids. The solanaceous plants of the genera *Atropa*, *Brugmansia*, *Datura*, *Duboisia*, *Hyoscyamus*, and *Scopolia* were already well known in ancient times. The term "tropane" originates from the name of the genus *Atropa*, which was named after one of the three Greek Fates, namely, Atropos (literally without turn) who was the Goddess that cut the thread of life and chose the manner of each person's death. Thus, she reflected the toxicity and lethality of the species *Atropa belladonna* [1]. At the beginning of the 19th century, extracts of *A. belladonna* were recommended to ophthalmologists to induce mydriasis, but it was in 1833 that Geiger isolated atropine from the roots of this species. *Scopolia carniolica* was studied by the Italian botanist Giovanni Antonio Scopoli, who isolated scopolamine, another tropane alkaloid with sedative properties. Fresh leaves of *Erythroxylum coca* have been traditionally chewed as a mild stimulant for many centuries. The active component, cocaine, was used as local anesthetic in surgical practice, but it has been replaced by synthetic local anesthetics because of its widespread abuse in western countries [2].

Tropane alkaloids are a group of tertiary or quaternary (*N*-oxides) bases comprising *ca*. 250 compounds that have the 8-azabicyclo[3.2.1]octane structure originating from L-ornithine and/or L-arginine in common, and bear at least one hydroxyl group in position 3 (Fig. 31.1A) [3]. The nitrogen atom in position 8 of the tropane skeleton is frequently methylated, but the methyl group may also be absent (*nor* derivatives). In most textbooks, tropane alkaloids are divided into two main groups according to the position of the substituent on carbon 3. 3α-Hydroxytropanes (tropine) carrying the hydroxy group in the axial position are the most frequently encountered derivatives, whereas 3β-hydroxytropanes (pseudotropine) with the hydroxy group in the equatorial position occur in Erythroxylaceae in particular. A typical alkaloid of this family is cocaine, which is distributed exclusively among the *Erythroxylum* genus. 3α- and 3β-hydroxytropanes are biosynthesized from tropinone, catalyzed by two enzymes, tropinone reductase I and tropinone reductase II, respectively (Fig. 31.1B). The majority of these alkaloids are carboxylated and benzoylated derivatives of mono-, di-, and tri-esters. They are distributed in various clades in the angiosperms, namely, in Solanaceae, Erythroxylaceae, Rhizophoraceae, Proteaceae, and Convolvulaceae. Occasionally, they have been found in Brassicaceae [4], Euphorbiaceae [5], Moraceae [6], Lamiaceae [7], and Olacaceae [8]. There are also structures with relatively restricted distribution among the tropane alkaloids bearing families such as pyranotropanes and C4 substituted tropanes [3]. Monocyclic analogues (pyrrolidinyl alkaloids) are considered side reactions of tropane alkaloid biosynthesis [9]. More than 30 acids, such as formic, acetic, hydroxyacetic, propionic, tiglic, methylbutyric, phenyllactic, tropic, senecioic, angelic, mesaconic, cinnamic, and benzoic acids, form esters with the alkamines. Substituents have been found at positions C1 to C4, C6, and C7 of

the tropane skeleton [3]. Dimeric esters appear in the Erythroxylaceae (truxillines and mooniines), the Solanaceae (schizanthines, belladonnines, scopadonnines), and the Convolvulaceae (convolvidine and subhirsine) families, while trimeric tropane esters (grahamines) have so far only been found in the Solanaceae [3, 10, 11].

Mono-, di-, or tri-esters of tropine are typical for the Solanaceae, although they have also been found in the other above-mentioned families. Hyoscyamine and scopolamine are the most characteristic alkaloids for this group. Still today, they are extracted from the solanaceous genera *Datura*, *Brugmansia*, *Hyoscyamus*, *Scopolia, Atropa*,and *Duboisia* for the pharmaceutical industry [12]. Hyoscyamine is a chiral molecule, whose chirality is introduced by the tropic acid moiety. Only the *R* form of the tropic acid occurs in nature. Racemization may easily occur during the isolation procedure yielding (*R*,*S*)-hyoscyamine, which is known as atropine [13]. Scopolamine, also known as hyoscine, racemizes in solution. Calystegines, a recently characterized *nor*tropane group with three to five hydroxyl groups (Fig. 31.1B), have been found in various Solanaceae, Convolvulaceae, Moraceae, Brassicaceae, and Erythroxylaceae [14, 15].

It has recently been demonstrated that the biosynthesis of tropane alkaloids follows separate pathways in the Solanaceae and the Erythroxylaceae, suggesting that the entire biosynthetic route has evolved more than once in the evolution of the angiosperms [16]. Such independent evolutions explain the vast structural diversity found for tropane alkaloids in the plant kingdom.

There is a lot of confusion in the literature about the numbering of tropane alkaloid molecules. Some authors used the anticlockwise numbering, making their compounds 3,6-disubstituted; others used the clockwise numbering resulting in 3,7-disubstituted derivatives (Fig. 31.1B). In some cases, both 6- and 7-substituted compounds have been described but are probably actually the same compound. The same confusion is encountered for 3,6,7-trisubstituted alkaloids. Frequently, the notation of 3,6/7-disubstituted derivatives has been chosen arbitrarily without taking into account the absolute configuration of these two positions [17]. Within the chemical class of tropane alkaloids, many compounds are 3α,6β-tropanediol derivatives that can exist as two stereoisomeric (3*R*,6*R* or 3*S*,6*S*) entities. This stereoisomerism is not well documented, and most of these molecules do not have a defined absolute configuration. Recent papers dealing with the determination of absolute configuration report on the use of vibrational circular dichroism (VCD) spectroscopy in combination with density functional theory (DFT) calculations [18, 19], electronic circular dichroism, also in combination with DFT calculations [20], or by the use of ^{1}H-NMR anisochrony (Δδ) induced by Mosher's chiral auxiliary reagents (*R*)-(−)- and (*S*)-(+)-α-methoxy-α-trifluoromethyl-phenylacetyl chlorides (MTPA-Cl) [17].

1.2 Pharmacology

Tropane alkaloids are competitive antagonists of acetylcholine, essentially by blocking its binding to muscarinic receptors. Some of them are widely used for their gastrointestinal, bronchial, genitourinary, and mydriatic effects. For these reasons, they are classified as parasympatholytic agents [21]. In addition, these compounds (those with a tertiary amine) also have pharmacological activities on the central nervous system, which may explain why some species of the Solanaceae family (*Brugmansia, Datura, Mandragora* spp.) have been used for centuries for their narcotic, hallucinogenic, and toxic properties. Biologically, cocaine acts as a serotonin–*nor*epinephrine–dopamine reuptake inhibitor. It is an addictive drug that increases alertness, feelings of well-being and euphoria, energy and motor activity, and feelings of competence and sexuality. Anxiety, paranoia, and restlessness are also frequent [22]. South American indigenous people have chewed the leaves of *Erythroxylum coca*, one of the four cultivated species that contains cocaine, for over a 1,000 years [23].

(−)-Hyoscyamine, its racemate atropine, (−)-scopolamine, and cocaine are among the oldest drugs used in medicine or as drugs of abuse. Furthermore, the purplish-black berries of *Atropa belladonna* L. (Deadly nightshade) and the beautiful red-to-pink, yellow, or white flowers of *Brugmansia* spp. (Angel's trumpet) are particularly attractive for children, causing serious intoxication in cases of ingestion. Because of their acute toxicity, it is of prime importance to have fast analytical methods able to unambiguously detect these alkaloids.

Tropane alkaloids are still of significant interest for the pharmaceutical industry, as well as for pharmacology, toxicology, and phytochemistry, which is evident from the number of articles on the topic which have been published since our previous review [15]. Thus, this chapter will essentially cover the evolution of analytical methods for this class of compounds over the past few years. Calystegines and other polyhydroxylated compounds will not be further discussed herein as they have been thoroughly reviewed by Dräger [14, 24].

2 Methods of Sample Preparation

2.1 Conventional Methods

Comprehensive reviews have been published on the classical and nonconventional extraction methods of tropane alkaloids [15, 24], and a brief overview of the different approaches will be mentioned here. Fresh or dried plant material may be used for the extraction. However, the drying process may change the chemical composition of the tissue, in particular, enzymatic degradation of the alkaloids may occur. It is therefore strongly recommended to freeze-dry the fresh plant and/or to store the plant material in a deep freezer (−18 °C). The classical procedures are based upon the physicochemical properties of alkaloids. The free bases are soluble in organic solvents, e.g., diethylether, chloroform, and dichloromethane, whereas the salts are soluble in water supplemented with inorganic acids. In most analytical experiments, tropane alkaloids are extracted by decoction, percolation, maceration, ultrasonication, turbo extraction, or hot continuous extraction (Soxhlet). These techniques have recently been summarized by Tiwari et al. [25]. However, they suffer from major drawbacks including the consumption of large volumes of polluting solvents and prolonged extraction time with alkali, which may lead to the formation of degradation products or artifacts (e.g., the racemization of hyoscyamine to atropine). Furthermore, these conventional methods often suffer from a lack of selectivity and allow only crude extracts to be obtained, which necessitates further cleanup procedures prior to chromatographic analysis. Liquid–liquid extraction (LLE) or solid phase extraction (SPE) using conventional sorbents (C_{18}, diatomaceous earth) are commonly used for this purpose [26].

With the advent of fast analytical methods (fast gas chromatography (GC), capillary electrophoresis (CE), ultrahigh performance liquid chromatography (UHPLC)) [27–29], it appears that the extraction methods are the bottleneck for most of the analytical processes. Thus, there is a need for appropriate fast and efficient extraction steps for plant samples.

2.2 Microwave-Assisted Extraction

Microwave-assisted extraction (MAE) is a technique which uses microwave energy to heat a solid sample immersed in a solvent to extract/desorb analytes from the matrix. Microwaves are electromagnetic radiation with a frequency ranging from 300 MHz to 300 GHz. They possess two oscillating magnetic and electric fields that are perpendicular to each other. The latter is responsible for the transformation of electromagnetic energy into calorific energy via two simultaneous mechanisms occurring into the sample, namely, dipole rotation and ionic conduction. This fast oscillation generates heat through collisions and friction between surrounding molecules. Therefore, microwave heating depends on the presence of polar molecules or ionic species. Unlike classical conductive heating methods, microwaves heat the whole sample simultaneously, thus leading to very fast and efficient extractions. It generates a rapid delivery of energy to the total volume of solvent, which leads to an extremely rapid heating process. The effect of microwave energy is strongly dependent on the nature of both the solvent and the solid matrix. Depending on the dielectric constants of the solvents used, the extracting selectivity and the ability of the medium to interact with microwaves can be modulated by using mixtures thereof. In some cases, the matrix itself, which contains residual water, interacts with microwaves, while the surrounding solvent remains cold as it possesses a low dielectric constant. This latter situation presents some obvious advantages in the case of thermosensitive compounds [30].

Microwave ovens can operate either under controlled pressure and temperature (PMAE) or at atmospheric pressure, which is also known as focused microwave-assisted extraction (FMAE). Most of the applications described so far have been used for digestions or acid mineralizations or for the recovery of pollutants from environmental matrices under drastic conditions, and very few studies have involved the use of the more moderate FMAE. Modified MAE, such as vacuum microwave-assisted extraction (VMAE), nitrogen-protected microwave-assisted extraction (NPMAE), ultrasonic microwave-assisted extraction (UMAE), and dynamic microwave-assisted extraction (DMAE), have been developed and reported by Chan et al. [31]. Only a few review articles deal with the application of MAE to the extraction of natural products [31–34]. Numerous papers have been published on the extraction of constituents from plants; however, very few articles reported on the extraction of alkaloids in general and on tropane alkaloids in particular. FMAE has been used to extract cocaine and benzoylecgonine from coca leaves [35]. Different parameters affecting the efficiency of the extraction of cocaine, such as the nature of the extracting solvent, the particle size distribution, the moisture of the sample, the applied microwave power, and the radiation time, have been investigated. A central composite design has been used to optimize microwave power and radiation time and to evaluate the robustness of the method. Results showed that methanol was the most appropriate solvent. It was found that moistening the leaves with water slightly improved cocaine recovery, while the addition of triethylamine or sodium bicarbonate significantly decreased cocaine recovery due to degradation of the latter in methanol. FMAE generated extracts similar to those obtained by conventional solid–liquid extraction but in a more efficient manner, as 30 s was sufficient to extract cocaine quantitatively from leaves. Cocaine distribution in the leaves of 51 wild *Erythroxylum* species was investigated by Bieri et al. [36]. Extractions have been performed in methanol within 30 s by FMAE on 100 mg of slightly hydrated leaves. After filtration, all samples were analyzed by GC-MS without any further purification. Cocaine was detected in 23 of the 51 species examined.

2.3 Pressurized Liquid Extraction

Pressurized liquid extraction (PLE) is also known as pressurized solvent extraction (PSE), enhanced solvent extraction (ESE), pressurized fluid extraction (PFE), or accelerated solvent extraction (ASE™) in the literature. PLE is considered an environmentally friendly extraction technique because it requires only small volumes of solvents. PLE was primarily used for the extraction of environmental samples, such as soils and sediments. Elevated temperatures (usually between 50 and 200 °C) and pressures (between 10 and 15 MPa) are used in closed vessels, which allow extractions to be completed in a very short time. High pressure allows the solvent to remain in its liquid state even at temperatures above its boiling point, and forces it into the matrix pores. High temperatures decrease the solvent viscosity and increase metabolite solubilization, the diffusion rate, and mass transfer kinetics, thus facilitating desorption of the analytes from the plant material. Most PLE applications reported in the literature employ the same organic solvents as those commonly used in conventional solid–liquid extraction techniques. When water is used as the extraction solvent, the technique is referred to as pressurized hot water extraction (PHWE). Extractions are carried out in stainless steel extraction cells of various volumes (typically 1–250 mL). One extraction cycle is generally applied for 5–20 min at temperatures ranging from 50 to 140 °C in the vast majority of applications.

There are two main setups for conducting PLE: static and dynamic modes. In the static mode, the extraction cell is filled with the dried powdered plant material and the solvent, placed in an oven, and then heated which results in the pressure increasing in the cell. After a specified period of time, the system is flushed into the collecting vial with a pressurized nitrogen flow. Static extraction is preferred for compounds that are strongly bonded to the matrix. In the dynamic mode, a few milliliters (typically 0.5–2.0 mL min^{-1}) of fresh solvent are continuously percolated through the cartridge under pressure at a constant flow rate for a fixed period of time. Dynamic extraction is preferentially used for easily extractable compounds. ASE instruments from Dionex are currently the only commercially available systems that allow static and dynamic extractions in the same run.

PLE also offers the possibility of performing extractions in an inert atmosphere that is protected from light, which represents an advantage for compounds that are very sensitive to these two factors. Some PLE devices offer the possibility of extracting up to 24 samples sequentially.

Numerous applications have been developed for a wide variety of compounds from different matrices, but surprisingly, only a few reviews dedicated to the extraction of medicinal plants have been published in the last few years [37–39]. ASE of cocaine and benzoylecgonine from coca leaves has been reported by Brachet et al. [40]. The influence of several extraction parameters such as the nature of the extracting solvent, the addition of alkaline substances, the pressure, the temperature, the extraction time, and the sample granulometry on cocaine recovery was systematically investigated. Methanol was found to be the most suitable solvent. Critical parameters were found to be pressure, temperature, and extraction time. A central composite design has been used to optimize these 3 parameters and to assess the robustness of the extraction method. The optimal conditions for the quantitative extraction of cocaine from leaves were the following: 20 MPa, 80 °C, 1 mL min^{-1}, 10 min extraction time, with a particle size distribution between 90 and 150 μm.

2.4 Supercritical Fluid Extraction

Supercritical fluid extraction (SFE) represents an interesting alternative to conventional methods. Supercritical fluids have interesting properties, such as a low viscosity and a high solute diffusivity, which increase the mass transfer and the extraction time. Carbon dioxide is the most frequently used solvent. It has many advantages such as a low critical temperature (31.1 °C) and pressure (73.8 bar/ 7.38 MPa), no toxicity, and is environmentally acceptable, cheap, and easily available. Extractions can be performed under mild conditions, thus reducing the risks of the thermal degradation of compounds. Its low solvating properties may be enhanced by the addition of 10–20 % of a polar modifier such as methanol or ethanol. Higher concentrations would lead to subcritical conditions.

Surprisingly, very little has been published on the extraction of tropane alkaloids by SFE. Even if hyoscyamine and scopolamine are soluble in pure CO_2, they are not extractable from plant material because target alkaloids are in the form of salts in the vacuoles of plant cells. Choi et al. [41] demonstrated that supercritical CO_2 supplemented with basified methanol as a polar modifier can extract hyoscyamine and scopolamine in the form of their free bases. Hyoscyamine, scopolamine, and cocaine have been extracted using SFE [42, 43]. The first two alkaloids were isolated from genetically transformed hairy roots of a *Datura* hybrid while cocaine was isolated from coca leaves. In both cases, a central composite design was used to optimize SFE parameters such as pressure, temperature, nature, and percentage of the polar modifier and to evaluate their influence on extraction recoveries. The quality of the models was verified and confirmed by the good agreement between experimental and predicted responses.

2.5 Solid Phase Microextraction

Solid phase microextraction (SPME) was introduced by Arthur and Pawliszyn over 20 years ago [44]. It is a straightforward, solvent-free, and fast sample extraction method. SPME has become a widely used technique in many areas of analytical chemistry, such as food analysis, environmental sampling, forensics/toxicology, and biological analysis. Recent reviews have been published showing the latest development of this versatile extraction method [45–48]. SPME is based on the partition of the analyte between the extraction phase and the matrix. The technique can be used to monitor analytes in liquid samples or in the headspace and is basically compatible with HPLC and CE, but most applications are made by GC. As indicated by its name, it is not an exhaustive extraction technique and only a fraction of the target analyte is actually extracted. The quantity of analyte extracted is proportional to its concentration, as long as the equilibrium between the analyte in the fiber and the sample is reached. It provides linear results for wide concentrations of analytes (typically from levels of parts per million to parts per billion).

SPME is realized with a fiber incorporated into a syringe and coated with a liquid (polymer), a solid (sorbent), or a combination of both. Extraction can be conducted as a direct extraction in which the coated fiber is immersed in the liquid sample or in the headspace configuration by exposing the fiber to the volatile fraction above the liquid sample. The SPME process consists of exposing the sorbent to the sample for a specified period of time. In a second step, analytes are desorbed by exposing the fiber in the hot injection port of a GC or in the desorption chamber of an HPLC interface. The selection of the fiber is determined according to the volatility and polarity of the analytes. SPME fibers are available in a variety of phases such as polydimethylsiloxane (PDMS), polyacrylate, Carbowax, polydimethylsiloxane/divinylbenzene, divinylbenzene/carboxen, carboxen/polydimethylsiloxane, divinylbenzene/carboxen/polydimethylsiloxane, polypyrrole, or molecularly imprinted polymers, as well as with different film thicknesses [49]. Reports on alkaloid analysis by SPME are scarce and mainly concern cocaine in biological fluids [50, 51] and human hairs [52, 53]. SPME has been used for the extraction of cocaine from leaves of *Erythroxylum coca* [54]. The plant material was first extracted by MAE in an open vessel for 30 s with methanol. A 7 μm PDMS fiber was immersed in the organic solution supplemented with cocaethylene as internal standard for 2 min, and the fiber was withdrawn and further inserted in the injection port of the fast GC for thermal desorption during 12 s. In this way, quantitative determination of cocaine was achieved in less than 5 min. Another study using a combination of MAE and SPME prior to gas chromatography was reported by Bieri et al. [55] for the analysis of cocaine in coca leaves. SPME was carried out in the direct immersion mode with a 100 μm PDMS fiber. A significant gain in selectivity was obtained with the incorporation of SPME in the extraction procedure. The analysis time was reduced to 6 min compared to 35 min with conventional GC.

3 Methods of Analysis

Recent advances in hyphenated analytical techniques, where a separation device is coupled online with detectors generating spectral information, have remarkably widened the analysis field of complex biological matrices. During the last few years covered by this chapter, a number of papers describing the application of TLC, GC-MS, HPLC-UV, HPLC-UV/MS, CE-MS, and NMR to the qualitative and quantitative analysis of tropane alkaloids in toxicological, physiological, forensic, phytochemical, and chemotaxonomical studies have been published.

3.1 TLC

Even though it seems to be an out-of-date technique, planar chromatography (TLC or HPTLC) still enjoys great popularity in phytochemical studies in general and in alkaloid chemistry in particular. Interesting reviews on the analysis of tropane alkaloids by TLC have been reported [24, 56]. The technique is typically used for the initial screening of plant extracts (Fig. 31.2), preparative purification, monitoring fractions after preparative column chromatography, or chemical synthesis. It is the method of choice for routine alkaloid analysis before more sophisticated instrumental chromatography. It can also be used for confirmation of the identity of natural products determined by other spectroscopic methods. Among the main advantages of TLC are its simplicity and versatility due to the large number of stationary phases available on the market, as well as to the numerous solvent systems reported in the literature [56]. Furthermore, many samples can be spotted on a single plate and developed simultaneously making (HP)TLC a very convenient method to control the separation process of individual compounds.

Because only a few alkaloids contain an aromatic ring which makes them detectable by UV light, tropane alkaloids are usually monitored around 205 nm. However, at this unspecific wavelength, other co-eluting compounds may also absorb and be detected. This is the reason why the addition of Dragendorff's, Mayer's, or iodoplatinate reagents is frequently used as a visualization agent of alkaloids. Reliable identification of the analyte is obtained by the combination of its *Rf* value and color after spraying a visualization reagent that is specific to a chemical class and comparison with authentic reference material [26]. TLC is an official assay in the *European Pharmacopeia* for *Atropa belladonna* and *Datura stramonium* monographies. Compound identification can be ascertained by using different separation conditions (i.e., different chromatographic supports or elution solvent mixtures).

Quantitative evaluation is carried out by densitometry, which requires additional instrumentation such as an automatic sample applicator, an automatic chamber for development, and a TLC scanner. Furthermore, an extensive calibration process is needed. TLC-densitometry, although less sensitive than HPLC and GC methods, can be regarded as an efficient quantitative tool for tropane alkaloids analysis [56].

has been optimized by Gadzikowska et al. [57]. The most effective and selective systems were applied for separation of the alkaloid fraction of *Datura innoxia*. A simple TLC method with Dragendorff's reagent as the visualization agent and image analysis was applied for nutrient medium optimization of hyoscyamine production, as well as in an assay of hyoscyamine biosynthesis in hairy root cultures from *Datura stramonium* with different ploidy levels [58, 59]. An interesting application of TLC has been demonstrated in the work of Abdel-Motaal et al. [60], who determined the antifungal activity of hyoscyamine and scopolamine by TLC-bioautography against 40 isolated fungal strains associated with *Hyoscyamus muticus*.

In recent years, high-performance HPTLC became an attractive alternative to HPLC due to the significant improvement of the stationary phases, automation for sample application, plate development, detection reagent applications, and densitometric scanning. The plates used for HPTLC are characterized by smaller particle size (≤10 μm), thinner layers (≤150 μm), and smaller plates (≤10 cm developing distance) than for conventional TLC layers, resulting in an improved resolving power per unit of distance, faster development times, and reduced solvent consumption. An increasing number of articles demonstrate the application of this technique for qualitative and quantitative analysis of different analytes. Like HPLC, GC, and CE, HPTLC allows method validation corresponding to the ICH criteria and achieving for some given applications a precision accuracy and trueness comparable to that of HPLC [61].

A HPTLC fingerprinting method on a pre-coated silica gel HPTLC $60F_{254}$ has been applied for identifying three wild morphotypes of *Datura metel* based on chemical markers, such as hyoscyamine and scopolamine [62]. The use of a CAMAG HPTLC system equipped with an automatic TLC sampler ATS 4, TLC scanner 3, and integrated software winCATS allowed the validation and quantification of the above-mentioned alkaloids. After development of the plates with chloroform to acetone to diethylamine (50:40:10) as the mobile phase and visualization of the alkaloids with Dragendorff's reagent, the quantitative evaluation was performed in the absorption–reflection mode at 530 nm. The calibration curves were linear in the range of 1,000–4,000 ng for hyoscyamine and 500–2,000 ng for scopolamine. The correlation coefficients of 0.9997 and 0.9996 for hyoscyamine and scopolamine, respectively, were similar, but the limits of detection (LOD, 60 ng and 25 ng) and quantification (LOQ, 1,000 ng and 500 ng) were much higher as compared to a previously validated method with UV densitometry at 205 nm [63]. HPTLC was also used for the quantification of hyoscyamine and scopolamine in in vitro experiments with leaf-derived root cultures. A mobile phase of toluene to ethyl acetate to diethylamine (7:2:1) was used, and quantifications at 290 nm and 230 nm for hyoscyamine and scopolamine, respectively, were applied [64].

3.2 Liquid Chromatography

When looking at the number of papers that have been published during the last 4 years, it seems that liquid chromatography (LC) is currently the most frequently used separation technique for the analysis of tropane alkaloids. An excellent review on the analysis of this class of alkaloids has been published by Aehle and Dräger [27]. It is the method of choice in many laboratories working with natural products because it offers the possibility to analyze thermosensitive, polar, and high molecular weight compounds. LC has an advantage over GC for the analysis of polar compounds such as *N*-oxides, polyhydroxy alkaloids, alkaloid salts, and glycosides because it does not require derivatization before analysis. However, classical HPLC coupled with UV detector is not suitable for alkaloids lacking chromophore groups, like the polyhydroxy tropane alkaloids called calystegines. In this case, pre- or post-column derivatization is necessary. An evaporative light scattering detector (ELSD) or a refractive index (RI) detector may represent an alternative solution [26].

Numerous methods for high-performance liquid chromatography (HPLC) of tropane alkaloids have been developed. The chromatographic conditions depend on the variability of the analyzed matrices (extracts from different plant tissues, pharmaceutical preparations, clinical, and forensic probes) and analytes (pure compounds or alkaloid mixtures with different composition). Most often, columns packed with reverse-phase C18 stationary phase are used for the separation of tropane alkaloids. Gradient or isocratic elution generally involves buffered mixtures at the acidic pH of water–acetonitrile or acetonitrile–methanol, such as acetonitrile–triethylammonium phosphate buffer (25:75) at pH 6.2 [65] acetonitrile–50 mM phosphate buffer at pH 2.95 (10:90 and 20:80) [66], methanol–0.05 M ammonium acetate at pH 4.6 (58:42), and 0.0025 M sodium dodecyl sulfate (SDS) [67]. Cardillo et al. [68, 69] separated tropane alkaloid fractions isocratically with a 0.01 M octanesulfonic acid at pH 3-methanol (65:35) mixture at 40 °C. An exception was the work of Andreola et al. [70], who achieved the separation of tropane alkaloids in basic conditions (pH 8) on a Phenomenex Hypersil 5 C_{18} column with 25 mM phosphate buffer–acetonitrile (70:30).

A novel isocratic chiral method was developed for the separation of *S*-hyoscyamine (t_R 31.1 ± 0.2 min) and *R*-hyoscyamine (t_R 33.4 ± 0.2 min) on two consecutively coupled α-glycoprotein (AGP) chiral columns (150 × 2.0 mm, 5 μm) at 40 °C with 0.01 M ammonium formate at pH 8.0 and 0.01 M ammonium formate in 25 % acetonitrile (85:15) [13]. The flow rate was set at 300 μL min^{-1} for 50 min.

In 2004, the separation science was revisited with the introduction of ultra-performance liquid chromatography (UPLC). Significant advances in instrumentation and column technology were made to achieve dramatic increases in separation power, resolution, speed, and sensitivity in liquid chromatography. Until recently, LC separation technology has not been able to benefit of reducing particle size of stationary phase aiming better efficiency due to the limited working pressure range. New UPLC instruments are able to withstand ultrahigh pressures (up to 1,000 bar) which allow operation with columns packed with sub-2 μm particles and with high mechanical resistance. UPLC offers high-throughput separations with reduced column lengths or high resolution with the same column of an appropriate length. Russo et al. [29] were the first who applied UPLC technology for the analysis of tropane alkaloids achieving separation of scopolamine, 6β-hydroxyhyoscyamine, hyoscyamine, and littorine with a RP C_{18} Acquity BEH (ethylene bridged hybrid, 50 × 2.1 mm, 1.7 μm) column in less than 4 min with a gradient from 10 to 15 % ACN in an aqueous buffer of 0.1 % TFA at a flow rate of 500 μL min^{-1}.

Hydrophilic interaction chromatography (HILIC) is a separation process involving polar stationary phases with mobile phases made of highly polar aprotic organic solvents (>80 %) and a small amount of aqueous solvents. It is particularly suitable for the separation of very polar analytes. HILIC coupled to mass spectrometry may offer a significant increase in sensitivity. The isocratic separation of three calystegines (A5, B4, and C1) on an Acquity HILIC (50 × 2.1 mm, 1.7 μm) column with MeOH–10 mM aqueous ammonium acetate buffer at pH 5 (95:5) and a flow rate of 400 μL min^{-1} was possible in less than 1.5 min [29].

LC is frequently coupled with UV, diode arrays, ELSD, MS, and more rarely with NMR for the peak detection. The tropane nucleus itself has no chromophore and the sensitivity of UV detection and diode array detectors (DAD) depends on the esterified moiety. UV and DAD are suitable for the detection of alkaloids with chromophore-bearing moieties such as hyoscyamine and scopolamine. For such alkaloids, routine analytical work and quantitation are mostly performed between 210 nm and 220 nm [66–68, 71], but an analysis at a wavelength of 254 nm was also reported [70]. Hosseini et al. [72] reported limit of detection (LOD) and limit of quantification (LOQ) values of 5.15 and 17.4 ppm for atropine and 1.92 and 6.4 ppm for scopolamine, respectively, for a validated HPLC method with UV detection at 215 nm, which is comparable with previous reports [15].

HPLC-UV is routinely applied for the quantitation of hyoscyamine and scopolamine produced by in vitro tissue cultures [73, 74], including hairy roots, different plant organs [71, 72], and regenerated [75] or transgenic plants [67]. The products of biocatalytic reactions of transformation of hyoscyamine by hyoscyamine 6β-hydroxylase was also studied by HPLC-UV [69]. Screening of scopolamine and hyoscyamine content of four *Hyoscyamus* species having grown at different geographical locations has been investigated by Bahmanzadegan et al. [65]. It was found that among the four species, scopolamine was the predominant tropane alkaloid in *H. pusillus*, *H. niger*, and *H. kurdicus*, while *H. reticulatus* contained a higher amount of hyoscyamine. Ashtiania et al. [66] analyzing *A. belladonna* and *A. acuminata* from Iran by HPLC reported a surprisingly high concentration of 8.06 % total alkaloids in the roots, 2.88 % in the leaves, and 1.42 % in the stem of a wild *A. belladonna*, whereas the concentration in the same cultivated species reached 1.76 % in the leaves, 3.3 % in the roots, 1.42 % in the stem, and 4.82 % in the seeds. The total alkaloid content of the leaves of *A. acuminata* was found to be 5.88 %. These results, if they are confirmed, would be the highest concentrations of tropane alkaloids ever found in the genus *Atropa*.

For tropane alkaloids lacking UV-adsorbing moieties or with a low sensitivity to UV detection, an evaporative light scattering detector (ELSD) is a good alternative because of its quasi-universality, versatility, low cost, and acceptable sensitivity [76]. In the work of Russo et al. [29], UV at 210 nm and ESLD detection were compared, and the results showed a two to threefold higher sensitivity with the ELSD compared to UV detection in terms of signal-to-noise ratio for hyoscyamine, littorine, 6β-hydroxyhyoscyamine, and scopolamine. The ELSD also showed excellent sensitivity for calystegines, which are chromophore-lacking polyhydroxytropane derivatives.

The use of detectors other than UV for the analysis of tropane alkaloids has been reviewed previously [15, 24, 27]. In contrast to conventional detectors such as UV, RI, fluorescence, and ELSD coupled with LC, the MS detector provides information on the molecular structure of the separated compounds (Fig. 31.3). Over the past decade, liquid chromatography coupled with mass spectrometry (LC-MS) has undergone tremendous technological improvement and is now one of the most powerful tools for the investigation of natural compounds.

Powerful new technologies of ion analyses (tandem MS, time-of-flight MS (TOF MS), and ion-trap MS) substantially increased the capability of MS analyzers with respect to specificity and the extent of data handling. The range of applications of LC-MS in the field of natural products is constantly increasing, especially with the introduction of tandem MS (MS/MS) for quantification and high resolution MS (HRMS) for unequivocal structural elucidation using mass accuracy and the elemental composition of precursors and product ions.

There are numerous key advantages of using a mass detector with HPLC. Among them are (1) the selectivity by means of which mass spectra of co-eluting peaks can be deconvoluted; (2) the peak assignment for which a unique mass spectrum for the compound of interest is generated, ensuring correct peak assignment in the presence of complex matrices; (3) the molecular weight information

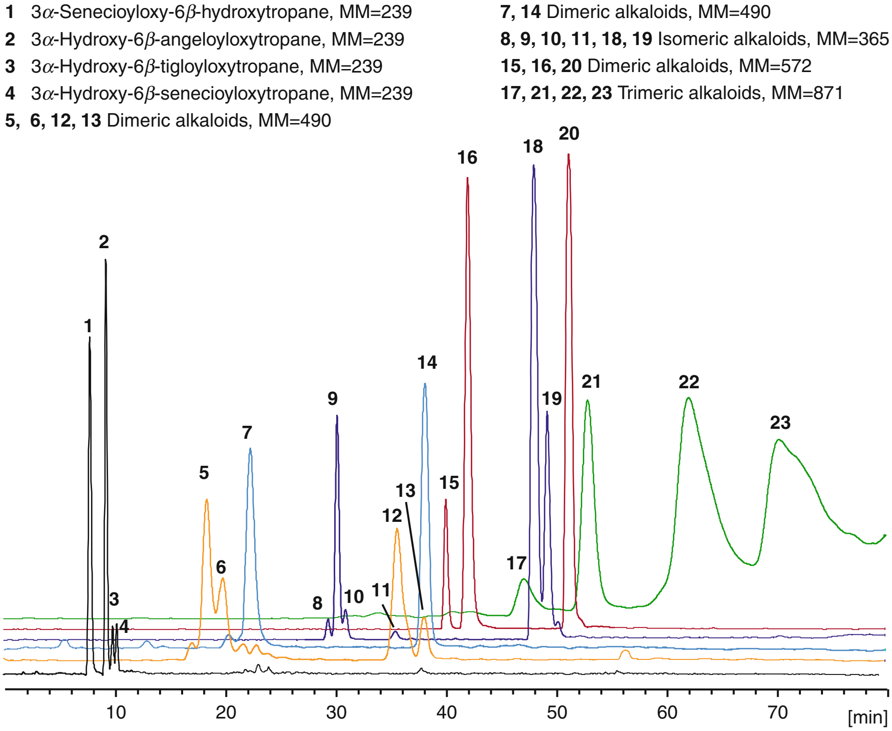

Fig. 31.3 Iontrap LC-MS profile (selected pseudo-molecular ions) of an alkaloid extract from *Schizanthus grahamii* (stem bark). Separation of isomeric series is achieved on a porous graphitic carbon column (Bieri, PhD thesis)

allowing confirmation of known and partially unknown compounds; (4) the structural information given by the controlled fragmentation of the compounds; and (5) the rapid method development allowing easy identification of eluted analytes with less tedious and time-consuming sample preparation procedures.

Among the different types of ionization techniques, electrospray ionization (ESI) is most frequently used in the analysis of tropane alkaloids. As easily protonated weak bases, the alkaloids are analyzed in positive mode. For this, 0.1 % formic acid or acetic acid is usually added to the mobile phase to enhance protonation and increase sensitivity. Only volatile buffers such as ammonium acetate can be used, as buffers such as phosphate may interfere with the ESI process. The latter is a soft ionization technique producing very little fragmentation, which provides information on the molecular mass of the compounds.

Tandem mass spectrometry typically examines mass transitions from precursors to fragment ions. The precursor ions of interest are isolated by a first analyzer according to their characteristic *m*/*z* values, which then undergo fragmentation achieved either spontaneously or by some activation technique to yield product ions and neutral fragments. These are then analyzed by a second mass analyzer. The main advantages of the MS/MS experiment are its enhanced sensitivity and specificity in both single reaction monitoring (SRM) and multiple reaction monitoring (MRM) modes. This is useful in isomer distinction, sequencing of biopolymers, and more particularly in the analysis of complex mixtures. Tandem mass spectrometry experiments eliminate or greatly reduce background signals due to other matrix components or instrumental noise. Due to its sensitivity, LC-ESI-MS/MS is an attractive approach for the analysis of tropane alkaloids and drugs of abuse, like cocaine in body fluids and forensic samples. These compounds are rapidly metabolized in the organism, and sensitive methods are needed for their accurate detection and measurement. A sensitive method was validated for the analysis of atropine, scopolamine, ipratropium, littorine, *N*-butylscopolamine, and cocaine by RP LC-ESI-MS/MS in MRM mode allowing quantification within a linear range of three orders of magnitude between 0.05 and 50 ng mL^{-1} of plasma [77]. The method, which proved to be precise (CV of 2–13 %) and accurate (87–122 %), was applied to stability studies in phosphate-buffered saline, human, and rabbit sera. In contrast to other tropane alkaloids used in medicine, such as atropine, scopolamine, ipratropium, or *N*-butylscopolamine, cocaine was found to degrade rapidly in human serum. Badoud et al. [78, 79] developed a method for the screening and confirmation of 103 doping agents including cocaine in urine samples by UPLC-qToF/MS. The separation was realized in less than 9 min on an Acquity column (BEH C_{18}; 100 × 2.1 mm, 1.7 μm) with a mixture of 0.1 % formic acid in water and 0.1 % formic acid in ACN. The automatic identification of analytes was based on retention time and mass spectra accuracy, with an automated tool for peak picking. The method was validated according to the International Standard for Laboratories described in the World Anti-Doping Code and was selective enough to comply with the World Anti-Doping Agency recommendations. The mass accuracy and the elemental composition of precursor and product ions were used to confirm compound identification.

Liu et al. [80] established liquid–liquid and solid phase extraction protocols which were coupled to LC-ESI-MS/MS using a 1.8 μm particle size analytical column operated at 50 °C for the analysis of 800 drugs and toxic compounds. Gradient elution of the analytes was conducted using a solvent system composed of methanol and water containing 0.1 % formic acid. Positive-ion ESI-MS/MS spectra and retention time of each compound were first established using standard solutions. These spectra and retention times were then transferred into the library and searched by the identification algorithm based on retention time matches and scores of fit, reverse fit, and purity resulting from the searching process for the confirmation of compounds found in test specimens. The established method was found to be highly effective when applied to the analyses of postmortem specimens (blood, urine, and hair).

Analysis of total cocaine residues in wastewater has been validated using LC-ESI-MS/MS [81]. After an alkaline hydrolysis step, the total cocaine was estimated by the amount of the degradation products ecgonine, anhydroecgonine, and *nor*ecgonine detected in the samples.

The pharmacokinetics of *S*- and *R*-enantiomers of hyoscyamine in humans have been examined by LC-ESI-MS/MS [13]. Plasma supplemented with atropine was incubated with human serum (not containing atropinesterase (AtrE)) and with rabbit serum possessing AtrE (EC 3.1.1.10), which stereospecifically hydrolyzes *S*-hyoscyamine into tropine and tropic acid while leaving *R*-hyoscyamine unaffected. The estimation of the differences between the total hyoscyamine content in the aliquots incubated with human and rabbit sera allowed the determination of the remaining *R*-hyoscyamine and hydrolyzed *S*-hyoscyamine. Both enantiomers were detected in the MRM mode. The method proved to be reproducible, precise (RSD 2–9 %), accurate (93–101 %), and selective. The enantioselective assay was applied to the analysis of atropine degradation in rabbit serum in vitro as well as to human in vivo plasma samples from a pesticide-poisoned patient treated with atropine. The method was also applied for kinetic studies of atropine administered to swine, where no obvious stereoselective elimination was found [82].

A rapid method for the determination of the most abundant *Datura* alkaloids atropine and scopolamine in leaves, flowers, stems, and seeds by LC-ESI-MS technique was developed and validated by Jakabova et al. [83]. After an extraction procedure using 30 min ultrasonication with a methanol–water (3:2) mixture followed by filtration, the analytes were separated within 5 min on a new generation of core-shell particle-packed columns. The use of a reversed-phase column (Ascentis Express C_{18}) packed with this type of sub-3 μm particles allows high speed and generates high efficiencies. Detection was performed in the more sensitive single ion monitoring (SIM) mode using the pseudomolecular ions at *m*/*z* 290 and 304 for hyoscyamine and scopolamine, respectively. The method was found to be selective, precise, repeatable, and very sensitive with LOD at 100 and 50 pg mL^{-1} and LOQ at 333 and 167 pg mL^{-1} for scopolamine and atropine, respectively.

During crop gathering, some parts of Solanaceae plants may be occasionally included. A method for the simultaneous determination of tropine, atropine, scopolamine, homatropine, anisodamine, α-solanine, and α-chaconine in grains and seeds (wheat, rye, maize, soybean, linseed) has been reported by Jandric et al. [84]. The analytes were separated by isocratic HPLC on a Chirobiotic V column and detected by ESI-MS/MS detector operating in the MRM mode. The method performances were presented in terms of linearity in the range 5–80 ng g^{-1}, specificity, selectivity, accuracy (recoveries from 61 % to 111 %), precision (CV <5 %), and ruggedness. The limits of quantitation (LOQ) were in the range 2.2–4.9 ng g^{-1}.

Boros et al. [85] investigated the floral nectar of different *Datura* species as a potential source of intoxication. Atropine and scopolamine were quantified by HPLC on an Ascentis Express C_{18} column (50 × 2.1 mm) packed with 2.7 μm fused-core particles and monitoring using the SIM acquisition mode by ESI-MS/MS detector.

Hou et al. [86] developed a method using a short C_{18} column for the separation of atropine, anisodamine, and scopolamine in Huashanshen dripping pills used in traditional Chinese medicine (TCM) in less than 1.5 min. The method showed linearity in the range of 250–4,000 ng mL^{-1} for atropine and anisodamine and 62.5–1,000 ng mL^{-1} for scopolamine. The intra- and inter-day precisions were less than 3.0 %, and the mean recoveries were more than 98.0 % for all analytes. This method is rapid, reliable, reproducible, and suitable for the routine use to control the quality of Huashanshen dripping pills.

The applicability of LC-MS for the structural elucidation of tropane alkaloids has been demonstrated in recent reports where the exact mass measurements providing elemental composition of the ion fragments are combined with fragmentation pattern recognition from MS/MS experiments. Jousse et al. [87] performed alkaloid profiling of hydroponic *Datura innoxia* plants by UFLC-ESI-HR/MS and LC-MS/MS. In total, 21 known compounds and four non-elucidated alkaloids were detected on the basis of their HRMS data and fragmentation pathway. Furthermore, by comparing the alkaloid profiles, the authors found that the alkaloid biosynthesis and particularly that of 3-acetoxy-6-hydroxytropane and 3-hydroxylittorine is higher in non-sterile conditions. Later, during the routine isolation of tropane alkaloids by preparative column chromatography, de Oliveira et al. [88] tentatively identified 2 possibly new tropane alkaloids by LC/ESI-MS/MS in fractions from the stem of *Erythroxylum caatingae*. Al Balkhi et al. [89] applied LC-MS to study the biosynthetic pathway of tropane alkaloids in *Datura innoxia* hairy roots. Fourteen alkaloids were separated by an isocratic method on an ODS AQ-C18 column and identified by LC–qToF/MS and LC–MS/MS analyses. Semi-preparative LC was used for the separation of *nor*littorine and *nor*hyoscyamine, which were shown to be induced under stress conditions by the conversion of littorine and hyoscyamine by isotope labeling experiments.

3.3 Gas Chromatography

Gas chromatography is a commonly used analytical technique in many research laboratories. A broad variety of samples can be analyzed as long as the compounds are sufficiently thermally stable and volatile enough. Pyrrolidine, pyrrolizidine, isoquinoline, piperidine, indole, and tropane alkaloids are routinely analyzed by GC [90]. A prerequisite is, however, that the alkaloids occur as bases, hydrochlorides, or picrates, and not as *N*-oxides, because of the extremely high boiling points of the latter. Tropane alkaloids had been analyzed by GC long before HPLC. Since the work of Hartmann et al. [91], the prevailing analytical approach for screening, identification, and quantification of tropane alkaloids was capillary GC combined with electron impact mass spectrometry (GC-EI/MS). It became widely recognized because of its sensitivity, accuracy, and versatility. The main advantages of GC-MS are the high resolution power of the capillary columns and the structural information provided by the mass detector. EI mass spectra collected under standard conditions (70 eV) are highly specific and reproducible, which allows their organization in mass spectral databases. The utilization of such libraries in combination with retention data (retention index or retention time locking) allows the automatic and quick identification of known components in an alkaloid mixture without the use of reference compounds. The mass fragmentation of tropane alkaloids is well known for about 50 years [92], and it has been possible to tentatively assign the structure of a number of new tropane alkaloids by applying the fragmentation rules [93, 94]. The development of gas chromatography for the analysis of tropane alkaloids has been described in several comprehensive reviews [15, 24, 27]. Here, we will mainly focus on the recent articles concerning the application of GC in the analysis of this class of alkaloids.

The limits and advantages of GC-MS for the separation and structural elucidation of complex mixtures of tropane alkaloids are fully demonstrated in the work of El Bazaoui et al. [93]. In alkaloid extracts of different organs of *Datura stramonium* cultivated in Morocco, the authors detected more than 70 alkaloids in less than 55 min. Among them, 67 tropane alkaloids were identified in the organs (roots, stems, leaves, seeds, and flowers) of the plant. Nine new tropane alkaloids (3,7-dihydroxy-6-propionyloxytropane, 6,7-dehydro-3-tigloyloxytropane, 3-tigloyloxy-6,7-epoxytropane, 3,7-dihydroxy-6-(2′-methylbutyryloxy) tropane, 6,7-dehydroapoatropine, 3-(3′-methoxytropoyloxy)tropane, 3-tigloyloxy-6-isobutyryloxy-7-hydroxytropane, 3-tropoyloxy-6-isobutyryloxytropane, and 3β-tropoyloxy-6β-isovaleroyloxytropane) were tentatively identified. In a similar important work [95], the authors reported 53 alkaloids in *D. innoxia*, including four new tropane esters, which were tentatively identified as 3-acetoxy-6,7-epoxytropane (acetylscopine), 3-acetoxy-6-propionyloxy-7-hydroxytropane, 6,7-dehydro-3-phenylacetoxytropane, and 3-(2′-phenylpropionyloxy)-6,7-epoxy*nor*tropane (dihydroapo*nor*scopolamine). The new alkaloids contributed less than 0.1 % each of the total alkaloid content. The configuration of the isomeric 3α- and 3β-tropane derivatives was deduced on the basis of their retention data and their relative abundances by comparison with those from the literature considering that the 3α-isomers occur in considerably higher amount than the corresponding 3β-isomers of the homologous tropine esters [96]. The unambiguous distinction between tigloyl and its isomeric angeloyl and senecioyl derivatives cannot be established upon mass spectral data only. Thus, the identity of the different tigloyl derivatives in the above-mentioned papers should be considered as a suggestion, only because it was based exclusively on their mass spectral fragmentation and retention data.

In the genus *Schizanthus* (Solanaceae), tigloyl, senecioyl, and angeloyl tropane derivatives have been identified using a combination of GC with MS, nitrogen phosphorus detector (NPD), and Fourier-transformed infrared spectroscopy (FTIR) for the resolution of four compounds of the same nominal mass in an alkaloid mixture extracted from the stem bark of *Schizanthus grahamii* [97]. The data obtained by GC-FID/NPD and GC-EIMS were insufficient for an unambiguous structure assignment. GC-NPD indicated the number of alkaloids in the sample, while GC-MS allowed their tentative identification as well as the position (C3 or C6) of the substituent. Four isomeric compounds possessing a molecular ion at *m*/*z* 239 were revealed from the GC-MS data. Among them, 3α-senecioyl-6β-hydroxytropane was easily distinguished by its base ion peak at *m*/*z* 94 and identified by cochromatography with a previously isolated reference compound. The 3 other alkaloids, however, displayed similar mass fragmentation with a base ion peak at *m*/*z* 113, which is characteristic for 3-hydroxy tropane derivatives and indicates a substitution at C6 with a tigloyl, senecioyl, or angeloyl moiety. The relative ion abundances of diagnostic fragments at *m*/*z* 55, 82, and 83 from the mass spectra of the four isomeric alkaloids displayed a characteristic pattern for each isomer, which allowed their tentative structure assignment as 3α-hydroxy-6β-angeloyloxytropane, 3α-hydroxy-6β-senecioyloxytropane, and 3α-hydroxy-6β-tigloyloxytropane. An unequivocal distinction between these isomers was obtained through IR spectra. Angelates are characterized by two absorption bands near 1,232 cm^{-1} and 1,156 cm^{-1}, while the corresponding tiglate absorption bands presented a specific band at 1,258 cm^{1} and another at 1,140 cm^{-1}. The contribution of each absorption band and their corresponding intensity made possible the assignment of the correct structures. As a result, the combined use of GC-MS (Fig. 31.4) and GC-FTIR rendered the analysis of complex mixtures and the direct identification of structurally similar tropane alkaloids more efficient and unambiguous. Additionally, the retention indices of the isomers, recorded on four stationary phases, were found to be different, which further assisted in the peak assignment and facilitated the identification of these isomers.

The sensitivity and selectivity of GC-MS was used for the development and validation of a novel analytical method for the rapid and simultaneous detection of scopolamine and atropine in buckwheat (*Fagopyron esculentum*) samples and related food products [98]. Low detection and quantification limits were achieved in the selected-ion mode (SIM) by derivatization (silylation) of the analytes. The LOD for atropine and scopolamine were found to be 0.3 and 1 μg kg^{-1}, respectively, while the LOQ were 1 and 6 μg kg^{-1}, respectively, which corresponds to less than one *D. stramonium* seed per million buckwheat fruits.

The application of internal standards (IS) is essential for recovery experiments in method development and validation, as well as for the accurate quantification of target analytes. When a mass spectrometer is used, the most appropriate IS is an isotope-labeled derivative of the analyte, as it has the same physicochemical properties but a different nominal mass. Isotope-labeled derivatives of drugs of abuse are preferred in clinical, toxicological, and forensic analyses, but they are very expensive and often difficult to obtain. Shaikh and Chen [99] reported on the synthesis of deuterium-labeled controlled drugs, including tropane alkaloids, having a main focus on GC-MS analyses.

The combination of gas chromatography and an isotope ratio measurement mass spectrometer (*irm*-GC-MS) was used to study the detoxification and degradation pathways of tropane alkaloids involving *N*-demethylation to the respective *nor*-compounds. Molinie et al. developed protocols for sample preparation, including liquid–liquid and SPE extraction, and analysis of the ^{15}N kinetic isotope effects (KIEs) with *irm*-GC-MS and *irm*-elemental analysis (EA)-MS [100]. Degradation experiments were performed with a *Pseudomonas* strain that uses tropane alkaloids as sole source of carbon and nitrogen. The authors found that liquid–liquid extraction from the aqueous medium in combination with *irm*-GC-MS was the most convenient method for measurement of the $^{15}N/^{14}N$ ratio. Later, Kosieradzka et al. [101] exploited derivatization of the alkaloids by reaction with ethyl chloroformate (ECF) in aqueous medium and their quantitative extraction. The

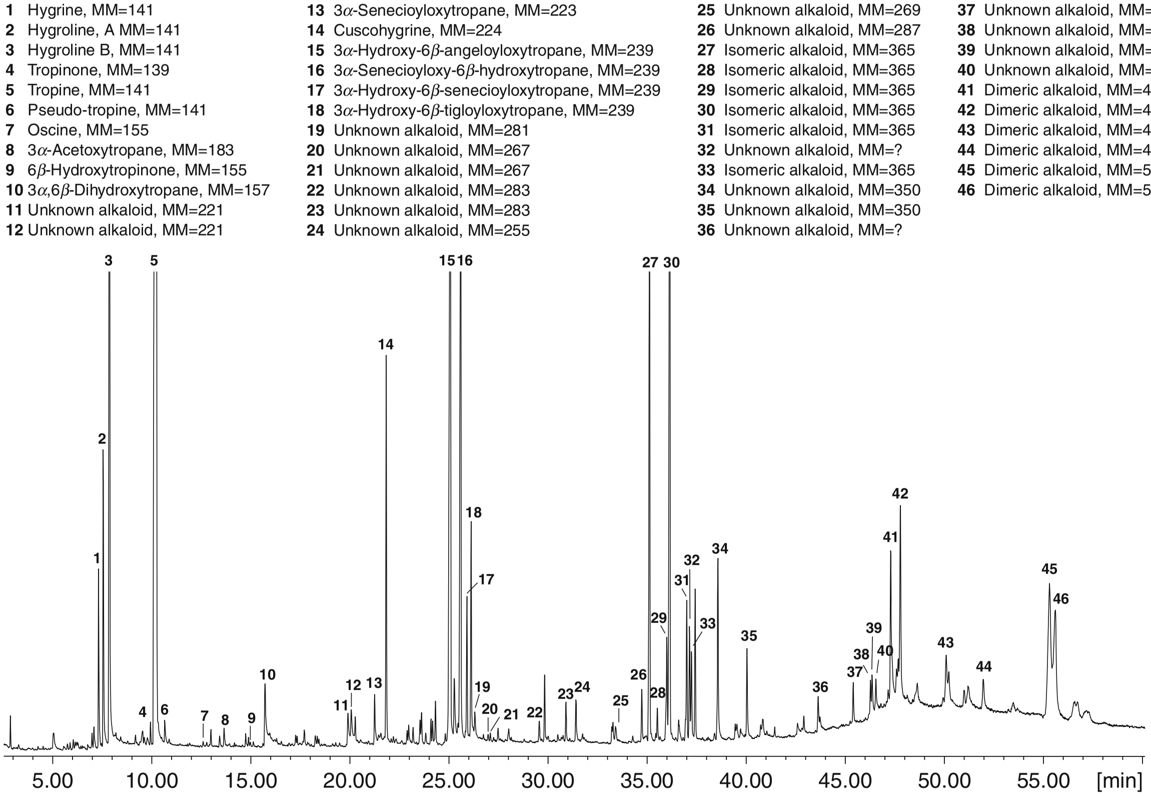

Fig. 31.4 GC-MS profile of an alkaloid extract from *Schizanthus grahamii* (stem bark). Tentative identification based upon characteristic mass fragmentation and authentic reference substances (Bieri, PhD thesis)

improved chromatographic properties of these derivatives resulted in better separation of the isomeric *nor*tropine and *nor*pseudotropine for measurement of their $\delta^{15}N$ (‰) values by *irm*-GC-MS. The achieved repeatability and precision were sufficient to measure the differences (>0.8‰) in the $\delta^{15}N$ values, with a standard deviation routinely *around* 0.3‰. The method was applied for the measurement of changes in the $\delta^{15}N$ values of *nor*tropine and *nor*pseudotropine during fermentation experiments with cell suspension cultures of a *Pseudomonas* strain expressing a specific capacity for tropine catabolism.

Conventional GC-MS has also been applied to study in vitro the biochemical response, namely, tropane alkaloid production, to minerals and elicitors in *D. stramonium* hairy roots [102], as well as in chemoecological experiments where the acaricidal activity of *Hyoscyamus muticus* extract against phytophagous mites *Tetranychus urticae* was attributed to the presence of high tropane alkaloidal content [103].

3.4 Capillary Electrophoresis

Capillary electrophoresis has been widely used in pharmaceutical and biomedical analysis due to its efficiency, accuracy, and high resolution [104]. It is a highly versatile alternative and complementary method to HPLC generating high efficiencies in a fast analysis time. Furthermore, the volume of organic solvent used for CE separations is dramatically reduced and can be restricted to only a few milliliters per day. It is a valuable technique for the quality control and analysis of medicinal plants [105]. When considering the number of reports published within the last 10 years, the analysis of alkaloids is among the most popular applications of CE for natural product separations. Its application in alkaloid analysis appears very attractive because these compounds are easily protonated and therefore easily separated by an electrophoretic process. Applications of capillary electrophoresis for analysis of tropane alkaloids in different matrices have been reviewed [15, 27]. One of the main advantages of CE in tropane alkaloid analysis that can be highlighted is its straightforward applicability for enantioseparation of atropine and other related chiral compounds [27, 106]. Despite all of its advantages, the practical implementation of capillary electrophoresis in the analysis of tropane alkaloids is relatively limited. This could be explained by the lower sensitivity of the most widely used UV detectors, the small injection volume also affecting the sensitivity and the intensive sample preparation required for reducing the influence of the complex biological matrices due to the lack of specificity when using UV. In addition, CE hyphenated with MS detectors is not as good as generally observed with HPLC-MS in terms of the reproducibility of peak area and retention times [107].

Various strategies have been applied during recent years to overcome the drawbacks associated with the analysis of tropane alkaloids by CE. Using atropine and scopolamine as model analytes, a comparison of UV and electrochemical detection (ED) in conjunction with non-aqueous CE (NACE) has been performed for capillaries with different internal diameters by Blasco et al. [108]. The results showed a significant increase in relative LODs with UV detection for capillaries with an internal diameter smaller than 25 μm. The absolute LODs remained nearly constant over a wide range of capillary dimensions. In comparison, ED showed some increase in relative LODs for capillaries smaller than 10 μm in diameter, but the absolute LODs decreased over the complete range of capillary diameters studied. Absolute LOD for scopolamine ranged from 2.4×10^{-15} to 7.9×10^{-18} mol in capillaries with an i.d. from 50 to 2 μm with electrochemical detection. With UV light detection, capillaries with an i.d. from 75 to 5 μm provided slightly improved absolute LOD for scopolamine of 213–120 nmol.

Ren et al. [109] established a method for the simultaneous determination of anisodamine, scopolamine, atropine, and anisodine by capillary electrophoresis with electrochemiluminescence detection (CE-ECL). The concentration and pH of the running buffer as well as the methanol content additive were investigated for the improvement of selectivity and sensitivity. These four alkaloids were separated within 6 min under optimal conditions in a buffer containing 20 mmol L^{-1} phosphate and 7 % methanol at pH 8.0. The method, showing RSD of the migration time less than 1.1 % and recoveries between 97.8 % and 102 %, was applied for the determination of anisodamine and scopolamine in an extract of *Przewalskia tangutica*.

The hyphenation of CE with MS detectors certainly offers the best opportunities for the qualitative analysis of natural compounds in general and of tropane alkaloids in particular, which is evident from the increasing number of articles published in recent years. Methods applying CE-MS for analysis of tropane alkaloids have been developed mainly in clinical and forensic laboratories. With this respect, HRMS detectors, enabling the identification of a compound through accurate mass measurement and isotopic pattern, are preferred for combination with CE. A comprehensive overview of principles and applications performed by CE coupled to TOF/MS detection has been published by Staub et al. [110].

A “metabolomic” approach using high resolution data was used to identify candidates with identical chemical formulae in urine, blood, and hair samples by CE-TOF/MS [111]. In this case, the detected peaks with their exactly determined mass were searched against a database with *ca* 50′500 pharmaco-toxicologically relevant compounds. Then, starting from the mass of the unknown, mass shifts corresponding to predefined biotransformations (e.g., demethylation, glucuronidation) were calculated, and the corresponding mass chromatograms were extracted from the total ion current (TIC) in order to search for metabolite peaks. The presence of metabolites in the TIC was correlated with functional group data in order to exclude candidates with structures that were not compatible with the observed biotransformations (e.g., loss of a methyl group from a structure not bearing methyls). The procedure was tested on 108 pharmaco-toxicologically relevant compounds, and their metabolites were detected in real positive samples resulting in a reduced list of possible candidates.

A method assessing forensic drugs including cocaine and benzoylecgonine by capillary zone electrophoresis (CZE) coupled with TOF-MS was developed by Gottardo et al. [112]. The separation was achieved by applying a constant voltage of 15 kV during 25 min in an uncoated fused-silica capillary (75 μm × 100 cm) using a 25 mM ammonium formate electrolyte solution (pH 9.5). LODs were in the range of 2–10 ng mL^{-1} and LOQs of 10–30 ng mL^{-1} for all analytes. The CVs, tested in biological matrices, were below 2.97 % for migration times and below 14.6 % for peak area. The analytes were identified in blood samples (real cases) based on matching measured exact mass and isotopic pattern.

Da Costa et al. [113] developed and validated a method for the simultaneous determination of cocaine, benzoylecgonine, cocaethylene, anhydroecgonine, anhydroecgonine methyl ester, and ecgonine methyl ester in human urine using CE-ESI-MS/MS. The electrolyte was 1 mol L^{-1} formic acid, whereas 0.05 mol L^{-1} formic acid in methanol to water (1:1) was used as the composition of the coaxial sheath liquid at the ESI nozzle. LODs were 100 ng mL^{-1} for cocaine and cocaethylene and 250 ng mL^{-1} for the other metabolites, whereas LOQs were 250 ng mL^{-1} for cocaine and cocaethylene and 500 ng mL^{-1} for all other compounds. Precision and recovery tests showed an RSD lower than 10 % (except for anhydroecgonine, 18 %) and recoveries ranged from 83 to109 % for all analytes. In real samples, cocaine and its derivatives were confirmed by MS/MS experiments.

NACE appears to be ideally suited for online coupling with mass spectrometry due to high volatility and surface tension of most of the organic solvents used [114]. Carefully optimized NACE-MS method was applied to a very large number of alkaloids in different psychoactive plant extracts, as demonstrated by Posch et al. [115]. The method allowed the separation of structurally closely related substances, such as diastereomers and other isobaric compounds, as well as to separate members of different alkaloid classes including tropane alkaloids without modification of the procedure.

CE-ESI-TOF-MS was successfully applied to analyze mixtures of unknown tropane alkaloids. Seven alkaloids (tropine, belladonnine, *nor*hyoscyamine, apoatropine, hyoscyamine, 6β-hydroxyhyoscyamine, and scopolamine) were simultaneously identified in a pharmaceutical preparation of *Atropa belladonna* leaf extract by TOF-MS by matching their mass accuracy and true isotopic pattern. CE-ESI-IT-MS was used to discriminate the putative presence of littorine. Optimal separation conditions were achieved with 60 mM ammonium acetate buffer at pH 8.5 containing 5 % isopropanol [116].

3.5 Non-Chromatographic Methods

There have been significant progresses in methods that hyphenate separation techniques with spectrometric or spectroscopic detectors for the unequivocal identification of target compounds. These hyphenated methods can provide the most complete information on the analyte distribution and even their chemical structures. However, they can be time-consuming, costly, and difficult to apply in routine analyses. Non-chromatographic procedures can sometimes provide sufficient information to identify the compounds of interest in a less time-consuming and more cost-effective way with competitive limits of detection. Thus, non-chromatographic target analysis continues to be a promising research area and has been applied to the development of several methodologies that facilitate this type of analytical approach. In the recent years, immunoassays and optical sensors, as well as standalone NMR and mass spectrometry, have been used as non-chromatographic analytical platforms dedicated to the analysis of tropane alkaloids. The advantages of immunoassay technology over other analytical techniques include low detection limits, high analyte selectivity, high sample throughput, reduced sample preparation, versatility for target analytes, cost-effectiveness for a large number of samples, and adaptability to field use. The limitations are matrix effects, cross reactivity with structural analogues of the target analyte, poor suitability for multi-analyte applications, low availability of reagents, and longer individual response times for assays compared to classical analytical methods. Recently, immunoassay methods for the analysis of cocaine and its derivatives have been applied in forensic and clinical samples. Cloned enzyme donor immunoassays (CEDIAs) for drugs of abuse screening were compared with chromatographic methods (GC-MS or LC-MS) to check and optimize the immunoassay cutoff values in blood serum using drug of abuse reagents in combination with a Hitachi 912 autoanalyzer [117]. Serum samples were measured directly or, in cases of hemolysis, after dilution with blank serum. Tests were performed for various amphetamines, cocaine, cannabinoids, methadone, benzodiazepines, and opiates. Sensitivity, specificity, positive and negative predictive values, and overall misclassification rates were evaluated by contingency tables and compared to receiver operating characteristic (ROC) analyses and Youden indices. Ideal cutoffs were statistically calculated on the basis of sensitivity and specificity as decisive statistical criteria with focus on a high sensitivity (low rate of false-negatives), i.e., using the Youden index. The LOD for benzoylecgonine was found to be 75 ng mL^{-1}.

Drugs of abuse, such as cocaine, cannabinoids, and amphetamines, were detected in hair by immunoassay followed by GC-MS for confirmation and quantitation [118]. Immunochemical screening was done with the Siemens EMIT® II Plus assays for opiates, amphetamines and ecstasy, and Microgenics CEDIA® assays for cocaine. All samples with positive results in the screening test for any drug and/or metabolite were analyzed by GC-MS for confirmation and quantitation. The cutoff value for cocaine was 0.20 ng mg^{-1}.

Wenger et al. [119] presented a fast and sensitive method for the detection of cocaine in liquid samples. The authors designed a system for the systematic monitoring of luggage at airport security controls. The system consisted of a waveguide grating sensor chip functionalized with cocaine antigen–protein conjugates. Drug molecules were covalently grafted onto immunoglobulin G carrier proteins. The detection was based on the changes of the effective refractive index of a waveguide grating upon adsorption of biomolecules. The sample which may contain cocaine is mixed with a fixed amount of monoclonal anti-cocaine antibodies and injected into the flow cell. The antibodies can either bind to free cocaine in solution or to the cocaine analogues present on the surface-bound carrier proteins. When the concentration of free analyte increases, fewer antibodies can bind to the surface. Thus, the instrument response decreases when cocaine is present in the sample. The sensitivity was substantially enhanced by three orders of magnitude using antibodies conjugated to gold nanoparticles. This effect is mainly attributed to the dielectric properties of the composite particles composed of gold and antibodies that amplify the observed changes of effective refractive index. The results obtained under optimized conditions showed that the working range was substantially shifted toward lower concentrations of cocaine. Its presence could be identified shortly after injection of the sample. Under optimized conditions, a lowest detectable concentration of 0.7 nM was reached within only 1 min.

Luminescence-based optical sensors have experienced significant growth during the past decade. Dispersed colloidal semiconductor nanoparticles, known as quantum dots (QDs), have attracted intensive research interests in scientific and technological applications. Because of their unique optical properties, such as broad excitation spectra, narrow and symmetrical emission peaks, enhanced photobleaching resistance, and tunable spectra, QDs have been applied in a variety of research areas as fluorescent species for cell labeling, clinical diagnosis, and tumor imaging.

Wu and Fan [120] developed an effective method for the quantitative determination of raceanisodamine (= 6-hydroxyatropine ?) hydrochloride and atropine in biological fluids by room temperature phosphorescence (RTP) detection applying Mn-doped ZnS quantum dots. Mn-doped ZnS QDs exhibit a phosphorescence spectra emission peak at 590 nm. ZnS is a wide gap semiconductor. Its conduction band and valence band can provide a wide range of energy levels for the doping ions. As Mn^{2+} and Zn^{2+} have equal electric charges and similar ionic radii, Mn^{2+} can be better incorporated into the ZnS crystal lattice without producing a greater impact. The alcoholic hydroxyl of raceanisodamine and atropine can be ionized to form a complex with a divalent cation under physiological conditions. Thus, it was possible to form the complex between the alkaloids and Mn^{2+}/Zn^{2+} on the surface of the Mn-doped ZnS QDs, and this combination significantly quenched the phosphorescence intensity of the Mn-doped ZnS QDs. To perform the analysis, 1 mL of a 50 mg L^{-1} Mn-doped ZnS QDs solution, 1 mL Tris–HCl (pH 7.5), and a range of concentrations of the drugs' standard solution or water sample solution were mixed, and RTP measured at an excitation wavelength of 305 nm and an emission wavelength of 590 nm. No pretreatments such as deproteinization or centrifugation were needed, except for a 100-fold dilution of urine and serum samples before analysis. The selectivity of the method was unaffected by excess of Na^{+}, K^{+}, Mg^{2+},Ca^{2+}, and amino acids. The method showed linearity in the range 0–9 μM, RSD below 2 %, and recovery from 95 to 104 %. It was shown to be rapid, easy to implement, selective and inexpensive, and displayed relatively high sensitivity. The LOD values were 0.11 and 0.09 μM for raceanisodamine hydrochloride and atropine, respectively.

Among the different techniques utilized for developing chemical sensors, those based on molecular fluorescence are the most sensitive. Oliveri and Di Bella [121] developed a powerful fluorescent probe based on an amphiphilic Schiff-base zinc (II) complex for the sensitive detection of alkaloids, including tropane and atropine. This complex exhibits fluorescent enhancement upon formation of 1:1 adducts with alkaloids. Its binding interaction, related to Lewis basicity, is strongly influenced by the steric characteristics of the coordinating alkaloid, leading to high selectivity in the micromolar range and sensitivity for pyridine-based alkaloids. The fluorescence emission wavelength was constant for all adducts except for cinchonine and tropane adducts and was independent of the excitation wavelength. LOQ for tropane and atropine were 4 and 15 μM, respectively.

NMR spectroscopy is of fundamental importance for the structural elucidation of natural compounds. In the past decade, NMR has been applied for metabolomics (qualitative and quantitative) studies in different matrices such as plant extracts and body fluids. The only variables in NMR spectroscopy are the solvent used and the magnetic field strength. The main characteristics of this nondestructive approach for quantification of target compounds are high reproducibility, high throughput, easy sample preparation, and a wide range of targets. The main drawback is, however, the low sensitivity as compared with other analytical detectors and the overlap of many signals when analyzing complex mixtures. The use of 2D NMR spectroscopy and 2D *J*-resolved spectra in particular can considerably improve the peak resolution. With the increasing field strength of the NMR magnets and the improved resolution, the application of NMR for quantification of target compounds became feasible. In contrast to the above-described non-chromatographic methods, NMR allows identification and quantification of several metabolites simultaneously [122].

Using an airlift system made from a NMR tube, Bartholomeusz et al. [123] performed in vivo quantitative ^{1}H NMR studies of tropinone metabolism in *Pseudomonas* AT3 cultures. In the range 1.8–4.2 ppm, tropinone was easily distinguished from the other compounds not only by its methyl peak but also by the H1, H2, H3, and H5 peaks. Tropine was distinguished by its H1 and H2 peaks, while pseudotropine was characterized by its H1, H2, and H6 peaks. Quantification of the metabolites by 1D NMR only proved to be difficult as a result of large overlaps in the ^{1}H spectrum due to similar metabolite structures. Good resolution of all target metabolites was obtained by using 2D TOCSY NMR. After optimization of the TOCSY mixing time with an equimolar solution, the 2D method was calibrated with solutions containing tropine, tropinone, and pseudotropine. The method showed a good linearity ($R^2 > 0.999$) between the concentration ratios and the peak ratios with a sensitivity of *ca*. 0.5 mM.

Lanfranchi et al. [124] developed a protocol using a ^{13}C NMR method to investigate the enantiomeric differentiation of hyoscyamine in plant extracts. ^{13}C NMR spectra are more suitable for that purpose because the signals are singlets and offer a large spectral width as compared to ^{1}H NMR. A chiral lanthanide shift reagent combined with trifluoroacetic acid (CLSR/TFA) was used. The addition of CLSR to a racemic compound having a Lewis basic site provokes deshielding of the signals of most carbons of the molecule and splitting of the signals for some of them. The enantiomeric differentiation of atropine free base was investigated with various CLSR, but only tris[3(heptafluoropropylhydroxymethylene)-(+)-camphorato] ytterbium(III), known as Yb(hfc)$_3$, resulted in weak deshielding and splitting of some carbons. For that reason, the free base was protonated with TFA. At molar ratios [Yb(hfc)$_3$]:[atropine-TFA] between 0.20 and 0.40, all the signals of the aromatic ring split. The method was optimized with various mixtures of (+) and (−)-hyoscyamine ranging from 50:50 (racemic mixture, i.e., atropine) to 98.5:1.5. The enantiomers were best differentiated by NMR using the split signals of aromatic C12 and C15, which were in agreement with the gravimetrically prepared samples. The method was applied to an extract of *Datura stramonium* revealing that *S*-(−)-hyoscyamine was the unique enantiomer.

A recent innovation in mass spectrometry is the ability to record mass spectra on samples in their native environment, without sample preparation or pre-separation by creating ions outside the instrument. A stream of ionizing or at least ion-desorbing fluid medium is directed onto a solid sample surface from which analyte ions are withdrawn and transported through air into the mass analyzer via a standard atmospheric pressure ionization interface. Direct analysis in real time (DART) and desorption electrospray ionization (DESI), two recently introduced mass spectrometric ionization techniques, have been found to be extremely useful for the direct detection of chemicals on surfaces without requiring any sample preparation such as solvent extraction. These techniques are rapid, providing the results within minutes, but can be regarded as semiquantitative only, as the detection of a compound largely depends on the matrix. Selectivity and accurate elemental composition assignment through exact mass measurement and MS/MS experiments are possible when coupled to a high resolution or tandem mass analyzer. The application of DESI-MS/MS for the analysis of tropane alkaloids *in Datura stramonium* and *Atropa belladonna* [125] have been discussed in a previous review [15].

Recently, the DART technique has been utilized for chemical profiling of hairy root cultures of *Atropa acuminata* [126]. The intact hairy roots were directly analyzed by holding them in the gap between the DART ion source and the mass spectrometer. Applying a resolving power of 6,000, two alkaloids were detected by their elemental composition and characterized as atropine and scopolamine on the basis of exact mass measurements.

4 Conclusion

Tropane alkaloids and the various plants containing them have attracted the interest of people for centuries due to their pharmacological effects and application in medicine. For these reasons, they continue to be in the research focus of many scientists working in the field of pharmaceutical, forensic and clinical analysis, plant physiology, biotechnology, and obviously in phytochemistry. Since the first analyses of tropane alkaloids by GC and LC in the early 60s, the analytical techniques have evolved remarkably with respect to both separation and detection capabilities. Basically, two main tendencies can be distinguished: continuous improvements of modern hyphenated techniques and the development of innovative non-hyphenated methods for the analysis of target molecules as well as screening of unknowns. Although a century-old technique, TLC is in its renaissance with the development of HPTLC instrumentation. This regained interest is primarily related to crude extract analysis and rapid plant profiling. The introduction of narrow bore columns (i.d. <0.25 mm) for GC and UPLC instruments capable of operating with columns packed with sub-2 μm particles considerably improved the separation power (increase in efficiency) or, alternatively, enabled the dramatic reduction of analysis time (reduction of column length) while maintaining initial resolution. Thus, manufacturers of both techniques introduced new terms and acronyms supporting the potential to considerably speed up analysis time. Simultaneously, the advance in benchtop mass spectrometers resulted in detectors coupled with a separation instrument, which provide structural rich information with extremely high sensitivity and selectivity. Consequently, GC-MS and LC-MS have become routine methods for the qualitative and quantitative analysis of tropane alkaloids, and researchers now have a wide choice of analytical techniques to solve almost any specific problem. The application of LC coupled with high resolution and tandem MS on the one hand, and NMR detectors on the other, is now expanding rapidly for the analysis of natural compounds, including tropane alkaloids. Such hyphenation reveals a new era of phytochemistry, where the isolation of the unknowns will not be a prerequisite (dereplication) for their complete structural elucidation. The innovative DART, DESI, and other mass spectrometry technologies allowing direct analysis of samples, without or with minimal sample preparation, are in their infancy, and it is expected that their applications are going to expand. Optical sensors and immunoassay methods are also in development due to their extreme sensitivity and applicability in forensic and clinical investigations. The future will certainly offer many exciting opportunities for scientists to continue to analyze, identify, and discover new tropane alkaloids while exploring the field of accessible natural products.

Abstract

Pyrrolizidine alkaloids poison animals grazing on toxic wild plants and those fed contaminated feed, causing economic losses. They poison humans through deliberate consumption of certain foods and herbal medicines and through consumption of food contaminated by wild plants, such as via transport of the toxins by bees into honey. Analytical methods are required for different purposes – to detect the presence of pyrrolizidine alkaloids, to quantify the total level of the toxins, or to measure the quantity of individual compounds. The task is made more challenging by the variety of PAs, their widespread nature and their different forms. Analytical methods are based on color reactions, enzyme linked immunosorbent assays (ELISAs), spectroscopy, and the full range of chromatographic techniques. A lack of reference standards and

validated methods has hampered the application of available methods to food surveys, but has not prevented the development of a number of very useful methods as are described in this chapter.

UV	Ultra-violet

1 Introduction

Pyrrolizidine alkaloids (PAs) are toxins produced as secondary metabolites by a very large number of plants widespread across the plant kingdom. They are ingested by animals as a results of direct grazing in the absence of preferred grasses, or by inadvertent contamination of hay and silage, or of composite feeds. PAs affect humans mostly through consumption of herbal supplements and teas, and of honey derived from *Echium* or contaminated with pollen or nectar from *Echium vulgare*, *E. plantagineum* or ragwort (*Jacobaea vulgaris*). Lesser routes include milk and animal tissues. PAs are used by insects to afford protection from predators and limited chemical studies have been carried out into these relationships.

PAs cause veno-occlusive disease of the liver after significant consumption and are associated with other ill effects. Comprehensive knowledge of the occurrence of PAs in food and feed is required for the calculation of exposure affecting animals and humans, and to support legislation formulate advice to consumers. Current research into improving or replacing older analytical methods has been prompted by advice to consumers from Australian and New Zealand authorities related to contaminated honey, and by requests from the European Commission via the European Food Safety Authority (EFSA).

PAs have a large variety of related structures, and include both tertiary (free base) compounds and their corresponding *N*-oxides (PANOs), which behave differently in many analytical systems. The analytical requirements are for methods for detecting PAs in wild and cultivated plants, in plants and plant preparations used for dietary supplements and herbal medicines, hay, silage and compound animal feeds, foods including honey, milk, and teas.

There is a need for rapid field tests that are either qualitative or give a measure of the total PA content, and for instrumental techniques for providing profiles of the PAs content of samples and accurate quantification of low levels. The techniques applied include colorimetric tests immunoassays, gas chromatography, liquid chromatography, and mass spectrometry. Extraction methods mostly follow classical procedures but clean-up methods have evolved from repeated liquid-liquid partitioning to the currently favored solid phase extraction (SPE) techniques. The following review concentrates on a range of methods that are likely to continue to be used to meet all requirements, and discusses their relative merits and disadvantages. Analytical methods have been reviewed [1–3]

2 Methods of Analysis

2.1 Sample Preparation

PAs are very widespread in plants and vary with species and variety, and also geographically, therefore analyses that are targeted at particular alkaloids should be carried out with positive identification of the plant species where possible. This is particularly important where the variations in the PA composition are to be related to the species. Consideration should be given to the relevance of misidentification of plants, for example PA toxins have been measured in herbal products labeled as being derived from *Senecio aureus*, which is generally believed to contain few PAs. Pollen analysis of honey can be used as a guide to the expected PA composition and to verify results of analysis. As some parts of plants such as seeds or root fragments might contain very high levels of PAs it is important to ensure that the sample is sufficiently large and also that it is homogenous, for which the familiar grinding and mixing techniques are appropriate.

Plant samples can be blended in their fresh state, in which case whole portions can be homogenized in the extracting solvent. In other cases it might be more convenient to freeze the sample and blend it with dry ice or with a pestle and mortar with liquid nitrogen. Plants can be dried in air or under vacuum, or heated in an oven or freeze dried. Unfortunately there have been no comparative studies into any changes in the PA composition induced by these drying methods. Quite severe methods such as oven drying at elevated temperature do not appear to produce gross changes to tertiary PAs such as decomposition or oxidation to a prominent degree. Senecionine was stable in pollen during extended heating at 56 °C under which conditions about 50 % of its PANO was lost [4].

2.2 Extraction Procedures

Early classical extraction methods for PAs were applied without much consideration of the range of chemical structures of the alkaloids and in particular were not optimized to obtain the maximum yields of both the tertiary and oxide forms. In fact few publications even today describe the recovery achieved with the extraction procedure used. PAs have either a reduced tertiary nitrogen atom with a characteristic basic function or an oxidized form (PANO). Both forms have little solubility in non-polar solvents such as hexane and are best extracted with polar solvents such as methanol or with aqueous dilute acid. These solvents dissolve both the PAs and the PANOs with relative ease.

Several approaches have been used to extract PAs from plants. The plant material, fresh or dried, can be steeped in solvent, blended, or placed in Soxhlet type extractors. The solvent can be left at ambient temperature or heated to boiling. Methanolic extractions in particular have been enhanced by the addition of acid. Ultrasonic agitation can speed up the extraction process. Many solvent systems have been applied, ranging from mid-polarity solvents such as chloroform, diethyl ether or ethyl acetate, or to mixtures, to polar organic solvents (methanol) and acidified water. Methanol and dilute aqueous sulfuric or hydrochloric acids are both good solvents for the PA tertiary alkaloids and PANOs. A 30 min single step extraction with 2 % aqueous formic acid can be used for PAs in freeze-dried powdered plant material prior to filtration, dilution and analysis by high performance liquid chromatography with mass spectrometric detection (LC-MS). The use of formic acid is advantageous in LC-MS as it forms volatile products in combination with ammonium salts added to the mobile phase [5]. Earlier methods more often used dichloromethane or chloroform alone or mixed with methanol but the use of chlorinated solvents is today considered unacceptable when alternatives are available.

There have been a few comparisons of extraction solvent systems. These have found that refluxing dry plant material in a relatively high proportion (1 l per 10 g) of methanol and aqueous citric acid (1:1) for just 15 min gave the highest yield of free PAs, but the performance with PANOs was not measured. Stirring in water at neutral pH and room temperature was unsatisfactory, as was Soxhlet extraction with methanol [6].

The extraction conditions used can affect the yield of PAs, their relative proportions, and the ratio of the tertiary alkaloid to PANO. For all extraction methods higher proportions of PANOs are obtained by extracting at room temperature than by methods that involved heating. Prolonged Soxhlet extraction causes a marked loss of PAs and a decrease of the proportion of PANO. An unidentified factor present in the plant material is suspected of being responsible for this loss. The best yields are obtained by relatively short treatments with acidified water or methanol, or their mixtures, at elevated temperature. The choice between water and methanol can be influenced by the sample. Some starchy products can swell and form a gel in hot water but methanol extracts more chlorophyll from green plants and lipid from e.g., animal feed samples.

The quantity of PAs extracted will vary with the sample to solvent ratio. It would be expected that using a high proportion of solvent to sample would extract analytes from the sample more thoroughly, but this is not always the case, and may not be desirable. Limits of detection may be lower for dilute solutions measured by LC-MS as the suppression effect of the matrix is reduced. In practice, limited comparisons have shown that whereas extraction of PAs from comfrey with a high proportion of methanol (500 mL per 5 g comfrey) gave high yields of PAs whereas when a 2 g comfrey sample was extracted with 200 ml methanol the percentage yield was lower.

Extraction with methanol at 100 °C for a short 2 h gave good yields, and these were increased by the addition of 1 % tartaric acid [7]. However this acid is not really sufficiently volatile for use in LC-MS. Increasing the extraction times to in excess of 6 h (up to 18 h) gives no advantage.

PAs can be extracted with organic solvents from aqueous systems and solid samples made basic with ammonia. In this case dichloromethane or chloroform have often been used as the organic phase. PAs can conveniently be transferred from an aqueous extract into an organic solvent by means of solid phase extraction (SPE) using columns packed with inert diatomaceous earth such as Extrelut® [8]. The aqueous extract is supported on the column matrix and the PAs eluted by passing organic solvents through. The solid matrix prevents the formation of emulsions. This method is much less satisfactory for the more polar PANOs.

Yields obtained by all methods are best improved by carrying out successive extractions, in which following a first extraction the solvent is separated from the sample by centrifugation and then replaced by a second volume. The extraction is repeated and the extracts combined. The process may be repeated, however in practice repeated extractions are rarely applied.

Particular extraction methods are required for more challenging matrices such as honey and milk. There is great interest in the analysis of honey as bees transfer toxic PAs from plants into this human food. The contamination of milk and eggs through animals and hens is much less of a problem, and their analysis has not be the subject of much scrutiny.

Honey has been extracted by shaking or blending with organic solvents but today it is almost always analyzed by means of SPE after dissolution in water or methanol, which effects a simultaneous clean-up and is detailed in following paragraphs.

A larger proportion of the PA content of plants and contaminated foods is in the PANO form. The *N*-oxides of PAs are less soluble than the tertiary alkaloids in non-polar solvents and were not regularly determined in the early days of monitoring. Before the widespread availability of LC-MS methods measurement of the PANOs depended on their conversion to the tertiary alkaloid and measurement of the tertiary alkaloids in duplicate samples, one with and one without conversion to the tertiary alkaloid form, from which the PANO content could be determined by difference [9]. The PANOs are best extracted into relatively polar solvents such as methanol, or mixtures of alcohol and acidified water, they can be extracted into the same medium as the tertiary alkaloids with ease.

Reduction of the PANO to the tertiary alkaloid has classically been carried out using zinc powder with dilute aqueous acetic, hydrochloric or sulfuric acid, but it can also be achieved with sodium or potassium dithionite or metabisulfite. The dithionite can be used in solution or adsorbed on to a redox resin [10]. Zinc reduction is efficient and can be checked by using commercially available PANOs, but a comparison of reduction conditions [11] found that the quality of zinc and the reaction time affected performance. The often used overnight reduction with zinc gave lower yields than treatment for 0.5–4 h. Dithionite in water is suspected of failing to reduce senecionine NO or of destroying it, and the reduction reaction with dithionite in formic acid is slow. Zinc reduction in the presence of sulfuric acid gave much higher yields of tertiary PA from many PANO than sodium bisulfite in aqueous formic acid [5].

Today, the ease of the determination of both tertiary alkaloid and oxide forms in the same extract in a single LC-MS experiment has led to a decline in the application of the oxide reduction procedures except when used for the GC-based summation methods described later.

Two plants that contain PAs, echium (*Echium plantagineum*) and borage (*Borago officinalis)*, each provide a valuable oil that is nutritious on account of its fatty acid profile. There is some concern that PAs might be present in oils from these plants, an issue addressed by analysis using simple liquid–liquid extraction processes in which a solution of the oil in a non-polar solvent is shaken with dilute aqueous acid. The method had an LOD of 0.6 μg L^{-1} when applied to borage oil, including a PANO reduction step [12, 13]. The procedure has had little application, and has not revealed a health problem.

An alternative sample preparation is based on the QuEChERS (Quick Easy Cheap Effective Rugged Safe) technique [14]. In this the sample is extracted into acetonitrile and magnesium sulfate, sodium chloride and citrate buffer salts at pH 5–5.5 are added. the mixture is shaken and then centrifuged to separate the phases. When applied to honey [15] the samples, containing isoproturon-d6 as an internal standard, were diluted with water and homogenized before addition of the QuEChERS salts described above, and acetonitrile. After extraction, centrifugation and concentration the extract was analyzed using LC-MS with an on-line SPE cleanup step.

Some determinations have been made of the occurrence of PAs by insects, which assimilate the alkaloids from toxic plants to use in their own defense or to produce pheromones. PAs have been extracted from insects, using acidic methanol, followed by limited clean-up [16]. There is also interest in the PA content of pollen, for which it has been shown that careful washing with cyclohexane and grinding with sand is necessary to obtain pure PAs quantitatively [17].

For preparative isolation of PAs, useful in providing analytical standards, the most successful approach has been countercurrent chromatography [18, 19]. This procedure, which is based on the partition of target compounds between a pair of immiscible solutions, has been enormously improved in efficiency in recent years, however no modern applications to PAs have been published. Column chromatography and preparative Thin Layer Chromatography (TLC) are alternate approaches, and preparative high performance liquid chromatography (HPLC) should be useful for separation of the minor alkaloids.

2.3 Clean Up

Clean up procedures are considered essential for most plant and food matrices analyzed for PAs, although extraction and clean-up can be combined for some samples such as honey.

Both the tertiary PAs and their oxides are relatively polar, and solutions in acidified water or water:methanol mixtures can be cleaned of non-polar material (fats, waxes, terpenes etc.) by washing with hexane or petroleum ether. The PA bases can be cleaned thoroughly by making the resulting aqueous phase strongly basic and extraction of the alkaloids into a moderately polar organic solvent such as ethyl acetate, diethyl ether or chloroform. Further partitions achieved by shaking the organic solution with dilute aqueous acid generally remove all non-basic substances. However this procedure is lengthy and consumes large volumes of solvent, it is therefore best reserved for preparative isolations of PAs from bulk materials or to extract tertiary PAs following the reduction of PANOs. These techniques are inapplicable to unreduced PANOs, and for both tertiary PAs and PANOs clean-up can be achieved by simpler means on a smaller scale. SPE has rapidly become the preferred method for samples to be analyzed by LC-MS, but careful cleaning by other means has been used for certain samples. For the determination of PAs in cow's milk the fats were precipitated by cooling and freezing in methanol and centrifugation [20].

2.4 Solid Phase Extraction (SPE)

SPE can be used to extract PAs from aqueous solution and simultaneously clean-up the sample and concentrate the extract. In its simplest form SPE is used without chromatographic separation. An alkaline aqueous extract (or urine sample) is held on column of inert diatomaceous earth commercially available as Chem Elute® or Extrelut®. A water-immiscible organic solvent, preferably also alkaline, is passed through the column and dissolves the PAs in a single application without risk of emulsion formation. The method has now been largely superseded by cation-exchange methods.

The more usual SPE method involves an interaction of the PA with the stationary phase which comprises non-polar phases such as octylsilane or octadecylsilane (C8 or C18), or cation-exchange materials packed into small cartridges [21]. Cation-exchange materials are preferred as non-polar sorbents do not effectively separate PAs from co-extracted materials that could interfere with subsequent chromatographic separations. Polymer-based Strong Cation Exchange (SCX) SPE traps both tertiary alkaloids and PANOs, removing many potentially interfering compounds [22], the SCX phase probably retaining PANOs by binding to the active sites of the sorbent rather than by a cation-exchange process [7]. In practice the cartridges are wetted with methanol and conditioned with dilute (e.g., 0.05 mol L^{-1}) hydrochloric or sulfuric acid. The sample extract is applied in dilute acid, and the cartridge washed with methanol before elution of the PAs with methanol containing gaseous or aqueous ammonia [10]. PAs can also be eluted from SCX columns under acid conditions, such as with mixtures of methanol with aqueous hydrochloric acid [23]. The method has been applied to test the urine from cows that had been fed on ragwort [20].

SPE based on SCX resins have been much used for the determination of PAs in honey [24–27]. The technique requires some care to avoid blockage of the cartridges. The honey needs dilution with dilute acid and centrifugation, and the cartridges sometimes require warming. The sample on the column is washed with water and the PAs eluted with water–methanol mixtures made acidic [23] or containing ammonia [10]. The performance of SCX-SPE varies with cartridge type, size and manufacturer and preliminary recovery experiments are advised before sample analysis takes place.

2.5 Chromatographic Methods

2.5.1 Thin Layer Chromatography (TLC)

TLC with both silica and aluminum oxide adsorbents has been used to separate and isolate tertiary PAs, sometimes with ion-pairing using lithium chloride, potassium chloride, or sodium iodide [28]. Unsaturated PAs can be detected on TLC plates after spraying with Erlich's reagent [28–30]. Calibration is obtained by comparison of spot color intensity with external reference standard alkaloids. PAs can be isolated from TLC plates by excising the PA spot or band and dissolving the alkaloids from the stationary phase with polar organic solvents. Spots on TLC plates can be scanned with instruments (densitometers) that can compare their intensity with those of standards of known concentration. By this means quantities of about 1 μg can be detected reasonably quickly.

2.5.2 Gas Chromatography (GC)

GC is limited in being unable to determine PANOs without prior reduction to the tertiary alkaloid, requiring a duplicated analysis with considerable manipulations. However it does have the considerable advantages of much higher resolution, which separates and reveals minor and isomeric compounds, and of providing detailed mass spectra from which structures can be elucidated. The detection methods used most often are flame-ionization detection (FID) and mass spectrometry (MS) but nitrogen–phosphorus detection (NPD) has also been used [5, 9, 17]. The latter is particularly useful as in nitrogen mode where nitrogen containing molecules such PAs are detected selectively and can be quantified with reference to a standard nitrogen containing compound. A wide range of GC stationary phases have been used including non-polar and polar types [16, 31]. On non-polar stationary phases retention times are approximately in order of molecular weight. Saturated PAs elute after unsaturated ones and esters substituted in the 9-position elute after those substituted in the 7-position. GC profiles and mass spectral data allow many PAs to be identified, and allow distinctions to be made between plant varieties of different species and chemotypes of the same species [32].

2.5.3 Gas Chromatography-Mass Spectrometry (GC-MS)

MS is the GC detection method most commonly used to identify and quantify PAs following GC separation. The electron impact (EI) mass spectra of PAs contain ions unique to the necine base and characteristic and specific fragments [33]. Many PAs have the same molecular mass and weak molecular ions, and so the fragmentation pattern is useful in identification and the monitoring of specific fragment ions is required for quantification with good sensitivity. Unsaturated PAs with a retronecine base have characteristic fragment ions at m/z 93, 120, 136, 137 and 138. PAs with an otonecine base have characteristic fragment ions at m/z 110, 151, and 168 with saturated-base PAs having ions two mass units higher.

Chemical ionisation (CI) in positive or negative mode can be used to reduce fragmentation and allow detection of the molecular ion [34, 35]. Reagent gases used in CI have included methane, *iso*-butane and ammonia. An EI-GC-MS method in Selected Ion Monitoring (SIM) mode able to separate and quantify most of the 1,2-unsaturated retronecine type PAs has been reported [25].

Most PAs have several polar hydroxy groups which produced problems of poor peak shape and resolution in the early days of capillary GC, which were addressed by reactions to cap the hydroxy function (derivatisation). With modern bonded and end-capped stationary phases PAs can be chromatographed without derivatisation, but it can help with identification and with ensuring resolution. The hydroxyl groups can be derivatised with silylating reagents to form trimethylsilyl ethers [35] or with alkylboronates (methyl, butyl, or phenyl boronic acids) which form bonds across 1–2 and 1–3 diol groups [36, 37]. The remaining single hydroxyl groups can be silylated after the boronate reaction, but this is not always necessary.

2.5.4 Summation Methods

Retronecine has been detected as a metabolite of PAs in body fluids using GC following derivatisation with heptafluorobutyric anhydride [38], and its relatively easy measurement forms the basis of recent methods to measure the sum of the individual PAs in plants, feed and foods. The total PA content of a sample can be determined by hydrolysis of all of the PAs to the retronecine base and measurement of this by GC after derivatization, but more recently alternative methods have been used. In one approach [15], following sample extraction and clean-up using SCX-SPE the PANOs are reduced with zinc dust and the necine base is released from its esterifying acids by reaction with lithium aluminum hydride ($LiAlH_4$). After reaction with the $LiAlH_4$, which does not reduce the necine double bond, the reagent is decomposed with alkali and the base extracted into dichloromethane. The base is then derivatised with *N*-methy-*N*-(trimethylsilyl)trifluoroacetamide to form trimethyl silyl ethers which are analyzed by GC-MS. An alternative method, which avoids the difficult handing issues associated with $LiAlH_4$, is to carry out a transmethylation of the PAs isolated by SCX-SPE with tetramethylammonium hydroxide in dichloromethane, which converts the -OH functions into methyl ethers which can be analyzed by GC-MS. Recoveries using this technique varied with PA and for echium PAs the total levels determined were lower than for LC-MS/MS methods [39].

Summation methods have only so far been applied to 1,2-unsaturated PAs and not to otonecine type PAs such as senkirkine or supinicine PAs having an additional oxygen molecule attached to the necine ring and a methyl group attached to the nitrogen. For these PAs an additional reference standard having the otonecine or supinicine ring structure would be required. Heliotrine has been used as an internal standard for retronecine, the sample treatment converts this into di-TMS-heliotridine, a diastereomer of di-TMS-retronecine. The isomers are well separated in the final chromatographic step [15].

LC-UV measurement has been applied to the summation methodology by pre-column derivatization of retronecine to (7-methoxy-1-methoxymethyl-6,7-dihydro-5 H-pyrrolizine). Photodiode array detection (DAD) was used and the derivative had an absorption maximum at 223 nm. The LOQ for standard solutions was about 1 ng mL^{-1} [40].

GC-MS based summation methods have been applied to honey, pollen and foods that contained honey. They have LODs equivalent to 1–10 μg kg^{-1} retronecine, or about 2–20 μg kg^{-1} PA in the food [15]. They do not provide the useful information on the relative proportions of PAs and PANOs.

2.5.5 Liquid Chromatography (LC)

High Performance Liquid Chromatography (HPLC, abbreviated to LC when used with MS) has a great advantage in allowing the simultaneous detection of PAs and PANOs without prior reduction of the oxides. Thus the procedure is simpler than for GC methods with fewer manipulations. Reverse phase columns are generally used and there is a gradual movement from HPLC to columns with a smaller particle size (<2 μm) which is referred to as UHPLC (Ultra High Performance Liquid Chromatography). UHPLC has a higher resolving power and sensitivity than

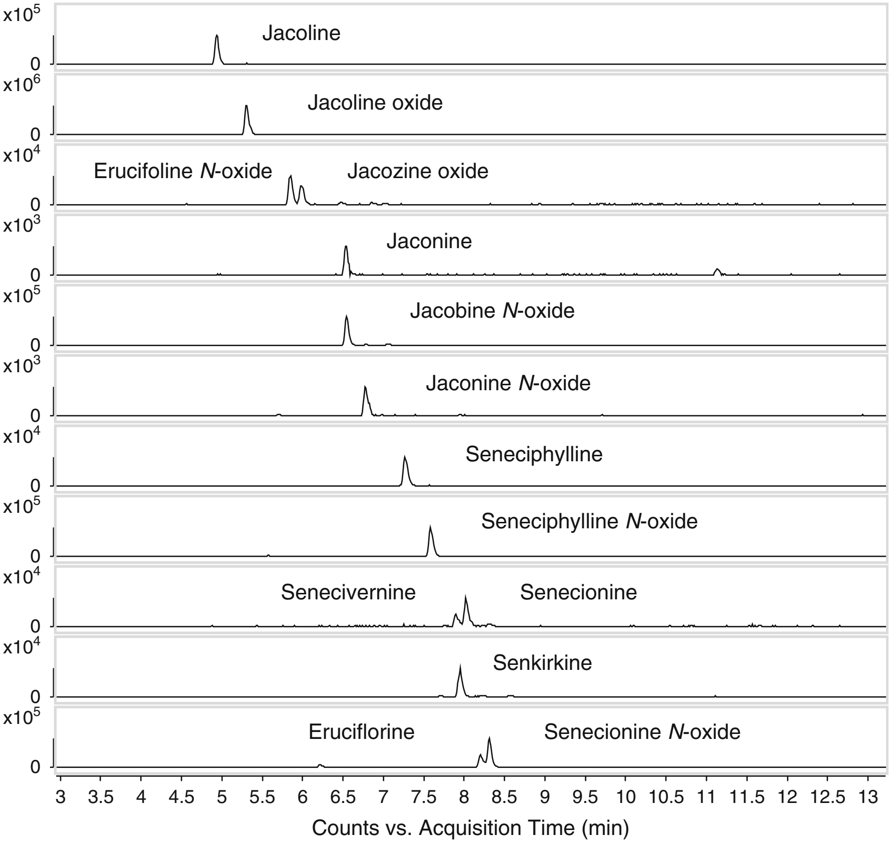

Fig. 32.1 Separation of ragwort PAs using UHPLC with LC- Time of Flight mass spectrometry

HPLC and retention times and correspondingly analysis duration are therefore much reduced [20, 26, 41].

The resolving power of LC-MS methods is not good enough to separate the many stereoisomers having the lycopsamine structure, including lycopsamine, echinatine, indicine, intermedine, and rinderine; or the stereoisomers of symphytine and symlandine. Figure 32.1 shows the elution of the major ragwort PAs using UHPLC with Time of Flight mass spectrometry.

Primary solvents of water, methanol and acetonitrile modified with acids (formic or acetic acid) or bases (ammonium hydroxide or diethylamine) have been most widely used. With acid solvents the PA tertiary alkaloids elute before their PANOs, whereas in basic conditions this order is reversed. Basic solvents at high pH (10–11) often give good peak shapes but at the expense of longer retention times. Peak shapes are however also good with acid solvents and retention times are shorter [42].

PAs have a non-specific UV absorption maximum of 214–220 nm and so simple UV detection has not been used very frequently. It has been applied to best effect in the purification of PAs, such as in the separation of the isomers intermedine and lycopsamine [43, 44].

Separation of tertiary PAs and of PANOs has been carried out on a C8 HPLC column with the aid of ion pairing with hexanesulfonic acid and detection by UV [7], but this approach has not been widely adopted, partly because the ion pair reagents are non-volatile and cannot be used with LC-MS. Some extracts have been analyzed with minimal clean-up simplified and less elaborate protocols [45]. Simple dilution and filtration of extracts and filtration can reduce matrix effects in LC-MS methods and the lack of coeluting compounds improves the background signal and the signal to noise ratio, therefore the sensitivity.

2.5.6 Liquid Chromatography- Mass Spectrometry LC-MS

LC-MS and LC-MS/MS methods have become the most popular approaches to the identification and quantification of PAs and PANOs as they combine reliability and high sensitivity with ease of sample preparation, and good data can be obtained for both tertiary alkaloids and PANOs as thermal decomposition is avoided. A range of mass spectrometer types have been used including ion traps, triple quadrupoles, and time of flight instruments. High sensitivity is provided by the ease with which the ring nitrogen is ionized in positive electrospray ionisation modes.

Ionisation methods investigated earlier, including thermospray, fast atom bombardment, and particle beam interfaces have been replaced by electrospray ionization (ESI) interfaces. Atmospheric pressure chemical ionisation (APCI) has also been applied but is less sensitive towards the PANOs. A combination of ESI with reversed-phase HPLC using acid mobile phases to protonate the PA molecules has most often been used [41].

Fragmentation is limited in single-stage LC–MS. This is a problem for the analysis of the many PAs that have the same empirical formula and are structurally similar, especially where authentic standards are not available to check the retention times and confirm peak identification. This drawback can be overcome for many PAs by the use of LC-MS/MS.

High resolution Time-Of-Flight (TOF) MS gives protonated molecular ions of most PAs with very high mass accuracy. This allows the determination of empirical sum formulae and easy searching for PAs using databases from empirical formulae with accurately calculated masses. Although less sensitive than LC-MS/MS methods, spectra are obtained for all ionizable compounds and the raw data can be searched retrospectively.

The limit of quantification (LOQ) for the individual PAs and their PANOs in dried plant material extracted with aqueous formic acid analyzed by LC-MS without SPE clean-up was between 0.2 and 0.5 mg kg^{-1} [5].

2.5.7 Liquid Chromatography- Tandem Mass Spectrometry LC-MS/MS

In LC-MS/MS methods collision-induced dissociation (CID) of the PA molecular ion provides fragment ions that can be used in single reaction monitoring (SRM), or multiple reaction monitoring (MRM). CID produces characteristic ions at m/z 94, 120 and 138 for 1,2-unsaturated retronecine base PAs and ions at m/z 122, 150 and 168 for 1,2-unsaturated otonecine-type PAs, which have an additional oxygen atom. Saturated ring platynecine-type PAs have characteristic fragment ions at m/z 122 and 140.

The retronecine PANOs have characteristic ions at m/z 118, 136, and 154. PANOs can form dimers in certain ESI interfaces which are not observed in the mass spectra of their precursor PAs [10].

MRM of the transitions from the protonated molecular ion to the fragments described above gives the highest sensitivity and specificity in PA analysis and has become a preferred method in recent years [15, 26, 27, 41]. The use of precursor ion scans can detect PAs in samples and give molecular weight information where the identity of the alkaloids is unknown. In this mode the (unknown) protonated molecular ion from which a known fragment ion is derived can be identified, indicating the molecular mass of the parent compound. LC-MS/MS measurements are conveniently carried out using ion-trap instruments, which have the capability for multiple dissociation experiments (MSn) and sensitivity in full scan mode. Certain TOF instruments also have a collision sector enabling high resolution detection of both parent and fragment ions. LC-MS/MS methods typically have LODs of 1–3 μg kg^{-1} for the common PAs.

Screening and quantification have been carried out simultaneously by LC-MS/MS with MRM of the characteristic fragment ions of 1,2-unsaturated PAs, which allows the detection and quantification of both known or targeted PAs and unknown ones in a single run [26]. The method had LOQs for the MRM approach of 0.8–36 pg ml^{-1} for standard solutions. UHPLC-MS/MS methods applied to *Senecio* plant material, including hay and silage typically can achieve a LOD of 3–10 μg kg^{-1} and a LOQ of 10–30 μg kg^{-1} [46].

2.6 Quantification

There are a very large number of PAs in the plant kingdom that can potentially contaminate feed and food. Although many are very minor components their determination is useful in plant classification. A considerable number of PAs that occur in sufficient quantity to be important in human and animal health and their determination has been recognized as a priority. These target PAs can be identified as senecionine, seneciphylline, jacobine, jaconine, jacoline and jacozine, erucifoline and acetylerucifoline (and their *N*-oxides) derived from ragwort and its relatives; lycopsamine/intermedine, acetyllycopsamine/acetylintermedine, symphytine, echimidine and their PANOs, derived from comfrey and *Echium.*

Certified pure reference standards are essential for accurate quantitation, particularly in LC-MS and LC-MS/MS. Standards of monocrotaline and retrorsine have long been commercially available at relatively low cost. The poor availability of most other PAs has handicapped identification of sample extracts and made quantification less accurate than desired. Additional PA standards are now becoming available in quantities of a few milligrams but are expensive. These include senecionine, seneciphylline and their oxides and lycopsamine. The PANOs are less easy to procure but can be synthesized from the tertiary alkaloid by oxidation with hydrogen peroxide or *m*-chloroperbenzoic acid [47] if loss of some material is tolerated. The isolation of bulk mixtures of PAs from plant material in quite high quantity is simple, as is the removal of non-PA material, but the separation of individual PAs on preparative scale is challenging. Quantities of a few mg of some PAs has been achieved with countercurrent chromatography.

In the absence of full sets of standards PA concentrations in food or plant samples can be estimated from calibration curves constructed from one or a few available PAs, or less frequently PANOs. Other PAs can be measured against these external standards and described in terms of equivalents of the standard alkaloid. This approach is compromised without correction for the different response factors. In GC-MS the quantification of PAs against a different external standard is possible using flame ionization detection, although response factors differ between open-chain and cyclic esters, and the use of nitrogen specific detectors is preferred.

Stable isotope labeled internal standards are used in most quantitative chemical investigations but no suitable standards are yet available for PAs, although radiolabeled and deuterium labeled PAs have been prepared for tracer studies by culture of PA-synthesizing plants in media containing labeled putrescine precursors [16]. In the absence of labeled internal standards, PAs that are believed not to occur in the plant or food sample have been used, including monocrotaline [41], heliotrine [5, 17], and (for *Echium* PAs) senecionine [24]. As a safety factor in this approach duplicate analyses with and without the presence of the internal standard, can confirm its absence in the native sample. A major problem associated with the lack of stable isotope labeled standards is that their use offers the best solution to the problem of matrix effects in LC-MS, in which the analyte signal is increased or more usually suppressed by coeluting compounds in the sample extract. Matrix effects can be overcome by quantification by the standard additions procedure where a calibration line is plotted by analyzing samples with different levels of added PA calibrants, or by the use of extracts of a non-PA containing plant as a medium for the calibration standards, for which purpose tansy (*Tanacetum vulgare*) has been used [20].

For the summation methods a single standard compound is required as a calibrant, and for internal standardization in the absence of a stable isotope labeled PAs, a base compound of a different structure is needed. To determine retronecine, heliotrine can be used.

2.7 Other Methods

2.7.1 Colorimetry

PAs give color reactions with numerous reagents typically applied to the detection of alkaloids. These methods have been developed to detect 1,2-unsaturated PAs and PANOs [30]. Tertiary PAs are oxidized to their PANOs, dehydrogenated to pyrroles with aqueous nitroprusside and coupled with Ehrlich’s reagent (4-dimethylaminobenzaldehyde) forming a red-violet colored dye that absorbs at 563 nm. Tertiary PAs plants are detected with *ortho*-chloranil followed by Ehrlich’s reagent. The reagent only reacts with unsaturated pyrrole rings and is therefore quite specific for PAs. The protonated PAs also give colored products on reaction with methyl orange, although this reaction is not specific to PAs.

2.7.2 Nuclear Magnetic Resonance (NMR)

NMR methods have been applied to PA analysis mainly for structural identification and identity confirmation of novel PAs [48–51]. A comprehensive review is available [48]. Proton NMR gives qualitative information more rapidly and from a smaller sample than C-13 NMR, whilst the latter gives more structural information. The necine base induces distinctive proton shifts showing the unsaturation and oxygenation of the PA molecule. Proton shifts due to the necic acid are less distinctive as the acids do not differ sufficiently in structure. Modern high-field NMR have much better performance characteristics, and linked with metabolomics can identify PAs in plant extracts [52].

2.7.3 UV–Visible Spectroscopic Methods

In spectroscopic methods Erlich’s reagent has been used with spectrophotometric detection to measure PAs quantitatively in wheat and flour. An alternative approach is to use aqueous methyl orange, which forms a yellow complex that is very soluble in organic solvents. Methyl orange can be released from the organic solution on treatment with strong acid, and measured with a spectrometer. These methods are not able to quantify individual PAs but allow determination of the total unsaturated PA content by construction of calibration series using the readily available standards such as monocrotaline and retrorsine.

2.7.4 Immunological Methods

The application of immunoassays to PA determination is relatively infrequent, the status last being reviewed in 2001 [53]. The technique is handicapped by the presence of some cross-reactivity precluding the easy detection of target PAs but more importantly a limitation to the degree of cross reactivity that prevents application to general screening. There is also cross-reactivity between the PANO and tertiary alkaloid forms. Sensitive quantitative ELISA techniques for detecting retrorsine and monocrotaline produced from immunogens based on quaternary pyrrolizidinium salts have shown variable cross reactivity to other PAs.

Antibodies raised to a retrorsine hemisuccinate-BSA conjugate have been used to determine total alkaloids including PANOs in reduced *Senecio* extracts [54]. Antibodies to a conjugate between the retronecine part of PAs and bovine serum albumin (BSA) detected retronecine and monocrotaline [55]. Antibodies that are specific to monocrotaline but which did not cross-react with retrorsine, retrorsine-*N*-oxide, riddelliine or retronecine have been reported [56]. Antibodies prepared to date react only to PAs that have related 12-membered macrocyclic structures closely related PAs but not to open chain or 11- or 13 membered macrocyclic PAs [57]. Polyclonal antibodies with a high specificity towards retrorsine, monocrotaline or retronecine were developed from immunogens based on ‘quaternary pyrrolizidinium salts linked to BSA or chicken egg ovalbumin [58].

Antibodies have been produced to both retronecine and monocrotaline and detected using an avidin-biotin antibody. Retronecine was obtained from the hydrolysis of monocrotaline, succinylated and coupled to bovine serum albumin or ovalbumin. Recently an ELISA lateral flow device (dipstick test) based on gold colloidal polyclonal antibodies has been developed for jacobine and lycopsamine in honey and animal feed [59].

2.7.5 Capillary Electrophoresis (CE)

CE has had only a few applications to PA determination, and reports of its performance have been mixed [6, 60]. Resolution if good when the concentrations of solvent and modifiers (buffer, sodium dodecyl sulfate, and methanol) have been optimized. The sensitivity has been improved by the use of preconcentration techniques.

3 Conclusion

Almost all methods for the determination of PAs and PANOs have complicated sample preparation stages. They require care and practice and a good understanding of the chemistry of the alkaloids and the extraction and clean-up procedures.

Qualitative screening methods can be based on colorimetry, TLC, or ELISA. They are suitable for analysis of fresh plant material containing relatively high levels of PAs, but they are not generally sufficiently sensitive or selective for quantification of PAs present at low levels. NMR methods are similarly not sensitive enough to determine the low levels of PAs in many food samples.

LC-MS and LC-MS/MS methods are much more suitable, combining a wide scope including PAs and PANOs of varying structures, with sensitivity, the ability to obtain confirmation of results, and reliable quantification at low level. GC-MS and GC-NPD methods remain useful in studies where high resolution of very similar PAs is required, and for the determination of necines in the summation methods that are becoming increasingly popular. GC–MS and LC–MS methods for the analysis of PAs can supplement each other where detailed knowledge is required [23]. LC-MS/MS methods can now measure about 70 PAs (tertiary bases and PANOs) encompassing monoesters, diesters and macrocyclic diesters, and the major PAs of interest in all of the more important plant families that produce them [46].

All methods are hindered by the poor availability of PA reference standards, the lack of interlaboratory validation of methods and proficiency tests, and the lack of certified reference materials.

Abstract

The control of drugs is an important task and will continue to be the subject of many publications. Many drugs have medical uses but a great number have recreational purposes with significant health risks which makes necessary both national and international control. While drugs remain controlled, it will be necessary, within the legal context, for the forensic scientist to carry out their analysis.

Among the numerous families of drugs, in this chapter, we have focused our attention on the most widely used methods of analysis found in the literature for the determination of six of the major alkaloids of the poppy plant (*Papaver somniferum*) named morphine, codeine, thebaine, papaverine, narcotine, and narceine. The choice of method will depend on the resources and equipment available to the analyst in the forensic laboratories, the legislative system in which the analyst is working, and the different forensic samples where

the analysis of these substances needs to be carried out. Many techniques are already available for the quantification of opiates and their derivatives. Most of them employ separation techniques, such as gas chromatography (GC) and high performance liquid chromatography (HPLC), with a great variety of detection methods, especially mass spectrometry (MS). More recently, capillary electrophoresis (CE) mostly coupled with MS is being an attractive alternative for the analysis of numerous drugs of abuse in samples of forensic interest.

1 Introduction

Natural products and their derivatives have been a valuable source of therapeutic agents throughout history. The alkaloids of the poppy plant (*Papaver somniferum*) are important natural products [1, 2] from which more than 40 active chemicals could be extracted. They fall into general categories, each producing much different effects. The six opium alkaloids which occur naturally in the largest amounts are morphine, codeine, thebaine, papaverine, narcotine, and narceine.

In relation to their chemical structure and action, they can be classified into two categories. The first are phenanthrene alkaloids and are under international control: morphine (MO), codeine (COD), and thebaine (TB), which act on the central nervous system and are used as analgesics, narcotics, and potentially addicting compounds (pain relievers). Heroin is synthesized from MO. The second group is isoquinoline alkaloids: Papaverine (PV) and narcotine (also known as noscapine). Narcotine acts only to relax involuntary smooth muscles, for which it is considered an antitussive, and lacks addictive, analgesic, respiratory, narcotic, depressant, and sedative properties. Next to MO, which constitute about 10% by weight of raw opium, is the second most abundant alkaloid present in opium. The three last alkaloids (PV, narcotine, and narceine) are not under international control; specially, narcotine and narceine which have scarcely any medical or other uses. Consequently, the five economically significant alkaloids of opium are MO, COD, TB, PV, and narcotine.

Being contraband substances, the detection and identification of trace amounts of opium alkaloids in various samples including gum opium and many other biological samples of considerable health and forensic importance (urine, blood, hair) is a major analytical issue. Nowadays, many techniques are already available for the quantification of opiates and their derivatives [3]. As an example, Pothier and Galand have recently investigated the analysis of opium alkaloids still using thin-layer chromatography (TLC) [4] but numerous more sophisticated and sensitive separation techniques are the most used in this type of analysis. These include gas chromatography (GC) [5, 6], high performance liquid chromatography (HPLC) [7], and capillary electrophoresis (CE) [8]. Most of these methods can be applied for the analysis of the major opium alkaloids avoiding most of the important problems associated with the analysis of these compounds, such as the separation between them and matrix constituents.

GC is the method of choice for bioanalysis of opium alkaloids [9, 10], but for the analysis of plant extracts it may be less convenient due to the many less volatile substances co-extracted [11]. The major constrain of the GC methods is the commonly used prior derivatization of the analytes in order to volatilize them, avoid broadening of the peaks in order to achieve easier quantification. This makes the sample preparation complex and increases the costs for the GC method. The coupling GC-MS is often used because of its sensitivity, but the necessity of sample derivatization and the cost of the technique itself are restricting its applicability.

On the other hand, HPLC appears as a technique that could separate a wide range of analytes without any chemical pretreatment. As such, it has become the preferred technique in most applications, using a variety of detection methods [12, 13]. Reflecting the large polarity range of the major opium alkaloids, most applications apply reversed-phase liquid chromatography with gradient elution and ion-pairing agent. Such methods can be very sensitive to minor changes in chromatographic conditions, contributing to prolonged duration of analysis, and narrow the column lifetime [14].

In recent years, CE has emerged as a promising technique with great potential for separation and analysis of anionic, cationic, and neutral organic molecules but since the first applications reported for the separation of opium alkaloids in opium tincture [15, 16], there has been quite little progress with respect to the other separation techniques previously mentioned. Nevertheless, the methodology most widely used, capillary zone electrophoresis (CZE) with UV detection, together with different preconcentration procedures, present similar sensitivity compared to the earlier reported chromatographic methods, such as GC and HPLC and are comparable to that of radioimmunoassay [17] having the advantage over HPLC wherein peak asymmetry and poor resolution was observed, while derivatizations of alkaloids are necessary for GC analysis. For such a reason, the CE methodologies may find application for the routine analysis of the six major alkaloids present in gum opium samples and biological samples of forensic importance.

2 Methods of Analysis

2.1 Analysis of Opium Alkaloids by Gas Chromatography

GC uses a gaseous mobile phase to transport sample components through either packed columns or hollow capillary columns containing the stationary phase. In most cases, GC columns have smaller internal diameter and are longer than HPLC columns. In GC analytes, samples must be volatile although derivatization can be applied to increase volatility. The most usual carrier gases are inert such as helium, argon, hydrogen, and nitrogen, depending in part on the detector and having weak intermolecular interactions with solutes. The gas can be fed through a molecular sieve to remove trace of water.

Separation columns are placed inside the oven to control temperature and can be produced from stainless steel, glass, or mainly fused silica tubes, coated with a sheath of polyimide, which provides a protective layer and allows a maximum operating temperature of around 360°C. It is possible to distinguish between packed columns and open tubular or capillary columns. Packed GC columns are typically manufactured from glass or stainless steel. They are packed with pellicular silica particles (typically between 30/40 mesh and 100/120 mesh) onto which the stationary phase is coated. The smaller the particle size the higher the column efficiency. A typical packed GC column will be between 2 and 4 m in length with an internal diameter of between 2 and 4 mm and with efficiencies in the order of 1,000–2,000 plates per meter. Today, the most part of GC applications are developed by using capillary columns. Open tubular capillary columns consist of a long narrow tube of silica coated on the inside surface with a very thin film of immobilized polymeric liquid, gum, particulate, or zeolite stationary phase. These columns are known as wall-coated open-tubular columns (WCOT) and provide the highest resolution and efficiency (usually in the order of 3,000–5,000 plates per meter). This is mainly due to the length and homogeneously thin stationary phase films that can be achieved with capillary column technology. Fused silica is the most popular material of construction for WCOT (capillary) columns as it is flexible, inert, and produces very high efficiency columns. The inner surface of fused silica tubing is chemically treated to minimize interactions of the sample with the tubing. The reagents and process used depend on the type of stationary phase being coated onto the tubing. A silylation process is used for most columns. The selection of the correct stationary phase is one of the most critical parameters in GC separations. As the interaction of the analyte molecules with the mobile phase is almost negligible, the column temperature and the interaction of the analyte with the stationary phase will govern the selectivity of the separation. A wide variety of liquid stationary phases have been employed for different applications in GC in the field of forensic analysis, being polysiloxanes the most common ones, because they are stable, robust, and versatile. Standard polysiloxanes are characterized by the repeating siloxane backbone. Each silicon atom contains two functional groups, and the type and amount of the groups distinguish each stationary phase and its properties.

Temperature is one of the two most important variables in GC and affects the retention capacity (k), selectivity (α) and, to a lesser extent, the efficiency (N) of the separations. Two modes of operation can be considered in relation to oven column temperature changes during the analysis: isothermal or gradient temperature GC. In isothermal GC, the temperature of the GC oven and the column remains constant during the course of the analysis, being adequate for the analysis of compounds whose boiling points do not differ significantly. In this mode, when analytes differ significantly in relation to retention behavior, to achieve a reasonable analysis time, a fairly high temperature has to be used. This has the disadvantage that poorly retained analytes elute with very low capacity and the separation cannot be so adequate. In temperature programming or gradient temperature programmed mode, the oven starts at a low temperature to assist with the separation of early eluting peaks, is then ramped and usually held for a specified time at an upper temperature. The well-resolved, highly volatile solutes are removed from the column at the lower temperatures before the compounds of low volatility leave the origin at the column inlet. This mode allows the analytes with significant differences in boiling point to elute within a reasonable time frame and to be sure that all analytes have eluted from the column. An important advantage is that all peaks elute with approximately the same width.

GC detectors respond to a physicochemical property of the analyte, amplify this response, and generate an electronic signal for the data system to produce a chromatogram. Many different types exist and the choice is based mainly on nature of analytes and required sensitivity. There are different detectors commonly used in drugs analysis: flame ionization (FID), electron capture (ECD), flame photometric (FPD), nitrogen-phosphorous (NPD), and MS detectors; the two last options being the most widely used. GC techniques produce fast analyses because of the highly efficient nature of the separations and by using a combination of oven temperature and stationary phase chemistry very difficult separations can be solved, being excellent for quantitative analysis of volatile compounds, mainly in combination with MS detectors for quantification and identification purposes. In fact, GC–MS is the long-accepted standard technique in confirmatory analytical methodologies for drug of abuse. GC–MS using EI ionization mode is the most widely used technique in drug of abuse analysis in biological matrixes, mainly urine. EI mode leads to a number of fragment ions providing more structural information. In addition, it allows identification of unknown compounds by comparison of their mass spectrum with reference mass spectra in commercially available libraries. However, due to the extensive fragmentation in the EI mode, the chemical ionization (CI) mode could provide more selectivity as this technique often gives molecular mass information. In addition, the sensitivity can be improved through the use of negative ion chemical ionization (NICI) ionization analytical methods. Both modes can be integrated as a multiple ionization mode approach of GC–MS, and this possibility has been applied in the simultaneous hair testing of common drugs of abuse, including opiates [18].

In GC, derivatization is usually performed after preconcentration and cleanup of the extracts. In order to decrease the polarity and increase the volatility of the analytes, derivatization of drugs of abuse and their metabolites prior to GC–MS analysis is required. The main requirements for a successful derivatization reaction are as follows: a single derivative should be formed for each compound; the derivatization reaction should be simple and rapid, and should occur under mild conditions; the derivative should be formed with a high and reproducible yield and should be stable in the reaction medium; in quantitative analyses the calibration curve should be linear [19]. Application of derivatization methods in recent years has been relevant, especially for silylation, acylation, alkylation, and the formation of cyclic or diastereomeric derivatives. The most common silylation procedure is trimethylsilylation. Higher alkyl homologs or halogen-containing analogs have been used to increase hydrolytic stability of the derivative, to improve detectability with some particular detectors, to improve resolution, or to obtain mass spectra of higher diagnostic value [20]. Trimethylsilyl (TMS) derivatives combine thermal and chemical stability and high volatility. They are easy to prepare, and show excellent GC behavior. A variety of trimethylsilylating reagents with different properties (such as volatility, reactivity, selectivity, by-product formation, etc.) have been developed including tri-methylhalosilanes [20]. The TMS amides, *N*,*O*-bis (trimethylsilyl)trifluoroacetamide (BSTFA) and *N*-Methyl-*N*-(trimethylsilyl) trifluoroacetamide (MSTFA) are the most commonly employed silylating reagents in analytical determination of opiates [19]. The addition of a catalyst has been used to increase the silylating power of these reagents to derivatize sterically hindered functions or to enhance reaction rates, TMCS being one of the most usual. BSTFA with 1% TMCS as a catalyst has been widely used to analyze drugs of abuse and their metabolites. Acylation is another commonly used derivatization method in GC–MS. It consists of the introduction of an acyl group in a molecule holding a reactive hydrogen. Acylated derivatives can be obtained from a great variety of functional groups. Acylation reactions can be performed using three main types of reagents:

acyl halides, acid anhydrides, or reactive acyl derivatives such as acylated imidazoles [19]. Haloalkylacyl derivatives are the most popular acyl derivatives. These derivatives increase the electron affinity of the compounds and make possible highly sensitive analyses using NCI-MS. Perfluoroacyl derivatives, including heptafluorobutyric acid anhydride (HFBA), are the most widely used in practice.

MDGC and especially comprehensive two-dimensional gas chromatography (GC × GC) is a recent trend that has advantages over classic one-dimensional GC in many areas of analysis by offering improved peak capacity, often enhanced sensitivity and, especially in the case of GC × GC, the unique feature of "structured" chromatograms. A recent paper reviews recent advances in MDGC and GC × GC in drug analysis with special focus on ecstasy, heroin, and cocaine profiling [21].

2.1.1 Main Applications of GC to the Analysis of Opium Alkaloids

Table 33.1 shows selected and relative recent applications of GC in the monitoring of opiates in different matrices, including sample treatments, derivatization procedures, detection modes, and sensitivity.

Blood and urine as the most important samples in forensic analysis by using GC. The differentiation between legal and illegal opiate product use through the detection of marker compounds in urine is one of the most important subjects in forensic toxicology. As example, TB can be detected by GC-MS and has been suggested as a good urinary marker of poppy seeds use in differentiation from that of illicit heroin. Although TB lacks the conventional functional group, it was found to form a trimethylsilyl derivative making possible to simultaneously detect TB together with MO and COD in the same urine sample to confirm opium use, thus saving time and cost of analysis [25].

There are other possibilities for monitoring drug of abuse, and specifically opiates. For example, oral fluids, which has some advantages such as its collection is easy and noninvasive and there is a lower risk of infection than in drawing blood, being sample volumes smaller. Also samples can be collected under supervision making more difficult to adulteration. Detection times of drugs in oral fluids (5–48 h) are similar to that in blood (1–2 days) whereas the detection times in urine can be much longer, from a couple of days up to 3 months. Due to short detection times, this is a feasible matrix for confirmation analysis of driving under the influence of drugs cases. However, some common habits, such as smoking or using mouthwash, and also some drugs or diseases may reduce salivation, limiting the sample volume available for analysis. Recently, this sample has been used for analysis of 50 drugs of abuse including opioids by GC-MS (COD, MO, 6-MAM) [41].

Other different sample is vitreous humor, a biological fluid frequently used in postmortem toxicological analysis since all substances present in blood are also present. This matrix is relatively protected from postmortem degradation and contamination and its analysis can provide information in those cases where other biological samples have suffered extensive chemical changes during the postmortem interval. This sample has been analyzed by GC-MS for controlling

Table 33.1 Selected applications of GC for the analysis of opiates in different matrices

Analytes	Sample/Preparation	Derivatives	Method characteristics	Sensitivity	References
COD, MO, 6- MAM	Oral fluid Extraction at pH 6 with Toxitube A	BSTFA + 1% TMCS (100°C for 20 min)	GC-PCI-MS (capillary column 12 m × 200 mm i. d, 0.33 mm thick film of 5% phenylmethylsiloxane) SIM	LOD: 0.7 ng/mL (COD), 2.0 ng/mL (MO), 0.6 ng/mL (6-MAM)	[22]
Opiates (COD, MO, 6-MAM) cocaine, benzoylecgonine	Hair Enzymatic hydrolysis overnight at 37°C: DTT + Pronase E in Tris–HCl (pH 7.2). SPE at pH 9.2 (Oasis HLB)	BSTFA + 1% TMCS (100°C for 20 min)	GC-EI-MS (HP-5 capillary column 30 m × 250 mm i.d.,5% phenylmethylsiloxane, film thickness 0.25 mm) SIM	LOD : 0.02 μg/g (COD), 0.04 μg/g (MO), 0.05 μg/g (6-MAM)	[23]
Opiates (MO and COD) and cocaine and its metabolites	Pericardial fluid Enzymatic hydrolysis at pH 5.2. SPE at pH 9.0 (Bond-Elut)	MSTFA (60°C for 10 min)	GC-EI-MS HP-Ultra 1 capillary column (cross-linked methylsilicone, 0.2 mm × 25 m) SIM	Low ng/mL levels	[24]
TB, MO and COD	Urine Enzymatic hydrolysis and extraction with Toxi-A Tube	BSTFA + 1% TMCS	GC-EI-MS	LOD: several nanograms on-column	[25]
MO, dihydrocodeine, COD, 6-MAM and other drugs	Urine Enzymatic hydrolysis at pH 5 and extraction with diethyl ether: chloroform (4:1)	PFPA + PFPOH (70°C for 40 min)	GC-MS (HP-5MS capillary column 30 m × 0.25 mm i.d., 0.25 μm film thickness) SIM	LOD: 250 ng/mL (MO), 50 ng/mL (MO, dihydrocodeine, 6-MAM)	[26]
COD, MO, 6-MAM, cocaine, benzoylecgonine	Meconium Extraction with MeOH and SPE at pH 9.2 (Oasis HLB)	BSTFA + 1% TMCS (100°C for 20 min)	GC-EI-MS (HP-5 capillary column 30 m × 250 μm i.d. with film thickness 0.25 μm) SIM	LOD: 30 ng/g (COD), 20 ng/g (MO, 6-MAM)	[27]
Opiates (MO, 6-MAM, dihydrocodeine, COD) and other drugs	Hair 0.1 M HCl (50°C overnight) and SPE (Bakerbond Narc-2 mixed-mode)	MSTFA + 1% TCMS (80°C for 1 h) + MBTFA (80°C for 30 min)	GC-EI-MS (capillary column Zebron ZB-5, 30 m × 0.25 mm i.d. × 0.25 μm d.f.) SIM	LOQ : 10 ng for all the opiates	[28]

COD, MO, 6-MAM and other drugs	Hair Ultrasound assisted enzymatic hydrolysis: DTT + Pronase E in Tris–HCl (pH 7.3). Sonication (30°C for 30 min). SPE at pH 9.2 (Oasis HLB)	BSTFA + 1% TMCS (100°C for 20 min)	GC-EI-MS (HP-5 capillary column (30 m × 0.22-mm i.d., 0.33-μm film thickness of cross-linked 5% phenyl methyl silicone)	LOD: 0.02 μg/g (COD), 0.04 μg/g (MO), 0.05 μg/g (6-MAM)	[29]
Opiates (MO, COD, 6-MAM), amphetamines, ketamine and metabolites	Hair Incubation overnight at 25°C in methanol/TFA SPE (Bond Elut)	HFBA (70°C for 30 min)	GC-EI-MS and GC-NCI-MS (HP-5MS, capillary column 5% phenyl methyl siloxane, 30 m × 0.25 mm i.d., 0.25 μm film thickness)	LOD: 2 pg/mg (MO and COD), 10 pg/mg (6-MAM)	[18]
Multianalyte (150 components controlled in doping) including MO, 6-MAM, ethylmorphine, and diacetylmorphine	Urine Enzymatic hydrolysis at pH 7 and extraction with diethyl ether and tert-butyl methyl ether at pH 9.5 and 14, respectively	MSTFA/NH_4I/ ethanethiol (640/1/2; v/w/v) (80°C for 1 m.)	GC-MS (J&W-Ultra 1 column, 17 m, 0.2 mm i.d., and 0.11 μm film thickness), SIM/full scan (screening method)	Linear range (MO): 250–2000 ng/mL	[30]
Opiates (MO, COD, 6-MAM), amphetamines, ketamine	Hair Incubation with methanol/TFA (9:1) overnight at 45°C. Extract with phosphate buffer at pH 6.0 and SPE (Bond Elut) eluting with a dichloromethane/isopropanol/ ammonium hydroxide (80:20:2, v/v/v)	HFBA (70°C for 30 min) and BSTFA (90°C for 20 min)	GC-EI-MS (HP-5MS capillary column, 5% phenyl methyl siloxane, 30 m × 0.25 mm i.d., 0.25 μm film thickness), SIM	LOD: 0.05 ng/mg (MO, COD), 0.08 ng/mg (6-MAM)	[31]
COD, MO, 6-MAM, 6-AC and other drugs and metabolites	Sweat Extraction from patches with 0.5 M acetate buffer (pH 4.0). SPE elution with methylene chloride:2-propanol:ammonium hydroxide (78/20/2, v/v/v)	BSTFA + 1% TMCS (60°C for 20 min)	GC-MS (HP-5MS capillary column (30 m × 0.32 mm i.d., 0.25 μm film thickness), SIM	LOD : 1.25 ng/patch (COD, MO), 2.5 ng/patch (6-MAM), 5 ng/patch (6-AC)	[32]

Table 33.1 (continued)

Analytes	Sample/Preparation	Derivatives	Method characteristics	Sensitivity	References
COD, MO and other drugs of abuse	Serum LLE	MSTFA	GC-MS (screening method)	LOQ: 0.025 μg/mL	[33]
COD and other anesthetic and analgesic drugs	Urine HS-SPME (fibers: 100 μm bonded PDMS, 85 μm PA)	non	GC-NPD	LOD: 1.5 ng/mL (COD)	[34]
COD, MO, 6-MAM, cocaine, benzoylecgonine	Meconium Extraction with MeOH and SPE at pH 6 (Bond Elut)	BSTFA + 1% TMCS (100°C for 20 min)	GC-EI-MS (HP-5 column 30 m × 250 μm, 0.25 μm film thickness), SIM	LOD: 5 ng/g (COD), 10 ng/g (MO and 6-MAM)	[35]
Multianalyte (128 compounds) including TB	Urine SPE	BSTFA + 1% TMCS	GC-EI-MS (screening method)	nr	[36]
COD, MO, and 6-MAM	Hair HS-SPME (fibers: 100 μm bonded PDMS, 85 μm PA)	BSTFA + 1% TMCS	GC-EI-MS (capillary column 30 m, 0.25 mm, i.d. 0.25 film thickness). Full scan	LOD: 0.002 ng/g (COD), 0.005 ng/g (MO, 6-MAM)	[37]
MO and other drugs	Adipose tissue HCl (1 h.). Extraction of the aqueous phase at pH 10–11 with SPE (Extrelut® NT3)	BSTFA (70°C for 20 min)	GC-MS (capillary column EVDX-5MS 5% PH ME Siloxane, 12.5 m × 0.20 mm i.d., 0.33-μm, film thickness). Full scan	LOD: 0.010 μg/g (MO)	[38]

MO, COD, and dihydrocodeine	Urine, serum Monolithic spin column	TMS	GC-MS	Linearity 10-2,500 ng/mL (urine) and 5-1,200 ng/mL (serum), LOD at ppb levels	[39]
MO, COD, and 6-MAM	Vitreous humor 25 mL HCl 0.1 M and 25 mL CH_3CN to precipitate collagen. Vortex and centrifugation. Disposable pipette extraction	MSTFA	GC-NPD	LOD: 0.50, 0.16, 1.25 μg/mL, respectively	[40]
50 drugs of abuse including opioids (codein, MO, 6-MAM)	Oral fluid LLE (3 mL BuAc) and SPE (Oasis MCX)	75% BuAc:MeCN 1:1 (v:v) + 25% MSTFA (80°C for 30 min)	GC-EI-MS	LOQ: 7 ng/mL (6-MAM), 59 ng/mL (codein), 12 ng/mL (MO)	[41]
Opiates (MO, COD, 6-MAM), tetrahydrocannabinol, cocaine, and analogs	Urine Enzymatic hydrolysis and LLE (3 mL mixture of chloroform/ isopropanol 9/1)	MSTFA + 1% TMCS (70°C for 20 min)	GC-MS (5% Ph Me silicone capillary column, 10 m length × 18 mm i.d)	LOD: 10 ng/mL (MO, COD, 6-MAM)	[42]
MO, 6-MAM, COD, 6-AC, tramadol	Hair Incubation with MeOH at 65°C and SPE (Oasis MCX)	MSTFA + 5% of TMCS (80°C for 25 min)	GC-EI-MS (capillary column 30 m × 0.25 mm i.d., 0.25 μm film thickness) with 5% phenylmethylsiloxane (HP-5 MS)	LOD: 0.05 ng/mg (all compounds)	[43]

heroin abuse [40], considering that heroin is quickly metabolized to 6-monoacethylmorphine (6-MAM), which is in turn de-acetylated to MO. The presence of 6-MAM is therefore a marker of heroin abuse and is often used to discriminate between heroin and MO exposure, since when MO is detected; one cannot know whether MO originates from heroin, COD, or MO itself. Since 6-MAM is rapidly converted to MO, it is regarded as an indicator of recent heroin intake. Because of its rapid conversion to MO, 6-MAM may not be present in detectable quantities in blood following heroin exposure. Nevertheless, it has been shown that 6-MAM persists in cerebrospinal fluid and vitreous humor and that these alternative specimens may be useful in proving heroin abuse.

In a similar way, pericardial fluid may be an alternative sample to blood for toxicological examinations in drug-related deaths. This body fluid is an ultrafiltrate of plasma with an extremely similar amount of proteins and is located within a tight compartment so that it is almost free of contamination by pathogens. The usual volume of 5–20 ml is enough for analytical purposes. In 2006, the first study reporting levels of drugs of abuse (opiates such as MO and COD, cocaine, and its related metabolites) in this body fluid was carried out by using GC-MS [24]. Also, several illicit drugs have the capability to be stored within the body for long time, being possible to use lipidic tissues. Postmortem adipose tissue can be used to detect absorbed drugs while living, provided that the drugs involved are highly lipophilic and bind to tissues. This is also an optimal sample in cases with extended postmortem time lag and whenever body fluids cannot be obtained, providing long-term information about an individual's drug use, which is especially useful when the history of drug abuse is not easily obtained. In 2010, the first extraction method for the detection of cocaine and metabolites, methadone, and MO was validated for this matrix, using GC-MS [38].

Over the past two decades, the use of hair in the field of toxicology has gained more and more relevance. This is due not only to the well-known advantages of this specimen over the more traditional blood or urine samples, for example, low invasiveness of the collection procedure, difficult adulteration, and wider detection window (months to years), but also to the evolution in chromatographic techniques. However, a difficulty in interpreting hair testing results is that the concentration of drugs in hair can be influenced by factors such as ethnic differences in hair pigmentation, more specifically, the natural melanin content in hair. Furthermore, it has been observed that drug concentration declines dramatically after cosmetic treatment (bleaching, dyeing, and permanent waving) as well as after UV exposure or exposure to water, soil, or natural weathering. One important issue regarding hair analysis for opiates is the real possibility of heroin or 6-acetylmorphine (6-AM) conversion to MO as an artifact, which is likely to occur under uncontrolled acidic or alkaline conditions. This spontaneous conversion would impair the reliable identification of heroin abuse, since the detection of 6-AM in hair is the definite proof of heroin consumption. This issue can also be dealt with if 6-acetylcodeine (6-AC), a specific marker of illicit heroin synthesis, is detected [44]. An application of this matrix was the qualitative and quantitative analysis of several opiates (MO, 6-MAM, COD, 6-AC) and tramadol [43]. The extracts were derivatized with

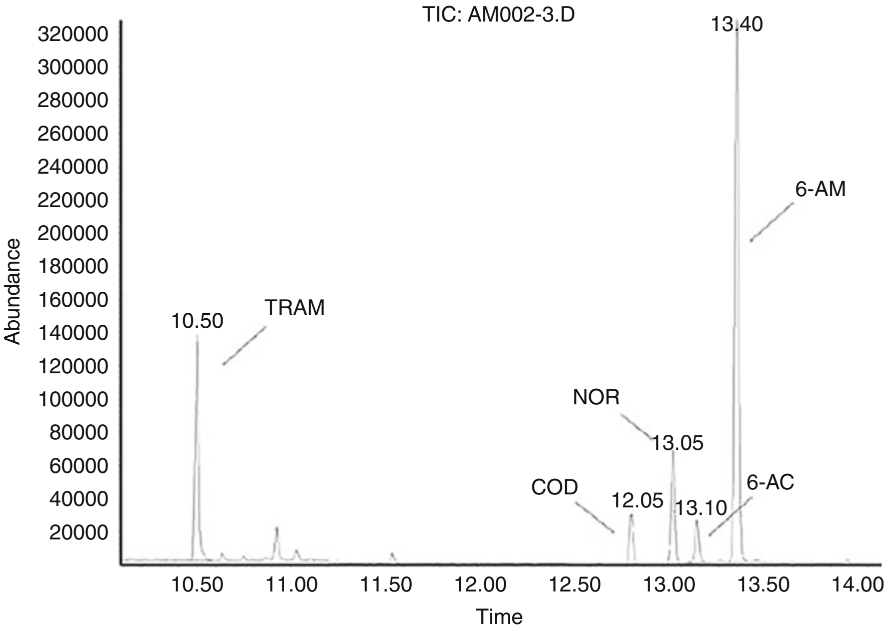

Fig. 33.1 Total ion chromatogram of an authentic hair sample (*TRAM*: 9.94 ng/mg; *COD*: 4.13 ng/mg; *MOR*: 20.45 ng/mg; *6-AC*: 15.38 ng/mg; *6-AM*: 102.45 ng/mg) (With permission, from Ref. [43])

MSTFA in presence of 5% TMCS and analyzed by GC-MS in the selected ion monitoring mode, accomplishing the cutoff values proposed by the society of hair testing (SHT) for the detection of these substances in hair (0.1 ng/mg). Figure 33.1 shows a total ion chromatogram of an authentic hair sample for the detection of these compounds.

Meconium is another important optimal matrix for identifying in uterus the consumption of toxic substances during pregnancy as it is considered to be static once deposited in the fetal intestine, thus being a preserved record of the ultimate exposure by the fetus [45]. In spite of increased sample preparation time relative to blood and urine, meconium's the long metabolite history, coupled with the ease and wide window of collection make meconium the ideal matrix for determining fetal drug use. A GC–MS method was proposed to analyze cocaine and opiates in meconium and validated according to internationally acceptance criteria, providing a wide window for the detection of fetal exposure to cocaine and opiates [35]. The analysis of meconium demonstrated the exposure to cocaine and COD during the last 20 weeks of gestation whereas urine was only able to prove that these drugs had been consumed in the last hours prior to birth.

Other alternative matrix in forensic analysis by GC is sweat. For this matrix, drug detection windows may be longer (up to 1–2 weeks) and sweat testing offers a cumulative picture of drug use over an extended time frame and noninvasive specimen collection. Another advantage includes a reduction in the potential for specimen adulteration; homeostatic mechanisms preclude the dilution (a method commonly used in urine testing to produce false negative results) of drug concentrations in sweat. As example, a method using GC-MS was validated for the simultaneous quantification of methadone, heroin, cocaine, and metabolites: 6-MAM, frequently encountered in sweat and also 6-AC and anhydroecgonine. 6-AC is an effective biomarker of illicit street heroin abuse for patients in pharmaceutical heroin treatment and although 6-AC is only present in small quantities in street heroin, its lipophilic nonpolar structure make it an interesting analyte to monitor in sweat [32].

2.1.2 Typical Sample Pretreatments Prior GC for the Analysis of Opium Alkaloids

For GC, the most part of reported methods have employed extraction protocols, typically liquid-liquid extraction (LLE) or solid phase extraction (SPE), which has become very popular in the pretreatment of forensic samples despite the fact that it requires relatively large volumes of solvents. SPE has several advantages over LLE: decreased solvent volumes, resulting in decreased solvent disposal costs; reduced operator time; high recovery of analytes; and low limits of detection and quantitation for the analytes. Most importantly, SPE yields clean extracts and minimizes the appearance of endogenous peaks, thereby increasing analyte sensitivity and specificity.

In recent years, solid-phase microextraction (SPME) offers an attractive alternative method for the sample preparation of biological samples. SPME integrates sampling, extraction, preconcentration and sample introduction in a simple single-step procedure. For the sampling and pretreatment of complex biological specimens, head-space (HS)-SPME provides a powerful tool especially for the extraction of volatile or semivolatile compounds [46]. Important parameters controlling SPME has to be studied: selection of SPME fiber, type and amount of salt added, preheating and extraction time, extraction temperature, sample volume, and desorption time. HS-SPME, in combination with GC-NPD, afforded a wide linear range, satisfactory detection sensitivity and repeatability for the analysis of COD and other anesthetics and analgesics in the form of the parent compounds rather than their metabolites, using directly urine samples [34]. The method was applied to the determination of the anesthetics and analgesics in human urine from patients that had undergone coronary bypass surgery operations. The proposed protocol can function as an attractive alternative for clinical acute intoxications and medicolegal cases.

Disposable pipette extraction (DPX) is a new approach in sample pretreatment, which has proved to be valuable in the analysis of drugs of abuse in biological matrices, such as urine and blood. DPX requires low-cost equipment and consumables and uses smaller volumes of samples and solvents, producing less waste. In contrast to SPE columns, DPX uses loosely packed sorbent and therefore does not require vacuum for elution. The sample is aspirated into the tip, where it is actively mixed with the sorbent to form a suspension. Furthermore, it minimizes the necessary conditioning steps and therefore speeds up the procedure of sample pretreatment being possible easy automation. This strategy has been performed for the monitoring of heroin abuse in postmortem samples such as vitreous humor by detecting MO, COD, and 6-MAM [40]. Recoveries obtained with DPX ranged from 61% to 74% for MO, from 78% to 85% for COD and from 80% to 99% for 6-MAM.

In relation to hair analysis, the most critical and time-consuming step in analysis for opiates is their quantitative extraction from within the matrix. This extraction can be performed in several ways, employing mild acidic hydrolysis [47] or methanol extraction [48], being the latter compatible with almost all drug substances [49]. The problem is that aqueous acid solutions can hydrolyze some analytes, for instance, partial hydrolysis of 6-MAM to MO. Recently, a method was described for the analysis of COD, MO, 6-MAM, 6-AC, and tramadol in hair samples by GC-MS, after a simple overnight incubation with methanol at 65°C, followed by sample cleanup using mixed mode SPE. Using these incubation conditions, the conversion of 6-MAM to MO was found to be minimal, with excellent repeatability and reproducibility. This is advantageous since there is no need to control strictly the sample pH to avoid MO production. In addition, this procedure uses a small amount (20 mg) of sample, which does not limit the usefulness of the technique since low limits of quantitation have been obtained [43]. Enzymatic hydrolysis is another common reported pretreatment for isolating illicit drugs from hair. These methods are more expensive than methanol- and acid-based treatments. An important drawback of enzymatic hydrolysis is the long time required for completing the hydrolysis process, commonly in the range of 6–24 h. This fact, together with the use of an efficient cleanup method, makes enzymatic hydrolysis of hair to be a tedious and time-consuming methodology. In this sense, ultrasound energy has been successfully applied for speeding up the Pronase E enzymatic hydrolysis of human hair for extracting illicit drugs, including opiates [29]. Variables affecting this ultrasound-assisted hydrolysis, such as hydrolysis temperature, hydrolysis time, enzyme concentration, catalyzer (1,4-dithiothreitol) concentration, ionic strength, pH, and ultrasound frequency, were simultaneously evaluated by experimental design. The most statistically significant variables were ionic strength and pH, which means that analyte extraction is mainly attributed to Pronase E activity. The optimization of all the factors allows completing the hydrolysis in 30 min.

2.2 Analysis of Opium Alkaloids by Liquid Chromatography

Liquid chromatography (LC) is an analytical method widely employed for the separation, identification, and determination of the chemical components of complex mixtures. The separation is based on the speed that a certain component passes through a stationary phase, swept along by a mobile liquid phase. In the "chromatography in column" the stationary phase is located inside a tube and the mobile phase is forced to pass through it by gravity or external pressure. Basically, HPLC is an improved form of the traditional chromatography in column. In HPLC, the mobile phase is pressure-driven through the column by an external pump at pressures up to 400 bar, which enables a faster separation. The use of high pressure pumps allows the use of column packing material of smaller particle size, which implies a huger surface area for interaction, with the subsequent improvement of the separation efficiency.

Two variants of HPLC can be distinguished according to the relative polarity of the solvent and the stationary phase: normal-phase high performance liquid chromatography (NP-HPLC) and reverse-phase high performance liquid chromatography (RP-HPLC), respectively. Polar stationary phases (typically, bare silica or silica derivatized with small organic ligands) and nonpolar solvents are employed in NP-HPLC. The elution power of the mobile phase in NP-HPLC increases with its polarity. In the case of RP-HPLC, the silica of the stationary phase is modified by long hydrocarbon chains (normally C8 or C18) attached in its surface, which makes it nonpolar. The elution in RP-HPLC is carried out by polar solvents or mixtures of them (e.g., water/methanol or water/acetonitrile) while in RP-HPLC, the eluting power of the mobile phase decreases with its polarity. On the other hand, the hydrophilic interaction liquid chromatography (HILIC) is sometimes the technique of choice for the analysis of hydrophilic and polar compounds. In HILIC, compounds are retained on a hydrophilic stationary phase (e.g., silica- and polymer-based), and a water miscible, normally MS compatible mobile phase is used to carry out the elution. Also, two elution modes can be employed in LC: isocratic or gradient elution. Under isocratic elution, the composition of the mobile phase is maintained during the whole run. In gradient elution, the elution power of the mobile phase is gradually increased along the run. Gradient elution implies the re-equilibration of the system to the initial mobile phase composition, which sometimes supposes longer analysis times. Nevertheless, gradient elution is a must to achieve the complete separation in a reasonable time of complex mixtures.

The last but not least part of an HPLC system is the detector. There are several ways to detect when a certain compound elutes from the column. Detection systems based on molecular absorption (UV, Visible, or DAD), fluorescence (FLD) or chemiluminescence, EC or MS are the most popular. It is worthy to highlight the high sensitivity and selectivity provided by detection systems based on fluorescence or chemiluminescence.

RP-HPLC (i.e., hydrophobic stationary phase/polar aqueous mobile phase) is the more usual mode to separate and analyze opium alkaloids. The most attractive advantage of RP HPLC is the ability to determine a wide variety of compounds, which have different molecular structures, polarity, and acidity/basicity. Analysis of opium alkaloids by NP-HPLC (i.e., polar stationary phase) is not common and no references have been found in the scientific literature. As it is reflected in Table 33.2, octadecyl columns (C18) are the most commonly employed. When monolithic columns are used, high flow rates are allowed, which gives rise to very short separation times [57] with no loss of resolution. MLC sometimes is an interesting alternative to RP-HPLC since it allows separating analytes with different hydrophobicity without gradient elution and with acceptable peak symmetry. MLC has also been successfully applied to the analysis of opium alkaloids [60, 63]. Although it has not been much exploited yet for opioids analysis, HILIC has been scarcely used for the determination of intact MO glucuronide conjugates in plasma [86, 87] and urine [74].

Ultra high performance liquid chromatography (UHPLC) or ultra performance liquid chromatography (UPLC) is a quite novel technique, but it is one of the most popular nowadays, due to the fact that it is much more rapid than conventional LC. UHPLC systems can work at very high pressures and are compatible with stationary phases with particle sizes of around two micrometers or even smaller. Thus, the development of UHPLC methods [69, 77, 80] or the conversion of HPLC to UHPLC methods is a current trend, due mainly to the speed of analysis and low solvent use.

For forensic applications, elution is normally carried out in gradient, especially when a high number of compounds are intended to be separated in a reasonable time. However, isocratic elution has also been successfully carried out for opioids analysis, as reflected in Table 33.2. Methanol and acetonitrile are the most common organic components of the employed mobile phases. Regarding the acidity, acid mobile phases are the most common for the analysis of opium alkaloids. Although more scarcely, neutral [72] and basic [77] mobile phases have been also employed.

Regarding the detection systems, MS has been the most employed in recent years. MS offers universality (it detects the most organic compounds), selectivity, and sensitivity. LC-MS has been widely used for the structural characterization of opium alkaloids, as well as for their quantitative analysis in a variety of matrices such as biological fluids, water, food, etc. Some authors refer to MS as the best detection system for LC. The role of LC-MS in the determination of opioids in biological fluids was exhaustively reviewed by Pichini et al. in 1999 [88]. Diode array detection (DAD) is the second detection system of election for the LC analysis of opium alkaloids, after MS. Ultraviolet wavelengths between 240 and 300 nm are the most commonly employed. Fluorescence detection (FLD) has been employed mainly to the analysis of MO and COD [60, 66]. Also, chemiluminescence (CLD) with tris (2,2′-bipyridil)ruthenium(III) and acidic potassium permanganate provide remarkable sensitivity and selectivity for the analysis of many opium alkaloids and it has been employed as detection system for the LC-analysis of MO, COD, oripavine (OR), ethylmorphine and TB [56, 57]. The use of CLD for the detection of opium poppy alkaloids was reviewed by Francis et al. in 2008 [89].

2.2.1 Main Applications of LC to the Analysis of Opium Alkaloids

LC has been widely employed for the analysis of opium alkaloid in several matrices. Applications within the clinical, forensic, environmental, food control, vegetal, and pharmaceutical analysis fields can be found in the scientific literature, as reflected in Table 33.2.

Table 33.2 Selected applications of LC for the analysis of opiates in different matrices

Analytes	Separation	Detection	Sample	Sample treatment	Notes	References
17 opium alkaloids	"high-speed" phenyl column Gradient elution with A: water:methanol 90:10 (v:v); B: methanol, both containing 25 mM triethylammoniumformate pH 4.5	DAD and FLD	Blood and urine	SPE with weak cation exchange (Bond Elut CBA)		[50]
PV, narcotine and narceine (among other alkaloids)	Zorbax Extend-C18 Mobile phase: Organic modifier (methanol, acetonitrile, tetrahydrofuran): ion-ion interaction reagents (sodium hexafluorophosphate, perchlorate, and trifluoroacetate): phosphate buffer at constant pH (2.7)	DAD				[51]
PV, narceine		UVD: 254 nm			Basic study	[52]
Pholcodine and its five structural analogs (treated like impurities): MO, COD, TB, oripavine, and PV	LiChrospher C-8 column Gradient elution with 2% ammonium hydroxide in water and acetonitrile	DAD	Pharmaceutical preparation	Direct dissolution in sample solvent	LOD 0.50 μg/mL LOQ 1.0 μg/mL	[53]

MO, COD, TB, PV, and noscapine	H5-ODS C18 column Isocratic elution with a mobile phase consisted of 55% buffer containing 10.0 mM sodium phosphate monobasic and 0.70 mM sodium dodecyl sulfate and 45% acetonitrile	UVD: 285 nm	Urine	Dispersive liquid-liquid microextraction (DLLME)	LODs in the range 0.2–10 μg/L	[54]
TB	ODS-3 column The mobile phase consisted of 10 mM phosphate buffer, pH 3.8, and methanol (70:30)	UVD: 285 nm	water, urine, poppy capsule, street heroine, and COD tablet	Electromembrane extraction (EME)	LOD < 15 μg/L Analysis time 10 min Recovery 44–54%	[55]
MO, pseudomorphine, COD, oripavine, ethylmorphine and TB	Hybrid FIA/HPLC system Monolithic column: Chromolith Flash RP-18e (25 mm length, 4.6 mm i.d.)	Chemiluminiscence detection (tris(2,2′-bipyridyl)ruthenium (III)/acidic $KMnO_4$	Urine	Dilution		[56]
MO, COD, oripavine, and TB	Chromolith SpeedROD RP-18e (50 × 4.6 mm i.d.) column	Chemiluminiscence detection (tris(2,2′-bipyridyl)ruthenium (III)/acidic $KMnO_4$	Process streams		Analysis time <2 min LODs < 10^{-9} M	[57]
MO and analogs	Winchrom-GP C18 (5 μm, 250 × 4.6 mm i.d.) column Mobile phase: methanol/ 0.05 M NaH2PO4, 17:83 v:v	UVD: 240 nm MS (API)	Compound liquorice	Aqueous two-phase system (ATPS) of poly(ethylene glycol)/K_2HPO_4	Recoveries: 91.7–100.3%	[58]

(*continued*)

Table 33.2 (continued)

Analytes	Separation	Detection	Sample	Sample treatment	Notes	References
MO, COD, oripavine, TB, PV, noscapine, and sanguinarine	Column: TSKgel ODS-120 Gradient elution with acetonitrile (solvent A) and 10 mM sodium 1- heptanesulfonate in water (adjusted to pH 3.5 with phosphoric acid) (solvent B)	UVD: 284 nm	Papaver plants	Extraction by 5% acetic acid by sonication followed by SPE with reversed-phase cation-exchange cartridges.	Recovery percentages between 100 and 112%	[59]
COD, MO and TB	Micellar LC: C18 column mobile phase 0.15 M SDS-7% (v/v) butanol buffered at pH 7	UVD (FLD for COD and MO)	Serum	Direct injection		[60]
COD and PV			Pericarpium papaveris	Ionic liquid-based aqueous two-phase system. (Ionic liquid: 1-butyl-3-methylimidazolium chloride)	Recoveries 90.0–100.2% for COD and 99.3–102.0% for PV	[61]
MO, COD, 6-acetylmorphine, and other drugs	Column: X-Terra RP8 Gradient elution with acetonitrile-phosphate buffer pH 6.53	DAD (200-400 nm) (285 nm for detection of MO, COD, and 6-acetylmorphine)	Plasma	SPE: Bond Elut Certify cartridges	LODs ranged between 0.010 and 0.055 μg mL^{-1}	[62]

MO, COD, PV, and noscapine	Micellar LC	UVD (280 nm)	“Omnopon, solution for injection”		LOD 0.45–1.94 μg mL^{-1}	[63]
	Column: reversed-phase Kromasil C18 (150 × 4.6 mm, 5 μm)					
	Isocratic elution with 0.10 mol L-1 SDS with 5% (v/v) of 1-butanol, adjusted to pH 2.5 by phosphoric acid					
PV and its photooxidation products (papaverinol, papaveraldine, and pyrrocolonium ion)	Column Hypersil Duet C18/ SCX (250 × 4.6 mm, 5 mm particle size)	DAD				[64]
	Isocratic elution with phosphate buffer (pH = 3.80)/acetonitrile (40:60, v:v)	(UVD 230 nm, 278 nm and 300 nm)				
PV	Column: μ-Bondapak C18 column (10 μm, 300 × 3.9 mm i.d.)	UVD at 250 nm	Pericarpium papaveris	Two-phase system (ATPS) of poly (ethylene glycol) (PEG)-$(NH_4)_2SO_4$	Extraction efficiencies for PV: 93–96%	[65]
	Isocratic elution with 0.5% ammonium acetate:1% triethylamine:methanol (v/v, 49:1:50)				LOD 2 ng/mL	

(*continued*)

Table 33.2 (continued)

Analytes	Separation	Detection	Sample	Sample treatment	Notes	References
MO	Column: μBondapak C18 (300 × 4 mm i.d., 10 μm) Isocratic elution with 5% methanol, 3% acetonitrile, 0.5 mmol/l sodium acetate, 0.012 mol/l potassium dihydrogen orthophosphate and 0.148 mmol/l phosphoric acid in distilled water	FLD (excitation wavelength of 235 nm and a 349 nm emission)	Plasma	Deproteination of plasma with zinc sulfate and bicarbonate buffer (pH = 10.5) and extraction with tetrahydrofuran prior to SPE with Zeolite Y column	LOD 10 ng mL^{-1}	[66]
MO and its 3- and 6-glucuronide metabolites, COD, 6-monoacetylmorphine	Column: C18 Atlantis Gradient elution with 20 mM ammonium formate buffer (pH 2.8) (solvent A) and acetonitrile/solvent A (90:10 v/v)	MS/MS (ESI+)	Dried blood spots	SPE (Oasis HLB cartridges)		[67]
MO, COD, 6-acetylmorphine, and other drugs of abuse	nano-HPLC-Chip-MS/MS Analytical column: ZORBAX 80 SB-C18 with 5 μm particle size Gradient elution by water with 0.1% formic acid (Eluent A) and acetonitrile with 0.1% formic acid (Eluent B)	QQQ/MS (ESI+)	Hair	Sonication. Extraction solution: methanol: acetonitrile:20 mM ammonium formate in a ratio of 25:25:50 (v/v/v)	LODs and LOQs from 0.1 to 0.75 and 0.2 to 1.25 pg/mg, respectively Separation time 15 min	[68]

MO, COD, oxycodone, buprenorphine, and other drugs of abuse	Column: Acquity HSS T3 Gradient elution with methanol (solvent A) and 10 mmol/L aqueous ammonium formate, pH 3.1 (solvent B)	MS/MS (ESI+)	Whole blood	LLE: ChemElute columns with Ethyl acetate/heptane (4:1)	LOQ ranging between 0.1 and 521 ng/mL	[69]
MO, COD, their metabolites 6-acetylmorphine dihydrocodeine, and drugs of abuse	Column: Fused-CoreTM Ascentis Express C18 (4.6 × 50 mm) with a 2.7 μm particle size Gradient elution with Milli-Q water with acetic acid (pH 2.8) (solvent A) and acetonitrile (solvent B)	MS/MS (ESI+)	Waste and surface waters	SPE: Oasis MCX sorbent	LODs for MO, COD, and their metabolites 0.5 ng/L (surface water) and 2-5 ng/L (wastewater)	[70]
MO, COD, norcodeine, oxycocodone, oxymorphone, normorphine, dihydrocodeine, buprenorphine, norbuprenorphine, among other drugs of abuse.	Column: ACQUITY UPLC BEH C18, 1.7 μm Gradient elution with 79.7% water, 20% methanol, 0.3% acetic acid (solvent A, pH 2.9) and 99.7% methanol, 0.3% acetic acid (solvent B, pH 3.30)	MS/MS (ESI+)	Wastewater and surface water	SPE: Oasis MCX sorbent	LODs for opioids ranged from 0.025 to 1 μg/L SPE recoveries >60%	[71]
MO, COD, 6-acetylmorphine, among other licit and illicit drugs	Column: Zorbax extend C18 (50× 2.1 mm i.d., 3.5 μm particle size) Gradient elution with 2 mM ammonium acetate at pH 6.6 (solvent A) and methanol (solvent B)	MS (ESI+)	Breast milk	SPE: Bond Elut Certify cartridges	LOD 1.5 ng/mL for MO and 1.0 ng/mL for 6-acetylmorphine and COD Recovery ranged between 51.6% and 86.5%	[72]

(*continued*)

Table 33.2 (continued)

Analytes	Separation	Detection	Sample	Sample treatment	Notes	References
MO, COD, 6-acetylmorphine, 6-acetylcodeine	Column: Synergi Polar-RP 80A (75 × 2 mm, 4 μm) Gradient elution with 0.1% formic acid and acetonitrile	MS/MS (ESI+)	Sweat (patches)	SPE: Extraction of sweat patches acetate buffer at pH 4.5; isolation of the supernatant and SPE on Strata-XC-cartridges	LODs 0.75 ng/patch Separation time: 15 min	[73]
MO, COD, morphine-3-glucuronide, morphine-6-glucuronide, and codeine-6-glucuronide	HILIC Column: Zorbax Hilic Plus column 100× 2.1 mm (3.5 μm) Gradient elution with 10 mM ammonium formate, pH 6.4 (solvent A) and 10 mM ammonium formate, pH 6.4 in 90% acetonitrile (solvent B)	TOF/MS (ESI+)	Urine	SPE on Sep-Pak C18 (50 mg) cartridges		[74]
MO, COD, and other 15 drugs of abuse	Varian Pursuit 3 C18, 3-μm particle size column Gradient elution with 2 mM ammonium formate buffer/ 8% acetonitrile pH 5.3 (solvent A) and 100% methanol (solvent B)	MS/MS	Whole blood	SPE: mixed-mode columns (Isolute Confirm HCX)	LOQs ranged from 0.0005 to 0.01 mg/kg	[75]

MO, morphine-3-glucuronide (M3G), morphine-6-glucuronide (M6G), COD, dihydrocodeine, noscapine, PV, and 6-acetylmorphine	Column: Phenomenex Synergi Polar Gradient elution with 1 mM ammonium formate and 0.1% formic acid – pH 2.7 (solvent A) and 70% acetonitrile, 1 mM ammonium formate, and 0.1% formic acid – pH 3.8 (solvent B)	Hybrid quadrupole linear ion-trap mass spectrometer	Plasma, whole blood and postmortem blood	SPE: Varian Bond Elut C18, 6 mL, 200 mg SPE column	Deuterated labeled internal standards Recovery in blood was greater than 90% and ion suppression/ enhancement was shown to be less than 15% LODs ranged between 0.34 and 3.33 μg L^{-1}	[76]
MO, COD, 6-monoacetylmorphine (6-MAM), pholcodine, oxycodone, ethylmorphine	UPLC Column: Acquity UPLC BEH C18 column (2.1mmID × 50 mm, 1.7 μm particles) Gradient elution with a basic mobile phase consisting of 5 mM ammonium bicarbonate buffer, pH 10.2 (solvent A), and methanol (solvent B)	MS/MS (ESI+)	Urine	SPE: mixed mode cation exchange (MCX) cartridge	Deuterium labeled internal standards Total run time, including injection and equilibration time was 5.7 min LODs ranged between 0.0010 and 0.0026 μg mL^{-1}	[77]

COD, MO, Hydrocodone, Hydromorphone, Oxycodone, and 6- Acetylmorphine	Column: Waters Nova-Pak CN HP analytical column (3,9 × 100 mm, 4 µm particle size). Isocratic elution with 15% acetonitrile and 85% 2 mM ammonium formate buffer at pH 3.0	MS/MS	Urine, serum, plasma, whole blood, and meconium	SPE. Direct elution into autosampler vials	LOD 1 ng mL^{-1}	[84]
MO and COD	Column: 150 × 2 mm i.d., 3 µm, RP18 Gemini Gradient elution with 20 mM ammonium hydrogen carbonate, adjusted with ammonia to pH 9 (solvent A) and water/methanol 5:95 (v/v), 20 mM ammonium hydrogen carbonate adjusted with ammonia to pH 9 (solvent B)	MS/MS (ESI+)	Poppy seed	Cold extraction with methanol/0.1% acetic acid		[85]

Many applications found in the literature are focused in biological fluids, mainly urine, plasma, and whole blood, as reflected in the selected works summarized in Table 33.2. The determination of the father alkaloids as well as their glucuronide metabolite(s) is of great importance in interpretive forensic and clinical toxicology. The estimation of metabolite/father compound ratios provides important information about route, dose, and time of exposure. Direct detection of glucuronide derivatives without previous enzymatic cleavage procedures and/or derivatization is the actual challenge of LC-methods. Opioids have also been LC-analyzed in dried blood spots (DBS) [67], which presents some advantages, such as it requires a less invasive sampling method, it offers a simple storage and easier transfer, and requires a smaller blood volume.

Monitoring residues of drugs in human breast milk is also a need. When drugs are administered to a lactating mother, a certain percentage of the drugs may be excreted into the breast milk, which can harmfully result in a transfer of the residues to the infant. Marchei et al. proposed in 2011 [72] a LC-MS/MS method to detect residues of opium alkaloids and other legal and illegal drugs in this type of sample, applying the validated methodology to screen samples from the largest Spanish milk bank.

Alternative matrices in forensic toxicology, such those also being analyzed by GC (oral fluid, sweat, and hair), are receiving increasing interest due to ease and noninvasiveness of collection and/or longer windows for drug detection, and LC has demonstrated to be a suitable analytical technique to monitor small amounts of opium alkaloids in them. The level of drugs in OF correlates well with plasma time courses of drug appearances/disappearances for which it can be employed as an alternative specimen to monitor the consumption of opium alkaloids having potential applications for roadside drug screening. UHPLC-MS/MS has been successfully employed to monitor the presence of opium alkaloids and other drugs of abuse in OF [80].

Sweat is collected with patches that are generally worn for 1 week, permitting drug monitoring over a relatively long period. Sweat patches are mainly used in treatment following and criminal justice monitoring programs, but on-site fast drug detection is also possible [90]. Concheiro et al. have recently proposed a sensitive and selective LC/MS-MS method to simultaneously quantify 14 drugs (among them, opiates) and metabolites in a single sweat patch [73].

Hair has been also an object of analysis to detect the consumption of opium alkaloids [68, 78, 83]. This matrix has attracted a lot of attention for the easy and noninvasive sample collection and difficult adulteration compared to the plasma, urine, and saliva specimens. In addition, hair samples are more stable in storage and can provide a wider detection time window, which can reveal the history of drug abuse.

Regarding the pharmaceutical analysis, it is important to point out that quality, safety, and effectiveness of drugs are essential concerns in pharmaceutical industry. Effective monitoring and controlling of impurities are a must to ensure the quality and safety of drugs intended for human consumption. Unequivocal analytical characterization of drug impurities is a challenge in modern pharmaceutical examinations. Pholcodine is an example of drug which must be submitted to this kind of control. Pholcodine is a semisynthetic drug and it might present residues which might come from impurities present in the MO starting material as well as from the manufacturing process itself. Thus, MO and possible MO-analogs impurities of pholcodine including COD, TB, and PV must be monitored, although the number of published LC-methods for pholcodine impurities determination is limited yet [53]. Another example of the applicability of LC into the pharmaceutical analysis is the preparation called "omnopon." "Omnopon" belongs to the group of narcotic analgesics and it is commercialized as solution for injection. It represents a mixture of opiate alkaloids: MO, COD, PV, and noscapine. In clinical medicine "Omnopon" is used as an analgesic in strong pain syndromes. Kulikov et al. [63] have recently proposed a rapid MLC method with isocratic elution, for the determination of MO, COD, PV, and noscapine.

Pericarpium papaveris, contains several bioactive alkaloids, such as PV, MO, and COD. It is a type of traditional Chinese herbal remedy commonly used to treat chronic cough, chronic lax, and cramp. The main benefits obtained from *P. papaveris* are due to the contained PV, which has the functions of relaxing smooth muscle and alleviating human suffering. However, the content of PV in *P. papaveris* varies with different growing conditions. Therefore, it is very important to determine PV accurately in *P. papaveris* for its quality control and LC has been employed for this purpose [61, 65].

Opium alkaloids have been also LC-determined in opium samples. In 2008, Remberg et al. [91] published a study which they claimed like the one dealing with the largest set of authentic opium samples analyzed in a work until 2008. They analyzed the content of MO, COD, TB, and papaverine and it allowed them assessing possible correlations between samples and selected external factors, such as region of origin within Afghanistan, year of harvest, or intra-batch variation. Compounds issued from the natural photooxidation of PV have been also investigated by LC. A solution of PV naturally photooxidized contains papaveraldine, papaverinol, pyrrocolonium ion, and PV. Due to the acid-based characteristics of these compounds, Badea et al. [64] developed a LC method a Duet C18/SCX column that ensured the separation of ionic and nonionic compounds in a single run, which enabled the determination of PV in the presence of its main oxidation products.

On the other hand, environmental analysis is an important field of application of opium alkaloids analysis. The presence of drugs of abuse in environmental samples is becoming a matter of global concern. The source of these residues in water is mainly from consumers, since unchanged drugs and their metabolites are excreted through urine. Drug residues reach natural surface waters primarily due to the insufficient removal of these compounds at wastewater treatment plants. The concentration of these residues in water is normally low and sensitive analytical methodologies including preconcentration stages and sensitive detection systems are needed. LC-MS/MS is normally the method of choice for the analysis of opium alkaloids in the aqueous environment due to the high signal-to-noise ratio and the selectivity offered. Pedrouzo et al. [70] and Baker et al. [71] have recently proposed LC-MS/MS methods to monitor the presence of opium alkaloids and other drugs of abuse both in waste- and surface-waters. Anyway, other detection systems have also demonstrated to be suitable to monitor such small concentrations of drugs, for example, Costin et al. proposed, in 2008, a rapid and sensitive LC method with chemiluminescence detection with two different reagents: acidic potassium permanganate and tris(2,2′-bipyridyl)ruthenium(III), for the detection of *Papaver somniferum* alkaloids in process streams [57].

Due to the high potential of LC coupled to MS or tandem MS, it is common practice to use the development of multiresidue methods to monitor the presence of opiates together with other families of illicit drugs or pharmaceuticals in general. Doping control [92, 93], forensic [94], and environmental [95, 96] applications can be found in the scientific literature. The presence of plant toxins in general is also very controlled in food and feed of vegetal origin and, for example, Mol et al. [97] published in 2011 a method of screening of a selection of 150 substances, among them opium alkaloids, in a variety of food and feed matrices using full-scan high resolution (Orbitrap) MS, obtaining excellent results.

2.2.2 Typical Sample Pretreatments Prior LC for the Analysis of Opium Alkaloids

In some of the methods summarized in Table 33.2, samples or sample extracts are directly injected into the chromatographic system without being previously treated [53, 60, 80, 83]. However, this is not usual, especially when dealing with complex samples. Normally, some sample treatment stages are carried out before LC, both for cleaning up and preconcentration of the target compounds.

SPE has been the most widely employed sample pretreatment prior to LC for the analysis of opium alkaloids, as it is reflected in Table 33.2. Reversed phase-cation exchange is the more common sorbent for SPE of opium alkaloids [59, 70, 71, 75, 77]. Øiestad et al. [69] employed supported LLE on ChemElute columns as sample treatment for the analysis of opiates in whole blood, prior to LC-MS/MS. However, LLE has not been that employed as SPE prior to LC for opiates analysis.

LLE and SPE require large volumes of toxic organic solvents, and can be highly time consuming. SME methodologies are the current trend in sample treatment being considered green pretreatment techniques, since they involve the reduction of organic solvent volumes, with the subsequent production of less toxic residues. Dispersive liquid-liquid microextraction (DLLME) can be cited within these green techniques. It is a novel SME technique, initially developed by Rezaee et al. [98], based on ternary solvents. Basically, this extraction procedure is based on the formation of tiny droplets of the extractant in the sample solution using water-inmiscible organic solvent (extractant) dissolved in a water-miscible organic dispersive solvent. Extraction of the analytes from aqueous sample into the dispersed organic droplets takes place, obtaining a high enrichment factor, high extraction recovery, simplicity of operation, and low cost. The use of DLLME prior to LC is not very exploited for the analysis of opium alkaloids yet. In 2011, Shamsipur and Fattahi [54] proposed a DLLME-HPLC-UV for the determination of MO, COD, TB, PV, and noscapine (NS) in urine samples. They compared their figures of merit with those of previously published SPE-FLC-DAD, SPE-CZE-DAD, SPE-HPLC-DAD methods, and concluded that RSDs was about the same with previous methods, but their LODs and extraction times were lower. Thus, they proved that DLLME prior to HPLC is a sensitive, fast, reproducible, and simple technique that can successfully be used for the preconcentration and determination of opium alkaloids in urine samples.

Aqueous two-phase system (ATPS) is another environmental-friendly sample pretreatment technique. It is formed by mixing two aqueous solutions of structurally different polymers or by mixing a polymer and a salt aqueous solution together when the concentrations of the components are higher than a critical value. Compared with conventional LLE or SPE, ATPS can be completed in one operation and it is less costly. ATPSs of poly(ethylene glycol)/K_2HPO_4 and poly(ethylene glycol)–$(NH_4)_2SO_4$ have been coupled with LC for the determination of MO in compound liquorice and PV in *P. papaveris*, respectively [58, 65]. An ionic liquid-based ATPS prior LC has been also employed for the determination of COD and PV in *P. papaveris* [61].

Electromembrane extraction (EME) has also been used as sample treatment prior to LC for the analysis of TB. In EME, an electric voltage is applied which facilitates the extraction of analytes across a hollow fiber membrane. The application of voltage helps to extract the analytes in a short time. Seidi et al. [55] proposed an HPLC-UV method, prior to EME for the determination of TB in water samples, biological fluids, the poppy capsule, and narcotic drugs. They compared the proposed method with different existing methods for extracting and determining TB and concluded that through selecting an appropriate organic solvent, EME can yield a high sensitivity as well as high cleanup after extraction in complex matrices. The employed device to perform EME is shown in Fig. 33.2 (with permission of Ref. [55]).

2.3 Analysis of Opium Alkaloids by Capillary Electrophoresis

In CE, electrophoretic or electrokinetic separations are carried out in tiny capillaries at high voltages (10–30 kV), thus achieving high efficiency ($N > 105$), resolution, power, and mass sensitivity (down to 10^{-18}–10^{-20} mol). The main characteristics of CE are versatility of application, use of different separation modes with different selectivity, low demands on sample volume, negligible running costs, the possibility of interfacing with different detection systems including MS, and the ruggedness and simplicity of the instrumentation.

For all of these characteristics, CE applications in the forensic sciences are now rapidly growing in the last years, particularly in forensic chemistry and toxicology [99, 100]. A recent paper briefly described the basic principles of CE and presents a selected review of its main applications to the analysis of illicit/controlled drugs in biological samples [101–103]. In these papers, it can be concluded that the peculiar separation mechanisms and the high complementarily of CE to chromatography make it a new powerful tool of investigation in the hands of forensic toxicologists.

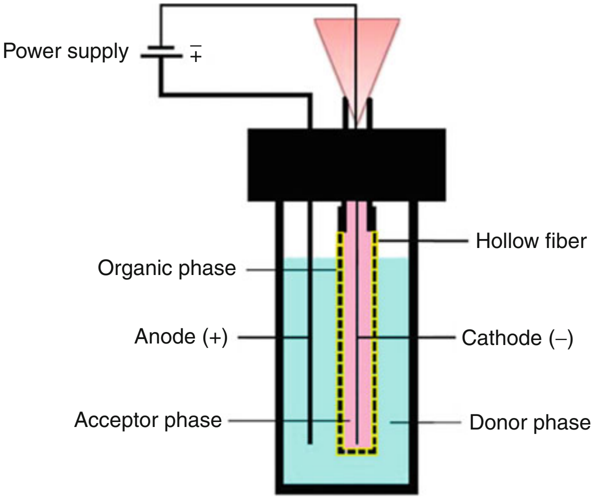

Fig. 33.2 Schematic illustration of the employed device for electromembrane extraction (EME) (With permission, from Ref. [55])

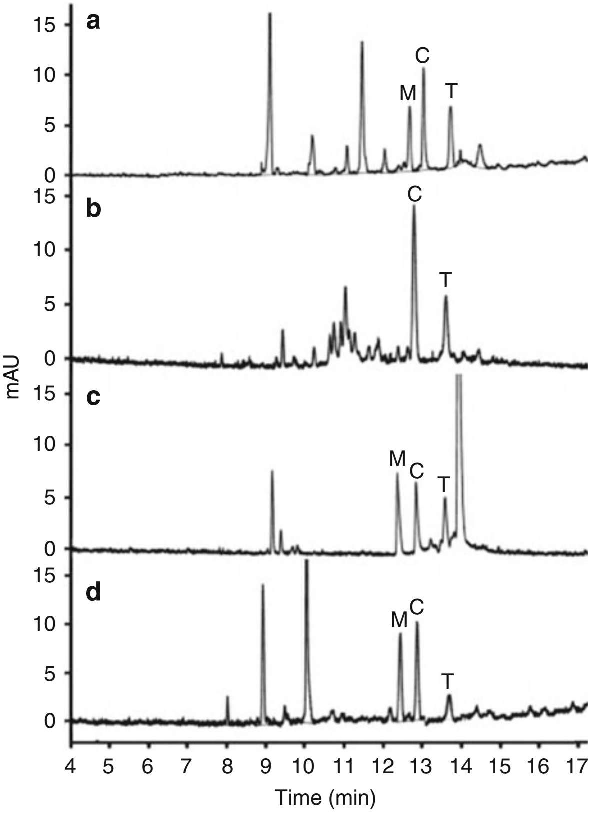
The exceptional power of separation and resolution, rapid analysis time, simplicity, versatility, low mass detection limits, economy of reagents, minimum sample requirements, and the possibility of direct sample injection without complex sample pretreatments make CE an attractive methodology to forensic scientists [104–106] where the sample matrix may be extremely complicated and contain a number of endogenous components which have to be resolved from the solute of interest. On the other hand, lack of sensitivity and “maturity” means that CE is not yet very well established in forensic laboratories as an additional tool to other analytical techniques.

Detection in CE has to face two challenging problems, namely, small amounts of analytes injected and tiny peak volumes. To the present, UV–vis detector is, by far, the most widely adopted despite the short internal diameter of the capillary limits the concentration sensitivity. Among the different modes of CE, CZE coupled with UV detection is the most widely found for the analysis of opium alkaloids in different matrices [107–111]. Nevertheless, to avoid the major disadvantage of CE related to its lack of sensitivity compared to HPLC, various approaches to this sensitivity limitation have been developed, mostly by the use of preconcentration procedures such as sweeping techniques [112, 113] or field-amplified sample injection (FASI) [107, 108].

Cyclodextrin (CD)-modified CZE with the same detection system has proven successful to increase both sensitivity and specially selectivity in this type of analysis [114, 115]. The most frequently background electrolyte (BGE) employed both in CZE-UV and CZE-CD-UV is sodium phosphate at acidic pH in the presence of a small percentage of organic solvents, such as methanol or acetonitrile (MeCN), to increase the selectivity of the CE separation. A good separation of morphine, codeine, and thebaine in different opium poppy plants can be seen in Fig. 33.3 [114].

Fig. 33.3 The typical electropherograms of the real samples: (**a**) *Papaver glaucum*, (**b**) *P. fugax*, (**c**) *P. dubium*, (**d**) *P. tenuifolium* morphine (*M*), codeine (*C*), and thabeine (*T*). Optimum conditions: 60 cm (50 cm to detector window) 50 μm id fused silica capillary operating at 25°C and 20 kV with UV detection at 214 nm and 100 mM phosphate buffer (pH 3) containing 5 mM α-CD (With permission, from Ref. [114])



The other mode of application widely used in CE for the analysis of the major opium alkaloids is micellar electrokinetic chromatography (MEKC). This mode can separate a wide variety of solutes (basic, acid, and neutral solutes) including compounds that are high polar, thermally labile, and/or nonvolatile, with high efficiency and selectivity, being an excellent technique for general drug screening and the analysis of substances, such as drugs of abuse and, among them, the opium alkaloids. Also, the UV detection system is frequently employed with the MEKC mode for the determination of different opiates in forensic samples [116, 117] but usually with the application of the preconcentration procedures such as cation-selective exhaustive injection (CSEI) together with sweeping [118–120]. These stacking CE methods could increase 2,500-fold sensitivity of the opium alkaloids being analyzed, when comparing with CZE. Most of them employ LLE or SPE as extraction procedures, which permit to obtain limits of detection in the ng/mL order when using a phosphate buffer at basic pHs as BGE in presence of a surfactant such as SDS and a percentage of an organic solvent, specially methanol or MeCN, between 7% and 30%.

Although UV is the most widely used detection technique found for the analysis of the major opium alkaloids in different matrices, another optical detection techniques have been found. Luminescence is also a very attractive detection system, due to its low sensitivity but it has been scarcely employed in the analysis of the major opium alkaloids of samples of forensic interest. FLD have been employed for the analysis of a binary mixture of MO and 6-AM based on the derivatization with diazomium salt of aniline at 0°C [121]. It was necessary to optimize all the conditions that affect derivatization (diazonium concentration and reaction time) and those related with the separation (electrolyte concentration, pH, β-CD concentration, organic additives, and separation potential) but good linearity was obtained in the range of 50–2000 ng/mL.

Due to the fact that laser induced fluorescence (LIF) allows high energy excitation, it is more sensitive but instrumentally more complex and expensive and has the limitation of the excitation wavelengths available with the different commercial lasers. LIF detection was also examined using a two-step pre-column derivatization procedure [122]. In this case, the drugs extracted from human urine were first subjected to an N-demethylation reaction involving the use of chloroethylchloroformate (ACE-CI) and then derivatized using fluorescein isothiocyanate (FITC) isomer I with excitation and emission wavelengths of 488 and 520 nm, respectively. The use of FLD/LIF in forensic analysis is mainly restricted to urine samples.

Also the ECL detection is an interesting alternative in the different detection systems based on optical methods. Two papers have been found that employ this detection system for the determination of opiate alkaloids [123, 124]. 1-butyl-3-methylimidazolium tetraborate and 1-buthyl-3-methylimidazolim tetrafluoroborate and 1-ethyl-3-methylimidazoliumtetraborate were used as ionic liquids in the BGE which resulted in significant changes in separation selectivity and obvious enhancement in ECL intensities for those alkaloids with similar structures. Under the optimal conditions, the four drugs being analyzed were well separated within 8 and 7 min, respectively.

Because of the importance of information provided by MS techniques, many efforts have been carried out for the development of interfaces between CE and MS, the electrospray ionization (ESI) being the most common interface, presenting enough sensitivity and selectivity for the determination of a wide range of analytes of clinical and forensic significance. For such a reason, one of the most potential techniques that can be use today in forensic laboratories is the hybrid analytical technique CE-MS [125]. The result is the possibility to separate and identify a wide variety of drugs of abuse, carrying out both as a screening and as a confirmatory method. The coupling of CE-MS, both with ESI or time of flight (TOF), combines efficiency and speed of separation with high mass accuracy and fast scanning capability for the analysis of drugs of abuse in forensic laboratories. CE with MS detection with direct electroinjection of different opioids from untreated urines has provided a rapid and simple approach for unambiguous urinary testing of drug of abuse [126]. A head-column FASI in presence of a water plug inserted at the capillary tip provides a more than 1,000-fold sensitivity enhancement when applied to real samples.

The coupling of CE-MS using ESI as interface has been employed for the simultaneous determination of stimulants and narcotics in urine samples [127] and different illicit drugs, including MO and cocaine in hair samples [128]. The buffers usually employed have to be considerably volatile, such as ammonium formate or acetate, working at basic pHs (9.0–9.5), with a sheath liquid composed by a mixture of isopropanol-water in presence of a small percentage of formic or acetic acid. Also, the analysis of hair samples have been carried out by CE-MS but, in this occasion using two different ionization procedures, ESI and TOF [129]. FASI stacking injection was employed to obtain detection limits below the cutoff values proposed by SHT for detecting these analytes in hair analysis (0.1 ng/mg) and a simple LLE procedure, allowing the detection of a broad spectrum of basic drugs and their major metabolites. The coupling of CE-TOF-MS was again employed for the analysis of illicit and controlled drugs in blood samples, using LLE extraction procedure and injected under FASI, applying the method to real samples [130].

The first application of charged AuNPs as semipermanent capillary coating in CE-MS is due to Zhang et al. [131]. The Au NPs enhanced the coating stability toward flushing by methanol which results in an improvement of the run-to-run and capillary-to-capillary repeatabilites, obtaining RDSs of migration time in the range of 0.43–0.62%.

The MS detector has been also coupled with another less employed mode of operation in CE, such as CEC in different occasions for the analysis of multiple drugs of abuse in human urine samples [132]. The coupling of packed CEC columns with MS as detector, using a liquid junction interface, provided several advantages such a better sensitivity, low dead volume, and independent control of the conditions used for CEC separation and ESI analysis. Also, pCEC with ESI-MS based on silica-based monolithic column have been developed for the five major opium alkaloids [133] and for the analysis of narcotics [134] combining the extremely high permeability and separation efficiency of silica-based monolithic columns with the high selectivity and sensitivity of pCEC-ESI-MS.

2.3.1 Main Applications of CE to the Analysis of Opium Alkaloids

Table 33.3 summarizes a representative selection of applications of CE to the analysis of opium alkaloids.

As it has been seen previously, forensic analysis of the six major opium alkaloids is usually carried out in biological samples, mainly in human urine, blood, and hair.

Urine is the most commonly used biological sample for the analysis of opiates in forensic laboratories by CE. It is generally used for the detection of these compounds in schools and workplaces because it is obtainable noninvasively, as compared to blood sampling. The main limitation in its use is that it provides direct evidence only for short-term use because they remain in urine no longer than for 10 days after use. Most of the applications in this type of samples by CE are carried out with the coupling CE-UV [107–112] obtaining limits of detection between 20 and 50 ng/mL.

Table 33.3 Selected applications of CE for the analysis of opiates in different matrices

Analytes	Mode of CE	Preconcentracion and extraction procedures	Experimental and instrumental parameters	Limits of detection	Matrix of application	References
MO, COD, PV, NS, TB, OR, reticuline, narceine	CZE-sweep-UV	Sweeping technique			Opium samples and poppy straws	[113]
Heroin, 6-MAM, MO, COD, PV, narcotine	CZE-UV	MAA-EGDMA Electrokinetic injection with FASI	0.1 M disodium hydrogen phosphate (pH 4.5 adjusted with 1 M hydrochloric acid) and 20% methanol (v/v). 25 kV at 25°C	6.6–19.5 ng/mL	Human urine	[107]
MO, COD, TB	CE-CD-UV	Ultrasound-assisted extraction procedure for 1 h, 60 kHz with water–methanol (80:20) at 40°C	Sodium phosphate buffer (100 mM, pH 3.0 with 5 mM β-CD	0.1 μg/mL	Iranian papaver plants	[114]
ME, TB, CP, AC	CE-ECL with ionic liquid (1-butyl-3-methylimidazolium tetrafluoroborate)			2×10^{-8} to 1×10^{-7} M	Human urine	[123]
Eight heroin related alkaloids	CE-MS with charged polymer-protected Au NPs		120 mM ammonium acetate (pH 5.2) with 13% methanol. 20 kV at 20°C	0.43–0.62% RSDs of migration time	Illicit samples	[131]
MO, COD, OR, TB	CZE-CD-UV		100 mM Tris (pH 2.8) with 30 mM hydroxypropyl-β-CD	2.5×10^{-6} M	Industrial process liquors	[115]
	MEEKC and MEKC-UV					[116]
TB, COD, NO, narcotine	CE-ECL	One-step extraction approach. FASI	Buffer (25 mM borax, 8 mM 1-ethyl-3-methylimidazolium tetrabflouoroborate	1×10^{-9} to 1×10^{-6} M	Chinese traditional medicine opium poppy samples	[124]

(*continued*)

Table 33.3 (continued)

Analytes	Mode of CE	Preconcentracion and extraction procedures	Experimental and instrumental parameters	Limits of detection	Matrix of application	References
			(EMImBF4) ionic liquid (pH 9.18). 15 kV			
8 illegal drugs (ketamine, amphetamines, opiates, and metabolites)	MSPE-CZE-UV	Hydrodynamic injection with FASI	30 mM phosphate buffer (PBS, pH 2.0) with 15% MeCN (v/v)	0.015–0.105 μg/mL	Urine samples	[108]
Amphetamine, ephedrine, methadone, pethidine, tetracaine COD, heroin	CE-ESI-MS		20 mM ammonium acetate (pH 9.0). 22 kV and sheath liquid of isopropanol/water (1:1 v/v) with 7.5 mM acetic acid with 3.0 μL/min flow rate	0.4–1.0 ng/mL		[127]
Amphetamines, cocaine, COD, heroin, MO	CEC-ESI-MS	SPE on a strong cation exchange cartridge	MeCN and 25 mM ammonium formate buffer (pH 3.0) (30:70 v/v). 12 kV	0.78–3.12 ng/mL	Human urine	[132]
MO, COD, 6-AM	CSEI-sweep-MEKC-UV	LLE Sweeping at -25 kV using phosphate buffer/20 mM, pH 2.5) and 80 mM SDS	Phosphate buffer (50 mM, pH 2.5) with 30% methanol and high condition buffer (100 mM phosphate, 41.3 kPa for 18 s). Electrokinetic injection (20 kV, 300 s)	10 ng/mL	Real urine samples from addicts	[118]
COD, ketamine, MA, MO, alprazolam, oxazepam, and metabolites	CZE-sweep-UV	Sweeping buffer (phosphate 75 mM, pH 2.5 and methanol (90:10 v/v with 65 mM SDS	Phosphate buffer (75 mM, pH 2.5) and methanol (70:30 v/v)	20–50 ng/mL	Urine samples from addicts	[112]

ME, MDA, MDEA MDMA, methadone, cocaine, MO, COD, 6-AM, benzoylecgonine	CZE-TOF-MS	LLE with FASI	25 mM ammonium formate electrolyte solution (pH 9.5) at 15 kV. Sheath liquid of isopropanol-water (1:1, v/v) with 0.5% formic acid	2–10 ng/mL	Blood samples of real cases	[130]
CF, TB, theophylline, paracetamol, propylphenazone, acetylsalicylic acid, salicylic acid, CP	MEKC-UVat 210 nm		20 mM phosphate buffer (pH 9.0), 80 mM sodium dodecyl sulfate and 7.5% acetonitrile (v/v). 25 kV at 25°C		Food, beverages, natural products, pharmaceuticals, and cosmetics	[117]
Narcotine, PV, TB, COD, MO	pCEC with monolithic column			1.5–6.0 μg/mL	Pericarpium papaveris	[133]
AM, MA, MDA, MDMA, ephedrine, cocaine, MO, COD, 6-MAM, bezoylecgonine	CE-ESI-MS and CE-TOF-MS	LLE with FASI	25 mM ammonium formate (pH 9.5)	0.1 ng/g	Hair samples	[129]
MO, COD, methadone, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine	CE-UV		Nearly neutral pH phosphate buffer and poly (ethylene oxide) as coating agent		Urine specimens	[109]
MO, COD, ketamine, MA	CSEI-sweep-MEKC-UV	Sweeping at -20 kV using phosphate buffer (25 mM, pH 2.5) with 20% methanol and 100 mM SDS	Phosphate buffer (50 mM, pH 2.5) with 30% methanol and high condition buffer (100 mM Phosphate, 6.9 kPa for 99.9 s). Electrokinetic injection (10 kV, 500 s)	15 ng/mL (MO and COD) and 5 ng/mL (MA)	Real urine samples	[119]

(*continued*)

Table 33.3 (continued)

Analytes	Mode of CE	Preconcentracion and extraction procedures	Experimental and instrumental parameters	Limits of detection	Matrix of application	References
MO, 6-AM	CE-FLD ($\lambda_{ex} = 350$ nm, $\lambda_{em} = 500$ nm)		Derivatization with diazonium, in presence of β-CD	1.0–3.3 ng/mL	Human urine	[121]
MO, COD, NM, M3G, M6G	CSEI-sweep-MEKC-UV at 200 nm	SPE. Stacking using phosphate buffer (25 mM, pH 2.5) containing 22% methanol and 100 mM SDS	Phosphate buffer (75 mM, pH 2.5) with 30% methanol and high condition buffer (120 mM phosphate, 10.3 kPa for 99.9 s)	10–35 ng/mL	Urine samples	[120]
Five narcotics	pCEC-ESI-MS with silica-based monolithic column		2 mM ammonium acetate (pH 6.0) with 65% MeCN (v/v) at 8 bar, 25 kV and 3 μL/min of sheath liquid	2.0–80 nM		[134]
6-MAM, MO, AM, MA, MDA, MDMA, benzoylecgonine, ephedrine, cocaine	CZE-MS	LLE after overnight incubation with 0.1 M HCl at 45°C	25 mM ammonium formate (pH 9.5). 15 kV. Sheath liquid composed of isopropanol-water (50:50 v/v) with 0.5% formic acid at 4 μL/min	0.1 ng/g	Hair samples	[128]
Lidocaine, bupivacaine, noscapine, PV	CZE-UV	SPE using Oasis HLB cartridges		300 ng/mL	Urine samples	[110]
TB, COD, MO, PV, narcotine	CZE-UV				Opium samples from India	[111]
Heroin, amphetamines, ketamine	CE-UV	DLLME	Chloroform (organic extractant) and isopropanol (dispersive solvent)	0.05–0.20 μg/L	Banknot, kraft paper, silver paper samples	[135]

Plasma and serum are typically used for emergency testing in forensic and toxicology, and in therapeutic monitoring, as they are suitable as samples to determine the short-term use of drugs. Drawbacks are that blood is an invasive sample, difficult to handle and reflects the patient's dosages for some hours only. CZE with TOF ionization coupled with MS have been used for the analysis of opiates in blood samples, obtaining limits of detection between 2 and 10 ng/mL [130].

Although urine and blood are the most common and preferred matrices used for the toxicological studies involving this type of analysis, hair is gaining in importance as an alternative specimen for documentation of use or exposure to drugs because of its different advantages, especially its stability and ease for sampling and storage, compared with the other conventional biological samples. Hair analysis is a useful specimen to provide evidence for previous drug use in legal cases. It is currently applied in workplace drug testing, postmortem toxicology, doping control, and certification of physical fitness to drive vehicles. As a sample, it is obtainable noninvasively, it is easy to preserve, and it is the only one that provides information about the quantity and historic pattern of drug use, having a retrospective period of months or years, saving drugs and their metabolites unchanged. Nevertheless, a limited number of papers have described methodologies for hair analysis based on CE and always coupled with MS, both employing ESI or TOF ionization procedures and using LLE as sample extraction procedure [128, 129]. In both cases, the limits of detection are below the cutoff of 0.1 ng/g proposed by the SHT.

The other field of application of the different methods of analysis is the cultivated opium plant (*P. somniferum L.)* itself, which produces TB. It has a long cultivation history worldwide and there are many varieties having various colors and shapes of flowers, shapes of capsules, and alkaloid composition and content. Despite the strict control of the plants, seeds of *P. somniferum* have been imported and sold as an ornamental gardening flower for which to control illegal cultivation of the plants, rapid and reliable extraction methods of opium alkaloids from many plant samples are required. CZE-UV has been employed for the analysis of opium samples and poppy straws [111, 113] and in presence of β-CD by CE-CD-UV in Iranian opium poppy plants [114]. Other detection systems such as MS and ECL with the same separation technique have been employed for the analysis of illicit samples [131] and Chinese traditional medicine opium poppy samples [124], respectively.

2.3.2 Typical Sample Pretreatments Prior CE for the Analysis of Opium Alkaloids

CE presents potential advantages in forensic science to carry out the analysis of opium alkaloids, as it can be in the different applications being published. Nevertheless, the lack of the sensitivity required for this type of analysis is always a great problem. One of the most basic approach for sensitivity enhancement is based on increasing analyte mass loading via online sample preconcentration techniques. The most widely employed in the analysis of major alkaloids is FASI that basically consists in a mismatch between the electric conductivity of the sample and that of the running buffer. It is achieved by injecting the sample diluted in a solvent of lower conductivity than that of the carrier electrolyte. Upon the application of the voltage (electrokinetic injection), an enhancement of the electric field strength occurs in the low-conductivity zone, which induces an increase of electrophoretic velocities. When electrokinetic injection is performed in normal polarity mode, cations experience the high field strength, move rapidly and concentrate in sharp bands in the tip of the capillary at the boundary between the sample and the separation buffer. Once in the separation buffer, the injected components of the sample migrate in different zones according to their charge/mass characteristics. FASI has been successfully applied to the analysis of opium alkaloids in many different forensic samples such as human urine [107, 108], hair [129], blood [130], and also in Chinese opium plants [124].

The most important prerequisite for achieving high sensitivity associated with FASI is that samples have to be free of electrolytes. Biological samples have high salts and ion contents which seriously interfere in FASI. For such a reason, online or off-line LLE [118, 128–130] and SPE [110, 120, 132] are traditionally the most employed pretreatment methods. However, LLE usually requires some poisonous volatile organic solvents while SPE is a method with good purification and concentration effects, but it requires a solvent desorption step with traditional volatile organic solvents and the pretreatment processes are relatively time consuming and, sometimes, sample recoveries are not satisfactory. Therefore, the development of simple and environment-friendly pretreatment methods such as the previously cited DLLME is of great interest. Until now, DLLME is widely applied to the preparation of environmental water samples but it is rarely applied to the analysis of drugs of abuse by CE. To our knowledge, the first time to combine DLLME with CE using UV detection for the separation of heroin, amphetamines and ketamine in different samples of forensic interest have been carried out by Meng et al. [135].

3 Conclusions

Determination of opiate alkaloids in samples of forensic interest at very low levels of sensitivity will be always required, thus new analytical strategies will have to take this trend into account. Gas chromatography, liquid chromatography, and capillary electrophoresis mainly coupled with tandem mass spectrometry are the methods of choice for the quantification of these drugs of abuse and their metabolites in numerous samples such as opium plants, food, pharmaceutical preparations, environmental samples, and mainly biological samples such as blood, urine, hair, meconium, vitreous humor, and sweat. Online sample cleaning methods, which allow the sample preparation and introduction steps to be combined into one, have been thoroughly investigated. LLE and SPE are the most widely employed but require large volumes of toxic organic solvents and are highly time consuming. SME methodologies are the current trend. Recently, the sample preparation step before analysis is getting more and more simplified, SME methodologies, especially EME and DLME, being the current trend because they are considered green pretreatment techniques, obtaining high enrichment factors, high extraction recoveries, simplicity of operation, and low cost.

Abstract

Catharanthus roseus is an important dicotyledonous medicinal plant that contains various anticancer components. The most important constituents with biological activity in *Catharanthus roseus* are terpenoid indole alkaloids. The analytical methods for determining bioactive compounds in *Catharanthus* alkaloid are summarized in this chapter. HPLC and CE methods are mainly introduced; the advantages and limitations of each technique are also compared and discussed.

Keywords

Alkaloids • analysis • *catharanthus roseus*

SFE	Supercritical fluid extraction
VCR	Vincristine
VLB	Vinblastine

1 Introduction

Catharanthus roseus (L.) G. Don (family of Apocyanaceae) is a tropical perennial subshrub which is rich in terpenoid indole alkaloids. Indigenous to Madagascar, *Catharanthus* is now cosmopolitan in distribution, spreading to South-East Asia, India, Indonesia, Australia, and North and South America [1]. It is a worldwide known medicinal plant used for the treatment of tumor, hypotensive, and arrhythmic diseases [2]. The *Catharanthus* (or Vinca) alkaloids comprise about 130 terpenoid indole alkaloids, in which vincristine (VCR) and vinblastine (VLB) are the most important alkaloids for the pharmaceutical industry [3]. VLB and VCR were discovered as a result of a drug-screening program which performed in the late 1950s. VLB and VCR have been applied in the treatment of several kinds of cancer, such as Hodgkin's disease, lymphosarcoma, choriocarcinoma, neuroblastoma, carcinoma of the breast, and chronic leukemia [3].

The growing interest in secondary metabolites of plants leads to the requirement of the development on analytical method for the secondary product analysis. Chromatographic procedures for the determination of alkaloids have been well established. Based on the literatures published in past years, further improvement of the current methods for the analysis of C*atharanthus* alkaloids are needed [4]. Besides, the chemical complexity and unique bisindole alkaloid structure of the aforementioned molecules hindered their laboratorial synthesis. The isolation of VLB and VCR is laborious and costly, mainly due to their low contents in the plant and coexistence in a large number of other alkaloids [5]. Therefore, it is important for separation, identification, and quantification of these *Catharanthus* alkaloids. The methods of extraction and purification were focused on liquid–liquid extraction, solid-phase extraction, supercritical fluid extraction (SFE), and molecularly imprinted polymers (MIPs)-based extraction. For separation, GC is not suitable for the bisindole alkaloids due to their high boiling point. The major methods for analysis of *Catharanthus* alkaloids are liquid chromatography (LC) and capillary electrophoresis (CE).

Different methods for analysis of *Catharanthus* alkaloids are employed for different purposes. (1) Plant tissues are analyzed when investigating the quality of plant raw material for alkaloid extraction, purification, and isolation. Chromatographic methods for this purpose must be highly selective for large numbers of similar alkaloid metabolites and highly sensitive for minute quantities. (2) In pharmaceutical quality control, the composition of the samples is usually relatively simple, but extraction reproducibility and automation of a method are also required. Sensitivity is necessary as well to ensure the detection of byproducts or degradation of the product. (3) In clinical drug monitoring or in toxicological cases, the sample matrix is complex. In forensic analysis, there are similar samples. Thus, sample preparation becomes a major issue as to provide sufficient concentration of analytes. The detection is usually combined with identification methods such as MS [4, 6].

Chromatographic method is commonly use and powerful technique for the analysis of *Catharanthus* alkaloids. Therefore, this chapter will focus on practical application of chromatographic and electrophoretical methods for analysis of *Catharanthus* alkaloids.

2 Method of Sample Preparation

Extraction and sample preparation are of importance in plant analysis. Clinic and forensic analyses usually rely on appropriate sample preparation to achieve a sufficiently low limit of detection. The pretreatment procedure before the chromatographic measurement must ensure exhaustive extraction of the analyte and removal of matrix that may interfere with analysis. Sample preparation methods for analysis of *Catharanthus* alkaloids include liquid–liquid extraction (LLE), supercritical fluid extraction (SFE), and molecularly imprinted polymers (MIPs)-based extraction.

Sample preparation methods without any loss of the target compounds are important, especially when a quantitative assessment of all alkaloids in a given plant sample is required. For many alkaloids, the sample preparation procedure is based on the difference in the solubility of the alkaloids salt in comparison with the free bases. An acidic aqueous extraction must be basified to transfer alkaloids into the free base for extracting into organic solvents nonmiscible with water. Excessive use of alkali, however, is detrimental for the ester alkaloids.

When LLE is used, it is advisable to do either very quickly or from only a moderately alkaline aqueous solution, which was basified by sodium carbonate or ammonia. The *Catharanthus* alkaloids was prepared by LLE from the 75 % ethanol extract at pH 3.5, then adjusted the basic to pH 12 and finally extracted by chloroform [7]. Three major alkaloids, vinblastine and its monomeric precursors (vindoline and catharanthine), were monitored in transformed root cultures of *Catharanthus roseus*, after rapid sample preparation by LLE in our previous work [8]. The extraction method was the same as above. Other Catharanthus alkaloids, such as vindoline, catharanthine, and anhydrovinblastine, were prepared by LLE from the methanol extraction [9].

An alternative to LLE is supercritical fluid extraction (SFE). SFE technique has been considered as a good option for the extraction of natural products, particularly for food and pharmaceutical ingredients. Supercritical carbon dioxide is the most common fluid used because of its physiological compatibility, nontoxicity, inflammability, inexpensiveness, and availability. In addition, high selectivity, convenient critical parameters and environmental friendliness are significant advantages of using carbon dioxide as supercritical fluid [10].

The procedure is described as follows: supercritical fluid extractions were performed with an automated ISCO SFX™ 3560 instrument using 6 mL extraction vessels. The extraction vessels were filled with 100 mg of dried plant samples mixed with anhydrous sodium sulfate. The extracted analytes were collected into 10 mL of methanol. The internal standard was added to the collection vials immediately after extraction. The collection temperature was 5 °C. The SFE instrument was equipped with a 260 mL syringe pump for the addition of carbon dioxide at a flow rate of 1.5 mL/min and a manually controlled Jasco PU-980 HPLC pump for addition of the modifier (methanol) at flow rates of 0.04–0.1 mL/min (2.6–6.6 %). The restrictor temperature was set at 60 °C in all extractions [11]. In this paper, the extracts from SFE were found to be much cleaner in comparison with those obtained by solid–liquid extractions or Soxhlet extractions. The results showed that supercritical fluid extraction is a valuable alternative technique to traditional extraction methods of *Catharanthus* alkaloids from dried leaves.

Ionic liquids are a class of salts that exhibit surprisingly low melting temperatures. They are liquid at room temperature, which is remarkable when the high melting temperatures of classical inorganic salts such as NaCl are considered. Ionic liquids have recently attracted much interest in a variety of applications because of their unique chemical and physical properties. They benefit from extremely low vapor pressure, high specific solvent ability, chemical and thermal stability, and nonflammability.

Ionic liquid-based ultrasound-assisted extraction (ILUAE) was successfully applied to the extraction of three alkaloids, vindoline, catharanthine, and vinblastine from *Catharanthus roseus*. Twelve ionic liquids, with different cations and anions were investigated in this work. In addition, ultrasound extraction parameters, including soak time, solid–liquid ratio, ultrasound power and time, and the number of extraction cycles, were optimized. ILUAE offered short extraction times (from 0.5 to 4 h) and remarkable efficiency. Therefore, the use of ionic liquids in the ultrasound-assisted extraction of key chemicals from medicinal plants shows great potential [12].

3 Analytical Methods

3.1 High-Performance Liquid Chromatography

HPLC analysis for pharmaceutical preparations of alkaloids started about 30 years ago. Gas chromatography (GC) is suitable for volatile compounds and requires laborious derivatization. Thus, GC is unsuitable to analyze the bisindole alkaloids due to their high boiling point. HPLC can provide better analytical precision and higher sample loading capacity. HPLC methods coupled to UV and MS detection have been applied for the determination of the active compounds in *Catharanthus roseus*.

In a previous work, we developed a LC-UV method for simultaneous determination of five active alkaloids vinblastine, vindoline, ajmalicine, catharanthine, and vinleurosine in *Catharanthus roseus*. HPLC analyses were performed on an 1100 HPLC instrument equipped with a binary pump, a UV detector, an autosampler, and

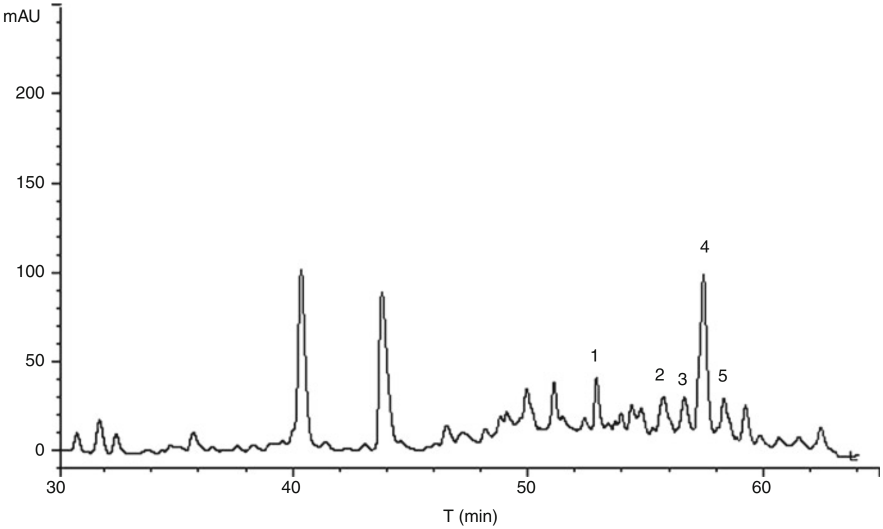

Fig. 34.1 Typical chromatograms of f sample by LC-UV. Peak identification: *1* vinblastine, *2* vindoline, *3* catharanthine, *4* ajmalicine, *5* vinleurosine

a column thermostat. Chromatographic separations were carried out on a DL-C_{18} column (5.0 μm, 250 × 4.6 mm, Japan) column at 25 °C. Elution was performed with a flow rate of 0.5 mL/min. Acetonitrile (A) and 10 mM ammonium acetate in water (B) were used as a mobile phase. Gradient elution was used as follows: 10 % A (2 min), 10–30 % B (10 min), 30–45 % B (30 min), 45–70 % B (50 min), 70–80 % B (65 min), 80–95 % (70 min). After the run, the gradient was set back to 10 % A and the system was allowed to equilibrate. The injection volume was 10 μL and the detection wavelength was 280 nm. The typical chromatograms of sample are shown in Fig. 34.1.

HPLC in combination with tandem mass spectrometry (MS) appears to be a more suitable technique for the screening of the active compounds in plant samples in terms of sensitivity and selectivity. In recent years, analytical techniques have made great advances. LC-MS and LC-tandem MS (LC-MS/MS) equipped with quadrupole time of flight (Q-TOF) and quadrupole-linear ion trap (Q-LIT) play a crucial role in plant analysis. Ion trap (IT) mass spectrometry is well used in the structure elucidation and in the identification of unknowns in complex matrices. Moreover, several reports show that IT mass spectrometry can also be very useful for quantitative analysis. The five alkaloids can be studied in positive-ion modes by IT-MS, due to their weak basicity from the azacyclo-group in the structure. More importantly, MS^2 can afford much more confidence for compound identification and much lower noise level for quantification. The fragmentation map of a target analyte is useful in performing MS^2 for either qualitative or quantitative analysis. The identical five active alkaloids were dissolved in methanol and analyzed by

ESI-MS^n in positive-ion mode. The protonated molecule ions of $[M + H]^+$ and major fragment ions were observed in the full scan MS and MS^2 spectra in positive-ion mode. We choose the protonated molecular ions and the highest intensity of product ions as the quantification ions. Thus, vinblastine, vindoline, ajmalicine, catharanthine, and vinleurosine were *m/z* 825 → 807, 457 → 397, 353 → 144, 337 → 144 and 809 → 748 were chosen by LC-IT-MS, respectively.

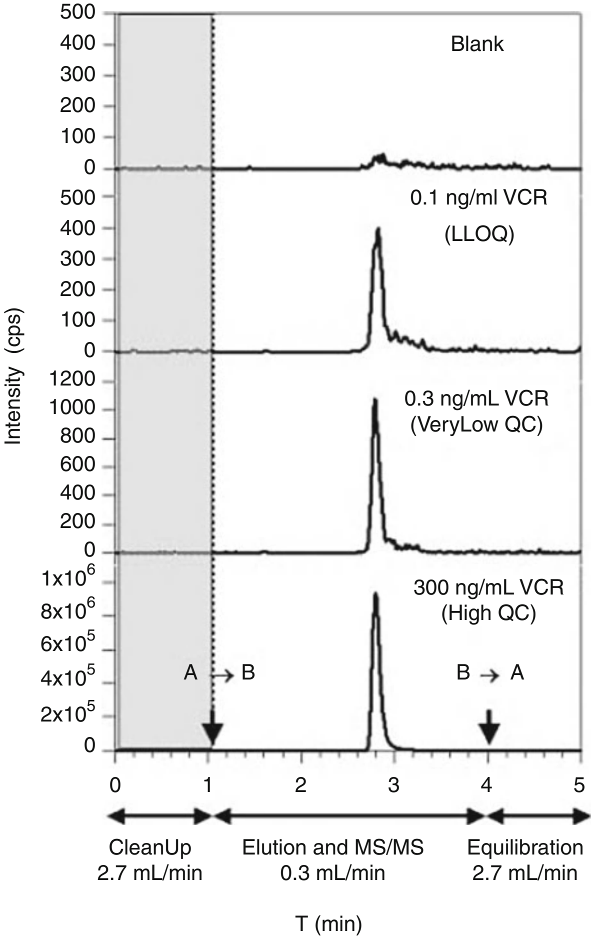
Recently, we developed a LC-MS method for simultaneous determination of these five active alkaloids. Comparing with the two methods, MS can supply a high selectivity and sensitivity for determination of the analytes in positive mode and UV can obtain an excellent repeatability for analysis of them in *Catharanthus roseus*. In conclusion, the two methods have a good linear, reproducibility, precision, accuracy and recovery, and could be used for quantitative analysis of the five active compounds in *Catharanthus roseus*.

For analysis of alkaloids in *Catharanthus roseus* roots, Ferreres et al. describe a phytochemical study on this species roots. Alkaloids in aqueous extracts, the usual form of consumption of this matrix, were studied by HPLC-DAD-ESI-MS/MS, which allowed the identification of 19-S-vindolinine, vindolinine, ajmalicine and an ajmalicine isomer, tabersonine, catharanthine, serpentine, and a serpentine isomer. Quantification of the identified compounds revealed that serpentine and its isomer were predominant (64.7 %) over the other alkaloids, namely, vindolinine and its isomer (23.9 %), catharanthine (7.7 %), and ajmalicine (3.8 %). The proposed procedures revealed to be simple, sensitive, and reproducible [13].

An ultra-performance liquid chromatography/mass spectrometry method for simultaneously quantifying vindoline, catharanthine, serpentine, and ajmalicine in *Catharanthus roseus* cell line C20hi was reported by He et al. Samples were extracted with 1 % acetic acid, basified to pH 10 with ammonia, then extracted with ethyl acetate, dried, reconstituted with methanol −1 % acetic acid water solution (1:1, v/v) and analyzed using an acetonitrile −0.1 % formic acid gradient as the mobile phase. Detection was carried out by electrospray ionization mass spectrometry in the positive-ion mode with selective ion monitoring. The analysis of one sample was achieved in 6 min. The limits of detection were 0.46–0.70 ng/ml in cell samples, and 0.10–0.16 ng/ml in medium samples. The linearity of detection was over the wide range of 1.00–6250.0 ng/ml. Intra- and inter-day accuracies (recovery 88.0–111.8 %) and precision (RSD 1.25–7.81 %) showed the performance of the assay. This method provides a more sensitive and high-throughput technique to quantify the four alkaloids in large amount of samples, and will be helpful in high-production cultivar screening [14].

Liquid chromatography coupled to mass spectrometry and tandem mass spectrometry (LC/MS and LC/MS/MS) lead to major breakthroughs in the field of quantitative bioanalysis due to high specificity, sensitivity, speed, and reliability, which becomes the preferred analytical tools for analysis of drugs and metabolites in biological matrices. A simple and rapid method has been developed and validated for the quantitation of vincristine in human plasma by LC/MS/MS with atmospheric pressure chemical ionization using on-line solid-phase extraction. The method uses vinblastine as internal standard and the sample preparation is

Fig. 34.2 Examples of MRM (m/z: 825.3 → 765.3) chromatograms for VCR. In a blank plasma sample, in plasma spiked with VCR concentration at 0.1 ng/mL (*LLOQ level*), 0.3 ng/mL (*Very-Low QC*), and 300 ng/mL (*High QC*). The *shadowed area* refers to the time section for sample loading and cleanup, the *A* and *B* are referred to switching valve positions (From Ref. 15)



limited just to a plasma protein precipitation step. Further sample cleanup is carried out on-line through a perfusion column preceding an analytical phenyl LC column, the latter directly connected to the mass spectrometer. Quantitation is performed in multiple reaction monitoring mode using the transitions of m/z 825.3 → 765.3 and 811.3 → 751.3 for vincristine and vinblastine, respectively. Figure 34.2 shows the typical chromatograms for a blank plasma sample, spiked plasma at LLOQ, and QC samples at very-low and at high concentrations. No peaks from interfering endogenous plasma components are present in the chromatograms, further supporting the high specificity of the 825 → 765 amu MRM transition.The assay was linear ($r^2 \geq 0.99$) in a concentration range from 0.1 to 500 ng/mL. Carryover, measured on the experimental setup, was less than 0.04 %. Recovery for vincristine and the internal standard was within 90–95 %. The intra-day and inter-day assay precision ranged from 1.2 % to 6.8 % RSD, while mean percentage deviation from nominal value ranged from 0.01 % to 6.1 %. The proposed assay was found suitable for pharmacokinetics investigations and clinical therapeutic drug monitoring especially in pediatric cancer patients [15].

3.2 Capillary Electrophoresis

CE appears well suited to alkaloid analysis because these compounds are natural cations if the appropriate acidic buffer is chosen. Migration of the analytes in the usual cationic mode is caused by the charged nitrogen atom. The sample volume in CE is very low, only a few nanolitres, and therefore very sensitive detection is required. The separation mechanism of CE fundamentally differs from HPLC and, therefore, CE can provide complementary or additional information on the composition of a sample. In general, CE separations can be achieved in a fast and highly efficient way without extensive sample pretreatment. Other advantages of CE include the very low or even the absence of organic solvent consumption, the small amount of reagents needed, and the use of simple fused-silica capillaries instead of the expensive LC columns. The relatively poor sensitivity of CE, resulting from the small loading volumes, could be circumvented by the incorporation of preconcentration strategies. While the advantages of MS detection are embodied in the improvement of detection sensitivity as well as the capability of both determining the exact mass of analytes and providing structural information, including the possibility to identify and determine co-migrating species in overlapping peaks.

Vincristine (VC) and vinblastine (VB) are dimeric catharanthus alkaloids isolated from the plant *Catharanthus roseus*. A capillary zone electrophoresis (CZE) was conducted for systematic and comprehensive study of the separation and quantification of two dimeric catharanthus alkaloids. Various separation parameters such as buffer concentration and pH, column internal diameter, and applied voltage were studied: column, 72 cm (57 cm effective length) × 75 μm I.D.; buffer, 0.2 M ammonium acetate solution, pH 6.2 and an applied voltage of 10 kV. Although the separation of VB and VC was the primary focus, the separation parameters determined in this study can be applied to the separation of other alkaloids as well. Separation of other alkaloids in the plant samples was observed under conditions presented in this work. A secondary objective of this study was to develop a method with experimental conditions which could be applied to electrophoresis-mass spectrometry. For this purpose, ammonium acetate buffers, which are more compatible with mass spectrometry than the widely used phosphate buffers, were used exclusively. Also, methanol–water-acetic acid was used as external buffer for the same reason [16].

An aqueous electrolyte solution was initially used to separate the indole alkaloids mentioned in the experimental. The electrolyte tested was potassium hydrogenphosphate at different pH values where poor resolution was observed. Efforts to improve the separation by adding different organic solvents such as acetonitrile and methanol were found to be invalid. The use of nonaqueous solvents as electrophoretic media offers many advantages, in comparison with aqueous media, such as low joule heating and provides different selectivity which can be used to improve separation. A rapid method for the determination of Vinca alkaloids by nonaqueous capillary electrophoresis with diode array detection has been developed. A group of 11 alkaloids (catharanthine, vinorelbine, anhydrovinblastine, vinflunine, vindoline, 4-*O*-deacetylvinorelbine, 4-*O*-deacetylvinflunine, vindesine, vinblastine, 49-deoxy-20′, 20′-difluorovinblastine, vincristine) could be readily separated within 10 min. The compounds were separated using a capillary of 38 cm effective length, a running buffer composed of 50 mM ammonium acetate and 0.6 M acetic acid in a methanol–acetonitrile (75:25, v/v) 3 mixture. A constant voltage of 25 kV with a ramp time of 1 min and a 344.7310 Pa pressure, applied simultaneously to inlet and outlet buffer vials, were used during sample analysis. Five of these alkaloids were selected for optimization of the separation and for validation studies with respect to specificity, linearity, range, limits of quantification and detection, and then accuracy. The feasibility of the assay was demonstrated by analyzing a commercial sample of vinorelbine (Navelbine, ampoule at 10 mg/ml of vinorelbine base). The results were compared to a high-performance liquid chromatography method [17].

In previous work, we describe simultaneous determination of VLB and its monomeric precursors by CE-IT-MS. A baseline separation for three components has been achieved by using a running buffer consisting of 20 mM ammonium acetate and 1.5 % acetic acid in less than 20 min. Quantification of three components was assigned in positive-ion mode at protonated molecular ion $[M + H]^+$. The CE-MS method was validated for linearity, sensitivity, accuracy, and precision, and then used to determine the content of the above components. The detection limits of vinblastine, catharanthine, and vindoline are 0.8, 0.1, and 0.1 μg/mL, respectively. The precision was no more than 4.54 % and the mean recovery of the analytes were 95.04–97.04 %. The CE-MS method has been successfully applied to determine vinblastine and its monomeric precursors in real sample *Catharanthus roseus* [8]. Under the optimized conditions, CE-ESI-IT-MS separations (shown in Fig. 34.3) were obtained for total ion chromatogram (TIC) and selected ion chromatograms of VLB, VLD and CTA. Separation of a standard mixture was shown in Fig. 34.3a under TIC mode by CE-MS. Within 20 min VLB, VLD, and CTA could be well separated. Figure 34.3b, c showed the extracted ion chromatogram (EIC) of a standard mixture and real sample *Catharanthus roseus* by CE-MS. A baseline separation for three components was obtained in the standard mixture and real sample.

4 Conclusions

HPLC with UV detection is the routine method for analysis of plant material, only if the intact ester alkaloids with an UV absorbing aromatic acid or other UV absorbing functionality are to be measured. HPLC methods are robust with widely available instrumentation and high sensitivity due to improved UV detectors. A wide range of other detectors is available for specific problems and more sensitive determination.

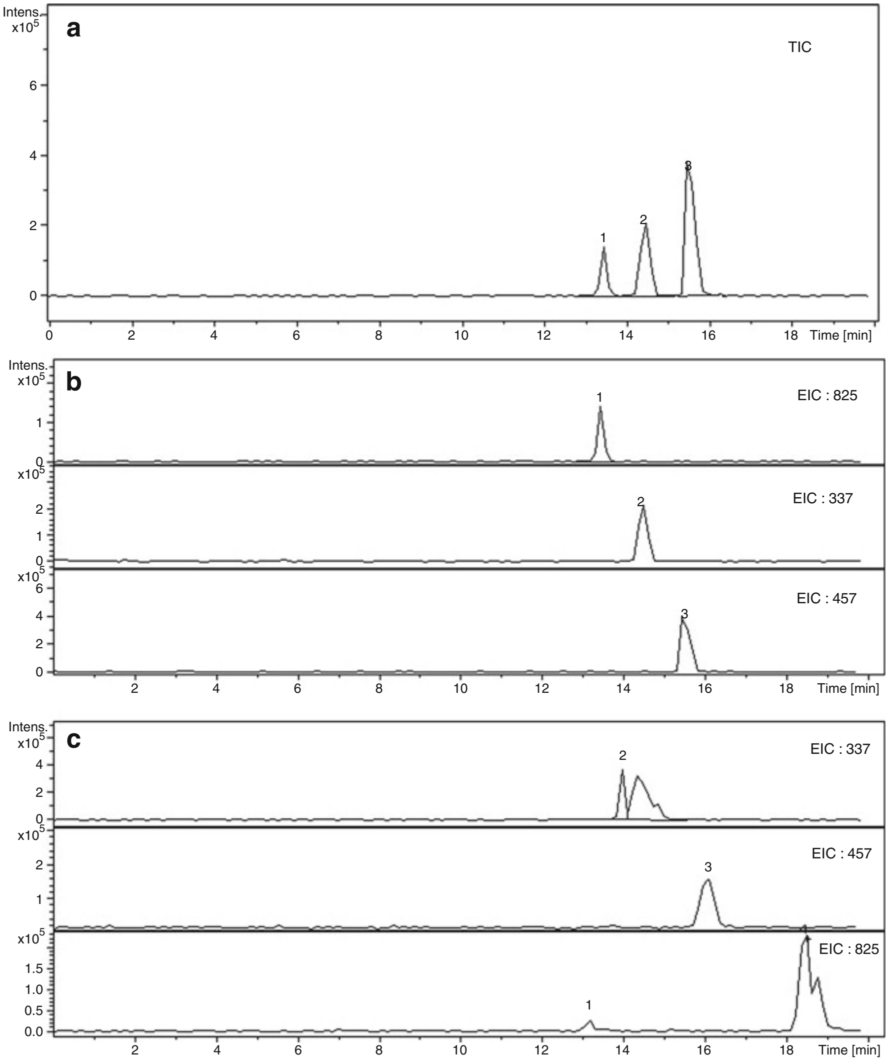


Fig. 34.3 Total ion chromatogram (**a**) and extracted ion chromatogram (**b**) of a standard mixture solution, and extracted ion chromatogram (**c**) of *Catharanthus roseus* extract by CE-MS. CE conditions: capillary, 65 cm length and 50 μm i.d, buffer: 20 mM s ammonium acetate aqueous with 1.5 % acetic acid, temperature: room temperature, sample, 50 mbar for 5 s injection; MS-conditions: ESI positive, sheath gas: 4 psi; dry gas: 6 L/min; dry temperature: 130 °C; capillary voltage: 3.5 kV; sheath liquid: methanol/water = 1/1, with 0.1 % acetic acid; flow rate of sheath liquid: 4 μL/min. Peak identification: *1* vinblastine; *2* catharanthine; *3* vindoline (From Ref. 8)

Usually, sample preparation for HPLC is relatively simple. For the sensitive measurement of *Catharanthus* alkaloids at low concentration, however, sample purification is required. HPLC, in contrast to GC or CE, can be scaled up to allow the preparative separation of alkaloids.

LC-MS for *Catharanthus* alkaloid analysis is a promising approach which will be increasingly used in the future, as interfaces are improved and highly selective solvent systems become available. The metabolites and catabolites of *Catharanthus* alkaloids can also be identified and determined by LC-MS conveniently.

CE possesses higher separation efficiency and could supply complementary information to HPLC. The LOD expressed as concentration in CE is higher than GC and HPLC because of the small sample volumes and the relatively low concentration for Catharanthus alkaloids. Using nonaqueous solvents, CE can be coupled to MS easily and would provide a powerful means for alkaloids separation and identification in the near future.

Abstract

The determination of contamination of feed and food by ergot alkaloids is of great importance in preventing poisoning of cattle and consumers and economic losses. Established but crude methods based on the gravimetric measurement of ergot fruiting bodies (sclerotia) after microscopy and manual selection are now being replaced by more sophisticated techniques. Enzyme linked immunosorbent assays (ELISAs) can rapidly indicate the total ergot contamination on several samples

simultaneously but give no information on the individual alkaloids. Methods based on liquid chromatography with detection by fluorescence measurement or mass spectrometry permit the quantification of individual ergot alkaloids and their epimers, which is important as their toxicities vary. The merits and handicaps of these methods are described, and associated factors such as the availability and stability of standards, and the extraction procedures are discussed.

1 Introduction

Ergot alkaloids are produced by various species of the fungus *Claviceps*, most notably by *Claviceps purpurea*. In cereals, the fungus replaces the developing grain with the alkaloid-containing sclerotium. Three major groups of ergot alkaloids are most commonly encountered, examples of which are shown in Fig. 35.1. The groups are clavines, water-soluble lysergic acid derivatives, and ergopeptides, which are lysergic acid derivatives insoluble in water.

Clavine alkaloids appear to be biosynthetic precursors of the other groups. The amount and pattern of these alkaloids vary between fungal strains and depend on the host plant and the geographical region, but the most frequently encountered alkaloids produced by *Claviceps* species are ergometrine, ergotamine, ergosine, ergocristine, ergocryptine, and ergocornine. Related compounds having the lysergic acid structure, notably its diethylamide (LSD) are of medicinal and forensic interest.

Ergot alkaloids that contain a C9 = C10 double bond readily undergo reversible epimerization at the asymmetric carbon atom in the 8 position in the lysergic acid part of the molecule to produce a mixture of left-hand rotational isomers with the C-8-(R) configuration which are called ergopeptines, and right-hand rotational (S)-isomers diastereomers called ergopeptinines, as shown in Fig. 35.2.

The epimers are reflected in the names, for example, where ergotamine is the ergopeptine form the ergopeptinine epimer is named ergotaminine. The C-8 epimers differ in biological and physicochemical properties, with the -ine forms being more biologically active. In nature the alkaloids always exist in both forms, and epimerization also occurs on storage of samples or during extraction from cereals.

A small proportion of -inine alkaloids, based on *iso*-lysergic acid, are commonly reported in extracts of sclerotia. These may be generated, at least in part, through the epimerization of lysergic acid during analytical extraction procedures.

Ergot alkaloids can cause adverse health effects in humans and animals. There are reports on human intoxications and on ergot poisoning of farm animals in particular cattle, horses, sheep, pigs, chicken, and even wild animals. Sclerotia will be harvested together with the cereal grains and can thus result in alkaloid contaminated cereal-based feed and food products. Sclerotia are most prevalent in rye and triticale, but they can also occur in wheat and other small grains. The average total alkaloid content of ergots found in central Europe varies between 0.01 % and 0.2 %. Normally, most intact ergot sclerotia are removed by sieving during the first cleaning process of grain in the mill. Grain can be rapidly checked for ergot before milling by examination under a stereo microscope, but more rapid and automated methods are desirable. Levels of ergot alkaloids in animal feed containing unground cereals are limited to a maximum of 0.1 % (1,000 mg kg^{-1}) under European Commission directive 2002/32/EC [1]. In 2012, the European Commission [2] recommended that the presence of ergot alkaloids in cereals and cereal products intended for human consumption or intended for animal feeding, in pasture/forage grasses for animal feeding and in compound feed and food be monitored, and that whenever possible, the sclerotia content in the sample should be measured simultaneously in order to be able to improve the knowledge on the relationship between the content of sclerotia and the individual ergot alkaloids. EFSA, the European Food Safety Authority stated in April 2005 that there is a special concern related to animal feed, and that validated analytical methods are required for the quantification of ergot alkaloids in feed material [3]. In 2012, EFSA issued an opinion on ergot alkaloids that included a call for laboratories to carry out

Fig. 35.2 Epimerization of ergot alkaloids containing a C9 = C10 double bond with respect to the center of symmetry at C-8 (From Krska and Crews [7]. Reprinted by permission of the publisher (Taylor & Francis Ltd, http://www.tandf.co.uk/journals))

a survey of ergot alkaloids in cereals intended for human consumption and animal feeding [4]. The EFSA Panel on Contaminants in the Food Chain has recommended that data on the variability of the ergot alkaloid patterns in feed materials should be collected in Europe and that validated analytical methods for the quantification of the major ergot alkaloids in feed materials should be developed.

EFSA has also indicated the procedures required for storing samples before and after pretreatment, milling, and other sample preparation steps. The preferred analytical methods are based on multianalyte liquid chromatography (LC).

LSD is used as a drug of abuse and has potential medical applications. There are therefore forensic requirements to measure LSD and its isomer *iso*-LSD in body fluids including urine. LSD is considered a semisynthetic drug, being made from some naturally occurring ergot alkaloids by hydrolysis to lysergic acid, which is then reacted with diethylamine to produce LSD.

Methods for the analysis of ergot alkaloids have been reviewed by several authors [4–7]. Sclerotia can be measured in grain by picking out the particles or by electronic imaging techniques. These are useful at the processing plant but to test for food and feed safety instrumental methods that measure the alkaloids in total or individually are preferred. The three major approaches of enzyme linked immunosorbent assays (ELISA), liquid chromatography with fluorescence detection (LC-FLD), high-performance liquid chromatography with mass spectrometry (LC-MS). Alternative methods such as gas chromatography with mass spectrometry (GC-MS) and thin layer chromatography (TLC) remain useful for certain applications. Nuclear Magnetic Resonance spectroscopy (NMR) is becoming more importance in analytical chemistry as instrument sensitivity increases. It has not been applied to the quantitative determination of ergot alkaloids in cereal products but has proven useful in structural determinations, particularly of products used as therapeutics.

Sclerotia have long been quantified in grain by visual inspection or microscopy. Today, more sophisticated and automated methods are available for counting the proportion of sclerotia in grains. For quantification of the total ergot alkaloid content methods based on color reaction tests, immunoassays, or NMR are available. For quantification of individual ergot alkaloids liquid chromatographic methods with fluorescence detection or mass spectrometry are required. The instrumental methods require effective extraction of the alkaloids, and some degree of clean up. Appropriate procedures are needed to avoid epimerization during the sample and extract handling stages.

The facile epimerization of ergot alkaloids is very important in their analysis. The -inine epimers are thought to be physiologically inactive but since they are readily converted to the –ine form it is greatly advantageous to determine both isomers. The active and inactive isomers cannot be differentiated by techniques that use the typical color reactions for ergot alkaloids, or by most methods that do not involve chromatographic stages. Epimerization affects standard solutions as well as sample extracts. It is influenced by temperature and solvent. For longer-term storage stock standards need to be kept free from solvent and frozen to at least −18 °C, being reconstituted immediately before use. For medium-term storage additives such as ethylene glycol, 1,2-propanediol, or tartaric acid dissolved in mixtures of ethanol and water have been recommended.

Ergopeptide alkaloids form water-addition products known as lumiergopeptines, and so analysis of plant materials and food needs to be carried out in subdued light. Another rearrangement occurs in the peptide part of ergot alkaloids, with isomers being slowly formed at room temperature. This reversible isomerization leads to rearrangement products (aci-alkaloids) that are practically inactive pharmacologically.

Although much progress has been made in this field in recent years method validation has been largely restricted to studies made in individual laboratories. The reported validations have included descriptions of the type of calibration, the limit of detection (LOD), and limit of quantification (LOQ), the recovery, repeatability, within-laboratory reproducibility, and ruggedness.

2 Methods of Analysis

2.1 Sampling

Ergot sclerotia are not distributed homogeneously throughout grain, and therefore sample sizes should if possible be fairly large (1–5 kg). Samples or subsamples may require drying, in which case the loss of weight should be recorded, and the measured alkaloid content corrected for the original weight.

2.2 Spectroscopic and Related Methods

Analytical methods based on visual and spectroscopic determination may be applied to both sclerotia (intact and broken) and to the total alkaloid content. Methods for detecting ergot bodies in cereals require passing a suitably sized (e.g., 250 g) sample through a range of sieves and collecting a fraction of 1–3.5 mm diameter. A portion of this is spread on a table, and the ergot sclerotia are picked out with tweezers and weighed.

In microscopy methods such as that for feed described by the International Association of Feedingstuff Analysis [8], sclerotia and sclerotia fragments with a particle size greater than 0.5 mm are selected and identified based on characteristic features and comparison to reference material. Confirmation can be achieved through color reaction. The sample is placed across a filter paper soaked with an ethanolic solution of sodium or potassium hydroxide. After about 5 min a red-violet halo appears around any ergot fragments, although this staining procedure is only applicable to fresh sclerotia material. The outer dark violet hyphae layers of sclerotia color solutions of chloral hydrate violet. The quantity of ergot is determined by weighing. Microscopy is rather slow, requiring 15–60 min to analyze 250 g cereal.

Ergot bodies can be quantified in cereals using an online near infrared (NIR) hyperspectral imaging system combined with chemometric tools [9]. This technique is more rapid than the classical microscopic method and enables a large quantity of material to be analyzed, thereby avoiding the sampling problems associated with representative sampling. NIR hyperspectral imaging allows fast (a 250 g sample can be analyzed in 1 min) and accurate inspection of food or feed in the laboratory or on the production line. This method scans a 30 cm wide conveyor belt width running at 100 mm/s and carrying up to about 100 kg grain per hour. Rapid chemometric-based data processing methods are required but the number of false negative and false positive results is low.

A large number of reagents react with ergot alkaloids to form colored products that can be detected visually, by colorimeters or by densitometers, they are thus used to show the presence of ergot alkaloids in test solutions and to identify them on TLC plates. The reagents act on all ergot alkaloids and therefore in quantitative analyses give a value for the sum of all of the ergot alkaloids present. The most widely used tests use van Urk's reagent, *p*-dimethylaminobenzaldehyde in acid solution, which reacts with two molecules of ergot alkaloids to give a blue color with an absorbance at 580 nm after exposure to light. The reagent has been refined by the addition of ferric chloride and sodium nitrite. Colorimetric tests cannot distinguish between ergot alkaloid epimers or between ergot alkaloids and some other alkaloids or amine-containing compounds such as tryptophan.

2.3 Extraction Procedures

Unlike the visual and spectroscopic techniques described above, instrumental analysis of the ergot alkaloids in food and feed samples and body fluids and tissues requires their extraction from the sample matrix. Ergot alkaloids can be extracted from cereals with nonpolar organic solvents under alkaline conditions or with polar solvents under acid conditions, with alkaline extraction conditions giving the highest yields. For modern chromatographic separations simple mixtures of acetonitrile with ammonium carbonate or ammonium hydroxide are preferred. When extraction solvents for the 12 major ergot alkaloids in cereals were compared the highest recoveries were obtained with an 84:16 v:v mixture of acetonitrile and ammonium carbonate buffer. Recoveries ranged from 91 % to 121 %. Basic conditions improve the solubility of ergot alkaloids. Alternatively mixtures of methanol or acetonitrile with dilute organic acids or buffers such as ammonium acetate can be used. Other solvent mixtures have included dichloromethane/ethyl acetate/methanol with ammonium hydroxide, and methanol/water/phosphoric acid where epimerization is less of a problem and when using HPLC with UV or fluorescence detection. Rather simple extraction procedures have been used, such as blending with acidified methanol, ethanol, or acetonitrile. Solid phase extraction using column-packed commercially available diatomaceous earth materials such (Extrelut®) as a support can be used to partition ergot alkaloids from aqueous medium into organic solvents. For the extraction of ergovaline from endophyte-infected grasses an improved performance in terms of sample losses and extraction times has been reported for the use of a mixture of 2-propanol and aqueous lactic acid solution [10].

For LC-MS methods where the LC solvent is evaporated in the instrument nonvolatile buffers must be avoided but for detection techniques such as ELISA there is no such problem and extraction solvents based on phosphate buffered saline solutions can be used alone or mixed with methanol.

Different ratios of sample to solvent might be expected to affect extraction recovery and sensitivity. The use of a high amount of solvent for a small sample size would give an extract that is relatively dilute in terms of its ergot alkaloid concentration, whereas extraction with a low solvent to sample ratio would give a more concentrated extract. A disadvantages of using a small sample size is that the chance of sampling errors is increased. However, the dilute nature of the analyte can bring increased sensitivity and mass spectrometer performance as matrix effects are reduced and there is less interference from the background signal. For ground cereals sample:solvent ratios (wt:vol) over the range 1:3 to 1:10 differ little in performance.

For LC-MS separation with highly specific detection methods simple extraction procedures and filtration can be followed by direct injection into the LC-MS. Extraction with methanol/water acidified with formic acid and subsequent ultrafiltration with a 30 kD filter has been used with success. Similarly simple approaches form the basis of most multi-mycotoxin methods which determine several ergot alkaloids along with other mycotoxins.

Solid phase extraction (SPE) is very often used to clean up sample extracts and provide more concentrated solutions of alkaloid analytes as described below but some ergot alkaloids can be extracted from comparatively clean sample matrices such as plasma or urine by direct liquid–liquid extraction or passing them through cationic SPE cartridges. LSD and *iso*-LSD have also been extracted from urine by making the sample basic and saturated with salt before shaking with 1-chlorobutane. Lysergic acid can be extracted from urine by adjusting the pH of the sample to 5.0–5.5 and passage through an SCX SPE column preconditioned with methanol followed by 0.1 M hydrochloric acid and a wash of water. After eluting unbound material with water the lysergic acid is eluted with dilute ammonium hydroxide in methanol and analyzed by LC-MS.

Another successful technique has been to use an immobilized primary and secondary amine (PSA), as dispersive PSA-SPE [11]. The PSA phase is a modified silica with ethylenediamine functional groups. It retains polar matrix compounds strongly and reduces matrix effects considerably.

Pressurized Liquid Extraction (Accelerated Solvent Extraction, ASE) has been used to extract multiple mycotoxins including ergotamine, ergocristine, ergocryptine, ergocornine, and ergonovine from grains [12]. Ground grain was mixed with drying matrix and packed into the sample cylinder. Mycotoxins were extracted with 90 % aqueous acetonitrile at 100 °C and a pressure of 10.3 MPa. Two sequential 5 min extraction steps were used. Following ASE the extracts were kept at +4 °C overnight when proteins were precipitated. An aliquot of the filtered and evaporated solution was dissolved in 50 % aqueous acetonitrile for LC-MS/MS.

2.4 Sample Cleanup

Solvent extracts usually need to be purified ("cleaned-up") prior to separation and detection. This can be achieved by liquid–liquid partitioning, column chromatography on silica gel, SPE typically using a strong cation exchange mode based on acid–base partition. Reasonably clean biological samples such as urine or plasma can be processed using SPE with considerably less prior treatment.

Cleanup can be achieved by partitioning of the alkaloids between immiscible solvents, including salting out techniques [13], following which dissolution in a polar solvent mixture and a simple wash with hexane produced a suitable sample for LC-MS/MS.

Various types of SPE have been applied, including the use of silica, basic alumina, cation ion exchange, C18 or mixed-mode cartridges [14, 15]. Ergot alkaloids can be isolated using short columns of silica gel or a commercially available chemically modified silica gel (Ergosil®) which will preferentially adsorb ergopeptine alkaloids such as ergotamine and ergovaline from plant extracts. However materials based on silica do not retain –inine isomers. Commercial “push-through” SPE cleanup columns are available for ergot alkaloids. They can reduce the time required for cleanup to less than 1 min.

2.5 Immunological Methods

Radioimmunoassays have had little use in ergot alkaloids analysis but ELISAs have been used quite extensively [16–19]. ELISA techniques are widely used in mycotoxin screening. An antibody specific for a particular antigen is immobilized on a solid support bound to another antibody specific to the same antigen. A multi-welled plastic microtiter plate is usually used. A detector antibody covalently linked to an enzyme (such as alkaline phosphatase) is added to form a complex with the antigen. The support is washed between steps to remove unbound material. The support is developed by adding an enzymatic substrate (such as *p*-nitrophenyl-phosphate) to produce a visible signal, which can be determined colorimetrically. For quantification standard curves are constructed using standards of the target analytes, preferably in a matrix extract based solution.

Both polyclonal and monoclonal antibodies have been used. Antibodies produced by exposing murine hybridoma cell lines to lysergol as the hapten have some cross-reactivity to most ergot alkaloids, except those such as dihydroergocornine and bromoergocryptine that have no substitution at the 9,10 double bond of the lysergic acid ring which changes the three-dimensional conformation of the ring.

ELISAs can screen many samples in one batch without the need for costly and complex instrumentation. They are therefore popular for screening agricultural crops and grains. They are fairly are nonspecific due to cross-reactivity, which can be high for one group of ergot alkaloids and low for another. Their specificity varies according to the antibody used. Polyclonal antibodies have been developed to bind to peptide ergot alkaloids such as ergotamine, ergostine, and ergocristine that have a phenylalanine substituent, but monoclonal antibodies have much more scope as they recognize the ergoline ring structure.

The lack of specificity is due in part to differences in the binding ability of different compounds to the antibody. Monoclonal antibodies generally bind to the lysergic acid ring of ergot alkaloids. An analysis targeted at a single compound such as lysergic acid or ergovaline is handicapped by the fact that other compounds of related structure can also bind and contribute to the nonspecific signal produced at the colorimetric measurement stage. Where classes of ergot alkaloids are targeted different binding affinities can give erroneous results. Ergocryptine, ergocristine, ergocornine, and ergotamine have the lysergic acid main ring structure but do not bind strongly to some antibodies due to the blocking effect of the large side groups on their molecules.

Competitive inhibition ELISAs are commonly used to detect ergovaline and clavine alkaloids in infected tall fescue grass [17]. Some comparisons have shown ELISAs to be in good agreement with LC-MS, but others have failed to do so. The lack of specificity means that the quantities of ergot alkaloids measured are often greater than the total amounts of ergot alkaloid content measured by chromatographic procedures in which individual compounds are quantified.

ELISA methods have LODs above 0.01 mg kg^{-1}, and reliable LOQs of 0.1 mg kg^{-1} or above. The method gives results for the “total alkaloids” and is best suited for providing a rough estimate of the contamination of food or feed. Some ELISA kits are available commercially today [20, 21]. They are often applied to the determination of ergovaline in tall fescue or in the urine of animals that have eaten infected fescue hay. The kit manufacturer claims a LOD of about 2 μg kg^{-1} total ergot alkaloids in plant tissue.

2.6 Thin Layer Chromatography

Early analyses of ergot alkaloids were carried out using paper chromatography, however, this was soon superseded by TLC methods based on silica gel or alumina supported on glass plates. TLC methods are inexpensive and relatively rapid, and they can often be carried out in the field, although they perform best with sclerotia or fungal cultures. Alkaloids can be quantified to some degree while on the plate, but are more often the spot and its supporting medium is excised from the glass plate and the alkaloids eluted from the medium and reacted with reagents that form colored derivatives that can be measured against a standard colorimetrically. TLC methods can separate isomers and have low limits of detection. Their major disadvantages are the inability for automation, a certain lack of specificity, and interference from other components of food and feed matrices.

Stationary phases of silica gel are most often used but alumina is a suitable alternative. A wide range of development solvents have been reported, many of which use chemicals (benzene, chloroform) considered undesirable today on account of their toxic properties. Mixtures of solvents are invariably required, such as chloroform/methanol; benzene/chloroform/ethanol; ethyl acetate/dimethylformamide/ethanol; benzene/acetone/diethyl ether; chloroform/acetone/acetic acid; and chloroform/ethanol.

Fluorescent ergot alkaloid spots can be identified by examination of the plate under UV light. The double bond at C9-C10 is responsible for the fluorescent properties enabling the detection of the major ergot alkaloids found in grain, but excluding clavine alkaloids. Excitation of the molecule is brought about by irradiation with light of 254, 313, 325, or 366 nm wavelength, and the fluorescence emission has a wavelength of 445 nm. Using automated detection and scanning instruments small quantities (15–100 ng of ergonovine and 50–200 ng of peptide alkaloids) can be measured. However, TLC plates are more often sprayed with Ehrlich's reagent (*p*–dimethylaminobenzaldehyde) or van Urk's reagent (described above) which produces a blue-colored product on reaction with the indole ring [22]. Examples of many other chemicals that can be used as spray reagents for ergot alkaloids can be found in the literature, including sodium 1,2-naphthoquinone-4-sulphonate in ethanol:water which gives red-purple spots on a light pink background, or 2-nitroso-1-naphthol followed by 10 % acetic acid which gives blue-black spots on a yellow background after heating.

TLC is restricted by its inability to separate the major alkaloids from each other, and is thus best used to get a picture of the overall contamination level where expense is an issue.

2.7 Gas Chromatography (GC) and Gas Chromatography–Mass Spectrometry (GC-MS)

Ergopeptide alkaloids decompose at the high injector temperatures required for common gas chromatographic (GC) split/splitless systems and the method has less value than LC methods for many applications [23].

LSD and *iso*-LSD can be measured in urine by GC-MS in electron impact (EI) mode [24]. Derivatization with bis(trimethylsilyl)trifluoroacetamide (BSTFA) is required to reduce the polarity of the LSD and increase its volatility. After solvent extraction and SPE and solvent partition cleanup the LSD was reacted with BSTFA at 70 °C for 15 min and analyzed by GC-MS in selected ion monitoring mode. Some loss of derivatized LSD occurred on GC. The overall recovery was found to be 69 % and the LOD was 50 ng L^{-1}. The LOD of the procedure is 50 ng L^{-1}.

Limited experiments have used GC-MS to identify the amino acids of the ergot peptides following hydrolysis. GC is in practice restricted to the determination of clavine alkaloids and lysergic acid amides, as in the determination of LSD in forensic samples. LSD is derivatized at the N1 position with trifluoroacetic anhydride or trimethylsilylating reagents to decrease its polarity and increase volatility for GC-MS.

2.8 Liquid Chromatography

High-performance liquid chromatographic (HPLC) procedures using reversed-phase columns and detection by ultraviolet (UV) light, fluorescence detection (FLD),

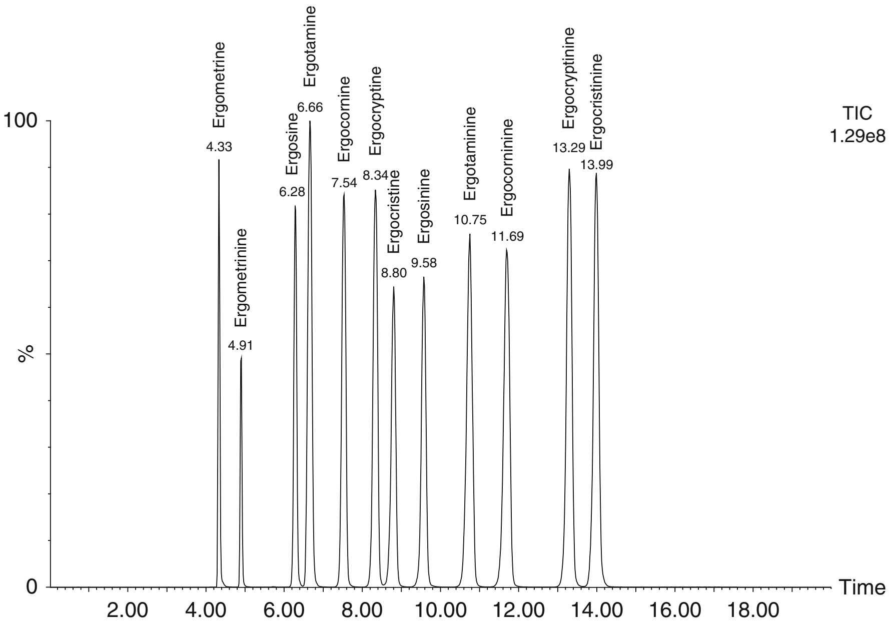

Fig. 35.3 LC-MS/MS chromatogram for the six major ergot alkaloids and their epimers (From Krska and Crews [7]. Reprinted by permission of the publisher (Taylor & Francis Ltd, http://www.tandf.co.uk/journals))

and mass spectrometry (MS) are ideally suitable for determination of ergot alkaloids in extracts of plant, cereal, and body tissues. The six major ergot alkaloids identified as being of concern by EFSA (ergometrine, ergotamine, ergocornine, ergocryptine, ergocristine, ergosine) and their respective -inine isomers are the major targets of analysis by LC methods. The epimeric forms are fairly readily separated by several mobile phase gradient programs. The ergot alkaloid content of food and feed samples can be reported as the sum of the individual alkaloids (the total alkaloid content) or as concentrations of the individual alkaloids. Figure 35.3 shows the separation obtained for the six major ergot alkaloids and their epimers.

Reversed-phase LC with C8, C18, or phenyl-hexyl stationary phases is universally used for ergot alkaloids, with isocratic or gradient mobile phases. The physical size and particle size of LC columns has decreased considerably in recent years, accompanied by an improvement in resolution and sensitivity and a reduction in analysis time. The use of ultrahigh-performance liquid chromatography columns (UHPLC) of short length and small particle size enables the confident separation of the major ergot alkaloids and their (R)- and (S)-epimers within in a run time of less than 10 min. Under alkaline mobile phase conditions the individual ergopeptines are eluted before the corresponding ergopeptinines.

The mobile phases used depend on both analytes and detection method. Those used most frequently are based on mixtures of water with methanol or acetonitrile made alkaline by the addition of ammonium carbonate, ammonium carbamate, ammonium hydroxide, or triethylamine. However, acidic mobile phases are preferred by some because many silica-based LC phases are degraded at high pH, but they do not permit the monitoring detection of both epimeric forms. Volatile weak acids are used in LC-MS to promote the ionization of basic compounds in electrospray positive mode.

Isocratic separation are preferred for UV detection to avoid drift in the baseline signal as the solvent changes. Solvents for this mode have included mixtures of acetonitrile with aqueous ammonium carbonate and of acetonitrile with a phosphate buffer. Ion pairing agent additives such as heptanesulfonic acid have been used. The nonvolatile components of some solvents used with UV detectors cannot be used in LC-MS methods where the solvent is fully evaporated in the instrument.

Epimeric conversion can take place during LC runs. This can be a real problem when large numbers of samples are stored in autosampler racks for continuous batch analysis at room temperature. In the usual solvents such as acetonitrile with aqueous ammonium carbonate epimerization from 4 % to 6 % of some ergot alkaloids over 18 h has been observed.

2.9 Liquid Chromatography-Fluorescence Detection (LC-FLD)

UV detection can be used to detect ergot alkaloids. Ergopeptines and ergopeptinines absorb at wavelengths of 310 nm and dihydroergopeptines at 280 nm, but LODs are relatively low (~0.1 mg kg^{-1}) compared to FLD, which is used far more frequently.

In LC-FLD, the analyte molecule is exposed to an excitation beam of light usually of wavelengths of 235–250 nm. The molecule absorbs a photon and is excited from its ground electronic state to higher vibrational states. Vibrational energy is lost in collisions with other molecules and the analyte molecule drops to one of several vibrational levels in the ground state, emitting a photon in the process. The photons emitted have a range of energies and thus frequencies can be detected by scanning in a spectrophotometer set to monitor specific emission wavelengths. LC-FLD has high sensitivity, selectivity, and repeatability [15, 25].

Response factors for different ergot alkaloids differ under fluorescence detection, that of ergometrine being about twice that of the other major ergot alkaloids, and so careful use of standards is required. Fluorescence detection used regularly for determining ergot alkaloids in sclerotia, endophyte-infected tall fescue grasses, cereal grains, and cereal-based foods.

Excitation wavelengths are in the range 235–250 nm or 310–360 nm, and emission wavelengths are in the range 410–420 nm for 9, 10-ergolenes. For 8, 9-ergot alkaloids and saturated D-ring ergot alkaloids the maximum fluorescence signal is obtained with an excitation wavelength of 272 nm and a detection wavelength of 371 nm. Lysergic acid has been measured in urine by LC-FLD with an excitation wavelength of 250 nm and an emission wavelength of 420 nm.

LC-FLD methods have good sensitivity with detection limits for individual ergot alkaloids in grains and grain foods of 0.01–0.5 mg kg^{-1}. The fluorescence response for ergometrine is about twice that of the other major grain ergot alkaloids. The identity of compounds measured as ergot alkaloids can be confirmed by heating the extract in dilute acetic acid, and monitoring the expected increase in the proportions of the ergopeptine –inine isomers.

2.10 Liquid Chromatography–Mass Spectrometry (LC-MS)

Sample preparation for LC-MS comprises cleanup of organic solvent extracts using the procedures described earlier, or simple dilution of the extracts and injection without cleanup, a procedure known as “dilute and shoot.”

The two major LC-MS techniques, single stage mass spectrometry (LC-MS) and LC tandem MS (LC-MS/MS), are used in ergot alkaloid determination, especially for animal feed and foodstuffs. Both LC-MS and LC-MS/MS have many advantages over other analytical methods for ergot alkaloids. They can be applied to all common ergot structures and unlike LC-FLD are unaffected by saturation at the C-10 position of the lysergic ring system.

The ionization mode most effective in ergot alkaloid analysis is positive electrospray ionization, which produces more intense protonated molecular ions than the deprotonated molecular ions that result from negative ionization, and this has become the preferred ionization method. When ergot alkaloids are ionized in positive electrospray mode the ions formed are predominantly the protonated molecular ions [M + H] + ions, with little evidence of adduct formation with ions of sodium, potassium, or ammonia, despite the ubiquitous presence of sodium in aqueous mobile phase solvents and the addition of comparatively high levels of ammonium salts.

LC-MS can be operated in scanning mode to obtain spectra of the alkaloids and is useful in identifying new compounds [26] but as the ionization methods are “soft” little fragmentation occurs. Focusing on a range of single ions (selected ion monitoring, SIM) increases sensitivity considerably and allows a number of alkaloids to be detected and measured, including coeluting compounds of different mass.

LC-MS/MS is more sensitive and selective than LC-MS. In tandem mass spectrometry a characteristic ion from the initial fragmentation is focused into a chamber where collisions with neutral atoms or molecules induce fragmentations to form product ions. Ergopeptides and lysergic acid ions form characteristic product ions at m/z 223 and 208 [27]. By selecting one or more product ions in the second mass analyzer and scanning in the first mass analyzer the precursor ions can be identified. This technique can be used be used to detect unknown ergot alkaloids in sample extracts. Studies of fragmentation patterns of ergot alkaloids have allowed the mass spectra of related compounds for which standards are not available to be predicted.

A mass spectrometric mode called selected reaction monitoring (SRM) is very useful for low level quantification of ergot alkaloids [28, 29]. In this approach, the first mass analyzer is set to monitor a specific ion derived from the target analyte, while the second mass analyzer measures a specific collision-induced transition of that ion. The resulting signal is very specific on account of the formation route, and the LOD is very low because of the lack of background signal. Ideally, further transitions are used (multiple reaction monitoring MRM) as one SRM transition or in some cases two transitions might not be sufficient to identify a compound with confidence. In MRM modes a principal transition is used for quantification and "qualifier" transitions for confirmation of identity. The relative intensities of the ions measured must agree within certain limits for the identity confirmation to be accepted. In a determination of LSD by LC-MS/MS in the SRM mode a minimum of three transitions were required for positive identification and elimination of a false positive, supported by the absence of *iso*-LSD in the sample.

Fragmentation experiments such as precursor ion scans using triple-stage quadrupole and ion trap mass spectrometers methods provide insights can identify common and characteristic product ions and allow the detection of minor ergot alkaloids not included in routine analyses today. Ion trap detection allows several fragmentations (MSn experiments) that can enhance the ability to elucidate the structures of unknown ergot alkaloid derivatives.

After epimerization at the C-8 position of the lysergic ring system the two epimers that are produced can be resolved chromatographically on LC systems, but on LC-MS the different epimers differ in the relative intensities of the two common ergot alkaloid fragments ions at m/z 223 and m/z 208. This fact can be used to distinguish between the epimers but it introduces an error requiring that both peaks be quantified if LC-MS/MS in SRM mode is used as a means of quantification. In addition, dehydration and hydrogenation of the analytes is suspected to occur during sample workup.

Mass spectrometric detection has a great advantage that all known ergot alkaloids can potentially be determined in one run and chromatographic coelution is not a problem for compounds having different MS/MS transitions. Furthermore, analogs not available as reference standards can be tentatively identified.

A currently remaining problem in resolution is the occasional coelution of some ergot alkaloids. β-ergocryptine and ergocristine coelute under some conditions, leading to errors in the quantification of both when they are detected by FLD. LC-MS/MS methods can distinguish between these compounds as they have different molecular masses. The situation is less satisfactory for the isomers α- and β-ergocryptinine, which are not separated on LC and have identical masses, and so LC-MS cannot tell them apart.

2.10.1 Matrix Effects

Matrix effects are frequently seen in LC-MS. These occur when compounds in the sample are extracted along with the ergot alkaloids and pass through any cleanup stages with the alkaloids. The co-extracted compounds are often of much higher concentration than the alkaloid, increasing the likelihood of coelution on chromatographic systems. Coelution leads to enhancement of ionization or more often to its suppression. Matrix effects can be reduced by dilution of the extract or by more specific cleanup such as ion exchange. Signal suppression in quantitative analysis is compensated for by preparing the calibration standards in a blank matrix extract known to be free of target analytes, such standards are known as “matrix-matched.”

LODs and LOQs are low for modern LC-MS and LC-MS/MS methods with LODs for the individual compounds measured in various cereal matrices ranging from 0.05 to 0.4 μg kg^{-1} and LOQs for the ergopeptine-isomers and ergometrine ranging from 0.2 to 2.8 μg/kg. Lower LOQ (0.01–0.06 μg kg^{-1}) have been achieved for five ergopeptines in wheat with UHPLC-MS/MS [12].

Very few comparisons based on the same samples have been made of LC-MS and ELISA methods, but for measurements of ergovaline in samples of seed and straw there was poor agreement with no consistent pattern [17]. The issue is important because some LC procedures determine ergovaline but do not detect simpler ergoline alkaloids such as lysergic acid, D-lysergic acid amides, lysergol, and ergonovine.

2.11 Alternative Methods

Capillary zone electrophoresis with UV detection has been used to separate ergometrine, ergotamine, and their epimers [30]. The addition of cyclodextrins in phosphate buffer at pH 2.5 was required to resolve five ergopeptine alkaloids and their epimers. Supercritical fluid chromatography has also been used with UV detection at 280 nm or mass spectrometry to identify clavine alkaloids in extracts of *Claviceps purpurea*.

Rapid lateral flow immunoassays for ergot alkaloids have been developed and are undergoing characterization and improvement [31]. The lateral flow devices are in the form of dipstick tests that can be used in the field. Following a rapid solvent extraction the stick is dipped into the extract, the solution migrates through a region containing the antibody conjugate, the bound sample-conjugate then flows to a “strip” area where dynamic control lines define positive and negative results by color changes, indicates the presence or absence of the alkaloid. A dipstick has been produced that reacts to ergotamine, ergocristine, and ergosine. The 50 % inhibitory concentration (IC_{50}) of the best polyclonal antibodies for ergotamine is 76 ng ml^{-1}, and cross-reactivity profiles determined by ELISA were ergotamine: 100, ergocristine: 70, ergosine: 5.

A novel approach to identifying the presence of ergot alkaloid has been to quantify the fatty acid ricinoleic acid, (R)-12-hydroxy-(Z)-9-octadecenoic acid [32]. The acid is not usually found in grain but is a major component of the lipid portion of *Claviceps*. The lipid extracted from sclerotia can be analyzed for the ricinoleic acid by GC with flame ionization detection after transesterification and derivatization of the hydroxy group by silylation. There is no correlation between the content of ricinoleic acid and the ergot alkaloids and so quantitative levels of ergot alkaloids cannot be provided by this method.

2.12 Multianalyte Methods

Multianalyte methods used to measure substantial numbers of mycotoxins in feed and food have often included ergot alkaloids [12, 33–35]. A multianalyte LC-MS/MS method without cleanup has been used to measure 87 different mycotoxins including 25 ergot alkaloids with LODs of 0.02–1.2 μg kg^{-1}. A similar approach has been used to perform a semiquantitative survey that included all 12 of the major *C. purpurea* ergot alkaloids and also another 12 other ergot alkaloids from different other Claviceps species.

These methods invariably have extraction and cleanup procedures that are not optimal for all analytes and for ergot epimerization, low recoveries, and higher LODs are more likely. They typically involve extraction with acetonitrile, evaporation of the solvent, and reconstitution in the LC mobile phase solvent. The detection method is by necessity LC-MS or LC-MS/MS.

2.13 Quantification Methods

Quantification methods can be based on standard additions or external calibration. Internal standards may be used to correct for some losses of material but for many analyses suitable compounds are unavailable. In LC-MS and LC-MS/MS the ideal internal standards are stable isotope analogs of the target compounds as these behave exactly as the native compound used but can be distinguished by their different masses. For LSD-related compounds with slightly different structures such as methysergide have been used, but trideuterated LSD is available commercially.

2.13.1 Purity and Stability of Standards

Currently commercially available standards have purity levels that can be considered good for mycotoxins [11]. LC-MS estimation of impurities in a typical batch of the six major ergot alkaloids and their epimers which did not account for non-ergot constituents such as salts showed purities considerably above 98 % apart from ergocristinine (94 %), ergosine (96 %), and ergosinine (96 %). Ergocristinine contained 1.7 % ergocristine, 0.8 % ergocorninine, and 3.3 % ergocryptinine. Ergosine contained 2.7 % ergotamine and 0.9 % ergocryptine. Ergosinine contained 2.0 % ergosine and 2.5 % ergotaminine.

Ergot alkaloids are more stable in solvents that do not participate in hydrogen bonding (aprotic solvents) whether these are organic, aqueous, or mixtures. Extracts of cereals can be kept refrigerated in the dark overnight without significant epimerization. After about 2 weeks under these conditions epimerization of ergocornine, ergocryptine, and ergocristine is apparent, with up to 50 % of ergocornine being altered. A decrease of the –ine forms is accompanied by an equivalent increase in the corresponding -inines. In practice it is advisable to store all extracts and solutions of standard frozen in the dark.

3 Conclusion

Analytical methods have so far concentrated mainly on ergot alkaloids from *C. purpurea* and few data are available for alkaloids from other *Claviceps* spp. infecting grain. Only a small number of all ergot alkaloids are well characterized, and several unknown compounds including bound forms might contribute to the health hazard posed by food and feed contamination.

There are as yet unresolved problems in the quantitative determination of ergot alkaloids in biological and environmental matrixes because of the reactivity of the alkaloids and the poor stability of suitable standards, especially in both isomeric forms. Similarly there are no certified matrix reference materials available, and only one proficiency study for the determination of ergot alkaloids is in regular use. The performance of many non-LC methods has not been well characterized. Only a single international ring trial of LC methods has been carried out [36]. In this study 27 participants analyzed 6 cereal flour test materials and 2 control solutions using a method based on extraction with ethyl acetate/methanol/25 % ammonia, cleanup using aluminum oxide SPE, and LC-FLD. The performance of the method was considered suitable for its proposal for use as an official method and its use in surveys. After elimination of 5 % of the results (mostly from four participants) as outliers, the relative repeatability for all analytes in flour was less than 10 % and the relative reproducibility was between 6.3 % and 18.9 %. LOQs ranged from 0.08 to 3.30 μg kg^{-1} [25].

The three major approaches of ELISA, LC-FLD, LC-MS are likely to continue to be applied to the currently increasing demand for information on occurrence. ELISA techniques are limited in the information provided and as they give variable between-run results, they are therefore best used as semiquantitative tools. Only LC-FLD and LC-MS/MS enable the identification and quantification of the major ergot alkaloids and their epimers. Mass spectrometry is required. LC-MS and LC-MS/MS methods provide unequivocal identification of the alkaloids, and the ability to obtain structural information through collision-induced fragmentation greatly enhances its usefulness for confirmation and elucidation of structure confirmation. LC-MS/MS methods therefore could be preferred to LC-FLD; however, the capital costs of equipment are higher.

Abstract

Capillary electrophoresis (CE) is a useful tool in phytochemical analysis, and it meets the requirements for the quality control of herbal drugs because of its versatility and high separation power. The wide opportunity for selectivity tuning allows the analysis of molecules with a wide range of polarity and molecular weight; in addition like high-performance liquid chromatography (HPLC), the method is suitable for hyphenation with mass spectrometry (MS).

In this chapter, an overview on the most relevant aspects of the analysis of alkaloids by electromigration methods, namely, capillary zone electrophoresis (CZE), nonaqueous capillary electrophoresis (NACE), micellar electrokinetic chromatography (MEKC), microemulsion electrokinetic chromatography (MEEKC), and capillary electrochromatography (CEC), is given. Selected recent applications of CE in analysis of alkaloids are summarized in a table following the classification according to the chemical nature of the considered compounds.

Keywords
Capillary electrochromatography (CEC) • capillary zone electrophoresis (CZE) • mass spectrometry (MS) • micellar electrokinetic chromatography (MEKC) • microemulsion electrokinetic chromatography (MEEKC) • nonaqueous capillary electrophoresis (NACE)

1 Introduction to Capillary Electrophoresis: Background and Instrumentation

Capillary electrophoresis (CE) is a separation technique that employs the basic concepts and separation mechanism of conventional electrophoresis in a capillary format. The core of the CE system is in fact a capillary, normally in fused silica, with an internal diameter of 50–100 μm that is filled with the buffer solution (defined as the background electrolyte (BGE)) to be used for separation of the charged molecules.

As in conventional electrophoresis, the separation occurs on the basis of the different rates of the ions through the capillary, resulting by their different charge-to-mass ratio. The electrophoretic mobility μ_{ep} describes the speed of movement of the charged molecule in the capillary, and it is given by

$$\mu_{ep} = q/(6\pi\eta r) \tag{36.1}$$

where q is the number of ionic charges in the molecule, η is the viscosity of the buffer solution, and r is the ionic radius. Therefore, when a mixture of ions possessing the same charge undergoes to the electrophoretic process, the smaller will migrate faster than the larger.

The electrophoretic mobility can also be expressed as a function of the zeta potential of the ion (ζ_i), the dielectric constant (ε), and viscosity of the solvent, according to

$$\mu_{ep} = 2\varepsilon\zeta_i/(3\eta) \tag{36.2}$$

Interestingly, the anticonvective properties of small internal diameter tube improve the resolution of the electrophoretic process because of the limited longitudinal diffusion of the analytical zones. Furthermore, in this format, high electric fields can be applied for fast separations, generating only modest Joule heating, and finally, small amounts of both analytes and buffer solutions are required.

The separated components can be conveniently monitored by UV on-capillary detection as they migrate in a portion of the capillary exposed to a monochromatic UV light beam. Using this approach the band broadening occurring in high-performance liquid chromatography (HPLC) as due to the post-separation mixing of the analytical zones eluting from the end of column is avoided. The UV absorption occurs according to the UV spectrum and concentration of the analytes; alternative detectors used in online CE analysis are fluorescence (FL), laser-induced fluorescence (LIF), and electrochemical detector (ED). In addition, the hyphenation of CE and mass spectrometry (CE-MS) is frequently used in CE analysis of phytochemical substances to achieve structural information on the separated analytes [1–3].

1.1 Electroendosmosis

The inner capillary fused-silica wall contains silanol groups (-Si-OH) that behave as weak acids; when the pH values of the background electrolyte used for CE separation are higher than 3, the dissociation of silanols generates a negatively charged inner capillary surface. The positive ions of the BGE are attracted to the fixed negative charge of the capillary to maintain the electroneutrality, and an electrical double layer is formed. The application of the high voltage for the electrophoretic run causes the migration of the hydrated cations of the double layer toward the cathodic end of the capillary thus resulting in a flow of the bulk solution contained in the capillary. The flow, defined as electroosmotic flow (EOF), is related to the charge of the inner capillary surface, and it is dependent on the pH of the buffer, its concentration, nature, and viscosity, as described by the following equation:

$$\mu_{\mathrm{eo}} = \varepsilon\zeta/(2\pi\eta \mathrm{d}) \qquad (36.3)$$

where μ_{eo} is the electroosmotic mobility (the rate of the EOF), ζ is the zeta potential (charge on the inner capillary surface), η is the viscosity of the running buffer, and d is the capillary diameter.

In the presence of a stable and strong EOF (generally obtained using alkaline buffers), the negatively charged molecules of a given sample are swept toward the cathodic end because their electrophoretic mobility is often lower than the electro-osmotic mobility. This condition allows for the simultaneous analysis toward the cathodic end of the capillary of both anionic and cationic species, whose differential migration driven by the difference in charge-to-mass ratio is still maintained [1–3].

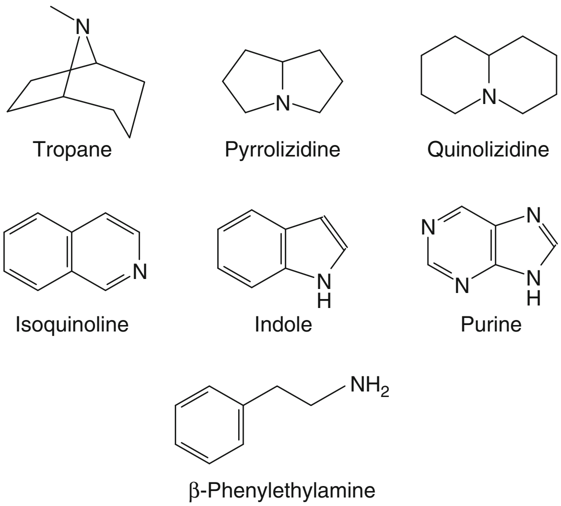

Fig. 36.1 Backbone structure of the principal alkaloids

The success of CE is due in large part to the wide range of separation modes available that allow for the application of different operating conditions often resulting in different separation selectivity. This feature makes CE suitable in analysis of molecules with a wide range of polarity and molecular weight, and because of its versatility and high separation power, the technique meets the requirements for the quality control of herbal drugs, phytopharmaceuticals, and natural products [4, 5]. The principal separation methods that have been applied in analysis of alkaloids are capillary zone electrophoresis (CZE), nonaqueous capillary electrophoresis (NACE), micellar electrokinetic chromatography (MEKC), microemulsion electrokinetic chromatography (MEEKC), and capillary electrochromatography (CEC). Each of these approaches will be discussed with selected examples of their application to the analysis of alkaloids in plants, herbal drugs, and natural products. Based on their general structures, alkaloids are divided into several subgroups, and the most important of them are reported in Fig. 36.1. In the Table 36.1, selected examples of application of CE from the recent literature are summarized following a classification according to the alkaloids structure.

2 Capillary Zone Electrophoresis in Analysis of Alkaloids

Capillary zone electrophoresis, CZE, is the simplest CE mode in which the separation is based on differences in the charge-to-mass ratio of the analytes. This approach can be effective in a number of applications; in particular, quaternary alkaloids owing to the permanent charge are ideal solutes in CZE, regardless of the pH of the running buffer. Below, the most important parameters affecting the CZE separation will be considered with emphasis on the relevant aspects involved in analysis of alkaloids in herbal drugs and medicinal plants.

Table 36.1 Application of electromigration techniques to the analysis of alkaloids

Alkaloids	Sample	Separation conditions	Detection	References
Tropane alkaloids				
Calystegine	*Solanaceae*	20 mM histidine, 20 mM BES, 20 % methanol	Indirect UV at 300 nm	[22]
		80 mM tetraborate buffer, pH 9.2	UV at 191 nm	[21]
Atropine	*Cannabis sativa*	20 mM ammonium acetate, pH 8.5	CZE-ESI-MS	[109]
Atropine, belladonnine, norhyoscyamine, apoatropine, hyoscyamine, 6β-hyoscyamine, scopolamine	*Atropa belladonna*	60 mM ammonium acetate (pH 8.5), 5 % isopropanol	CE-ESI-TOF-MS	[9]
Atropine, scopolamine, anisodamine	*Flos daturae*	20 mM phosphate (pH 7.0), 4 mM βCD	ECL	[43]

2.1 Effect of pH of the Running Buffer in CZE

Alkaloids are cyclic organic compounds containing nitrogen in a negative oxidation state exhibiting pKa values above 5; thus, they can be easily protonated in a wide pH range, and CZE can be considered as the electrokinetic technique of choice for their analysis. In particular, using running buffers at pH values below the pKa, the molecules exist mainly in the protonated water-soluble form [4, 5]. In addition, according to the Henderson–Hasselbalch equation, it can be derived that the ionized base still exists also at pH values well above the pKa; for example, when pH of the electrolyte is pKa + 1, the fraction of the protonated base $[BH^+]/[B]$ is 1:10 [6]. Obviously, the presence of additional basic functions in the molecule of the alkaloid leads to higher charge density (thus higher electrophoretic mobility) whereas acidic functions, because of dissociation, can generate negative charge leading to a reduced mobility. Therefore, alkaloids containing both acidic and basic functions have to be dealt by considering the existence of a critical pH value corresponding to the average of the pKa values of acidic and basic function, i.e., the isoelectric point, p*I*.

Several examples of CZE methods for analysis of the main alkaloid groups show that often the separations are carried out under neutral/alkaline conditions (Table 36.1). A strong and stable EOF is in fact obtained using BGE at pH values higher than 8, thus allowing for fast and reproducible separations [1–3]. In addition, as theoretically demonstrated, the optimum separation selectivity is obtained if the pH value of the running buffer is close to the pKa of the analytes [7]. As an example, atropine and scopolamine, the two active tropane alkaloids found in *Flos daturae*, are characterized by pKa values of 9.7 and 8.2, respectively; their CZE separation could only be obtained at pH higher than 7.5, and the optimum condition was achieved using a BGE at pH 8.5 [8]. Similar conditions were also successfully applied to a more challenging separation of tropane alkaloids (among them atropine, belladonnine, apoatropine, hyoscyamine, scopolamine) in *Atropa belladonna* leaf extracts [9]. Alkaline BGE was used also for separation of the quinolizidine alkaloids oxymatrine, sophoridine, and matrine in *Sophora flavescens* Ait.; in particular, the isomers sophoridine and matrine (Fig. 36.2), exhibiting pKa values of 6.51 and 7.72, respectively [11], could be separated using a phosphate buffer at pH 8.5 [10, 12].

Excellent separation selectivity can be obtained using acidic running buffers as was shown by Stöckgit et al., in analysis of fully protonated alkaloids. The migration order of 15 indole alkaloids under CZE acidic conditions (100 mM ammonium acetate buffer, pH 3.1) was evaluated, and it was found that the separated compounds could be clustered in different groups with decreasing mobility according to the increased molecular mass. Interestingly, the migration velocity of β-methylajmaline despite its higher molecular mass (Mw 341) was found to be much higher than that of ajmaline (Mw 326). Since β-methylajmaline shows a quaternary amine function, it does not be involved in formation of the intermolecular forces between the nitrogen atom and solvent molecules of the acetate buffer used as the medium. This leads to lower solvation degree, and the mass-to-charge ratio decreases accounting for the higher electrophoretic velocity [13].

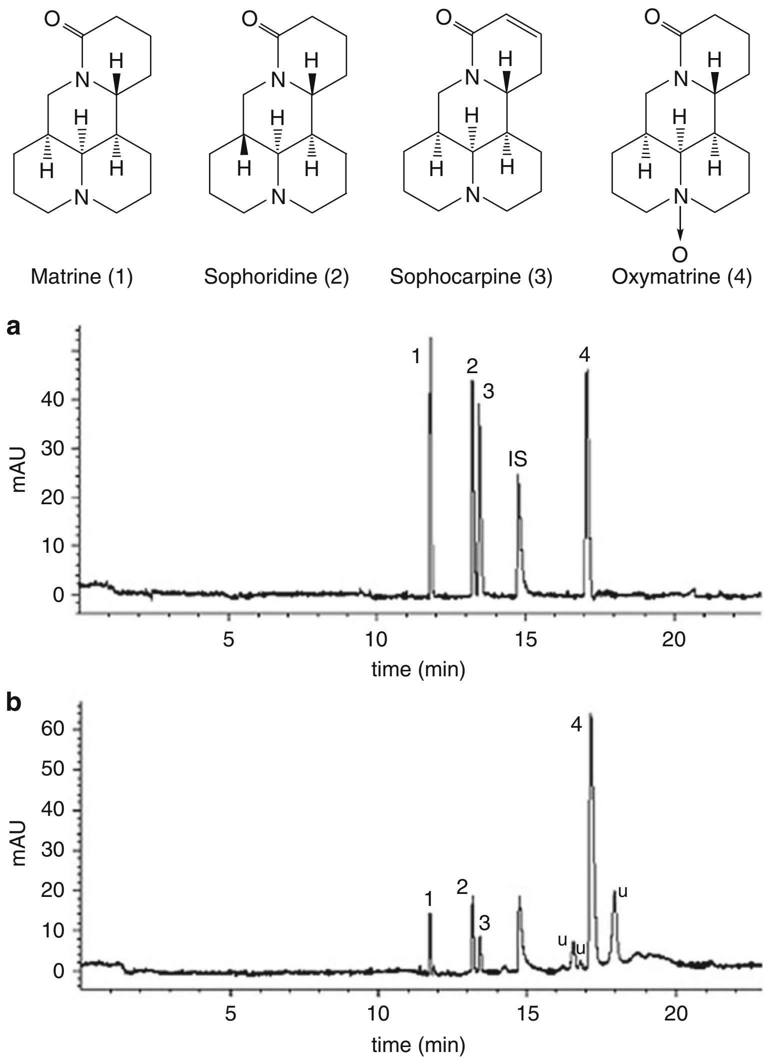

Fig. 36.2 Chemical structures of quinolizidine alkaloids in *Sophora flavescens* and their CZE separation in (**a**) standard solution and (**b**) real sample (Kushen crude drug). IS, jatrorrhizine (internal standard); u, unknown. CZE conditions: 60 mM borate at pH 8.5, applied voltage 12 kV, detection at 204 nm, capillary effective length 56 cm (i.d. 75 μm) (Modified from reference [10])

Recently, Kulp et al. observed a similar behavior in CZE analysis of isoquinoline alkaloids in extracts of *Chelidonium majus* L. [14]. These compounds exhibit distinct anti-inflammatory, antimicrobial, and antitumor activities, and the most effective alkaloid components of the plant are protopine, chelidonine, coptisine, sanguinarine, allocryptopine, and chelerythrine. Being strongly basic molecules with a heterocyclic-bound nitrogen, these compounds show pKa values above 5; thus, in acidic

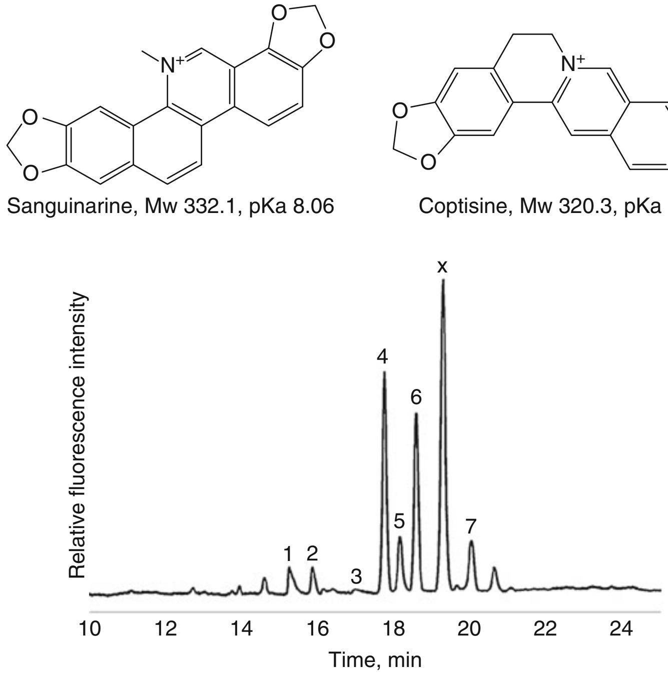

Fig. 36.3 Chemical structures of sanguinarine and coptisine and CZE separation of seven alkaloids in an extract of *Chelidonium majus* L. Peaks: (*1*) sanguinarine, (*2*) coptisine, (*3*) chelerythrine, (*4*) stylopine, (*5*) chelidonine, (*6*) protopine, (*7*) allocryptopine, and (*x*) unknown component. Conditions: 20 mM phosphate buffer, pH 3.1. Separation capillary: 75 μm, i.d. uncoated fused silica, 50 cm in length (40 cm effective length). Applied voltage 16 kV. Light-emitting-diode-induced fluorescence (LED) excitation wavelength 280 nm (Modified from reference [14])

electrolytes, they are protonated and migrate as cations. The best selectivity and resolution was obtained using 20 mM phosphate buffer, pH 3.1 (Fig. 36.3). According to their basic properties and their molecular masses, the isoquinoline alkaloids migrated in the predictable order: (I) strongly basic alkaloids such as sanguinarine, coptisine, and chelerythrine; (II) alkaloids with medium basic character such as stylopine, chelidonine, and protopine; and (III) allocryptopine, characterized by high molecular mass and very weak basic properties. Unexpectedly, the migration velocity of sanguinarine (Mw 332.1) was higher than the migration velocity of coptisine (Mw 320.3); according to the explanation provided by Stöckgit et al. [13], this is due to the presence of an additional methyl group at the nitrogen of sanguinarine, which prevents the formation of intermolecular forces between the nitrogen atom and the solvent molecules of the phosphate buffer medium. In the same study, the impressive separation of chelidonine and protopine, two compounds with the same mass and charge, was also shown. Apparently, slightly different basic properties and the presence of the electronegative oxygen atom, which shifts electron density from the nitrogen in protopine molecule, caused the difference in migration velocities of these two alkaloids [14]. These findings underline the importance of intermolecular interactions between functional groups of the alkaloids on their migration behavior.

A further interesting example showing, in this case, the influence of the molecular geometry on the electrophoretic velocity is given by the excellent selectivity of CZE performed under strongly acidic conditions of hydroindole alkaloids isolated from *Sceletium* species. These psychoactive compounds are mainly represented by (−) mesembrine (Mw 289) with a 3a-aryl-*cis*-octahydroindole skeleton; other congeners include the Δ^4 mesembrenone and Δ^7 mesembrenone with a double bond at either the position $4 - 5$ or $7 - 7a$, respectively (Mw 287). In addition, *Sceletium* phytopreparations may contain mesembranol and its stereoisomer epimesembranol (Mw 291) with the carbonyl function of mesembrine reduced to the corresponding hydroxy group. A simple CZE method based on phosphate buffer at pH 1.5, involving the full protonation of the basic nitrogen of the indole, was successfully applied to the separation of the alkaloids in real samples. The complete separation of the alkaloids was achieved, and the two isomers, namely, Δ^4 mesembrenone and Δ^7 mesembrenone, migrated respectively as the first and the last compound of the series [15].

2.2 Effect of Nature and Concentration of the Running Buffer in CZE

The running buffer selection is a key factor to the success of any CE separation. As a general rule, it has to be considered that the buffer system effectively works in a pH range approximately corresponding to two units centered to the pKa value. Phosphate and citrate having more than a pKa value show good buffering capacity in a wide pH range [1–3]. In particular, phosphate is often selected as a useful counterion for analysis of alkaloids in CZE, and as an alternative, tetraborate buffer, exhibiting a native pH of 9.2, can be used for analysis of strongly basic alkaloids. The low absorbance at the wavelength of detection (often in the UV range) makes these buffers as ideal for conventional CZE separations. In addition, phosphate and borate showed to be suitable for CZE coupled with a number of detection systems including electrochemiluminescence (ECL) detection and LIF detection; differently, the compatibility of phosphate and borate BGEs with MS detection is rather poor. The buffer concentration affects the electrophoretic behavior of the alkaloids by influencing the separation selectivity, the EOF strength, and stacking effect. In particular, by increasing the buffer concentration, the EOF is decreased because of the increased viscosity of the medium (see Eqs. 36.2 and 36.3). In addition, a stacking effect, leading to the reduction of the width of the sample zone before separation, occurs when the capillary is filled with a separation electrolyte with a higher ionic strength than that of the sample solution. Marsh et al. observed that the CZE separation of nicotine and nicotine-related alkaloids could be significantly improved by using a 100 mM phosphate running buffer (pH 2.5) instead of a diluted BGE (25 mM), used in previous experiments. In particular, at higher BGE concentration, the migration of cationic analytes was slackened and the separation enhanced. Furthermore, because of the sample stacking effect, narrowed peaks were obtained and detection sensitivity improved [16]. Running buffers at relatively high concentration showed to be useful also in preventing the adsorption of strongly basic alkaloids to the inner capillary wall, as it was observed in CZE analysis of berberine and hydrastine in root powder of *Hydrastis canadensis* performed using as the BGE, a 100 mM solution of ammonium acetate/acetic acid at pH 3.4 [17].

Borate buffers are often applied in CZE for their ability to give in situ complexation of polyhydroxy compounds such as carbohydrates and polyphenol aglycones. In particular, they form charged mobile five-membered-ring complexes (with 1,2-diols) and six-membered-ring complexes (with 1,3-diols), and as a consequence, an increased selectivity of separation can be achieved [18]. Interestingly, the interaction of borate ions with the polyhydroxy compounds results in UV absorbance enhancement; thus, the formed complexes can be detected using conventional spectrophotometric mode, despite the absence of significant chromophores in the original analyte molecule [19, 20]. A typical example of the described approach is given by the CZE analysis of calystegines, an interesting class of bioactive nortropane polyhydroxylated alkaloids isolated from different species belonging to the *Solanaceae*, *Convolvulaceae*, and *Moraceae*. Although calystegines possess a very low molar absorptivity, the CZE analysis approached using tetraborate solution (80 mM, pH 9.2) as the BGE allowed good UV detection sensitivity (limit of detection, LOD within 25–50 μg mL^{-1}). The migration behavior was found to be significantly dependent by the chemical structure of the analytes (i.e., number and position of hydroxy groups) and could be tuned by the proper choice of tetraborate concentration. Under optimized conditions, baseline separation of the selected compounds was achieved in less than 12 min [21]. As an alternative, indirect UV detection was applied using histidine as the UV marker [22]. The effect of using borate buffer to improve resolution was also shown in separation of opium alkaloids. Gao et al. observed that only partial separation was achieved by optimizing pH and concentration of phosphate buffer in separation of codeine, thebaine, morphine, and narcotine. Advantageously, by employing tetraborate as the BGE, the four alkaloids could be baseline separated [23].

2.3 Effect of the Presence of Organic Solvents in CZE Running Buffer

Under neutral or alkaline CZE conditions, most of the alkaloids are present as free bases showing low water solubility; therefore, the addition of organic solvents is a good choice to avoid precipitation of the solute during the electrophoretic run. Since the addition of organic solvents to the aqueous running buffer changes zeta potential and viscosity, a variation in electroosmotic velocity is then observed. In particular, by addition of organic solvent, the EOF is generally reduced even when the silanol groups of the capillary wall are fully ionized, i.e., at high pH. Furthermore, application of organic solvents as constituents of the buffer solution can lead variation of the pKa of the alkaloids with consequent effects on their absolute and actual mobility [24]. Methanol, ethanol, *n*-propanol, isopropanol, and acetonitrile (ACN) are the most used solvents because of their aqueous solubility and low UV absorption. It has been shown that using mixtures of water–alcohols (e.g., methanol and isopropanol), the EOF decreases compared to the pure aqueous buffer; differently, addition of ACN, because of its very low viscosity, decreases the EOF [24, 25]. Besides the described general effects, the separation selectivity can be altered by the presence of organic solvents, even though they are added in small percentage with respect to the aqueous components of the BGE. It can be concluded that the impact of the organic solvent addition on the electromigration of the analytes is the combination of a number of effects including the extent of interaction with the analytes through solvational, dissociative, or multimolecular complex formation phenomena; thus, the results in term of CE separation using aqueous–organic mixtures have to be experimentally determined. The separation of strongly basic isoquinoline alkaloids has been often performed using mixed aqueous–organic running buffers. Protoberberine alkaloids, namely, berberine and hydrastine, were analyzed in *Hydrastis canadensis* L. samples by optimizing the CZE separation through addition of methanol and ACN to the aqueous BGE. The electrolyte used was a solution of ammonium acetate, which proved to be suitable for preparation of both nonaqueous and mixed aqueous–organic buffers. Addition of methanol (80 %, v/v) increased the run time and improved the separation selectivity [17]. Similarly, methanol (70 % v/v) in 100 mM sodium acetate buffer was found to be the best choice for the separation of major alkaloids of gum opium (thebaine, codeine, morphine, papaverine, and narcotine) in real samples [26]; a similar mixed aqueous–organic buffer using ACN instead of methanol resulted in faster separation of the same compounds, but it could be only applied to standard mixture because of the interferences with the components of the matrix [27]. High methanol percentage (80 %, v/v) in 100 mM sodium acetate electrolyte was found to be necessary in obtaining the desired separation selectivity and to reduce peak tailing in analysis of the isomeric quaternary benzo[c]phenanthridine alkaloids such as chelerythrine and nitidine in *Zanthoxylum nitidum*, a common Chinese herbal medicine used to promote blood circulation and relieve pain [28]. Using a BGE composed of a 50:50 v/v water: ACN, containing 50 mM ammonium acetate at pH 6.8, Chen et al. achieved a fast separation of 8 isoquinoline alkaloids in real samples of *Rhizoma coptidis* [29]. Huhn et al. developed a mixed aqueous–organic CE method for the analysis of β-carbolines in extracts of *Psychotria viridis*. Using 200 mM formic acid and 7 mM ammonia in water with ACN 10 %, the baseline separation of norharmane, harmane, and tetrahydroharmane was accomplished. A dual detection system, LIF and electrospray mass spectrometry (ESI-MS), was developed; in particular, the use of optical fibers allowed the LIF detection to be set close to ESI source making easy the comparison of the LIF and MS electropherograms [30]. Finally, also isopropanol, whose behavior in term of effect on the EOF is similar to that of methanol, can be used for selectivity tuning as it was shown in some applications to the analysis of tropane alkaloids [9] and quinolizidine alkaloids [31].

In analysis of aconitine and the congeners mesaconitine and hypaconitine, the main diester-diterpene alkaloids of aconitum plants (*Ranunculaceae*), sample preparation involves extraction with nonpolar solvents (e.g., ether) under reflux of the pulverized roots. After evaporation of the organic solvent, the residue is reconstituted with ACN; thus, the CZE analysis can be conveniently carried out using mixed aqueous–organic buffers in order to improve the compatibility of the organic sample plug injected into the capillary [32, 33]. A BGE composed of 200 mM Tris buffer containing 150 mM perchloric acid and dioxane 40 % at pH 7.8 showed compatibility with the injected samples and allowed for the simultaneous separation of three diester-diterpene alkaloids (the native aconitine, hypaconitine, and mesaconitine) and related degradation products (benzoylaconine, benzoylmesaconine, and benzoylhypaconine). In particular, the study focused on the evaluation of the stability of the native aconitum alkaloids, which undergo to hydrolysis of the ester moiety. Monoester diterpenes, namely, benzoylaconine, benzoylmesaconine, and benzoylhypaconine, can occur in processed aconitum herbal drugs, and, interestingly, these artifacts showed less toxicity compared to the parent compounds. The analysis of crude and processed herbal preparations clearly showed that the manufacture process affected the content of aconitum alkaloids with a significant decrease of the native diester diterpenes [33].

2.4 Effect of Buffer Additives in CZE

2.4.1 Ionic Liquids

Ionic liquids are substances with melting points at or close to room temperature, and they are composed entirely of ions, most of them having organic cations, in particular alkyl imidazolium. The anions in ionic liquids could be inorganic, including often PF_6^- and BF_4^-, as well as organic anions such as trifluoromethylsulfonate and trifluoroethanoate. Their unique properties are wide liquid range, low volatility, thermal stability, electrolytic conductivity, noninflammability, and so on. Recent reviews dealing with different aspects of the use of ionic liquid in analytical separations have shown that they can be good candidates as additives to the CE running buffers because of the ability in creating pseudo-stationary phases as well as to behave as simple modifiers of the aqueous buffer. In particular, ionic liquids can interact with the silanols of the capillary, thus modifying the EOF and reducing adsorption of macromolecules on the inner capillary wall [34–36]. In addition, as widely reported in separation of polyphenols [37], alkyl imidazolium cations were found to be able in establishing hydrogen bonding interactions with the analytes. In case of CZE analysis of verticine and verticinone, two isosteroid alkaloids with a hexacyclic benzo[7,8]fluoreno[2,1-*b*]quinolizine nucleus isolated from plants belonging to *Liliaceae* family such as *Bulbus fritillariae*, these interactions were favorable and resulted in improved separation selectivity. In particular, the ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate (1B-3MI-TFB) 40 mM in a pH 8.0 phosphate solution allowed for the complete separation of the alkaloids in less than 10 min [38]. Addition of 1B-3MI-TFB to the aqueous BGE was found necessary to accomplish separation of aconitine, hypaconitine, and mesaconitine in *Aconitum* extracts [39].

2.4.2 Cyclodextrins

Cyclodextrins (CDs) are cyclic oligosaccharides composed of D-glucopyranose molecules bonded through α-1,4 linkages and produced by enzymatic reaction on starch. In details these macrocyclic compounds are the main end products of the glycosyltransferase enzyme, defined as αCD, βCD, and γCD. Because of their capacity to form inclusion complexes with a considerable number of analytes (host–guest interaction), CDs can modify the physicochemical characteristics of the guest molecule, resulting in altered retention and/or migration behavior. Several reviews deal with the use of CDs in capillary electrophoresis as selective agents for analytical separations of isomers since they can form inclusion complexes discriminating between positional isomers, molecular substructures, homologues, and enantiomers [40–42]. Examples of the application of CDs as additives to the CZE-BGE for improving resolution of strictly related alkaloids are given by analysis of tropane [43] and morphinane alkaloids. The latter are typically determined in *Papaver somniferum*, and earlier studies by Bjørnsdottir and Hansen showed the necessity to supplement the acidic running buffer (pH 4) with heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (DM-βCD) to obtain the simultaneous separation of morphine, codeine, papaverine, thebaine, and noscapine, not only in crude opium but also in illicit drugs and cough mixtures [44]. Successively, other CZE systems involving different CDs were optimized for separation of different mixtures of opium alkaloids and derivatives in forensic samples [45, 46] and in the extracts produced during the industrial manufacture processes of alkaloids extraction (i.e., the process liquors). In Fig. 36.4 are reported the electropherograms related to the separation of opiate alkaloids using different CDs as additives to the BGE. Depending on the nature of the CD, different separation selectivity could be obtained. The optimum conditions were selected by evaluating parameters such as analysis time, resolution between adjacent peaks, peak symmetry, and separation of alkaloids from interferences by sample matrix. Suitable conditions for analysis of morphinane alkaloids in samples of different origins were achieved using acidic running buffer (pH 2.8–3.0) supplemented with hydroxypropyl-βCD (HP-βCD) 30 mM or α-cyclodextrin (αCD) 5 mM [47, 48].

Lurie et al. used a combination of HP-βCD and DM-βCD in a dynamically coated capillary (to increase the strength and stability of EOF) for separation of opium alkaloids in opium gum and latex [49].

Medicinal herbs containing phenylethylamine alkaloids (i.e., *Citrus* species and *Ephedra sinica*) are widespread used for their effects on human metabolism in particular by stimulating lipolysis and thus promoting the fat mass reduction in obese people. Specifically, ephedra extracts such as *Ephedra herba* (ma huang) contain alkaloids such as (1*R*,2*S*)-(−)-ephedrine, (1*S*,2*S*)-(+)-pseudoephedrine, (1*R*,2*S*)-(−)-norephedrine, (1*S*,2*S*)-(+)-norpseudoephedrine, (1*R*,2*S*)-(−)-*N*-methylephedrine, and (1*S*,2*S*)-(+)-*N*-methylpseudoephedrine. The possible adverse effects associated to the use of these products prompted the U.S. Food and Drug Administration (FDA) to ban ephedra-containing dietary supplements depending on the dosage [50]. In addition, the National Institute of Standards and Technology (NIST) issued standard reference materials with certified values for ephedra

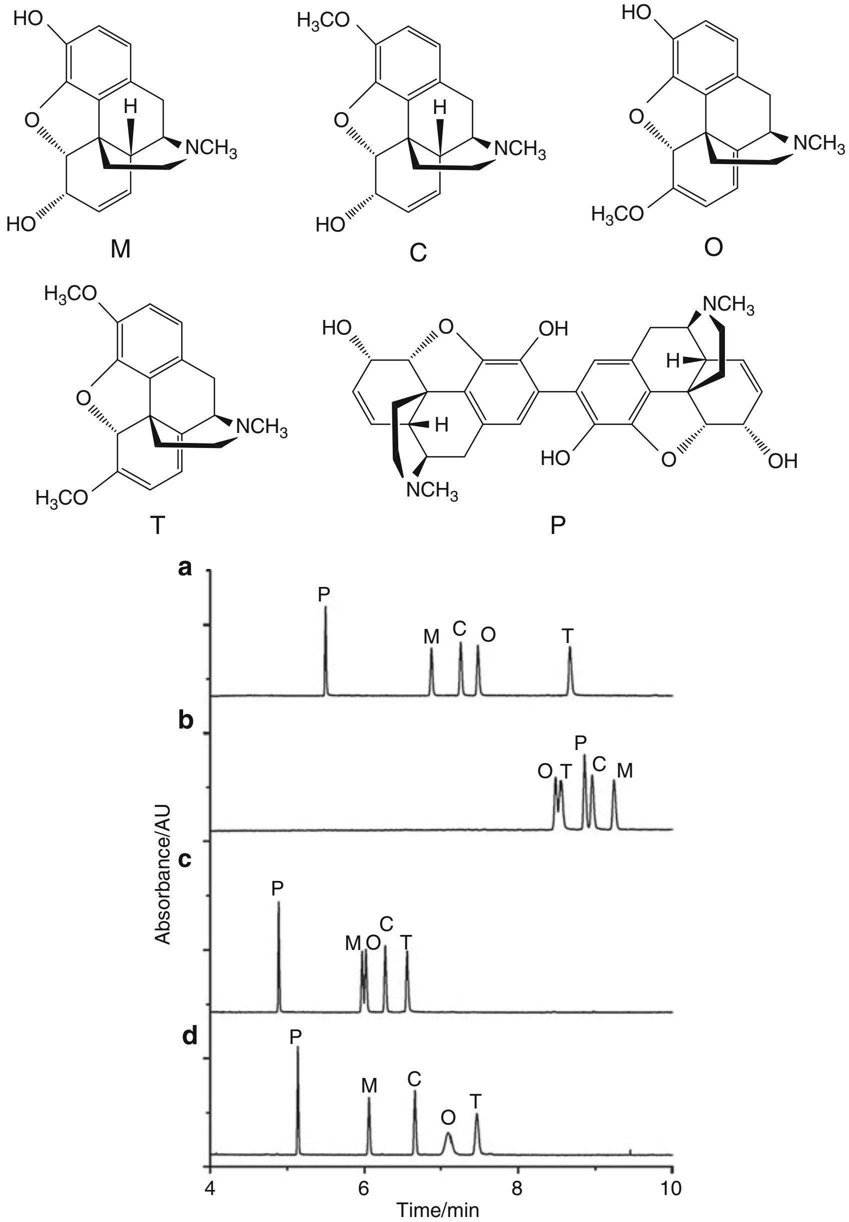

Fig. 36.4 Chemical structures of morphine (M), codeine (C), oripavine (O), thebaine (T), and pseudomorphine (P) and their separation by cyclodextrin-modified CZE using different CDs. Conditions: (**a**) HP-βCD, (**b**) γCD, (**c**) βCD, and (**d**) αCD. Buffer: 100 mM Tris–phosphate, pH 2.8; CD concentration of 30 mM except for βCD (10 mM due to limited solubility); applied voltage of 25 kV; 2 s injection at 50 mbar; 20 °C; capillary 50 cm × 50 μm i.d.; UV absorption detection at 214 nm (Modified from ref. [47])

alkaloids, synephrine, and caffeine [51]. As a consequence several analytical methods have been developed with the aim to provide reliable quantitation of ephedrine and pseudoephedrine in ephedra extracts and herbs [52]. Biosynthetic pathways involved in plant kingdom drive often to enantiomerically pure compounds. Furthermore, although several factors affect the chiral composition of the plant metabolites, detecting a distortion of the enantiomeric ratio can be considered as an acceptable hint of the natural origin of the compounds [53]. In characterization of *Ephedra sinica* and its medicinal phytopreparations, chiral analysis provides a useful tool because only (1*R*,2*S*)-(−)-ephedrine and (1*S*,2*S*)-(+)-pseudoephedrine enantiomers are found in nature. Simple CZE analysis of ephedrine and pseudoephedrine in herbal drugs (tablets) was carried out in a 25 mM triethanolamine phosphate buffer (pH 2.5) in condition of reversed EOF. Highly sulfated β-cyclodextrin was supplemented as the chiral additive to obtain the required enantioselectivity and to allow the separation of ephedrine and pseudoephedrine enantiomers from other herbal drug constituents [54]. A combination of three neutral cyclodextrins, namely, βCD, HP-βCD, and DM-βCD, under acidic conditions was used as a chiral system to achieve the simultaneous enantioresolution of octopamine and synephrine enantiomers in the presence of tyramine and *N*-methyltyramine in *Citrus* species dietary supplements. In particular, the chiral analysis was applied to evaluate the thermal racemization of *l*-synephrine. Although information on the kinetics of the conversion was not provided, the study demonstrated that the extraction procedure applied to the real samples did not lead to any chiral artifacts since the racemization of synephrine occurs at relatively high temperature (i.e., 100 °C) [55].

Phinney et al. developed three CE-UV methods that allowed the enantioseparation of ephedrine and pseudoephedrine using neutral HP-βCD, DM-βCD, and charged sulfated βCD as chiral selectors. The combination of negatively charged sulfated βCD (2.8 %) and DM-βCD (1.2 %) under acidic conditions (pH 2.5) provided the best separation of the two couples of enantiomers. Standard reference materials (SRMs) containing ephedra in development at NIST were analyzed by each of three CE methods. In the SRM samples, only the naturally occurring enantiomers (−)-ephedrine and (+)-pseudoephedrine were found; however, the method proved to be suitable in detecting product adulteration by its potential in identification of specific stereoisomers [56]. The neutral HP-βCD was also found to be a useful chiral selector in the presence of tetrabutylammonium chloride as additive, for the simultaneous enantioseparation of ephedrine, pseudoephedrine, *N*-methylephedrine, and norephedrine enantiomers in *Ephedra sinica* extracts [57].

3 Nonaqueous Capillary Electrophoresis, NACE

The term “nonaqueous capillary electrophoresis” (NACE) is used to describe the application of pure organic solvents, or their mixtures, in preparation of running buffers for CE experiments. The most important advantages of using nonaqueous running buffers are (1) the improved solubility of hydrophobic analytes and

(2) opportunity in gaining specific selectivity because of the effect of the solvent (or mixtures) on acid–base properties of the solutes. In particular, pKa values of alkaloids in organic solvents are notably different from those in water, thus allowing separations which are difficult to be obtained in aqueous running buffers.

NACE widens the set of physicochemical characteristics of the running buffers, which are known to affect the electrophoretic behavior of the solutes by influencing interactions with solvents, additives, and ion–ion interactions that are too weak or cannot take place in aqueous BGEs. In particular, the dielectric-constant-to-viscosity ratio (ε/η) of an organic solvent affects both the electrophoretic mobility of ions and the electroosmotic mobility (see Eqs 36.2 and 36.3); therefore, mixing organic solvents in different ratios is an effective strategy in optimization of the CE separation. Furthermore, NACE appears to be ideally suited for online coupling with mass spectrometry due to the high volatility and low surface tension of many organic solvents [58–62].

Acetonitrile and methanol can be considered as the best solvents for NACE of alkaloids [63]. In particular, methanol possesses a favorable dielectric constant (33.7 at 20 °C), ability in intermolecular hydrogen bonds, and autoprotolysis; therefore, it is suitable to dissolve the supporting electrolytes necessary to the CE experiments. A few of recent applications have dealt with NACE of alkaloids in pure methanol; this choice is mainly driven by the necessity for compatibility of the BGE with the solvent used in samples preparation and to achieve the desired separation selectivity [64, 65]. In most of the applications, however, methanol is mixed with different organic solvents such as ethanol, isopropanol, and tetrahydrofuran (THF). In a study by Humam et al., the potential of NACE by approaching the challenging separation of four isomeric tropane alkaloids that was unsuccessful in aqueous BGEs was shown. Mixtures of methanol with either ethanol or THF led to interesting results. Using ethanol, because of the higher viscosity compared to that of THF, the analysis time was longer; however, for complex plant extract samples, a mixture methanol/ethanol (40:60, v/v) was selected as a compromise between analysis time and resolution of the alkaloids. In Fig. 36.5, the separation achieved under optimized conditions of the four strictly related solutes (3α-senecioyloxy-7β-hydroxytropane, 3α-hydroxy-7β-senecioyloxytropane, 3α-hydroxy-7β-angeloyloxytropane, and 3α-hydroxy-7β-tigloyloxytropane) is reported [66].

The presence of ACN in NACE BGEs is useful to increase both the electrophoretic and electroosmotic mobility because of the high (ε/η) of this solvent. Therefore, in separation of protonated alkaloids, the percentage of ACN in methanol can be adjusted to tune analysis time and separation selectivity [67–78]. An interesting example was given by Sturm et al., in analysis of isoquinoline alkaloids in *Fumaria officinalis* and *Corydalis* species [75, 76] and pyrrolo- and pyrido[1,2-*a*]azepine alkaloids in *Stemona* [77]. The authors developed a system to be hyphenated with ESI-MS, and because of the requirement of the instrumental setup for a 90-cm-long capillary, ACN was used as major component (90 % v/v) of the solvent mixture to achieve fast separations. In these applications quaternary alkaloids showed the shortest migration time; then, the migration order was found to follow the pKa values with some exceptions related to the structural subtypes of the compounds.

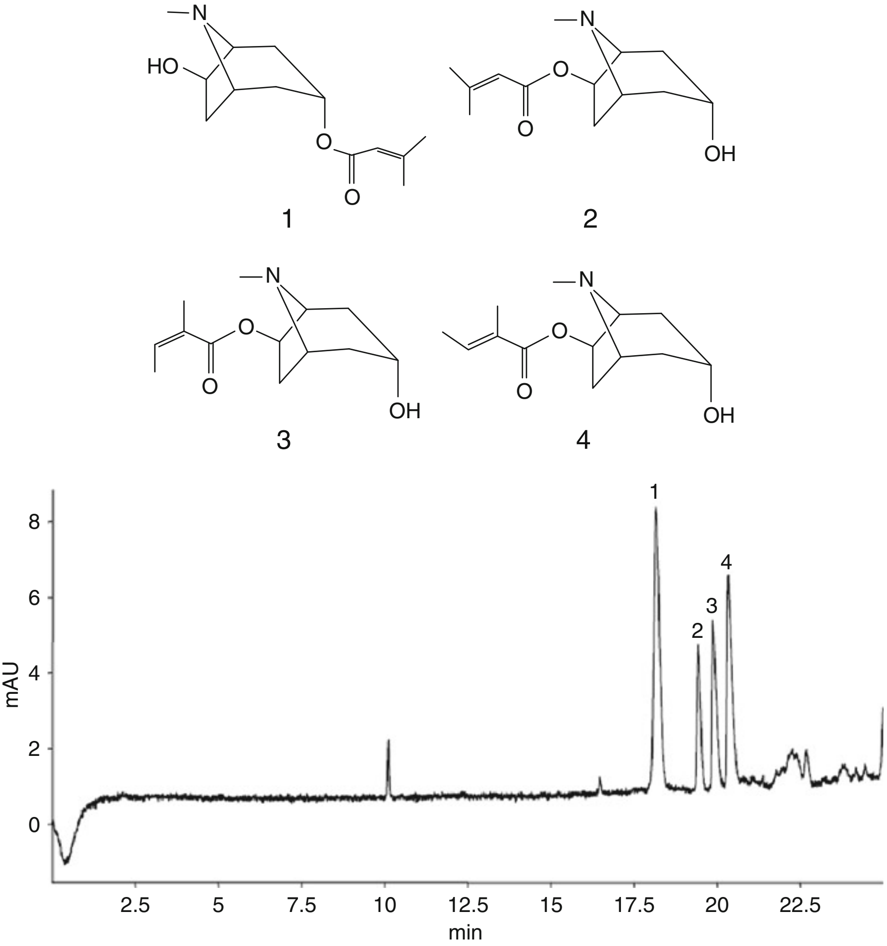

Fig. 36.5 Chemical structures of 3α-senecioyloxy-7β-hydroxytropane (**1**), 3α-hydroxy-7β-senecioyloxytropane (**2**), 3α-hydroxy-7β-angeloyloxytropane (**3**), and 3α-hydroxy-7β-tigloyloxytropane (**4**) and their NACE separation using a fused-silica capillary (64.5 cm total length, 50 μm i.d.) and BGE of 1 M trifluoroacetic acid, 25 mM ammonium formate in methanol/ethanol (40:60, v/v). Electrophoretic conditions: 25 kV; T, 25 °C; injection, 25 mbar (8 s); UV detection, 220 nm (Modified from ref. [66])

Liu et al. developed NACE methods for analysis of quaternary protoberberine alkaloids in Chinese herbal medicines by using LIF detection. It was found that the native fluorescence signal of the analytes decreased in mixtures of ACN: methanol compared to that observed in pure solvents; thus, it was suggested that the optimization of solvent system composition for sensitive LIF detection has to be carried out by considering this effect [68, 69].

The analysis of toxic quinolizidine alkaloids like lupanine, angustifoline, and 13α-hydroxylupanine in *Lupinus* species was carried out in nonaqueous buffer systems to obtain high compatibility with MS analysis. The effect of the most relevant separation parameters was carefully evaluated; interestingly, it was observed that without addition of a small percentage of water (10 %) and acetic acid (1 %) to the electrolyte solution, lupanine and angustifoline could not be resolved. This was explained invoking a different electrophoretic mobility of the alkaloids in charged versus neutral state. On the other hand, when the content of water and/or acetic acid was too high, a general decline in resolution was observed [78].

Because of their solubility in organic solvents mixtures, the most used supporting electrolytes in NACE are ammonium acetate, ammonium formate, and sodium acetate. The migration time of the alkaloids was found to increase with increasing electrolyte concentration; this effect is explained by the diminished EOF due to the decreased zeta potential caused by reduced thickness of the electric double layer on the inner capillary wall. High concentration levels of supporting electrolytes lead enhanced resolution ascribed to the effect of the interaction between the protonized alkaloids with the acetate co-ion in nonaqueous environment. In most of the applications, the supporting electrolyte concentration was within 25–100 mM; higher concentration should be avoided because of the negative effect on analysis time that was attributed to the increase in the mass transfer resistance of the analytes with the increase of ionic strength and viscosity [60, 61, 68, 74]. The acidity of nonaqueous buffers affects the alkaloid protonization extent; thus, by lowering the pH of the BGE, the migration of the alkaloids is expected to be faster. However, it has to be underlined that in organic solvents, the common pH measurement carried out using the glass electrode provides the apparent pH (pH*) that is not correlated to the H^+ activity. Acetic acid in the concentration range within 0.5–3 % is often used for the acidity control of nonaqueous BGEs [60, 61].

4 Micellar Electrokinetic Chromatography (MEKC) and Microemulsion Electrokinetic Chromatography (MEEKC)

Electrokinetic chromatography (EKC), and in particular micellar electrokinetic chromatography (MEKC), has been introduced in 1984 by Terabe and proved to be not only the method of choice in analysis of neutral compounds but also one of the most versatile separation approach among the electromigration methods. In MEKC a surfactant (often sodium dodecyl sulfate, SDS) is introduced into the BGE at concentration above the critical micelle concentration in order to generate the so-called pseudo-stationary phase constituted by the anionic SDS micelles in which the hydrophilic head groups form the outer shell and the hydrophobic tails create the core. In most of the MEKC applications, alkaline BGEs are used, and the electroosmotic velocity is faster than the electrophoretic velocity of the micelles; thus, the latter also migrates in the same direction of the EOF. The neutral analytes that are driven toward the cathode by the EOF can be incorporated into the micelle depending on their hydrophobicity; therefore, the separation mechanism is a combination of chromatographic partitioning of solutes between the pseudo-stationary phase and continuous phase. In analogy, the charged solutes undergo to the same process; however, in such a situation, the separation is the result of the combination of the chromatographic partitioning to the pseudo-stationary phase and the electrophoretic behavior of the ionic molecule. In MEKC the separation selectivity can be modulated not only by variation of BGE type, pH, and concentration but also by the proper selection of the surfactant as well as by optimizing its concentration [79–81].

Because often alkaloids have to be analyzed in plant materials containing neutral compounds, MEKC is a useful method providing the full characterization of complex extracts. Typical examples are EKC methods developed for analysis of methylxanthines in a variety of sources. These alkaloids, characterized by a purine backbone, are represented by caffeine, theophylline, and theobromine, and because of their stimulant effects on cardiovascular and nervous system, methylxanthine-containing plants are sometimes used as phytopharmaceuticals and dietary supplements. Methods for quantitation of the active compounds are necessary because, depending on the country, the level of the methylxanthine alkaloids could be limited. The U.S. FDA sets the limit of 0.02 % [82]; however, the so-called energy drinks when classified as "supplements" may contain more. Further, natural caffeine levels are exempt from these regulations; thus, coffee-based drinks may have more caffeine than 0.02 % without being classified as a supplement. Methylxanthine content is also used as an index of the quality of edible products such as coffee, tea, and cocoa; however, in order to achieve a comprehensive information on the biological value of these products, the quantitative determination of antioxidant polyphenols (mainly catechins) is required. The simultaneous CE analysis of methylxanthine alkaloids and catechins is conveniently accomplished by MEKC. Alkaline BGEs can be used [83, 84]; however, at high pH values, Pomilio et al. observed a peak splitting of theobromine and caffeine due to the keto-enolate tautomers, which could have different partitioning into the SDS micelle [84]. Thus, neutral or acidic running buffers could be conveniently used also to improve the stability of catechins [85–87]. Under these conditions, the addition of cyclodextrins to the micellar solution (CD-MEKC) showed to be a useful approach to obtain highly chemoselective and stereoselective systems that were successfully applied to the analysis of catechins and methylxanthines in tea and *Theobroma cacao* samples [86, 87]. Selectivity modulation in EKC methods can also be achieved by addition of organic solvents as it was shown in MEKC of ephedrine and pseudoephedrine [88] and pyrrolizidine alkaloids [89]. In particular, alkaloids such as senecionine and seneciphylline contain the 4-azabicyclo[3.3.0]octane system, and they differ only for the presence in seneciphylline of the C_{13}–C_{23} double bond. Owing to the same pKa values (5.44), these strictly related compounds could be separated only by MEKC. The addition of methanol (20 %) to the BGE was necessary to achieve the required selectivity [89]. In analysis of camptothecins, a valuable family of quinoline alkaloids from *Camptotheca acuminata*, *Nothapodytes foetida*, *Ophiorrhiza pumila*, and *Tabernaemontana heyneana*, the main issue is their poor water solubility. Extraction of active alkaloids from plant material was optimized using dimethyl sulfoxide; subsequently, an MEKC method was developed for the separation of camptothecin and 9-methoxycamptothecin. In order to achieve compatibility of the separation medium with the extraction solvent, dimethyl sulfoxide was added to a borate-based BGE. Interestingly, borate ($pH > 8$) running buffer was found to be effective in increasing the solubility of camptothecin and derivatives by promoting the equilibrium of the lactone forms to the carboxylate as a consequence of the complexation with borate ions. Owing to the characteristic UV spectrum, the selective detection in real samples was performed at the wavelength of 369 nm and the LOD could be assessed as about 2 $\mu g\ mL^{-1}$, thus adequate to this application [90].

Although SDS is the most versatile and useful micellar agent, different surfactants can be introduced in MEKC to gain specific selectivity. Interestingly, Hou et al. performed the simultaneous MEKC enantioseparation of four pairs of ephedrine related compounds, namely, (±)-ephedrine, (±)-pseudoephedrine, (±)-norephedrine, and (±)-*N*-methylephedrine, using a polymeric chiral surfactant, i.e., polysodium *N*-undecenoxycarbonyl-L-leucinate. Because of the high molecular mass of the surfactant, the BGE showed to be compatible with the online ESI-MS detection [91]. In Fig. 36.6, the effect of the chiral surfactant concentration on the separation of the studied analytes is shown.

The method was applied for assays of ephedra products in dietary supplements in an effort to possibly reduce health risks, which are associated with the use of these products [91, 92].

The separation and determination of tetrandrine and fangchinoline, two bioactive alkaloids found in Radix *Stephaniae tetrandrae*, was accomplished under MEKC conditions using an acidic running buffer supplemented with Tween 20 as a nonionic surfactant which was found to enhance the solubility of the hydrophobic cationic alkaloids [93]. Lauric acid was used as a convenient alternative to SDS in MEKC of seneciphylline and senecionine, two hepatotoxic pyrrolizidine alkaloids in *Gynura segetum* extracts; in particular, it was found that micelles from lauric acid exhibited lower conductivity compared to those from SDS, thus allowing for application of high electric field resulting in fast analysis and limited Joule heating [94]. Using sodium deoxycholate 50 mM as the surfactant, MEKC separation of coptisine, berberine, and palmatine was achieved simultaneously to that of neutral bioactive compounds such as flavonoids (wogonin, baicalein, baicalin) and anthraquinones (sennosides A and B, emodin, rhein, physcion, chrysophanol, and aloe emodin). The method showed excellent selectivity and was applied to the analysis of *Coptidis rhizoma*, *Scutellariae Radix*, *Rhei Rhizoma* (rhubarb), and phytopreparations containing the three herb mentioned above. The sample preparation was carried out by exhaustive extraction using methanol–water (70:30, v/v) in ultrasonic bath. The extracts were concentrated under vacuum and dissolved in acetonitrile–water (70:30, v/v). The method was validated for linearity, precision, and accuracy (recovery values were in the range 98.12–107.58 %, RSD % inter-assay < 5.21, $n = 9$), and the detection limits in analysis of protoberberine alkaloids were $<0.65\ \mu g\ mL^{-1}$ [95].

Microemulsion electrokinetic chromatography (MEEKC), similarly to MEKC, utilizes as the separation medium a pseudo-stationary phase defined as

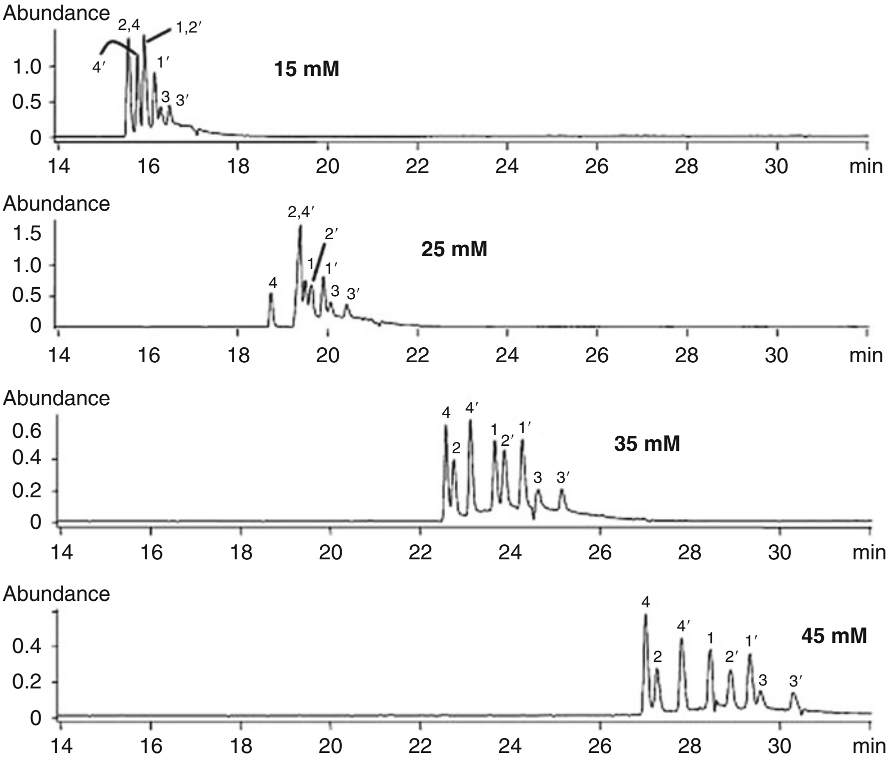

Fig. 36.6 Optimization of MEKC conditions for enantioseparation of ephedrine alkaloids using polysodium *N*-undecenoxycarbonyl-L-leucinate (poly-L-SUCL) as chiral surfactant. In the electropherogram, the effect of surfactant concentration on the separation is reported. Conditions involved the use of 35 mM ammonium acetate – 30 % ACN at pH 7.0 and ESI-MS detection. Peak identification: (1) (1*R*, 2*S*)-(–)-ephedrine, (1′) (1*S*, 2*R*)-(1)-ephedrine, (2) (1*R*, 2*R*)-(–)-pseudoephedrine, (2′) (1*S*, 2*S*)-(+)-pseudoephedrine, (3) (1*R*, 2*S*)-(−)-Norephedrine, (3′) (1*S*, 2*R*)-(+)-Norephedrine, (4) (1*R*, 2*S*)-(–)-*N*-methylephedrine, and (4′) (1*S*, 2*S*)-(+)-*N*-methylephedrine (Modified from ref. [91])

microemulsion. Typically the microemulsions are composed of nanometer-sized oil droplets suspended in aqueous buffer (oil-in-water microemulsions, O/W). These systems are stabilized by the presence of a surfactant, i.e., SDS and a cosurfactant, which is a short-chain alcohol such as butanol. The oil droplets are obtained by dispersion of *n*-octane or other types of hydrophobic solvents [80, 81, 96]. In MEEKC separation selectivity can be modulated not only by using different concentration and type of surfactant but also by the proper selection of cosurfactant and the oil phase. Yu et al. used sodium cholate (the surfactant), 1-butanol (the cosurfactant), and ethyl acetate (the oil phase) to obtain a microemulsion for analysis of quinolizidine alkaloids in *Sophora flavescens* preparations [97]. Pomponio et al. investigated the effect of different cosurfactants on the MEEKC separation of methylxanthines and green tea catechins. It was found that while the migration order and resolution of the hydrophilic catechins could be changed by using different and unconventional cosurfactants, the migration order of methylxanthines remained unchanged. However, the proper selection of cosurfactant allowed for the complete separation of caffeine and theophylline (the internal standard) from the other neutral components of real samples (tea from different countries) [98].

5 Capillary Electrochromatography (CEC)

Capillary electrochromatography (CEC) is included among the electrokinetic techniques because it combines the electromigration of charged solutes with chromatographic partition in capillary format. Differently to MEKC and MEEKC, the chromatographic partition is established between a liquid mobile phase and a solid stationary phase (small particles, ~3 μm), packed in a fused-silica capillary and fixed by frits prepared by silica sintering. CEC can also be performed in monolithic stationary phases formed by the in situ (in-capillary) polymerization of monomers. The CEC column is inserted in the cartridge of the conventional CE instrumentation, and the mobile phase is then driven through the stationary phase by the EOF generated by the inner capillary wall as well as by the charged groups of the solid stationary phase [99].

Specific CEC applications on natural products have been recently extensively reviewed [100, 101]. In general, the CEC experiments are carried out using stationary phases commonly prepared in laboratory by application of specific procedures that, in case of packed column, include the critical frit fabrication. This step of the preparation often limits the analytical reproducibility; in addition the frits have been considered the source of frequent bubble formation in the mobile phase with a consequent lost of sensitivity and system stability during the chromatographic run. The separation of opiate compounds was achieved by CEC using a reversed-phase packed column (1.5 μm particles) in about 2 min with very high separation efficiency. It was found that bubble formation could be limited by addition of a small concentration of SDS to the mobile phase [102]. The advances in column technology have led to an increasing preference for application of CEC monolithic column consisting of porous structure fabricated inside the fused-silica capillary tube and forming a continuous bed of chromatographic material, thus avoiding frits. A monolith consisting of hydrophilic/cation-exchange mixed stationary phase was found to be suitable to perform CEC separation of narcotine, papaverine, thebaine, codeine, and morphine in *Pericarpium papaveris*. The cation-exchanger function was based on sulfonic groups which not only affected the separation but also afforded for the EOF. It was shown that high concentration of organic modifier (90 % ACN) promoted hydrophilic interaction of the analytes with the stationary phase containing the diol groups that effected as hydrophilic interaction sites [103]. Using a similar monolithic CEC column, very fast separation of the major protoberberine alkaloids in extracts of *Coptis chinensis* Franch could be obtained. The mobile phase used was composed of phosphate buffer pH 7.4 in the presence of 60 % ACN as organic modifier [104]. CEC using hybrid silica monolith columns allowed a very fast analysis of methylxanthines in tea beverages. In the analyzed samples, theophylline was not detected whereas the caffeine content was found to be more than 10-fold lower compared to the tea infusions [105].

6 Capillary Electrophoresis–Mass Spectrometry (CE-MS)

Hyphenation of separation techniques with MS allows the direct sensitive detection of the resolved analytes regardless the presence in their molecule of chromophore/ fluorophore or electroactive groups. Most importantly, by MS hyphenation, structural information useful to the unambiguous identification of the analytes can be achieved, making this approach one of the method of choice in phytochemical studies [106]. Among the hyphenated techniques including the well-established gas chromatography–MS (GC-MS) and liquid chromatography–MS (LC-MS), CE-MS has been introduced more recently. The electrospray ionization source (ESI) is well suited for CE-MS interfacing, since it produces ions directly from liquid solutions at atmospheric pressure. Some of the limitations are related to buffer composition and upon the necessity for introduction of “makeup” liquid (sheath flow) to support the ionization. The advantages of CE-MS using ESI ionization source are mainly (a) the wide application range (from small ions to macromolecules, such as proteins) and (b) separation of charged species that can be easily transferred by the source from liquid to gas phase [60, 107].

Alkaloids that are separated in CZE as cationic species, on application of positive ESI mode, give rise to the corresponding pseudomolecular $[M + H]^+$ ions whose *m*/*z* values provide a useful confirmatory information for univocal identification. Often the CE separation is optimized for conventional UV detection; thus, some modifications have to be introduced for development of effective CE-MS methods. The specific parameters to be considered in hyphenation with ESI mode include electrospray voltage, nebulizing gas flow rate, drying gas flow rate, and temperature. In addition, the composition of the coaxial makeup liquid and its flow rate significantly affect the ionization efficiency and have to be appropriately selected for good coupling performances. The drying gas is used to accelerate buffer desolvation, and to increase sensitivity however is a critical factor to be optimized because the nebulizing gas has been reported to have an aspirating effect which influence the quality of the separation of the analytes because of a pressure-induced flow [108]. The most common buffers used for a conventional electrophoretic separations such as borate and phosphate are not suitable for CE coupling with ESI-MS because of their poor volatility and the risk of MS source contamination. More suitable buffers are based on formic and acetic acid, ammonium carbonate, and ammonium acetate. A fully aqueous BGE composed of ammonium acetate 20 mM pH 8.5 with sheath liquid constituted of 2-propanol/water (50/50, v/v) was used for CE-MS analysis of choline and atropine in hairy root cultures of *Cannabis sativa* L. [109]. Atropine and isomeric tropane alkaloids (Fig. 36.4) from extracts of *Atropa belladonna* L. and *Schizanthus grahamii* were also analyzed by CE-MS using mixed organic–aqueous BGEs [9, 66]. Highly sensitive and reproducible analysis of tobacco alkaloids was obtained using NACE-MS based on a BGE constituted of ACN:methanol (70:30, v/v) containing ammonium formate [110]. Anticancer alkaloids such as vinblastine and the monomeric precursor vindoline and catharanthine were determined by CE-MS in *Catharanthus roseus* obtaining LOD lower than 0.8 μg mL^{-1} [111].

In a series of studies, Sturm et al. showed the advantages of CE-MS in analysis of isoquinoline alkaloids in *Fumaria officinalis* herba and its phytotherapeutic tablets [75]. NACE-MS/MS conditions were optimized for the selective separation of structurally related compounds detected and identified by specific migration times and characteristic pseudomolecular $[M + H]^+$ ion. In Fig. 36.7a, the CE-MS electropherogram of a real sample of *F. officinalis* is reported. The peaks **7** and **8** corresponding to (−)-fumarophycine (*m*/*z* 398) and (−)-O-methylfumarophycine (*m*/*z* 412), respectively, were only partially resolved; however, the different Mw as determined by ESI-MS allowed for their selective qualitative and quantitative determination. In addition, the usefulness of MS/MS experiments in providing typical fragmentation pattern for the unambiguous identification of isobaric analytes was shown. As an example, compounds **4** and **5** corresponding to (+)-adlumine and (−)-α-hydrastine showed pseudomolecular ions with the same *m*/*z* at 384. In this case, the MS/MS experiments resulted in different fragmentation patterns; in particular, the signals at *m*/*z* 206.0 of compound **4** (Fig. 36.7b) were associated with the substitution of the isoquinoline moiety bearing to methoxy groups, whereas the signal at *m*/*z* 190 of compound **5** was assigned to the methylenedioxy group. The same authors applied NACE-MS conditions to analyze a set of 79 samples belonging to *Corydalis* species; 39 analytical peaks were characterized by the MS spectra, and a number of them were unambiguously identified as isoquinoline alkaloids [76].

Principal component analysis (PCA) performed using peak areas as the data basis allowed selection of eight compounds (including allocryptopine, protopine, corycavidine, bulbocapnine, and tetrahydropalmatine) as putative biomarkers for discrimination of the *Corydalis* species. The proposed method provided also the sensitive quantitation of palmatine, protopine, bulbocapnine, corydaline, and tetrahydropalmatine (LOD values in the range 0.7–8.3 μg mL^{-1}) [76]. A further study aimed to the characterization of *Stemona* alkaloids possessing a complex molecular structure defined as pyrido[1,2-*a*]azepine. NACE coupled with ESI-MS detection was developed to characterize the highest number of alkaloids in *S. curtisii*, *S. collinsae*, and *S. tuberosa*, and at least 40 and 50 alkaloids or charged *N*-bearing compounds were detected. Interestingly, notable differences in the alkaloids profiles of the three species were observed; in addition by the availability of references compounds, the unambiguous identification was achieved. CE-MS^n experiments were then undertaken to acquire information useful to elucidate the structure of additional *Stemona* alkaloids. Due to the structural complexity and number of reported *Stemona* alkaloids, reflected in the highly diverse fragmentation patterns, MS/MS experiments were not sufficient for a proper identification of unknowns but allowed unambiguous peak assignment of the single compounds in the various samples [77].

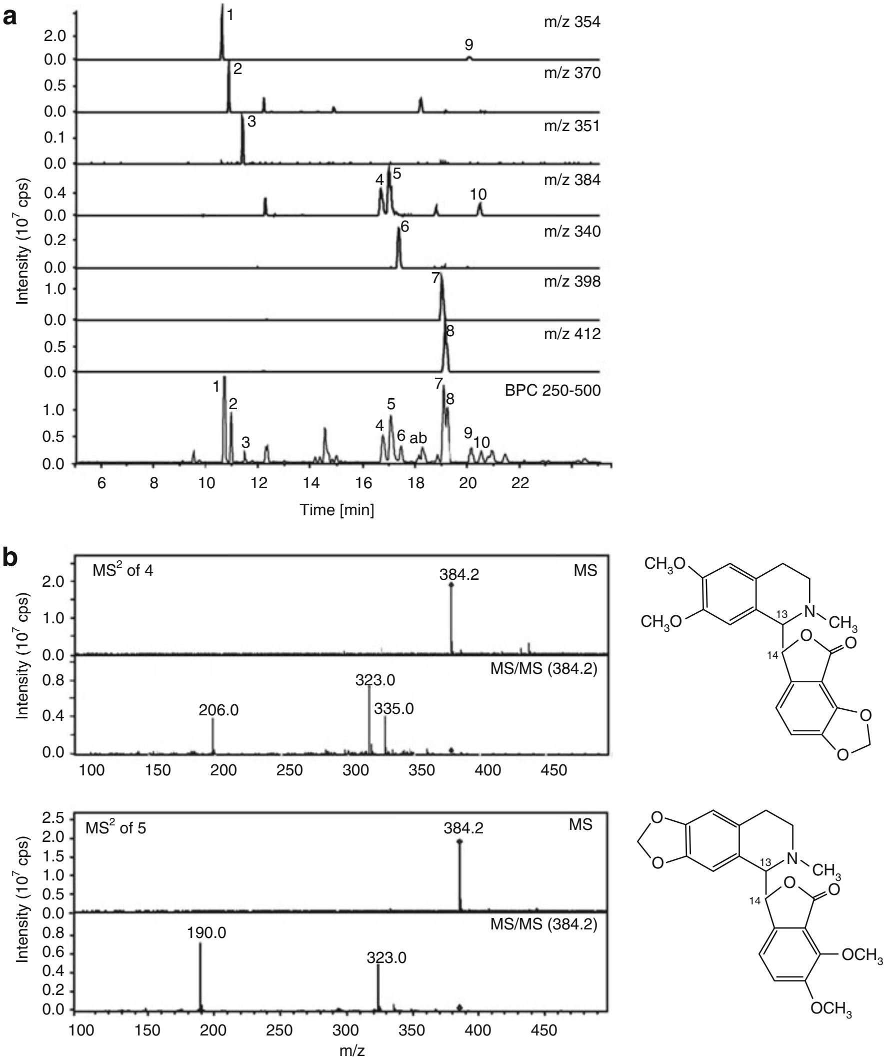

Fig. 36.7 (**a**) CE-MS electropherogram of the ten isoquinoline alkaloid fraction of F. officinalis (base peak chromatogram and selected ion traces). The peaks **7** and **8** are (−)-fumarophycine and (−)-O-methylfumarophycine, respectively. (**b**) CE-MS-derived mass spectra (MS and MS/MS) of alkaloids **4** and **5** (see related structure) identified as *13S/14S*, (+)-adlumine and *13R/14R*, (−)-α-hydrastine, respectively (Modified from ref. [75])

TOF-MS (time of flight MS), with its high mass-resolving power is capable of generating mass data of sufficient accuracy and precision to establish the elemental composition of an analyte. The high accuracy, fast response time, and ease of peak deconvolution capability make TOF-MS an ideal online detector to interface with high-resolution separation techniques. The hyphenation of TOF-MS with CE enhances further the capability of CE-MS for the unequivocal identification of components in complex samples. This approach was applied in characterization of *Atropa belladonna* L. compounds [9] and to the analysis of protoberberine alkaloids in *Rhizoma coptidis* [29]. In particular, the high accuracy of mass measurements allowed the unequivocal identification of eight protoberberine alkaloids in real extracts. Besides mass measurement, the isotopic mass distributions could be achieved, and this data provided information about the elemental composition of the species. The software in TOF-MS approach was capable of calculating all possible molecular formula satisfying the observed data. By means of this approach, the analytes could be unequivocally identified. As an example, in Fig. 36.8a, the CE-ESI-TOF-MS electropherograms of the eight alkaloids in *R. coptidis* extract are reported. The peaks **5** and **7** showed the same *m/z* 338 and also the same elemental composition ($C_{20}H_{20}NO_4$); thus, it was concluded that the two compounds were considered to be structural isomers. CE-MS experiments with a higher fragmentor voltage were performed providing extensive fragmentation in both compounds. The characteristic fragmentations were found to be closely similar (see Fig. 36.8b). Since also the exact masses of these fragmentation ions could be determined by TOF analysis, the determination of elemental compositions with mass errors under 5 ppm for each of the fragments was achieved. Finally, by comparing the observed MS data with the literature values, the analytes corresponding to peaks **5** and **7** could be identified as columbamine and jatrorrhizine, respectively [29].

7 Detection Sensitivity Improvement in Analysis of Alkaloids by CE

The small inner diameter of the separation capillary used in CE implies a short optical pathway, and the consequent poor concentration sensitivity when conventional UV detection is used. To overcome this drawback several techniques have been developed; some of them consist in application of general approaches that are not specifically addressed to CE analysis of alkaloids. One is the use of LIF detector for analysis of alkaloids with native fluorescence [68, 69] or after their off-line derivatization [64, 88, 112]. Sample pretreatment, a second major approach, is popularly employed in combination with sample extraction and can be conveniently applied in analysis of alkaloids because they can be easily retained in cationic-exchange sorbents in solid-phase extraction (SPE) mode [113, 114]. It may be interesting to focus on more specific aspects to detect very low levels of analytes using limited amounts of samples; to this regard chemiluminescence reactions and the use of online preconcentration methods will be considered.

7.1 Chemiluminescence Coupled to CE

Analytes separated by CE can be subjected to chemiluminescence reactions using specific reagents. The chemiluminescence emission can be measured using

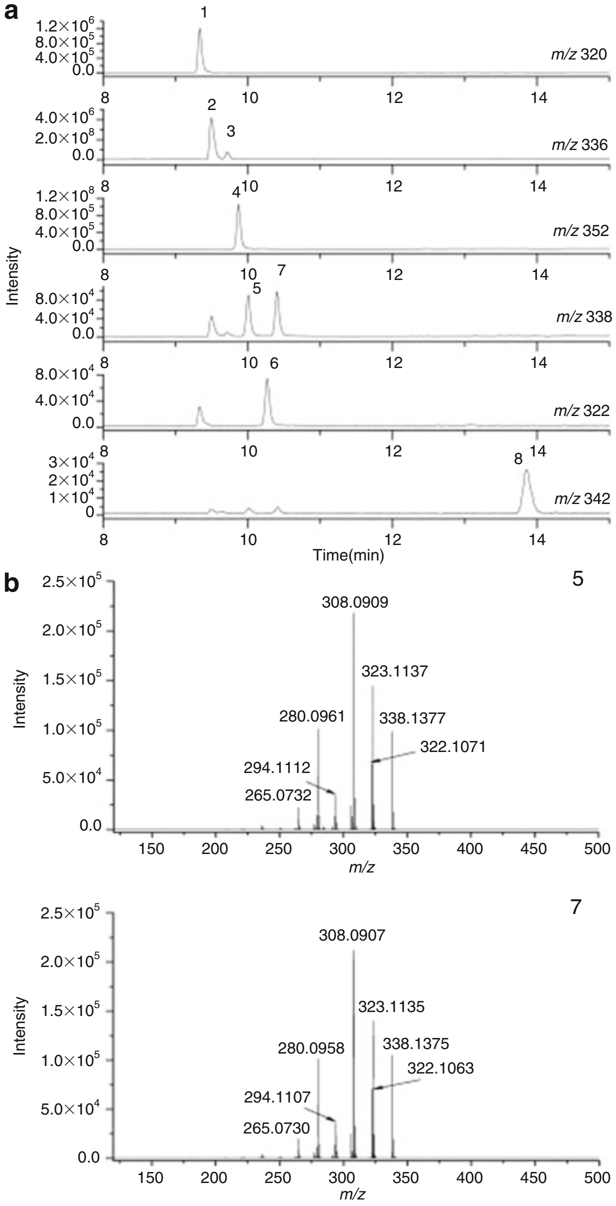

Fig 36.8 (**a**) CE-ESI-TOF-MS of eight alkaloids in *R. coptidis* extract. (*1*) Coptisine, (*2*) berberine, (*3*) epiberberine, (*4*) palmatine, (*5*) columbamine, (*6*) tetradehydroscoulerine/tetradehydrocheilanthifolinium, (*7*) jatrorrhizine, and (*8*) magnoflorine (**b**). Characteristic fragmentations of peaks 5 and 7 that were found to correspond to columbamine (*5*) and jatrorrhizine (*7*) (Modified from ref. [29])

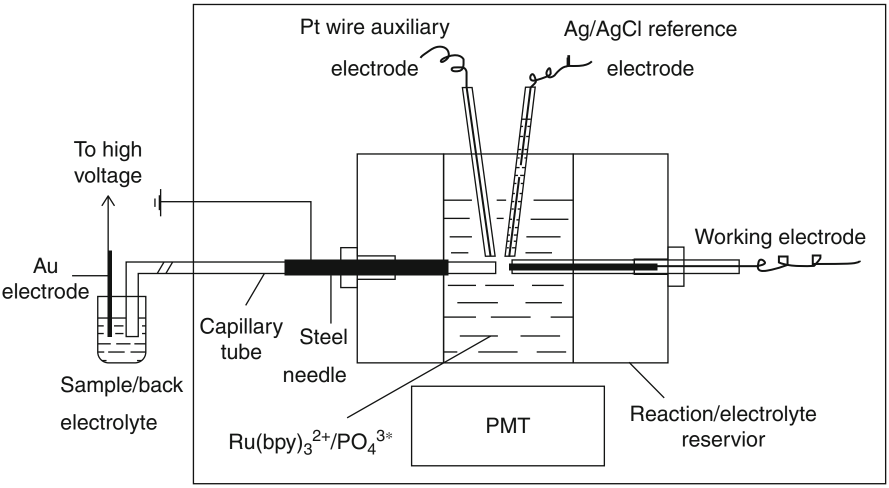

Fig. 36.9 Schematic diagram of the CE-ECL detection system (Modified from ref. [116])

a multichannel data collection analyzer based on a sensitive photomultiplier tube (PMT). Using the described configuration, no external light source is needed; the optical system is simple; and since strong background light levels are excluded, the noise signal is reduced with the result of an improved sensitivity [115]. Chemiluminescence reactions that involve species generated by electrochemical reactions give the so-called electrochemiluminescence (ECL) detection that has found several applications in sensitive and selective CE analysis of alkaloids. To this regard, the complex tris(2,2′-bipyridyl)ruthenium, Ru(bpy)$_3^{2+}$ is often selected as an ECL label. Solutions of this specie, typically in phosphate buffer (i.e., 75 mM, pH 8.0), are used to fill a reservoir of the detection cell as reported in the schematic diagram of Fig. 36.9 describing a system developed for the sensitive analysis of sinomenine, a morphinane alkaloid in *Sinomenium acutum* [116]. The complex undergoes oxidation on the working electrode surface, in general at the voltage of +1.3 V to generate the reactive specie Ru(bpy)$_3^{3+}$.

The alkyl amine groups of alkaloids eluting from the separating capillary react with the complex to form the excited state [Ru(bpy)$_3^{2+}$]* which will decay to the ground state emitting orange light at 610 nm. The detection potential and the distance of the separating capillary to the electrode are important instrumental aspects to be designed; other relevant parameters affecting the ECL response are the nature, concentration, and pH of the buffer in the detection reservoir and in the separating CE capillary [115, 116]. Importantly, tris(2,2′-bipyridyl)ruthenium is stable and soluble in aqueous media, and the high efficiency over a wide pH range makes it compatible with most buffers used in CE. The reactivity of the complex Ru (bpy)$_3^{3+}$ follows the order tertiary>secondary>and primary alkyl amines; thus, alkaloids are efficient co-reactants in the electrochemical process as highlighted by several applications in the field of plant analysis. A remarkable example is related to analysis of quinolizidine alkaloids from *Sophora* species (e.g., *S. tonkinensis* and *flavescens*) used in traditional Chinese medicine (TCM) for treating acute hepatitis and jaundice. Interestingly, at relatively high-dose levels, the compounds exhibit adverse effects, and the quality control of the quinolizidine-containing herbal drugs needs for accurate quantitation. Most of these alkaloids (i.e., sophoridine, matrine, and oxymatrine, Fig. 36.2) lack significant chromophores; thus, ECL detection can be considered as the method of choice for their sensitive analysis. Sophoridine and matrine, owing to the presence of tertiary amine function, react with $Ru(bpy)_3^{3+}$ to produce an intense ECL response, thus providing very low detection limits (1.0 nM). Unexpectedly, the ECL response was also observed for oxymatrine (quinolizidine *N*-oxide) that however showed higher detection limit (40 nM). Actually, in oxymatrine, the withdrawing oxygen attached to the nitrogen atom carries the charge from negative to positive, thus destabilizing the electrooxidation product. Under these detection conditions, the LOD values were 1,000-fold compared to those achieved by CE-UV at 200 nm [10, 12, 31, 117]. The highly sensitive detection of ECL using tris(2,2′-bipyridyl)ruthenium (II) was advantageously applied in CE analysis of aconitine alkaloids in TCM (caowu and chuanwu). The study was undertaken because of the necessity to provide efficient and sensitive analytical methods for the quality control and the safe use of *Aconitum* plants characterized by limited therapeutic index. Using ECL, detection limit of 10^{-8} M (in the order of ng mL^{-1}) was achieved [118]. Similar CZE (18 mM aqueous phosphate buffer, pH 9.0) and ECL detection conditions were applied to the analysis of galanthamine in *Bulbus Lycoridis Radiatae*, widely used in TCM. The ECL detection allowed LOD of 0.25 ng mL^{-1} to be achieved; however, the level of galanthamine found in the *Bulbus Lycoridis Radiatae* phytopreparations was 0.13 mg g^{-1} thus affordable also by UV detection [119]. The versatility of ECL detection mode is shown by several applications of CE performed in the presence of additive to the running buffer usually supplemented to tune the separation selectivity and using nonaqueous conditions. As an example, the analysis of anisodamine, atropine, and scopolamine in *Flos daturae*, a traditional Chinese crude herb, used as antitussive, antispasmodic, and analgesic agent, was performed in aqueous alkaline [8] or neutral conditions [43] and NACE [120]. In order to improve the separation of scopolamine and atropine, β-cyclodextrin (βCD) was supplemented at the concentration of 4 mM to the BGE showing to be compatible with the ECL detection. The reported detection limits were in the order of 0.3–13 ng mL^{-1} [43]. Ionic liquids may be used to prepare BGEs in CE with ECL detection [23, 38, 121]. In particular, a separation buffer constituted of 25 mM borate alkaline solution supplemented with the ionic liquid 1-ethyl-3-methylimidazolium tetrafluoroborate (1E-3MI-TFB) was used for separation of aconitum alkaloids in TCM products [121] and morphinane alkaloids in opium poppy [23]. In particular, borate buffer was useful in improving the separation selectivity by complexation of borate anions with the hydroxyl groups of the studied alkaloids. On the other hand, the ionic liquid, because of the higher conductivity compared to that of phosphate buffer present in the detection cell, provided a field-amplified effect, resulting in improved sensitivity (LOD of 1 × 10^{-6} to 1 × 10^{-9} M) [23]. Similar conditions, involving a running buffer constituted of alkaline phosphate solution in the presence of 40 mM 1B-3MI-TFB ionic liquid, were successfully used for separation of steroidal alkaloids verticine and verticinone. These compounds have been isolated from plants belonging to *Liliaceae* family, i.e., *Bulbus fritillariae*, used as a traditional herb remedy in Japanese, Turkish, Pakistani, and Southeast Asian folk medicines [122]. The *B. fritillariae*-based phytopreparations are used as antitussive, anti-asthmatics, and expectorants. Extracts from different *Fritillariae* species were obtained with chloroform in the presence of ammonia to afford the free base of the alkaloids that are characterized by cholestane carbon skeleton (isosteroid alkaloids) with a hexacyclic benzo[7,8]fluoreno[2,1-*b*]quinolizine nucleus devoid of significant chromophores. Under ECL detection conditions a very low LOD (about 50 pg mL^{-1}) was achieved. The analysis of real samples showed that verticine was found in any of the analyzed extracts (*Fritillariae hupehensis*, *F. walujewii*, *F. cirrhosa*, *F. thunbergii*, *F. ussuriensis*, *F. pallidiflora*, and *F. przewalski*) at amounts ranging within 5.40–12.35 mg L^{-1}, whereas verticinone was found at lower levels (5.66–8.07 mg L^{-1}) only in *F. hupehensis*, *F. cirrhosa, F. thunbergii*, and *F. ussuriensis* [38].

7.2 Online Sample Preconcentration

Online sample preconcentration is the term used to indicate CE techniques where a large volume of sample is injected into the separation capillary; successively, the analytes dissolved in the large sample zone are focused into a narrow zone before separation, in order to obtain improved concentration sensitivity [123]. One of the simplest online preconcentration technique is field-amplified sample stacking (FASS) that can be easily performed by injecting charged solutes in highly diluted buffer. When the injection voltage is applied, the charged analytes experience enhanced velocity in the lower-conductivity sample zone and are stacked into a narrow zone at the boundary sample/BGE because they experience the higher conductivity of the separation buffer. Yu et al. applied FASS in analysis of quinolizidine alkaloids (sophoridine and congeners) by using for separation, an MEEKC system based on the use of sodium cholate as surfactant [97]. The proposed system, that involved addition of magnesium salts to suppress the EOF, allowed LOD of 0.1 ng mL^{-1} using UV detection at 200 and 214 nm. Wang et al. applied FASS using a nonaqueous buffer (ACN/methanol, 30:70, v/v) in combination with ESI-MS detection in analysis of quinolizidine alkaloids in *Sophora flavescens* and *S. tonkinensis*, achieving LOD values of 0.02–0.04 ng mL^{-1} [124].

Sweeping is a phenomenon whereby analytes are injected in a CE system containing a pseudo-stationary phase (micelles or microemulsions) that by penetrating the sample zone allows for the accumulation of the solutes. Higher is the hydrophobicity of the analyte, and higher is the concentration efficiency. Although the sweeping technique proposed by Quirino and Terabe was originally used for

Steps: (**a**) large-volume sample injection, (**b**) beginning of pH junction sweeping, (**c**) end of pH junction weeping, and (**d**) normal MEKC separation (Modified from ref. [131]). The analysis is performed on four pyrrolizidine alkaloids whose pKas were in the range 5.44–6.65

concentration of neutral molecules [125], it has shown to be applied equally well to ionic analytes as long as they have high affinity toward the pseudo-stationary phase [126]. A typical example is related to the analysis of berberine, coptisine, and palmatine (all containing a quaternary nitrogen) by means of an MEKC method. By working under strongly acidic conditions (pH 1.82), the EOF was significantly suppressed; the pseudo-stationary phase was obtained using SDS at 15 mM concentration, and in order to optimize the separation of the alkaloids, 10 % (v/v) THF was added. The sample solution was prepared at the same pH and electrolyte concentration as the BGE. After the introduction of a very long sample zone by pressure, a negative voltage is applied in order to drive the micelles of the BGE toward the sample zone. Under this condition, the cationic analytes move in the opposite direction so that the length of the sample zone becomes smaller and the solutes are incorporated into the micelles. With this sweeping method the LOD of the alkaloids was found to be 2.5 ng mL^{-1} which is 500-fold lower than that obtained using conventional injection [127]. Similarly, highly sensitive analysis of ephedra alkaloids in *Ephedra herba* samples [128], strychnine and brucine in *Strychnos nux-vomica* L. [129], and morphinane alkaloids in poppy straw samples [130] was carried out by sweeping methods optimized by means of a careful selection of separation buffer composition. The obtained sensitivity was 100-fold higher compared to that of conventional CE method.

In *dynamic pH junction* the analytes are dissolved in buffer whose pH provides either ionization or its suppression; then, they are injected in a CE system containing a BGE providing significant changes in ionization states of the analytes. The pH discontinuity is the key to focus the analytes at the boundary of sample plug and BGE. Yu and Li applied dynamic pH junction for sensitive detection in CE of pyrrolizidine alkaloids. In particular, senkirkine, senecionine, retrorsine, and seneciphylline with pKa ranging within 5.37–6.55 were dissolved in an acidic sample plug and injected in a CE filled with a BGE at pH 9.1. After application of the voltage, since the protonated alkaloids experience alkaline pH at the boundary with the BGE, their migration resulted to be stopped. The described dynamic pH junction could not be effective, in this specific situation, because the unprotonated alkaloids were only pushed out by the EOF. Thus, the dynamic pH junction was coupled to sweeping using as a BGE an SDS solution; the micelle by penetrating the neutral alkaloids provided an electrokinetic focusing of the large sample volume. After the compression of the sample plug, the MEKC led to separation. The schematic diagrams of the described method are reported in Fig. 36.10 [131].

8 Conclusion

Capillary electrophoresis can be considered a versatile separation technique useful in analysis of alkaloids for the quality control of herbal drugs and medicinal plants. The optimization of experimental parameters affecting separation, such as (a) nature, concentration, and pH values of background electrolyte in CZE; (b) choice of surfactant type and concentration in MEKC and MEEKC; (c) use of organic solvents; (d) use of additives which can form inclusion complexes such as CDs; and (e) opportunity to combine hybrid separation mechanisms (chromatographic and electrophoretic in CEC), represents valuable feature for the development of selective and fast analytical methods. The variety of separation mechanisms involved in EKC approaches offers the opportunity to achieve orthogonal selectivity compared to HPLC and GC, thus providing effective alternative analytical methods. The possibility to combine CE with LIF and ECL detectors, beside the online preconcentration systems, greatly enhances the sensitivity making CE useful in analysis of toxic alkaloids and for standardization of phytopharmaceuticals containing bioactive compounds with low therapeutic index. More advanced detection approaches, as CE-ESI-MS and CE-ESI-TOF-MS, are mainly addressed to the phytochemical characterization of new potentially bioactive alkaloids and plant metabolites.

Abstract

Constituents of marine algae gained importance in the last four decades due to the growing interest in their potential for medicinal use. Till today, 44 alkaloids were isolated from macroalgae; some of which were reported to induce important pharmacological effects. These alkaloids can be classified under four groups as 2-phenylethylamine, indole, halogenated indole, and 2,7-naphthyridine derivatives, and each group displays a relatively distinguished activity profile. Overall, pharmacological effect spectrum of macroalga alkaloids is wide and includes neuromodulation, neurotransmission, growth regulation, cytotoxicity, angiogenesis, antioxidation as well as antibacterial, antifungal, and larvicidal activities.

1 Introduction

Seaweeds were used in the era of folk medicine since old Chinese and Egyptian civilizations [1]. The importance and the need for increasing knowledge on seaweed use in pharmaceutical, cosmetic, food, and textile industries grew over years [2]. Advances in isolation methodologies yielded more information about the potential for medicinal use of marine algae and their constituents, especially in the last four decades [3]. Compounds isolated from marine algae were demonstrated to have anticoagulant, hypolipidemic, hypoglycemic, antitumor, and antiulcer activities [4]. Progressively increasing data reveal interesting pharmacological properties of macroalga alkaloids and may provide valuable avenues for further research.

Following isolation of the first alkaloid hordenine, many alkaloids were found in marine algae, which were presented in the recent reviews [5, 6]. TYR, DOP, and HORD are biological amines, and among these, only HORD is defined as an alkaloid. These amines were included in this chapter because all are derived from the parent compound PEA and have important pharmacological activities.

2 PEA Derivatives

2.1 Structure Activity Relationship of PEA Derivatives

PEA derivatives isolated from marine algae are PEA, *N*-ACPEA, TYR, *N*-ACTYR, HORD, and DOP. All possess sympathomimetic activity, i.e., their effects resemble the activity observed when sympathetic nervous system is stimulated.

%PEA can be considered as the parent compound and is composed of a benzene ring plus ethylamine moiety. A hydroxyl group is substituted at position 4 (C4) of the benzene ring in TYR, HORD, and DOP. DOP has an additional hydroxyl substitute at position 3 (C3) of the benzene ring. Activity of α- and β-receptors of sympathomimetic amines is determined by hydroxyl group substitution on positions 3 and 4. If the biogenic amine lacks either of these groups and if there is no aromatic substitution, sympathomimetic potency is reduced [7]. Positioning of hydroxyl group modifies activity, e.g., introduction of a β-hydroxyl group weakens, but phenolic-hydroxyl substitution strengthens sympathomimetic potency [8].

2.2 PEA Derivatives as TA Family Members

TAs were previously referred to as little more than metabolic by-products [9] or false transmitters, microamines, and noncatecholic amines [10]. Today, TAs are well-characterized neurotransmitters and neuromodulators, as well [9–12]. These endogenous monoamines are present at relatively lower concentrations, approximately a thousandfold, than classical monoamines, namely, DA, norepinephrine, and serotonin, although their synthesis rates are nearly equivalent. PEA and TYR are among traditional members of TA family. They are found as endogenous ligands in the central nervous system, but also produced in foods from the natural breakdown of the amino acids [9, 10].

Endogenous TAs act as agonists of a TA-associated receptor 1 (TAAR1) [12–14]. Thyronamines like 3-iodothyronamine, which are thyroid hormone derivatives, also show potent agonistic activity for TAAR1 [12]. TAAR1 mRNA is expressed in trace (in cerebellum, dorsal root ganglia, hippocampus, hypothalamus, liver, medulla, pancreas, pituitary, pontine reticular formation, prostate, skeletal muscle, and spleen), low (amygdala, kidney, lung, and small intestine), and moderate (stomach) amounts in human tissues [13].

TAAR1 functions as an important modulator of dopaminergic neurotransmission [15, 16]. In mouse brain slices, TAAR1 agonists inhibit firing frequency of dopaminergic and serotonergic neurons in the ventral tegmental area and dorsal raphe nucleus, respectively. Thus TAAR1 activation prevents hyperdopaminergic and hypoglutamatergic activity [16]. TAAR1 agonist 3-iodothyronamine induces anergia, hypothermia, bradicardia, hypoglycemia, and hyperinsulinemia [17]. In brief, accumulating evidence has rendered this receptor a promising therapeutic target for the treatment of affective disorders, psychosis, addiction, hyperactivity, and primary headache [12, 16].

Both PEA and TYR are agonists of TAAR1, but PEA is more potent than TYR [18]. On the other hand, TYR and PEA are partial allosteric antagonists at beta-adrenergic receptors 1 and 2, which are highly similar to TAAR 1 [18].

2.3 PEA

In 1990, PEA was proposed to act as a neuromodulator of catecholamine neurotransmission [19]. TAAR1 activation by PEA alters the function of dopamine transporter which is co-localized with TAAR1 in dopaminergic neurons of rhesus monkey and mouse brain substantia nigra [20]. DOP transporter mediates reuptake of DOP and thus terminates the action of synaptically released DOP [21].

Localization of TAARs particularly in amygdala may explain the role of PEA in affective disorders. 24-h mean urinary levels of phenylacetic acid (PAA), end catabolic product of PEA in healthy males, were measured following treadmill exercise. PAA level was increased by 77%. It was concluded that antidepressant effects of exercise may be related to increased PEA activity [22]. PEA has shown antidepressant effect in several preclinical and clinical studies, and its effect is nearly indistinguishable from those of classical antidepressants [9]. Urinary excretion of PEA is also elevated following profound stress, like a parachuting exercise [23]. Accordingly, in preclinical studies, stress was accompanied by elevated PEA levels, indicating its endogenous anxiogen role [11].

PEA is synthesized from phenylalanine by the enzyme aromatic L-amino acid decarboxylase (AADC). Accordingly, high phenylalanine levels in the brain as in the case of phenylketonuria disease result in increased PEA levels. Altered AADC activity, hence altered steady-state level of PEA, has been linked to the pathogenesis of schizophrenia, attention deficit and hyperactivity disorder, and addiction like nicotine dependence and alcoholism [11].

Phenylalanine is a precursor in both PEA and DOP synthesis in the dopaminergic neurons of the nigrostriatal system; therefore, both metabolic pathways are closely related. For this reason, decreased PEA level in body fluids may reflect nigrostriatal degeneration. Significantly lower PEA levels were reported in cerebrospinal fluid of patients with Parkinson's disease than controls and patients with peripheral neuropathy [24]. Similarly, lower plasma levels of PEA were found in patients with Parkinson's disease as compared to controls. Three years of follow-up of patients with Parkinson's disease, PEA levels showed a downward trend in the progressive group but remained unchanged in the nonprogressive group [25].

PEA produced a reversible hyperpolarization and inhibited spontaneous firing in mesencephalic dopaminergic neurons [26]. Modulation of dopaminergic transmission is actualized by reduction of both presynaptic and postsynaptic $GABA_B$ receptor-mediated responses. PEA, and also TYR, in the presence of specific DOP receptor antagonists, inhibited $GABA_B$ receptor-dependent presynaptic inhibition of GABAergic inputs to dopaminergic neurons of substantia nigra [27]. In a study conducted in rat midbrain dopaminergic neurons, PEA depressed the amplitude of electrically evoked $GABA_B$-mediated slow inhibitory postsynaptic potential, interfering with the inwardly rectifying potassium channels. These observations indicate a probable role of PEA in neural regulatory mechanisms related to emotion, reward, addiction development, and locomotion [28].

PEA induced seizures in a dose-dependent manner, and its convulsant effects could be prevented by increasing brain GABA levels [29]. Seizure inducing effect of PEA at high doses was dependent on inhibition of K^+ currents, as examined in the cell membranes of rat cerebral cortical neurons. PEA suppressed both time- and voltage-dependent K^+ current (M-current) and leakage K^+ current. Suppression of M-current weakens the control on excessive neural firing, and suppression of the leakage K current triggers neuronal excitation. As a result of hyperexcitation, generalized convulsions occur at high PEA doses [30].

PEA has a similar structure to amphetamine and is well known to increase locomotion and induce stereotyped behaviors like amphetamine at higher, supraphysiological doses [10, 11, 19]. It was shown that the psychomotor effect of PEA may involve cholinergic and glutamatergic pathways in the striatum. PEA increased acetylcholine release in the striatum. PEA-associated stimulation of acetylcholine release was mediated by AMPA-type glutamatergic receptors [31].

2.4 TYR

TYR is the decarboxylation product of tyrosine, which is the precursor of DOP and norepinephrine. TYR is an indirect-acting sympathomimetic and promotes norepinephrine release from the nerve terminals. Consumption of TYR-rich food like cheese, sour creams, chocolate while taking antidepressant monoamine oxidase inhibitors may interfere with the body's ability to metabolize endogenous and exogenous monoamines and result in hypertensive crisis, which is known as "cheese effect" [32]. Potency of TYR on blood pressure rise was found to be a 100-fold weaker than adrenalin [33]. TYR's effect on membrane potential and conductance was investigated in frog ventricular myocytes. TYR induced a concentration-dependent decrease in sodium currents and blocked sodium channels directly as shown by a whole-cell voltage clamp technique [34].

The effects of TYR in TAAR1 were investigated in knockout mice. Their aim was to dissociate dopamine transporter-related and receptor-mediated effects. In TAAR1 knockout mice, dopaminergic neurons had a higher spontaneous firing rate in the ventral tegmental area. TYR did not decrease spike frequency of these neurons in TAAR1 knockout mice in contrary to the wild type. This finding supports TAAR1-related neuromodulator role of TYR in dopaminergic neurotransmission [15].

TYR also modulates GABAergic transmission. TYR depressed $GABA_B$-mediated inhibitory postsynaptic potential in a concentration-dependent and reversible manner in dopaminergic neurons [28].

TYR predisposes susceptible patients to epileptic seizures. Oral TYR was reported to activate preexisting EEG abnormalities in epileptic patients, whereas chocolate (which is a PEA-rich food) and PEA had weaker effects [35].

TA directly mediates feeding threshold determination. In the blowfly *Phormia regina*, proboscis extension reflex was used as an indicator of behavioral sensitivity for taste. Acquired experiential effects of nonappetitive or appetitive odors were linked to TYR levels in the brain [36].

2.5 *N*-ACPEA and *N*-ACTYR

PEA and TYR are substrates for *N*-acetyltransferase (NAT)-mediated biotransformation process. NATs metabolize agents that contain an aromatic amine or hydrazine group. Addition of an acetyl group leads to a less soluble molecule, altering its pharmacokinetics [37]. Therefore, *N*-acetylation is used by cells as an inactivation process of excess amines. Substrate specificity of NAT for biogenic amines was investigated *in Fasciola Hepatica*. TYR and PEA were found to be the best substrates with a relative rate of 98–100 % as compared to serotonin, norepinephrine, and DOP [38].

N-ACTYR is the neutral metabolite of TYR. *N*-ACTYR is excreted after conjugation with glucuronic acid and sulfate, and less than 0.2% is detected as free unchanged compound [39]. In neuroblastoma, elevated levels of catecholamines or its metabolites can be found in the urine, and urinary *N*-ACTYR was detected in these patients [40].

N-acetyl derivatives are alike their parent drugs with immediate onset and short duration of action [33]. However, *N*-acetyl derivatives were shown to elicit weaker responses with regard to their parent compounds. *N*-ACTYR had a weaker sympathomimetic potency than TYR, as shown on a rat carotid artery model [33]. PEA and *N*-ACPEA were compared with respect to their effects on the rotational behavioral response in animals with a unilateral 6-hydroxydopamine lesion of the nigrostriatal dopamine system. Intravenous (i.v.) injections of both agents induced rotations ipsilateral to the side of the brain lesion, but activity of *N*-ACPEA was 90% less active than β-PEA [41].

N-ACPEA and *N*-ACTYR were compared for their inhibitory effects on sepiapterin reductase, a catalyzing enzyme for synthesis of tetrahydrobiopterin which is a required cofactor for phenylalanine, tyrosine, and tryptophan hydroxylases. In MOLT-4 T cell leukemia and MCF-7 breast cancer cell lines, both *N*-ACPEA and *N*-ACTYR (*N*-acetyl-p-tyramine) showed poor inhibitory effects on sepiapterin reductase, whereas *N*-acetyl-m-tyramine was a strong inhibitor [42].

2.6 HORD

Since HORD was used to feed animals, its toxicity was investigated in several animal species. In rats and dogs, HORD showed a positive inotropic effect, increased systolic and diastolic pressures, enhanced peripheral blood volume, and inhibited gut movement. All effects are short and only observable at high doses [43]. HORD administered at an oral dose of 2.0 mg/kg body weight to horses did not change heart rate, respiratory rate, basal body temperature, and behavior. But when HORD was injected by rapid i.v. route to horses, defecation within 60 s, substantial respiratory distress, approximately 250% increase in heart rate, and profuse sweating were observed [44]. These effects were transient and abolished within 30 min.

The vasopressor effect of HORD is not centrally induced but by its stimulatory action on the heart muscle [45]. In isolated vas deferens of guinea pig, relative maximal response of HORD ethiodide was found to be higher (0.22) than tyramine (0.09) as compared to norepinephrine (1.00), which served as the reference [46]. HORD isolated from *Phyllophora nervosa* increased blood pressure, contracted nictating membrane when injected by i.v. route to cats. This epinephrine-like effect was less potent but more durable than epinephrine [5].

HORD and its derivatives are central depressants [47]. At very high doses, the consequence could be fatal, causing respiratory arrest and death [45].

In the past, plants containing HORD have been used as a diuretic and also for the treatment of diarrhea and dysentery as folk remedies. HORD was shown to be a weak antiseptic and inhibit some soluble ferments [45].

2.7 DOP

DOP is a key neurotransmitter in the body. It's synthesized from phenylalanine and tyrosine. DOP binds to five distinct groups of receptors. D1 receptor is abundant in kidney, retina, cardiovascular system, and especially in CNS. DOP decreases blood pressure by vasodilatation and increasing urinary sodium excretion. DOP decreases prolactin secretion from the pituitary gland. DOP modulates many functions of CNS, like addictive behavior, emotions, cognition, learning, memory, and locomotor activity. DOP receptor agonists are indicated in the treatment of Parkinson's disease, hyperprolactinemia, and restless leg syndrome. DOP receptor antagonists are used in schizophrenia and other psychotic diseases, show promise in the treatment of addiction [21]

3 Indole Derivatives

Indole group alkaloids with reported pharmacological activity include CLP, CLS, FRG, MRT, MRF, and DTC.

3.1 CLP

Although *Caulerpa* material was reported to cause poisoning, one of its constituents, a red pigment, namely, CLP exhibited low toxicity [48, 49]. Acute toxicity study in mice followed up for 15 days revealed that LD50 of CLP is greater than 2 and 0.2 g/kg, following oral and i.v. administration, respectively [50].

CLP regulates plant growth and stimulates shoot and root growth [51–54]. Effect of CLP on cell growth was studied in a *Saccharomyces cerevisiae* tryptophan auxotroph with human indoleamine 2, 3-dioxygenase (IDO) expression. IDO is a degradation enzyme for tryptophan, and its overexpression when accompanied by low tryptophan levels restricts cell growth. In this yeast assay, CLP was able to restore growth [55].

Cytotoxic activity of CLP has been extensively investigated. CLP exhibited a moderate in vitro antitumor activity against crown-gall tumor [56]. The crude acetone extract of *Caulerpa racemosa* had a cytotoxic effect on C32 human amelanotic melanoma cells. C32 cells were treated for 72 h within 5.0–100 mcg/ml concentration range, and cytotoxic activity was measured by sulforhodamine (SRB) assay. The growth inhibitory effect of the crude extract at 50.0 and 100.0 mcg/ml concentrations continued for 3 days following exposure. However, CLP, purified from the crude extract, displayed no cytotoxicity in C32 cell line following 72 h of exposure. CLP had a high cytotoxic effect on normal fibroblast cell line FEK4 at 10.0 and 50.0 mcg/ml as compared to the control group [57]. Similarly, a cell line-dependent cytotoxic activity of CLP was demonstrated. CLP (1, 3, 10, and 30 mcM for 48 h) inhibited cell growth in breast tumor (T47D, MCF-7, and MDA-MB-231), prostate tumor (DU145 and PC-3), and primary human mammary epithelial cell (HMEC) lines as determined by SRB assay. Growth inhibitory effect varied between cell types. PC-3 was the most susceptible cell line, and viability was inhibited by 52% at 30 mcM [58]. CLP showed no cytotoxic activity in HL-60 leukemic and MCF-7 breast cancer cell lines [59].

Hypoxia increases intracellular concentration of a gene regulatory protein, hypoxia-inducible factor-1a (HIF-1), which stimulates vascular endothelial growth factor (VEGF). In T47D cells, CLP suppressed HIF-1 activation. This concentration-dependent effect of CLP is observed in hypoxia (1% O_2) as well as chemically induced hypoxia. In the same assay, CLP also suppressed hypoxia-induced secretion of vascular endothelial growth factor (VEGF), an important protein in tumor angiogenesis. Antimetastatic activity of CLP was further demonstrated in a MDA-MB-231-based wound healing model. In this wound healing process in cell culture, CLP inhibited migration of MDA-MB-231 cells in a dose-dependent manner [58]

Exposure of the marine sponge *Geodia cydonium* to nontoxic (non-apoptotic) concentrations of water pollutant tributyltin together with CLP (10 mcg/ml) led to apoptosis. Increased toxicity of tributyltin was at least partially attributed to inhibition of multixenobiotic resistance pump by CLP [60]. This important observation elucidates the potential effect of CLP in overcoming resistance against chemotherapeutic agents.

In addition to its effects on cell growth, CLP elicits antinociceptive and anti-inflammatory activities. Peripheral antinociceptive activity was investigated by acetic acid-induced writhing model. CLP (0.1–100 mcM/kg) inhibited acetic acid-induced abdominal constrictions dose dependently (IC50 = 0.0945). Central antinociceptive activity of CLP was demonstrated in the hot plate test. CLP (100 mcM/kg, p.o.) increased latency time 90, 120, and 150 min after treatment. Similarly, CLP caused an inhibition of nociception in formalin test. Anti-inflammatory activity of CLP was evaluated in capsaicin-induced ear edema and carrageenan-induced peripheral inflammation tests. Following oral administration at a dose of 100 mcM/kg, CLP inhibited capsaicin-induced ear edema by 55.8% and reduced leukocyte migration to the inflammatory sites by 48.3% [61].

CLP was shown to exhibit antifungal [51], antibacterial [62], and larvicidal [63] activities.

CLP also attracted attention in type II diabetes and obesity-related research. CLP inhibited human protein tyrosine phosphatase 1B (hPTP1B) which can hydrolyze phosphotyrosines on the insulin receptor and deactivates it [59].

3.2 FRG

ROS scavenging ability of FRG was tested using 2,2-diphenyl-1-picrylhydrazyl radical (DPPH) solution-based chemical assay and a 2,2,7,2-dichlorodihydrofluorescein diacetate (DCFH-DA) HL-60 cell line-based assay. The cell-based fluorescent DCFH assay enables detection of antioxidant molecules which can penetrate cell membranes and inhibit ROS production in living cells. The antioxidant activity was determined by TPA-stimulated control cells with and without FRG. FRG showed strong antioxidant activity in both systems [64].

3.3 MRT A

MRT A showed antimicrobial activity against *Bacillus subtilis*, *Staphylococcus aureus*, and *Mycobacterium smegmatis* [65].

3.4 MRF A

MRF A is an antioxidant and a potent inhibitor of lipid peroxidation [66–68]. MRF A showed inhibitory activity on NADPH-dependent lipid peroxidation (IC50 = 2.8 mcM) in rat liver microsomes, being 30 times and 70 times stronger than alpha-tocopherol (IC50 = 87 mcM) and ascorbic acid (IC50 = 200 mcM), respectively. Indole (IC50 = 330 mcM) and tryptamine (IC50 = 260 mcM), the partial structures of MRF A, had much weaker effects on lipid peroxidation [67]

3.5 DTC

DTC(s) have an anti-photo-oxidative activity [69].

4 Halogenated Indole Alkaloids

4.1 BRI

2,3,5, 6-Tetrabromo-1 *H*-indole showed antimicrobial activity and, at a level of 100 mcM per 12.7-mm disk, produced inhibition zones of 16 and 14 mm for *Bacillus subtilis* and *Saccharomyces cerevisiae*, respectively [70, 71].

4.2 PHLI

Strong antifungal activity detected in the crude extract of *Rodophyllis membranacea* Harvey was related to the presence of polyhalogenated indoles [72].

5 2, 7-Naphthyridine Derivatives

5.1 LO A and LO B

Although structurally similar, LO A and LO B possess distinct pharmacological properties. As measured by SRB assay, LO B had moderate cytotoxic activity in MDA-MB-435 breast cancer and NCI-H460 lung cancer cell lines with IC50 of 3.1 mcM and 64.6 mcM, respectively. However, LO A was inactive in these two cell lines. Both LO A and LO B did not display any cytotoxicity in neuro-2a neuroblastoma cell line [73].

LO B induced cell cycle arrest at G2/M phase in MDA-MB-435 cells. Cytotoxic effect was related to microtubule inhibition. LO B was shown to be a moderate tubulin depolymerizer in a rat aortic smooth muscle cell line, A-10 [73].

Affinity studies with LO A and LO B at 10 mcM were conducted in muscarinic, opiate, GABA, and histaminergic receptors. LO A was found to be antagonist of δ-opioid and NMDA receptors [73].

6 Conclusion

Available results highlight the potential of macroalga alkaloids for medicinal use. Further research in this field seems likely to yield promising results for the development of anticancer, anti-inflammatory, antioxidant, and antimicrobial agents as well as novel therapies against affective disorders, psychosis, addiction, hyperactivity, and locomotor diseases.

Abstract

Ephedrine is a sympathomimetic agent that has widespread use as an adrenergic stimulant. It comes from plants of the genus *Ephedra* sp., being an alkaloid mainly found in the specie *Ephedra sinica*. This amine can be obtained by industrial synthesis, as a product of biotransformation or by extraction of the plant. Other derivatives of ephedrine can also be found in *Ephedra*, such as

pseudoephedrine that also has adrenergic activity. The purest form of ephedrine is used for therapeutic purpose, primarily as a bronchodilator and decongestant. Its pharmacological applications are related to its sympathomimetic properties, which in turn occur due to its stimulating action on α-, β1-, and β2-adrenergic receptors through direct and indirect effects. Nowadays, there is a concern about the indiscriminate use of ephedrine, since it started to be used to weight loss and enhance athletic performance. Associated with this tendency, a large number of adverse effects related with cardiovascular issues started to be reported. This chapter will discuss botanical, chemical, pharmacological, toxicological, and analytical aspects of ephedrine.

Keywords
Ephedra • Ephedraceae • Ephedrine • Phenylethylamine alkaloid • Sympathomimetic amine

TLC	Thin-layer chromatography
VMT	Vesicular monoamine transporter

1 Introduction

Ephedrine (1*R*-2*S*-2-methylamino-1-phenylpropan-1-ol) is an adrenergic amine present in many kinds of pharmaceutical preparations, obtained by synthesis or from natural sources. Belonging to the genus *Ephedra* (Ephedraceae), the Chinese species *Ephedra sinica* and *Ephedra equisetina*, also known as ma huang, and the Indian and Pakistani species *E. gerardiana*, *E. intermedia*, and *E. major* are the primary source of ephedrine [1]. Besides *Ephedra* species, low amounts of ephedrine (less than 2 %) can also be found in the leaves of the Malvaceae *Sida cordifolia* (Linn) (known as country mallow) [2, 3] and in the Chinese herb *Pinellia* (known as ban xia), with around 0.003 % of ephedrine [4].

Ephedrine belongs to β-phenylethylamine core structure (**1**) and is kinetically and dynamically close related to amphetamine-type derivatives that include stimulants, psychedelics, and entactogens, as well as anorectics, bronchodilators, decongestants, and antidepressants [5]. Ephedrine (**2**) and its analogues pseudoephedrine, norephedrine (phenylpropanolamine) and norpseudoephedrine (cathine), as well as methylephedrine and methylpseudoephedrine (**3–7**) cannot be considered typical alkaloids, since they do not have the nitrogen as part of a heterocyclic ring system, being called protoalkaloids into the *sensu lato* alkaloid class [1].

The medicinal herb *Ephedrae* (ma huang or merely "ephedra") has been millenary used in traditional Chinese medicine to induce perspiration, reduce fever, and treat coughs and asthma. Recently, *Ephedra*-containing dietary supplements have been used as an aid in diets and as a stimulant to boost energy and athletic performance. The activity of ephedra is attributed to the presence of three pairs of diastereoisomeric alkaloids: (1*R*,2*S*)-(−)-ephedrine and (1*S*,2*S*)-(+)-pseudoephedrine, (1*R*,2*S*)-(−)-norephedrine and (1*S*,2*S*)-(+)-norpseudoephedrine, and (1*R*,2*S*)-(−)-*N*-methylephedrine and (1*S*,2*S*)-(+)-*N*-methylpseudoephedrine (**2–7**), being ephedrine the major constituent of it. More than 50 species of *Ephedra* are known and at least 18 of them contain these alkaloids. The amounts of ephedrines vary according to the species, time of harvest, geographical location, and growing conditions [6].

The long history of *Ephedra*'s use has begun in oriental medicine, especially for the treatment of asthma, colds, cough, fever, headache, and nasal congestion [7, 8]. Some applications still remain in modern medicine, but much has changed after the beginning of ephedrine's use for weight loss and muscle gain [9]. The record of cardiovascular adverse effects attributed to the use of ephedrine usually associated with others substances such as caffeine, salicin, and/or p-synephrine led to a higher concern about the use of this amine. Thus, after several attempts, the FDA banned the sale of ephedrine-containing products in the United States [10]. However, the pharmacological and toxicological properties strongly depend on the concentration of ephedrine, interactions with other drugs, individual susceptibility, and the presence of contaminants [8].

Based on these considerations, this chapter presents a literature review over several aspects of ephedrine, focusing on its botany, chemical composition, general uses, pharmacological properties, toxicity, and analytical aspects.

1.1 Occurrence

Plants of the genus *Ephedra* sp. (Ephedraceae, Gnetales) are the main natural source of ephedrine and related alkaloids. The aerial parts of different *Ephedra* species contain at least six optically active constituents that are structurally related to ephedrine. Among these, ephedrine and pseudoephedrine are the main psychoactive constituents, although others as optical isomers and methylated derivatives are also important [11].

A major source of *Ephedra* is near to the seacoast in southern China and this local formerly supplies most of the American market [12]. These popular herbs, also known as ma huang in traditional Chinese medicine, can be found in subtropical zones in Asia, Europe, and America [8, 13]. The name ma huang has Chinese origins, in which "ma" means astringent and "huang" means yellow, probably referring to the taste and color of the plant or tops of *Ephedra sinica* Stapf [12].

The *Ephedraceae* family consists of branched shrubs, rarely being small trees, with opposite leaves, scales and very small size [14]. The shrubs can reach 1 m in height and can grow in semiarid and desert conditions, being the six continents suitable for the growth of that genus [15]. Studies indicate that there are between 50 and 65 species of *Ephedra* in the world [16]. The plants are small bushes, dioecious, and with minute leaves, giving the appearance of leafless shrub. The shrub grows 60–90 cm high and has slender aerial stems, which are green, erect, small ribbed, and channeled. It is 1.5 mm in diameter and usually terminates in a sharp point. At the nodes, which are 4–6 cm apart, the leaves appear as whitish, triangular, scarious sheaths. Small blossoms appear in the summer [12, 17]. The concentration of ephedrine alkaloids can vary from 0.02 % to 3.40 % according to species and the isomer (−)-ephedrine represents from 30 % to 90 % of the total content of alkaloids [17, 18].

The different proportions of the alkaloids vary between plants of the same species and between different species of the genus *Ephedra* [19]. The collection aspects are also important. The plant should be collected in the autumn, since the amount of alkaloid shows considerable variation at different seasons [1].

Ephedrine and pseudoephedrine are the main active constituents of the *Ephedra*. Described in pharmacopoeias of China, Germany, and Japan, the dried young branches of *Ephedra sinica, E. equisetina*, *and E. gerardiana* contain not less than 1.25 % of alkaloids [20]. Japanese pharmacopoeia specifies not less than 0.6 % [21].

Ephedra sinica is the primary source of ephedrine alkaloids, although other species of this genus may contain the active constituents as *E. equisetina, E. intermedia*, *E. gerardiana, E. alata*, *E. distachya, E. botschantzevii*, *E. fragilis, E. major*, *E. minuta, E. monosperma*, *E. pachyclada, E. likiangensis*, *E. saxatilis, E. lomatolepis*, *E. lepidosperma, E. przewalskii*, and *E. regeliana* [22]. Eurasian species are characterized by the presence of alkaloids, while American species are considered devoid of such metabolites [7, 22–24]. Approximately 40 species of *Ephedra* are grown for commercial purposes; among them are *Ephedra sinica* Stapf and *E. equisetina* Bunge, from southern China, and *E. intermedia* Schrenk and *E. gerardiana* Wall, from India and Pakistan [17, 25]. The less-known alkaloid ephedroxane was found in *Ephedra intermedia* and at least in six more species [26].

Besides *Ephedra* species, low amounts of ephedrine can also be found in the leaves of the Malvaceae *Sida cordifolia* (Linn) (known as country mallow), with less than 2 % of content [2, 3] and in the Chinese herb *Pinellia* (known as ban xia), with around 0.003 % of ephedrine [4, 27]. Due to the low content of ephedrine, no stimulatory effects were observed in pharmacological tests with *Pinellia*, showing the opposite effect of sedation [28]. In addition to other species previously mentioned, other monoamine alkaloids can be found in khat (*Catha edulis* Forsk.) such as norpseudoephedrine and norephedrine [29, 30].

1.2 Biosynthesis and Chemical Aspects

L-phenylalanine (Phe) is the precursor of the biosynthesis of ephedrine in plants, unlike the majority of alkaloids [31]. Although the backbone of this amino acid has clear resemblance with ephedrine, phenylalanine provides only the aromatic ring and the first carbon of the side chain (C1–C6) of this amine. Supporting this finding, it was shown that cinnamic acid, benzoic acid, and benzaldehyde are easily incorporated into ephedrine [32], being the remaining two carbons (C2–C3) derived from pyruvate and the nitrogen introduced by reaction of transamination at the end of biosynthesis, as can be seen in Scheme 38.1 [33, 34]. The biosynthetic route from phenylalanine occurs with the metabolism of L-phenylalanine through cinnamic acid to benzoic acid. The conversion of phenylalanine into *trans*-cinnamic acid is well characterized by the enzyme L-phenylalanine ammonia-lyase (PAL) [35]. At least two possible courses of Phe side-chain shortening is currently accepted in benzoic acid biosynthesis: the β-oxidative and non-β-oxidative pathway [36]. Besides PAL, no other enzymes involved in biosynthesis of amphetamine analogues were isolated [31]. Benzoic acid may undergo esterification with coenzyme

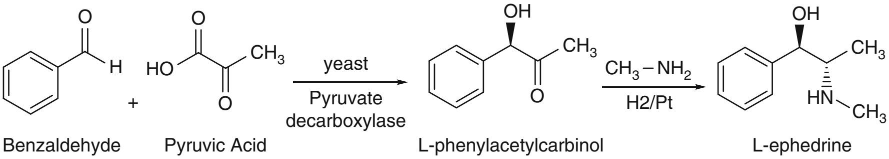

Scheme 38.2 Synthesis of ephedrine by fermentation reaction on benzaldehyde, followed by reductive condensation with methylamine

A following by acetylation with pyruvate, which in turn is decarboxylated to diketone. A transamination reaction occurs with diketone giving cathinone. Reduction of the carbonyl group of cathinone provides norephedrine or norpseudoephedrine which in turn suffer *N*-methylation generating ephedrine or norpseudoephedrine [37].

The ephedrine and pseudoephedrine commercially available and used for medicinal purposes are obtained either synthetically or by the extraction of plant material. Three possible methodologies can be used for the commercial production of ephedrine. The first one is the extraction from plants, especially from those of the genus *Ephedra*, and it is still used for herbal formulations, although being an expensive and prolonged method. The extraction method consists basically in the treatment of the alkaloids with alkali followed by addition of an organic solvent to extract the substance [31]. The commercial production can also occur by a chemical synthesis that has been developed to obtain racemic mixtures of ephedrine [38]. The third method is the most common and consists of a combination of fermentation and chemical synthesis, being a semisynthetic process. [31]. It involves the biotransformation of benzaldehyde to L-phenylacetylcarbinol, catalyzed by the enzyme pyruvate decarboxylase. The chemical procedure of fermentation usually uses brewer’s yeast (*Saccharomyces* sp.) or others species of yeast. The chemical counterpart of the method is based on a reductive condensation with methylamine in combination with hydrogen and metals as catalysts, as shown in Scheme 38.2. The growth phase is followed by biotransformation and added sugars, seeking to maximize L-phenylacetylcarbinol production. This process yields (−)-ephedrine with very high enantioselectivity, [12, 17], being (1S,2R)-pseudoephedrine produced from its diastereomer via Welsh rearrangement [31].

Considering the chemical characteristics, ephedrine has two chiral centers, and therefore four isomers can be identified: (±)-ephedrine and (±)-pseudoephedrine [39]. (1R,2S)-(−)-ephedrine is the major isomer found in Ephedra sp., and pharmacological studies have shown it as responsible for the pharmacological activities of ephedra. Not only (−)-ephedrine has the widespread use but also (+)-pseudoephedrine is added in over-the-counter decongestant preparations [40]. The four isomers of ephedrine may be naturally present in *Ephedra* species, and they are usually used as a hydrochloride form, being the classical purification method for ephedrine hydrochloride a combination of conventional infusion and organic solvent extraction or adsorption [41]. Other alkaloids are also present in smaller amounts, and the minor ephedrine alkaloids include (+)-pseudoephedrine and the demethyl analogues (−)-norephedrine and (+)-norpseudoephedrine [40].

Ephedrine occurs as white, rosette, needle, and crystals. It is soluble in water, alcohol, chloroform, ether, and in liquid petrolatum [12] and has a melting point of 187 °C–188 °C. It is marketed as ephedrine hydrochloride and may be found some traces of benzoic acid as a by-product of the process [42].

1.3 Analytical Aspects

A great number of publications on ephedrine-containing products analysis are proposed in the literature [43]. Extraction of ephedrines in body fluids and pharmaceuticals using liquid–liquid extraction procedures (LLE), solid-phase extraction (SPE), solid-phase microextraction (SPME), and headspace (HS) have been reported [44]. Gas chromatographic (GC) and liquid chromatographic (LC) procedures with different detectors (e.g., mass spectrometer, MS; nitrogen–phosphorus detector, NPD; flame ionization detector, FID; and ultraviolet, UV) have been used as analytical strategies, in addition to immunoassays, thin-layer chromatography (TLC), and capillary electrophoresis (CE). The employ of them depends on the purpose of analysis and the kind and amount of matrix used. Ephedrine-related compounds may be quantified in blood, plasma, or urine to monitor possible abusers, such as athletes, or to confirm a diagnosis of poisoning and to assist a medicolegal death investigation.

The choice of the method depends on the sensitivity and the resolution required for the analysis, the complexity of the sample matrix, and the time needed for sample pretreatment. Considering that extracts of the plants are a complex matrix, the analysis need to be preceded by preparative methodologies in order to clean up the samples. Nowadays, solid-phase extraction (SPE) is considered the gold standard for pretreatment of samples. This methodology allows the passage of large volumes of sample through the extractor column, which will selectively retain the analytes. The interfering compounds can then be discarded and the previously retained analytes are eluted with small amounts of organic solvent in a concentration range suitable for instrumental analysis. SPE also pre-concentrate the analyte, improving the sensitivity of the analysis [24] consisting in a better approach when compared with liquid–liquid extraction.

Analytical strategies including GC–NPD [45], GC–FID [46], GCxGC [47], GC–MS [48–50], LC–UV [6, 51], and LC–MS/MS [6, 52–55] have been employed in the routine laboratories to normal and chiral analysis. The use of mass spectrometry detection is mandatory to the confirmatory steps of the analyses. Methods by CE have been successfully used to separate chiral isomers of ephedrine and related compounds [56, 57]. Chromatographic techniques can easily distinguish (−)-ephedrine from other phenylethylamine derivatives and diastereoisomers.

LC–MS/MS procedures have the advantage of decrease work-up time due to the ability to analyze underivatized compounds. These techniques have also shown the ability to separate structural isomers such as norpseudoephedrine and norephedrine with relatively short analysis times, having a reported instrument cycle time of 8 min per sample [53, 58]. Currently, GC–MS is still the preferred method for forensic confirmation and has the advantage of low equipment costs. However, a previous derivatization step should be employed in order to improve the accuracy and the chromatographic profile of the analysis. An attractive analytical approach for routine confirmations can be created by combination of extractive–derivatization techniques with fast GC–MS, considering that the analytes of interest are separated by chromatography and accurately quantified [59], through a well-validated method.

2 Pharmacological Applications

Ma huang is one of the oldest known drugs and has been used as a medicine in China for more than 5,000 years [17]. Its use in modern medicine began in 1923 with the discovery of the valuable properties of ephedrine [12] which in turn was discovered in 1887 [37].

Ephedrine is a sympathomimetic amine with similar effects to those of adrenaline, so it is taken most commonly as a decongestant or for weight loss and energy enhancement as a dietary supplement [17, 60]. The purest form of ephedrine is currently used as a bronchodilator, decongestant, and vasopressor due to its sympathomimetic effects. The bronchodilator activity promotes relief in asthma, relaxing the bronchial smooth muscle in asthmatic patients. The vasoconstrictor action on mucous membranes makes it a superior nasal decongestant [17], being that the main clinical use for ephedrine. It may be used alone or in combination with other agents for the relief of cold symptoms being used topically and orally [20].

Other presentations of ephedrine have the same or very similar clinical uses. Ephedrine sulfate, for example, is used to combat hypotensive states, nasal congestion, and allergic disorders, such as bronchial asthma. Ephedrine hydrochloride is used similarly to ephedrine as a sympathomimetic agent [12]. Ephedrine hydrochloride or sulfate has been used as a bronchodilator, but the more selective β2-sympathomimetic bronchodilating agents, such as salbutamol, are now preferred. The salts of ephedrine have been given parentally to combat a fall in blood pressure during spinal anesthesia, since ephedrine is no longer generally advocated for orthostatic hypotension due to risk of shock, circulatory collapse, or hemorrhage. They are sometimes used in motion sickness, usually associated with hyoscine or an antihistaminic. Other uses include diabetic neuropathic edema and nocturnal enuresis, although other treatments are usually preferred [20]. Ephedrine derivatives are also largely employed, being pseudoephedrine widely used for the treatment of cough and cold and as a decongestant [17].

Besides the features already mentioned, ephedrine has also the capacity to stimulate thermogenesis in human subjects [61]. Probably because of its ability to stimulate the CNS and thermogenic properties, ephedrine may be employed to lose weight and enhance performance in endurance training and body building [62]. Thus, this pharmacological property triggered an unbridled use of it as a weight-loss compound, as well as an enhancer of athletic performance. So, ephedrine became quickly one of the main active components used in dietary supplements, gaining market share. The marketing of ephedrine for this purpose was restrained only after serious adverse effects reports arising from its use. Thus, the toxicity of this alkaloid began to be studied in order to determine the toxicological profile of this amine either alone or in combinations with stimulants such as caffeine. Ephedrine is considered nowadays one of the substances most widely used in sport, together with amphetamines, cocaine, caffeine, and anabolic steroids [63].

Owing to its sympathomimetic activity, ephedrine may be contraindicated for individuals with hypertension or other cardiovascular diseases, glaucoma, diabetes, and hyperthyroidism [64].

It is currently being traded as “herbal ecstasy” due to its CNS stimulation that in overdoses can lead to hallucinations, paranoids, and psychosis [17]. However, the large number of reports of serious adverse effects related to the use of this substance increased the attention to its use.

3 Mechanism of Action

The adrenergic effects caused by ephedrine occur mainly due to its capacity to be a sympathomimetic agonist at both α- and β-adrenergic receptors. As consequence of these stimulations, an increase in cardiac rate and contractility, peripheral vasoconstriction, bronchodilation, and CNS stimulation can be observed as general effects caused by the use of this amine [62, 65].

Ephedrine stimulates α-, β1-, and β2-adrenergic receptors through direct and indirect effects on adrenergic receptors [20]. The β-adrenergic effects are believed to be pronounced by the activation of adenylcyclase which increases the productions of cyclic AMP, while α-adrenergic effects result from inhibition of adenylcyclase [12].

Considering the chemical structure of ephedrine, it is interesting to observe the lack of the phenolic group, characteristic of catecholamines. However, ephedrine remains capable to stimulate α- and β-receptor directly and displace norepinephrine (NE) from storage vesicles, releasing these catecholamines at synaptic areas in the brain and in the heart. These released substances act on receptors promoting the adrenergic effect [17, 66].

Due to this mechanism of releasing catecholamines, ephedrine is also classified as indirect-acting sympathomimetic amine. The chemical similarity between ephedrine and epinephrine allows the transport of ephedrine into the nerve terminal by NE transporter. Inside the terminal nerve, an exchange of NE by ephedrine occurs by the vesicular monoamine transporter (VMT). Thus, NE accumulates in cytosol, being part of it degraded by MAO and partly released in the synaptic cleft by NE transporter. This causes an increase in the amount of NE in the synaptic cleft and consequently increases the effect on noradrenergic postsynaptic receptors. Although the indirect action of ephedrine is well established, it is known that there are other adrenergic mechanisms, such as direct stimulation of adrenergic receptors, inhibition of NE transporter (NE remains longer in the synaptic cleft), and partial inhibition of MAO (the metabolism of NE is reduced) [63].

As expected, there are many drugs that can strongly interact with ephedrine, increasing or decreasing its effect. Classically, these drugs are those capable of modifying the noradrenergic transmission. So, MAO inhibitors potentiate the effect by preventing the inactivation of NE previously displaced from the vesicle. Drugs that inhibit NE transport prevent the catch of ephedrine by the nerve endings, decreasing the ephedrine effect [63].

By the mechanisms mentioned above, it is possible to correlate the clinical effects observed with the use of ephedrine, as well as to establish the possible effects before the consumption. The use of ephedrine in therapeutic doses raises the blood pressure by increasing cardiac output and also by inducing peripheral vasoconstriction. It may cause tachycardia. Its action on β- adrenergic receptors in the heart produces a positive ionotropic effect. Ephedrine has a stimulant action on the respiratory center. It also causes bronchodilatation, reduces intestinal tone and motility, and usually reduces the activity of the uterus. Its effects on α-adrenergic receptors results in vasoconstriction in the skin and mucous membranes [12], leading to hypertension, which may produce cerebral hemorrhage and pulmonary edema.

Sympathomimetic agents are capable to produce a wide range of adverse effects, most of which are due to excessive stimulation of the sympathetic nervous system. Therefore, these effects depend on the relative agonist activity of the drug at a given dose on different types of receptor. General adverse effects related to the use of sympathomimetic agents are fear, anxiety, restlessness, tremor, insomnia, confusion, irritability, and psychotic effects. Cardiovascular issues such as tachycardia and cardiac arrhythmias, angina pain, palpitations, and cardiac arrest may be produced by stimulation of β1-adrenergic receptors of the heart. On the other hand, vasodilatation caused by β2-stimulation may lead to hypotension with dizziness and fainting and flushing. These kinds of stimulants have important effects on the CNS. The development of tolerance and dependence and the significant abuse of these drugs are consequences related to the CNS effects of ephedrine [20].

Considering the foregoing, it is reasonable to recommend patients at risk of stroke, myocardial infarction, uncontrolled blood pressure, seizures, and general anxiety disorder to avoid ephedrine [67].

4 Toxicity

If used for therapeutic purposes with dose control, ephedrine has no potential toxicity. However, the toxicity of this amine may be expressed in overdosages, which can lead to paranoid psychosis, delusions, and hallucinations [20]. Large doses of ephedrine may cause hypertension, headache, dizziness, palpitations, vomiting, nervousness, and insomnia [12].

Nowadays, the use of ephedrine with nontherapeutic purpose, being marketed as an herbal or a dietary supplement containing *Ephedra* species, is common. The whole issue with *ephedra* alkaloids is most of the time a paradox: depending on the relevant legislation of each country, the whole extract is considered a supplement, while the purified or synthesized alkaloids are considered pharmaceuticals being marketed as drugs. This usually means that the manufacturers of the alkaloid are compelled to prove both safety and efficacy of their products through clinical trials before being allowed to bring them to market, while the supplements have less demanding legislation [68]. Since ephedrine has thermogenic properties and is capable to stimulate lipolysis, the use of this amine had turned the attention to promote weight loss and improve athletic performance. Then a variety of compounds containing ephedrine, mainly dietary supplements, appeared on the market, being marketed with the appeal of easily promoting weight loss. Besides, the increasingly widespread use has been accompanied by the misconception of safety of ephedrine, mainly due to its natural origin [60]. In these cases, the use of ephedrine does not obey doses and leads to an uncontrolled consumption pattern often related to overdoses. Furthermore, there is no reliable quality control of these products due to a lack of effective monitoring on it, becoming difficult to ensure that the levels of ephedrine are consistent with that expressed in the label.

Scientific papers report that the pharmacological and toxicological properties of *Ephedra*-containing products depend strongly on the content of ephedrine and other associated substances. Clinical and preclinical studies and the long history of use of *ephedra* and its alkaloids indicate that its use can be safe if administrated according to the recommendations of the official codes. The serious adverse effects observed are related mainly to its overuse in dietary supplement formulations, to the associations and interactions with other drugs, individual susceptibility, and presence of contaminants, among other factors. Thus, the knowledge of the chemical composition of species of *Ephedra* and the correct orientation are essential to prevent accidents [8].

The study of the toxicity of commonly used associations became important when considering that it may cause an increase in cardiovascular risks when ephedrine is associated with other substances. Among the possible associations, the combination of ephedrine with *p*-synephrine (*Citrus aurantium* extract), salicin, and caffeine is one of the most usually found in the market, and it is used as an athletic performance enhancer and as a weight-loss compound. Recent studies have elucidated the acute and subchronic toxicity of this association. In the acute toxicity test in mice for both sexes, there were observed signs of toxicity such as ptosis, piloerection, and alterations in locomotor activity in all doses. A curious difference between genders not previously related in the literature was found. Signs were more intense in males possibly due to hormonal or metabolic differences. Other findings were alterations in locomotor activity, motor coordination, and body temperature, besides death by cardiopulmonary hemorrhage, corroborating with clinical reports that indicated the association of *p*-synephrine, ephedrine, and caffeine as potentially toxic [69]. These data indicate that the mechanism of action and toxicity of the mixtures is more complex than it was taught, involving alterations in the pharmacokinetic and pharmacodynamic properties when the substances are administered together, promoting unexpected adverse responses [69]. The results of subchronic test in rats helped to establish the toxicological profile of the association. The repeated dose given orally showed no clinical signs of toxicity, neither weight alterations nor deaths occurred as well as any significantly alterations in hematological parameters. There were observed lipid peroxidation, hepatic and renal damages, and a reduction in glutathione levels in male rats. In females, there were no alterations observed, showing again the different toxicity profile displayed by male and female probably due to hormonal influence. Although results showed the capacity of the association to change the oxidative status and promote renal and hepatic damages, it is still necessary that more studies be conducted to elucidate the role of hormones on toxicological effects presented by the weight-loss association [70].

The toxicity of ephedrine is closely related to adverse cardiovascular events, since the clinical presentation of toxicity reflects the sympathomimetic activity of these agents. The adrenergic effects can shorten cardiac refractory periods, permitting the development of reentrant cardiac arrhythmias. The worst complication related to the use of ephedrine is thrombotic stroke, presumably resulting from vasoconstriction of large cerebral arteries that in turn leads to local thrombosis [71]. Other adverse effects include hypertension, diaphoresis, hypothermia, and agitation. The best treatment in an overdose is the rapid identification of the symptoms followed by supportive management.

Arbo and coworkers [72] performed a study to evaluate the female reproductive toxicity of *E. sinica*, *C. aurantium*, ephedrine, and *p*-synephrine. The uterotrophic assay was used, which is commonly applied to detect (anti)estrogenic activity of chemical substances or mixtures. Ephedrine at the dose of 0.5 mg/kg/day showed a reduction of the uterus relative mass, indicating an antiestrogenic effect of this amine. However, the authors emphasized the need of more studies to completely characterize the mechanism of action of ephedrine in the endocrine system, since the uterotrophic assay is only a screening assay. Another interesting result obtained in this study was a reduction in the adrenals relative mass in the groups which received ephedrine, *p*-synephrine, and both doses of the extracts. The authors attribute this finding to the α1-adrenoceptor agonist activity of these substances through the vasoconstriction and reduction of the liquid in the organ [72].

In 2004, the Food and Drug Administration banned the sale of ephedra-containing over-the-counter dietary supplements due to a several number of reports involving adverse effects related to its use [73]. However, these products remain available to the public through illicit channels. Anticipating the possible ban of ephedrine sales, the industry of supplements quickly reformulated and developed “Ephedra-free” products, intending to replace those which contain ephedrine. The strategy used was the replacement of ephedrine by *p*-synephrine, a structural analogue of ephedrine primarily found in *Citrus* sp. extracts. There are two chemical differences between ephedrine and *p*-synephrine: the presence of a hydroxyl group replacing a hydrogen atom and the absent of a side-chain methyl group replaced by hydrogen, both in *p*-synephrine. It is believed that the pharmacological effects of *p*-synephrine do not differ from ephedrine, providing the same stimulatory and potentially toxic effects on the CNS and cardiovascular system as ephedra [74]. The lipolytic effect of *p*-synephrine is alleged to occur by specific stimulating of β3-adrenergic receptor, and consequent thermogenesis [75, 76] is questionable.

In spite of its popularity, there is no strong evidence confirming the effectiveness of *p*-synephrine as a thermogenic agent. The use of *p*-synephrine in dietary supplements has been accompanied by human toxicity reports, which lead to the idea of high toxicity of this amine. The most common adverse effects were the cardiovascular ones, as well as those that happened with ephedrine. However, the complex combination of different compounds must be considered, since *Citrus* extracts contain other compounds than *p*-synephrine. The presence of contaminants or other stimulants may influence the pharmacological and toxicological profiles of the products, being difficult to attribute the occurrence of adverse events only to *p*-synephrine [77].

Considering that, studies have been developed to establish the toxicological profile of *p*-synephrine. The acute administration of *C. aurantium* extract (2.5 % *p*-synephrine) and *p*-synephrine produced reduction in locomotor activity, gasping, exophthalmia, piloerection, and salivation, corroborating to the hypothesis that *p*-synephrine acts not only in β3-adrenoreceptors but also in other adrenergic receptors. However, all the effects were reversible and persisted for 3–4 h. The adrenergic stimulation alerts for the same possible side effects of *p*-synephrine and *C. aurantiu*m [78]. The subchronic toxicity of *Citrus aurantium* extract and *p*-synephrine were also determined and indicated a low subchronic toxicity in mice but a possible alteration in the oxidative metabolism [79].

5 Bioavailability and Metabolism

The administration of ephedrine may be given orally or topically as nasal drops or sprays [20].

Ephedrine is orally active, being readily and completely (about 100 %) well absorbed from the gastrointestinal tract after oral administration. It has longer duration though less potent action than epinephrine [17, 20, 80]. The absorption is better with the oral administration of the pure alkaloid than with herbal alkaloid extracts, which the presence of many others substances may retard the rate of absorption. The heat stress may increase the absorption rate of ephedrine [81], as well as it may elevate blood pressure significantly greater under these stress conditions. Considering that *Ephedra* extracts are often taken prior to exercise in a warm environment, these stress conditions may enhance the cardiovascular effects experienced during physical activity [68].

Ephedrine has a large volume of distribution and is not bound to plasma proteins, remaining in the free form with high tissue affinity and capacity to reach high concentrations in the CNS. High doses of sympathomimetic drugs may cross the blood–brain barrier due to lipophilic properties of the molecule and therefore exercise adrenergic stimulation on the CNS, especially when orally administrated [82]. This amine is reported to have a plasma half-life ranging from 3 to 6 h, but its effects last about 1 h. The plasma half-life is influenced by the elimination process, which in turn depends on the urinary pH, since in acid urine, the elimination is enhanced, being the half-life in these cases accordingly shorter [20, 80].

Scheme 38.3 Biotransformation and excretion of ephedrine

Ephedrine undergoes hepatic biotransformation being excreted mostly unchanged in urine [83]. From 8 % to 20 % of ephedrine is excreted after demethylation and delamination according to its metabolism showed in Scheme 38.3.

Excretion is dependent on several factors including urine volume, urinary pH, and individual variability. Ephedrine and amphetamines are weak organic bases, and therefore, they are easily ionized in acidic medium because of an ionizable amino group on the molecule. The acidification prevents reabsorption promoting excretion because of the positively charged amino group. Alkaline urine has the opposite effect [84, 85]. The excretion of ephedrine also occurs in breast milk and crosses the placenta, which poses concerns for women who may be taking ephedrine during pregnancy or breast-feeding. It is excreted primarily unchanged and with small amounts of metabolites in the urine over 24 h [20]. It is resistant to metabolism by monoamine oxidase, increasing its activity by oral ingestion.

6 Clinical Trials

Ephedrine is the most commonly used drug among the vasopressors to prevent hypotension during spinal anesthesia. A study randomized 42 women undergoing elective Cesarean section under spinal anesthesia into two groups (n = 21 per group), a control and an ephedrine-treated group. Shortly after the spinal injection, ephedrine 0.5 mg/kg in the ephedrine group or saline in the control group was injected intravenous for 60 seconds. The mean of highest and lowest heart rate in the ephedrine group was higher than those of control group. Also, there were significant lower incidences of hypotension and nausea and vomiting in the ephedrine group compared with the control group. The findings suggest the prophylactic bolus dose of 0.5 mg/kg intravenous ephedrine given at the time of intrathecal block after a crystalloid fluid preload, plus rescue boluses reduce the incidence of hypotension [86]. A similar randomized, double-blinded, controlled trial was conducted using propofol as anesthetic inducer (n = 156). Authors concluded that adding 30 mg of ephedrine to 20 ml of 1 % propofol is as effective as adding lidocaine in preventing injection pain, and it results in a more stable hemodynamic profile in the patients [87].

Ephedrine was first reported to be effective in the treatment of myasthenia gravis in the 1930s but was subsequently superseded by anticholinesterases and corticosteroids. The mechanism by which it may affect neuromuscular transmission at pharmacologic doses is unclear. Anecdotally, patients with congenital myasthenic syndrome (CMS) have reported benefit from ephedrine, often tried because of a failed response to other therapies. A study was conducted following 10 patients with Dok-7 mutation CMS. Dok-7 is an adaptor protein that is a key component of the muscle-specific tyrosine kinase (MuSK) signaling pathway and is essential for postsynaptic specialization of the neuromuscular junction. In this rare condition, the clinical phenotype is typically characterized by a definite onset of weakness in early childhood, although in retrospect symptoms consistent with a CMS may have been present at birth, sparing of the external ocular muscles in most cases, and a predominant limb–girdle distribution of weakness. A surprising feature of this form of CMS is the lack of response or worsening of weakness with anticholinesterase treatment and a variable response to 3,4-diaminopyridine (3,4-DAP), the conventional CMS treatments. This study provided Class IV evidence that ephedrine given at doses between 15 and 90 mg/day improves muscle strength and mobility in Dok-7 CMS [88].

A randomized, controlled, double-blind, clinical trial was conducted to assess the efficacy and safety of herbal extracts of *E. sinica* in Korean premenopausal women (n = 125). Subjects were administered ephedra extract in capsules (pseudoephedrine 31.52 mg) or placebo capsules as well as participating in a low-calorie diet for 8 weeks. Ephedra combined with a low-calorie diet was effective in reducing body mass index [89].

7 Conclusion

Ephedrine is a classical sympathomimetic agent used for centuries in medicine. In spite of its natural origin, most of the commercial ephedrine comes from synthetic or semisynthetic processes. Nowadays, it is commonly used as a nasal decongestant and for weight loss and for recreational purposes. Furthermore, promising uses have been investigated, such as for the reduction of the incidence of hypotension during spinal anesthesia and for the treatment of some cases of myasthenic syndrome. In spite of the reports of serious adverse cardiovascular side effects attributed to ephedrine, it is a safe drug if correctly used. However, some attention has been given to the toxicity of the association of ephedrine with other stimulant compounds for weight-loss purposes.

Abstract

The aim of this work is to review the current knowledge on the lycopodium alkaloids with an emphasis on their pharmacology and potential medical application. Lycopodium alkaloids are produced by club mosses, a vulnerable group of slow-growing lower plants. (−)-Huperzine A (hupA) isolated from *Huperzia serrata* is known for its potent and reversible acetylcholinesterase (AChE) inhibiting activity and is used as a drug for Alzheimer's disease (AD) in China. In addition, hupA has been shown to have neuroprotective effects in preclinical studies. It is by far the most intensively studied lycopodium alkaloid and clinical trials do indicate positive effects on AD symptoms with minimum adverse effects. At present, the greatest hurdle for research and application of lycopodium alkaloids is the lack of sustainable methods to supply these compounds. Lycopodium alkaloids which resemble hupA in having favorable bioavailability, pharmacokinetics, and toxicological profiles, in addition to interesting biological activities, are likely to be included in the search for new drug leads in the future, for example, in the development of multi-target and multidrug therapies for AD and other neurodegenerative diseases.

1 Introduction

Club mosses comprise an ancient group of spore-forming, slow-growing vascular plants that have survived since the late Silurian geological period or about 400 million years [1]. The classification of the order of club mosses, that is, Lycopodiales, is still a matter of debate and some taxonomists consider them to consist of one family of Lycopodiaceae, subdivided into four genera: *Lycopodium*, *Diphasiastrum*, *Lycopodiella*, and *Huperzia* [2], while others have suggested seven or even more genera and placed *Huperzia* in a separate family Huperziaceae [3, 4]. More than 500 club moss species grow worldwide [5, 6] and the alkaloid content has been studied for about 10 % of the species [7]. They produce alkaloids of condensed polycyclic structures commonly known as the lycopodium alkaloids [6–9].

Huperzia serrata is a club moss species that has been used in traditional Chinese medicine for centuries for various ailments including myasthenia gravis, an autoimmune neuromuscular disease, caused by circulating antibodies that block acetylcholine (ACh) receptors at the postsynaptic neuromuscular junction, consequently inhibiting the stimulative effect of the neurotransmitter [10]. This traditional use of *H. serrata* motivated Chinese scientists in the 1980s to search for compounds that might be effective in treatments of diseases that included cholinergic dysfunction such as AD [3, 11, 12]. This led to the isolation of the potent AChE inhibitor hupA [13, 14]. This alkaloid was previously isolated from Canadian *H. selago* and named selagine; however, the structure was incorrect and was later corrected and shown to be identical to hupA [15, 16]. The discovery of the potent inhibition of AChE by hupA evoked a renewed interest among scientists for the lycopodium alkaloids. HupA, in particular, has been the subject of intense research in relation to its cholinergic as well as non-cholinergic activities, and to its beneficial effects on AD patients in clinical trials [17]. Thus, the overwhelming majority of pharmacological studies on club moss alkaloids have been performed on hupA and the following chapter will reflect this fact; however, other lycopodium alkaloids will be included whenever appropriate.

2 Lycopodium Alkaloids

The first lycopodium alkaloid was isolated from the club moss *Lycopodium complanatum* by Bödeker as early as 1881 [18]; much later its structure was shown to be lycopodine [19]. Since the first comprehensive review on lycopodium alkaloids was published in 1968 [20], new structures have been isolated and the chemistry and biology of this class of compounds have been reviewed several times [6–9, 21]. According to Ayer [6], the lycopodium alkaloids are generally considered to comprise of four major classes. Compounds **1–4** are representatives of each group: lycopodine **1** (class I), lycodine **2** (class II), fawcettimine **3** (class III), and phlegmarine **4** (miscellaneous class IV).

For class I compounds represented by lycopodine **1**, the A, B, and C rings are stable and the structural variations are mainly in the D ring. For class II or lycodane-type alkaloids, the B, C, and D rings are as in lycopodine **1**; however, the A ring is opened and rearranged. HupA and hupB belong to this class. Class III comprises of compounds that result from a C4-C13 to C4-C12 bound migration from lycopodane-type precursors. The miscellaneous group represented by phlegmarine **4** includes all compounds that do not belong to the other three classes [6, 8]. The reported structures of lycopodium alkaloids are now close to 250 [7]. They are all structurally related, usually having 16-carbon skeletons although they can have up to 32 carbons (dimers) and down to 15 as in hupA [8]. Further discussion on the chemistry and structures of the lycopodium alkaloids in general is beyond the scope of this chapter and will be restricted to relevant structures in connection with the pharmacological activities discussed.

3 Pharmacological Applications

3.1 Club Mosses and Chinese Traditional Medicine

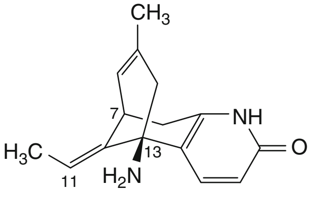
Qian Ceng Ta, a Chinese medicinal herb *H. serrata* (Thunb) Trev., as well as some other species of club mosses, have a long history of use for the treatment of a number of indications including bruises, strains, swellings, and, more recently, schizophrenia, myasthenia gravis, and organophosphate (OP) poisoning [3, 8]. This herb is described in old Chinese pharmacopeias sometimes under the name Shi Song, which is somewhat confusing as this name was used to describe several different medicinal herbs. However, all of the Shi Song herbs were species of Lycopodiaceae, e.g., *L. japonicum*, *L. annotinum*, *L. obscurum*, *D. complanatum*, besides *H. serrata* [3]. When Chinese scientists discovered that *H. serrata* contained lycopodium alkaloids with potent and reversible AChE-inhibiting activity, this herbal medicine gained worldwide attention based on scientific evidence that indicated positive effects on learning and memory which might benefit patients suffering from AD [3, 21].

3.2 Alzheimer's Disease and AD Drugs

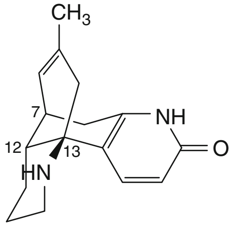
AD is an age-related degenerative brain disorder that affects elderly people and the prevalence is increasing with rising age of the population. AD destroys neurons and neuronal connections in the cerebral cortex, leading to loss of brain mass and brain function. The symptoms are progressive cognitive impairment that leads to death usually within 3–10 years. The pathophysiology of AD is complex and far from fully understood. However, it is known that level of ACh in the brain is lowered in AD and after years of studies in both animals and humans, it is clear that cholinergic pathways in the brain contribute considerably to the modulation of several important aspects of cognition [22, 23]. In addition, the postmortem brains of AD patients show several distinct neuropathological features such as beta-amyloid (Aβ) peptide-containing senile plaques and intracellular neurofibrillary tangles which cause neurodegeneration [17, 24, 25]. Other non-cholinergic neurodegenerative factors are also believed to play a role, e.g., overstimulation of *N*-methyl *D*-aspartate (NMDA) receptors by glutamate and oxidative stress [26]. There is no cure for AD but the currently approved symptomatic drug treatments in Western countries consists of the AChEIs donepezil, rivastigmine, and galanthamine as well as memantine which is a NMDA receptor antagonist. These treatments have their limitations as they are not effective for all patients, and a number of cholinergic side effects such as nausea, vomiting, diarrhea, and tremors can also limit their use [27]. It is evident that the need for new and better treatments for AD is immense. "Mild cognitive impairment" or MCI is a condition defined for people suffering from less severe but abnormal cognitive impairment and a high risk for developing AD [27, 28]. This group could undoubtedly benefit from new medicines, especially neuroprotective and disease-modifying drugs that could prevent the MCI from developing into AD [29].

3.3 Huperzine A and B

The lycopodium alkaloids, hupA **5** and hupB **6**, were isolated from *H. serrata* and shown to be potent AChEI. Their natural configurations are 7*R*,13*R*,11*E* and 7*S*,13*R*,12*R*, respectively, or the (−)-form [13, 14]. They have the rigid lycodane-type polycyclic structures **5** and **6**.



5



6

The (+)-enantiomeric form of huperzine A has been synthesized and tested for AChE inhibition in vitro and the activity compared to the natural (−)-enantiomer. The (−)-enantiomer of huperzine A was shown to be the more active form, as well as being the most potent of all lycopodium alkaloids currently reported [13, 30].

3.4 Products on the Market

The discovery of AChEIs among the lycopodium alkaloids and the growing evidence supporting the cholinergic hypothesis of AD promoted the development of commercial products. Shuangyiping, a tablet form of hupA, was developed from *H. serrata* extracts and was marketed in China in 1996, for symptomatic treatment of AD [31]. Powdered *H. serrata* plant material containing hupA is sold in USA as a dietary supplement in tablets or capsules [3] and marketed as a memory enhancer. Although hupA is currently not approved by the Food and Drug Administration (FDA) as an AD drug, these products are commercially promoted as a treatment for AD [32].

3.5 Methods to Supply HupA and Other Lycopodium Alkaloids

The club mosses are the only natural sources of lycopodium alkaloids and they are vulnerable slow-growing plants which are very difficult to cultivate; in addition, their alkaloid content is low, e.g., about 0.005–0.025 % in *H. serrata* for the much demanded hupA [17]. At present, the market is supplied with *H. serrata* plant material and isolated hupA primarily from the wild growing plants of *H. serrata* and other *Huperzia* species in China, which are subsequently becoming endangered species [3, 8]. Accordingly, it is important to find sustainable methods to produce these compounds. The synthesis of hupA has been studied since 1989 and different approaches have been reported in the literature but none of them seem to be industrially feasible [17]. However, a new eight-step enantioselective synthetic route to hupA in 35–45 % yield was recently published by Tun et al., and the authors conclude that the method will provide a reliable supply of this compound for future applications [33].

Besides synthesis, other alternative methods to supply hupA have been sought. An in vitro propagation in *Phlegmariurus squarrosus* was described by Ma and Gang; prothalli and sporocytes were produced from in vitro cultures and grown to plants which produced higher yields of hupA than the naturally occurring plants [34]. Another approach has been to culture hupA-producing endophytic fungi from *H. serrata*. Wang et al. [35] recovered over 120 endophytic fungi from *H. serrata* and nine of them, belonging to seven different fungal genera, were found to produce hupA. The most potent AChE inhibition effect was found in a *Shiraia* sp. and the yield of (−)-hupA produced in a potato dextrose broth was 327.8 μg l^{-1}. Interestingly, two extracts of endophytic fungi sp. which did not contain hupA, showed potent AChE inhibition, indicating the presence of unknown AChEIs [35].

4 Mechanism of Action

The generally recognized mechanism of action for the beneficial effect of hupA and other AChEI in the symptomatic treatment of AD is the inhibition of AChE which results in elevation of the abnormally low ACh level in the brains of AD patients [27]. In addition, preclinical studies show that hupA is a NMDA receptor antagonist and it has been suggested that hupA, and possibly other lycopodium alkaloids might have neuroprotective effects through several mechanisms that altogether, could contribute to a disease-modifying action on AD [26].

4.1 Classical Cholinergic Effects

AChE is an enzyme that terminates transmission at cholinergic synapses and neuromuscular junctions by rapid hydrolysis of ACh [36, 37]. In an animal study, the cortical ACh levels in rats were shown to increase in a dose-dependent manner after p.o. administration of hupA, and to be higher than for equimolar doses of the AD drugs donepezil and rivastigmine, indicating more potency and longer lasting effect of hupA [38].

The interactions of hupA and hupB with AChEs have been studied extensively by molecular modeling and docking studies, revealing that the catalytic site resides inside a narrow gorge lined with hydrophobic aromatic amino acid residues. Comparison of X-ray structures of native AChE from *Torpedo californica* (*Tc*AChE) with and without bound hupA or hupB showed surprisingly few interactions between the protein and the ligand and a significant change of the main chain conformation of the protein [30, 39]. Figure 39.1 shows hupA docked in the active site of *Tc*AChE and the main interactions between hupA and the amino acids lining the active gorge of the enzyme.

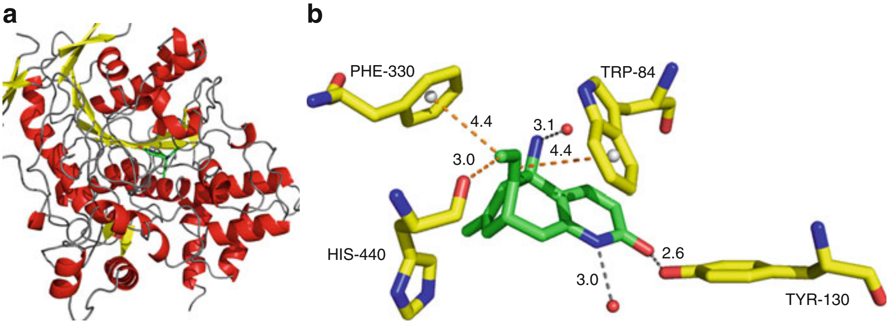


Fig. 39.1 Stereoview of hupA **5** within the active sited gorge of *Tc*AChE (PDB code 1VOT). (**a**) HupA (*green*) in complex with the enzyme (*cartoon*). (**b**) Selected protein residues (*yellow*) and water molecules (*red spheres*) showing important interactions with hupA **5** (*green*) within the binding site. Hydrogen bondings are labeled as *gray dashed lines*, other interactions as shown as *orange dashed lines*

On the one hand, the structure-based design of AChEIs is challenged by the large-amplitude fluctuations of the gorge structure and the fact that it contains more buried water molecules than a typical protein [40–42]; on the other hand, this renders opportunities which could involve lycopodium alkaloids and their analogues as possible ligands for this enzyme.

The ChE inhibition of hupA has been evaluated in vitro and in vivo using the colorimetric method of Ellman et al. [43]. It is a potent and reversible inhibitor of ChE with a high selectivity toward AChE over BuChE which has been linked to hupA's lower incidence of side effects in humans compared to registered AD drugs [8]. Another factor that has been suggested to contribute to hupA lower peripheral side effect profile is its preference toward the tetrameric G4 form of the enzyme which resides predominantly in the brain [44]. The AChE inhibition has been published for several lycopodium alkaloids isolated from different species of club mosses. The most active ones **5**–**11**, having IC50 $<$ 20 μM, are listed in Table 39.1 together with **12**–**15** which have low or no activity. However, it should be noted that these results are not directly comparable since they are from different studies and use different sources for the ChEs.

Two of the lycopodium alkaloids with IC50 < 20 μM, i.e., carinatumin A **8** and carinatumin B **9**, have structures similar to hupA **5** and hupB **6** except for an additional hydroxy group. Sieboldine A **7** with two carbonyl groups and an N-hydroxy group and the phlegmarane-type cryptadine **11**, are somewhat different tetracyclic and pentacyclic structures, respectively. Lycoposerramine H **10** resembles the lycopodane-type skeleton although it has a C8-C15 double bond similar to hupA **5** and hupB **6**. Lycopodane-type alkaloids tested by Halldorsdottir et al., e.g., anhydrolycodoline **12**, annotine **13**, annotinine **14**, and lycodoline **15**, all have low or no activity. Molecular modeling studies have indicated weaker interaction of these lycopodane-type compounds **12–15** with the active site of the enzyme compared with the lycodane-type hupB **6**. However, novel binding orientation of anhydrolycodoline **12**, which has a C11-C12 double bond, found in these docking studies suggests the possibility of designing analogues with increased potency [50].

Chronic inflammation is considered to be a contributing factor in AD. Besides the low ACh levels in the brains of AD patients, decreased number of nicotinic (nAChR) and muscarinic acetylcholine receptors (mAChR) has been detected in AD patients brains as well as in experimental AD animals [24, 27]. In a recent publication, hupA has been shown to reduce both acute and chronic cerebral inflammation in rats, by a mechanism that is believed to be mediated through the nAChR [11].

4.2 NMDA Receptor Antagonism

Glutamate overstimulation of NMDA receptors is considered to contribute to the neurodegeneration seen in AD and other neurodegenerative diseases. HupA was shown to protect cultured rat brain cells from glutamate-induced cell death [52, 53], and both hupA and hupB have been shown to exert an antagonistic effect on NMDA receptors in rat cerebral cortex [54, 55] and could therefore reduce neuronal cell death caused by glutamate. In contrast to the different activities of the two enantiomeric forms of huperzine A toward the AChE enzyme, their potency is similar toward the NMDA receptor, reflecting a non-stereoselective interaction with the receptor [30, 56].

4.3 Neuroprotective Effects

Several preclinical studies have suggested that hupA might also be neuroprotective through non-cholinergic mechanisms, e.g., modification of Aβ peptide processing, reduction of oxidative stress, neuronal protection against apoptosis, and regulation of the expression and secretion of nerve growth factor (NGF) and NGF signaling [3, 26, 57]. A simplified overview of several connected factors suggested to contribute to an overall neuroprotective effect of hupA in AD that is presented in Fig. 39.2. More detailed description can be found in reviews by Zhang and coworkers [26, 57].

These effects of hupA are considered to protect the cells from toxic and apoptotic effects caused by Aβ. In contrast to the AChE-inhibiting effect, the neuroprotective effects in rats have been shown to be non-stereoselective toward the two enantiomeric forms of huperzine A [58]. In summary, the therapeutic effect of hupA observed in the treatment of AD is probably based on a multi-target mechanism [26, 57], where neuroprotective effects could be contributing factors [26].

5 Toxicity

In general, the lycopodium alkaloids are considered to be "…moderately toxic, but owing to the inedible nature of the club mosses, no fatalities appear to have been recorded in either humans or farm animals…" [59]. Studies describing the toxicity of lycopodium alkaloids besides hupA are scarce; however, a study from 1947 describes moderate toxicity of lycopodine and annotinine in frogs, mice, and rabbits and lethal doses were accompanied by symptoms of muscle cramps [60].

Toxicological studies of hupA have been conducted after acute and chronic administration in several animal species including mice, rats, rabbits, and dogs [61–63]. Cholinergic symptoms characterize its side effects and toxicity, similar to

Fig. 39.2 Suggested effects leading to neuroprotective activity of hupA in AD. HupA is considered to modulate the APP processing by inducing the activity of α-secretase. The increased activity of α-secretase causes enhancement of nutritional APP (sAPPα) and consequently inhibition the Aβ pathway. These APP-modulating effects are mediated through M1 muscarinic receptor–mediated PKC-dependent cascade and Trk receptor–mediated ERK/MAPK-dependent cascade and caused by increased levels of ACh and NGF in the synaptic junction. Increased release of sAPPα and decreased Aβ release from APP followed by inhibition of Aβ fibril formations affects the regulation of the expression of apoptotic proteins, attenuates oxidative stress, and allows the mitochondria, respiratory chain, and TCA cycle to function normally. *APP* amyloid precursor protein, *PKC* protein kinase C. *ERK* extracellular signal-regulating kinase, *MAPK* mitogen-activated protein kinase, *TCA* tricarboxylic acid cycle (citric acid cycle)

that of other ChE inhibitors, with the earliest sign of muscular tremor, followed by drooling, tears, increased bronchial secretions, and incontinence. The experimental data for the toxicity of hupA were included in the investigational new drug (IND) submission to the FDA (IND#63,997). In rats, the LD50 administered as a single oral dose is 2–4 mg kg^{-1} of body weight for females, and >4 mg kg^{-1} for males. The chronic toxicity of hupA studied in rats for 180 days indicated tolerability at 1.5 mg kg^{-1}day^{-1}. In a similar study in rabbits and dogs, deaths started to occur at an i.m. dose of 0.6 mg kg^{-1}day^{-1} for the rabbits, while the dogs showed transient muscle twitching at this dose. Pathological examination of the treated rabbits and dogs showed abnormalities in heart and brain [62].

The no-observed-adverse-effect-levels (NOAEL) for hupA have been determined after chronic 30-day oral administration. The NOAEL was found to be 1 and 3 mg kg^{-1}day^{-1} for female and male rats, respectively, and the only drug-related effect detected was a transient decrease in food consumption. The NOAEL for dogs was 0.1 mg kg^{-1}day^{-1}, and after a single dose of 10 mg kg^{-1} the dogs showed signs of acute cholinergic toxicity such as convulsions, salivation, lacrimation, tremors, impaired limb function, emesis, and death [62].

The maximum recommended human daily dose of hupA in China is 0.45 mg [64]. Studies to evaluate the toxicity of this natural product have also been carried out in China and support the seemingly favorable therapeutic index of hupA. The LD50 per kg in mice was shown to be 4.6 mg (p.o.), 3.0 mg (s.c.), 1.8 mg (i.p.), and 0.63 mg (i.v.). Histopathological examination in dogs (0.6 mg kg^{-1} i.m.) and in rats (1.5 mg kg^{-1} p.o.) performed to evaluate subacute toxicity showed no changes in liver, kidney, heart, lung, or brain after administration of hupA for 180 days. No mutagenicity was detected in rats, and no teratogenic effect in mice or rabbits [63]. Atropine exerted a significant antagonistic effect on the toxicity induced by hupA [65].

6 Bioavailability and Metabolism

The pharmacokinetic profile of hupA has been studied in healthy volunteers with oral as well as transdermal administration [66, 67]. In a recent study, hupA was administrated p.o. to 12 healthy, young volunteers as a single therapeutic dose of 0.4 mg and was found to be well tolerated with no adverse events reported. HupA was absorbed rapidly, and occurred in the plasma 5–10 min after administration and reached $C_{\max}$ 2.59 ng ml^{-1} at a $T_{\max}$ of 58.33 min. It was shown to distribute widely in the body at a moderate rate and to cross the blood–brain barrier (BBB) easily. The results conformed to a two-compartment model with the elimination half-life of α-phase and β-phase to be approximately 21 and 716 min, respectively [66]. Another study performed in China in 1995 which included six volunteers receiving a single 0.99 mg p.o. dose of hupA showed somewhat different results with shorter absorption and elimination half-lives, i.e., 13 and 288 min, respectively, compared to the previous study. However, both studies revealed rapid absorption and wide distribution, followed by a slower elimination rate [17, 66].

Since most oral AChEIs exhibit a dose-dependent relationship with undesirable cholinergic adverse effects, researchers have in recent years been focusing on slow-release administration to minimize the fluctuations in plasma concentration [67, 68]. Ye and coworkers have developed transdermal patches containing 4 mg of hupA with the average daily dose of 0.456 mg absorbed [68]. A recent clinical study on 30 healthy volunteers revealed that the transdermal administration provided continuous drug delivery over 120 h and the pharmacokinetic behavior in vivo presented linear dynamic characteristics with prolonged $T_{\max}$, lowered $C_{\max}$, and relatively constant plasma concentrations. This indicated similar efficacy of the patches to orally administrated hupA and a more favorable tolerability profile [67]. In addition, comparison of a single and multiple dose pharmacokinetics between patches and conventional tablets of hupA in six beagle dogs showed that transdermal administration exhibits good controlled-release properties with prolonged $T_{\max}$ (24 h vs. 3 h), lowered $C_{\max}$ (3.4 ng ml^{-1} vs. 9.8 ng ml^{-1}), and reduced fluctuations in serum concentrations [68]. Furthermore, pharmacokinetic studies of hupA in rat plasma and cerebrospinal fluid (CSF) after intranasal administration [69, 70] were compared to i.v. infusion. Approximately 20 % of the concentration in plasma reached the CSF after both routes of administration, indicating no direct transport of hupA from nasal cavity to CSF in rats [69].

An autoradiographic study in mice after i.v. injection of a dose of 183 μg kg^{-1} showed the presence of [^{3} H]-hupA in all regions of the brain 60 min after injection. Radioactivity was practically absent in all parts of the body after 12 h [71]. In an additional study on mice receiving [^{3} H]-hupA p.o., the highest radioactivity was observed in the kidneys and liver [65].

An in vitro study on rat liver microsomes was performed to identify which cytochrome P450 (CYP) isoenzymes are involved in the major metabolic pathway of hupA. The results revealed that the metabolism was primarily inhibited by a CYP1A2 antibody (76.2 %), with a probable secondary contribution of CYP3A1/2 antibody (17.8 %), while inhibitory effects produced by CYP2C11 and 2E1 antibodies were minor [72]. CYP1A2 is about 13 % of total CYP isoenzymes in the liver [73] with both pharmacological and toxicological significance [74]. In addition, hupA showed little effects on the activity and expression of CYP in rats that demonstrate: The isoenzymes were not affected at pharmacological doses, but may elicit a slight inductive response in CYP1A2 at a toxicological dose [75].

ZT-1, a semisynthetic prodrug of hupA, is transformed nonenzymatically into hupA. It has been administered by i.v., oral, immediate-release and by sustained-release formulations in the form of implants [76]. In vitro studies show that ZT-1 inhibits AChE similar to hupA, but a weaker BuChE inhibition was observed. Pharmacokinetic studies suggest that ZT-1 has similar properties to hupA regarding oral bioavailability, the ability to cross the BBB, and longevity of action [8].

7 Other Biological Activities

Prophylaxis and treatment of OP poisoning: *O*-Pinacolyl methylphosphonofluoridate or soman is an extremely toxic OP poison that has been used in chemical warfare and terrorism. However, most OP compounds are used in industry and in veterinary and human medicine as insecticides [77, 78]. OPs are irreversible inhibitors of AChE, resulting in accumulation of ACh at the synaptic junctions, which causes severe cholinergic symptoms, e.g., tremors and seizure, progressing to impairment of respiratory drive and coma [77]. HupA has been tested as a pretreatment of OP poisoning in animals. The advantages of hupA over current treatment (pyridostigmine) are that it crosses the BBB and acts in a slow and reversible manner, partially protecting the peripheral and central AChEs from binding with OP [3, 79]. Animal studies have been promising, showing hupA to be active against soman-induced seizures and mortality; however, this pretreatment has not been authorized for human use [79–81].

Insecticidal activity: HupA was shown to be insecticidal against the Australian carpet beetle, *Anthrenocerus australis* (LD50 110 ppm), the Australian sheep blowfly *Lucilia cuprina* (LD50 2,380 ppm), and the webbing clothes moth, *Tineola bisselliella* (LD50 630 ppm) and reduced the feeding by *A. australis* by 97 % at 63 ppm [82].

Cytotoxicity against cancer cells: Several lycopodium alkaloids have been shown to possess cytotoxic effects on cancer cells. Cermizine A, B, and D, cernuine N-oxide, and lycocernuine N-oxide isolated from *L. cernuum*, senopodine G and H isolated from *L. chinense* [83], lycopladine A isolated from *L. complanatum* [84], and the dimeric lycopodium alkaloid complandine D isolated from *L. complanatum* [85] exhibited cytotoxicity against murine lymphoma L1210 cells in vitro, with IC50 ranging from 4.9 to 8.2 μg ml^{-1}. Furthermore, nankakurine A isolated from *L. hamiltonii* was shown to be cytotoxic to human epidermoid carcinoma KB cells (IC50 3.1 μg ml^{-1}) in vitro [86].

Antifungal activity: Lycovatine A isolated from *L. clavatum* var. *robustum* and complanadine C and D were shown to have antifungal effect on *Cryptococcus neoformans* (MIC 0.52, 0.52, and 0.26 μg ml^{-1}, respectively) and *Aspergillus niger* (MIC 2.06, 2.05, and 4.16 μg ml^{-1}, respectively) [85].

8 Clinical Trials

Several clinical trials on the efficacy of hupA for the treatment of AD have been conducted in China, and recently, a phase II trial was completed in the USA. Clinical tests, e.g., MMSE (Mini Mental State Examination) and ADL (Activities of daily living), as well as other memory tests, were used to evaluate the effects of the treatment. Table 39.2 reviews the setup, trial conditions, and results from the clinical trials. Note that for the trials conducted in China, only the four studies selected by a meta-analysis performed by Wang et al. in 2009 are included in Table 39.2 [64, 87–90].

Wang et al. evaluated 11 clinical studies conducted in China on efficacy and safety of hupA in the treatment of AD, and four placebo-controlled, randomized trials (Table 39.2) using MMSE and ADL as outcome measures were included in their meta-analysis. A total of 474 AD patients were included, 235 received 0.3–0.5 mg of hupA p.o. daily for 8–24 weeks, and 239 in the control group. The results presented a significant improvement in both MMSE and ADL and a meta-regression showed that the estimated effect size of MMSE and ADL was increased over the treatment time. Adverse events were mild-to-moderate peripheral

Table 39.2 Clinical trials on hupA as a treatment for AD

Location publication year	Number of patients (*n*) (HupA/Control)	Study design	Treatment	Memory test and results	Adverse effects	References
China 1995	103 (50/53)	DB, M, PC, RC	0.4 mg/day (0.2 mg b.i.d.), 8 weeks	MMSE: HupA, +3.0; placebo, +1.0	No significant difference found between groups	[60, 86]
				HDS: HupA, +4.0; placebo, −1.0		
				ADL: HupA, −4.0; placebo, +0.1		
				MQ: HupA, +12.0; placebo, +4.0		
China 2002	202 (100/102)	DB, M, PC, RC, DE	Up to 0.4 mg/day (0.2 mg b.i.d.), 12 weeks[a]	MMSE: HupA, +2.7; placebo, +0.19	Mild adverse events observed for 3 % of patients in the treatment group	[60, 87]
				ADAS – Cog: HupA, 56.1 %; placebo, 10.1 %		
				CIBIC-plus: HupA, 59.2 %; placebo, 40.6 %		
				ADAS – non-Cog: HupA, 70.0 %; placebo, 36.3 %		
				ADL (p = 0.001): HupA, −2.4; placebo, −0.5		
China 2003	65 (35/30)	SB, PC, RC	0.3 mg/day (0.15 mg b.i.d.), 16 weeks	MMSE: HupA, +4.3; placebo, +0.1	No serious adverse events, only mild adverse effects	[60, 88]
				ADL: HupA, −6.6; placebo, 0.0		
China 2006	120 (60/60)	SB, PC, RC	0.5 mg/day, 24 weeks[b]	MMSE: HupA, +5.0; placebo, +0.0	Gastrointestinal effects, ALT increase	[60, 89]
				ADL: HupA, −5.0; placebo, +2.0		
USA 2008	15 (12/3)	PC, RC, DE Phase Ia	Up to 0.4 mg/day (0.2 mg b.i.d.), 4 weeks	No clinically significant abnormalities were detected in the studies	No serious adverse events	[62]

USA 2008	15 (12/3)	PC, RC, DE Phase Ib	Up to 0.8 mg/day (0.4 mg b.i.d.), 4 weeks	No clinically significant abnormalities were detected in the studies	No serious adverse events, only mild cholinergic events	[62]
USA 2011	210 (70/70/70)	DB, M, PC, RC, DE Phase II	0.2 mg/day or 0.4 mg/day, 16 weeks	MMSE: HupA 0.4 mg/day, +0.65; HupA 0.8 mg/day, +1.10; placebo, −0.40 ADAS – Cog: HupA 0.4 mg/day, −0.32; HupA 0.8 mg/day, −1.92; placebo, −0.34 ADCS-ADL: HupA 0.4 mg/day, −1.18; HupA 0.8 mg/d, −0.85; placebo, −2.64 ADL and NPI – not significant in either dose	No serious adverse events	[90]

[a] Both groups got Vitamin E: 200 mg/day (100 mg b.i.d.)

[b] Control group received *Salvia miltiorrhiza* tablets

cholinergic side effects, including nausea, vomiting and diarrhea and no serious adverse events occurred [64].

In the USA, powdered *H. serrata* is available as a dietary supplement, and the recommended dose contains 50 μg b.i.d. of hupA [3]. Two US phase I studies were conducted to determine the safety and tolerability of hupA. Phase Ia and phase Ib (Table 39.2) were identical in design except for the dose which was up to 0.2 mg and 0.4 mg b.i.d in phase Ia and phase Ib, respectively. No serious adverse events occurred in these studies, although mild-to-moderate side effects were observed in the phase Ib study with the higher dose [62].

Subsequently, a multicenter phase II study was organized by NIH in over 30 sites in the USA (Table 39.2). The results showed that hupA was generally well tolerated at doses up to 0.4 mg b.i.d. for 24 weeks, even though many of the patients participating had been unable to tolerate at least one previous trial of treatment with a marketed ChE inhibitor. The cognitive benefits as indicated by the change in the Alzheimer's disease Assessment Scale – Cognitive Section (ADAS – Cog) score after 16 weeks, for the 0.2 mg b.i.d. dose on the one hand, did not indicate efficacy, although it had favorable influence on the MMSE score. On the other hand, the 0.4 mg b.i.d. dose showed evidence of cognitive enhancement in both ADAS – Cog and MMSE. The effect on ADL was not significant in either dose. The authors conclude that the results suggest a possible benefit of hupA which requires confirmation in additional studies [91].

It is evident from Table 39.2 that the scores for MMSE, ADL, and ADAS – Cog cognitive tests are considerably higher in the Chinese studies than in the US study for comparable doses of hupA. However, studies in both countries indicate dose-dependent improvements of symptoms, although they do not agree on the effective therapeutic dose [62, 64, 91]. It has been implied that results are not directly comparable across trials which are conducted in different countries, as different inclusion/exclusion criteria may have been used, and other factors in the implementation may differ as well [62, 64]. According to the US phase II study, the recommended doses for the marketed products for AD treatment in both USA and China are too low to be effective. All the studies in Table 39.2 agree on the good tolerability of hupA up to a dose of 0.8 mg/day in the phase II US study. However, if hupA is to become an established AD drug first, the maximum tolerable dose needs to be determined and secondly, large, well-designed, multinational phase III clinical trials are needed.

ZT-1, a semi-synthesized prodrug of hupA, has been tested for the treatment of AD symptoms. An open label phase II study in patients with mild-to-moderate AD with once-daily oral formulation of ZT-1 was reported to have good efficacy and tolerability comparable to donepezil [76]. A phase I study for a sustained-release ZT-1 implant dosage form concluded that the implants were safe up to a dose of 15 mg month^{-1} and continuously released the active component over a period of 28 days [76]. Subsequently, a phase II study was designed for this implant and the investigators argued that a continuous slow-release form of ZT-1 could reduce the side effects and increase the compliance for AD treatment compared to donepezil [76]; however, to our knowledge, the results of these trials have not yet been published.

9 Conclusion

The traditional use of club mosses in Chinese herbal medicine promoted the interest for lycopodium alkaloids as possible drug leads for dementia. HupA, the most potent AChEI of the natural lycopodium alkaloids tested so far, binds selectively and reversibly to the enzyme with prolonged biological half-life. In addition, preclinical studies indicate an overall neuroprotective effect of hupA which implies, although not clinically confirmed, a disease-modifying potential in AD. HupA has many other advantageous characteristics favoring a CNS drug lead, e.g., to cross the BBB smoothly and having good bioavailability and pharmacokinetic properties, low toxicity, and mild adverse effects in humans.

The lycopodium alkaloids, in general, are interesting molecules to explore as drug candidates. They often have rigid and stable structures which can interfere with numerous targets both outside and within the CNS, thus representing feasible model molecules for multi-target or multidrug development aimed at AD and other neurodegenerative diseases. Noteworthy, the dose-limiting adverse effects of hupA and other AChEIs used for AD are indeed cholinergic in nature, suggesting that instead of focusing on more potent AChEIs, future drug development should aim at multi-target approach including some of the many targets of neuroprotection. The numerous structurally diverse lycopodium alkaloids already discovered are likely to play a role in this future quest for more effective drugs. An important challenge in that respect is to develop sustainable methods, e.g., synthesis and bioprocessing of lycopodium alkaloids, to supply these interesting natural products for future studies and application.

One of the major barriers in the current clinical evaluation of potential drug candidates for AD is the definition of the therapeutic effect in AD clinical trials, including the lack of tests evaluating the progression of the disease [29] and to clarify symptomatic versus disease-modifying potential. More accurate methods of evaluation of AD symptoms together with better understanding of the complex pathophysiology behind the disease would definitely benefit the development of more efficient drug treatment for AD.

Abstract

Leishmaniasis, a parasitic disease resulting from infection of macrophages by obligate intracellular parasites of genus *Leishmania*, is prevalent in tropical and subtropical regions of 88 countries, affecting about 12 million people in the world. Leishmaniasis displays a spectrum of clinical manifestations, ranging from mucocutaneous and cutaneous lesions to visceral leishmaniasis, which is usually fatal for untreated patients. Moreover, significant increases in the rate of *Leishmania*-HIV coinfections across the world and cases of resistant parasites are aggravating this problem. Chemotherapy is the only effective treatment for leishmaniasis. However, the growing incidence of resistance for most of the antileishmanial drugs in endemic and nonendemic regions has seriously hampered their use in these regions. The present chapter briefly illustrates leishmaniasis epidemiology, occurrence, parasite biology, drug targets, bioavailability and metabolism, and treatment around the world and also critically discusses the key points in alkaloids-based drug discovery protocols.

Keywords

Alkaloids • leishmaniasis • natural products • parasite biology • therapeutic options

1 Introduction

The vector-borne parasitic disease leishmaniasis continues to be one of the six entities on the World Health Organization tropical disease list [1]. The disease threatens about 350 million men, women, and children in 88 countries around the world covering tropical and temperate regions of world ranging from rainforests in

Central and South America to deserts in West Asia and the Middle East. As many as 12 million people are believed to be currently infected, with about 1–2 million estimated new cases occurring every year [2].

The protozoan parasites of family Trypanosomatidae and order Kinetoplastida are responsible for three main clinical syndromes of leishmaniasis: cutaneous (caused by *Leishmania tropica* and *L. mexicana*), mucocutaneous (caused by *L. braziliensis*), and visceral (caused by *L. donovani*). The *Leishmania* species, *L. tropica* and *L. donovani* found in Africa, Europe, and Asia, are often termed as the "Old World," while the species *L. mexicana* and *L. braziliensis* are restricted to the America and commonly referred to as the "New World" [3]. The visceral leishmaniasis (VL) has an estimated incidence of 500,000 new cases and 60,000 deaths each year with more than 90% of cases are centralized to India, Bangladesh, Nepal, Sudan, and Brazil [4].

Leishmaniasis is caused by 20 species of *Leishmania* and transmitted by 30 species of sand fly. Females of *Phlebotomus* (in the Old World) or *Luztomiya* (in the New World) sand flies are the proven vector of the disease [5]. These sand flies are about one-third the size of typical mosquitoes, thus are too small to see and get realized by the people. Sand flies become infected by biting an infected animal (e.g., rodents or dogs) or human and spread the disease to other healthy vertebrates [6]. Besides, leishmaniasis can also be spread by blood transfusions or contaminated needles. The disease rarely spreads from a pregnant woman to her baby. Usually, the disease is more common in rural than urban areas, and people of all ages if living or travel in disease prevailing region are at high risk [7].

The symptoms for leishmaniasis include fever, weight loss, enlarged spleen, swollen glands, skin sores, splenomegaly, lymphadenopathy, hepatomegaly, pancytopenia, progressive anemia, and hypergammaglobulinemia with hypoalbuminemia. People suffering from cutaneous leishmaniasis (CL) usually develop one or more skin sores (either painful or painless, with or without a scab) within few weeks to months after bitten by an infected female sand fly. Some people may have swollen glands near the sores. VL patients may have low blood counts (including a low RBC, WBC, and platelet count); progressive emaciation; enlargement in visceral organs (liver and spleen); hyperpigmented skin of the forehead, abdomen, hands, and feet in light-skinned persons; and occasional bleeding. Leishmaniasis is always fatal when left untreated, and sometimes patients, i.e., 50% in Sudan and 1–3% in India, develop post-*kala-azar* dermal leishmaniasis (PKDL) [8].

There are a growing number of reports of *Leishmania*-human immunodeficiency virus (HIV) coinfections across the world. *Leishmania*-HIV coinfection has been globally controlled in southern Europe since 1997 by highly active antiretroviral therapy (HAART), but it appears to be an increasing problem in other countries such as Ethiopia, Sudan, Brazil, or India where both infections are becoming more and more prevalent [9]. The situation is particularly alarming in southern Europe, where 50–75% of adult VL cases are HIV positive. Among the 45 million people infected by HIV worldwide, an estimated one-third lives in the zones of endemic *Leishmania* infections [10]. Over 850 *Leishmania*-HIV coinfection cases recorded worldwide, the majority are from Europe, where 7–17% of HIV-positive individuals with fever have amastigotes, suggesting that *Leishmania*-infected individuals without symptoms will express symptoms of leishmaniasis if they become immunosuppressed. However, there are indirect reasons and statistical data demonstrating that intravenous drug addiction plays a specific role in transmission *Leishmania* species. To date, the greatest prevalence of *Leishmania*-HIV coinfection has been recorded in the Mediterranean basin, where among more than 2,000 cases notified to the WHO, 90% of them belong to Spain, Italy, France, and Portugal [11]. Still no comparative clinical studies about the leishmaniasis in HIV-infected and non-HIV-infected patients have been reported, and aspects of its epidemiology, clinical features, and management remain unknown.

The present chapter briefly illustrates the current status of leishmaniasis, occurrence, morphology and life cycle, drug targets, bioavailability and metabolism, and treatment around the world and also critically discusses the key points in natural product-based drug discovery protocols. Finally, a comprehensive coverage of alkaloids with significant activity against *Leishmania* species has been given substantially. In order to highlight any possible structure-activity relationships, the chapter has been organized according to chemical structural class.

2 Taxonomy of *Leishmania* spp.

Earlier various classifications have been successively applied to heteroxenous protozoan *Leishmania*; however, the simplest one can be summarized from Fig. 40.1 [1, 4].

3 Parasite Biology

The obligate intracellular *Leishmania* parasites exist in two morphologic forms: promastigotes and amastigotes. The long spindle-shaped flagellated (15–28 μm) promastigotes measuring about 114.3–20 μm in length and 1.5 to 1.8 μm at their widest part [12] are found in digestive tract of sand fly [13]. The small, round to oval bodies called amastigotes (2–3 μm in length) are the noninfective *Leishmania* parasites occurring in monocytes, polymorphonuclear leucocytes, or endothelial cells of vertebrate hosts.

The *Leishmania* promastigotes are transmitted by sand fly to vertebrate hosts, e.g., canines, marsupials, edentates, and rodents (Fig. 40.2). Once inside the bloodstream of reservoirs for the disease, promastigotes are phagocytosed by the mononuclear phagocytic cells and are transformed to amastigotes which multiply by means of binary fission. On lyse of host cell, the free parasites spread to new cells and tissues of different organs including the spleen, liver, and bone marrow. Amastigotes in the blood as well as in the monocytes are ingested during a blood

meal by female sand fly. Once ingested, the amastigotes migrate to the midgut of the sand fly and transform into the promastigotes. Infected sand fly during the second blood meal regurgitates the infectious promastigotes from its pharynx into the bloodstream of the vertebrate host, and the life cycle is repeated [1, 14].

4 Drug Targets

Identification and characterization of novel cellular targets and answering the problem of drug resistance in *Leishmania* has always been the main thrust of protozoal research worldwide. However, putative target in a pathogen can be identified and validated successfully only if it is either absent in the host or substantially different from the host homolog. The cell organization in *Leishmania* species is significantly different from the mammalian cells, and thus, it is possible to find targets that are unique to these pathogens. Secondly, the target selected should be absolutely necessary for the survival of the pathogen [15]. Some of the crucial targets significant in drug discovery and development against leishmaniasis have been discussed below.

4.1 Sterol Biosynthetic Pathway

Sterols are important components of the cell membrane that are vital to various cellular functions and maintenance of cell structure. The major sterol in promastigotes of *Leishmania tropica*, *L. donovani*, and 3 subspecies of *L. mexicana* is ergosta-5,7,24(28)-trien-3*β*-ol. Ergosta-7,24(28)-dien-3*β*-ol is the major constituent of *L. major*. 24-Methylcholesta-5,7,22-trien-3*β*-ol and 24-ethylcholesta-5,7,22-trien-3*β*-ol are the minor constituents, while traces of ergosta-5,7,22,24(28)-tetraen-3*β*-ol and a C27-diene have also been detected in some species. Lanosterol and 4,4-dimethylcholesta-8,24-dien-3*β*-ol have been also identified in these species, while squalene is known to occur in *L. tropica*. The enzyme D24,25-sterol methyltransferase (SMT) is a putative target in ergosterol biosynthesis. The occurrence of this enzyme is limited to trypanosomatids only (absent in human host), thus would be exploited effectively as a potential drug target [16].

4.2 Glycolytic Pathway

Glycosomes are peroxisome-related organelles containing glycolytic enzymes that are found only in kinetoplastids. The unique compartmentalization of glycolytic enzymes in glycosomes of *Leishmania* and their large phylogenetic distance with the mammalian hosts can be exploited by designing specific inhibitors that can bind to parasitic enzymes with the high affinity. In this context, the specific inhibitors have been designed for the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Studies have shown that the adenosine being a poor inhibitor of the enzyme shows enhanced inhibition on substitutions at the 20-position of ribose and *N*6-position of adenosine (disubstituted analogs). Likewise, *N*-(1-naphthalenemethyl)-2′-(3-methoxybenzamido) adenosine inhibits the growth of *L. mexicana* with IC_{50} of 0.28 μM [17]. Thus, with the design and development of specific inhibitors of enzymes frequently involved in glycolytic pathway, the energy production in parasite can be blocked effectively. Since glycolysis is the only source of energy for these parasites, it can serve as an excellent drug target.

4.3 Nucleoside Transporters

In *Leishmania*, the LdNT1 and LdNT2 are the two specific transporters that transport the nucleosides across the membrane. LdNT1 occurs in promastigotes as well as amastigotes and transports adenosine and pyrimidine nucleosides, while LdNT2, occurring in amastigotes only, is responsible for transportation of purine nucleosides, i.e., inosine and guanosine [18]. Similarly, among the two purine nucleobase transporters, namely, LmaNT3 and LmaNT4 identified from *L. major*, the LmaNT3 is known to transport hypoxanthine, xanthine, adenosine, and guanine bases only but none of nucleosides, while LmaNT4 at neutral pH takes up adenine only but also takes up hypoxanthine, guanine, and xanthine at acidic pH [19]. The parasitic transporters are different from the mammalian transporters in terms of their higher specificity toward the substrate. There are so many pathways for the uptake of purines; thus, it is very difficult to target them with selective inhibitors. But, they will remain pharmacologically important as these transporters also uptake toxic nucleoside analogs which are inhibitory to the cell growth.

4.4 Purine Salvage Enzymes

Salvage pathway, a pathway in which nucleotides (purine and pyrimidine) are synthesized from intermediates in the degradative pathway for nucleotides, is used to recover bases and nucleosides that are formed during degradation of RNA and DNA. Since *Leishmania* species cannot synthesize purine nucleotides de novo, they rely predominantly upon therapeutically germane phosphoribosyltransferase (PRT) enzymes. There are three PRTs identified in *Leishmania* for acquisition of purine from the host: hypoxanthine-guanine PRT (HGPRT), adenine PRT (APRT), and xanthine PRT (XPRT) [20]. Among these enzymes, the HGPRT is particularly important due to its difference in substrate specificity with the host enzyme. HGPRT converts hypoxanthine to inosine monophosphate and guanine to guanosine monophosphate. Allopurinol is a most common HGPRT inhibitor used which on phosphorylation by HGPRT gets incorporated into nucleic acid and cause selective death of the parasite [21]. However, it has been established that PRTs are not essential for survival of *Leishmania* because there may be various alternative purine salvage pathways present in the parasite. Therefore, in antileishmanial chemotherapy it is necessary to target more than one enzyme at a time.

4.5 GPI Biosynthetic Pathway

In promastigotes of *Leishmania* parasites, the cell surface is coated by glycocalyx consisting of glycosylphosphatidylinositol (GPI)-anchored glycoproteins, GPI-anchored lipophosphoglycan (LPG), and a family of free GPIs, called as glycoinositolphospholipids (GIPLs) [22, 23]. GPI anchors are synthesized in endoplasmic reticulum membrane and after attachment to the nascent proteins, are transferred to the plasma membrane via the secretory pathway. GPI biosynthesis in case of parasites involves mannosylation of GlcN-PI which is followed by inositol acylation, whereas in yeast and human, inositol acylation is a prerequisite for mannosylation. The trimannosyl core of GPI anchors is added stepwise and involves three distinct mannosyltransferases (MTs) in which the structure of mannosyltransferase III (MTIII) in trypanosomes has been found to be significantly different from mammalian MTIII. Thus, species-specific inhibition can be achieved by synthesizing small molecule inhibitors [24].

On completion of GPI anchor synthesis, lipid remodeling comprising the exchange of fatty acid components with other fatty acid of the lipid moiety or the whole lipid component takes place. The mature GPI precursor is transferred to the protein through transamidation reaction by a multimeric protein complex, where -COOH terminal signal peptide is replaced by the formation of amide linkage to amino group of ethanolamine phosphate linked to the third mannose of GPI anchor. The protein components differ in different species, suggesting that these differences between the parasite and mammalian enzymes can be exploited for drug designing [24].

4.6 Proteinases as Drug Targets

Proteinases are of four main types – cysteine, serine, aspartate, and metalloenzymes. The name is given on the basis of the residue present in the active site. In case of parasitic protozoa, the most identified and characterized are the cysteine proteinases (CPs), which are homologous to mammalian cathepsins. CPs play an important role in the infection, replication, development, and metabolism of protozoan parasites [25], and their activity is necessary for the survival of *L. mexicana* within the macrophages, in vitro [26]. Knockout studies in *L. mexicana* have shown that cysteine proteases not only are virulence factors but also act as modulators of host immune responses [27]. Thus, CPs have become a potential target for chemotherapy and a candidate for vaccine development. Initial studies have confirmed the efficacy of CP inhibitors in treatment of *L. major* [28]. Immunization with the hybrid protein vaccine, consisting of *L. major* cysteine proteases CPB and CPA, is partially protected against leishmaniasis [29]. So far, functionally well-characterized CPs are from the New World species of *Leishmania* causing the cutaneous forms of leishmaniasis. The members of *L. donovani* complex also possess multiple classes of CPs, which are developmentally regulated and are not functionally well characterized. Therefore, there is a need to study the function of these proteases and their role in VL.

4.7 Folate Biosynthesis

A biochemical pathway that has been exploited earlier in the treatment of infectious diseases is the folic acid biosynthetic pathway. Folic acid consists of three building blocks: a pterin, *p*-aminobenzoic acid (*p*ABA), and glutamic acid. Analogs of folic acid that can inhibit cellular growth are called antifolates, while folates are important cofactors essential for cellular growth. The enzymes that are involved in their synthesis have been of great interest as drug targets, particularly, thymidylate synthase (TS) and dihydrofolate reductase (DHFR) that converts dihydrofolate to tetrahydrofolate, an important cofactor in the synthesis of thymine. Both the enzymes exist on a single polypeptide in case of trypanosomatids, with DHFR domain on amino terminus and TS domain on carboxy terminus. The protozoan parasite *Leishmania* is a folate and pterin auxotroph. The main biopterin transporter (BT1) and pterin reductase (PTR1) have already been characterized in *Leishmania*. A number of compounds have been screened against PTR1 in *L. major* [30]. Several compounds were found to be inhibiting both DHFRTS and PTR1. However, only few of them inhibited both the enzymes and the growth of the parasite potently. Thus, design and development of suitable inhibitors to target both the enzymes simultaneously or a combination of two compounds that can be used specifically for inhibiting both the enzymes may be crucial for antileishmanial drug discovery.

4.8 Glyoxalase System

The glyoxalase system is responsible for detoxification of the cell through removal of toxic and mutagenic intermediates (i.e., methylglyoxal) formed as a by-product of glycolysis. The glyoxalase system functions by activity of two enzymes, namely, glyoxalase I (lactoyl glutathione lyase) and glyoxalase II (hydroxyacyl glutathione hydrolase), and uses glutathione as a cofactor. Glyoxalase I has been characterized from *L. donovani* [31] and *L. major* [32], while glyoxalase II has been characterized from *L. donovani* [33]. Glyoxalase I is highly substrate specific and lacks the basic residues in its active site which are conserved in human homolog. These residues are important for binding to glutathione. The substrate for *L. donovani* glyoxalase II is thioester of trypanothione, which is positively charged, therefore, cannot be accommodated in the active site of the human enzyme. This observation strongly suggests that the parasitic enzymes are highly substrate specific. Therefore, trypanothione-dependent glyoxalase pathway has drawn attention for additional biochemical and genetic investigations as a possible target for rational drug design.

4.9 Topoisomerases

In kinetoplastids, the DNA topoisomerases play a key role in cellular processes affecting the topology and organization of intracellular DNA and play an important role in DNA replication, transcription, chromosomal condensation, segregation, and many other vital cellular processes. They are broadly classified as type I and type II topoisomerases. Type I and II topoisomerase have been characterized from *L. donovani* [34]. Interestingly, the topoisomerase II from *L. donovani* was found to contain both ATP dependent and independent activities. Many of the topoisomerase II inhibitors have shown strong activity against *Leishmania* species [35, 36]. The structural analysis of these enzymes will give us an insight into their catalytic mechanisms and will also enable us to design specific inhibitors against *Leishmania*.

4.10 Hypusine Pathway

Hypusine, an unusual amino acid derived from the polyamine spermidine, occurs in all the eukaryotes. The name is given on the basis of two structural components, hydroxyputrescine and lysine [37]. It is synthesized as a result of posttranslational modification occurring exclusively on one cellular protein, eukaryotic initiation factor 5A (eIF5A). Recent researches have shown that hypusine biosynthesis also occurs in *L. donovani*. Moreover, *Leishmania* has two genes containing DHS domains, namely, DHS-like gene (DHSL20) and DHS34 gene, of which only DHS34 protein was found to contain functional activity in vitro and is essential for the survival of parasite [38]. Structural modeling of DHS34 protein has shown that one of the NAD^+ binding domains lies in a 225-amino acid long insertion present in DHS34 protein, as compared to the human homolog. The recombinant DHS34 remained uninhibited by most potent inhibitors of the human enzyme like GC7 and other spermidine analogs, indicating that there is a difference between the spermidine binding sites of both the enzymes which could be exploited while designing new inhibitors.

5 Bioavailability and Metabolism

A little is known about the energy metabolism exhibited by *Leishmania* parasite during its life cycle. Studies have shown that *Leishmania* and trypanosomes share many features due to development from a common ancestor, and many of the genes in different trypanosomatids are proven orthologues. In spite of many common features, some substantial biological differences between *Leishmania* and trypanosomatids can be figured out by comparing their life history strategies [39]. The biology (e.g., their food source) of trypanosome vectors is significantly differing from sand flies. In mammalian host, *Leishmania* thrives inside a parasitophorous vacuole within mononuclear cells. Amastigotes are fully adapted for reaching this niche, and their appropriate metabolic capabilities have been evolved to ensure the intracellular existence. *Leishmania* exists as promastigote forms adapted to survive in different parts of the intestinal tract in sand fly excluding salivary glands or hindgut (except braziliensis complex of *Leishmania*).

The metabolism of in vitro grown promastigotes in nutrient-rich medium compared to those occurring naturally in sand flies is still not fully understood. The biochemical researches involving mixed populations of promastigotes (e.g., metacyclic promastigotes in addition to multiplicative forms) have indicated for the metabolic similarities with the vector stages of *T. cruzi* and *T. brucei*. The amino acids (notably proline) and sugars (including glucose) are the probable energy sources. The energy is supposed to be generated by both glycolysis (and glycosomes) and mitochondrial metabolism through an active electron transport chain. Experimental evidences have indicated for the presence of enzymes of tricarboxylic acid (TCA) cycle; however, cycle is not active [40]. Researches have shown for reversible metabolic arrest in promastigotes on inhibition of the electron transport chain, which might be an adaptation for survival during life in the sand fly [41].

Earlier, the presence of a glyoxylate cycle was reported [42] but was found to be unlike on the basis of genome analysis. The pathways that produce acetate and succinate are supposed to be responsible for CO_2 production. The succinate, acetate, pyruvate, and D-lactate have been identified as end products. Alanine, ammonia, and urea are also released. Due to less availability of *Leishmania* amastigotes for metabolic studies in compared to promastigotes, the knowledge of the energy metabolism in amastigotes is considerably more fragmentary. Studies using amastigotes isolated from in vivo lesions of *L. mexicana* have evidenced for an increased β-oxidation of fatty acids and a reduced need for proline and glucose consumption in compared to promastigotes [43]. The amastigotes contain considerably fewer glycosomes but greater number of enzymes, i.e., phosphoenolpyruvate carboxykinase and malate dehydrogenase than promastigotes [44–46].

The importance of some of the detected differences in gene content between trypanosomatids can be readily hypothesized. Moreover, some of the known metabolic differences between trypanosomatids are not fully explained by the presence or absence of genes that encode metabolic enzymes. Clearly, the situation will be affected by the control of gene expression and by enzyme stability at different stages of the life cycle. The current “best guess” on the metabolism that occurs in *Leishmania* amastigotes and promastigotes now requires detailed studies, and gene mining has indicated some sensible approaches to pursue and experiments that should be done [39].

6 Current Chemotherapy of Leishmaniasis

6.1 Pentavalent Antimonials

Pentavalent antimonials, sodium stibogluconate (Pentostam®), meglumine antimoniate (Glucantime®), etc., are being used for treatment of leishmaniasis over more than five decades. The pentavalent antimoniate (Sb^V) is a prodrug of trivalent antimonite (Sb^{III}), an active form of the drug which is generated by reduction from Sb^V either in macrophages or in the parasite [1]. Aquaporin-1 transporters in the plasma membrane of amastigotes are able to transport trivalent metalloids into the cell, though reduction into the trivalent form occurs only in a minor amount in phagolysosomes of the macrophage while the major amount is supposed to be converted within the parasite. These compounds are supposed to exert antileishmanial activity by inhibiting enzymes involved in the glycolysis and oxidation of fatty acids.

Instead of costly branded sodium stibogluconate (approximately 200 USD per patient), a generic sodium antimony gluconate (SAG, Albert David Ltd., India, 13 USD per patient) was used to treat patients satisfactorily without any significant difference in final cure [4]. Antimonials are administered intravenously or intramuscularly, and side effects like chemical pancreatitis, elevations in serum aminotransferases, and electrocardiographic abnormalities are usually reversible. One major drawback of therapy is the drastic emergence of resistance against antimonials. A prominent example is Bihar State in India, where the cure rate of antimony therapy against VL has declined to merely 35%, making conventional treatment no longer useful [47].

6.2 Pentamidine

Pentamidine is an aromatic diamine used to cure leishmaniasis as a second-line drug. Its isothionate and methanesulfonate salts are mainly used for the treatment of VL. The drug gets accumulated in mitochondria and enhances efficacy of mitochondrial respiratory chain complex II inhibitors suggesting its leishmanicidal activities due to decreased mitochondrial membrane potential. Pentamidine was the first drug used for the treatment of patient refractory to Sb^V in India [48]. Biophysical analysis, foot-printing studies, and the crystal structure have proved that the charged amidinium groups of pentamidine establish hydrogen bonding with O_2 of thymine or N_3 of adenine and form complexes with the minor groove of DNA. However, declining efficacy (cures only 70% of patients) and high resistance risk have led to its closure in India.

Pentamidine is highly toxic; causes myalgias, pain at the injection site, nausea, and headache; and less frequently results in a metallic taste, a burning sensation, numbness, and hypotension. Reversible hypoglycemia occurs in about 2% of cases [49].

6.3 Amphotericin B

Amphotericin B (AmB) is a pollen antibiotic that was recommended as first-line drug in India by National Expert Committee for Sb^V refractory regions of VL. At doses of 0.75–1.0 mg/kg for 15 infusions on alternate days, it cured more than 97% of patients. AmB shows high affinity for ergosterol, the predominant sterol of fungal and leishmanial cell membrane [50]. Despite high efficiency, AmB is toxic and treatment with it can cause serious adverse reactions including fever with rigor and chills, thrombophlebitis, and occasional serious toxicities like myocarditis, severe hypokalemia, renal dysfunction, and even death [51].

Currently, toxic effects of AmB have been largely ameliorated with the advent of lipid formulations. In these formulations, deoxycholate has been replaced by other lipids that mask AmB from susceptible tissues, thus reducing toxicity and facilitating its preferential uptake by reticuloendothelial cells. Thus, this drug delivery results in increasing efficacy and reduced toxicity. Three lipid-associated formulations of amphotericin are commercially available: liposomal amphotericin B (AmBisome), amphotericin B lipid complex (Abelcet), and amphotericin B colloidal dispersion (Amphocil). These compounds have been considered between the most striking advances in *Leishmania* therapy [52].

The antileishmanial activity of AmB and its lipid formulation is due to its interaction from both sterols, i.e., ergosterol of *Leishmania* and cholesterol of host macrophages. Since cholesterol is complexed by AmB, it markedly inhibits the binding of *L. donovani* promastigotes to macrophage. Further, at higher concentration (<0.1 M), it induces the formation of aqueous pores in leishmanial promastigotes cell membrane that result in osmotic changes leading to the cell lysis.

6.4 Miltefosine

Miltefosine, an alkylphosphocholine (hexadecylphosphocholine) developed originally as an antitumor agent, was approved in India at 50–100 mg (~2.5 mg/kg) doses for 4 weeks against VL patients including children. The activity of miltefosine is due to intracellular accumulation of drug, which is regulated by two transporters, LdMT and its *β*-subunit LdRos3, a P-type ATPase, belonging to aminophospholipid translocase family. Miltefosine mediates apoptotic-like cell death in *L. donovani*, and, moreover, inhibition of alkyl-specific-acyl-CoA acyltransferase has also been reported [53]. Miltefosine blocks *Leishmania* proliferation, alters phospholipid and sterol composition, and activates cellular immunity. However, due to high cost and serious side effects, i.e., teratogenic and abortifacient nature, medical advisors generally avoid the drug in their prescriptions [54].

Miltefosine has been hailed as a novel oral drug for treatment of VL. Success in immunocompetent and immunocompromised patients is perhaps the most significant recent advance [55]. However, some studies have demonstrated the insensibility of *Leishmania* species from the New World including *L. braziliensis*, *L. guyanensis*, and *L. mexicana*. These results are disappointing as miltefosine was believed to provide a better alternative to drug therapy in America. The efficacy of miltefosine against *L. infantum* infection has been conducted in animals and needs a validation in clinical trials [56].

6.5 Paromomycin

Paromomycin, an amino glycoside antibiotic originally identified as an antileishmanial drug in the 1960s, acts synergistically with antimonials in vitro and was demonstrated significant (93% cure rate) at a dose of 16 mg/kg when given intramuscularly for 21 days to VL patients in India. Recent study has shown that cationic paromomycin binds to the negatively charged leishmanial glycocalyx suggesting mitochondria as a primary target. Like other amino glycosides, the drug acts by impairing the macromolecular synthesis and alters the membrane properties of *Leishmania* [57]. It binds to the 30 S ribosomal subunit, interfering with initiation of protein synthesis by fixing the 30 S–50 S ribosomal complex at the start codon of mRNA, leading to accumulation of abnormal initiation complex [58]. In parallel, experimental evidences have shown that paromomycin promoted ribosomal subunit association of both cytoplasmic and mitochondrial forms, following low Mg^{2+} concentration; induced dissociation; and also caused dysfunction in respiratory systems [59].

Three preparations of paromomycin ointments have been used for CL: paromomycin 15% plus methylbenzethonium chloride 12%, paromomycin 15% with urea 10%, and paromomycin plus gentamicin 0.5%. These formulations have shown variable results according to the species of *Leishmania* involved and the epidemiologic situation [4]. The most common side effect associated with the paromomycin is ototoxicity as well as problems in liver function [60]. In patients treated with the ointment formulation, skin rashes, local pruritus, and burs have been the side effects encountered.

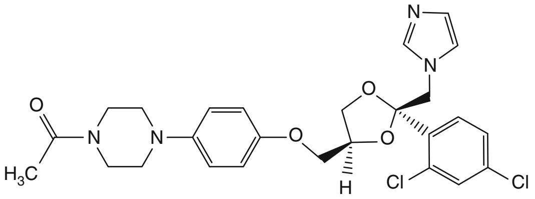
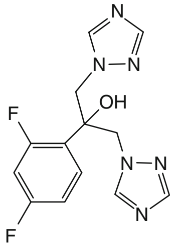
7 Other Drugs

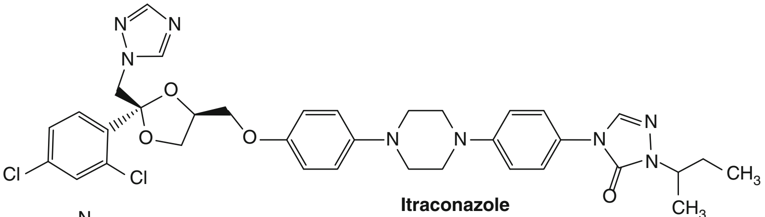
Some of imidazoles and triazoles are the potential inhibitors of 14-demethylase, a key enzyme in the sterol biosynthesis pathway, thus directly interfere with cell wall biosynthesis in *Leishmania*. Fluconazole, a triazole antifungal drug used in the treatment and prevention of superficial and systemic fungal infections, has been used for the treatment of *L. major* in Old World. Similarly, ketoconazole has been used in the New World against *L. panamensis* and *L. mexicana*. Itraconazole has been used in Old and New World but suffers from low efficacy. Itraconazole at a concentration of 0.75 μM/L causes complete cell lyses after 72 h against *L. major* promastigotes. Likewise, posaconazole shows activity against experimental *L. amazonensis* infection but still has not been evaluated in clinical trials [61].



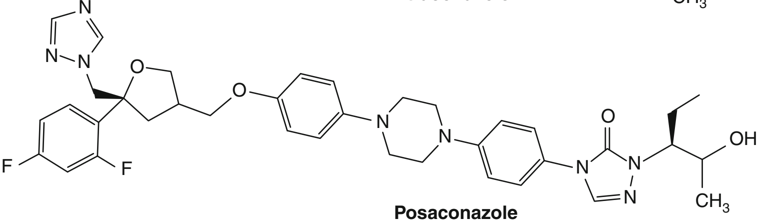
Ketoconazole



Fluconazole



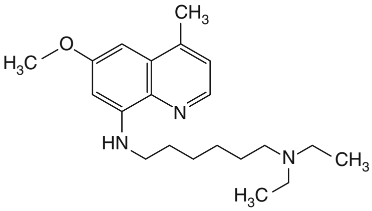
Itraconazole



Posaconazole

Sitamaquine, an orally active analog of 8-aminoquinoline, is in clinical development by the Walter Reed Army Institute in collaboration with GlaxoSmithKline (formerly SmithKline Beecham) to use for the treatment of VL. Sitamaquine at high concentration affects parasite motility, morphology, and growth. The drug involves electrostatic interaction between phospholipid anionic polar head groups and positively charged sitamaquine and then with phospholipid acyl chains leading to drug insertion within biological membranes. After binding to the membrane, sitamaquine accumulates in *Leishmania* cytosolic acidic compartments, acidocalcisome. However, correlation between its action and accumulation is not yet understood.

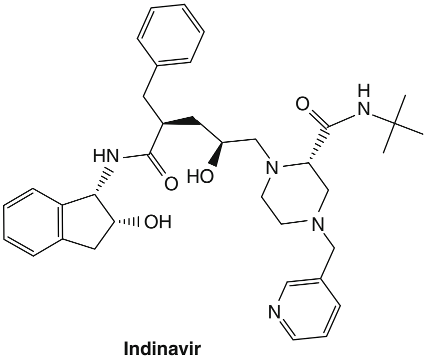
In a randomized, open label, and multicenter phase II trial in India and Kenya, the drug was found efficacious and well tolerated at various dose levels [62]. Despite efficacy, few side effects like vomiting, dyspepsia, cyanosis, nephritic syndrome, and glomerulonephritis were also observed in Indian phase II trial. However, the Kenyan phase II trial showed somewhat equal efficacy but observed side effects were abdominal pain, headache, and kidney dysfunction. As on March 2002, the drug is currently in phase III trials for the treatment of VL.



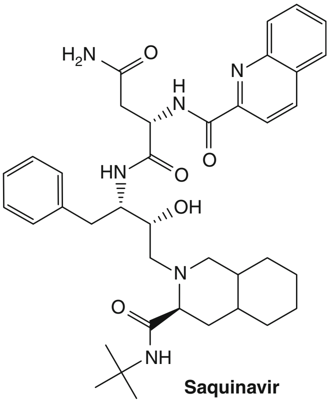
Sitamaquine

Leishmania-HIV coinfection is regarded as an “emerging” infectious disease, for in certain countries up to 70% of adult cases of leishmaniasis are related to HIV infection-AIDS. To date, the greatest prevalence of *Leishmania*-HIV coinfection has been in the Mediterranean basin. Among more than 2000 cases notified to the WHO, 90% of them belong to Spain, Italy, France, and Portugal. The most common species involved in *Leishmania*-HIV coinfection is *L. infantum*. Currently, no treatment has been completely effective, and the mortality rate is high (approximately 25%) during the first month after diagnosis [1, 4].

Indinavir and saquinavir, the two antiretroviral drugs capable of inhibiting the protease enzymes, have shown significant pharmacological activity against *L. major* and *L. infantum*. These results add new insights into the wide-spectrum efficacy of protease inhibitors and suggest for the study of their action on amastigote forms of *Leishmania* in order to validate their potential contribution against opportunistic infections in treated seropositive patients [63].



Indinavir



Saquinavir

8 Natural Products as Folk Medicines Against Leishmaniasis

Drugs derived from plants have been empirically used in the treatment of various human disorders for thousands of years in the form of the traditional Ayurvedic and Chinese medicine. A number of plants, i.e., *Cinchona calisaya* (bark), *Strychnos pseudoquina* (bark), *Deianira erubescens* (roots and leaves), and *Remijia ferruginea* (bark), were historically used against wide range of diseases. Drugs derived from microbial fermentations have played an equally seminal role in modern discovery and have revolutionized medicine, saving both human and animal lives. A number of plant-based natural products, e.g., aspirin, morphine, quinine, etc., are still in use today.

Ancient records have established the effectiveness of natural products as potentially rich sources of new and selective agents for the treatment of important tropical diseases caused by protozoans and other parasites. For example, in traditional Chinese medicine, the potential of plant extracts for the treatment of infectious diseases was recognized more than 2,000 years ago. Today, several compounds derived from plants or medical plants are applied in standard therapies, e.g., artemisinin, an important antimalarial drug was identified in the 1970s from traditional Chinese medicine *Artemisia annua*, and since then, many artemisinin derivatives have been prepared and evaluated in various preclinical and clinical trials to use in the treatment of malaria. In the year 2000, artemisinin (Artemotil®) was approved for the treatment of chloroquine-resistant *Plasmodium falciparum* malaria and cerebral malaria. However, the WHO has restricted the use of Artemotil® as a monotherapy since malarial parasites are developing resistance to the drug. However, combination therapies that include Artemotil® are the preferred treatment for malaria and are both effective and well tolerated in patients. Artemotil® is currently used only as a second-line drug in severe cases of malaria and is also increasingly being used against *P. vivax malaria*. As of May 2009, arterolane (RBx11160, OZ-277), a trioxolane modeled on artemisinin pharmacophore, is under phase III clinical development for the treatment of malaria by Ranbaxy in combination with piperaquine.

Plants are valuable sources for the screening of bioactive secondary metabolites, but also bacteria, fungi, and terrestrial or marine invertebrates produce pharmaceutically useful compounds. For example, paromomycin (Humatin™, King Pharmaceuticals), obtained from *Streptomyces krestomuceticus*, is an orphan drug that was approved by Drug-Controller General of India in September 2006 against VL. Paromomycin was originally developed by the Institute for OneWorld Health and is an off-patent antibiotic marketed in the USA to treat intestinal parasites also.

Natural products literature provides a growing research on several plant-derived compounds with a wide range of pharmacological activities, thus may be of potential utility in drug development and biomedical researches. Many plant-derived substances of diverse structural classes have been described in the literature showing antileishmanial properties, but none of them have been clinically evaluated in studies or projected to reach the clinical applications in near future. In this chapter, we have provided a brief overview of *Leishmania* occurrence, morphology and life cycle, bioavailability and metabolism, drug targets, *Leishmania* chemotherapy, and the active principles of established drugs. Furthermore, we have focused to cover the entire formal and constant researches on antileishmanial alkaloids up to July 2011 from the mid-1980 with special attention on structure-activity relationship (SAR)-based activity and mechanism of action (Table 40.1). Finally, a comprehensive coverage of plant-derived alkaloids with significant activity against *Leishmania* species has been given in detail. In order to highlight any possible structure-activity relationships, the chapter has been organized according to chemical structural classes.

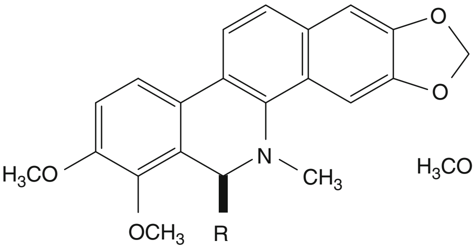
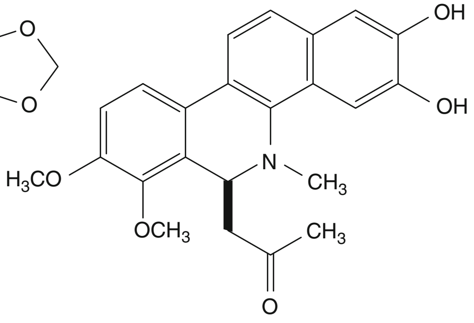
9 Alkaloids

9.1 Benzo[*c*]phenanthridine Alkaloid

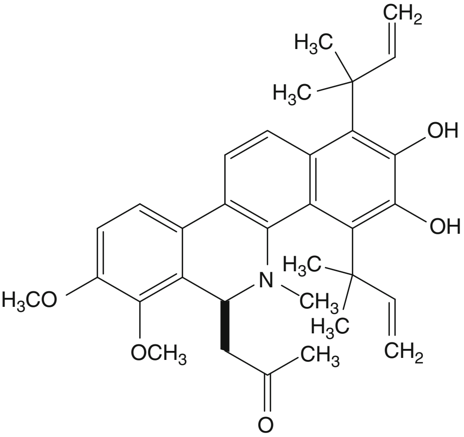
The alkaloids constitute an important class of natural products exhibiting significant antileishmanial activities. The benzo[*c*]phenanthridine alkaloids, dihydrochelerythrine (1), 6-acetonyldihydrochelerythrine (2), and their semisynthetic derivatives lucidamine-A (3) and -B (4), isolated from the stem bark of *Garcinia lucida* (Clusiaceae), exhibit attractive antiprotozoal activity against *L. donovani*, with little toxicity to Vero cells and the host cells. Among these, the compound 1 with IC_{50} value of 2.0 μM shows promising antileishmanial activity, while compounds 2, 3, and 4 with IC_{50} values of 6.6, 10.8, and 6.8 μM, respectively, exhibit comparatively lower activity against *L. donovani* axenic amastigotes [64].



1 R = H
2 R = CH_2COCH_3



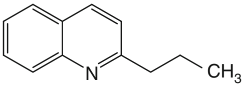
3



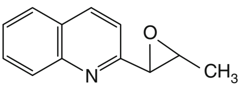
4

9.2 Quinoline Alkaloids

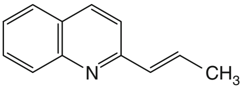
The quinoline alkaloids, 2-n-propylquinoline (5), chimanine-D (6), and chimanine-B (7), isolated from *Galipea longiflora* (Rutaceae), exhibit antileishmanial activity against promastigotes of *L. braziliensis* with an IC_{90} values of 50, 25, and 25 μg/mL, respectively. Oral in vivo studies using 5 in BALB/c mice demonstrate 99.9% suppression of liver parasites, while subcutaneous treatment with 6 causes 86.6% parasite suppression when given for 10 days at 0.54 mmol/kg [65]. However, oral treatment with 6 for 5 days results in 72.9% parasite suppression only. Likewise, dictylomide-A (8) and B (9), isolated from the bark of *Dictyoloma peruviana* (Rutaceae), causes total lyses of *L. amazonensis* promastigotes at 100 μg/mL concentration [66].



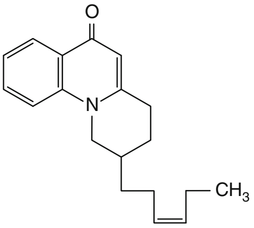
5



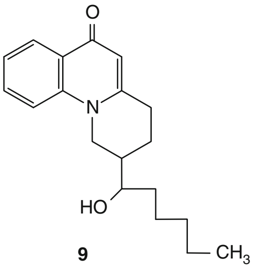
6



7



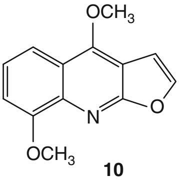
8



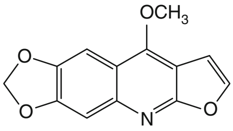
9

9.3 Furoquinoline Alkaloids

The furoquinoline alkaloids are biogenetically derived from the 2-substituted oxygenated 4-quinolones after a prenylation at C-3. The furoquinolines, γ-fagarine (10), and maculine (11), isolated from the stem bark of *Helietta apiculata* (Rutaceae), exhibit significant in vitro antileishmanial activities (IC_{50} between 17 and 30 mg/mL) against promastigote forms of *L. braziliensis*, *L. amazonensis*, and *L. donovani*. In vivo study reviles that the treatment with reference drug or compound 10 produces a significant reduction of the lesion weight by 66.9% (po0.01) and 90.5% (po0.001), respectively, and a drastic reduction of the lesional parasites by 95.2% (po0.01) and 97.4% (po0.005) [67].



10



11

9.4 Isoquinoline Alkaloids

O-methylmoschatoline (12) and liriodenine (13), isolated from *Annona foetida* (Annonaceae), display in vitro activity against promastigote forms of *L. braziliensis* with an $IC_{50} < 60$ μM [68]. The SAR study among these oxoaporphine alkaloids reveals that 13 bearing methylenedioxy moiety is eight times more active against *L. braziliensis* and *L. guyanensis* than the 12. Berberine (14), occurring in many plant species of Annonaceae, Menispermaceae, and Berberidaceae, exhibits in vivo leishmanicidal activity with an IC_{50} value of 10 μg/mL against *L. major*. Isoguattouregidine (15) isolated from *Guatteria foliosa* (Annonaceae) shows activity at a concentration of 100 μg/mL against *L. donovani* and *L. amazonensis*. Anonaine (16) isolated from *Annona spinescens* (Annonaceae) exhibits activity against promastigotes of *L. braziliensis* and *L. donovani* [69].

The alkaloids (+)-neolitsine (17) and cryptodorine (18), isolated from *Guatteria dumetorum* (Annonaceae), display significant activity against promastigotes of *L. mexicana* at 15 and 3 μM concentrations, respectively. Xylopine (19), an aporphine alkaloid isolated from *Guatteria amplifolia* (Annonaceae), shows activity against promastigotes of *L. mexicana* (IC_{50} value 3 μM) and *L. panamensis* (IC_{50} value 6 μM) [70]. Unonopsine (20), a dimeric aporphine alkaloid isolated from the *Unonopsis buchtienii* (Annonaceae), displays antileishmanial activity (IC_{100} value 25 μg/mL) against *L. donovani* promastigotes [71].

The alkaloids, duguetine (21), duguetine *β*-*N*-oxide (22), dicentrinone (23), *N*-methyltetrahydropalmatine (24), and *N*-methylglaucine (25), isolated from subterranean stem bark of *Duguetia furfuracea* (Annonaceae), exhibit good to moderate antileishmanial activity. Among these, dicentrinone (23) with an IC_{50} value of 0.01 μM shows strongest leishmanicidal activity, however, at the same time also shows weak cytotoxicity. Likewise, metabolite 22 with an IC_{50} value of 0.11 μM shows promising leishmanicidal effect. The isoquinoline alkaloids 21, 25, and 24 with IC_{50} values of 4.32, 4.88, and 17.03 μM, respectively, display good to moderate activity against *Leishmania* parasites [72].

9.5 Naphthylisoquinoline Alkaloids

Among the naphthylisoquinoline alkaloids, ancistroealaine-A (26) isolated from *Ancistrocladus ealaensis* (Ancistrocladaceae) exhibits activity against *L. donovani* promastigotes with an IC_{50} value 4.10 μg/mL. Ancistrocladinium A (27) and B (28) isolated from yet an undescribed Congolese Ancistrocladaceae species require 2.61 and 1.52 μg/mL concentrations, respectively, to reach the IC_{50} toward *L. major* promastigotes. An apoptosis like death pathway is the possible mode of action for compounds 27 and 28 [73, 74]. Ancistrocladidine (29), isolated from *Ancistrocladus tanzaniensis* (Ancistrocladaceae), shows relatively weak activity by a factor of 2 against *L. donovani* when compared to ancistrotanzanine-B (30) (IC_{50} = 1.6 μg/mL) while by a factor of 10 in comparison to miltefosin (positive control) [75, 76].

Likewise, ancistrotanazanine-A (31) exhibits activity against promastigotes of *L. donovani*. SAR-based studies among the alkaloids suggest that the compound-bearing *C,C*-biaryl axis connecting the naphthyl and isoquinoline moiety shows weak or no leishmanicidal activity. The korupensamine A (32) and ancistrocongolines B-D (33–35) isolated from *Ancistrocladus congolensis* exhibit weak to moderate antileishmanial activity. Among these, the ancistrocongolines 33, 34, and 35 show activity against *L. donovani* with IC_{50} value of 18.8, 19.3 and >30 μg/mL, respectively. The compound 32 with an IC_{50} value of 25.1 μg/mL demonstrates activity against *L. donovani* when compared to Pentostam as a standard drug (IC_{50} value of 47.2 μg/mL) [77].

9.6 Bisbenzylisoquinolinic Alkaloids

Daphanandrine (36) isolated from *Albertisia papuana* (Menispermaceae), obaberine (37) obtained from *Pseudoxandra sclerocarpa* (Annonaceae), gyrocarpine (38) produced by *Gyrocarpus americanus* (Hernandiaceae), and limacine (39) isolated from *Caryomene olivasans* (Menispermaceae), display activity against *L. donovani*, *L. braziliensis*, and *L. amazonensis* with an IC_{100} of ~50 μg/mL. SAR studies among these metabolites demonstrate that alkaloids with methylated nitrogen are more active than those with nonsubstituted or aromatic nitrogen, while quaternization of one or more nitrogen atoms results in the loss of antileishmanial activity [78].

9.7 Indole Alkaloids

Dihydrocorynantheine (40), corynantheine (41), and corynantheidine (42), isolated from the bark of *Corynanthe pachyceras* (Rubiaceae), are the respiratory chain inhibitors exhibiting IC_{50} of 3 μM against *L. major*. Pleiocarpine (43) isolated from stem bark of *Kopsia griffithii* (Apocynaceae) shows in vitro antileishmanial activity with an $IC_{50} < 25$ μg/mL against *L. donovani* promastigotes. Gabunine (44), a bis-indole alkaloid obtained from stem bark of *Peschiera van heurkii* (Apocynaceae), exhibits in vitro activity with an IC_{50} 25 μg/mL against *L. amazonensis* amastigotes [79].

The indole alkaloids, ramiflorines-A (45) and -B (46), isolated from the stem bark of *Aspidosperma ramiflorum* (Apocynaceae), exhibit significant activity against *L. amazonen*sis with LD_{50} values of 16.3 ± 1.6 μg/mL and 4.9 ± 0.9 μg/mL, respectively, using pentamidine as standard drug (LD_{50} = 10.0 μg/mL) [80].

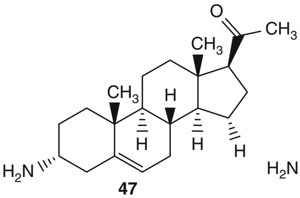
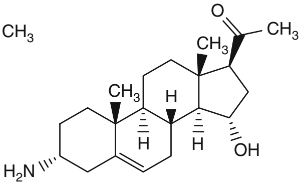
9.8 Steroidal Alkaloids

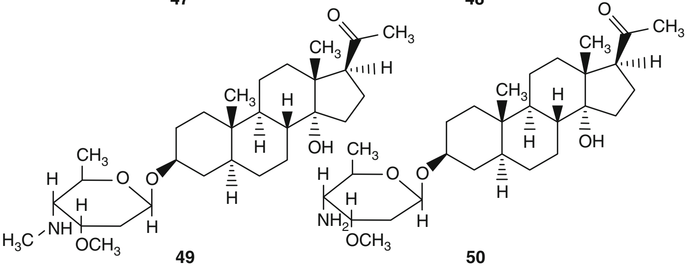
Among the alkaloids, holamine (47), 15-α-hydroxyholamine (48), holacurtine (49), and *N*-desmethylholacurtine (50), obtained from *Holarrhena curtisii* (Apocynaceae), the metabolite 47 exhibits strongest activity against *L. donovani* (1.56 > IC_{50} > 0.39 μg/mL) in compared to 48, 49, and 50 (6.25 > IC_{50} > 1.56 μg/mL) [81].



47



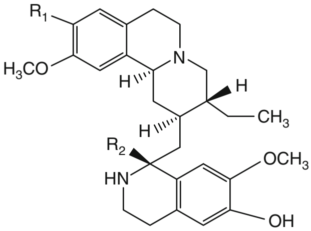
48



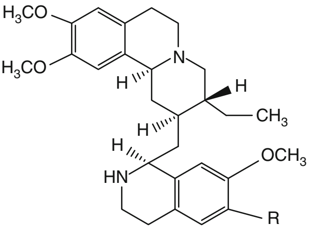
49 **50**

9.9 Benzoquinolizidine Alkaloids

Klugine (51), cephaeline (52), isocephaeline (53), and emetine (54), demonstrating significant leishmanicidal activity against *L. donovani*, have been isolated from *Psychotria klugii* (Rubiaceae). Among these metabolites, the compound 51 (IC_{50} of 0.40 μg/mL) and 53 (IC_{50} 0.45 μg/mL) exhibit <13- and <15-fold less potent activity in compared to 52, while compound 52 with IC_{50} of 0.03 μg/mL demonstrates >20- and >5-fold more in vitro activity against *L. donovani* when compared to pentamidine and amphotericin B, respectively. The alkaloid 54 exhibits activity against *L. donovani* with an IC_{50} value 0.03 μg/mL, however, produces toxicity in treatment of CL caused by *L. major* [82, 83].



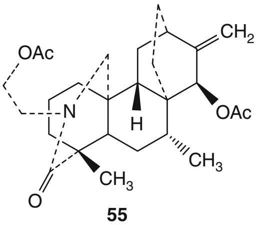
51 R_1 = OH; R_2 = OH
52 R_1 = OCH_3; R_2 = H



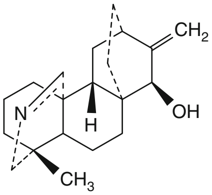
53 R = OCH_3
54 R = OH

9.10 Diterpene Alkaloids

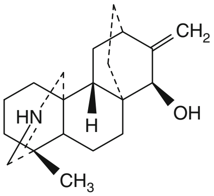
The alkaloids 15,22-*O*-diacetyl-19-oxo-dihydroatisine (55), azitine (56), and isoazitine (57), isolated from *Aconitum*, *Delphinium*, and *Consolida* species, show significant leishmanicidal activities. The metabolite 57 exhibits strongest activity against promastigotes of *L. infantum* with IC_{50} values 44.6, 32.3, and 24.6 μM at 24, 48, and 72 h of culture, respectively. The compound 56 and 55 with IC_{50} values of 33.7 and 27.9 μM at 72 h of culture, respectively, exhibit activity against promastigotes of *L. infantum* [84].



55



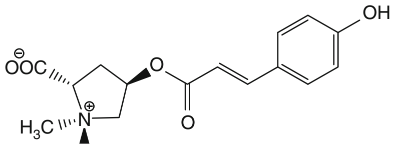
56



57

9.11 Pyrrolidinium Alkaloids

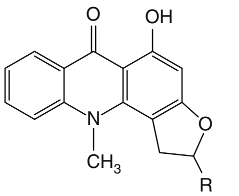
The pyrrolidinium alkaloid (2*S*,4*R*)-2-carboxy-4-(*E*)-*p*-coumaroyloxy-1,1-dimethylpyrrolidinium inner salt (58), isolated from *Phlomis brunneogaleata* (Lamiaceae), display activity with an IC_{50} of 9.1 μg/mL against axenic amastigotes of *L. donovani* [85].



58

9.12 Acridone Alkaloids

The rhodesiacridone (59) and gravacridonediol (60) isolated from *Thamnosma rhodesica* (Rutaceae) exhibit 69 % and 46 % inhibition at 10 μM concentration, respectively, against promastigotes of *L. major*. The compounds also display activity against *L. major* amastigotes and cause over 90 % and 50 % inhibition at 10 and 1 μM concentration, respectively [86].



59 R = $C(OH)(CH_2OH)COCH_3$
60 R = $C(OH)(CH_3)CH_2OH$

9.13 *β*-Carboline Alkaloids

The harmaline (61), isolated from *Peganum harmala* (Nitrariaceae), exhibits amastigote-specific activity (IC_{50} of 1.16 μM). Harmine (62) isolated from same plant species reduces spleen parasite load by approximately 40, 60, 70, and 80% in free, liposomal, niosomal, and nanoparticular forms, respectively, in mice model [87].

Canthin-6-one (63) and 5-methoxycanthin-6-one (64) occurring in plant species of Rutaceae and Simaroubaceae demonstrate in vivo activity against *L. amazonensis* in BALB/c mice model [88]. *N*-hydroxyannomontine (65) and annomontine (66) isolated from *Annona foetida* (Annonaceae) show efficient leishmanicidal potentials. The SAR studies suggest that the metabolite 66 (IC_{50} = 34.8 μM) displays 6 times more activity compared to 65 against *L. braziliensis* promastigotes. The compound 65 also exhibits activity against promastigotes of *L. guyanensis* while 66 remain inactive [68].

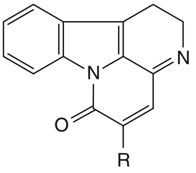
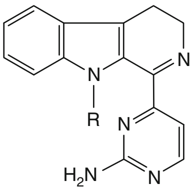
62 R = CH_3



63 R = H
64 R = OCH_3



65 R = OH
66 R = H

9.14 Alkaloids from Marine Sources

Many marine sponges, e.g., *Amphimedon viridis*, *Acanthostrongylophora* species, *Neopetrosia* species, *Plakortis angulospiculatus*, and *Pachymatisma johnstonii*, serve as rich sources of alkaloids with significant antileishmanial potentials [89]. Renieramycin A (67) isolated from *Neopetrosia* species is a La/egfp (expressing enhanced green fluorescent protein) inhibitor that shows efficient antileishmanial activity against *L. amazonensis* with IC_{50} 0.2 μg/mL [90].

Araguspongin C (68), isolated from a marine sponge *Haliclona exigua*, displays leishmanicidal activity against promastigotes as well as amastigotes at 100 µg/mL concentrations [91].

Among the ciliatamides A-C (69–71) isolated from *Aaptos ciliata*, the peptide 69 and 70 at 10.0 µg/mL concentrations inhibit 50 % growth of *L. major* promastigotes. The lipopeptides, almiramides A-C (72–74) isolated from cyanobacterium *Lyngbya majuscule*, exhibit significant in vitro antileishmanial activity against *L. donovani*. The SAR studies among these peptides suggest that 73 and 74 exhibit strong activity against *L. donovani* with EC_{50} values of 2.4 and 1.9 µM, respectively. The metabolites 73 and 74 also display weak cytotoxicity to mammalian Vero cells at 52.3 and 33.1 µM concentrations, respectively [92]. Dragonamide A (75), E (76) and herbamide B (77), isolated from same cyanobacterium strain, exhibit in vitro activity against *L. donovani* with EC_{50} values of 6.5, 5.1 and 5.9 µM, respectively [93].

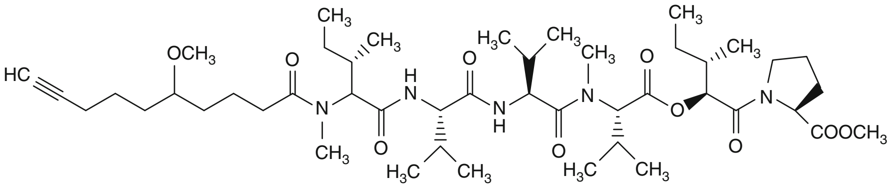
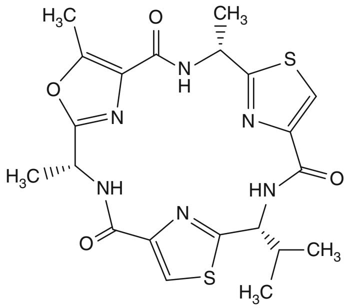
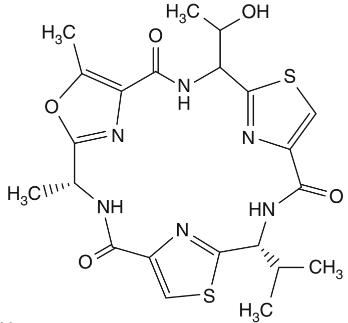
Viridamide A (78) isolated from *Oscillatoria nigroviridis* shows activity against *L. mexicana* with EC_{50} of 1.5 μM [94]. Venturamides A (79) and B (80) obtained from cyanobacterium *Oscillatoria* species exhibit activity against *L. donovani* with $EC_{50} > 19.0$ μM. Valinomycin (81), a dodecadepsipeptide isolated from *Streptomyces* strains, exhibits activity against promastigotes of *L. major* with $EC_{50} <$ 0.11 μM but at the same time shows cytotoxicity to 293 T kidney epithelial cells and J774.1 macrophages [95].



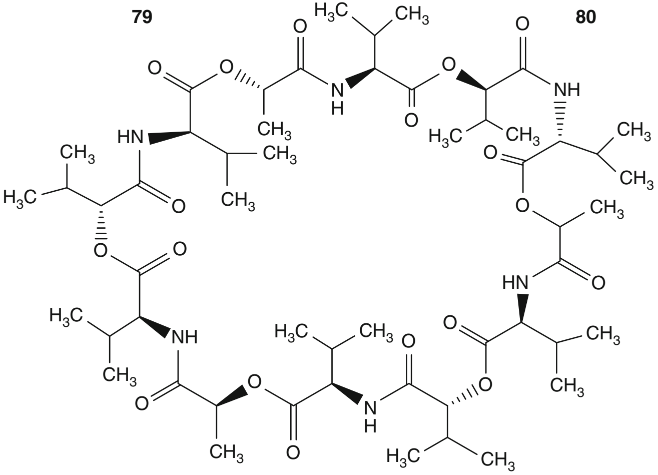
78



79



80



81

Manzamine-type alkaloids, namely, manzamine J (82), manzamines A (83), manzamine A *N*-oxide (84), (+)-8-hydroxymanzamine A (85), manzamine E (86), 6-hydroxymanzamine E (87), manzamine F (88), and ircinol A (89), isolated from a common Indonesian sponge of the genus *Acanthostrongylophora* show significant in vitro antileishmanial activity against *L. donovani* [96]. Comparison of antileishmanial activity among 83 and 82 suggested that the bond between N-27 and C-34 appears to be crucial for the leishmanicidal effect and provides valuable insight into the structural moieties required for activity against *Leishmania* parasites. The metabolites 83 and 89 with IC_{50} values of 0.9 µg/mL display excellent activity against parasites of *L. donovani* while 82 with IC_{50} value of 25 µg/mL exhibits lowest activity among all. Likewise, 84, 87, 86, 88, and 85 with IC_{50} values of 1.1, 2.5, 3.8, 4.2, 6.2, respectively, display good to moderate activity against *L. donovani* parasites [96].

10 Future Perspectives

Despite the advances in the parasitological and biochemical researches using various species of *Leishmania*, the treatment options available against leishmaniasis are far from satisfactory. In current situation, development of new drugs to combat leishmaniasis requires increased input from the disciplines of chemistry, pharmacology, toxicology, and pharmaceutics to complement the advances in molecular biology that have been made in the past 21 years. New potential drug targets should be identified with establishment of new methods for the rapid validation and characterization of targets. Instead of the conventional reductionist approach of finding a single drug that hits a single target, the systems biology approach should be followed using multiple compounds that hit multiple targets in different pathways to achieve the desired outcome. Mechanism of drug resistance and interspecies variation in drug susceptibility are also important areas to explore. Drug susceptibility in relation to genetic heterogeneity in *Leishmania* species and strains is another area of interest. Efforts should be made to develop drugs that target well-characterized genes essential for survival of the parasite selectively.

In determining the way forward to the development of plant-based drug candidates against leishmaniasis, the alkaloids as a source of antileishmanial drugs need to be discussed with respect to biochemical differences between protozoa and hosts. Ethnobotanic studies have identified many plants used by the local population in disease-endemic regions that would lead to the identification of new scaffolds for the future synthesis of second-generation compounds with optimized pharmacological profile for the treatment of leishmaniasis. The tremendous chemical diversity present in plants and the promising leads that have already been demonstrated significant against parasitic diseases are needed to be addressed also against *Leishmania* parasites. The development of antileishmanial natural products or their analogs in accordance to the considerations outlined above would have a dramatic positive impact on the treatment of leishmaniasis. A safer, shorter, and cheaper treatment; identification of the most cost-effective surveillance system and control strategies; and suitable vector control approach are some among the important aspects for the control and complete eradication of this deadly disease.

Acknowledgments We are grateful to Professor Vyasji Tripathi, Department of Chemistry, for his useful discussions during preparation of the manuscript. Financial assistance from CSIR, New Delhi, is greatly acknowledged.

Abstract

Berberine is a yellow alkaloid naturally produced by a diversity of plants. It is extracted from the roots, rhizome, and stem bark of several plants. This natural product has been used for centuries in the Chinese medicinal herb. Berberine presents a wide range of pharmacological applications such as antidiabetic, hypolipidemic, antihypertensive, anti-inflammatory, antioxidant, antidepressant, anticancer, antidiarrheal, hepatoprotective, and, above all, antimicrobial. It has been tested clinically in the treatment of oriental sore, diarrhea, trachoma, diabetes mellitus type 2, hypercholesterolemia, and congestive cardiac failure. This alkaloid is also used in the treatment of gastric and inflammatory diseases and more recently is being investigated for its application in neurology, cardiology, and oncology.

Keywords

Alkaloid • berberine • bioavailability • medicine

Abbreviations

AChE	Acetylcholinesterase enzyme
AML	Acute myeloid leukemia
AMPK	Adenosine monophosphate-activated protein kinase
ATP	Adenosine triphosphate
AD	Alzheimer’s disease
Aβ peptide	Amyloid β-peptide
AR	Androgen receptor
ACE	Angiotensin-converting enzyme
ATM	Ataxia-telangiectasia mutated
Bcl-2	B cell lymphoma 2
COX2	Cyclooxygenase-2
ER	Endoplasmic reticulum
ERK1/2	Extracellular signal-regulated kinase1/2
HDL	High-density lipoprotein
HIV	Human immunodeficiency virus
iNOS	Inducible nitric oxide synthase
IC50	Inhibition concentration 50%

LD50	Lethal dose 50
LXR	Liver X receptor α
LDLR	Low-density lipoprotein receptor
MMP	Matrix metalloproteinase
MDR	Multidrug resistance
NF-κB	Nuclear factor-κB
PPAR	Peroxisome proliferator-activated receptor α
PI	Protease inhibitor
SREBPs	Sterol regulatory element-binding protein ()

1 Introduction

Berberine (Fig. 41.1) is an isoquinoline plant alkaloid with a bright yellow color that under ultraviolet light provides a strong yellow fluorescence. It belongs to the protoberberine structural class and represents one of the most natural alkaloids studied [1]. It is extracted from the plant *Coptidis rhizoma*, which has been used for centuries as a traditional Chinese medicinal herb where it was found to have curative properties. Berberine appears in the roots, flowers, shoots, and bark of a number of important medicinal plants like *Berberis* (Berberis aquifolium, Berberis vulgaris, Berberis aristata), *Hydrastis canadensis* (goldenseal), *Coptis chinensis*, *Tinospora cordifolia*, and *Eschscholzia californica* and has been medicinally used in many traditional medical cultures, including Ayurvedic herbal and Chinese herbal medicine. Berberine is an important traditional medicinal herb, which has been effectively used in the treatment of dysentery, diarrhea, stomatitis, throat infections, and hepatitis as folk medicine for a long time in China and other countries [2].

This compound has a wide range of pharmacologic effects, including protective effects on some gastric ulcer [3], treatment of inflammatory [3], cardiovascular or lipid, and glucose-related [4–11] diseases. In addition, berberine possesses antimicrobial activity against some bacterial [12, 13] or fungal infections [14]. Recent evidence has indicated that berberine has also anticancer properties and is currently being used to treat a variety of different diseases or medical disorders like diarrhea, high cholesterol levels, diabetes, and microbial infections such a fungal (*Candida*) or bacterial (*Salmonella*).

2 Pharmacological Applications and Mechanism of Action

2.1 Diabetes

The hypoglycemic effect of berberine was accidentally found in the 1980s in China when it was administered to diabetic patients with diarrhea [15].

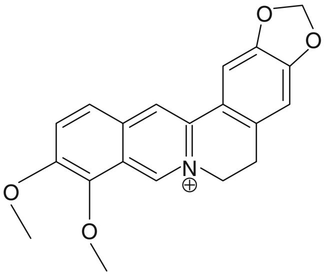

Fig. 41.1 Berberine cation

A large number of studies reported berberine to have antidiabetic properties in vivo in animal models as well as during human clinical trials [16–21], although its mechanism of action has not yet been completely elucidated. There are many studies that describe and propose different mechanisms of action of berberine related to the antidiabetic properties. Berberine is implicated in protection of β-cells (cells responsible for insulin secretion) in pancreas as well as contributing to their regeneration [22, 23]. In addition, it protects liver cells from ER stress, suggesting that berberine is able to exert a glucose-lowering effect in hepatocytes [24]. It regulates insulin secretion from β-cells acting as an agonist of the fatty acid receptor GPR40 [25]. Some works in vitro and in vivo [26, 27] show that berberine treatment results in increased AMPK activity in 3T3-L1 adipocytes and L6 myotubes. The consequence of this regulation is increased translocation of GLUT4 in L6 cells and reduced accumulation of lipid in 3T3-L1 adipocytes. These findings suggest that berberine displays beneficial effects in the treatment of diabetes and obesity at least in part via stimulation of AMPK activity.

On the other hand, berberine is also able to induce the expression of insulin receptors (at least in liver) in a dose-dependent manner, through upregulation of insulin receptor mRNA [28, 29]. This effect was dependent on the presence of insulin. Berberine has also been linked to improving post-receptor signal transduction [24].

The "lipotoxicity" hypothesis indicates that fat-induced hepatic insulin resistance (FIHIR) may play a major role in the pathogenesis of type 2 diabetes, the most common form of diabetes mellitus. It has been suggested that berberine exerts a therapeutic effect on FIHIR in a model of type 2 diabetes in hamsters by modulating the hepatic SREBPs, LXRα, and PPARα transcriptional programs [30].

One study has analyzed the hypoglycemic activity of berberine in comparison with current hypoglycemic drugs like metformin [5]. This study indicated that berberine might be beneficial for the recovery of β-cell function during diabetes or prediabetes.

Some of the studies mentioned above were found in in vitro models and should be interpreted with caution. As described later, berberine has low bioavailability and shows poor absorption, supporting the hypothesis that berberine may exert its antihyperglycemic effect in the intestinal tract before absorption before reaching other organs like pancreas or liver [2]. Recent evidences suggest that the gut microbiota composition is associated with obesity and type 2 diabetes [31], which are closely associated with a low-grade inflammatory state. This study hypothesizes that gut microbiota modulation may be one mechanism of the antidiabetic effect of berberine although the mechanism has not been yet explained.

2.2 Hyperlipidemias

Berberine presents promising lipid-lowering capabilities. It was found to reduce cholesterol in serum of human volunteers by a mechanism different to that of statins [4]. They showed in a rat model that berberine upregulated the LDLR in the liver [4, 32]. Recently Abidi et al. have shown that the root extract of goldenseal, an herbal supplement that contains the alkaloids hydrastine, berberine, berberastine, hydrastinine, tetrahydroberberastine, canadine, and canalidine, had a similar effect in a hamster model [11]. In both studies, the effect of this increase in LDLR was the reduction of LDL-associated cholesterol in blood.

Although there is striking evidence that berberine lowers cholesterol through mechanisms independent of statins, its ability to regulate cholesterol biosynthesis has yet to be considered.

A few studies have demonstrated that berberine increases bile formation and secretion [33–35]. It has also been shown that berberine is able to interact with micelles through hydrophilic and hydrophobic binding sites to form alkaloid–bile salt agglomerates [36, 37]. This process is thought to decrease the capacity of micelles to solubilize cholesterol and thus affects cholesterol absorption. However, the effect of berberine on cholesterol absorption has not been directly studied.

The hypothesis that berberine lowered plasma cholesterol and non-HDL cholesterol levels through a combination of inhibition of cholesterol absorption and stimulation of bile acid synthesis was recently analyzed. This study shows that berberine used in combination with other natural products, plant stanols, which lower cholesterol through a different mechanism, improved the cholesterol-lowering efficacy through a synergistic inhibition on cholesterol absorption.

Although the in vitro and in vivo evidences indicate that berberine possesses cholesterol-lowering potential, a recent work suggested that promotion of foam cell formation by berberine could counterbalance its beneficial effects [38]. By using the model of atherosclerosis in apolipoprotein E-deficient mice, they showed that berberine induced in vivo foam cell formation and promoted atherosclerosis development. Thus, this effect could counterbalance the beneficial effect of this cholesterol-lowering compound on atherosclerosis.

2.3 Inflammatory Disorders

The anti-inflammatory properties of berberine have been used worldwide for the treatment of several inflammatory diseases including rheumatism and lumbago [39, 40]. In some traditional medicines, the use of berberine to reduce fever is also described [39, 41]. Although many studies have shown the anti-inflammatory activity of berberine, the exact mechanism is unknown. However, it seems to be related to the ability of berberine to inhibit prostaglandin biosynthesis in vivo [2, 42]. This effect seems to be mediated by the inhibition of COX2 expression and activity [40, 42]. COX2 activity was not directly inhibited by berberine but through the inhibition of COX2 regulatory proteins.

It has also been suggested that berberine reduces inflammation by inhibiting TNF-α secretion from differentiating adipocytes [40]. Since cyclooxygenases have been implicated in inflammation and carcinogenesis, those in vivo observations may help to explain the anti-inflammatory and anticancer (see below) activity of berberine.

The beneficial effects of berberine as anti-inflammatory agent have also been shown in vivo during endotoxin-induced sepsis. Berberine treatment reduces mortality [43] and prevents heart and lung injury after endotoxin administration in mice [43–45]. The mechanism by which berberine exerts this function seems to be related to the inhibition of TNF-α production and phospholipase A2 activity [45].

2.4 Cardiovascular Disease

Berberine has been used in the treatment of several heart diseases including hypertension and arrhythmia in folk medicine [46, 47]. Several pharmacological studies have shown the beneficial effects of berberine on diverse cardiovascular disorders in animal and human, including prevention of ischemia-induced ventricular tachyarrhythmia, improvement of cardiac contractile function, and reduction of peripheral vascular resistance and blood pressure [48, 49]. Berberine has also positive inotropic, negative chronotropic, antiarrhythmic, vasodilator, and anti-atherosclerosis properties [50].

Data from in vivo studies in animals [51–53] and humans [49, 54] suggest berberine may be useful for patients with severe congestive heart failure.

Berberine is a known vasorelaxant in animals [46, 48] and has been used with success in humans [55], suggesting its possible clinical usefulness in the treatment of arrhythmias. Although the mechanism for berberine's antiarrhythmic effect is not clear, results from a rabbit model indicated it may be related to suppression of delayed afterdepolarization in the ventricular muscle [56]. Another work in rats suggested that, in addition to affecting several other parameters of cardiac performance, berberine has a vasodilatory/hypotensive effect attributable to its potentiation of acetylcholine [48]. The cardiovascular effects of berberine have been attributed to the blockade of delayed rectifier and ATP-sensitive potassium channels and stimulation of Na^+–Ca^{2+} exchanger. This alkaloid is also able to prolong the duration of ventricular action potential. Diverse cellular mechanisms regulated by berberine have been proposed to explain its vasodilator activity. It appears to work on both the endothelium itself and underlying smooth muscle [57]. Other mechanisms proposed involve the angiotensin-converting enzyme and the NO–cGMP system [58] or blockade of the α1-adrenoceptor [59, 60]

Berberine is also able to interfere with platelet function through diverse mechanisms like inhibition of thromboxane synthesis [61], enhancement of thrombolysis (breaking of clots) [2], interaction with α2-adrenoceptor on platelets [62], and inhibition of calcium influx [63].

Finally, berberine has been shown to protect myocytes in a model of ischemia reperfusion [64].

2.5 Gastrointestinal Disorders

In the case of gastric ulcers, berberine has also been shown to have beneficial effects [3]. It was shown that berberine could significantly protect gastric mucosa from damage by ethanol in rats. This effect may be due to reduced expression of iNOS. Thus, berberine may affect nitric oxide production and associated damage by inhibiting iNOS expression in damaged gastric tissue and, ultimately, improve in the healing of ulcers.

Several in vitro works conclude that berberine can ameliorate intestinal epithelial tight junction damage induced by the release of proinflammatory cytokines [65, 66]. This effect has been attributed to the downregulation of the NF-κB and myosin light chain kinase pathway. These findings suggest that this compound may help to restore barrier function in injured intestinal mucosa [65, 66].

Berberine is currently being used to treat gastrointestinal-related medical disorders due to infections including bacterial diarrhea caused by *Vibrio cholerae* and *Escherichia coli* and intestinal parasites. The mechanism of the antidiarrheal activity of berberine has not been described yet. According to the study performed by Eaker et al., berberine significantly inhibits myoelectric activity and transit of the small intestine that appears to be partially mediated by opioid and α-adrenergic receptors, concluding that the antidiarrheal properties of berberine may be mediated, at least in part, by its ability to delay small intestinal transit [67].

2.6 Neurological Disorders

Berberine seems to have antidepressant and neuroprotective effects in several neurodegenerative and neuropsychiatric disorders. It has been reported to modulate neurotransmitters and their receptor systems in the brain. Moreover, some works indicate a beneficial effect of berberine in the treatment of central nervous system-related disorders including Alzheimer's disease, cerebral ischemia, schizophrenia, anxiety, and mental depression [68–71]. Supporting the observed effect of berberine on the central nervous system, Wang et al. showed that berberine can cross the blood–brain barrier and could be transported into the neurons in a concentration- and time-dependent manner [72].

2.7 Cerebral Ischemia

Stroke, known as a cerebral vascular accident (CVA), is the third leading cause of death in industrialized countries and the leading medical cause of acquired adult disability [73], but few effective therapeutic drugs have been used in clinical practice.

Recently, it was reported that berberine protects neurons from ischemic injury in gerbils and mice by reducing N-methyl-D-aspartate (NMDA) receptor 1 activity [69] and by suppressing apoptotic processes [74]. Studies in vitro suggested that this effect was due to inhibition of ROS production and subsequent blockade of the mitochondrial apoptotic pathway [74]. MMPs are responsible for maintaining and remodeling the extracellular matrix, and in addition to these physiological roles, abnormal MMP expression and activity may be involved in the pathophysiology of cerebral disease. However, it is not much known about the effect of berberine on MMPs, which are closely related to ischemic cerebral injury. By using a mouse model of brain ischemia, Hong et al. concluded that berberine may attenuate the delayed hippocampal neuronal cell injury [75] that normally follows transient global cerebral ischemia. Their results suggest that suppression of MMP-9 activity contributes to the protective effect of berberine.

2.8 Alzheimer's Disease

AD is the most common form of dementia in elderly people, becoming one of the most threatening diseases in this population. However, there is no efficient therapeutic agent to combat it. It is not easy to find a single target to treat AD, since its pathogenesis is very complex [76]. Diverse factors seem to be involved in the development of AD including oxidative stress, acetylcholinesterase enzyme (AChE), butyrylcholinesterase (BChE), monoamine oxidase (MAO), and Aβ peptide aggregation [77–82].

New experimental results suggest berberine may have a potential for inhibition and prevention of AD due to the multiple activities that berberine possesses including antioxidant activity, AChE and BChE inhibitory activity, MAO inhibitory activity, and its abilities to reduce Aβ peptide level and to lower cholesterol. Many studies have proved AChE-inhibiting property of berberine [83–85]. AChE is mainly present in the central nervous system and its major role is to catalyze the hydrolysis of the neurotransmitter acetylcholine to choline. This process can return an activated cholinergic neuron to its resting state. The pathogenesis of AD is linked to acetylcholine deficiency in the brain.

The effect of berberine in vivo has been studied in a rat model of AD concluding that intraperitoneal administration of berberine increased the spatial memory of animals by increasing IL1β and iNOS expression in hippocampus [68].

It has also been shown in vitro that berberine reduces the secretion of Aβ peptide by human neuroglioma cells [86]. Since accumulation and aggregation of Aβ peptide seems to be the crucial event in the pathogenesis of AD [87, 88], inhibition of Aβ peptide generation is a promising therapeutic strategy to treat

AD. According to Zu et al., berberine decreases the production of Aβ peptide by inhibiting the expression of BACE via activation of the ERK1/2 pathway. However, the effect of berberine on Aβ peptide accumulation was not shown in vivo until recently. By using a well-established model of AD, the TgCRND8 transgenic mouse, Durairajan et al. showed that berberine ameliorated neuropathology and cognitive impairment in these mice [89]. The mechanism responsible for this effect was studied in vitro and seems to be dependent of the modulation of the PKB/glycogen synthase kinase 3 (gsk3) signaling pathway.

2.9 Anxiety

Peng et al. showed using two different models of experimental anxiety that high doses of berberine (100, 500 mg/kg) have anxiolytic effect, which was similar to that observed with 1 mg/kg diazepam and 2 mg/kg buspirone. They concluded that this effect might be related to the enhancement of turnover rates of monoamines in the brain stem and the reduction of serotonergic system activity. Moreover, berberine was able to reduce serotonergic system activity by regulating the activity of somatodendritic 5-HT1A autoreceptors and postsynaptic 5-HT1A and 5-HT2 receptors [71].

2.10 Schizophrenia

Prolyl oligopeptidase (POP) is a cytosolic serine peptidase that is known to hydrolyze proline-containing peptides at the carboxy terminus [90]. This enzyme has been associated with schizophrenia, bipolar affective disorder, memory loss, depression, and related neuropsychiatric disorders and therefore may be a relevant therapeutic target to treat these disorders. It is known that the activity of POP enzyme is decreased in depression and increased in psychotic conditions, such as mania and schizophrenia. However, current antipsychotic drugs do not affect the function of this enzyme [91]. According to Tarrago et al., berberine inhibits POP in a dose-dependent manner. As berberine is a natural compound that has been safely administered to humans, it is hypothesized that berberine might be used in the treatment of schizophrenia, opening up new perspectives for the treatment of neuropsychiatric diseases. Moreover, berberine also has D2 dopamine receptor antagonistic and D1 dopamine receptor agonistic activity [92], which may also play a role in its action.

2.11 Mental Depression

Depression is a common mental disorder. In vivo experimental evidences suggest that berberine possesses central nervous system activities, particularly the ability to inhibit monoamine oxidase-A, an enzyme involved in the degradation of norepinephrine and serotonin (5-HT) [70]. In this study, the effect of berberine was attributed to the nitric oxide pathway and/or sigma receptors.

During a mouse in vivo study, berberine was found to enhance the inhibitory neural pathway and decrease morphine dependence [93]. In addition, it modulated locomotor activity and induced hypnosis.

2.12 Infectious Diseases

Berberine possesses antimicrobial activity against bacterial [13, 94–96], fungal [97], protozoan [98, 99], and viral [100–102] infections. In vitro studies have shown that berberine is effective against *Entamoeba histolytica*, *Giardia lamblia*, *Trichomonas vaginalis* [98, 103], *Candida* spp. [97, 104], *Plasmodium falciparum* [99], *Staphylococcus aureus* [95, 105, 106], influenza virus [100], human immunodeficiency virus (HIV) [107], human cytomegalovirus [101], herpes simplex virus, [102] *Chlamydia trachomatis* [105], *Helicobacter pylori* [96], and *Leishmania donovani* [99].

However, few studies have analyzed the in vivo relevance of these findings. Overall, most of the data suggest that berberine is a weak antimicrobial per se, but its activity is strongly synergized by other drugs.

One of the major problems in treating bacterial and fungal infections is the acquisition of the so-called MDR. The weak antimicrobial activity of berberine is mostly due to the MDR pump present in the membrane of the microorganisms, and combination with MDR inhibitors highly enhances the antimicrobial activity of berberine. Ball et al. showed that covalently linking berberine to INF-55, an inhibitor of major facilitator MDRs, results in a highly effective antimicrobial compound that readily accumulates in bacteria [108]. In addition, it has been shown that its activity is strongly synergized by 5′-methoxyhydnocarpin, an inhibitor of the bacterial multidrug resistance pump (MDR). Since gram-positive bacteria are the main targets of plant-derived MDR inhibitors, this may explain why so few of these bacteria are plant pathogens. Plants produce compounds structurally similar to berberine that intercalate into the DNA helix. Since berberine also binds to DNA irrespective of its sequence [109–113], this compound fulfills the requirements for a highly effective antibacterial agent since it is unaffected by mutations.

There are several other examples in which berberine is combined with other substances to potentiate its antibacterial activity. Flavones, chrysosplenol-D, and chrysoplenetin from *Artemisia annua L. (Asteraceae)*, which possess very weak antibacterial action by themselves, produce potent combinations with berberine resulting in very effective inhibition of *Staphylococcus aureus* growth. The combination of amphotericin B and berberine can reduce by approximately 75 % the amphotericin B dose in the treatment of candidiasis in mice, implying that berberine indeed has synergy with amphotericin B against *C. albicans* [104]. Another example is methicillin-resistant *Staphylococcus aureus* (MRSA) bacteria, which are responsible for substantial morbidity and mortality in hospitals. According to Yu et al., berberine is able to restore the effectiveness of β-lactam antibiotics against MDR strains of *Staphylococcus aureus* (MRSA) and inhibit the MRSA adhesion and intracellular invasion in HGFs (human gingival fibroblasts) [95]. However, the in vivo relevance of this finding is not clear. In chloroquine-resistant malaria, the combination of pyrimethamine and berberine gives the best results in clearing the parasite and is more effective than both tetracycline and co-trimoxazole [114]. Berberine also inhibits *T. vaginalis* and its effect is comparable to metronidazole as regards potency [103]. In the mechanistic aspect, one study has shown that berberine has potent inhibitory activity against sortase A (SrtA) and sortase B. The inhibition of sortase enzymes results in a marked reduction in the virulence and infection potential of *S. aureus*, so it may be an important mechanism in the antibacterial activity of berberine [106].

A clinical study also showed the beneficial effects of the administration of aqueous berberine for the treatment of *Chlamydia trachomatis* infection [115]. It was found that the conjunctival scrapings of patients receiving the berberine chloride eye drops were negative for *C. trachomatis* and there were no relapses, even 1 year after treatment. The results suggested that berberine chloride had no direct antichlamydial properties, but it seemed to cure the infection by stimulating some protective mechanism in the host.

Several studies have analyzed the efficacy of berberine analogs and/or derivatives as antimicrobial agents [116–118]. These studies suggest that the presence of lipophilic substituents with moderate sizes contribute to the optimal antimicrobial activity [116]. In addition, the replacement of methoxyl groups at different positions of the ring by a methylenedioxy group results in increased antibacterial activity [117]. Finally, it was found that alkyl-substituted analogs of berberine are more active than berberine against two strains of *Staphylococcus aureus* and fungal infections [118].

There are some studies where the ability of berberine to inhibit the HIV-I has been evaluated [107, 119]. Zha et al. identified a key cellular mechanism underlying the protective effect of berberine on HIV PI-induced inflammatory response in macrophages. Modulation of the endoplasmic reticulum (ER) stress response represents a potential therapeutic target for various inflammatory diseases and metabolic syndromes, including HIV PI-associated atherosclerosis. However, in vivo and clinical studies are needed to further clarify the putative application of berberine in anti-HIV therapy.

2.13 Anticancer Properties

Different chemotherapeutic drugs currently used to treat cancer patients are alkaloids like vincristine and vinblastine or taxanes paclitaxel and docetaxel. Although berberine is still not used in a clinical setting, it also possesses antitumoral activity against a number of tumor types. Indeed, a study using 60 tumor cell lines showed that the IC50 value for berberine was similar to that of other alkaloids used in chemotherapy like paclitaxel or vinblastine [120]. Moreover, in contrast to other antitumoral drugs, the secondary toxicity of berberine is very low as explained in

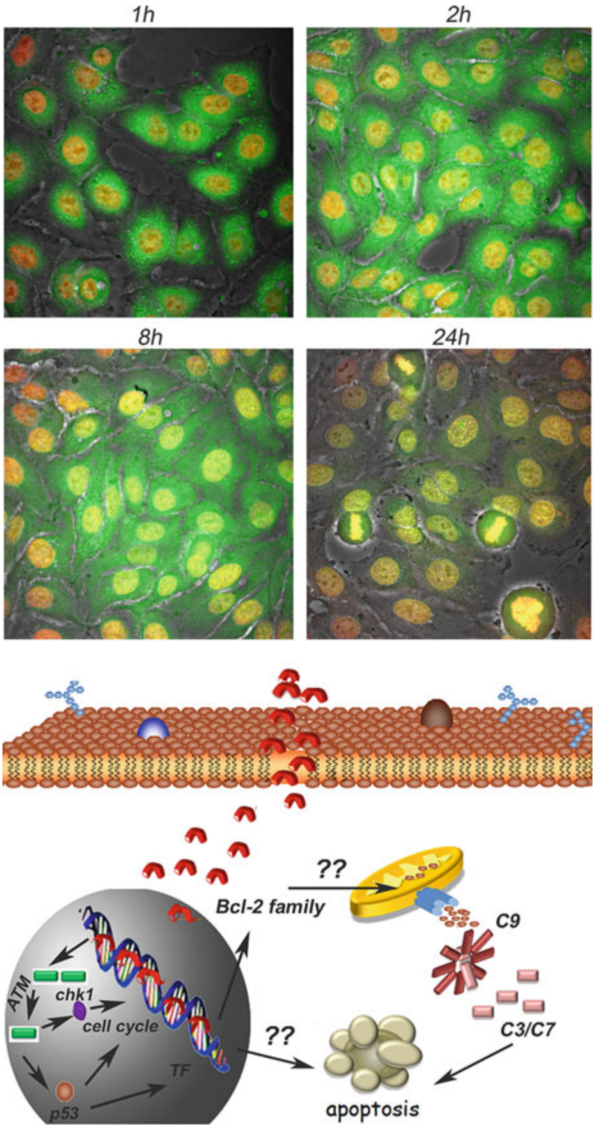

Fig. 41.2 Cellular location and schematic representation of the apoptotic pathways activated by Berberine in tumor cells. *Upper panels*, *berberine accumulates in the nucleus of A549 lung carcinoma cell line*. Cells were incubated with berberine (50 μM) for the indicated times and, subsequently, nuclei were stained with the fluorescent dye DRAQ5. Images were taken in a Leica TCS SP2 confocal microscope. Pictures correspond to the central section in a confocal z-stack acquired sequentially. Green: berberine; Red: DRAQ5; Grey: DIC image. *Lower panel*, *berberine activates in vitro the intrinsic cell death pathway*. Berberine-induced apoptosis is initiated after DNA damage by cell cycle arrest in G0/G1 mediated by the ATM/p53 pathway. In addition, berberine is able to block cell cycle in G2M by activation the ATM/Chk1 p53-independent pathway in some tumor cell types. Activation of these pathways leads to transcription (TF) of

next sections. Cancer cells sensitive to berberine include hematological malignancies or solid carcinomas as explained below in more detail [121]. Most of the antitumor activity is based on the in vitro evidence on the ability of berberine to affect several steps of tumor development including cell proliferation, cell death, and invasiveness [122, 123]. However, there are increasing evidences suggesting that berberine is also able to inhibit tumor growth in vivo [122]. In addition, berberine enhances the efficiency of chemotherapy or radiotherapy effects. During the next sections, we will summarize the ability of berberine alone or in combination with other treatments to induce tumor cell death or to inhibit tumor cell invasiveness.

2.14 Regulation of Cell Death and Proliferation

Cell death induced by berberine in vitro mostly exhibits a typical apoptotic phenotype, including the activation of a family of proteases, the caspases, and cytochrome c release from mitochondria. Berberine has been shown to activate the two major proapoptotic mechanisms known as extrinsic and intrinsic pathways. Intrinsic (also known as mitochondrial) pathway is regulated by the members of the Bcl-2 family. This family comprises proapoptotic (Bak, Bax, Bid, Bim, Puma, etc.) or antiapoptotic (Bcl-2, Bcl-XL, Mcl-1, A1, etc.) proteins [124]. Activation and/or inhibition of proapoptotic or antiapoptotic members, respectively, induces the permeabilization of the mitochondrial outer membrane and, subsequently, the release of apoptogenic factors like cytochrome c, serine protease Htr/Omi, endonuclease G, SMAC/Diablo, or apoptosis-inducing factor (AIF). Cytochrome c together with Apaf-1 and caspase 9 forms a complex known as apoptosome that activates caspase 3 by proteolysis. Active caspase 3 is the ultimate effector molecule, responsible for cell dismantling including chromatin condensation and DNA fragmentation. The intrinsic pathway is activated at different levels like cell cycle arrest, disruption of antiapoptotic/proapoptotic ratio of Bcl-2 family members, DNA damage, and subsequent activation of the p53 repairing factor or proteasome inhibition. The extrinsic (also known as death receptor) pathway is activated after a specific ligand (death ligand, i.e., FasL) binds to its receptor (death receptor, i.e., Fas) on the cell membrane [125]. This binding activates a proteolytic signaling pathway initiated by caspase-8 that induces the direct or mitochondrial-mediated caspase 3 activation and the subsequent apoptotic cell death.

Berberine activates in vitro the intrinsic cell death pathway in several mouse and human tumor cell lines. Most of the studies suggest that berberine-induced

Fig. 41.2 (continued) several pro-apoptotic genes, including members of the Bcl-2 family. Berberine promotes the release of cytochrome c from mitochondria to the cytosol and the formation of the apoptosome, inducing the activation of caspase-9 and, subsequently, of the effector caspase-3 and caspase-7. However, it is not clear the molecular mechanism that links nuclear damage with activation of the mitochondrial pathway apoptosis is initiated after DNA damage by cell cycle arrest in G0/G1 mediated by the ATM/p53 pathway [122, 126–129]. However, it has been recently showed that cell cycle arrest in G2M induced by berberine is mediated by the ATM/Chk1 p53-independent pathway in prostate cancer cells [130] (Fig. 41.2). Indeed, berberine is a cationic molecule able to interact with DNA in cell-free systems as well as in intact cells (Fig. 41.2) [110, 112–114]. Although apoptosis induced by berberine seems to be caspase dependent in most cell types [127, 131–133], the molecular mechanism/s that links cell death after DNA damage and cell cycle arrest with caspase activation, overall the role of the different members of the Bcl-2 family, is not known. Indeed, all evidences suggesting the involvement of Bcl-2 family members during cell death induced by berberine are indirect, and it has not been shown yet how overexpression or inhibition of those proteins affects this process. Thus, a formal proof of the implication of these proteins in cell death induced by berberine is still pending.

Two studies have proposed that berberine induces cell death by the extrinsic pathway in human colon carcinoma [134] and human hepatoma [131] cell lines; however, direct evidences of this mechanism were lacking. In neither of those studies, the role of Fas or FasL was tested if blocking the ligand or receptor could prevent cell death induction by berberine.

2.15 Solid Carcinomas

Berberine is active against diverse types of solid carcinomas when tested in vitro, including tongue, liver, lung, thyroid, prostate, breast, brain, skin, esophageal, oral, or colon carcinomas [133–143].

Most interestingly, berberine also prevents the development of solid carcinomas in vivo in both tumor xeno- or syngeneic transplants and carcinogen-induced tumorigenesis. Regarding models of tumor xenotransplants in immunocompromised mice, it has been shown that berberine inhibits the growth of different human lung [127] as well as human prostate cancer cell lines [144]. In both cases, p53-positive cell lines were more sensitive to berberine than p53-negative cell lines, suggesting a crucial role of this protein in the antitumoral effect of this alkaloid in vivo. Concerning human prostate cancer cells, it was later shown that berberine reduced the expression of the androgen receptor in tumor cells in vivo, indicating that it could interfere with pro-survival function of this receptor during the different stages of prostate cancer [145]. Finally, it was also showed that administration of berberine inhibited the growth of human tongue cancer SCC-4 cells, suggesting a beneficial effect of berberine-containing plants in the prevention of this type of neoplasm [135].

Strikingly, although berberine inhibited the growth of human Lewis lung carcinoma implanted subcutaneously in nude mice [127], it did not affect the growth of a mouse Lewis lung carcinoma after orthotopic implantation in lung parenchyma [141]. These apparent contradictory results could be due to the usage of different lung cell lines, the site of implantation, or the usage of xeno- versus syngeneic transplant models. Thus, the interpretation of results coming from human tumor xenotransplant models must be made with caution.

A beneficial effect of berberine has been also described for chemical-induced carcinomas. In a mouse model of two-stage chemical-induced carcinogenesis, it was found that berberine inhibited the enhancer effect of teleocidin in skin tumors induced by 7,12-dimethylbenz[a]anthracene (DMBA) [146]. This effect was attributed to the ability of berberine to inhibit 32Pi incorporation into phospholipids of cell membrane and hexose transport mediated by teleocidin. Supporting the efficacy of berberine against DMBA-induced tumorigenesis, using another tumor model, an independent group showed that berberine also prevented oral carcinogenesis induced by this chemical in mice [147]. Berberine was also active against methylcholanthrene- or N-nitrosodiethylamine-induced carcinogenesis in mice and rats [148].

2.16 Hematologic Malignancies

As well as in solid carcinomas, berberine is also able to kill diverse types of hematologic tumor cell lines in vitro such as acute myeloid leukemias, acute lymphocytic leukemias, and some types of non-Hodgkin lymphomas [111–114, 122, 129, 139, 149]. Despite that the first analyses about the antitumoral activity of berberine were conducted in leukemic cells [112, 114], at present there are much fewer studies about the efficacy of berberine against hematologic neoplasias than against solid carcinomas. Specifically, only one study has analyzed the activity of berberine against cells from patients with AML [150]. The results showed that berberine was able to inhibit migration of AML cells by reducing the levels of stromal-derived factor-1 secreted by the bone marrow stromal cells from AML patients. The same effect was observed against cancer stem cells isolated from those patients.

A number of studies have analyzed the efficacy of berberine in vivo against transplanted hematologic tumor cell lines as well as during virus-induced leukemia. Specifically, it has been showed that berberine has antitumoral potential in vivo against transplanted mouse acute lymphocytic leukemia P388 [112] and acute myeloid leukemia WEHI-3 [151]. In addition, this alkaloid was able to inhibit the progression of erythroleukemia induced by mouse retrovirus, Friend, in immunocompetent mice [152].

2.17 Combined Therapies

One of the main problems during cancer management is the presence and/or apparition of resistant tumor cells due to mutations in the molecule/pathway targeted by the selected therapy [153]. During the last years, the combination of two or more treatment modalities (i.e., combination of different drugs or combination of drugs with radiotherapy) has emerged as a promising tool to overcome tumor resistance. Berberine has also been shown to enhance the antitumoral effect of chemo- and radiotherapy [122, 154].

Esophageal cancer has a very bad prognosis due to the low efficacy of current treatments. It was recently found that berberine enhances the sensitivity of human esophageal squamous cell carcinoma lines to radiotherapy [140]. This effect was related to the downregulation of the repair protein RAD51. Although this protein was present in specimens from patients with esophageal carcinoma, its role in disease pathogenesis is not clear. Other tumor cell lines that show enhanced susceptibility to radiotherapy in the presence of berberine are lung carcinoma [155], hepatoma [156], and glioma cells [157].

Berberine also enhances the cytotoxicity of chemotherapeutic drugs against tumor cells, including cisplatin [158], evodiamine [159], arsenic trioxide [160], 5-fluorouracil [154], doxorubicin [154], TNF-a [154], TRAIL [161], or nitrosourea [143]. It has been suggested that this effect was due to the suppression of antiapoptotic gene products by inhibiting the activity of the transcription factor NF-kB [154]. This transcription factor that is constitutively expressed in several tumor cell types is regulated by the upstream IkB (inhibitory subunit of NF-kB) kinase (IKK). IKK phosphorylates IkB, promoting nuclear translocation of active NF-kB and transcription of target genes. Berberine was able to inhibit IKK and, thus, prevented IkB phosphorylation and NF-kB activation.

2.18 Inhibition of Tumor Invasiveness

Apart from its cytotoxic potential, berberine is able to inhibit tumor cell motility and invasiveness in vitro at noncytotoxic doses in a number of human tumor cell lines like lung, melanoma, liver, breast, gastric, tongue, or nasopharyngeal carcinoma cell lines [123, 162–167]. In most cell types, inhibition of cell invasiveness by berberine was dependent on the downregulation of matrix metalloproteinase expression by interfering with diverse signaling pathways like those regulated by ERK, PI3K, or Rho GTPases [163–167]. Moreover, the finding that berberine is able to directly inhibit the activity of the transcription factor NF-kB [154] suggests that this alkaloid may reduce the expression of matrix metalloproteinases by passing the above-mentioned upstream signaling pathways.

Concerning the ability of berberine to interfere with tumor cell invasiveness in vivo, it was shown that this alkaloid inhibited the formation of lung metastasis after inoculation of mouse melanoma B16 cells [167]. In addition, it was found that berberine inhibited the apparition of mediastinal lymph node metastasis after orthotopic implantation of mouse Lewis lung carcinoma cells in lung parenchyma [141]. At the berberine dose tested, it was not observed to have any effect on the growth of the tumor at the site of implantation. However, the combination of both camptothecin-11 and berberine was able to inhibit both tumor growth and metastasis. This promising result suggests the usage of berberine as antimetastatic drug in combination with other cytotoxic antitumoral agents.

2.19 Other Applications

Berberine has also been employed as an analgesic for the treatment of neurological conditions. Berberine has been shown to ameliorate tolerance inducement to some narcotics like morphine [168].

Berberine has been shown to suppress lipid synthesis from sebaceous glands, and thus, it has potential to be used as a topical agent in skin-related infections [169]. In addition, it has surfactant activity, enhancing skin permeability to polar drugs [170]. However, it should be noted that when used on skin, berberine has the potential to form free radicals induced by sunlight [171].

3 Bioavailability and Metabolism

It is widely accepted in the pharmaceutical industry that the distribution, metabolism, and efficacy of many drugs can be modulated depending on their affinity to serum albumin [172]. Hu et al. [173] investigated the association of human serum albumin (HSA) with berberine. It was found that an interaction occurred at the IIA domain of HSA. Since other alkaloid drugs may share with berberine binding sites in HSA, this finding may help to design therapeutic drugs with reduced binding constant to HSA and, thus, more efficient than current ones.

As described above, berberine has a wide spectrum of pharmacological actions, but the poor bioavailability may limit its clinical use. According to Pan et al., berberine is hardly absorbed in the intestine (less than 5 % in 2.5 h) [174]. Some studies [175, 176] suggest that the poor intestinal absorption is due to the negative effect of intestinal P-glycoprotein on this process. If true, P-glycoprotein inhibitors could be of therapeutic value by improving berberine bioavailability. Some works have been directed to improve berberine bioavailability showing that the use of a water-soluble form of vitamin E, called “D-α-tocopheryl polyethylene glycol 1,000 succinate” (TPGS), enhances the bioavailability of berberine [177–179]. For example, 2.5 % TPGS content of the solution enhanced berberine absorption by 1.9-fold [178]. This effect was attributed to the inhibition of P-glycoprotein efflux [179]. Another study concludes that sodium caprate could significantly promote the absorption of berberine in intestine and enhance its antidiabetic effect without any serious mucosal damage [180].

4 Secondary Toxicity

The most promising finding concerning the use of berberine as a therapeutic agent, especially in cancer, is its low secondary toxicity. One of the major problems of drugs used in chemotherapy is the secondary toxic effect against healthy tissues

Table 41.1 Clinical trial

Study	Status	Condition	Interventions
Polycystic Ovary Syndrome (PCOS): Effect Of Letrozole and Berberine	Recruiting	Polycystic ovary syndrome	Drug: letrozole–berberine Drug: letrozole Drug: berberine
Role of Pioglitazone and Berberine in Treatment of Non-Alcoholic Fatty Liver Disease	Completed	Nonalcoholic fatty liver disease	Lifestyle intervention Drug: pioglitazone Drug: berberine
Effect of Berberine on Hormonal and Metabolic Features in Obese Women With Polycystic Ovary Syndrome (PCOS)	Active, not recruiting	Polycystic ovary syndrome Obesity	Drug: berberine Drug: placebo
Efficacy and Safety of Berberine in the Treatment of Diabetes With Dyslipidemia	Completed	Diabetes mellitus, type 2 Metabolic syndrome	Drug: berberine
Therapeutic Effects of Berberine in Patients With Type 2 Diabetes	Completed	Type 2 diabetes	Drug: berberine Drug: metformin
Armolipid Plus and Metabolic Syndrome	Completed	Metabolic syndrome	Dietary supplement: Armolipid Plus
The Role of a Combination of Nutraceuticals in the Control of Cardiovascular Risk	Active, not recruiting	Metabolic syndrome	Drug: Armolipid Prev
Combined Effects of Bioactive Compounds in Lipid Profile	Recruiting	Hyperlipidemia low-density-lipoprotein-type elevated triglycerides	Dietary supplement: Armolipid Plus Dietary supplement: placebo
Effects of Armolipid Plus on Cholesterol Levels and Endothelial Function	Completed	Hyperlipidemia endothelial dysfunction	Dietary supplement: mixture of berberine, policosanol, red yeast, placebo
Ezetimibe Versus Nutraceuticals in Statin-intolerant Patients	Not yet recruiting	Coronary artery disease	Drug: ezetimibe Drug: nutraceuticals

and/or cells. This is due in part to the low number of specific targets in transformed cells. Indeed, most of the drugs target processes in cancer cells, which are still ongoing in normal cells and tissues.

In vitro and in vivo evidences suggest that berberine is more targeted than other chemotherapeutic drugs. It has been reported that naive or activated T cells are resistant to berberine [181]. Furthermore, it has been shown that berberine is able to protect thymocytes (precursors of T cells) from cell death induced by dexamethasone, etoposide, or camptothecin [182]. Finally, it has been reported that macrophages are not only resistant to berberine-induced cell death but also able to get activated and produce immune-stimulatory cytokines like IFNgamma and IL12 in vitro [183] and in vivo [184].

Concerning other organs and/or cell types, recently it was reported that berberine killed hepatoma cells without affecting the viability of normal hepatocytes. In addition, berberine shows much higher specificity for oral-derived tumor cells than for normal oral tissue [185]. Finally, it has been showed that berberine inhibits pathogenic forms of the androgen receptor in prostate cancer cells without affecting its function in normal cells and the morphology of normal prostates [186].

Apart from the low toxicity of berberine against normal tissues, it has also been showed that this molecule exerts a protective effect on lung tissue during irradiation [187].

Several groups have studied the pharmacokinetics and toxicity of berberine in mouse and rat models in vivo. Berberine toxicity is low in rat and mouse models when tested by histopathological criteria and with relatively high LD50 (dose at which 50 % of animals die) values [123]. The results show that the lethal dose 50 (LD50, amount of a compound required to kill 50 % of the treated animals) in rats is 205 mg/kg when given intraperitoneally and that it was well tolerated in doses of 100 mg/kg when given orally to rats [188]. An independent study found that the LD50 of berberine in mice after intravenous or intraperitoneal administration was 9 mg/kg and 57 mg/kg, respectively [189]. This group did not find any LD50 for berberine after oral intragastric administration. However, as indicated in the previous section, low amounts of berberine enter the circulation by this way. Of note, during a 3-month trial with patients suffering from type 2 diabetes, it was found that therapeutic doses of berberine did not affect liver or kidney and only produced transient gastrointestinal effects on around 35 % of the patients [190]. Janhke et al. published in 2006 for first time the developmental toxicity evaluation of berberine in rats and mice and no fetal adverse effects were noted [191].

Although berberine has not been reported to be mutagenic, this compound is able to intercalate into the DNA double helix [192, 193]. Thus, it is possible that this binding may lead to mutations in the genome of exposed cells. Some studies have shown than non-transformed cells take up much lower levels of berberine than do tumor cells [194]. However, at present the basis of this phenomenon is not understood and needs to be investigated.

The most common side effects include constipation, laxative, anaphylaxis, and other skin allergies such as dermatitis and rashes, and high dosages may cause respiratory and circulatory system problems [123]. Furthermore, berberine could displace bilirubin from serum-binding proteins, causing jaundice, kernicterus, and brain damage in infants [195–197]. Therefore, exposure of pregnant women to berberine is not recommended because it may lead to jaundice and kernicterus in the fetus [196].

5 Clinical Trials

Clinical trials have been conducted using berberine suggesting that this compound may be beneficial in the treatment of trachomas (eye infections), bacterial diarrhea, and leishmaniasis (parasitic disease). Berberine has been shown to be safe in the majority of clinical trials. However, there is a potential for interaction between berberine and many prescription medications, and berberine should not be used by pregnant or breastfeeding women, due to potential for adverse effects (Table 41.1).

6 Conclusions

Berberine, a natural alkaloid used for centuries in folk medicine, shows proven as well as promising therapeutic effects against a number of disorders including infection, cancer, inflammation, diabetes, or cardiovascular diseases. The versatility of this alkaloid to treat this great variety of apparently nonrelated affections may be due to the ability of berberine to target key molecular pathways including NF-kB, ROS, iNOS, COX, or AMPK. The low toxicity of berberine as well as its synergistic and protective effects in combination with other drugs becomes a promising molecule for the treatment of diseases with serious drug-associated sequelae like cancer. A weakness of berberine is its low bioavailability during in vivo administration. However, several efforts have been developed during last years in order to solve these problems and ensure a targeted therapeutic activity of berberine.

Abstract

Neurodegenerative diseases include a range of disorders that involve dysfunction of the central nervous system, due to degeneration of neurons and associated pathological processes. These diseases include Lewy body dementia, vascular dementia, Huntington's, Parkinson's (PD), and Alzheimer's diseases (AD). Treatment strategies are limited and frequently only provide symptomatic relief through the use of drugs that modulate neurotransmitter disturbances. Of the five drugs developed to treat symptoms of AD, the most common form of dementia, two are derived from plant alkaloids: galantamine, originally from *Galanthus*

woronowii, and rivastigmine, which is based on the chemical structure of physostigmine from *Physostigma venenosum*. These drugs inhibit acetylcholinesterase to improve cholinergic neuronal dysfunction and the associated cognitive symptoms that occur in AD. Many other alkaloids and their derivatives have been investigated for their ability to modulate cholinergic functions in AD and other dementias. Other alkaloids have been explored as potential treatments for the motor symptoms that occur in PD, via modulation of dopaminergic neurotransmission. Lead compounds for drug discovery include ergot alkaloids from *Claviceps purpurea*, which provided templates for the development of synthetic drugs such as bromocriptine, used to alleviate PD symptoms. Numerous other alkaloids and their derivatives have been investigated for their ability to alleviate symptoms in neurodegenerative diseases, with some also emerging as disease-modifying agents. Other alkaloids, such as nicotine and caffeine, have been suggested to provide protective effects against the development of some neurodegenerative diseases and are discussed from an epidemiological perspective, with consideration of their mechanistic effects.

PDD	Parkinson's disease dementia
PKC	Protein kinase C
RCT	Randomized controlled trial
TGF-β_1	Transforming growth factor β_1
VaD	Vascular dementia

1 Introduction

Neurodegenerative diseases encompass a range of disorders including the dementia pathologies such as Lewy body (LBD) and vascular (VaD) dementias and Huntington's, Pick's, Parkinson's (PD), and Alzheimer's (AD) diseases; the latter is the most common form of dementia, with PD as the second most common neurodegenerative disorder [1, 2]. Symptoms of dementia are associated with multiple cognitive impairments, particularly memory loss, with deficits in attention, language, and social skills. These symptoms can occur in addition to movement disorders associated with PD (Parkinson's disease dementia [PDD]) and LBD, and cerebrovascular events in VaD [3]. In addition, behavioral and psychological symptoms of dementia (BPSD) can include psychosis, agitation, anxiety, sleep disorders, and depression [3].

Treatments for neurodegenerative diseases are limited and frequently only provide symptomatic relief. This appears to reflect a relative lack of knowledge of the etiology and pathology of dementias such as AD. The discovery that deficits in the cholinergic neuronal system occur in the central nervous system (CNS) in senile dementia [4, 5] provided a breakthrough in the understanding of the pathology of dementia, particularly AD. This pioneering work led to the hypothesis that drugs that could prolong or mimic the action of the neurotransmitter acetylcholine (ACh) at cholinergic (muscarinic [mAChR] and nicotinic [nAChR]) receptors might restore cholinergic function and thus reduce symptoms in AD. In AD, the $\alpha_4\beta_2$ nAChR subtypes in particular are reduced [6]; thus, nicotinic agonists including the alkaloid nicotine have been explored for potential modulation of cholinergic function in dementia. Agonists at M_1 mAChRs can improve cognitive functions in animals and in AD patients, and antagonists at central presynaptic M_2 mAChRs can increase ACh release to improve cognition [7]; thus, ligands for these mAChRs have also been sought as dementia treatment strategies. In addition to the search for compounds that interact directly with cholinergic receptors, compounds that inhibit acetylcholinesterase (AChE) to reduce the hydrolysis of ACh by this enzyme have also been investigated to prolong the action of ACh at cholinergic receptors. Also emerging as a potential therapeutic target in AD is inhibition of butyrylcholinesterase (BChE). BChE is predominantly localized in glial cells, and although its function has not been fully elucidated, it is now known to metabolize ACh, and it is suggested that some neuronal pathways may function via BChE [8].

Other neurotransmitter abnormalities occur in dementia pathologies, including glutamatergic and serotonergic, and in LBD/PD, dopaminergic neuronal degeneration occurs, particularly in the substantia nigra [2, 3]. Thus, compounds that modulate these neurotransmitter systems are also relevant to alleviate symptoms. There are limited treatment options for neurodegenerative diseases such as Huntington's disease and the prion diseases. Those natural products, which include some alkaloids, that have been explored for use in these and some other neurodegenerative diseases have been recently reviewed [9] and will therefore not be the focus of this chapter. Other treatment strategies for neurodegenerative diseases have focused on the discovery of disease-modifying agents. For neurodegenerative diseases, inhibition of protein aggregation pathologies via prevention of β-amyloidosis and abnormal tau, for AD in particular, and reduction of α-synuclein deposition in LBD/PD are treatment strategies being investigated [10]. Compounds displaying more than one mode of action relevant to the multiple pathologies that are associated with neurodegenerative diseases may provide therapeutic advantages over drugs targeting just one mode of action.

Five drugs (four AChE inhibitors [AChEIs] and one glutamate receptor antagonist) have now been developed to treat symptoms of dementia (primarily in AD but for some drugs also PDD). Three of these drugs are synthetic (donepezil, tacrine, and memantine), but two (galantamine and rivastigmine) are AChEIs derived from plant alkaloids. There are numerous other alkaloids of natural origin, or their derivatives (semisynthetic and synthetic), that are being explored for their ability to modulate cholinergic functions, or to target other mechanisms, as our understanding of neurodegenerative disease pathology is evolving. There are many alkaloids and their derivatives that are cholinesterase (ChE) inhibitors (ChEIs) [11–13], but their inhibitory potency and therapeutic potential for use in neurodegenerative diseases vary considerably. This chapter summarizes some of the most therapeutically promising ChEIs derived from alkaloids; for other ChEI alkaloids of natural origin, readers are directed to reviews by Houghton et al. [11], Howes and Houghton [12], and Williams et al. [13]. In summary, this chapter presents examples of alkaloids that have been investigated in drug discovery studies for their therapeutic relevance to neurodegenerative diseases, with an emphasis on alkaloid drug leads for two of the most common forms of neurodegenerative disease, AD and PD.

2 Cholinesterase (ChE) Inhibitor Alkaloids and Derivatives

2.1 Galantamine

The isoquinoline alkaloid galantamine (**1**) was first isolated in the early 1950s from *Galanthus woronowii* Losinsk. (Amaryllidaceae), the snowdrop, and it was reported to have AChE inhibiting properties [14]. It was then isolated from *G. nivalis* L., species of *Narcissus* and *Leucojum aestivum* L. (summer snowflake), in the late 1950s when its ChE inhibiting action was confirmed [14]. Although galantamine (also referred to as galanthamine) was initially used therapeutically for several indications including in ophthalmology, gastroenterology, cardiology, and physiotherapy, it was not until the 1980s that it began to be explored for its potential to alleviate symptoms of dementia [14], prompted by the discovery in the 1970s of the cholinergic deficits that occur in dementia [4, 5]. Following the licensing of synthetic ChEIs for symptomatic treatment of AD, galantamine was the first naturally derived anti-ChE drug licensed to treat symptoms of mild to moderate dementia in AD.

Cochrane reviews assessing controlled trials for the effects of galantamine in AD concluded it could improve cognitive functions and activities of daily living, in addition to behavioral symptoms, in AD patients [15, 16]. Limited clinical data are available for the effects of galantamine in other forms of dementia, although some cognitive improvements have been observed with this drug in LBD [17], PDD [18], and VaD [19], with some improvements in BPSD also observed in VaD [20]. Studies in patients with mild cognitive impairment (MCI) showed galantamine to provide only marginal clinical benefit with increased death rates; thus, use in MCI is not recommended [16].

With regard to cholinergic function, galantamine is also an allosteric modulator of nAChRs particularly the $\alpha_4\beta_2$ and α_7 subtypes, an action that was considered to provide additional cognitive enhancement in AD. More recently, however, improved cognitive function by galantamine in early stage AD was not correlated with $\alpha_4\beta_2$ nAChR modulation [21]. However, the potentiation of presynaptic nAChRs by galantamine was associated with increased glutamatergic neurotransmission to increase cognitive performance in AD patients [22].

Although selective and competitive AChE inhibition is considered the primary mode of action of galantamine, other mechanistic effects relevant to treating neurodegenerative diseases have since been discovered (summarized in Table 42.1). However, many of these activities are reported in vitro only, with further studies needed to investigate if any of these effects occur with therapeutic relevance in humans.

Numerous other Amaryllidaceae alkaloids have been isolated and, in addition to many synthetic and semisynthetic derivatives, have been investigated for their ChE inhibitory effects and potential to improve cognitive functions, although few appear to have reached more advanced stages of clinical development. One prodrug of

Table 42.1 Mechanistic effects of acetylcholinesterase inhibitors

Mechanistic effect	Galantamine	Huperzines A and B, and derivatives	Physostigmine and derivatives
Neuroprotective/ anti-apoptosis	• Neuroprotective against Aβ via inhibition of calpain-calcineurin signaling [23] and against glutamate toxicity in vitro [24] • Prevents Aβ-induced oxidative damage via antioxidant effects [25] • Prevents Aβ-induced apoptosis in vitro [24]; apoptosis prevention may be via increased Bcl-2 expression [26] • Protects against oxygen-glucose deprivation-induced damage in rat hippocampal slices [24] • Rat primary cortical cells are protected by pretreatment with galantamine [24] • Prevents mitochondrial dysfunction and endoplasmic reticulum stress [27]	*Huperzine A* • Neuroprotective against Aβ, oxygen-glucose deprivation, free-radicals, H_2O_2, and glutamate; also an NMDA receptor antagonist [24, 32, 33] • Protects isolated rat brain mitochondria from Aβ [34] • Attenuates apoptosis via modulation of gene expression [24] • Neuroprotection may be via inhibition of caspase 3 activation [35] *Huperzine B* • Neuroprotective in vitro via attenuation of H_2O_2- and oxygen-glucose deprivation-induced injury [1] *Synthetic derivatives* • A huperzine B dimer derivative is neuroprotective against Aβ [12, 36] • Enantiomers [(+)- and (−)-] of dimethylhuperzine are neuroprotective against glutamate [1] • Bis(12)-hupyridone prevents H_2O_2-induced neuronal apoptosis (independent of AChE inhibition) [37]	*Rivastigmine* • Neuroprotective involving the synapse; observed in rat primary cortical cultures [41] • Neuroprotective against Aβ in vitro [42] *Neostigmine and pyridostigmine* • Neuroprotective against glutamate toxicity in vitro [24] *Ganstigmine* • Neuroprotective against Aβ toxicity in vitro [24]
Anti-Aβ	• Inhibits Aβ release and BACE1 expression via modulation of α_7 nAChRs and other messengers (e.g., PKC) [28] • Inhibits aggregation and cytotoxicity of Aβ [29] • Enhances microglial phagocytosis and Aβ clearance from brains of rodent AD models [30]	*Huperzine A* • Regulates APP processing via PKC and mitogen-activated protein kinase pathways in vitro [38] *Huprine X* • In animal AD models, reduces insoluble Aβ in the hippocampus (3xTg-AD mice) but had no effect in APPswe mice [39]	*Physostigmine* • Lowers cortical concentrations of insoluble Aβ and decreases Aβ deposition [26] *Physostigmine and analogues* • (Include phenserine, cymserine, and tolserine) modulate soluble APPα and Aβ [26, 43]

(*continued*)

Table 42.1 (continued)

Mechanistic effect	Galantamine	Huperzines A and B, and derivatives	Physostigmine and derivatives
			Cymserine analogues • Reduce Aβ levels in vitro and in a transgenic mouse AD model [44] *Phenserine* • Reduces Aβ levels by regulating APP translation in vitro [45]; (+)-enantiomer reduces APP in vivo [46] *Rivastigmine* • Lowers Aβ levels and increases soluble APPα levels in vitro [47]
Neurotrophic	• Limited evidence for neurotrophic effects, but galantamine increases ACh in anti-NGF transgenic rodents and reverses behavioral deficits and neurodegeneration [31]	*Huperzine A* • Increases neurite-bearing PC12 cells and upregulates NGF mRNA in vitro [33] • Enhances mRNA and protein levels of NGF, BDNF, and TGF-β_1 in the cerebral cortex and hippocampus in vivo [33] *Bis(12)-hupyridone* • Induces neurite outgrowth and promotes neuronal differentiation more potently than huperzine A (possibly via regulation of α_7 nAChRs) [40]	*(+)-Phenserine* • Increases neuronal differentiation of implanted human neural stem cells in mouse hippocampus and cortex [46] *Rivastigmine* • Potential synaptotrophic effects [41]

galantamine, Gln-1062 (Memogain$^{®}$), is being considered for drug development as an AChEI and nAChR modulator since it improved cognitive functions in an animal model of amnesia and had CNS bioavailability 15-fold that of galantamine, in addition to fewer gastrointestinal (GI) effects [10, 48]. Many other Amaryllidaceae ChE inhibitory alkaloids and their derivatives with potential for use in CNS disorders have been reported [11–13]. Those with more potent AChE inhibitory activity than galantamine include ungeremine (**2**), isolated from *Nerine bowdenii* W. Watson (also occurs in species of *Galanthus* and *Narcissus*) [13], and the *N*-alkylated galantamine derivatives *N*-allylnorgalanthamine (**3**), and *N*-(14-methylallyl)norgalanthamine (**4**), obtained from *Leucojum aestivum* L. leaves during the industrial production of galantamine [49] (Scheme 42.1).

2.2 Huperzines

Huperzia serrata (Thunb.) Rothm. (Lycopodiaceae) is a traditional Chinese medicine that has been used to alleviate memory impairment [1] and was also marketed in the USA as a dietary supplement as powdered *H. serrata* for this purpose [50]. The quinolizidine-related alkaloids, huperzines A (**5**) and B (**6**), were isolated from *H. serrata* and identified as AChEIs [51, 52]. Both huperzines A and B improve cognitive functions in vivo [12, 32, 36]. Huperzine A (also occurs in other species including *H. selago* (L.) Bernh. ex Schrank and Mart. [53]) inhibits AChE more potently and selectively than huperzine B [3], with the naturally occurring isomer (−)-huperzine A, being more potent than the (+)-isomer [54]. Other biological activities that may have relevance for neurodegenerative diseases have been discovered for both huperzines A and B and their derivatives (summarized in Table 42.1), although AChE inhibition is considered the principal mode of action (Scheme 42.2).

Most studies to investigate the cognitive effects of these alkaloids have therefore focused on the more potent AChEI huperzine A, which has been evaluated in numerous controlled trials in dementia patients. Promising effects on cognitive functions are reported in elderly subjects and in those with AD and VaD [55–58], although evidence for efficacy in VaD is more limited compared to AD [58]. A meta-analysis of randomized controlled trials (RCTs) associated huperzine A with improved cognition (measured by Mini-Mental State Examination [MMSE]) and activities of daily living in AD patients [57]. Although huperzine

5 Huperzine A

6 Huperzine B

A had reached the phase II trial stage, further trials on this oral formulation were suspended; a transdermal formulation has reached the phase I trial stage [10].

To optimize the AChE inhibitory potency and selectivity of the huperzines, an array of synthetic derivatives have been investigated. Dimerization of the inactive fragment of huperzine A produced dimers (hupyridone fragments linked with an 11 or 12 methylene tether) that were twice as potent at AChE inhibition compared to huperzine A [59]. Further studies with bis(12)-hupyridone (**7**) revealed that it inhibits AChE in the CNS in vivo, also indicating the ability to cross the blood-brain barrier (BBB) [60]. Other huperzine A analogues are in development in drug discovery programs as new AChEIs for neurodegenerative diseases [10]. To modify the binding to AChE, it has been rationalized that the H-bond between the C-14 methyl of huperzine A and the backbone carbonyl of His440 on AChE may be enhanced by replacing the C-14 methyl of huperzine A with fluorine. However, (±)-14-fluorohuperzine A was considerably less potent than huperzine A in the inhibition of AChE [61]. Other fluorinated huperzine A analogues have been developed but, disappointingly, were also less potent AChEIs than huperzine A [62, 63]. Substitution of the C-5 amino group in huperzine A with fluorine (hydroxyl or acetoxyl C-5 substituted and 5-desamino derivatives were also investigated) also produced less potent AChEIs compared to the natural alkaloid, presumably due to the importance of the C-5 amino group in the huperzine A structure for AChE inhibition, to imitate ACh by forming a quaternary ammonium under physiological conditions [64, 65].

Other compounds have been developed by combining structural features of both huperzine A and the synthetic AChEI tacrine [66, 67], to optimize AChE inhibitory activity. The hybrid compounds with structures based on these two AChEIs include the huprines X (**8**), Y (**9**), and Z (**10**). Huprine X has significantly greater affinity for AChE than huperzine A, tacrine, or the AChEI drug donepezil [68], in addition to reported affinity for M_1 and M_2 mAChRs and nAChRs [69], which may provide additional modulation of cholinergic function in the CNS. (±)-Huprines Z and Y are also potent AChEIs, with the latter (chlorine at position 3 in the structure, instead of fluorine) the more active [70]. Although the huprines are being pursued in drug development programs as AChEIs, M_1 mAChR, and nAChR agonists [10], there is a lack of available data on their toxicity. Hepatotoxicity is associated

with the AChEI tacrine [71], which limited its clinical use. Since the huprines consist of some structural features of tacrine, it is essential to consider their potential to cause hepatotoxicity. Other huperzine A hybrid structures have included the benzylpiperidine moiety of another synthetic AChEI drug, donepezil (E2020), but compounds developed were weaker AChEIs compared to donepezil [72]. Other huperzine derivatives in development include the prodrug Debio 9902 (ZT-1) (**11**), an AChEI and *N*-methyl-D-aspartate (NMDA) receptor antagonist, which improved cognitive functions in AD patients in a phase IIa trial [73, 74] (Scheme 42.3).

2.3 Physostigmine

The calabar bean, seeds from *Physostigma venenosum* Balf. (Leguminosae), was used traditionally in Africa, particularly southeast Nigeria, for ritual deaths associated with the funeral of a chief and as an ordeal poison to determine the guilt or innocence of persons accused of a crime [1]. The pyrroloindole alkaloid physostigmine (**12**) (also referred to as eserine) was first isolated from the seeds of *P. venenosum* in the nineteenth century [75]. It is a short-acting and reversible inhibitor of AChE [12].

Physostigmine improves cognitive functions in vivo; it protects against oxygen deficit-induced cognitive impairment, improves learning in mice, and it antagonizes scopolamine-induced cognitive impairment in rats [1] and in zebrafish [76]. Although physostigmine improves cognitive functions in vivo and in AD patients [77], a Cochrane review in 2001 concluded there is limited evidence for efficacy in AD and adverse effects are common [78]. It should be noted, however, that although there is a lack of evidence to support the use of physostigmine for dementia, it is suggested to be of clinical value in severe cases of poisoning due to ingestion of *Datura* species (Solanaceae) [79].

Physostigmine has been used as a template for the development of new ChEIs, with the aim of improving efficacy and reducing adverse effects, which limited the development of physostigmine for clinical use. The only synthetic derivative to reach the phase IV clinical trial stage is rivastigmine (**13**), a reversible AChEI drug licensed to treat symptoms in mild to moderate AD and PD. Many rivastigmine analogues have been synthesized and investigated to produce optimized structures for ChE inhibition, with the aim of developing new pharmaceuticals [80]. Numerous other synthetic compounds based on the carbamate moiety of the physostigmine structure have also been developed for potential use in dementia; some examples of these are summarized below.

Eptastigmine (**14**), a more lipophilic heptyl derivative of physostigmine, inhibits AChE and BChE and improves cognition in AD, but hematologic effects hindered further investigation [81]. Ganstigmine (**15**) is a selective AChEI, and it attenuates scopolamine-induced amnesia in vivo [35]. Although investigated in phase I and II clinical trials, adverse events at higher doses have limited further clinical development [35] (Scheme 42.4).

Phenserine (**16**) is a phenylcarbamate derivative of physostigmine that inhibits both AChE and amyloid precursor protein (APP) synthesis [73]. Phenserine appears to be a more suitable drug candidate than physostigmine since it inhibits AChE more potently and selectively; it is more lipophilic, thus readily crosses the BBB, and it has a longer duration of action, reducing dosing frequency [82]. In a small trial, treatment of healthy elderly volunteers ($n = 32$) with phenserine tartrate was well tolerated, with dose-limiting adverse effects reported at doses $\geq$20 mg [83]. (−)-Phenserine, a more potent AChEI than the (+)-enantiomer [84], improved short-term memory in a placebo-controlled phase II study in 72 AD patients, when administered at 5 mg twice daily for 2 weeks, then 10 mg twice daily for 10 weeks [85]. It also improved cognitive functions in a small trial with 20 AD patients (30 mg/day) [86]. However, a phase III trial showed no difference in efficacy from placebo [87]. The (+)-enantiomer (Posiphen®) has reached the phase II trial stage [10]. The principal mode of action of (+)-phenserine is inhibition of APP synthesis, with associated reductions in β-amyloid (Aβ) and β-secretase levels [45, 88]. Various methyl analogues of phenserine have also been investigated for AChE and BChE inhibition and selectivity [89]. The C2′ methyl substitute of phenserine, tolserine (**17**), is a more selective inhibitor of AChE than BChE [87]. Tolserine is a potential drug candidate, as it is more hydrophobic than phenserine, augmenting transport across the BBB and is a potent and selective AChEI with

14 Eptastigmine

15 Ganstigmine

Scheme 42.4 Physostigmine and synthetic derivatives that inhibit cholinesterase

a long duration of action [90]. In addition to ChE inhibition, other modes of action are associated with physostigmine and derivatives and are summarized in Table 42.1.

Other compounds based on the structure of physostigmine that inhibit BChE (BChE inhibition is also considered a relevant AD treatment strategy [91]) more selectively than AChE include cymserine [92, 93], bisnorcymserine (*N*-demethylated cymserine) [94], dihydrobenzodioxepine cymserine [95], and tetrahydrofurobenzofuran cymserine [96]. Some cymserine analogues improved cognitive performance in aged rats [44]. Other synthetic carbamates are also under investigation as ChEI drug candidates [97].

To target both cognitive symptoms and BPSD, pharmacomodulation of carbamate derivatives has been attempted to produce compounds with dual modes of action. These include derivatives that incorporate structural features of physostigmine and the propargylamine pharmacophore of selegiline to produce compounds that inhibit both AChE and monoamine oxidase (MAO), although these compounds appear to lack therapeutic potential due to poor oral bioavailability and limited transport across the BBB [98]. Other compounds combine structural features of rivastigmine and fluoxetine to inhibit both AChE and the serotonin transporter, with one such compound, RS-1259 (BGC20-1259) (**18**), having completed phase I studies in healthy volunteers [99] (Scheme 42.5).

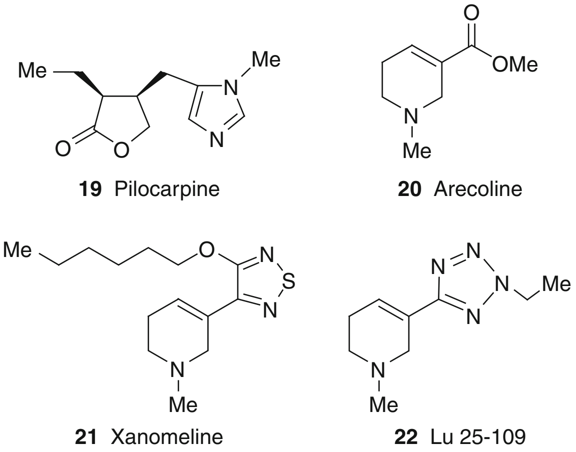
3 Alkaloids and Derivatives as Ligands at Cholinergic Receptors

3.1 Muscarinic Receptor Ligands

The primary mode of action of mAChR ligands is to modulate cholinergic function, but some M_1 mAChR ligands may also reduce amyloidosis and decrease phosphorylated tau [100, 101]. Alkaloid ligands for the mAChR have been discovered from natural sources; although for many, toxicity appears to have limited their potential for clinical use. The alkaloid muscarine was first isolated from the fly agaric fungus *Amanita muscaria* (L.) Lam. (Amanitaceae) and also occurs in *Inocybe* (Inocybaceae) and *Clitocybe* (Tricholomataceae) species [102]. Although it is an agonist at mAChRs, along with the *Amanita* isoxazole alkaloids muscimol and ibotenic acid, it is considered to contribute to the psychotropic and other toxic effects of ingestion of *Amanita* species [102]; thus, *Amanita* alkaloids have not been pursued for clinical development in cognitive disorders. However, the chemical structures of other alkaloids that are mAChR ligands, such as pilocarpine (**19**) and arecoline (**20**), have provided templates for the development of semisynthetic/synthetic mAChR ligands aimed to modulate cholinergic function, with more appropriate pharmacokinetic and adverse effect profiles.

The use of *Pilocarpus* species (Rutaceae) as traditional medicines, particularly *P. microphyllus* Stapf ex Wardleworth and *P. jaborandi* Holmes, dates back to 1570 in Brazil, where *Pilocarpus* species were used to treat mouth ulcers, and around 100 years later, they were documented as remedies for various other purposes, including as an antidote to plant toxins [103]. The leaves of *Pilocarpus* species contain imidazole alkaloids including pilocarpine [104], an agonist at mAChRs, that has a chemical structure with features similar to those of ACh [105]. Although pilocarpine enhances cognitive functions in vivo [106–108], systemic use may cause adverse effects such as nausea, vomiting, sweating, and palpitations [109], and ocular administration may induce or exacerbate CNS symptoms in AD patients



Scheme 42.6 Muscarinic receptor ligand alkaloids and synthetic derivatives

[110, 111]. Among the synthetic pilocarpine derivatives, a thiolactone analogue, SDZ ENS 163 was suggested to be centrally active via agonism at M_1 and antagonism at M_2 mAChRs, with the advantage of no peripheral adverse effects [112]. However, this analogue was unsuccessful in reversing scopolamine-induced cognitive impairment in normal (non-AD) humans [113].

Arecoline is a reduced pyridine alkaloid derivative from *Areca catechu* L. (Arecaceae) (commonly known as betel nut) [104]. An agonist at mAChRs, arecoline may enhance cholinergic function [114, 115], explaining why it could improve scopolamine-induced cognitive impairments in vivo [116, 117] and cognitive functions and recognition skills in AD patients [118, 119]. However, arecoline is genotoxic and neurotoxic [120] and is associated with other therapeutic limitations. These include bioavailability issues, a short duration of action, and peripheral cholinergic effects [105]; consequently, numerous analogues have been synthesized. These include several morpholino and thiazolidinone arecoline derivatives, which bind to M_1 mAChRs and improve learning and memory in vivo [121, 122]. A synthetic analogue of arecoline is xanomeline (**21**), which contains a thiadiazole moiety in its structure instead of the labile ester moiety in arecoline. Although xanomeline improved cognition in clinical trials via M_1 mAChR agonism, in addition to alleviating BPSD (possibly via M_4 mAChR-mediated antidopaminergic activity), cholinergic adverse effects make this analogue unsuitable as a dementia treatment [7]. The fluorinated xanomeline derivative EUK1001 improved cognition in aged mice [123] and in an animal AD model (presenilin double knockout mice) [124]. Another arecoline derivative is Lu 25–109 (**22**), an M_1 mAChR partial agonist and M_2 mAChR antagonist, but this analogue failed to improve cognition in patients with mild to moderate AD and caused adverse effects such as nausea, diarrhea, and anorexia, when investigated in a 6-month double-blind, placebo-controlled trial [125] (Scheme 42.6). Numerous other functionally selective M_1 mAChR agonists, including those derived from alkaloids, have also been considered as potential treatments for cognitive disorders [7] but appear to be generally unsuccessful due to limited efficacy and unacceptable adverse effects.

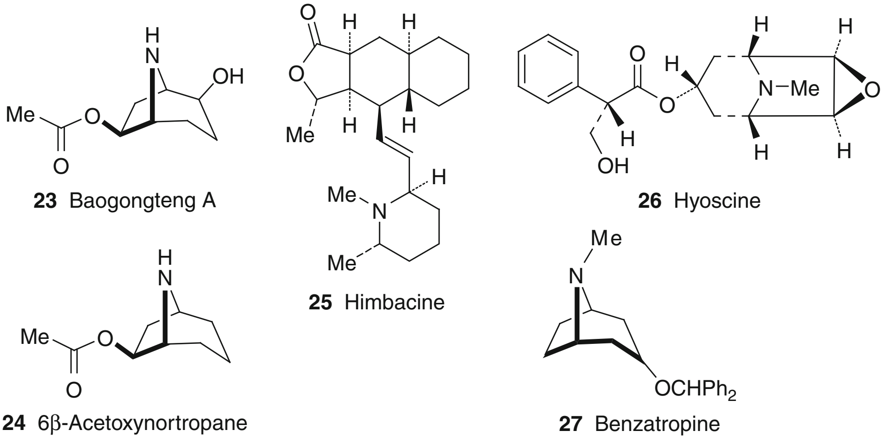
Although some tropane alkaloids (including atropine/hyoscyamine and hyoscine [scopolamine]) from *Atropa* and *Hyoscyamus* species, and other genera in the Solanaceae [104], are known mAChR antagonists [105], the nortropane alkaloid baogongteng A (**23**) from the stem of *Erycibe obtusifolia* Benth. (Convolvulaceae) is reported to be an mAChR agonist [126], although it does not appear to have been assessed for efficacy in cognitive dysfunction. The synthetic derivative 6β-acetoxynortropane (**24**) is considered a selective M_2 mAChR agonist, and it improved cognitive function in vivo [126]. Other derivatives of baogongteng A have been synthesized as mAChR agonists [127] but have yet to be further characterized pharmacologically. Other alkaloid derivatives under investigation as M_1 mAChR agonists for neurodegenerative disorders are the huprines, hybrid structures of the alkaloid huperzine A and tacrine [10] (see Sect. 2.2).

Compounds that antagonize M_2 mAChRs can increase ACh release and improve cognition, although may also cause tachycardia due to their effects on cardiac M_2 mAChRs [6]. *Galbulimima belgraveana* (F.Muell.) Sprague (synonym is *G. baccata* F.M.Bailey [Himantandraceae]) bark is a source of the pyridine alkaloid himbacine (**25**) [128], a selective antagonist at M_2 and M_4 mAChRs [105]. Most synthetic analogues of himbacine do not appear to show advantages over himbacine with regard to M_2 mAChR binding affinity [7], with limited data on analogues (e.g., 3-norhimbacine) that do show higher M_2 mAChR binding affinity [129].

With respect to PD, antimuscarinic compounds are used therapeutically to reduce the effects of the relative central cholinergic excess that occurs with dopamine (DA) deficiency, but since they are associated with cognitive impairment, they are generally not used for idiopathic PD [109] and may be unsuitable for use in those with PDD. Anticholinergic tropane alkaloids, such as hyoscine (**26**) and hyoscyamine, that occur in members of the Solanaceae (e.g., *Atropa*, *Hyoscyamus*, *Datura*, and *Duboisia* species) have been used to alleviate PD symptoms since they are antagonists at mAChRs but are not used routinely for this purpose [130], although synthetic derivatives such as benzatropine (**27**) are occasionally used to provide mild symptomatic control in PD [131] (Scheme 42.7).

3.2 Nicotinic Receptor Ligands

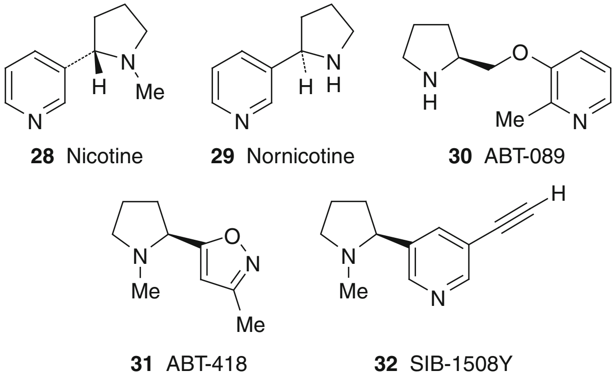
The pyridine and pyrrolidine alkaloid nicotine (**28**) (occurs in *Nicotiana* species [Solanaceae]) has shown numerous mechanistic effects relevant to neurodegenerative diseases. Nicotine can modulate cholinergic transmission via interaction with nAChRs, but may be more effective for attention deficits rather than memory, and more effective for MCI due to preservation of nAChRs compared to AD [3]. In addition to effects on cognitive functions in vivo, nicotine inhibits amyloidogenesis at different stages, is neuroprotective, upregulates nerve growth



Scheme 42.7 Muscarinic receptor ligand alkaloids and synthetic derivatives

factor (NGF) pathways, inhibits apoptosis, and reduces oxidative stress [1, 13, 50]. However, nicotine is reported to increase aggregation and phosphorylation of tau [13], which would be undesirable with respect to neurodegeneration. Early epidemiological data suggested smoking tobacco (*N. tabacum* L.), a source of nicotine, could protect against AD [50], which appeared to support the documented mechanistic effects of nicotine. Subsequent studies show smoking either has no effect or perhaps increases AD risk [3]. An inverse relationship between smoking and PD risk has been concluded; however, effects of tobacco smoking on PDD or LBD risk have not been determined, and the effects of smoking on risk of VaD are complicated, due to the association of smoking with cardiovascular disease [50]. With respect to PD, nicotine facilitates DA release by acting at somatodendritic and presynaptic nAChRs on mesolimbic and nigrostriatal neurons [132] and inhibits formation of α-synuclein fibrils in vitro [2]. The tobacco alkaloid nornicotine (**29**) is also an agonist at nAChRs, and it stimulates DA release from dopaminergic presynaptic nerve terminals [133]. Clinical trials investigating the effect of nicotine on cognitive performance in PD subjects have not consistently shown nicotine to improve cognition [134].

To optimize the therapeutic and pharmacokinetic profile, numerous nAChR agonists have been developed using nicotine as a template structure. Nicotine analogues that contain the pyrrolidine ring in their structure have been explored for their nAChR binding and cognitive effects, including ABT-089 (**30**) and ABT-418 (**31**). ABT-089, a pyridyl ether, is a partial agonist at $\alpha_4\beta_2$ and $\alpha_6\beta_2$ nAChRs, and it is neuroprotective; it reversed scopolamine-induced cognitive deficits in healthy volunteers but lacked efficacy in a phase II RCT in patients with mild to moderate AD [135, 136]. ABT-418, an $\alpha_4\beta_2$ nAChR agonist containing an isoxazole in place of the pyridine moiety of nicotine, reduced anxiety and enhanced cognition in animal models; the latter effect was also reported in an acute study with AD patients, but efficacy was not apparent in a larger placebo-controlled trial [137, 138]. SIB-1508Y (5′-ethynyl nicotine) (**32**) is an nAChR agonist that stimulates release of DA from rat



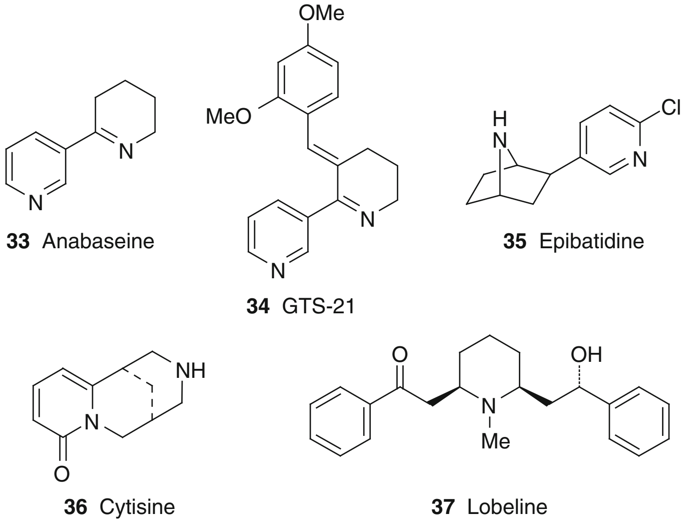
Scheme 42.8 Nicotinic receptor ligand alkaloids and synthetic derivatives

striatum, shows efficacy in animal models of PD, and has been investigated in clinical trials for PD [137, 139] (Scheme 42.8).

In addition to nicotine, minor alkaloids in tobacco modulate DA release from rat striatal slices and are suggested to be neuroprotective [140]. One of these alkaloids is anabaseine (**33**), which also occurs in some marine worms (Phylum *Nemertinea*) and aphaenogaster ants, but it is a relatively nonselective nAChR agonist [141–143]. A series of anabaseine derivatives have been associated with α_7 nAChR agonist and memory-related effects, with (*E*,*E*)-3-(2-methoxy-cinnamylidene)-anabaseine identified as the most potent in improving passive-avoidance behavior in rodents; (*E*,*E*)-3-(cinnamylidene)-anabaseine was also neuroprotective [144]. GTS-21 (3-(2,4-dimethoxybenzylidene)-anabaseine) (**34**) is a more hydrophobic derivative of anabaseine (thus favoring BBB permeability) that shows high affinity and partial antagonist activity for $\alpha_4\beta_2$ nAChRs and partial agonist activity at α_7 nAChRs [135, 143, 145]. In addition to neuroprotective activity in vitro, GTS-21 enhanced cognitive behaviors in vivo [135, 145]. GTS-21 improved cognitive functions in phase I clinical trials with healthy volunteers [145], and it has reached the phase II trial stage in AD patients [10], but outcomes are yet to be reported.

Alkaloids with affinity for nAChRs have been isolated from the frog, *Epipedobates tricolor* (Dendrobatidae). Most pharmacological studies have focused on one of these alkaloids, epibatidine (**35**), as it is antinociceptive and toxic, with selectivity for $\alpha_4\beta_2 > \alpha_3\beta_4 > \alpha_7$, $\alpha_1\beta_{1\gamma}\delta$ nAChRs; numerous synthetic analogues based on the structure of epibatidine are also reported [146]. Epibatidine increases DA output in the nigrostriatal pathway, and it is presumed to desensitize nAChRs, controlling the hyperactivity of this pathway that is associated with motor complications [147] (see Sect. 4), thus suggesting it may have some relevance as a lead compound for drug development in PD.

Numerous other alkaloids from natural origin are known ligands at nAChRs, such as the tropane alkaloid ferruginine (and several synthetic derivatives) [146, 148, 149], although there are limited data on their therapeutic potential in neurodegenerative diseases. Other alkaloids include the quinolizidine alkaloid cytisine (**36**) (occurs in



Scheme 42.9 Nicotinic receptor ligand alkaloids and the synthetic anabaseine derivative GTS-21

Sophora species [Leguminosae]) and the piperidine alkaloid lobeline (**37**) (from *Lobelia inflata* L. [Campanulaceae]), which have high affinity for $\alpha_4\beta_2$ nAChRs; lobeline also improves learning and is anxiolytic in vivo [137, 150, 151] (Scheme 42.9). Cytisine and derivatives may also be of therapeutic interest for PD (see Sect. 4). Huperzine A and tacrine hybrid structures (huprines) are also under investigation as nAChR agonists for AD, in addition to their documented ChE inhibitory and M_1 mAChR agonistic properties [10] (see Sect. 2.2).

4 Alkaloids and Derivatives that Modulate Dopaminergic Function

Dopamine (DA) agonists stimulate DA receptors directly to modulate dopaminergic function and reduce PD symptoms related to dopaminergic deficits. Levodopa (L-DOPA) (**38**) therapy aims to correct the striatal dopaminergic deficit in PD, and it is one of the principal drugs used to alleviate symptoms. Levodopa is also used for symptomatic treatment in Huntington’s disease [152]. It is a precursor of DA and is converted into DA via decarboxylation in the CNS; this conversion also occurs peripherally, thus extracerebral decarboxylase inhibitors are frequently prescribed in addition to levodopa to minimize peripheral adverse effects such as nausea and vomiting [109]. Levodopa has been detected in some members of the Leguminosae, including broad bean (*Vicia faba* L.) seedlings, and when extracts from *V. faba* were administered to rats, free DA was detected in the striatum, and urinary metabolites were consistent with those observed with levodopa administration [153].

V. faba beans have been suggested as an adjunctive therapy for PD, and short-term benefits have been observed in PD patients consuming *V. faba* beans [2], although evidence for efficacy is limited and their regular consumption has been associated with complications such as hemolytic anemia [154]. Levodopa also occurs in *Mucuna pruriens* (L.) DC., also known as the velvet bean [2]. An extract from beans of *M. pruriens* attenuated 6-hydroxydopamine (6-OHDA)-induced dopaminergic loss when administered to rats [2], although a later study showed an extract from *M. pruriens* beans could not significantly antagonize degeneration of dopaminergic neurons in a rat model of PD [155]. Levodopa as a treatment for PD is associated with motor complications [109], and other DA agonists have been developed to minimize adverse effects and to improve on the relatively short elimination half-life of levodopa [131].

The ergot fungus, *Claviceps purpurea* (Fr.) Tul. (Clavicipitaceae), can infect cereal crops such as rye (*Secale cereale* L. [Poaceae]), and it is a known poison [130]. The toxicity is due to the presence of indole alkaloids such as ergotamine (**39**) that cause vasoconstriction. The ergot alkaloids, such as ergocryptine (**40**), interact with DA receptors and may also increase neuronal DA release [156]. Synthetic derivatives of these alkaloids have shown dopaminergic activity, thus have been developed for clinical use in PD. These include the D_2 receptor agonists bromocriptine (**41**), pergolide (**42**), cabergoline (**43**), and lisuride (**44**) [130]. Neuroprotective properties have also been suggested for the DA receptor agonists, including bromocriptine and pergolide [131, 157]; bromocriptine protects against 6-OHDA and MPTP-induced cell loss and attenuates DA depletion in mouse striatum; pergolide upregulates superoxide dismutase in basal ganglia [158]. Bromocriptine also induces neurite outgrowth in vitro [159]. Although there is some evidence for their efficacy in PD, the use of these drugs has been limited by pulmonary, retroperitoneal, and pericardial fibrotic reactions [109]. Another synthetic ergot alkaloid derivative is nicergoline (**45**), and it enhances cognition in dementia; mechanistic effects include cholinergic activity and modulation of APP processing; it is also neuroprotective against Aβ [75] (Scheme 42.10).

The indole alkaloid ibogaine (**46**), from *Tabernanthe iboga* Baill. (Apocynaceae), enhances DA release in isolated striatal tissue and binds to NMDA receptors to prevent glutamate-induced cell death in hippocampal cultures [130, 160]. However, it has psychoactive and memory-altering effects, in addition to being tremorigenic at high doses [160], thus would be an unsuitable drug candidate for neurodegenerative diseases unless the alkaloid structure is modified to improve the adverse effect profile.

The opium poppy (*Papaver somniferum* L. [Papaveraceae]) latex contains benzylisoquinoline alkaloids and is a widely known source of the analgesic drugs morphine and codeine. The biosynthesis of benzylisoquinoline alkaloids begins with a condensation reaction catalyzed by norcoclaurine synthase of DA [161]. The structural features of benzylisoquinoline alkaloids derived from DA might provide some explanation for the documented affinity of some natural alkaloids of this class, and some synthetic derivatives, for DA receptors [162]. Indeed, the chemical structure of morphine has been used as a template for the development of the PD drug, apomorphine (**47**). Apomorphine includes a catecholaminergic moiety in its

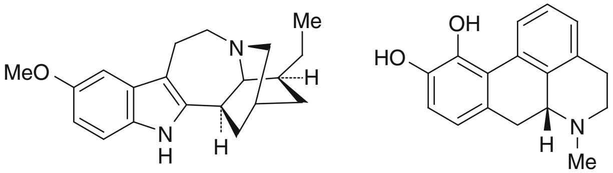
45 Nicergoline

Scheme 42.10 Alkaloids and synthetic derivatives with affinity for dopamine receptors

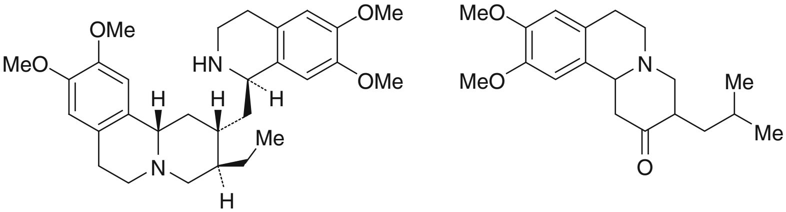
structure, similar to that in DA, and has D_1 and D_2 receptor agonist activity [130]. It is also suggested to be neuroprotective [157]; it protects neuronal cells against H_2O_2 and 6-OHDA in vitro via antioxidant effects [163]. It is effective at reducing symptoms in PD when administered subcutaneously, but its use may be limited by high first pass metabolism, so is unsuitable for oral administration, and by adverse effects such as nausea and vomiting [2]. Numerous synthetic analogues of apomorphine have been investigated [162], but none appear to have reached more advanced stages of drug development for PD (Scheme 42.11).

Cytisine (**36**) (see Sect. 3.2) and its derivative 5-bromocytisine significantly prevented the decrease of striatal DA loss induced by 6-OHDA in rats [164];



46 Ibogaine **47** Apomorphine

Scheme 42.11 The alkaloid ibogaine and the synthetic apomorphine, which modulate dopaminergic function



48 Emetine **49** Tetrabenazine

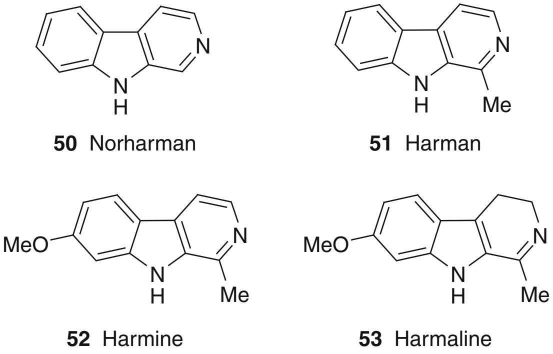
Scheme 42.12 Emetine and the synthetic derivative drug tetrabenazine

although 3-bromocytisine did not produce this effect [164], it increased motor activity in rats via effects on nAChRs in the striatum to modulate dopaminergic function [165]. These results suggest cytisine, or its bromo-derivatives may be relevant to explore as lead compounds for PD. Another nAChR ligand is epibatidine (**35**) (see Sect. 3.2), which enhances DA output in the terminal areas of the nigrostriatal and mesolimbic pathways, and it enhances locomotor activity [147].

Other alkaloids are reported to indirectly modulate dopaminergic function by neuroprotective effects and include *N*-fatty acyl derivatives of tryptamine that occur in some members of the Annonaceae (e.g., *Annona muricata* L.). When synthesized, these tryptamine-derived alkaloids (which occur at low levels in plant sources) were neuritogenic and neuroprotective in dopaminergic neurons in vitro [166].

Emetine (**48**) is an isoquinoline derived alkaloid from *Cephaelis* species (Rubiaceae) [104]. It was first isolated in 1817 [167] and was the lead compound for the development of the drug tetrabenazine (**49**). Tetrabenazine was originally developed as an antipsychotic drug in the 1960s, but in 2008 was approved by the US Food and Drug Administration for use in Huntington's disease chorea [168, 169]. The mode of action of tetrabenazine is reversible inhibition of the human vesicular monoamine transporter 2 to deplete monoamines, including DA, from nerve terminals [168]. Consequently, adverse effects can include extrapyramidal dysfunction and parkinsonism [109] (Scheme 42.12).

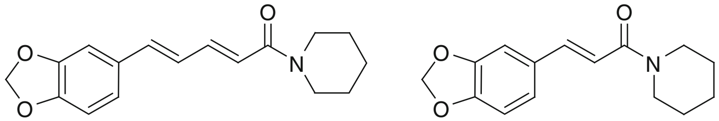
Scheme 42.13 Monoamine oxidase inhibitory alkaloids



5 Monoamine Oxidase Inhibitory Alkaloids and Derivatives

Inhibitors of the enzyme monoamine oxidase B (MAO-B) can increase the concentrations of both endogenous DA and exogenously administered levodopa by blocking the metabolism of DA in the CNS [131]. The indole β-carboline alkaloids, norharman (**50**) and harman (**51**), from natural products that include coffee (*Coffea arabica* L. [Rubiaceae]; for other *C. arabica* alkaloids, see Sect. 7), tobacco (*Nicotiana* species [Solanaceae]), and raisins (*Vitis vinifera* L. [Vitaceae]), inhibit MAO-A and -B, with the latter showing selectivity for MAO-A [9, 170, 171]; lack of selectivity for MAO-B may result in additional adverse effects due to MAO-A inhibition; thus, these alkaloids may not be suitable to pursue as drug leads for PD. There are reports of the roots from *Banisteriopsis caapi* (Spruce ex Griseb.) Morton (Malpighiaceae) being used to treat PD patients in Ecuador, which may be explained by the occurrence of β-carboline alkaloids (harmine (**52**) and harmaline (**53**)) in this species, which are MAO inhibitors (MAOIs) and they stimulate DA release from striatal cells [130]. However, harmine is selective for MAO-A [9] and not MAO-B, the target enzyme to inhibit in PD. Although harmine is also associated with causing convulsant effects and is hallucinogenic, it has been shown to increase glutamate transporter expression in vivo [172]. Thus, harmine may provide a lead chemical structure to develop compounds with MAOI activity that also modulate glutamatergic function in neurodegenerative diseases (Scheme 42.13).

Piperine (**54**) and antiepilepsirine (**55**), piperidine alkaloids that occur in *Piper* species (Piperaceae), are MAOIs with greater selectivity for MAO-B [173], yet they have not been studied extensively for therapeutic potential in PD. Some *Vinca* alkaloids, including vincristine, vinblastine, leurosine, and vindoline from *Catharanthus roseus* (L.) G.Don (Apocynaceae), are reported as selective MAO-B inhibitors, but cytotoxicity limits their development as potential drug candidates for PD [174, 175] (see Sect. 6) (Scheme 42.14).



54 Piperine **55** Antiepilepsirine

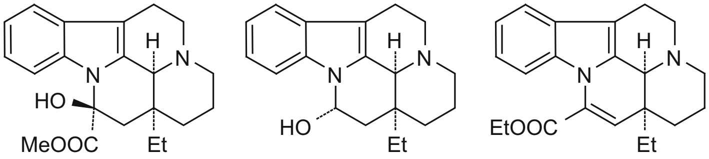
Scheme 42.14 Piperidine alkaloids that inhibit monoamine oxidase B

6 *Vinca* Alkaloids and Derivatives

Although some indole alkaloids from genera in the Apocynaceae are known to be cytotoxic, including the anticancer drugs vincristine and vinblastine from *Catharanthus roseus* (L.) G.Don (the Madagascan periwinkle; synonym is *Vinca rosea* L.) [104], and alkaloid fractions from *Vinca minor* L. (the lesser periwinkle) are cytotoxic [176]; some indole alkaloids derived from *V. minor* have shown potential for use in neurodegenerative diseases, particularly VaD. Mechanistically, *Vinca*-derived alkaloids are reported to be neuroprotective (including against hypoxia and ischemia), to modulate neurotransmitter (including ACh and DA) release and to stimulate cerebral metabolism, with vincamine (**56**), and the derivative vincanol (**57**) also reported to block voltage-gated Na^+ channels [177–179]. Vincamine and the synthetic derivative vinpocetine (**58**) also enhance cerebral blood flow, reduce cerebral insufficiency due to ischemia, and improve short-term memory [177, 180]. Vinpocetine and its metabolite, *cis*-apovincaminic acid, also protect against NMDA-induced neurotoxicity [181]. In addition, vinpocetine could improve learning and memory, possibly via cholinergic, neuroprotective, and antioxidant mechanisms, in an animal model of AD [182]. Studies in humans have focused on the effects of vinpocetine, which increased cerebral blood flow and improved cognitive functions in patients with MCI in a 12-week pilot study [179]. Double-blind placebo-controlled trials suggest vinpocetine is also efficacious in neurodegenerative dementia and VaD [177]. Although vinpocetine appears to show efficacy in dementia, particularly VaD, trial design flaws make promising data inconclusive [183, 184]; thus, it has been concluded there is insufficient evidence to support the use of vinpocetine in dementia [185] (Scheme 42.15).

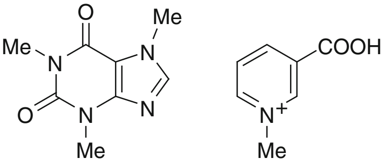
7 *Coffea arabica* L. Alkaloids and Derivatives

Epidemiological data suggest that dementia (AD in particular) risk is reduced in coffee (*Coffea arabica* L. [Rubiaceae])/caffeine (**59**) drinkers, compared with no or low coffee intake [186–188], although other studies do not support this conclusion since any protective effect of coffee or caffeine consumption against AD was not evident [189, 190]. Studies also suggest a high intake of coffee or caffeine is associated with a lower incidence of PD [2, 191], and an open-label pilot study



56 Vincamine **57** Vincanol **58** Vinpocetine

Scheme 42.15 *Vinca*-derived alkaloids



59 Caffeine **60** Trigonelline

Scheme 42.16 *Coffea arabica* alkaloids

with 25 PD subjects also indicated caffeine may improve some motor and nonmotor symptoms of PD [192].

Any effect of coffee on neurodegenerative disease risk therefore requires further evaluation, and the phytochemicals in coffee that might contribute to such an effect would also need to be assessed. Trigonelline (**60**) is a pyridine alkaloid that occurs in coffee, and it increases neurite outgrowth, inhibits AChE in vitro, and it improves memory retention in vivo [193, 194] (Scheme 42.16).

Most studies on coffee in relation to neurodegenerative diseases have focused on another alkaloid component, caffeine. This purine alkaloid produces several mechanistic effects that could be relevant to neurodegenerative diseases. Both coffee and caffeine are associated with neurodegenerative disease-modifying effects via reduction of Aβ [195], in addition to the CNS stimulant and cognitive enhancing effects [186, 188, 195]. Caffeine is also antagonistic at adenosine A_{2A} receptors, an effect that inhibits glutamate release and attenuates excitotoxicity, thus is neuroprotective [196]. Caffeine attenuates dopaminergic deficits and protects against neuronal degeneration in animal models of PD and AD, respectively [196]. In addition, caffeine protects against BBB disruptions in animal models of AD and PD, which may be protective against disease progression since BBB dysfunction has been implicated in the pathogenesis of neurodegenerative diseases [196]. Some synthetic caffeine analogues show dual modes of action relevant to PD. Analogues of (*E*)-8-(3-chlorostyryl) caffeine and of (*E*,*E*)-8-(4-phenylbutadien-1-yl) caffeine inhibit MAO-B and are antagonists at adenosine A_{2A} receptors [197, 198], thus have the potential to modulate dopaminergic neurotransmission and to provide neuroprotection in PD.

8 Conclusion

There are many examples of drugs that are derived from alkaloids, including those with CNS activities [199]. Of the drugs developed for neurodegenerative diseases, alkaloids have been a valuable source of lead compounds. The development of two ChEI drugs (galantamine and rivastigmine) from plant alkaloids to alleviate symptoms in AD or PD has set a precedent for drug discovery. Numerous other ChEI alkaloids of natural origin have been discovered [11–13], with many showing other mechanistic effects not related to ChE inhibition but relevant to neurodegenerative diseases (examples in Table 42.1). For PD, numerous alkaloids display activities relevant to modulating dopaminergic neurotransmission, with some ergot alkaloids providing template chemical structures for the development of the D_2 receptor agonist drugs such as bromocriptine; and for VaD, the *Vinca*-derived alkaloids such as the synthetic vinpocetine have shown promising although inconclusive results in controlled clinical trials.

Although alkaloids and their synthetic derivatives with mechanistic effects relevant to treating neurodegenerative diseases are widely reported, relatively few have reached the clinical trial stage of drug development. This may reflect the decline in natural product drug discovery by challenges such as reluctance from an industry perspective to invest in the costs of patenting, and technical issues such as isolation of a sufficient yield of a compound from a limited resource, or complex routes for total synthesis. However, since current treatment strategies for neurodegenerative diseases are limited, there is a need to discover new drugs that are more therapeutically successful with fewer adverse effects than those currently available, and natural sources continue to be a vast resource of alkaloids yet to be fully explored as new drug leads to treat neurodegenerative diseases.

From an epidemiological perspective, smoking tobacco that contains nicotine has been associated with a reduced risk of PD, and caffeine consumption in the diet has been suggested to reduce the incidence of AD and PD. Any protective effects that these or other alkaloids have against neurodegenerative diseases require further assessment, yet epidemiological data may be useful to determine the role of alkaloids in the treatment and prevention of neurodegenerative diseases.

Abstract

Opiates are medications derived from the poppy plant that attach to opioid receptors in the brain. The extraction of morphine from opium marked the beginning of organic alkaloid chemistry and has led to the synthesis of a variety of semisynthetic and synthetic analgesics. Opium and its derivatives have been used for thousands of years not only for pain relief but also for the euphoria that they produce. It is this dual effect that allows them to be so useful but also addictive and therefore dangerous. Understanding their structure, action, use, and abuse reflects the close connection that we have with the plant world.

Keywords

Addiction • analgesia • codeine • laudanum • morphine • opiate • poppy • thebaine

Abbreviations

CGRP	Calcitonin gene-related peptide
CYP	Cytochrome P50
GABA	Gamma aminobutyric acid
NMDA	N-methyl-D-aspartate
NSAIDs	Nonsteroidal anti-inflammatory drugs
PCA	Patient-controlled analgesia
SNP	Single-nucleopeptide polymorphone

1 Introduction

Papaver alkaloids are compounds extracted from *Papaver somniferum*, the opium poppy. The historical record shows that the psychoactive properties of this plant have been known for millennia. Around 3400 BCE, the Sumerians described the poppy as *Hul Gil*, “the joy plant,” [1] and it was well known to the ancient Egyptians, Babylonians, Minoans, and Greeks [2]. In 1300 BCE, in Thebes, the Egyptians cultivated a poppy variety known as *opium thebaicum*, which they traded all over the known world. Hippocrates, the “father of medicine,” acknowledged opium’s usefulness as a pain reliever [3]. While the seeds and oil of the poppy plant are also consumed, the most important product is certainly opium, produced by scoring the unripe seed pods. The exuded latex “tears” of yellowish material, which darkens when dried, can be scraped off and collected. This bitter, granular material can be eaten, smoked, or made into a tincture with alcohol, known as laudanum. Laudanum was first described by the author Paracelsus (about 1522) [4], who recommended using it only sparingly, but laudanum later became a very popular remedy for numerous conditions in European medicine.

In 1805, a German pharmacist, Friedrich Sertürner, first reported that he had isolated an alkaloid substance from opium [5]. This isolation, produced by boiling the opium followed by immersing it in ammonia, yielded an insoluble substance. This

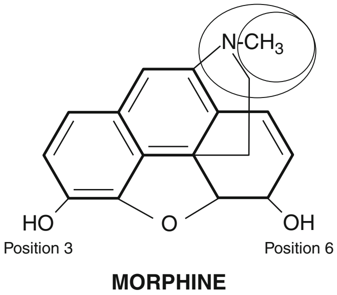

Fig. 43.1 Structure of morphine (Reprinted with permission from Trescot AM, Datta S, Lee M, Hansen H (2008) Opioid pharmacology. Pain Physician 11:S133–S53)

was the first example of the successful isolation of the "natural product," or active portion, of a plant-based medicine. He named this compound "morphium" in 1817, for Morpheus, the Greek god of sleep, after experimenting with its effects. The French chemist Joseph Guy-Lussac changed this to "morphine" upon translation of Sertürner's article into French, suggesting that "-ine" be used as a suffix to denote an organic base. The very existence of organic bases was widely disputed at the time, and this new substance fascinated many chemists of the era, though determination of the formula and synthesis were not accomplished until the mid-twentieth century.

The discovery of morphine marked the beginning of organic alkaloid chemistry, and the further analysis of papaver alkaloids proceeded quickly. There are over 50 papaver alkaloids in all, nitrogenous organic bases, but they can be divided into two major classes of papaver alkaloids – the isoquinolines and phenanthrenes. The phenanthrenes are the most medically significant, with morphine, codeine, and thebaine acting as important opioid agonists.

Morphine makes up about 10–20% of the mass of opium. Morphine (the archetypal opioid) consists of a benzene ring with a phenolic hydroxyl group at position 3 and an alcohol hydroxyl group at position 6 and at the nitrogen atom (Fig. 43.1). Both hydroxyl groups can be converted to ethers or esters. For example, codeine is morphine that is O-methylated at position 3, while heroin is morphine O-acetylated at position 3 and 6 (diacetyl morphine). The tertiary form of the nitrogen appears to be crucial to the analgesia of morphine; making the nitrogen quaternary greatly decreases the analgesia, since it cannot pass into the central nervous system. Changes to the methyl group on the nitrogen will decrease analgesia as well, creating opioid antagonists.

The second most common alkaloid in opium is codeine, at 0.5–1% of total mass. Codeine is a weak opioid, and is commonly used as an analgesic, sometimes in combination with acetaminophen. The third most common alkaloid is thebaine, at 0.3–1%. Thebaine has similar chemistry but very different biological effects than morphine or codeine, causing dysphoria and agitation in low doses and seizures in high doses. Thebaine is commonly used as a precursor for synthetic opioids. Papaverine is also about 1% of opium, and is a smooth muscle relaxant with little CNS effect. It should be noted that many specialty varieties of *P. somniferum* have

Table 43.1 Papaver alkaloids

Compound	% Opium	Action	Use
Morphine	10–20%	Analgesic	Pain relief
Codeine	0.5–1%	Weak analgesic	Pain relief, cough, diarrhea
Thebaine	0.3–1%	Dysphoria	Synthetic opioid precursor
Papaverine	1%	Smooth muscle relaxer	

been bred, some of which produce higher levels of one alkaloid or another, some that have been bred to minimize alkaloid production (Table 43.1).

2 Pharmacological Applications

The primary modern use of the papaver alkaloids is for analgesia. Morphine is considered the classic example of a high-potency opioid. *Opiates* are medications derived from the poppy; *opioids*, the more general term, refer to medications that work at the opioid receptors. All opiates are therefore opioids, but not all opioids are opiates.

2.1 Analgesia

2.1.1 Morphine

Morphine is still very widely used for analgesia. Indeed, it has been recommended by the World Health Organization as the standard opioid for cancer pain [6], since it is widely available and inexpensive. In the W.H.O. pain ladder, first published in 1986, the first step in pain management is described as adjuvant medications. The second step is weak opioids, such as codeine, while the third step is high-potency opioids such as morphine.

Morphine is available in a great variety of formulations, including short-acting and long-acting oral forms, as well as vaginal and rectal suppositories. There are several different morphine long-acting formulations, while the active ingredient in these remains identical, their duration of action and other characteristics may vary significantly. Some long-acting forms may be removed from their capsules to give in apple sauce or through a feeding tube, while the individual particles retain their timed release characteristics; on the other hand, time-released tablets should never be cut or crushed in order to prevent too much morphine becoming available all at one. Morphine is also available for injection or intravenous infusion in various strengths. Intravenous or subcutaneous infusion is the route of choice when patients cannot take oral medication. Morphine can also be given intrathecally, within the subarachnoid space surrounding the spinal cord. Recently, topical morphine has been used for skin ulcers and mucositis, and inhaled morphine has been used to treat pain and shortness of breath associated with cancer.

2.1.2 Codeine

Codeine is the prototypical weak opioid; when given orally, it is only about 25% as potent as oral morphine. Codeine as monotherapy is a less effective analgesic than NSAIDs or acetaminophen [7]. Therefore, it is commonly given in a combination with acetaminophen for improved pain relief.

3 Mechanism of Action

While opioids have been known to medicine since ancient times, the site of action in the brain was not clearly identified until the 1970s, when it was found that electrical stimulation of the periaqueductal gray in rats seemed to greatly reduce their avoidance of noxious stimuli [8]. Shortly thereafter, it was recognized that the brain was rich in opioid receptors in this area [9]. The nearly contemporaneous discovery of endogenous opioids [10] answered the question of why this elaborate system existed – the body makes use of opioid transmission to regulate pain perception and other bodily functions. Opioid receptors are found throughout the body, but primarily in the brain, spinal cord, and intestinal tract. These receptors are complex structures made up of seven amino acid chains, each of which bridges the membrane, forming a channel which can allow calcium ions to pass in or out of the neuron. When activated, an opioid receptor activates in turn a second messenger called a G-protein, which then detaches from the receptor complex and can have effects in distant parts of the cell (Fig. 43.2).

There are three families of opioid receptors: mu, delta, and kappa. Each type of receptor has a different affinity for specific opioids, and specific effects when activated. Each opioid receptor can cause analgesia; mu-agonists (such as morphine) also tend to cause more dependency, while kappa-agonists such as the endogenous opioid dynorphin cause more dysphoria.

Opioid-induced analgesia is produced through the action of opioid receptors on presynaptic terminals of the C-fibers and A-delta fibers. These fibers, which transmit nociceptive messages, are inhibited by the indirect effects of opioids, which in turn reduce the release of neurotransmitters such as substance P, CGRP, and glutamate. This effect occurs in the peripheral nervous system as well as at the primary afferent terminals in the spinal cord.

Another important site of opioid-mediated analgesia is the periaqueductal gray matter. This area of brain, as noted above, is rich in opioid receptors, and exercises descending anti-nociceptive influence on the dorsal horn of the spinal cord.

3.1 Tolerance

Opioid tolerance is a well-known phenomenon, which involves increasing dosage requirements with repeated opioid dosing in order to maintain the same analgesic effect. This effect is a common reason for dose escalation in pain patients. In humans, tolerance can be divided into *associative* and *nonassociative* forms.

Associative, or learned tolerance is related to environmental cues and psychological factors. For example, opioid addicts may have greater tolerance for opioids used illicitly at home than an unfamiliar form given in the medical context of a hospital. Nonassociative, or adaptive tolerance, is a neurophysiological adaptation of the opioid receptor system, involving downregulation of the opioid receptors or decrease of opioid receptor sensitivity [11]. This process involves the NMDA receptor and increased expression of dynorphin.

4 Toxicity

4.1 Physical Toxicity

4.1.1 Respiratory Depression

The most significant and concerning side effect of opioids is respiratory depression. This effect of morphine was quickly recognized, with Sertürner himself reporting in 1827 the death of a dog he had injected with morphine. He and several human volunteers also suffered respiratory depression in the course of their experimentation [12].

Respiratory depression is mediated by the effect of mu-opioid receptors [13]. Opioid receptors in the brainstem at the nucleus accumbens have a dual effect, decreasing the respiratory drive as well as the response to decreasing oxygen levels and carbon dioxide levels in the bloodstream. Thus, patients on high doses of morphine feel less need to breathe, even when their respirations are becoming inadequate. This effect is the most serious and life-threatening toxicity associated with opioids. Recent research has shown that this risk is significantly greater when opioids are co-administered with sedatives such as benzodiazepines, or when patients have respiratory diseases or sleep apnea, as they may already have significant changes to their respiratory drive and be used to high partial pressures of carbon dioxide in the blood. The opioid antagonist naloxone can be used to quickly and safely reverse overdoses; it is memorable to see an unconscious, apneic patient suddenly "come to life" with the administration of naloxone – usually in a foul mood, as the naloxone also provokes acute withdrawal. With IV administration of morphine, the respiratory depression reaches full effect as quickly as 10 min after injection.

4.1.2 Other Neurological Symptoms

Opioids cause miosis (pinpoint pupils) in a dose-dependent manner. Sedation and hearing loss are also common at higher doses of opioids.

4.1.3 Hypotension

Especially when given intravenously, morphine can cause orthostatic hypotension and venous pooling.

4.1.4 Gastrointestinal

The decreased gut transit time associated with opioids, when not desired, can cause severe constipation and even bowel obstruction. Patients do not usually develop tolerance to these effects of opioids, even after long-term treatment. Morphine is also associated with spasms in the bile duct and sphincter of Oddi and the bladder. At higher doses, nausea and vomiting related to the chemoreceptor trigger zone in the fourth ventricle of the brain can be a limiting factor in opioid therapy.

4.1.5 Allergic Symptoms

Morphine triggers histamine release from mast cells in the skin. This reaction is not mediated by opioid receptors. This histamine can cause bronchospasm, hypertension, vasodilation, and facial flushing. True allergic reactions, including anaphylactic reactions, to opioids are rare but have been reported.

4.1.6 Hyperalgesia

Increased pain sensitivity is common in post-acute injury, nerve injury, and some forms of chronic pain. This sensitivity can take the form of hyperalgesia, or abnormally increased sensitivity to painful stimuli. For example, a patient with neuropathic pain may find a mild pinprick in the affected area unbearably painful. Allodynia is the perception of ordinary touch as painful, such as when a patient with neuropathic pain has a "hot coals" sensation when walking on a cool smooth floor. Considerable evidence suggests that chronic opioid use can contribute to hypersensitization of pain perception by affecting the responsiveness of nociceptive nerves in a manner analogous to chronic neuropathy [14]. This opioid-induced hyperalgesia has been described in patients taking opioids for pain as well as those taking opioids for addiction. In animal models of this phenomenon, changes take place in the neurons in the dorsal horn of the spinal cord to make them more reactive. These changes are long term and mediated by the NMDA receptor system, which is also involved in animal models of neuropathic pain and neurotoxic nerve damage. This sensitization occurs clinically in patients on long-term higher-dose opioids, who manifest both tolerance and sensitization.

4.1.7 Endocrine System

Chronic opioid use can affect the body's hormone balance, most notably in the adrenal hormones and gonadal hormones [15]. Chronic morphine use decreases blood levels of cortisol, a stress hormone. Opioids also change the balance of the pituitary hormones that regulate sex hormone production, increasing prolactin and decreasing luteinizing hormone, follicle-stimulating hormone, and the sex steroids of estrogen and testosterone. These changes in hormone levels cause effects in behavior, sexual function, and body physiology, including decreased libido, irregular menses or amenorrhea, galactorrhea, loss of muscle strength, and osteoporosis [16]. In patients who will receive long-term opioid treatment, sex steroid supplementation may be beneficial if there are no contraindications.

4.1.8 Immune System

Opioids affect the function and development of the immune system, both indirectly through its control system, and directly via the opioid receptors on immune cells. Bone marrow progenitor cells, macrophages, natural killer cells, immature thymocytes, B cells, and T cells, all express opioid-related receptors on their surfaces and have been shown to change their behavior in the presence of opioid agonists. Prolonged opioid exposure suppresses immune function in animal models, as

Table 43.2 Elements of aberrant behavior with opioid treatment

"Lost" prescriptions

Diversion of medication
Failure to comply with treatment plans

does opioid withdrawal and untreated pain. Morphine may have greater immunosuppressive effects than some synthetic opioids. This is clinically relevant, particularly in AIDS patients, who are already suffering immune system difficulties and who may have higher viral loads when on high dose opioid regimens.

4.2 Behavioral Toxicity

4.2.1 Addiction

Opioids inhibit the release of GABA, an inhibitory neurotransmitter, in the ventral tegmentum of the brain. This facilitates the release of dopamine in the nucleus accumbens, the reward center of the brain, which is thought to be responsible for the habit-forming property of opioids. Despite enormous effort, little progress has been made in developing a compound that would possess the analgesic effect of morphine without morphine's addiction reinforcing effects.

4.2.2 Aberrant Behavior

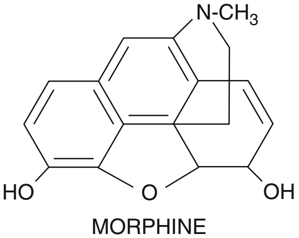
Aberrant behavior is a common complicating factor in opioid treatment, and sometimes leads to the failure of opioid treatment. Aberrancy has many potential causes, including miscommunication, and genuine under-treatment of pain, but should always be considered a red flag and potential indicator of such problematic situations as addiction and drug diversion. Many providers use a risk management approach with all patients who receive these medications, screening for risk factors associated with addiction and misuse and utilizing urine drug testing [17] (Table 43.2).

5 Bioavailability and Metabolism

5.1 Morphine

5.1.1 Chemical Properties

Morphine in the pure state is a white crystalline compound that is basic and insoluble in water. Since this has very poor bioavailability, morphine is available for pharmaceutical purposes as a salt, most commonly as morphine sulfate, but also sometimes as morphine acetate or morphine hydrochloride.



MORPHINE

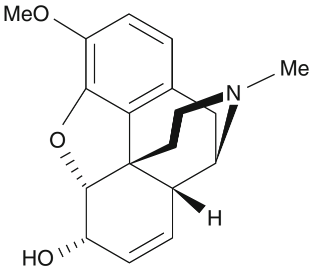
5.1.2 Pharmacodynamics of Morphine

Morphine, even in salt form, has poor solubility in lipids and therefore has trouble crossing the blood-brain barrier. It is primarily metabolized by conjugation with glucuronic acid, and is subsequently excreted renally. The majority of this is morphine-6-glucuronide (M-6-G), which also has an analgesic effect, but a small fraction is morphine-3-glucuronide (M-3-G), which is thought to contribute to opioid hyperalgesia. Morphine also has significant protein binding in the bloodstream. Therefore, less than half of an oral dose is available to the nervous system. Time to onset of analgesic effect of immediate-release oral morphine is about 30 min, and half-life is about 120 min. Therefore, immediate-release morphine is commonly given every 3–4 h. Long-acting morphine takes up to 90 min to take effect and can last from 8 to 24 h, depending on dosage and formulation.

Morphine is also hepatically metabolized to normorphine by the cytochrome P-450 enzymes CYP 3A4 and CYP2C8. Small amounts of codeine and hydromorphone are also produced, which is not clinically significant but can cause false positive urine drug tests for these substances. Morphine dosage should be reduced in patients with impaired renal function.

5.1.3 Codeine

Codeine is well absorbed after oral administration but has highly variable bioavailability and a plasma half-life of only 2.5 h.



CODEINE

Its metabolism is similar to that of morphine, with 80% being glucuronidated to codeine-6-glucuronide (C-6G) and smaller fractions being demethylated, creating morphine and norcodeine. It has been hypothesized that the small amount (roughly 10%) of morphine created through demethylation by the cytochrome P450 enzyme CYP2D6 is responsible for the majority of the analgesic effect, since people with the slow-acting variant of CYP2D6 get very little analgesic benefit from codeine [18]. Conversely, rapid CYP2D6 metabolizers may be at risk for morphine overdose, for themselves, or for breast-fed babies [19]. Codeine administration will produce both morphine and codeine in the urine. Codeine dosage should be reduced in patients with impaired renal function.

5.1.4 Pharmacogenetics of Opioids

There are multiple ways in which genetic variability can interact with opioid treatment in patients. Receptor polymorphisms can lead to a drug being more or less effective in an individual. Of the receptors that can be affected, OPRM1 (the mu-1 opioid receptor subtype) is the most clinically significant. A specific single-nucleotide polymorphism has been identified, (118A > G SNP) which causes a missense mutation that, through unclear mechanisms, greatly reduces the analgesic effect of opioids [20]. This is found in approximately 16% of Caucasians. However, a meta-analysis concluded that this polymorphism, though identifiable, was not clinically significant in pain treatment, and the authors did not recommend genotyping [21].

The other significant genetic effect on opioid treatment is the variability of the cytochrome P450 enzyme system, particularly CYP2D6. This enzyme is responsible for converting roughly 10% of the oral dose of codeine into morphine, which is primarily responsible for the analgesic effect of codeine. CYP2D6 effect is largely regulated at a single gene site, and, depending on which alleles are inherited, it can be rated as poor, intermediate, extensive, and ultrarapid [22]. Poor metabolizers (about 10% of Caucasians), those with two deficient alleles, will have almost no analgesic effect from normally therapeutic doses of codeine. These patients are also prone to developing toxicity due to elevated blood levels of numerous other drugs. Intermediate metabolizers are heterozygous for the deficient allele and will have some limited analgesic effect with codeine. Extensive metabolizers have the normally functioning alleles and respond to medications in the expected way. Ultrarapid metabolizers, who are only 1% of Caucasians but up to 30% of the North African population, may have greater than expected blood levels of morphine given standard codeine dosing. This has resulted in the death of breastfeeding babies when their mothers, who were ultrarapid metabolizers, were given codeine for postdelivery pain [19]. Some authorities have suggested that the genetically mediated variability of codeine effectiveness should lead to it being taken out of the first line of therapies for mild to moderate pain [18]. Others speculate that CYP2D6-deficient patients may be at less risk of addiction [23], perhaps because they do not get the euphoria from the morphine metabolite.

6 Other Biological Activities

6.1 Gastrointestinal

The gastrointestinal system is also liberally lined with opioid receptors. Mu-agonists, in particular, are known to cause decreases in gastric emptying, gut transit, and intestinal secretions. The constipating effects of codeine are not less than any other opioid, despite the weaker analgesia. Therefore, codeine may be used for diarrhea, although this use has now been largely supplanted by opioids that do not act centrally, such as diphenoxylate and loperamide.

6.2 Antitussive

The antitussive effects of opioids occur both centrally and peripherally. Mu-receptors [24] in the brainstem cough center and in the sensory arm of the vagus nerve, which controls airway reflexes, appear to mediate this effect. The weak analgesia associated with codeine makes it a good choice as an antitussive and it has frequently been used as a component of cough syrups. These cough syrups are sold over-the-counter in some areas and have been a source of opioid misuse and diversion. Codeine is not an active antitussive in young children and has potential for respiratory suppression in this patient population; for that reason, it is not recommended for children [25].

6.3 Antihypertensive

Morphine has hypotensive effects, increasing peripheral vascular capacity and decreasing blood pressure, which may be mediated through adenosine. For this reason, as well as its analgesic properties, intravenous morphine has been given for myocardial infarction, although it is not a part of the current standard of treatment.

7 Clinical Trials

7.1 Opioids for Acute Pain

Codeine has frequently been prescribed for mild acute pain, such as following dental procedures. The Cochrane Review database conducted large-scale meta-analysis of single-dose treatment for postoperative pain, which concluded that single-dose codeine 60 mg postoperatively was not an effective analgesic [7]. Codeine together with acetaminophen (paracetamol) yielded good relief in 50% of patients in the studies [26]. Codeine with acetaminophen is less effective that ibuprofen for pediatric arm fractures [27]. Codeine continues to be useful as a short-term medication for acute pain in adults when given short term.

Morphine is frequently given intravenously or orally for acute pain. Many patients prefer patient-controlled anesthesia (PCA) to intramuscular injections [28]. Morphine is also highly effective when given epidurally for postsurgical pain [29]. Comparisons of epidural and patient-controlled intravenous morphine suggest that both are equally effective for pain control, but epidural morphine may have slightly greater side effects [30]. The ability to combine epidural morphine with a long-acting local anesthetic such as ropivicaine or bupivacaine has allowed anesthesiologists to lower morphine dosages for epidural anesthesia [31].

7.2 Opioids for Chronic Pain

Codeine is effective for treatment of moderately severe chronic pain [32]. A Norwegian study indicated that while nearly 10% of the adult population was prescribed codeine at some point during the year 2005, only 1% had more frequent dosing, suggesting chronic administration [33]. An extensive systematic review of long-acting opioid preparations for chronic non-cancer pain has continued to show no difference between morphine and other long-acting opioids [34].

The subject of chronic opioid treatment for non-cancer pain has become significantly more contentious in the last decade, with studies suggesting that high-dose opioid use is concentrated in a small group of relatively high-risk patients [35]. Daily doses of opioids greater than 100 mg of morphine-equivalents/day have been shown to carry much higher risks of death [36]. And in the United States, an alarming trend toward high rates of opioid overdoses and overdose-related deaths has been seen in public health data since the year 1990 [37].

7.3 Opioids for Cancer Pain and Palliative Care

The World Health Organization guidelines for cancer pain recommend opioid treatment of moderate-to-severe cancer pain using oral medication whenever possible [6]. An extensive systematic review of opioids for cancer pain did not find clear evidence of superiority or inferiority of morphine over other opioids for cancer pain, and it remains a very commonly used treatment for cancer pain [38]. The variety of routes for morphine, including oral, rectal, intramuscular, intravenous, subcutaneous, and intrathecal, make it a highly versatile medication.

Many patients with moderate-to-severe cancer pain will be treated with a combination of a long-acting opioid as well as an immediate-release opioid for breakthrough pain. Immediate-release morphine can be given at 5–15% of the dose of long-acting morphine, and has been shown to work within 30–40 min [39]. Opioid treatment of cancer pain is sometimes limited by side effects such as sedation and nausea. In these cases, switching to intravenous administration can rapidly reestablish pain control [40]. Intravenous morphine for cancer pain must be closely monitored in patients with renal impairment, as the active metabolite morphine-6-glucuronide may accumulate [41].

In developed countries, cancer treatment centers should have access to pain specialists who can manage the complex issues involved in cancer pain, including changing medication requirements, changes in metabolism and pharmacokinetics of medications related to cancer treatments, and the tradeoffs between comfort and sedation frequently involved in end-of-life care. A large Italian study showed that access to palliative/supportive care teams was associated with a 31% lower chance of suffering severe pain during cancer care [42].

8 Conclusion

Poppy extracts have been the source of pain relief and euphoria for thousands of years. Opium derivatives, such as morphine and codeine, are the most effective analgesics available, and they have a wide variety of uses as well as potentially serious side effects. Recognition of the variability of receptor response and metabolism can help to explain the wide range of responses to the same dose of medications, and perhaps also explain why some people become addicted and others do not.

Abstract

Background: Herbal-induced injury to the liver is a many-faceted phenomenon. The diverse aspects include the nature of the hepatotoxic agents, the character of the injury, the mechanism for the hepatotoxic effects, the circumstances of exposure, and the medical and social importance.

Purpose: The objectives are to encourage recognition and prevention of common morbidity encountered when using complementary and alternative medicine and 2) to review the toxic effect of herbal remedies containing pyrrolizidine alkaloids (PAs).

Design and Methods: A systematic literature search and review, and data interpretation are provided.2.

Conclusions: Our results suggest that herbal remedies containing *PAs* induce veno-occlusive disease of the liver (VOD). Long-term use, monitoring, and avoiding overdose of such remedies may prevent the mitochondrial injury due to the glutathione depletion, which ultimately leads to the liver cell damage. Moreover, immediate "remedy" discontinuation will prevent further liver damage. The role of liver toxicity induced by "natural" herbal remedies and elucidating the herbal-drug interaction require further research.

Keywords

Complementary alternative medicine • herbal remedies • pyrrolizidine alkaloids • veno-occlusive disease of the liver • natural treatments or therapy

Abbreviations

PA	Pyrrolidizine alkaloids
VOD	Veno-occlusive disease

1 Introduction

1.1 Traditional Herbal Medicines

Herbal medicine – defined by the World Health Organization (WHO) as "herbs, herbal materials, herbal preparations and finished herbal products, that contain as active ingredients parts of plants, or plant materials, or combinations thereof" – is used to treat a multitude of ailments throughout the world. (http://whqlibdoc.who.int/hq/2002/WHO_EDM_TRM_2002.1.pdf).

We will review several herbal medicines used throughout the world, but we will focus on two genii *Senecio* spp. and *Callilepis laureola (Impila)* used in South Africa. It is currently estimated that 80 % of the South Africa population consult with traditional healers and use some form of traditional herbal medicine, usually in combinations [1–4]. Reports indicate it is used to treat cough [5], stomach problems [6], impotence [7, 8], to induce fertility [9], to facilitate labor [1, 10], or against "evil spirits" [11].

Acute poisoning due to the use of traditional medicines causes severe morbidity and mortality globally. The pyrrolizidine alkaloids are hazards posed by the environment that are ingested in ignorance of their toxicity or are taken as folk medicines. The toxicity of Senecio plants and related species has been a subject of interest for almost 100 years. At the turn of the century, they were suspected of causing disease in grazing domestic animals. The inappropriate use of medicinal herbs has resulted in numerous fatalities, especially in young children [11–20]. Within a few years, this suspicion was confirmed by a series of studies that have been reviewed in the excellent publication of McLean [20]. This chapter will review pyrrolizidine alkaloid characteristics, their role and pathological features of hepatotoxicity, VOD of liver, histopathological characteristics as well as extrahepatic toxicity characteristics, sources of PA, and description of preliminary efforts to combine conventional and traditional medicine.

2 Pyrrolizidine Alkaloids

Pyrrolizidine alkaloids (PA) are complex molecules named for their inclusion of a pyrrolizidine nucleus: a pair of linked pyrrole rings. Each pyrrole can be drawn as a five-sided structure with four carbons and one nitrogen forming the ring [21]. Pyrroles are incorporated into the chlorophyll molecule; the biological role of PAs in plants remains unknown.

PAs are present in over 450 different species from 14 distinct plant families that grow worldwide [22–28]. The poisoning is usually accidental, by the ingestion of grain contaminated with pyrrolizidine-containing weeds, as has been reported in Tajikistan [29] and South Africa [30], expenditure of herbal or bush teas in the United States [23], or when taken as herbal infusions for medicinal purposes [31].

PAs are of special interest currently because several of them have been shown to cause clinical toxicity in humans. Comfrey, a well-known medicinal herb, contains PAs that are capable of causing liver damage [19].

Presently, there are over 300 PAs characterized with the highest numbers found in the genus *Senecio* (Asteraceae family), which contains senecionine with concentrations of up to 18 % of the dry weight of the plant [22], retrorsine [28], integerrimine, neosenkirkine, and florosenine [32].

Senecio spp. including golden ragwort proves to be a source of fatal poison that affects cattle [32]. Furthermore, the toxic effects are usually not detected until irreversible liver damage has occurred [33]. *S. latifolius* leaves are equipped as to treat wounds and burns, whereas decoctions are used to induce abortion or to cure infants [1, 5, 34–37].

3 Hepatocytotoxicity

The character of the injury produced by PAs includes several categories. Some agents lead to necrosis, steatosis, and cirrhosis. Others lead only to interference with bile secretion and to jaundice with little injury to the hepatic parenchyma. The possible relationship of the toxicity to glutathione binding leads to experimental in vitro exploration presenting similarity of the lesion to that of acetaminophen, and the recorded glutathione depletion [28]. Some PAs produce degenerative or vascular lesions. The entire range of known hepatic lesions can be produced by PAs. In the typical case of poisoning (with clinical and biochemical findings), ascites occurs in 96 % of patients, hepatomegaly in 85 %, and elevated liver enzymes in 92 % [33].

There is a growing concern over the use of herbal remedies containing PAs since pyrrolizidine-induced liver damage can be cumulative. The toxicity of PAs depends on the exposure time, dosage amount, and susceptibility of the organism. In humans, the dosage appears to fall within the range of 0.1–10 mg/kg per day [38]. Low levels of exposure to PAs likely results in lung lesions while high amounts of exposure often give rise to liver lesions [20, 39]. In a recent study looking at the five women (41–72 years old) that consumed for a long time PA-containing herbal remedies presented clinical ascites, jaundice, and hepatomegaly [40]. The imaging features were diffused, patchy hepatic enhancement, periportal edema, and ascites. Pathology ascertained that blood flow was obstructive at the site of sinusoid. PAs (senecionine and seneciphylline) were identified in all the three available herbal preparations ingested by the patients. Pyrrole-protein adducts were unequivocally found in all the five blood samples. Two patients recovered, two developed chronic illness, and one died due to liver failure and hepatic encephalopathy [40]. In other studies, mixed inflammatory cell infiltration, hepatocyte cytomegaly and karyomegaly, cytoplasmic vacuolization, centrilobular necrosis, bile duct hyperplasia, and hepatocellular adenomas are detected [41].

Enlargement of the liver and distension of the abdominal cavity were evident in cattle after ingestion of golden ragwort [42–44].

Watson and colleagues reported 50 toxicity cases at one hospital with fatal *Impila* poisonings in children between the ages of 0–12 [17].

There appear to be two clinical presentations of *Impila* poisoning. The most common is one in which severe hepatocellular failure predominates. In many of these cases, signs of renal failure accompany the hepatic necrosis [33]. The second and less common clinical presentation of *Impila* poisoning is where renal failure [7] is an early finding and precedes the development of hepatic failure [8].

Impila toxicity is very sudden in onset, and it is suspected that many patients, especially those residing in rural areas, do not reach the hospital alive [1, 7, 8]. Documented cases indicate that symptom duration prior to hospital admission is less than 1 day in 40 % of patients [3, 6]. In fatal cases, death occurs either within a few hours (<24) from hypoglycemic coma [33] or within a few days (<4) from acute hepatic failure [3, 17, 34]. In a few cases, patients have succumbed after several days from uremia due to acute renal tubular necrosis [3, 6]. The chance of survival after severe *Impila* intoxication is low. It is estimated that 63 % of patients die within 24 h and a further 28 % die within 4 days; thus, the total mortality from severe *Impila* poisoning is up to 91 % [3, 17].

4 Review of Clinical and Pathological Features: Autopsy Findings and Histopathology

Pathological features associated with *Impila* poisoning in humans are limited to only a few reports. In most of the cases, liver biopsies were not performed due to the severity of the symptoms [8].

The most detailed report of the pathological features associated with *Impila* poisoning in humans reviewed 235 cases of suspected *Impila*-related deaths (30 % of cases were children under the age of 5 years) [3]. Autopsy findings indicated good nutritional status, especially in children, with no evidence of other organic disease. In 50 % of cases, the liver was reduced in weight and appeared pale and yellow. In 70 % of cases, the renal weight was increased and the cortex was pale and swollen. Hemorrhages were often present in the lungs, skin, and intestine.

Histopathology of the liver showed centrilobular necrosis with a sharp demarcation. Death occurred rapidly, due to hypoglycemia. In these cases, centrilobular hepatocytes appeared swollen and showed karyolysis. In cases where death occurred only after a few days from liver failure, hepatocytes were necrotic. Fat vacuoles were seen in some hepatocytes, and the liver had minimal inflammatory infiltration. In cases of kidney failure, renal histology showed necrosis of the proximal convoluted tubules and loop of Henle. In these cases, the liver showed centrilobular collapse of the reticulum framework and cholestasis.

Watson and his colleagues examined 50 autopsy reports of children poisoned with *Impila* [17]. Upon presentation to hospital, 80 % of patients showed a disturbed level of consciousness (confusion, stupor, or coma), and in 52 %, this was associated with convulsions. Other common symptoms included abdominal pain, vomiting and diarrhea. Hypoglycemia (blood glucose <2.5 mmol/L) was found in 93 % of cases, metabolic acidosis (serum bicarbonate <19 mmol/L) in 87 %, uremia (elevated blood urea >6.64 mmol/L) in 60 %, hyperkalemia (serum potassium >5.3 mmol/L) in 63 %, hyponatremia (serum sodium <130 mmol/L) in 45 %, and leukocytosis (total white cell count $>11 \times 10^9$/L) in 80 %. In patients who survived more than 24 h, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and lactic dehydrogenase (LDH) were elevated up to 5–10 times the normal levels, and the prothrombin time was elevated up to 50 % of upper limit of normal. In all cases documented to date, concomitant jaundice has rarely been observed in the patients with hepatotoxicity, and the progression to death was very rapid.

Despite its reputed toxicity, *Impila* continues to be a commonly used traditional remedy in South Africa [1, 35–38]. The concentration of toxins found in plants has been shown to vary with season and soil and climate conditions [37, 39]. Also, the levels of toxin(s) in the poisonous plants may vary with the location [40, 41]. PAs are hepatotoxins, which have both acute and chronic effects in man and animals [3]. Depending on the dose, the observed toxicity is evident within days, weeks, or even months [3, 11–20]. A dose of 10 mg/kg per day produces acute toxicity in1–6 days. On the contrary, ingestion of 0.1 mg/kg/day poses chronic toxicity that presents clinically within months. A group of researchers from Brazil analyzed blood samples from 30 intoxicated animals that presented pathological liver lesions. Comparing the results with samples from 30 healthy animals, the investigators demonstrated that poisoning by *Senecio* spp. causes an increase in lipid peroxidation and consequently oxidative stress in bovine erythrocytes contributing to hemolysis [43].

5 Veno-Occlusive Liver Disease

Evidence of toxicity may not become apparent until some time after the alkaloid is ingested. The acute illness has been compared to the most common pro-thrombotic disorders that lead to Budd–Chiari syndrome, portal vein thrombosis, and sinusoidal obstruction syndrome, previously known as hepatic veno-occlusive disease of the liver. The term veno-occlusive disease of the liver refers to a form of toxic liver injury characterized clinically by the development of hepatomegaly, ascites, and jaundice. Histologically, there is a diffuse damage in the centrilobular zone of the liver. The cardinal histologic features of this injury are marked sinusoidal fibrosis, necrosis of pericentral hepatocytes, and narrowing and eventual fibrosis of central veins. The primary site of the toxic injury is suggested as the sinusoidal endothelial cells, followed by a series of biologic processes that lead to circulatory compromise of centrilobular hepatocytes, fibrosis, and obstruction of liver blood flow.

Other investigators have observed similar cases to the case we previously described with VOD, only the central veins of the liver lobule or sublobular veins are occluded. Toxic pyrrolizidines have acute and chronic effects on the liver, which frequently manifest as VOD [44]. Tomioka and his team report a case of a young woman developing VOD after taking cough remedies prepared using *S. tephrosioides* over a long period of time [45]. Additionally, VOD has been reported after a patient had taken commercial herbal preparations containing *S. vulgaris* [46]. Moreover, VOD has been associated with consumption of PA-containing dietary supplements [47]. Ridker and colleagues showed that as low as the 15 μg PA/kg body weight/day may cause VOD in humans [47].

Roulet and colleagues presented a. hepatic VOD in a newborn infant of a women drinking herbal tea [48]. Kumana's group described herbal tea induced hepatic VOD and was able to quantify the toxic alkaloid exposure in adults [49]. Investigators from Rio de Janeiro described a pediatric VOD case [50]. Hepatic VOD in Egyptian children has been documented [51].

In Peru, Ortiz and colleagues reported *a* VOD due to intake of *S. vulgaris* tea [52]. In Arizona, hepatic VOD due to pyrrolizidine (*Senecio*) poisoning was also described [53]. Tandon et al. reported "an epidemic of VOD in Afghanistan [54] and in Central India [55]. Moreover, ingestion *of* comfrey has been suggested to produce VOD [56, 57]. In the United States, the cases reported so far are four incidents related to comfrey ingestion in adults, two incidents of *Senecio* ingestion in infants and two incidents of Senecio ingestion in adults, four cases of *Heliotropium* ingestion in adults, two cases involving coltsfoot substitution by other PA-containing herbs in infants, and five other cases involving adults with unknown PA-containing herbs (three in China, one during a visit to Ecuador, and one using a tea product from South America). Although some cases of liver damage may have been due to something other than the herbs, in most instances, other sources of the intoxication were not evident or were deemed improbable.

6 Use of Herbal Remedies and Extrahepatic Toxicities

Some species have been reported to contain antimicrobial and therapeutic properties. *S. aureus* is used for injuries and serves as a diaphoretic and diuretic, although high dosages may cause abortion [1, 58]. Other species may cause other extrahepatic manifestations and teratogenesis [59].

S. bicolor is used to treat cataracts and conjunctivitis in the form of eye drops [60]. *S. scandens* possesses antipyretic activities [61]. In traditional Chinese folk medicine, *S. scandens* is known as "qianliguang" and classified in the 1977 edition of Chinese Pharmacopoeia as medication for bacterial diarrhea, enteritis, conjunctivitis, and respiratory tract infections [24]. Other Chinese herbals include *S. argunensis* and *S. integrifolius*, both of which are used in the treatment for febrile disease, inflammation, diarrhea, and cataracts. Both cause hepatotoxicity and extrahepatic manifestations [62]. In Perú, the decoction of the leaves of *S. culcitioides*, *S. tephrosioides*, and *S. canescens* are used to treat coughs, bronchitis, and asthma [63]. In addition, extracts of *S. canescens* have shown to exhibit antipyretic and barbiturate activities, consistent with its role as an analgesic in the treatment of breast pain [64]. *S. rhizomatosus* is used to treat wounds and increase biliary secretion. In Perú, it is used in the treatment of pneumonia [65].

People continue to be vulnerable to complementary and alternative medicine poisoning present in folk remedies, which are usually administered chronically. The concentration of PA in the plant extract differs since it depends on the area it was collected in, the season, and other climatic conditions. The standardization is not possible for several reasons: first, the content of the remedies are often poorly understood, thus making it difficult to discern toxicity level and almost impossible to place regulatory standards on which remedies are safe. Secondly, many patients are reluctant to disclose practice of folk remedies. This complicates the diagnosis process, which is already compromised due to poor analytical techniques [66, 67].

7 Sources of Poisoning

In addition to South Africa, there are many other countries which reported cases of deadly poisonings by herbal remedies in humans and animals: Afghanistan [54], Argentina [42], Brazil, Uruguay and Paraguay [32], Great Britain [56], Egypt [51], Greece [68], Hong Kong [49], India [55], Israel [41], Italy [69], Jamaica [70], Morocco [71], Scotland [72], and United States [23, 52].

In some countries, the larger population are exposed to low levels of alkaloids in commonly available foods, such as honey in Australia [73] and milk [74] and comfrey tea in Europe [19, 56].

S. *jacobaea* has been reported to contribute to honey production in Albania, Brazil, Italy, Switzerland, United Kingdom, United States, and Zimbabwe [75]. There is an alarming 3.9 μg of PAs per gram of honey from *S. jacobaea*, which translates to approximately 50–75 % of the plant when extraction efficiency is taken into consideration [75]. Although acute PA poisoning is still unlikely even when assuming maximum honey consumption of around 93 g per day for adults and 32 g per day for infants, the German Federal Health Bureau and the International Program on Chemical Safety both conclude that the level of PAs present in honey may contribute to chronic liver disease and liver tumors [76, 77].

S. longilobus is often confused with *Gordolobo yerba*, a popular Mexican herb obtained from *Gnaphalium macounii* [40]. This confusion often leads to erroneous preparation of the “yerba” herb, and resultant deaths include a 2-month-old boy and a 6-month-old girl after exposure to *S. longilobus* in *Gordolobo yerba* [40].

8 Combining Herbal and Conventional Medicine

In the last years, herbal medicines have frequently been used as an alternative or in addition to medical therapy for human immunodeficiency virus (HIV)-positive individuals and acquired immunodeficiency syndrome (AIDS) patients. A group of infectious disease specialists treated a pediatric population with antiviral and herbal remedies [78]. Others aimed to summarize research findings for herbal medicines, which are endowed with the ability to inhibit HIV. A Chinese herbal medicine, *Scutellaria baicalensis* and its identified components (i.e., baicalein and baicalin) have been shown to inhibit infectivity and replication of HIV [79]. There is insufficient evidence to support the use of herbal medicines in HIV-infected individuals and AIDS patients. Potential beneficial effects need to be confirmed in large, rigorous trials. Moreover, the possible toxicities due to the herbal remedies interactions with the antiviral therapy have to be considered.

9 Clinical Significance and Conclusions

Studying the facts involved in *herbal remedies*-induced toxicity has immense medical significance. Fatal or near-fatal poisoning cases that result from the use (or misuse) of traditional herbal medicines continue to be a common problem in many countries. Currently, there is no antidote or neutralization method for natural substances that induce veno-occlusive disease of the liver, *a*nd supportive care is the only therapy provided to these patients if time permits. This has been largely unsuccessful due to unavailability of medical support and/or fast deterioration of patient status due to long time lapse from ingestion or ingestion of high dose. As such, many of the cases often resulted in imminent death. The case and review presented here may contribute to the medical community awareness and thus finding a rational approach to limit or prevent VOD cases due to herbal remedies. Based on our clinical case of herbal remedies-induced VOD, this subject deserves further investigation and education. From a social point of view, the present knowledge on the pathophysiology of herbal remedies-induced VOD may assist in gaining a larger awareness of the problem, which will be required for the development of educational strategies aimed at physicians and the public about the potential dangers of these commonly used remedies. Herbal products are gaining widespread popularity across the globe. In the United States, it is estimated that up to 40 % of the adult population use herbal remedies [80], with similar trends occurring in Canada [81], Europe [72], and Australia [82]. The safety of these compounds, therefore, is not only a concern for third world countries, but should be made a priority in developed countries as well. While many medicinal plants offer significant therapeutic benefits, it is imperative that their potential risks are also recognized [83–85].

The common view that all “natural” compounds are safe compounds is a myth, and further studies on herbal-induced hepatotoxicity are needed to expose this dangerous misconception. Herbal remedies were used for centuries [86–88]. Diseases of domestic animals now known to be caused by the hepatotoxic PAs were a matter of concern to British farmers at the end of the eighteenth century until our days in Australia [89]. Moreover, in Germany, poisoning of horses and cattle by *Senecio jacobaea* is of renewed relevance for veterinary medicine. In addition, European and international authorities are concerned about possible residue levels in food of animal origin. The disease occurs almost entirely as a consequence of chronic poisoning and ends fatally due to formation of toxic metabolites of pyrrolizidine alkaloids in the liver, leading to cirrhosis. In addition, many pyrrolizidine alkaloids possess mutagenic and a few also carcinogenic properties [90].

Medicinal plants undoubtedly play a role in the treatment of disease, especially in developing countries. Although their toxicity has been known for a long time, PA-containing plants are still in use in many traditional medicines. Traditional healing systems have become of increasingly employed alone or as complementary medicine since many people believe that they can be used without any risk and side effects. This also applies to the traditional medicine of Madagascar and the Mascarene Islands, South Africa, Romania, and Israel [91, 92]. As with most therapeutic drugs, however, there is also a potential to cause toxicity, especially veno-occlusive disease of the liver [92]. It is important to understand the need of monitoring the use of herbal medicine with the aim of optimizing clinical complementary medicine use and maximizing the clinical and economic benefits, as well as, to enhance communication between scientists and physicians of all disciplines involved in complementary alternative medicine and clinical toxicology.

Abstract

The distinct biting quality of black pepper (*Piper nigrum*) widely used in human dietary is attributed to the alkaloid piperine. Black pepper is also used as a food preservative and as a vital component in traditional medicines in India and China. Several physiological effects of black pepper and its bioactive alkaloid piperine have been reported in recent decades. By stimulating the digestive enzymes of pancreas, piperine enhances the digestive capacity. Piperine has been documented to enhance the bioavailability of a number of therapeutic drugs as well as phytochemicals by its inhibitory influence on drug transformation reactions in liver and intestine. It strongly inhibits hepatic and intestinal aryl hydrocarbon hydroxylase and glucuronyl transferase. Piperine's bioavailability

DOI 10.1007/978-3-642-22144-6_184, © Springer-Verlag Berlin Heidelberg 2013

enhancing property is also partly attributed to increased absorption as a result of its effect on the ultrastructure of intestinal brush border. Piperine has been evidenced to have antidiarrheal property and an effect on intestinal motility and on the ultrastructure of intestinal microvilli improving absorbability of micronutrients. Piperine has been demonstrated in in vitro studies to protect against oxidative damage by inhibiting or quenching reactive oxygen species. Piperine treatment also lowers lipid peroxidation in vivo and beneficially influences antioxidant status in situations of oxidative stress. Piperine has been found to possess antimutagenic and antitumor influences.

Capsaicin, the pungent alkaloid of red pepper (*Capsicum annuum*), has been extensively studied for its biological effects which are of pharmacological relevance. These include cardioprotective influence, anti-lithogenic effect, anti-inflammatory and pain-relieving effect, thermogenic influence, and effects on gastrointestinal system. The involvement of neuropeptides, substance P, serotonin, and somatostatin in the pharmacological actions of capsaicin has been extensively investigated. Tropical application of capsaicin is proved to alleviate pain in arthritis, postoperative neuralgia, diabetic neuropathy, psoriasis, etc. Toxicological studies on capsaicin administered by different routes are documented. Capsaicin inhibits acid secretion and stimulates alkali and mucus secretion and particularly gastric mucosal blood flow which helps in prevention and healing of gastric ulcers. Antioxidant and anti-inflammatory properties of capsaicin are established in a number of studies. Chemopreventive potential of capsaicin is evidenced in cell line studies. The health beneficial hypocholesterolemic influence of capsaicin besides being cardioprotective has other implications, namely, prevention of cholesterol gallstones and protection of the structural integrity of erythrocytes under conditions of hypercholesterolemia. Beneficial influences of capsaicin on gastrointestinal system include digestive stimulant action and modulation of intestinal ultrastructure so as to enhance permeability to micronutrients.

1 Piperine of Black Pepper (*Piper nigrum*)

1.1 Introduction

Black pepper (*Piper nigrum*) – the dried berries of the plant belonging to the family Piperaceae – is one of the most widely used among spices, valued for its distinct biting quality. Black pepper has been used as a spice in India since prehistoric times; it is known to Indian cooking since at least 2000 BC [1]. Black pepper is produced from the green unripe berries of the pepper plant by briefly cooking in hot water [2]. White pepper which is commonly found in Western countries is produced

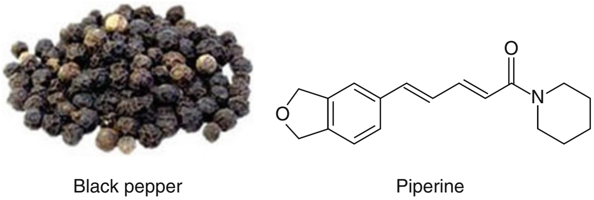

Fig. 45.1 Black pepper and piperine

by soaking ripe pepper berries in water for about a week, during which the flesh of the fruit softens and decomposes; rubbing off the skin would result in the naked seed which is then dried [2] (Fig. 45.1).

Black pepper is historically used also in traditional medicines and home remedies in India [3]. Black pepper figures in remedies in *Ayurveda*, *Siddha*, and *Unani* medicine in India for such illnesses as constipation, diarrhea, earache, gangrene, heart disease, hernia, hoarseness, indigestion, insect bites, insomnia, joint pain, liver problems, lung disease, oral abscesses, sunburn, tooth decay, and toothaches. Black pepper was relied upon to treat specific conditions such as diarrhea and fevers, but it appears that the extensive, generalized use was to enhance the effects of many herbal remedies [3].

Long pepper (*Piper longum*) and black pepper (*Piper nigrum*) (both of which are now known to contain piperine) have been prescribed in *Ayurvedic* system of medicine in India for thousands of years, a practice which may have enhanced pharmacological actions of other compounds in traditional herbal medicines. Black pepper is a component of *trikatu* (three acrids) along with long pepper and ginger (*Zingiber officinale*) in equal proportions; *trikatu* is widely used in combination with other *Ayurvedic* medications. Black pepper is specifically cited in *Ayurveda* to internally treat fevers, gastric and abdominal disorders, and urinary problems [4]. Medicinal external treatments with black pepper include treatments for rheumatism, neuralgia, and boils [4]. Possible uses of black pepper in Indian folk medicine include the treatment of respiratory diseases, dysentery, pyrexia, and insomnia [4]. Black pepper is part of a herbal, folk remedy relied to treat diarrhea [5]. Black pepper is also a constituent of traditional Chinese medicine for stimulation of digestion and relieving diarrhea [6]. Black pepper has been used in China as a folk remedy for epilepsy.

The spiciness of black pepper which is characterized by a distinct biting quality is due to the alkaloid compound piperine, which is found both in the outer fruit and in the seed [2]. Refined piperine is about 1 % as hot as the capsaicin of red chili pepper. The bioactive and pungent ingredient of black pepper was identified as piperine and isolated in 1820 by the Dutch chemist Hans Christian Oersted [2].

1.2 Biological Effects of Piperine

Many health beneficial physiological effects of black pepper or its bioactive alkaloid – piperine – have been reported in recent decades and been reviewed [7].

1.2.1 Inhibition of Drug-Metabolizing Enzyme System

In the context of piperine having been reported to enhance drug bioavailability, Atal et al. studied the interaction of piperine with hepatic drug biotransformation reactions in vitro and in vivo [8]. Piperine inhibited hydroxylation of aryl hydrocarbon, *N*-demethylation of ethylmorphine, *O*-deethylation of 7-ethoxy-coumarin, and glucuronidation of 3-hydroxybenzo (α-) pyrene (3-OH-BP) in rat liver in vitro in a dose-dependent manner. Piperine inhibited hepatic microsomal aryl hydrocarbon hydroxylase (AHH) noncompetitively from the untreated and 3-methylcholanthrene-treated rats with a K_i of 30 μM. Similarly, the kinetics of inhibition of ethylmorphine-*N*-demethylase from control rat liver exhibited noncompetitive inhibition with a K_m of 0.8 mM and K_i of 35 μM. These studies demonstrated that piperine is a nonspecific inhibitor of drug metabolism which shows little discrimination between different cytochrome P_{450} forms. Oral administration of piperine in rats strongly inhibited the hepatic AHH and UDP-glucuronyl transferase activities. Pretreatment with piperine prolonged hexobarbital sleeping time and zoxazolamine paralysis time in mice. These observations suggest that piperine is a potent inhibitor of drug metabolism. The mechanism of inhibition of glucuronidation by piperine has been explored by examining the rate of glucuronidation of 3-OH-BP and UDP-glucuronic acid (UDPGA) concentration in isolated epithelial cells of the guinea pig small intestine [9], and it was found that glucuronidation of 3-OH-BP was dependent on duration of incubation, cellular protein, and endogenous UDPGA concentration. Piperine caused a concentration-related decrease in UDPGA content and the rate of glucuronidation in these cells. Piperine noncompetitively inhibited hepatic UDP-glucuronyltransferase with Ki of 70 μM. The study demonstrated that piperine modifies the rate of glucuronidation by lowering the endogenous UDPGA concentration and also by inhibiting the transferase activity (Table 45.1).

Twenty-four hours following intragastric administration of piperine (800 mg/kg) in adult rats, a significant decrease in the hepatic levels of cytochrome P_{450}, benzphetamine *N*-demethylase, aminopyrine *N*-demethylase, and aniline hydroxylase has been observed [13]. An *i.p.* administration of rats with piperine (100 mg/kg) produced a significant decrease in hepatic cytochrome P_{450} and activities of benzphetamine *N*-demethylase, aminopyrine *N*-demethylase, and aniline hydroxylase 1 h after the treatment [15]. Twenty-four hours later, these parameters along with cytochrome b_5 and NADPH-cytochrome-C reductase remained depressed in piperine-treated rats. Piperine noncompetitively inhibited aromatic hydrocarbon hydroxylase (AHH) and 7-ethoxycoumarin deethylase activities in lung microsomes of rats and guinea pigs in vitro [10]. Piperine given at a dose of 25 mg/kg to rats caused a maximal inhibition of both the enzymes at 1 h. Similarly, upon daily treatment of piperine (15 mg/kg) to rats for 7 days, deethylase activity was consistently inhibited, while AHH showed faster recovery. Piperine thus appeared to cause differential inhibition of two forms of cytochrome P_{450} and thus would accordingly affect the steady-state level of those drugs metabolized by these pulmonary forms of cytochrome P_{450}.

Table 45.1 Inhibitory effects of piperine on drug-metabolizing enzyme system in vitro and in vivo

System	Observed effect	References
In vitro	(a) Inhibition of aryl hydroxylation, *N*-demethylation, *O*-deethylation, and glucuronidation in vitro by piperine	[8]
	(b) Decreased UDP-glucuronic acid concentration and rate of glucuronidation in isolated epithelial cells of guinea pig small intestine by piperine	[9]
	(c) Inhibition of aryl hydroxylase and *O*-deethylase activities by piperine in vitro in pulmonary microsomes	[10]
	(d) Suppression of aryl hydroxylation in cell culture is mediated by direct interaction of piperine with cytochrome P_{450} and not by downregulation of its gene expression	[11]
	(e) Piperine decreased the activities of liver microsomal aryl hydroxylase, *N*-demethylase and UDP-glucuronosyl transferase, and cytochrome P_{450}	[12]
Rats	(a) Lower aryl hydroxylase and UDP-glucuronyl transferase activities, prolonged hexobarbital sleeping time in piperine-treated rats	[8]
	(b) Inhibition of aryl hydroxylase and *O*-deethylase activities by piperine in vivo in pulmonary microsomes	[10]
	(c) Decreased activities of hepatic microsomal cytochrome P_{450}, *N*-demethylase, aryl hydroxylase by intragastric/intraperitoneal piperine	[13]
	(d) Inhibition of UDP-glucose dehydrogenase and UDP-glucuronyl transferase in liver and intestine by piperine	[14]
	(e) Lowered activity of *N*-demethylase, UDP-glucuronosyl transferase, and NADPH-cytochrome-C reductase as a result of piperine feeding	[12]
Guinea pig	(a) Inhibition of UDP-glucose dehydrogenase and UDP-glucuronyl transferase in liver and intestine by piperine	[14]

Piperine caused a concentration-related strong noncompetitive inhibition of UDP-glucose dehydrogenase (UDPGDH) reversibly and equipotently in rat and guinea pig liver and intestine [14]. However, the UDPGA contents were decreased less effectively by piperine in isolated rat hepatocytes compared with enterocytes of guinea pig small intestine. Data on UDPGA content and rate of glucuronidation suggested that piperine is a potent inhibitor of UDPGDH and it exerts stronger effects on intestinal glucuronidation than in rat liver. The effect of dietary piperine (0.02 %) on the activities of the liver drug-metabolizing enzyme system has been examined in rats [12]. Piperine significantly stimulated the activity of aryl hydroxylase, while the activities of *N*-demethylase, UDP-glucuronyl transferase, and NADPH-cytochrome-C reductase were lowered as a result of piperine feeding. Piperine also significantly decreased the activities of liver microsomal AHH, *N*-demethylase and UDP-glucuronosyl transferase, and cytochrome P_{450} in vitro when included at 1×10^{-6} mol/L.

A study of the modulation of benzo(α-)pyrene metabolism and regulation of cytochrome CYP1A1 gene expression by piperine in 5 L cells in culture revealed that piperine-mediated inhibition of AHH activity and consequent suppression of the procarcinogen activation results from direct interaction of piperine with cytochrome P_{450}1A1-protein and not because of downregulation of its gene expression [11]. Piperine was evaluated for beneficial effects in Alzheimer's disease by studying the potential for herb-drug interactions involving cytochrome P_{450}, UDP-glucuronosyl transferase, and sulfotransferase enzymes. Piperine was a relatively selective noncompetitive inhibitor of CYP3A with less effect on other enzymes evaluated [16]. Piperine inhibited recombinant CYP3A4 much more potently than CYP3A5.

1.2.2 Enhancing Effect on the Bioavailability of Drugs and Phytochemicals

Piperine is now established as a bioavailability enhancer of various structurally and therapeutically diverse drugs and other substances. Potential of piperine to increase the bioavailability of drugs in humans is of great clinical significance. Most of the clinical trials have shown that piperine increases levels of medications: phenytoin (used in epilepsy), propranolol (used for hypertension), rifampicin (used in tuberculosis), theophylline (lung medication), and coenzyme Q_{10}. This effect is due to the inhibitory interaction of piperine with cytochrome P_{450} enzymes of the liver and small intestine that are involved in drug metabolism, namely, CYP1A2, CYP1A1, CYP2D6, CYP3A4, and P-glycoprotein [17] (Table 45.2).

The scientific basis of the use of acrids (long pepper, black pepper, and ginger as constituents of *trikatu*) in a large number of medications in the indigenous *Ayurvedic* system of medicine in India has been evaluated by Atal et al. [18]. The observed >200 % increase in the blood levels of the test drug vasicine by *Piper longum* and of test drug sparteine by >100 % under the influence of piperine in a clinical study suggested that these acrids have the capacity to increase the bioavailability of certain drugs. These authors concluded that the *trikatu* group of drugs increases bioavailability of drugs either by promoting rapid absorption from the gastrointestinal tract, or by protecting the drug from being metabolized in its first passage through the liver after being absorbed, or by a combination of these two mechanisms. The effect of piperine on the bioavailability of propranolol and theophylline has been examined in a crossover study, wherein subjects received a single oral dose of propranolol (40 mg) or theophylline (150 mg) alone or in combination with piperine (20 mg/day for 7 days) [19]. An enhanced systemic availability of oral propranolol and theophylline was evidenced as a result of piperine treatment.

A pharmacokinetic study has examined the effect of piperine, a known inhibitor of hepatic and intestinal glucuronidation on the bioavailability of curcumin, the bioactive ingredient of the spice turmeric administered with piperine in healthy human volunteers [20]. After a dose of 2 g curcumin taken without piperine, serum levels were very low, while concomitant administration of piperine (20 mg) produced 2,000 % higher concentrations from 0.25 to 1 h post-drug. The study shows that in the dosages used, piperine enhances the serum concentration, extent of absorption, and bioavailability of curcumin in humans. When curcumin was given alone at 2 g/kg to rats, moderate serum concentrations were achieved over a period of 4 h [20]. Concomitant administration of piperine (20 mg/kg) increased

Table 45.2 Modulation of bioavailability of drugs, phytochemicals, and carcinogens by piperine

System	Remarks	References
Humans	(a) Increased bioavailability of vasicine and sparteine as a result of *Piper longum*/piperine treatment	[18]

	(c) Increased serum concentration of curcumin by concomitant administration of piperine	[20]
	(d) Increased plasma levels of coenzyme Q_{10} by co-administration of piperine	[21]
	(e) Increased plasma concentration of phenytoin when co-administered along with piperine	[22]
	(f) Increased plasma concentration of antiretroviral agent nevirapine when co- administered along with piperine	[23]
Rats	(a) Decreased metabolic activation of fungal toxin aflatoxin B_1 and hence its increased accumulation in plasma	[24]
	(b) Enhanced bioavailability of β-lactam antibiotics – amoxicillin trihydrate and cefotaxime – by co-administration of piperine	[25]
	(c) Enhanced bioavailability of curcumin when administered concomitantly with piperine	[26]
Mice	(a) Delayed elimination of antiepileptic drug – phenytoin – by treatment of piperine	[27]
	(b) Increased plasma levels and delayed excretion of epigallocatechin-3-gallate from green tea as a result of intragastric co-treatment with piperine	[28]

the serum curcumin concentration for a short period of 1–2 h post-drug, and the bioavailability was increased by 154 %. Enhanced bioavailability of curcumin was evidenced when the same was orally administered concomitant with piperine in rats [26]. Intestinal absorption of curcumin was relatively higher when administered concomitantly with piperine, and it stayed significantly longer in the body tissues. This assumes importance in the context of diverse medicinal properties of curcumin.

Black pepper extract consisting of 98 % piperine has been shown to increase plasma levels of orally administered coenzyme Q_{10} in a clinical study [21]. The relative bioavailability of 90 and 120 mg of coenzyme Q_{10} administered in a single dose or for 14 and 21 days with placebo or with 5 mg of piperine was determined by comparing measured changes in plasma concentration. Supplementation of 120 mg coenzyme Q_{10} with piperine for 21 days produced a significant 30 % greater AUC than with coenzyme Q_{10} plus placebo. Piperine has been reported to enhance the oral bioavailability of phenytoin, an antiepileptic drug in human volunteers [22]. Piperine (20 mg administered along with phenytoin) increased significantly the mean plasma concentration of phenytoin in patients receiving either a 150 or 200 mg twice daily dose of phenytoin. A similar effect of piperine in altering the pharmacokinetics of phenytoin has been reported from a study on mice, where pretreatment of piperine significantly delayed the elimination of phenytoin [27]. There was a significant increase in AUC, C_{max}, and K_a. Enhanced bioavailability of nevirapine, a potent non-nucleoside inhibitor of HIV-1 reverse transcriptase indicated for use in combination with other antiretroviral agents for the treatment of HIV-1 infection, has been evidenced when administered along with piperine [23]. Mean maximum plasma concentration, area under the plasma concentration-time curve post-dose, was increased significantly when co-administered with piperine (20 mg) in healthy male subjects.

It has been observed that intragastric co-treatment with dietary piperine enhances the bioavailability of epigallocatechin-3-gallate (EGCG) from green tea in mice [28]. Co-administration of 164 μmol/kg EGCG and 70 μmol/kg piperine to mice increased the plasma C_{max} and AUC by 1.3-fold compared to mice treated with EGCG only. Piperine appeared to increase EGCG bioavailability by inhibiting glucuronidation and gastrointestinal transit. Co-administration of piperine enhanced the bioavailability of β-lactam antibiotics amoxicillin trihydrate and cefotaxime significantly in rats [25]. The improved bioavailability is reflected in various pharmacokinetic parameters, namely, t_{max}, C_{max}, half-life, and AUC of these antibiotics. The effect of piperine on the metabolic activation and distribution of aflatoxin B_1 (AFB_1) in rats has been studied [24]. Rats pretreated with piperine accumulated considerable AFB_1 in plasma and in the tissues examined as compared to the controls.

1.2.3 Beneficial Influences on the Gastrointestinal System

Digestive Stimulant Action

While studying the effect of spices on the secretion and composition of saliva in human subjects, it has been observed that black pepper enhances the secretion of saliva and the activity of salivary amylase [29]. The digestive stimulant action of spices is exerted through (1) a beneficial stimulation of the liver to produce and secrete bile rich in bile acids, which play a very important role in fat digestion and absorption, or (2) a beneficial stimulation of the activities of enzymes of pancreas and intestine that participate in digestion [30]. Black pepper and its bioactive alkaloid piperine, examined for their effect on bile secretion as a result of dietary intake for a period of time in experimental rats, did not show any beneficial stimulatory influence on bile acid production by the liver and its secretion into bile [31]. On the other hand, oral administration of piperine as a single dose significantly increased bile acid secretion. Influence of dietary intake of piperine on the pancreatic digestive enzymes and the terminal digestive enzymes of the small intestinal mucosa has been examined in experimental rats. Significantly increased activities of pancreatic lipase, amylase, chymotrypsin, and trypsin were observed as a result of dietary intake of piperine in these experimental rats [32]. Such beneficial influence of this spice on the activity of these enzymes was not evident when administered as a single oral dose. Piperine also significantly enhanced the activity of intestinal lipase and amylase in animals given single oral dose of piperine [33] (Table 45.3).

Dietary piperine (0.02 %) was examined for its influence on bile secretion, digestive enzymes of pancreas, and absorption of dietary fat in rats fed high fat (30 %) for 8 weeks [34]. Piperine enhanced the activity of pancreatic lipase and

	(c) Oral administration of piperine increases biliary bile acid secretion	[31]
	(d) Enhanced activity of pancreatic lipase, higher secretion of bile acids in high-fat-fed rats which was associated with enhanced fat absorption	[34]
Influence on intestinal motility and food transit time		
Humans	(a) Increased orocecal transit time after black pepper consumption	[41]
Rats	(a) Gastrointestinal food transit time shortened by dietary piperine	[35]
	(b) Piperine inhibited gastric emptying of solids/liquids	[36]
Mice	(a) Piperine inhibited gastrointestinal transit	[36]
	(b) Piperine dose-dependently delayed gastrointestinal motility	[37]
Effect on gastric mucosa		
Humans	(a) Black pepper caused increases in gastric parietal and pepsin secretion and increased gastric cell exfoliation in humans	[38]
Rats	(a) Black pepper increased gastric acid secretion in anesthetized rats	[39]
	(b) Piperine increased gastric acid secretion	[40]
	(c) Piperine had protective action against stress-induced gastric ulcer	[41]
	(d) Dietary piperine showed protective effect on gastric and intestinal mucosa with respect to activities of antioxidant enzymes and gastric mucin content	[42]
	(e) Dietary piperine alleviated the diminished activities of antioxidant enzymes in gastric and intestinal mucosa during ethanol-induced oxidative stress	[42]
Mice	(a) Piperine had protective action against stress-induced gastric ulcer	[41]
Antidiarrheal property		
Mice	(a) Piperine inhibited diarrhea produced by castor oil, arachidonic acid, etc.	[36]
	(b) Piperine reduced castor oil-induced intestinal fluid accumulation	[43]
Influence on absorptive function		
Rats	(a) Piperine stimulated γ-glutamyl transpeptidase activity and enhanced uptake of amino acids in isolated epithelial cells of rat jejunum	[44]
	(b) Piperine modulated membrane dynamics and permeation characteristics, increasing absorptive surface and induction of synthesis of proteins associated with cytoskeletal function	[45]
	(c) Dietary piperine induced alteration in BBM fluidity and permeability property, associated with increased microvilli length, resulting in higher absorptive surface of the small intestine	[46]
	(d) Duodenum, jejunum, and ileum portions of small intestines isolated from rats pre-fed piperine showed higher uptake of iron, zinc, and calcium	[47]
	(e) Higher in vitro absorption of β-carotene in the intestines was evidenced in piperine-fed animals	[48]
	(f) Dietary piperine improved intestinal absorption of orally administered β-carotene	[49]

caused higher secretion of biliary bile acids in high-fat-fed rats which was associated with enhanced fat absorption. Stimulation of lipid mobilization from adipose tissue was suggested by the decrease in perirenal adipose tissue weight by dietary piperine. This was also accompanied by prevention of the accumulation of triglyceride in liver and serum in high-fat-fed rats. Activities of key lipogenic enzymes in liver were reduced which was accompanied by an increased activity of hormone-sensitive lipase. Thus, dietary piperine enhances fat digestion and absorption in high-fat-fed situation through enhanced secretion of bile salts and a stimulation of the activity pancreatic lipase. At the same time, the energy expenditure is facilitated to prevent the accumulation of absorbed fat.

Influence on Absorptive Function

Piperine (25–100 μM) has been shown to significantly stimulate γ-glutamyl transpeptidase (γ-GT) activity in vitro and enhance the uptake of amino acids in freshly isolated epithelial cells of rat jejunum [44]. The kinetic behavior of γ-GT was altered in the presence of piperine, suggesting that this alkaloid may interact with the lipid environment to produce effects leading to increased permeability of the intestinal cells. It is hypothesized that piperine's bioavailability-enhancing property may be partly attributed to increased absorption [45]. Piperine also caused an increase in intestinal brush border membrane fluidity and stimulated the activities of leucine aminopeptidase and glycyl-glycine dipeptidase due to the alteration in enzyme kinetics. This suggests that piperine modulates the membrane dynamics due to its apolar nature by interacting with surrounding lipids and hydrophobic portions in the protein vicinity, which may decrease the tendency of membrane lipids to act as stearic constrains to enzyme proteins and thus modify enzyme conformation. Ultrastructural studies with piperine showed an increase in microvilli length with a prominent increase in free ribosomes and ribosomes on the endoplasmic reticulum in enterocytes, suggesting that synthesis or turnover of cytoskeletal components or membrane proteins may be involved in the observed effect. Thus, piperine may induce alterations in membrane dynamics and permeation characteristics, along with induction of the synthesis of proteins associated with cytoskeletal function, resulting in an increase in the absorptive surface, thus assisting efficient permeation through the epithelial barrier.

Beneficial influence of black pepper and its bioactive alkaloid piperine on the small intestinal ultrastructure has been revalidated in a recent study [46]. Groups of rats were maintained on dietary black pepper (0.5 %) or piperine (0.02 %) for 8 weeks. Membrane fluidity study using an apolar fluorescent probe showed increased BBM fluidity in these spice-fed animals. This was corroborated by decreased cholesterol: phospholipid ratio in jejunal and ileal regions of the intestine. The dietary spice or its bioactive compound stimulated the activities of BBM enzymes – glycyl-glycine dipeptidase, leucine aminopeptidase, and γ-glutamyl transpeptidase – in jejunal mucosa, suggesting a modulation in membrane dynamics due to the apolar spice bioactive compounds interacting with surrounding lipids and hydrophobic portions in the protein vicinity and thus modify enzyme conformation. Scanning electronic microscopy of the intestinal villi in these spice treatments revealed alteration in the ultrastructure, especially an increase in microvilli length which would mean a beneficial increase in the absorptive surface of the small intestine, providing for an increased bioavailability of micronutrients. Thus, dietary black pepper and piperine were evidenced to induce alteration in BBM fluidity and passive permeability property, associated with the induction in the increased microvilli length, resulting in increased absorptive surface of the small intestine.

In view of dietary black pepper and piperine specifically altering the ultrastructure and permeability characteristics of small intestines, these dietary interventions have been examined for their possible influence on intestinal absorption of minerals [47]. Everted segments of duodenum, jejunum, and ileum portions of small intestines isolated from rats pre-fed this spice for 8 weeks and examined for the uptake of iron, zinc, and calcium from incubations containing digesta of finger millet showed higher absorption of these minerals. Dietary black pepper and piperine have also been studied for their possible influence on absorption of β-carotene by examining its uptake by the intestinal segments from rats pre-fed these spices [48]. Higher in vitro absorption of β-carotene in the intestines was evidenced in piperine-fed animals which was 47 % higher than control, while dietary black pepper produced 59 % increase. An animal study has also evaluated the influence of dietary piperine on the absorption of orally administered β-carotene and its conversion to vitamin A [49]. Concentration of β-carotene significantly increased in serum, liver, and intestine of piperine-fed rats 4 h after single oral administration of β-carotene suggesting improved intestinal absorption of β-carotene. Retinol concentration was not however changed in these animals suggesting that bioconversion of β-carotene to vitamin A was not similarly influenced. Activities of the two enzymes involved in the bioconversion of β-carotene to vitamin A, namely, β-carotene-15,15′-dioxygenase and retinal reductase in intestines and liver, remained unaffected by dietary piperine. Activities of these two enzymes involved in the bioconversion of β-carotene to retinal were inhibited by piperine in vitro, thus corroborating with in vivo observation.

Influence on Gastrointestinal Motility and Food Transit Time

An increase in orocecal transit time has been observed in human subjects after black pepper (1.5 g) consumption in a study of the effect on small intestinal peristalsis [50]. Piperine inhibited gastric emptying of solids/liquids in rats and gastrointestinal transit in mice in a dose- and time-dependent manner [36]. It significantly inhibited gastric emptying of solids and gastrointestinal transit at the doses extrapolated from humans (1 and 1.3 mg/kg *p.o.* in rats and mice, respectively). One week oral treatment with the same dose in rats and mice did not produce a significant change compared to single dose administration. Gastric emptying inhibitory activity of piperine is independent of gastric acid and pepsin secretion. Piperine which activates vanilloid receptors (0.5 – 20 mg/kg *i.p.*) dose-dependently delayed gastrointestinal motility in mice [37]. The inhibitory effect of piperine (10 mg/kg) was strongly attenuated in capsaicin (75 mg/kg)-treated mice. The study indicated that the vanilloid ligand piperine can reduce upper gastrointestinal motility. The effect of piperine involves capsaicin-sensitive neurons but not vanilloid receptors.

The gastrointestinal food transit time in experimental rats was significantly shortened by dietary piperine [35]. The reduction in food transit time produced by dietary piperine roughly correlated with its beneficial influence on digestive enzymes [30]. Thus, dietary piperine which has enhanced the activity of digestive enzymes also has markedly reduced the food transit time at the same level of consumption. This reduction in food transit time could probably be attributed to acceleration in the overall digestive process as a result of increased availability of digestive enzymes.

Antidiarrheal Property

Peppers are added in traditional antidiarrheal formulations of different herbs. In a study made in experimental mice, the antidiarrheal activity of piperine against diarrhea produced by castor oil, $MgSO_4$, and arachidonic acid has been evidenced at 8 and 32 mg/kg *p.o.* dose [51]. Inhibition of castor oil-induced entero pooling by piperine suggests its inhibitory effect on prostaglandins. Piperine (2.5–20 mg/kg, *i.p.*) dose-dependently reduced castor oil-induced intestinal fluid accumulation in experimental mice; piperine reduces castor oil-induced fluid secretion with a mechanism involving capsaicin-sensitive neurons [43].

Effect on Gastric Mucosa

Pungent spices have long been implicated to cause gastric mucosal injury. The effects of black pepper on the gastric mucosa were assessed using double-blind intragastric administration of the spice (1.5 g) to healthy human volunteers and found to be similar to aspirin [38]. Black pepper caused significant increases in parietal secretion, pepsin secretion, and potassium loss. Gastric cell exfoliation (as reflected in DNA loss in gastric contents) was increased after black pepper administration and mucosal micro bleeding was also observed.

On the other hand, protective action of piperine against experimental gastric ulcer has been evidenced in rats and mice wherein the gastric mucosa damage was induced by stress, indometacin, HCl, and pyloric ligation [41]. Piperine at 25 − 100 mg/kg *i.g.* protected animals from gastric ulceration in a dose-dependent manner as indicated by inhibition of the volume of gastric juice, gastric acidity, and pepsin activity. Black pepper has been reported to significantly increase gastric acid secretion in anesthetized rats [39]. Piperine has been shown to produce dose-dependent (20–142 mg/kg) increase in gastric acid secretion in rats [40]. Involvement of cholinergic receptors in the observed piperine-induced increase in gastric acid secretion is ruled out as the effect of piperine was significantly antagonized by cimetidine (1 mg/kg) but not by atropine (1 mg/kg). There is however an indication that increased acidity induced by piperine could be due to stimulation of histamine H_2 receptors by this pepper alkaloid.

In a recent study, the protective effect of dietary black pepper (0.5 %) and piperine (0.02 %) with respect to activities of antioxidant enzymes in gastric and intestinal mucosa was examined [42]. These dietary interventions significantly enhanced the activities of antioxidant enzymes − superoxide dismutase, catalase, glutathione reductase, and glutathione-*S*-transferase – in both gastric and intestinal mucosa, suggesting a gastrointestinal protective role for black pepper and piperine. In a separate study, these were found to alleviate the diminished activities of antioxidant enzymes in gastric and intestinal mucosa under conditions of ethanol-induced oxidative stress. The gastro protective effect was also reflected in their positive effect on mucosal glycoproteins, thereby lowering mucosal injury. The amelioration of the ethanol-induced decrease in the activities of antioxidant enzymes in gastric and intestinal mucosa by dietary spices suggests their beneficial gastrointestinal protective role.

1.2.4 Antioxidant Effects

Piperine has been demonstrated in in vitro experiments to protect against oxidative damage by quenching free radicals and reactive oxygen species and inhibiting lipid peroxidation [52]. Piperine is reported to have marginal inhibitory effects on ascorbate/Fe^{2+}-induced lipid peroxidation in rat liver microsomes even at high concentrations (600 μM) when compared to the beneficial inhibition of lipid peroxidation by antioxidants – vitamin E, *t*-butylhydroxy toluene and *t*-butylhydroxy anisole [53]. Both water and ethanol extract of black pepper exhibited strong total antioxidant activity and significant inhibition of peroxidation of linoleic acid emulsion [54]. Piperine is shown to be an effective antioxidant and offers protection against oxidation of human low-density lipoprotein (LDL) [55]. The aqueous extract of black pepper and piperine have been examined for their effect on human PMNL 5-lipoxygenase (5-LO), the key enzyme involved in biosynthesis of leukotrienes [56]. The formation of 5-LO product was significantly inhibited in a concentration-dependent manner. Thus, piperine might exert an antioxidant physiological role by modulating 5-LO pathway (Table 45.4).

Piperine treatment (10 mg/kg/day, *i.p.* for 14 days) has been assessed for protection against diabetes-induced oxidative stress in streptozotocin-induced diabetic rats [58]. Treatment with piperine reversed the diabetic effects on glutathione concentration in brain, on renal glutathione peroxidase and superoxide dismutase activities, and on cardiac glutathione reductase activity and lipid peroxidation. Thus, treatment with piperine for 14 days is only partially effective as an antioxidant in diabetes. The ability of piperine to reduce the oxidative changes induced by chemical carcinogens (7,12-dimethyl benzanthracene, dimethyl aminomethyl azobenzene, and 3-methyl cholanthrene) has been investigated in rat intestinal model [57]. A protective role of piperine against the oxidative alterations by these carcinogens was indicated by the observed inhibition of TBARS, a significant increase in the glutathione levels and restoration in γ-glutamyl transpeptidase and Na^+, K^+-ATPase activity in intestinal mucosa. Oral supplementation of piperine (50 mg/kg) effectively suppressed lung carcinogenesis by benzo (α)pyrene as revealed by a decrease in the extent of mitochondrial lipid peroxidation and concomitant increase in the activities of enzymatic antioxidants and nonenzymatic antioxidant levels when compared to lung carcinogenesis-bearing mice [61]. This suggests that piperine may extend its chemopreventive effect by modulating lipid peroxidation and augmenting antioxidant defense system.

The effect of supplementation of black pepper or piperine for a period of 10 weeks on tissue lipid peroxidation and enzymic and nonenzymic antioxidants has been examined in rats fed a high-fat diet (20 % coconut oil and 2 % cholesterol),

Mice	Piperine treatment decreased mitochondrial lipid peroxidation and augmented antioxidant defense system during benzo(α) pyrene- induced lung carcinogenesis	[60]

and it was observed that these can reduce high-fat diet-induced oxidative stress [59]. Simultaneous supplementation with black pepper or piperine lowered TBARS and conjugated diene levels and maintained antioxidant enzymes and glutathione levels in the liver, heart, kidney, intestine, and aorta near to those of control rats.

1.2.5 Antimutagenic and Tumor Inhibitory Effects

Black pepper has been shown to be effective in reducing the mutational events induced by the promutagen ethyl carbamate in *Drosophila* melanogaster [62]. Suppression of metabolic activation or interaction with the active groups of mutagens could be mechanism by which this spice exerts its antimutagenic action. While studying piperine for its immunomodulatory and antitumor activity, piperine was found to be cytotoxic toward Dalton's lymphoma ascites (DLA) and Ehrlich ascites carcinoma (EAC) cells at 250 μg/mL [63]. Piperine was also found to be cytotoxic toward L929 cells in culture at a concentration of 50 μg/mL. Administration of piperine (1.14 mg/animal) could inhibit the solid tumor development in mice induced with DLA cells and increase the life span of mice-bearing Ehrlich ascites carcinoma tumor (Table 45.5).

The effect of piperine on the cytotoxicity and genotoxicity of aflatoxin B_1 (AFB_1) has been studied in rat hepatoma cells H4IIEC3/G-(H4IIE) using cellular growth and formation of micronuclei as endpoints [64]. Piperine markedly reduced the toxicity of aflatoxin. That is, AFB_1-induced formation of micronuclei in a concentration-dependent manner probably by suppressing cytochromes P_{450} mediated bioactivation

Table 45.5 Antimutagenic and cancer preventive effects of piperine

	(d) Chemopreventive effect of piperine on benzo(α)pyrene induced experimental lung cancer	[61, 70, 71]

of the mycotoxin. The potential of piperine for inhibiting the activity of cytochrome $P_{450}2B1$ and protecting against AFB_1 has been investigated in Chinese hamster r2B1 cells engineered for the expression of rat $CYP_{450}2B1$ [65]. Piperine at 60 μM completely counteracted cytotoxicity and formation of micronuclei by 10 μM AFB_1 and reduced the toxic effects of 20 μM AFB_1 by > 50 %. The results suggest that (1) piperine is a potent inhibitor of rat $CYP_{450}2B1$ activity, (2) AFB_1 is activated by r2B1 cells to cytotoxic and genotoxic metabolites, and (3) piperine counteracts $CYP_{450}2B1$-mediated toxicity of AFB_1 in the cells and might, therefore, offer a potent chemopreventive effect against procarcinogens activated by $CYP_{450}2B1$.

The antimutagenic effect of piperine has been studied with respect to its influence on chromosomes in rat bone marrow cells [66]. Wistar rats orally administered piperine (100, 400, and 800 mg/kg) were challenged with cyclophosphamide (*i.p.* 50 mg/kg). Piperine (100 mg/kg) produced significant reduction in cyclophosphamide-induced chromosomal aberrations, suggesting that it may have antimutagenic potential. Black pepper extracts have been demonstrated to possess tumor inhibitory activity [72]. Tumor-reducing activity of orally administered extracts of black pepper was studied in mice transplanted *i.p.* with Ehrlich ascites tumor, wherein life span was increased in these mice by 65 % [68]. The antimetastatic activity of piperine has been demonstrated by the inhibition of lung metastasis induced by B16F-10 melanoma cells in C57BL/6 mice [69].

The cytoprotective effect of piperine on benzo(α-)pyrene-induced lung cancer has been investigated in mice and observed that piperine may extend its chemopreventive effect by modulating lipid peroxidation and augmenting antioxidant defense system [70]. Oral administration of piperine (100 mg/kg) effectively suppressed this experimental lung cancer. The protective role of piperine was examined during experimental lung carcinogenesis with reference to its effect on DNA damage and detoxification enzyme system [73]. The activities of detoxifying enzymes such as glutathione transferase, quinone reductase, and UDP-glucuronyl transferase were decreased while the hydrogen peroxide level was increased in the lung cancer-bearing animals. Supplementation of piperine (50 mg/kg) enhanced these detoxification enzymes and reduced DNA damage. These results explain the association between anti-peroxidative effect of piperine and ultimately the capability of piperine to prevent cancer. A significant suppression in the micronuclei formation induced by benzo(α-)pyrene and cyclophosphamide following oral administration of piperine at doses of 25, 50, and 75 mg/kg in mice has been reported [74].

Piperine has been evidenced to show chemopreventive effects when administered orally on lung cancer-bearing animals [61]. The beneficial effect of piperine is primarily exerted during initiation phase and post-initiation stage of benzo(α-) pyrene-induced lung carcinogenesis, via beneficial modulation of lipid peroxidation and membrane-bound ATPase enzymes. The ability of piperine to prevent lung carcinogenesis induced by benzo(α-)pyrene in mice and its effects on cell proliferation has been studied [60, 71]. Administration of piperine significantly decreased the levels of lipid peroxidation, protein carbonyls, nucleic acid, and polyamine synthesis that were found to be increased in lung cancer-bearing animals. Piperine could effectively inhibit benzo(α-)pyrene-induced lung carcinogenesis in albino mice by offering protection from protein damage and also by suppressing cell proliferation. Dietary (0.5 %) black pepper has been evidenced to suppress colon carcinogenesis induced by 1,2-dimethylhydrazine in rats [67].

1.2.6 Negative Influence on Reproductive System

Black pepper is used as contraceptive in folk medicine in parts of India. The reproductive toxicity of piperine has been studied in albino mice with respect to the effect on estrous cycle, toxicity to male germ cells, fertilization, implantation, and growth of pups [75]. Piperine (10 and 20 mg/kg) increased the period of the diestrous phase resulting in decreased mating performance and fertility. Postpartum litter growth was not affected by the piperine treatment, and sperm shape abnormalities were not induced at doses up to 75 mg/kg. Considerable anti-implantation activity was recorded after 5 days post-mating oral treatment with piperine. These results suggest that piperine interferes with several crucial reproductive events in a mammalian model. The effect of piperine on the fertilization of eggs with sperm has been investigated in female hamsters intragastrically treated with piperine at doses of 50 or 100 mg/kg from day 1 through day 4 of the estrous cycle [76]. During piperine treatment, these females were superovulated and artificially inseminated (AI) with spermatozoa from untreated male hamsters at 12 h after hCG injection. Administration of piperine to the superovulated animals markedly enhanced the percent fertilization at 9 h after AI (Table 45.6).

Neuropharmacological activity		
Rats	(a) Piperine-administered animals possessed antidepression-like activity and cognitive-enhancing effect	[82]
	(b) Antidepressant-like effects of chronically administered piperine depend on the augmentation of the neurotransmitter synthesis	[83]
Anticonvulsant effects		
Human	Piperine treatment reduced the number of seizures in epileptic children	[84]

Piperine administration (10 mg/kg for 30 days) in mature male albino rats caused a significant reduction in the weights of testis and accessory sex organs [78]. Histological studies revealed that piperine caused severe damage to the seminiferous tubule, decrease in seminiferous tubular and Leydig cell nuclear diameter, and desquamation of spermatocytes and spermatids. The effect of piperine on the fertilizing ability of hamster sperm was investigated in vitro [77]. Addition of $0.18 - 1.05$ mM piperine reduced both the percentage of eggs fertilized and the degree of polyspermia in a dose-dependent manner. Rats orally administered piperine at doses of 1, 10, and 100 mg/kg for 30 consecutive days showed a decrease in the activity of antioxidant enzymes and sialic acid levels in the epididymis and thereby increased reactive oxygen species levels that could damage the epididymal environment and sperm function [85].

1.2.7 Other Physiological Effects

Anti-inflammatory activity of piperine has been reported in rats employing different experimental models like carrageenan-induced rat paw edema, cotton pellet granuloma, and croton oil-induced granuloma pouch [79]. Piperine acted significantly on early acute changes in inflammatory processes and chronic granulative changes. Pungent principles of dietary spices including piperine have been reported to induce a warming action via adrenal catecholamine secretion [86].

Piperine has been reported to exert a significant protection against *t*-butyl hydroperoxide and carbon tetrachloride-induced hepatotoxicity by reducing lipid peroxidation, by leakage of enzymes – alanine aminotransferase and alkaline phosphatase – and by preventing the depletion of glutathione and total thiols in the intoxicated mice [80]. The neuropharmacological activity of piperine-administered Wistar rats (5, 10, and 20 mg/kg once daily) was determined after single, 1, 2, 3, and 4 weeks of treatment [82]. Piperine showed antidepression-like activity and cognitive-enhancing effect at all treatment duration, suggesting its potential to improve brain function. Antidepressant-like effects of piperine have been demonstrated in two depressive models: forced swimming test and tail suspension test [83]. The results indicated that after 2 weeks of chronic administration, piperine (10 − 20 mg/kg) significantly reduced the duration of immobility in both the models. The study demonstrated that the antidepressant-like effects of piperine and antiepilepsirine might depend on the augmentation of the neurotransmitter synthesis or the reduction of the neurotransmitter reuptake.

Melanocyte stimulants are of interest as potential treatments for the depigmentary skin disorder vitiligo. Black pepper water extract and piperine promote melanocyte proliferation in vitro. Black pepper extract was found to possess growth-stimulatory activity in cultured melanocytes [81]. Its aqueous extract at 0.1 mg/mL was observed to cause nearly 300 % stimulation of the growth of a cultured mouse melanocyte line, in 8 days; hence, it is inferred that piperine is a potential repigmenting agent for the treatment of vitiligo.

A study of the in vitro effects of piperine on three bioenergetic reactions, namely, oxidative phosphorylation, ATPase activity, and calcium transport by isolated rat liver mitochondria, suggested that piperine inhibits mitochondrial oxidative phosphorylation at the level of respiratory chain [87]. Piperine did not inhibit the mitochondrial ATPase activity induced by dinitrophenol and was found to diminish calcium uptake. The influence of piperine on the enzymes and bioenergetic functions in isolated rat liver mitochondria and hepatocytes has been studied, and it was observed that piperine produces concentration-related site-specific effects on mitochondrial bioenergetics and enzymes of energy metabolism [88].

Piper longum and *Piper nigrum* are conventionally used as immuno-enhancers in Indian system of medicine. The underlying mechanism however remains unknown. Pepper has been used in China as a folk remedy for epilepsy. Piperine has been identified by researchers as having anticonvulsant effects in animal models, and antiepilepsirine, a derivative of piperine, has been used in China to treat epilepsy since 1975. A clinical trial on epileptic children-tested antiepilepsirine (10 mg/kg; two or three times a day) decreased the number of seizures in majority of subjects [84].

1.3 Absorption and Metabolism of Piperine

Tissue distribution and elimination of piperine has been examined following its oral intake in rats. Piperine administered to rats at a dose of 170 mg/kg by gavage or

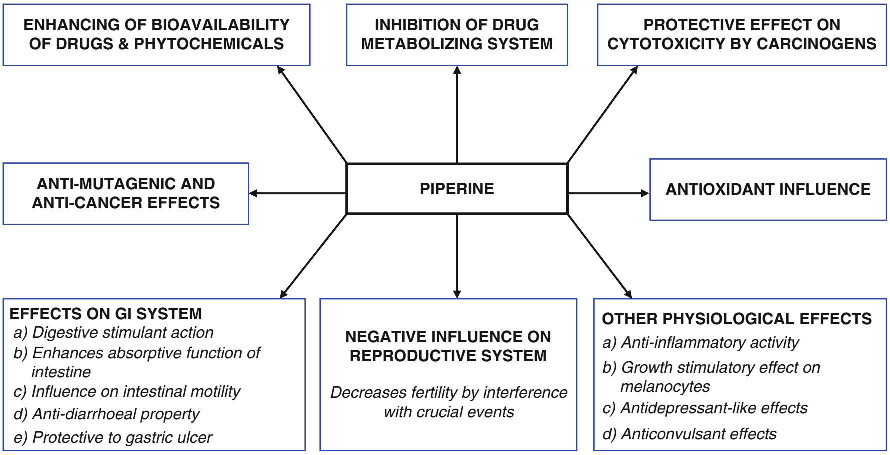
85 mg/kg *i.p.* was absorbed to an extent of about 97 % [26, 89]. A maximum of 10.8 % of administered piperine was seen in tissues at 6 h. Only 3 % of the administered dose was excreted as piperine in the feces, while it was not detectable in urine. When rat intestinal segments were incubated with 100–1,000 μg of piperine, about 44–63 % of the added piperine disappeared from the mucosal side [89, 90]. Absorption of piperine in this in vitro system which was maximum at 800 μg per 10 mL was about 63 % [89]. The absorbed piperine could be traced in both the serosal fluid and in the intestinal tissue. When piperine was associated with mixed micelles, its in vitro intestinal absorption was relatively higher [90].

Highest concentration in stomach and small intestine was attained at about 6 h post-piperine dosage [91]. Only traces of piperine were detected in serum, kidney, and spleen from 30 min to 24 h. About $1 - 2.5$ % of the *i.p.*-administered piperine was detected in the liver during $0.5 - 6$ h after administration as contrasted with $0.1 - 0.25$ % of the orally administered dose. The increased excretion of conjugated uronic acids, conjugated sulfates, and phenols indicated that scission of the methylenedioxy group of piperine, glucuronidation, and sulfation appear to be the major steps in the disposition of piperine in the rat. After oral administration of piperine (170 mg/kg) to rats, the metabolites in urine were identified to be piperonylic acid, piperonyl alcohol, and piperonal and vanillic acid in the free form, whereas only piperic acid was detected in $0 - 6$ h bile [91]. Kidney appears to be the major excretion route for piperine metabolites in rats as no metabolite could be detected in feces. In a later investigation [92], a new major urinary metabolite 5-(3,4-methylenedioxy phenyl)-2,4-pentadienoic acid-*N*-(3-yl propionic acid)-amide was detected in rat urine and plasma using HPLC. This metabolite has a unique structure in that it retains methylenedioxy ring and conjugated double bonds while the piperidine ring is modified to form propionic acid group.

The absorption dynamics of piperine in intestine has been studied, and the data suggested that piperine is absorbed very fast across the intestinal barrier [93]. It may act as an apolar molecule and form apolar complex with drugs and solutes. It may modulate membrane dynamics due to its easy partitioning thus helping in efficient permeability across the barriers. Being essentially water insoluble, piperine is presumed to be assisted by serum albumin for its transport in blood after its intestinal absorption. The binding of piperine to serum albumin has confirmed by employing steady-state and time-resolved fluorescence techniques [94]. These observations are significant in understanding the transport of piperine in blood under physiological conditions.

1.4 Conclusions

Black pepper or its main bioactive alkaloid piperine, the ingredients used in a number of ancient and folk medicines, is now demonstrated to possess diverse health beneficial physiological effects. The most far-reaching attribute of piperine has been its inhibitory influence on hepatic and intestinal drug-metabolizing system. It strongly inhibits a particular cytochrome P_{450} and hence phase-I reactions



ENHANCING OF BIOAVAILABILITY OF DRUGS & PHYTOCHEMICALS
INHIBITION OF DRUG METABOLIZING SYSTEM
PROTECTIVE EFFECT ON CYTOTOXICITY BY CARCINOGENS

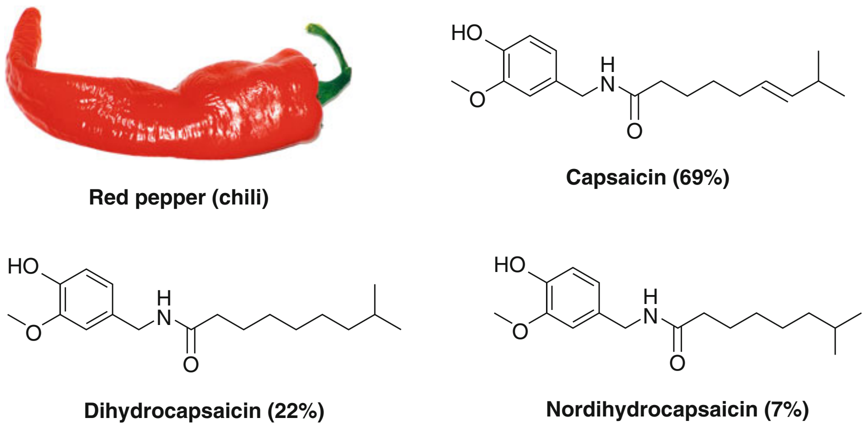
mediated by the same, especially aromatic hydroxylation. It also strongly retards glucuronidation reactions of phase-II. As a result of interference with crucial drug-metabolizing reactions in the liver, piperine enhances the bioavailability of therapeutic drugs, i.e., increases their plasma half-life and delays their excretion. This particular inhibitory effect of piperine on drug metabolism and hence on drug bioavailability may be harnessed for increasing therapeutic effects. Gastrointestinal system is affected by black pepper and piperine in many ways. Both black pepper and piperine have been evidenced to have antidiarrheal property and an effect on intestinal motility and on the ultrastructure of intestinal microvilli improving absorbability of micronutrients. Piperine has been evidenced to protect against oxidative damage by inhibiting or quenching free radicals and lower lipid peroxidation and beneficially influence cellular antioxidant status in different situations of oxidative stress. Piperine also possesses cytoprotective effect by retarding the activation of certain procarcinogens by the drug-metabolizing system. Antimutagenic and antitumor properties of piperine have been evidenced in a few animal and cell line studies. Among other physiological effects piperine exerts, its potential antifertility influence on reproductive system has been clearly established in in vitro and animal systems (Fig. 45.2).

2 Capsaicin of Red Pepper (*Capsicum annuum*)

2.1 Introduction

Capsaicin (8-methyl-*N*-vanillyl-6-nonenamide) is the major pungent principle of chili peppers, belonging to the genus *Capsicum*. Dihydrocapsaicin and nordihydrocapsaicin are the other two alkaloids in the order of relative abundance. Chili peppers are extensively used in food as pungent spice, particularly in tropical



Red pepper (chili)

Capsaicin (69%)

Dihydrocapsaicin (22%)

Nordihydrocapsaicin (7%)

Fig. 45.3 Red pepper and capsaicinoids

countries. This alkaloid responsible for the pungency of the spice is also an irritant that produces a burning sensation with which it comes into contact. Capsaicin and several related compounds are called capsaicinoids and are produced as a secondary metabolite by chili peppers, probably as deterrents against certain herbivores and fungi. Pure capsaicin is a hydrophobic, colorless, odorless, crystalline compound. Capsaicin is the main capsaicinoid in chili peppers, followed by dihydrocapsaicin (Fig. 45.3).

Capsaicin is present in large quantities in the placental tissue (which holds the seeds), the internal membranes, and, to a lesser extent, the other fleshy parts of the fruits of Capsicum plants. The seeds themselves do not produce any capsaicin, although the highest concentration of capsaicin can be found in the white pith of the inner wall, where the seeds are attached [95]. Capsaicin is believed to be synthesized in the interlocular septum of chili peppers by addition of a branched-chain fatty acid to vanillylamine; specifically, capsaicin is made from vanillylamine and 8-methyl-6-nonenoyl Coenzyme-A [96].

2.2 Biological Effects of Capsaicin

Many health beneficial physiological effects of red pepper or its bioactive alkaloid – capsaicin – have been reported in recent decades which are summarized below:

2.2.1 Hypocholesterolemic and Hypolipidemic Effects

Red pepper, known for its characteristic pungency and its pungent principle capsaicin have been reviewed for their biological activity [97, 98] was probably the first investigator who studied the metabolic changes caused by feeding red pepper. The beneficial influence of red pepper or its pungent principle capsaicin on lipid metabolism is documented by several investigators. While studying the influence of red pepper and capsaicin on fat absorption in rats on a choline-free high hydrogenated fat (40 %) diet, Sambaiah et al. [99] observed that 5 % red pepper or equivalent levels of capsaicin (15 mg%) included in the diet had a tendency to lower serum and liver cholesterol levels. In another investigation, Srinivasan et al. [100] have reported a reduction in serum total cholesterol levels in rats on a 10 % groundnut oil diet incorporated with 1.5, 3.0, or 15 mg% capsaicin. In yet another study, capsaicin at as low as 0.2 mg% in the diet led to a lowering of serum total cholesterol in both 10 % and 30 % fat-fed rats [101]. An increase in LDL-cholesterol and a reduction in HDL-cholesterol were also observed in the 30 % hydrogenated fat group. In a subchronic toxicity study [102], rats were administered 50 mg/kg/day of capsaicin by gavage or 0.5 g/kg/day of a crude extract of capsicum fruit for 60 days. At 30, 40, 50, and 60 days, plasma total cholesterol levels were significantly reduced along with triglycerides and phospholipids (Table 45.7).

The effect of 14 mg% capsaicin in a diet containing 30 % lard has been studied [103]. The dose of capsaicin fed to rats was reported to be related to that commonly ingested by the Thai people. At the end of the 10-day isocaloric feeding period, serum cholesterol and pre-β-lipoprotein levels were not altered. The influence of capsaicin has also been studied in sucrose-induced hypertriglyceridemia in rats [112]. Capsaicin was fed at 0.15, 1.5, and 15 mg% levels in the diet (the lowest dose is comparable to human intake) for a period of 1 week. Total cholesterol and HDL-cholesterol were either significantly elevated.

The efficacy of capsaicin as a hypocholesterolemic agent has also been investigated in animals fed cholesterol in their diets. Sambaiah and Satyanarayana [104] have reported that the serum cholesterol levels in rats on a 1 % cholesterol + 5 % red pepper diet were lower than those not fed with red pepper. Liver cholesterol was lower in the red pepper- as well as capsaicin (an equivalent level of 15 mg%)-fed groups. Fecal excretion of free cholesterol and of bile acids was enhanced in animals fed the spice and capsaicin. The anti-hypercholesterolemic efficacy of dietary capsaicin has been evidenced in rats fed an atherogenic high-cholesterol diet, and such an influence also resulted in countering of the changes in membrane lipid profile in the erythrocytes [105]. In streptozotocin-induced diabetic situation however, dietary capsaicin did not show any beneficial hypolipidemic property [106].

Intubation of rabbits with 8 mg capsaicin/rabbit (body wt of about 850 g/day for 35 days) did not have any effect with regard to plasma cholesterol, triglyceride, and HDL-cholesterol when they were on a normal diet [108]. In contrast, in rabbits on a 0.5 % cholesterol diet, capsaicin had a beneficial effect in that the plasma cholesterol, triglycerides, and total cholesterol: HDL-cholesterol ratio were significantly lower than in animals fed cholesterol only. Turkeys on a 2–3 mg capsaicin/kg feed for 9 days along with 0.5 % cholesterol had lower total serum cholesterol than the controls [109]. Hypercholesterolemia was produced by feeding a 0.2 % cholesterol-supplemented diet, and capsaicin and dihydrocapsaicin were administered daily via the buccal route at dose of 4 mg per bird for 6 weeks [110]. In

Table 45.7 Hypolipidemic effects of capsaicin and red pepper in animal models

Animal model	Effect demonstrated	References
Rats on 40 % fat	5 % red pepper or 0.015 % capsaicin lowered serum and liver cholesterol	[99]
Rats	1.5, 3, and 15 mg% capsaicin reduced serum cholesterol	[100]
Rats on 10 % or 30 % fat	0.2 % capsaicin effectively lowered serum cholesterol	[101]
Rats	Subchronic levels of capsaicin (50 mg/kg for 60 days) lowered cholesterol and triglycerides	[102]
Rats on 30 % lard	14 mg% capsaicin produced hypocholesterolemic effect	[103]
Rats on 1 % cholesterol	Effective hypocholesterolemic effect; higher excretion of fecal sterols and bile acids	[104]
Rats on 0.5 % cholesterol	15 mg% capsaicin produced anti-hypercholesterolemic effect	[105]
Diabetic rats	15 mg% dietary capsaicin did not reverse hypercholesterolemia and hypertriglyceridemia	[106]
Hypercholesterolemic rats	Dietary capsaicin stimulated activity of hepatic cholesterol-7α-hydroxylase	[107]
Hypercholesterolemic rabbits	Reduced blood cholesterol, triglycerides	[108]
Hypercholesterolemic turkeys	Reduced blood cholesterol; ameliorated aortic atherosclerotic lesions by capsaicin	[109, 110]
Gerbils	75 mg oleoresin/kg decreased blood cholesterol and triglycerides; prevented lipid accumulation in liver and aorta	[111]

animals on a normal diet, total cholesterol, LDL-cholesterol, and HDL-cholesterol concentrations in plasma were increased, whereas VLDL-cholesterol was significantly decreased. Plasma total and LDL-cholesterol were significantly lower in birds on the cholesterol diet administered dihydrocapsaicin. Both the compounds brought about a reduction in VLDL-cholesterol and an increase in HDL-cholesterol in the cholesterol-fed group. Dihydrocapsaicin was more effective than capsaicin. The effect of capsicum oleoresin on dietary hypercholesterolemia was observed in gerbils at a dose of 75 mg/kg body weight/day [111]. The oleoresin reduced serum cholesterol and triglycerides as well as liver cholesterol and triglycerides. Capsaicin oleoresin feeding prevented the accumulation of cholesterol and triglycerides in the liver and aorta. The fecal excretion of cholesterol and triglycerides was significantly increased in oleoresin-fed gerbils.

The possible mechanism of action of capsaicinoids is the net effect of decreased cholesterol absorption and increased excretion of cholesterol and bile acids in the feces which may lead to a decrease in plasma LDL-cholesterol concentration by induced expression of hepatic LDL receptors [110]. These authors also have discussed the differences in response between normal and cholesterol-fed animals to possible hypocholesterolemic compounds. It has been demonstrated that dietary capsaicin stimulates hepatic conversion of cholesterol to bile acids through a stimulation of the activity of cholesterol-7α-hydroxylase, an important pathway for elimination of cholesterol from the body [107]. However, simultaneous stimulation of cholesterol synthesis as well through the activity of HMG-CoA reductase by this spice principle suggests that there may not be any significant contribution of the stimulation of bile acid biosynthesis to the hypocholesterolemic action of this spice principle, and the latter action may solely be due to interference with exogenous cholesterol absorption.

Heat processing of red pepper results in a significant loss of active principle [113, 114]. The hypocholesterolemic potency of raw and pressure-cooked red pepper was evaluated in experimental rats rendered hypercholesterolemic by feeding cholesterol-enriched diet and maintained for 8 weeks on 5 % spice diet [115]. The results suggested that although heat processing of red pepper by pressure cooking resulted in a considerable loss of capsaicin, the hypolipidemic potency of the parent spice was not significantly compromised.

2.2.2 Influence of Capsaicin on Biliary Cholesterol and Bile Acids: Anti-lithogenic Influence

Feeding of 7.5 and 15 mg% capsaicin to rats led to a significant increase in biliary total bile acids [116]. One of the implications of hypocholesterolemic influence is anti-lithogenic potential. Since capsaicin, besides being hypocholesterolemic agent, also enhances bile secretion and influences its composition, its influence on gallstone formation has been examined. Dietary capsaicin (0.015 %) caused a significant reduction in the formation of gallstones in mice and hamsters maintained on a lithogenic diet [117, 118]. Further, capsaicin effected a marked regression of preestablished gallstones in mice [119]. Increased cholesterol saturation index, cholesterol: Phospholipid ratio, and cholesterol: bile acid ratio in the bile caused by lithogenic diet was countered by dietary capsaicin. The anti-lithogenic influence of this spice compound was attributable to the cholesterol-lowering effect of these in blood and liver and their ability to lower cholesterol saturation index by altering the bile composition. When a combination of capsaicin and curcumin were given during experimental induction of cholesterol gallstone (CGS) in mice, there was no additive influence in reducing the incidence of CGS; nevertheless, the combination was more beneficial in reducing the oxidative stress in lithogenic situation [120]. The antilithogenecity of capsaicin has been considered to be due not merely to their ability to lower cholesterol saturation index but also to their influence on biliary proteins [121].

2.2.3 Protective Effect on Erythrocyte Integrity

Hyperlipidemic conditions are believed to affect the fluidity of red blood cells [122]. Hypolipidemic spice compound capsaicin in the diet might offer beneficial protective influence on the integrity of erythrocyte membranes, which are presumably altered in hyperlipidemic situation. In rats rendered hypercholesterolemic by feeding a cholesterol-enriched diet for 8 weeks, erythrocyte membranes were relatively enriched in cholesterol, resulting in elevated cholesterol: phospholipid ratio of their membranes affecting their structural integrity [105]. Inclusion of capsaicin (0.015 %) along with high cholesterol in the diet produced not only the hypolipidemic effect but also countered this altered lipid profile of erythrocyte membranes and thus corrected the increased osmotic fragility of erythrocytes [105]. Dietary capsaicin partially countered the changes in erythrocytes of hypercholesterolemic rats, namely, fatty acid profile of the membranes, phospholipid composition of the membrane bilayer, and reduced Ca^{2+}, Mg^{2+}-ATPase [123]. ESR spectra and fluorescence anisotropy parameters also revealed altered fluidity of erythrocytes in hypercholesterolemic rats which was significantly reversed by dietary capsaicin. In rats rendered hypertriglyceridemic by maintaining them on a high (30 %)-fat diet for 8 weeks, the lipid profile of erythrocyte membranes was not affected, but the erythrocytes displayed a resistance to osmotic lysis [124]. Inclusion of capsaicin (0.015 %) along with high fat in the diet which produced the hypotriglyceridemic effect appeared to beneficially correct this altered osmotic fragility of erythrocytes.

2.2.4 Antioxidant Effects

Lipid peroxidation in human erythrocyte membranes was found to be inhibited by capsaicin [125]. The antioxidant property of capsaicin in terms of inhibiting lipid peroxidation in rat liver [53] and in soybean phosphatidylcholine liposomal biomembrane has been reported [126]. Capsaicin is observed to inhibit copper ion-induced lipid peroxidation of human LDL [55]. The data suggested that capsaicin is an effective antioxidant and offers protection against oxidation of human LDL. Capsaicin inhibited the lipid peroxidation in rat liver mitochondria induced by ADP/Fe^{2+} significantly, more than the well-known antioxidant α-tocopherol [127]. Capsaicin was also found to scavenge 1,1′-diphenyl-2-picrylhydrazyl (DPPH) radicals in membranes. Capsaicin was found to scavenge radicals both at/near the membrane surface and in the interior of the membrane. Vanillin and 8-methyl-6-noneamide were major reaction products of capsaicin with DPPH radicals, thus suggesting that the radical scavenging site of capsaicin is the C7-benzyl carbon. Phenolic compounds of various spices, including capsaicin, modulate 5-lipoxygenase (5-LO) in human PMNL cells, the key enzyme involved in the biosynthesis of leukotrienes [56] (Table 45.8).

Wistar rats administered capsaicin (*i.p.* 3 mg/kg body weight) for three consecutive days showed a reduction of oxidative stress measured as malondialdehyde in the liver, lung, kidney, and muscle [128]. From this study, it is hypothesized that capsaicin can be a potent antioxidant even when consumed for a short period. The influence of capsaicin on the antioxidant status of red blood cells and liver tissue in hyperlipidemic rats is reported [129]. Capsaicin (0.015 %) in the diet which produced the hypotriglyceridemic effect was also effective in reducing the oxidant stress, which was indicated by countering of the depleted antioxidant molecules and antioxidant enzymes in erythrocytes and liver, and decreasing of the elevated lipid peroxide content. The beneficial influence of capsaicin on the antioxidant status of red blood cells and liver in induced hypercholesterolemic rats is also evidenced [130]. The depletion in intracellular thiols and GSH in red blood cells under hypercholesterolemic situation was effectively countered by dietary (0.015 %)

Table 45.8 Antioxidant influence of capsaicin in in vitro and in vivo systems

Animal model	Effect demonstrated	References
Human erythrocyte membranes	Lipid peroxidation was inhibited by capsaicin	[125]
Rat liver microsomes	Ascorbate-Fe^{++}-induced lipid peroxidation was inhibited by capsaicin	[53]
Soybean phospholipid liposomal membrane	Inhibition of oxidation of methyl linoleate micelles by capsaicin	[126]
Rat liver mitochondria	Inhibition of lipid peroxidation induced by ADP/Fe^{2+} and scavenging of DPPH radicals by capsaicin	[127]
Human low-density lipoprotein	Inhibition of Cu^{2+} induced lipid peroxidation by capsaicin	[55]
Human PMNL cells	Inhibition of 5-lipoxygenase	[56]
Rats	Capsaicin administration reduced oxidative stress in the liver, lung, kidney, and muscle	[128]
High-fat-fed rats	Beneficial influence of dietary capsaicin on antioxidant status of red blood cells	[129]
Hypercholesterolemic rats	Beneficial influence of dietary capsaicin on antioxidant status of red blood cells	[130]

capsaicin. Glutathione reductase activity that was lowered in hypercholesterolemic conditions was completely countered by the dietary spice principle. Decreased hepatic total thiols in the hypercholesterolemic situation were partially corrected by dietary capsaicin treatment. Similarly, the lowered activities of hepatic antioxidant enzymes – GSH-reductase, GSH-transferase, catalase, and superoxide dismutase – in hypercholesterolemic rats were effectively countered by the dietary capsaicin.

2.2.5 Anti-inflammatory Property

With increasing interest in alternatives to nonsteroidal anti-inflammatory agents in the management of chronic inflammation, the use of food-based approaches is emerging. Lipid peroxides play a crucial role in arthritis and other inflammatory diseases. Both in vitro and in vivo animal studies have documented the anti-inflammatory potential of capsaicin (of red pepper). Animal studies have revealed that capsaicin also lowers the incidence and severity of paw inflammation and also delays the onset of adjuvant-induced paw edema in rats [131, 132]. This spice principle inhibited the formation of arachidonate metabolites (PgE_2, leukotrienes) and increased the secretion of lysosomal enzymes – elastase, collagenase, and hyaluronidase – by macrophages. It is noteworthy that the levels of 6-keto PgF_{1a} – a vasodilator – increased [133].

Natural anti-inflammatory compound capsaicin appears to operate by inhibiting one or more of the steps linking pro-inflammatory stimuli with COX activation, such as the blocking by capsaicin of NF-kB translocation into the nucleus [134].

It has been shown recently that the natural anti-inflammatory compounds such as capsaicin were as effective as indomethacin (a nonsteroidal anti-inflammatory drug) in inhibiting aberrant crypt foci in the rat.

2.2.6 Chemopreventive Potential

This phytochemical has been found to interact with microsomal xenobiotic-metabolizing enzymes in rodents. Capsaicin has been proposed to inactivate cytochrome P-450 HE1 by irreversibly binding to the active sites of the enzyme [135]. Besides cytochrome P-450 HE1, other isoforms of the P-450 super family are also reported to be inhibited by capsaicin. The inhibition by capsaicin of microsomal monooxygenases involved in carcinogen activation implies its chemopreventive potential.

Studies suggest that capsaicin is able to kill prostate cancer cells by causing them to undergo apoptosis [136]. The studies were performed on tumors formed by human prostate cancer cell cultures grown in mouse models, and showed tumors treated with capsaicin were about one fifth the size of the untreated tumors. There have been several clinical studies conducted in Japan and China that showed capsaicin directly inhibits the growth of leukemic cells [137]. Another study suggests capsaicin is able to trigger apoptosis in human lung cancer cells as well. An epidemiological study has found significantly higher rates for stomach and liver cancer in counties inhabited by groups with high consumption of capsaicin-rich foods [138].

2.2.7 Antidiabetic Potential

Substance P, a neuropeptide released by capsaicin, has been shown to reverse diabetes in mice [139], but the effects to insulin secretion seem to be species dependent. In humans, substance P seems to decrease insulin release and cause fluctuations in blood sugar levels [140]. Capsaicin is also being explored as a possible prophylaxis for type 1 diabetes. Capsaicin was injected subcutaneously in neonatal diabetes-prone NOD mice to permanently remove a prominent subset of pancreatic sensory neurons, which express the transient vanilloid receptor protein (TRPV1). Insulin resistance and β cell stress of prediabetic NOD mice are prevented when TRPV1+ neurons are eliminated. In other words, mice which were genetically predisposed to type 1 diabetes were prevented from developing type 1 diabetes via removal of these neurons, which are thought to attract pathogenic T cells to attacking pancreatic β cells thus causing type 1 diabetes [141].

2.2.8 Thermogenic and Weight-Reducing Influence

According to animal and human studies, the oral intake of capsaicin increases the production of heat by the body for a short time. Dietary red pepper or its pungent principle capsaicin affects satiety and has a promising thermogenic influence that could play an important role in the prevalence and severity of obesity [103], although more data are required to substantiate this benefit. The use of this spice to displace fats and salt in the diet (to make the food palatable) may reduce cardiovascular risk. Although there is no evidence showing that weight loss is directly correlated with ingesting capsaicin, there is a positive correlation between ingesting capsaicin and a decrease in weight regain. Capsaicin is said to cause a shift in substrate oxidation from carbohydrate to fat oxidation [142] which leads to a decrease in appetite as well as a decrease in food intake. Both oral and gastrointestinal exposure to capsaicin increase satiety and reduce energy as well as fat intake [143]. Oral exposure proves to yield stronger reduction suggesting that capsaicin has sensory effects. Short-term studies suggest that capsaicin aids in the decrease of weight regain. However, long-term studies are limited because of the pungency of capsaicin [144]. Another recent study has suggested that the ingestion of capsaicinoids can increase levels of brown adipose tissue through an increase in energy expenditure and oxidation caused by the capsaicin [145]. In yet another recent study, the beneficial effects of dietary tender cluster beans (*Cyamopsis tetragonoloba*) in checking the weight gain and adverse changes in lipid profile in high-fat-fed condition were potentiated by co-administration of capsaicin in rats [146].

2.2.9 Antiulcer Activity

In recent years, infection of the stomach with *Helicobacter pylori* which disrupts the normal inhibitory control for acid secretion resulting in excess acid destroying the mucosal barrier has been understood to be the main cause of gastric ulcers [147]. Excessive acid secretion in the stomach and reduction in gastric mucosal blood flow are considered responsible for ulcer formation. The colonization of *H. pylori* in the stomach is associated with a phospholipase likely to damage the protective layer of stomach. *H. pylori* thrives in the stomach by producing the enzyme urease.

In view of its irritant and likely acid-secreting nature, persons with ulcers were being advised to avoid consumption of red pepper (chili). However, recent studies have revealed that capsaicin of red pepper is not the cause for ulcer formation but a benefactor. Numerous studies suggest that eating hot peppers regularly is protective against stomach cancer [148]. Detailed studies have revealed that capsaicin per se does not stimulate but inhibits acid secretion, stimulates alkali and mucus secretions and gastric mucosal blood flow which help in disposing of acid from the stomach, thus prevention and healing of ulcers [149]. Capsaicin acts by stimulating afferent neurons in the stomach and signals for protection against injury causing agents. An epidemiological study has found three times higher peptic ulcer incidence among Chinese population in Singapore as compared to Malaysians and Indians who are in the habit of consuming more pungent chili in their daily diets [150].

Interestingly, capsaicin has been found to specifically inhibit the growth of *H. pylori*. Capsaicin inhibits also the release of gastrin and stimulates that of somatostatin, the physiological inhibitor of acid secretion. It is also a potent inhibitor of NF-kB whose activation may lead to various pathological conditions and reactive oxygen species. Phosphodiesterase inhibitors are powerful vasodilatory agents and their likely increase of cAMP levels has an antiulcer effect. Capsaicin is a phosphodiesterase inhibitor and may exert its protective effect in this way besides its stimulation of gastric mucosal blood flow. Numerous studies have substantiated the protective role of capsaicin. Seminal to these studies is the discovery about the selective sensitization and desensitization of unmyelinated neurons by capsaicin [151]. Reactive oxygen species are known to be involved in the pathogenesis of gastritis, gastric ulcers, and gastric cancer. Capsaicin has proved to be an antioxidant protecting cellular membranes, cardiac and skeletal muscles, etc., against reactive oxygen species. Capsaicin inhibited lipid peroxidation induced by ethanol in the gastric mucosa [152].

2.2.10 Capsaicin in Pain Relief

Capsaicin has received considerable attention as a pain reliever. In two trials with 70 and 21 patients with osteoarthritis and rheumatoid arthritis, topical application of creams containing 0.025 % or 0.075 % capsaicin was an effective and safe alternative to analgesics employed in systemic medications which are often associated with potential side effects [153, 154]. Capsaicin has also been suggested for the initial management of neuralgia consequent to herpes infection [155].

Capsaicin has been shown to be useful in diabetic neuropathy. In a study involving 219 patients, topical application of 0.075 % capsaicin cream was effective in pain management [156]. Capsaicin is currently used in topical ointments, as well as a high-dose dermal patch (under the trade name *Qutenza*), to relieve the pain of peripheral neuropathy such as post-herpetic neuralgia caused by shingles [157]. It may be used in concentrations of between 0.025 % and 0.075 % as a cream for the temporary relief of minor aches and pains of muscles and joints associated with arthritis, simple backache, strains, and sprains, often in combination with other rubefacients [157]. Capsaicin creams are used to treat psoriasis as an effective way to reduce itching and inflammation [158, 159]. Capsaicin is also the key ingredient in the experimental drug *Adlea*, which is in Phase 2 trials as a long-acting analgesic to treat postsurgical and osteoarthritis pain [157]. Moreover, it reduces pain resulted from rheumatoid arthritis [160] as well as joint or muscle pain from fibromyalgia.

2.2.11 Beneficial Influences on Gastrointestinal System

Beneficial Modulation of Small Intestinal Ultrastructure

The beneficial influence of dietary capsaicin has been examined in experimental rats with respect to (i) the membrane fluidity of intestinal brush-border membranes (BBM), (ii) the activity of intestinal membrane-bound enzymes, and (iii) the ultrastructural alterations in the intestinal epithelium [46]. In this study, Wistar rats were maintained on dietary red pepper (3·0 %) and its bioactive compound capsaicin (0·01 %) for 8 weeks. A membrane fluidity study using an apolar fluorescent probe showed increased BBM fluidity in the spice-fed or capsaicin-fed animals. This was corroborated by decreased cholesterol: phospholipid ratio in the jejunal and ileal regions of the intestine. These dietary spices stimulated the activities of BBM enzymes (glycyl-glycine dipeptidase, leucine amino peptidase, and γ-glutamyl transpeptidase) in the jejunal mucosa, suggesting a modulation in membrane dynamics due to the apolar spice bioactive compound interacting with surrounding lipids and hydrophobic portions in the protein vicinity, which may decrease the tendency of membrane lipids to act as steric constraints to enzyme proteins and thus modify enzyme conformation. Scanning electronic microscopy of the intestinal villi in these spice treatments revealed alterations in the ultrastructure, especially an increase in microvilli length which would mean a beneficial increase in the absorptive surface of the small intestine, providing for an increased bioavailability of micronutrients. Thus, dietary red pepper or capsaicin was evidenced to induce alterations in BBM fluidity and passive permeability property, associated with the induction of an increased microvilli length, resulting in an increased absorptive surface of the small intestine.

Digestive Stimulant Action

The digestive stimulant action of spices is probably exerted through stimulation of the liver to produce and secrete bile rich in bile acids, which play a very important role in fat digestion and absorption. Capsaicin has been examined for its effect on bile secretion in rats, after dietary intake for a period of time or as a one-time oral intake [116]. The hypocholesterolemic spice compound capsaicin stimulated bile acid production by the liver and its secretion into bile. The influence of dietary intake and single-dose administration of capsaicin on the pancreatic digestive enzymes and the terminal digestive enzymes of the small intestinal mucosa has been reported [32, 33]. Dietary intake of capsaicin stimulated pancreatic lipase activity significantly. In contrast to the continued intake, single oral dose consumption of capsaicin failed to exert a stimulatory effect on pancreatic lipase. Pancreatic amylase activity was elevated by dietary capsaicin (72 %) as well as single-dose administration of capsaicin. Capsaicin when incorporated in the diet, stimulated trypsin activity by over 100 %. Chymotrypsin was also significantly higher in animals fed capsaicin. Similar influence of the spice compound on the activity of proteases was not evident when administered as a single oral dose. Capsaicin prominently enhanced the activity of intestinal lipase. The stimulation of this enzyme activity was more than 100 % of the control in spice principle-treated group. Similarly, dietary capsaicin significantly increased the activity of intestinal amylase. Dietary capsaicin moderately stimulated the activities of intestinal disaccharidases.

Based on the evidences from animal studies, the well-recognized digestive stimulant action of red pepper or its active compound capsaicin may be considered to be mediated through two possible modes: (1) stimulation of the liver to secrete more bile enriched in bile acids and (2) stimulation of enzyme activities that participate in digestion, both of pancreatic and intestinal origin. Such stimulation of bile secretion and of the activities of digestive enzymes leads to an accelerated overall digestive process, resulting in a significant reduction in the duration of passage of food through the gastrointestinal tract [35].

Since capsaicin is known to stimulate secretion of bile with higher amount of bile acids which play a major role in digestion and absorption of dietary lipids, capsaicin has been studied to verify if it enables efficient digestion and absorption during high-fat intake [34]. In this context, dietary capsaicin (0.015 %) has been examined for its influence on bile secretion, digestive enzymes of pancreas, and absorption of dietary fat in high-fat (30 %)-fed rats for 8 weeks. Dietary capsaicin enhanced the activity of pancreatic lipase, amylase, trypsin, and chymotrypsin and enhanced dietary fat absorption. It also increased bile secretion with higher bile acid content. Stimulation of lipid mobilization from adipose tissue was suggested by the decrease in perirenal adipose tissue weight by dietary capsaicin. This was also accompanied by prevention of the accumulation of triglyceride in liver and serum in high-fat-fed rats. Activities of key lipogenic enzymes in liver were reduced which was accompanied by an increased activity of hormone-sensitive lipase. Thus, dietary capsaicin enhances fat digestion and absorption in high-fat-fed situation through enhanced secretion of bile salts and a stimulation of the activity pancreatic lipase. At the same time, the energy expenditure is facilitated by this spice compound to prevent the accumulation of absorbed fat.

Enhanced Absorption of Micronutrients

Since dietary pungent spices may alter the ultrastructure and permeability characteristics of intestines, capsaicin has been examined for a possible influence on intestinal absorption of iron, zinc, and calcium by examining their uptake by the intestines from rats pre-fed spice compound for 8 weeks [47]. Everted segments of duodenum, jejunum, and ileum portions of small intestines isolated from these rats were examined for ex vivo uptake of iron, zinc, and calcium from incubations containing digesta of finger millet. Higher in vitro absorption of iron, zinc, and calcium in the intestines was evidenced in capsaicin-fed animals. The positive influence of dietary capsaicin on the mineral uptake by the intestinal segments was highest for calcium. The positive influence of dietary capsaicin was more pronounced on zinc uptake as compared to that of iron. These pungent spices alter permeation characteristics presumably by increasing absorptive surface and thereby enhance intestinal absorption of micronutrients.

Dietary red pepper and capsaicin which alter the ultrastructure and permeability characteristics of intestines are also reported to favorably enhance the intestinal uptake of β-carotene in vitro [48]. In an animal study conducted to evaluate the influence of dietary spice compounds on the absorption of orally administered β-carotene and its conversion to vitamin A, hepatic β-carotene was significantly increased in capsaicin-fed rats suggesting improved absorption of β-carotene [49]. Retinol concentration was not however changed in these animals suggesting that bioconversion of β-carotene to vitamin A was not similarly influenced. Among the two enzymes involved in the bioconversion of β-carotene to vitamin A, activity of intestinal and hepatic β-carotene-15,15′-dioxygenase was lowered in capsaicin treatment, while the activity of intestinal and hepatic retinal reductase was unaffected. Activity of intestinal and hepatic β-carotene-15,15′-dioxygenase was also inhibited by capsaicin in vitro, thus corroborating with in vivo observation.

2.3 Mechanism of Burning and Painful Sensation of Capsaicin

Capsaicin causes a burning sensation when it comes in contact with mucous membranes. The burning and painful sensations associated with capsaicin result from its chemical interaction with sensory neurons. Capsaicin, as a member of the vanilloid family, binds to a vanilloid receptor (TRPV1) [161], an ion channel-type receptor that resides on the membranes of pain and heat sensing neurons [162]. VR1, which can also be stimulated with heat and physical abrasion, permits cations to pass through the cell membrane and into the cell when activated. The resulting depolarization of the neuron stimulates it to signal the brain. By binding to the VR1 receptor, capsaicin produces the same sensation that excessive heat or abrasive damage would cause.

The TRPV1 ion channel has been shown to be a member of the super family of TRP ion channels. There are a number of different TRP ion channels that have been shown to be sensitive to different ranges of temperature. Thus, capsaicin does not actually cause a chemical burn, or indeed any direct tissue damage at all, consequent to exposure to chili peppers. The inflammation resulting from exposure to capsaicin is believed to be the result of the body's reaction to nerve excitement. TRPV1 is a heat-activated calcium channel, which opens between 37 °C and 45 °C. When capsaicin binds to TRPV1, it causes the channel to open at temperature below 37 °C (normal human body temperature), which is why capsaicin is linked to the sensation of heat. Prolonged activation of these neurons by capsaicin depletes presynaptic substance P, one of the body's neurotransmitters for pain and heat. Neurons that do not contain TRPV1 are unaffected. Thus, capsaicin mimics a burning sensation, the nerves being overwhelmed by the influx. Capsaicin will be unable to evoke pain for an extended period of time since with chronic exposure, neurons are depleted of neurotransmitters, leading to reduction in sensation of pain and blockade of neurogenic inflammation. If capsaicin is removed, the neurons recover [163, 164]. The mode of action of capsaicin in inducing bronchoconstriction is thought to involve stimulation of C fiber culminating in the release of neuropeptides [165]. Essentially, the body inflames tissues as if it has undergone a burn or abrasion, and the resulting inflammation can cause tissue damage in cases of extreme exposure.

2.4 Absorption and Metabolism of Capsaicin

Capsaicin fed to rats was rapidly absorbed from the stomach, with 85 % of a 3-mg dose absorbed within 3 h [166]. Doses of 5.12 mg/mouse/week led to maximum plasma concentrations of 51.5 ng/mL and 84.8 ng/mL in male and female mice, respectively [167]. Little absorption of capsaicin also occurs across the skin. When 0.8 g of gel containing 0.075 % of capsaicin was applied to the skin of human volunteers, the average absorbed dose after 8 h of exposure was 22.7 μg/cm^2 [168]. Topical application of pure capsaicin to the skin of mice resulted in peak plasma concentrations occurring 4–12 h later, and capsaicin was detectable in the blood 24 h after dosing [167].

Rats injected intravenously accumulated capsaicin primarily in the brain and spinal cord 3 min after dosing, with lower levels found in the liver and blood, while 10 min after dosing, the greatest concentrations remained in the spinal cord [169]. Subcutaneously injected capsaicin was detected in all tissues of rat 10 min

following dosing, but residues were undetectable in any tissues 17 h later. Blood concentrations peaked 5 h following dosing, and brain and spinal cord tissue concentrations were somewhat lower. Kidneys contained the greatest concentrations and liver concentrations were low presumably due to metabolic breakdown of the capsaicin [169]. Tissue distribution and elimination of capsaicin has been examined following its oral intake (30 mg capsaicin/kg body weight) in rats [26]. Maximum distribution of 24.4 % of administered capsaicin was seen at 1 h, while no intact capsaicin was detectable after 4 days. Absorption of capsaicin was about 94 % and very rapid.

Metabolism of capsaicin occurs primarily in the liver in the rat [170, 171]. Although the same metabolites were produced, the relative amounts of each metabolite were species dependent. Metabolism of capsaicin by P_{450} enzymes may follow a number of pathways and produce a variety of metabolites, some of which may be associated with increased toxicity [172]. Less than 10 % of an oral dose of capsaicin given to rats was excreted unchanged 48 h after dosing [166].

2.5 Conclusions

The pungent principle of red pepper (hot chili) capsaicin is endowed with several biological activities which are of pharmacological relevance. These include thermogenic influence, effects on gastrointestinal system, cardioprotective influence, anti-lithogenic effect, and anti-inflammatory and pain-relieving effect. The involvement of neuropeptide substance P, serotonin, and somatostatin in the pharmacological actions of capsaicin has been extensively investigated. Tropical application of capsaicin has been proved to alleviate pain in arthritis, postoperative neuralgia, diabetic neuropathy, psoriasis, etc. Contrary to the general belief, capsaicin inhibits acid secretion, stimulates alkali and mucus secretion, and stimulates gastric mucosal blood flow, all of which help in prevention and healing of gastric ulcers. Antioxidant and anti-inflammatory properties of capsaicin are established in a number of in vitro and in vivo studies. Chemopreventive potential of capsaicin has been evidenced in a few animal and cell line studies. The hypocholesterolemic influence of capsaicin has additional implications in the prevention of cholesterol gallstone disease and protection of the structural integrity of erythrocytes under conditions of hypercholesterolemia. Beneficial influences of capsaicin on gastrointestinal system include digestive stimulant action and modulation of small intestinal ultrastructure so as to enhance permeability to micronutrients (Fig. 45.4).

Abstract

Angiogenesis, the formation of new blood vessels from preexisting capillaries, is an important research field. As the understanding of this process increases, this new knowledge will have a significant impact on several angiogenesis-dependent diseases. A wide variety of plants are rich in alkaloids, and these

compounds have traditionally been of interest due to their pronounced effects on various physiological activities in animals and humans. Nowadays, it is known that many alkaloids obtained from plants exhibit antiangiogenic activity, and these alkaloids may act through different mechanisms to inhibit angiogenesis. Herein, we will discuss the most important alkaloids obtained from plants, focusing especially in their antiangiogenic activity. Because of the great diversity of plants, certainly, there are many antiangiogenic alkaloids that have yet to be discovered.

Keywords

Angiogenesis • antiangiogenic activity • angiogenesis-dependent diseases • natural products • plants • alkaloids

Abbreviations

Akt	AKT8 virus oncogene cellular homologue
AP-1	Activator protein 1
APL	Promyelocytic leukemia
ATF-2	Activating transcription factor 2
BAEC	Bovine aortic endothelial cells
Bax	B cell lymphoma-associated X
Bcl-2	B cell lymphoma 2 protein
bFGF	Basic fibroblast growth factor
BrdU	Bromodeoxyuridine
CAM	Chorioallantoic membrane
CD-31	Cluster of differentiation 31
CDK-2	Cyclin-dependent kinase-2
CDK-4	Cyclin-dependent kinase-4
COL1α2	Collagen type 1, alpha 2
COX-2	Cyclooxygenase-2
CREB-1	cAMP response element-binding protein
ECM	Extracellular matrix
ECs	Endothelial cells
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
ERK1/2	Extracellular-signal-regulated kinases 1 and 2
FBS	Fetal bovine serum
FCA	Freund’s complete adjuvant
FGF	Fibroblast growth factor
G6PDH	Glucose-6-phosphate dehydrogenase
GFR-Matrigel	Growth factor reduced-Matrigel
GM-CSF	Granulocyte macrophage colony-stimulating factor

HCC	Hepatocellular carcinoma cells
HIF-1	Hypoxia-inducible factor-1
HIF-1α	Hypoxia-inducible factor-1 – subunit alpha
HIF-1β	Hypoxia-inducible factor-1 – subunit beta
Hsp70	Heat shock p70
HUVEC	Human umbilical vein endothelial cells
IC_{50}	Half maximal inhibitory concentration
IL-1α	Interleukin-1 alpha
IL-1β	Interleukin-1 beta
IL-2	Interleukin-2
IL-6	Interleukin-6
IL-12	Interleukin-12
iNOS	Inducible oxide nitric synthase
IUPAC	International Union of Pure and Applied Chemistry
JAG2	Jagged-2
MAPK	Mitogen-activated protein kinase
MDS	Myelodysplastic syndrome
MMP-2	Matrix metalloproteinase-2
MMP-13	Matrix metalloproteinase 13
MMPs	Matrix metalloproteinases
MVD	Microvessel density
NFκB	Nuclear factor kappa B
NSCLC	Non-small cell lung cancer
p38 MAPK	p38 mitogen-activated protein kinase
p42/p44 MAPK	p42/p44 mitogen-activated protein kinase
$p125^{FAK}$	p125 focal adhesion kinase
PDB ID	Protein data bank identifier
PDGF-$\beta\beta$	Platelet-derived growth factor subunits beta beta
PLCγ1	Protein kinase C-gamma 1
PlGF	Placental growth factor
pRb	Retinoblastoma protein
RT-PCR	Reverse transcription-polymerase chain reaction
TGF-β1	Transforming growth factor beta1
TIMP	Tissue inhibitor of metalloproteinase
TNF-α	Tumor necrosis factor-alpha
TrpRS	Tryptophanyl-tRNA synthetase
TRPV-1	Transient receptor potential vanilloid-type 1
TUNEL	Terminal transferase dUTP nick end labeling
VASP	Vasodilator-stimulated phosphoprotein
VE-cadherin	Vascular endothelial cadherin
VEGF	Vascular endothelial growth factor
VEGF-A	Vascular endothelial growth factor-A
VEGFR-2	Vascular endothelial growth factor receptor subtype 2

1 Introduction

Angiogenesis research has a solid scientific foundation. It started with the theory of Judah Folkman (1933–2008) that tumor growth is always accompanied by neovascularization. He postulated that in order to survive and grow, tumors require blood vessels, and that by blocking the blood supply, a cancer could be starved into remission [1, 2].

In the past, the blood vessels in the body have long been considered to basically function as a transport compartment of the blood. Nowadays, it is recognized that the vasculature is one of the main organs in the body, extending more than 900 m^2 and playing a major role in supporting the body's integrity in various ways [3].

During the last decade, the field of angiogenesis has been characterized by an enormous increase in research activity [4]. The knowledge of endothelial cells (ECs) physiology and tumor angiogenesis improved, and it provided the necessary background to develop effective antiangiogenic strategies [5].

Nowadays, it is known that many alkaloids obtained from plants exhibit antiangiogenic activity and they can act through different mechanisms to inhibit angiogenesis. In this chapter, we will discuss the most important alkaloids obtained from plants, focusing especially in their antiangiogenic activity.

1.1 Angiogenesis

Angiogenesis, the sprouting of new capillaries from preexisting vessels, is a complex multistep process. It requires extensive interactions between a variety of cells and molecules and is controlled by various peptides and other modulating factors [4, 6].

In order for vascular sprouting to occur, a cascade of events must be concluded. First, extracellular matrix degradation must occur, a process that is facilitated by the activity of matrix metalloproteinases (MMPs). Next, chemoattractants and mitogens are activated in order to assist EC migration and proliferation, respectively. Finally, the tube formation occurs and requires inhibitory signals as well as those that enable formation of junctional complexes and reconstitution of a basement membrane. Formation of the basement membrane, which signals the onset of vessel maturation, involves recruitment by ECs of pericytes that embed within the basement membrane. If this microvessel is to become a larger vessel with a medial layer, then appropriate signals are required for the recruitment of smooth muscle cells [4, 6, 7]. It is known that during angiogenesis, vascular ECs interact with pericytes and such cell–cell contact inhibits EC proliferation. Thus, lack of sufficient number of pericytes around an EC layer may result in an uncontrolled development of microvasculature [8].

Imbalanced expression of pro- and antiangiogenic factors and their receptors on EC may determine the development or regression of new blood vessels. More than 200 pro-angiogenic factors have been identified. Among those, the most important factors include vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), angiopoietins, cytokines, chemokines, and angiogenic enzymes. These factors initiate angiogenesis by modulating the migration and/or proliferation of ECs and the formation of neovasculature [8, 9].

The significance of the angiogenic process increases considerably every year as new findings reveal novel mechanisms through which this process can modulate disease development and recovery [10].

1.1.1 Angiogenesis, Inflammation, and Immune System

It is widely accepted that angiogenesis is the result of a net balance between the activities exerted by positive and negative regulators. This balance is conceptually very similar to that of the pro- and anti-inflammatory mediators that modulate an appropriate and specific inflammatory response [11].

Inflammatory mediators can also, either directly or indirectly, promote angiogenesis. Angiogenesis, in turn, contributes to inflammatory pathology. New blood vessels maintain the chronic inflammatory state by enabling the transport of inflammatory cells to the site of inflammation and supplying nutrients and oxygen to the proliferating inflamed tissue. The increased endothelial surface area also creates a massive capacity for the production of cytokines, adhesion molecules, and other inflammatory stimuli. Although inflammation is essential to protect the body against pathogens, it has adverse effects on surrounding tissue. Some of these effects induce angiogenesis. Inflammation and angiogenesis are thereby linked processes [12].

Therefore, it is well established that the immune system plays an important role in the regulation of angiogenesis. Next to the regulation of angiogenesis by leukocytes, angiogenic processes can influence the cells of the immune system and the development of an immune response as well. Normal EC contributes to the recruitment of immune cells to the site of inflammation by the expression of adhesion molecules. Some authors suggest that several advantages of antiangiogenic therapy for chronic inflammatory diseases can be visualized analogous to those of tumor growth antiangiogenic strategies. First of all, suppression of blood vessel growth leads to a decreased nutrient supply to the metabolically active cells present in inflamed tissue. Second, by preventing blood vessel formation, the entry route of inflammatory cells into the tissue becomes blocked. A third possible advantage of inhibiting EC activation, proliferation, and vascular remodeling in chronically inflamed lesions is the inhibition of the production of EC-derived soluble factors such as MMPs and cytokines [3].

It is also important to mention that monocytes, macrophages, platelets, mast cells, and lymphocytes, cells that are frequently infiltrated in chronic inflammatory sites, directly release or stimulate other cells to produce angiogenic factors [8]. Furthermore, it is well accepted that hypoxia is a potent stimulus for abnormal angiogenesis in these chronic inflammatory sites [13, 14].

1.1.2 Angiogenesis-Dependent Diseases

Angiogenesis occurs in physiologic and pathologic processes. In the physiological condition, the activity of inducers and inhibitors of angiogenesis maintains it in equilibrium. Normal tissue growth, such as in embryonic development, wound healing, and menstrual cycle, is characterized by dependence on new vessel formation for the supply of oxygen and nutrients as well as removal of waste products. However, persistent and upregulated angiogenesis is often found to be a critical causal factor in several diseases, including cancer (both solid and hematologic tumors), cardiovascular diseases (atherosclerosis), chronic inflammation-associated disorders (rheumatoid arthritis, Crohn's disease), diabetes (diabetic retinopathy), psoriasis, endometriosis, and adiposity. These diseases may benefit from therapeutic inhibition of angiogenesis [15–18].

Pathological angiogenesis is closely associated with almost all of the major diseases afflicting human life [19]. Angiogenesis is therefore necessary for tumors and their metastases to grow beyond a microscopic size, and it can give rise to bleeding, vascular leakage, and tissue destruction. These consequences of pathological angiogenesis can be responsible, directly or indirectly, for the symptoms, incapacitation, or death associated with a broad range of "angiogenesis-dependent diseases." In fact, according to Folkman, the concept of angiogenesis-dependent diseases originated in 1972 with the recognition that certain nonneoplastic diseases depend on chronic neovascularization to provide a conduit for the continual delivery of inflammatory cells to the inflammatory site. Examples of such diseases include cancer, autoimmune diseases, age-related macular degeneration, and atherosclerosis. Subsequently, other nonneoplastic disorders were recognized to be in part angiogenesis dependent, for example, infantile hemangiomas, peptic ulcers, ocular neovascularization, and rheumatoid arthritis [20].

1.1.3 The Inhibition of Angiogenesis

The term "antiangiogenesis" was introduced to describe treatments designed to prevent the induction of new blood vessels and perhaps reduce the number of those already present [21]. Angiogenesis inhibition has been proposed as a general strategy to fight cancer and other angiogenesis-dependent diseases [15].

In the treatment of cancer, the inhibition of angiogenesis is a major area of therapeutic development. Whereas conventional chemotherapy, radiotherapy, and immunotherapy are directed against tumor cells, antiangiogenic therapy is aimed at the vasculature of a tumor and will either cause total tumor regression or keep tumors in a state of dormancy [2]. Angiopreventive drugs may have the potential to repress angiogenesis during early steps of carcinogenesis where they might retard the angiogenic switch, preventing unrestrained tumor growth [22].

Moreover, in the treatment of angiogenesis-dependent disease, angiogenesis inhibitors may be useful adjuncts to conventional therapies. When all conventional therapy has failed, an angiogenesis inhibitor may be successfully used as has been demonstrated in the treatment of multiple myeloma by thalidomide [23].

Definitely, angiogenesis can be targeted at several stages. The strategies for therapies are targeting growth factors and their receptors, interrupting the downstream signaling, blocking matrix degrading enzymes, using endogenous inhibitors, or attempting to mimic naturally occurring angiogenesis inhibitors, such as thrombospondin [24, 25].

1.1.4 Evaluating Potential Antiangiogenic Agents Obtained from Plants

Since angiogenesis mainly depends on proper activation, proliferation, adhesion, migration, and maturation of ECs, most approaches to modulate angiogenesis are focused on these endothelial functions during blood vessel formation [3].

Various in vitro and in vivo assays have been utilized to analyze angiogenesis experimentally. In vitro, ECs such as human umbilical vein endothelial cells (HUVECs) cultures are widely used. Migration or invasion of HUVECs could be assayed by transwell, and proliferation could be determined by bromodeoxyuridine (BrdU) incorporation. Differentiation is determined by tube formation assay using HUVECs seeded on Matrigel with or without angiogenic activator. In vivo, the Matrigel plug assay is widely performed in mice subcutaneously inoculated with angiogenic factor treated Matrigel, and the content of hemoglobin is measured in the Matrigel plugs to indirectly quantify functional new blood vessel formation. Taken together, these angiogenesis experimental tools can be useful in studies focused on antiangiogenic activity screening of plants used in traditional folk medicine [10, 26].

Some authors believe that bioactive compounds from natural sources may be used as regulatory agents in the formation of new blood vessels offering an enormous potential for therapeutic intervention of many disorders. An increasing number of bioactive compounds from natural sources and whose chemical structures have already been elucidated are reported as potential inhibitors of angiogenesis [27].

Ng et al. consider that naturally occurring bioactive compounds may be good candidates for the prevention of angiogenic disease, when standard therapy is unsuitable or lacking. They suggest that these products can also complement chemotherapy or radiotherapy, in combination with other anticancer drugs for therapy at different stages, and increase the survival time of the patients [28].

According to Tai-Ping Fan et al., the identification of new drugs from plants has a long and successful history, and certain pro-angiogenic and antiangiogenic plant components have been used in traditional Chinese medicine for thousands of years. Thus, it is rational to explore these medicinal plants as a source of novel angiomodulators [29].

2 Antiangiogenic Alkaloids from Plants

Plant metabolites bearing different structural patterns have showed potent effects on angiogenesis process [30–32]. Several of these substances are alkaloids, and their structures and biological effect on angiogenesis process are detailed below. In this chapter, we have used a broad concept to the alkaloid term, which was based on IUPAC recommendations. Its definition includes any plant metabolite containing basic nitrogen or clearly derived from an amino acid and still retaining its nitrogen atom, whether it demonstrates basicity or not [33]. Herein, the alkaloids have been separated according to their hypothetical amino acid precursor.

2.1 Alkaloids Derived from Tyrosine

2.1.1 Berberine

Berberine (**2**) is a quaternary ammonium salt from the protoberberine class. It is found in several occidental and oriental medicinal plants, including *Hydrastis canadensis* L. (Ranunculaceae) and *Coptis chinensis* Franch var. *chinensis* (Ranunculaceae), also known as Goldenseal and Huanglian, respectively [34].

Berberine has exhibited cytotoxicity against several cancer cell lines from different histological origins, including bone, breast, brain, colon, esophagus, liver, lung, and stomach. This activity was correlated to two main effects: (1) antimitotic, through protein and DNA synthesis inhibitory activities, and (2) proapoptotic, by regulating apoptotic gene expression and decreasing mitochondrial transmembrane potential [35].

Low micromolar concentrations of **2** reduced the capacity of hepatocellular carcinoma cells (HCC) to stimulate HUVEC proliferation, migration, and endothelial tube formation. In addition, **2** prevented secretion of VEGF from HCC and decreased VEGF mRNA expression. Altogether, these data indicated that **2** showed antiangiogenic properties, which could influence the cross talk between HCC cells and HUVEC [36].

In other experiments, **2** decreased directly the ability of HUVEC migration and capillary tube formation and inhibited gastric adenocarcinoma cancer cell line SC-M1 to stimulate HUVEC migration. The influence of **2** on the cross talk between HUVEC and SC-M1 was studied under hypoxic culture conditions. These experiments indicated that **2** caused a downregulation on the expression of VEGF and hypoxia-inducible factor-1alpha (HIF-1α), two key factors in mediating tumor angiogenesis [37].

2.1.2 Noscapine

Noscapine or narcotine (**3**) is a phthalideisoquinoline alkaloid from plants of the Papaveraceae family. It is an important alkaloid from the opium poppy (*Papaver somniferum* L.), occurring in variable quantities (level ranges from 2% to 10%) [38]. Unlike opioid morphinane drugs, noscapine lacks hypnoanalgesic, euphoric, and respiratory depressant properties. Its main therapeutic application is as oral antitussive drug, which is indicated to treat nonproductive coughs [39, 40].

Noscapine displayed HIF-1 inhibitory activity on human glioma cells under different types of hypoxic stress. This activity was determined through variations in the HIF-1α expression. The reductions of the HIF-1α expression were due to accumulation in the nucleus and its degradation through the proteasome pathway [41]. Considering that the expression of HIF-1α protein promotes transcriptional activation of VEGF gene [42, 43], noscapine decreased VEGF production through upregulation of VEGF gene. However, noscapine inhibited the ability of HUVEC to form capillary-like structures in vitro, corroborating its potential as antiangiogenic agent [41].

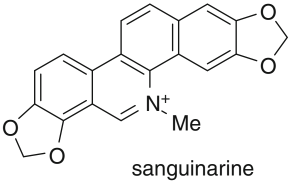
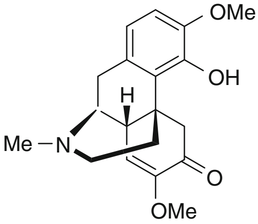
noscapine
3



sanguinarine
4



sinomenine
5

2.1.3 Sanguinarine

Sanguinarine or pseudochelerythrine (**4**) is quaternary ammonium salt belonging to the benzo[*c*]phenanthridine class. It constitutes approximately 50% of redroot latex of *Sanguinaria canadensis* L. (Papaveraceae), an herbaceous medicinal plant popularly known as bloodroot [44]. The main pharmacological application of sanguinarine is in dental formulations, including mouthwashes and toothpastes. It shows antimicrobial and anti-inflammatory properties, reducing gingival inflammation and supragingival plaque formation [45].

Sanguinarine possess antiproliferative activity against several human cancer cell lines, exhibiting differential apoptosis-inducing effect in tumorigenic cells *versus* normal cells [46]. In preclinical experiments, oral treatment with sanguinarine suppressed murine tumor growth in a syngeneic host (B16 melanoma 4A5 cells implanted in C57BL/6 mice) and in a human melanoma tumor xenograft (A37) in athymic mice [47].

Sanguinarine has been recognized as a potent antiangiogenic agent, suppressing VEGF-induced migration, sprouting, and survival in primary cultured ECs, at nanomolar levels. On the other hand, sanguinarine was a relatively mild inhibitor of VEGF-induced DNA synthesis. In vivo assays, using mouse Matrigel plug and chorioallantoic membrane (CAM) of chick embryos, evidenced its potent action on vasculogenesis. Preliminary biochemical experiments revealed that sanguinarine strongly suppressed basal and VEGF-induced Akt (AKT8 virus oncogene cellular homologue) phosphorylation and not interfered on VEGF-induced ERK1/2 (extracellular-signal-regulated kinases 1 and 2) and PLCγ1 (protein kinase C-gamma 1) phosphorylations [48]. More recently, the effects of sanguinarine on Akt phosphorylation inhibition were confirmed by immunoassays [49].

Considering that physiological angiogenesis is a crucial step to ovarian follicle development, under normal conditions, sanguinarine attenuated VEGF production by swine granulosa cells, interfering negatively on female reproductive performance [50].

2.1.4 Sinomenine

Sinomenine or cocculine (**5**) is a morphinane alkaloid identified as antirheumatic chief component from the *Sinomenium acutum* Rehder and Wilson (Menispermaceae). The whole plant has been used to treat joint pain and arthritis for over 2,000 years, and its preparations have been adopted by traditional Chinese medicine [51, 52].

Sinomenine inhibited basic fibroblast growth factor (bFGF)-induced in vitro angiogenesis, acting through four different modes of action on HUVEC: (1) inhibiting of proliferation, (2) arresting their cell cycle in G1 phase, (3) suppressing chemotactic mobility, and (4) disrupting tube formation. Furthermore, in vivo and ex vivo antiangiogenic assays corroborated its in vitro results. It reduced the neovascularization and microvascular outgrowth, which are measured by Matrigel plug and rat aorta ring sprouting experiments, respectively [53].

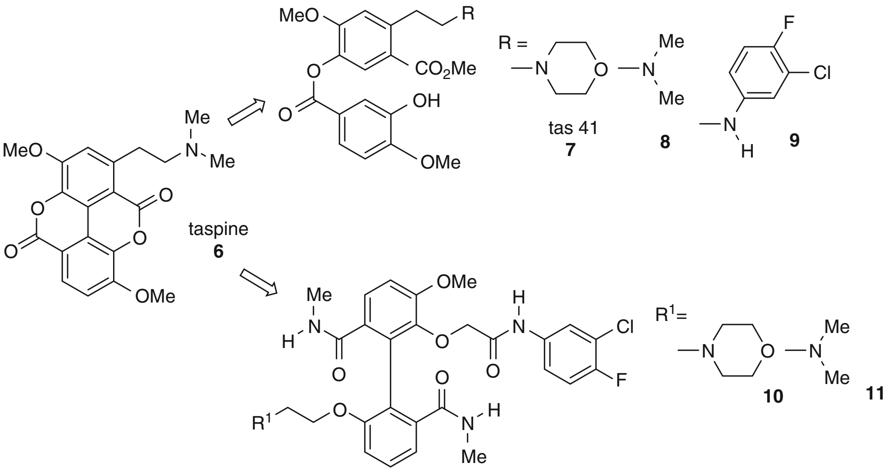
Recent studies revealed that sinomenine showed modulatory effects on gene expression of the IL-1β activated in human synovial sarcoma using Hs701.T cell line. Sinomenine suppressed the expression of genes associated with angiogenesis and vascular remodeling, such as JAG2 (jagged-2), a transmembrane ligand of notch receptor; COL1α2 (collagen, type 1, alpha 2); MMP-13 (matrix metalloproteinase 13); and P1GF (placental growth factor), a member of VEGF family [54].

2.1.5 Taspine and Its Synthetic Analogues

Taspine (**6**) is unusual alkaloid with two lactones, resembling ellagic acid, and a *N*, *N*-dimethylaminoethyl side chain, which hypothetically arisen from tyrosine metabolism [55]. It has been showed several biological activities, such as cicatrizing capacity and acetylcholinesterase inhibition [56, 57].

Taspine has displayed several in vitro antiangiogenic properties on HUVEC, including reduction on its VEGF secretion. It exhibited HUVEC growth inhibition by inducing its apoptosis in a concentration-dependent manner. Its apoptosis-inducing activity was confirmed by transmission electron microscopy, which showed chromatin agglutination, nuclear karyopyknosis, and typical apoptotic bodies. Immunoassays indicated a decreased in the Bcl-2 (B cell lymphoma 2 protein) expression, as well as an increased in the Bax (B cell lymphoma-associated X) expression, anti-apoptotic and pro-apoptotic proteins, respectively [58]. Considering that Bcl-2 overexpression is closely related to the angiogenesis process [59], the dual action of taspine on this target and VEGF could constitute its mechanism of antiangiogenic activity [58]. More recently, taspine showed antiangiogenic and apoptosis-inducing activities against epidermoid carcinoma cells in a manner closely related to HUVEC. Additionally, taspine has increased the expression of caspase-3, cleaved caspase-3, CDK2 (cyclin-dependent kinase-2), and CDK4 (cyclin-dependent kinase-4) [60].

The potential antiangiogenic of taspine encouraged the synthesis of novel analogues (**7**–**9**). Tas 41 (**7**) showed potent antiproliferative activity against human umbilical endothelial (ECV304 cell line) and human epithelial colorectal adenocarcinoma cells (Caco-2 cell lineage), exhibiting IC_{50} values of 2.67 nM and 52.5 nM, respectively. These data indicated that tas 41 was more effective against ECV304 than Caco-2 (approximately 19-fold), suggesting this compound may inhibit vascular endothelial growth factor receptor subtype 2 (VEGFR-2). Docking studies of tas 41 in the active site of VEGFR-2 (PDB ID: 3C7Q), using Sybyl/FlexX, showed its binding mode. It included hydrogen bond interactions to the Asn 923, Arg 1032, and Cys 913 residues [61]. Further studies confirmed the antiangiogenic properties of tas 41, which showed effects closely related to the taspine [62]. More recently, biphenyl taspine analogues (**10** and **11**) showed inhibitory activity against cell lines express abnormally high levels of EGFR (epidermal growth factor receptor). Their predicted physicochemical properties, including distribution and partition coefficients, indicated these compounds were more water-soluble than taspine. Altogether, these studies led to pivotal structural features of ring-opened analogues, including the importance of lactone ring B for antiangiogenic activity. On the other hand, the cleavage of lactone ring A did not interfere to biological activity [63, 64].



2.1.6 Tetrandrine and Its Synthetic Analogues

Tetrandrine (**12**) is a *bis*-benzylisoquinoline alkaloid identified as bioactive chief alkaloid from *Stephania tetrandra* S. Moore (Menispermaceae) [65, 66].

It has been traditionally used for the treatment of inflammatory process by several oriental systems of herbal medicine. In the traditional Chinese medicine, this species is among 50 fundamental herbs used, belonging to the Pharmacopoeia of the People's Republic of China [67]. Tetrandrine showed potent antiproliferative activity against a broad panel of human cell lines, including those derived from hepatocellular carcinoma, colorectal, and esophageal cancers [68, 69].

The potential antiangiogenic of tetrandrine was evaluated by several experiments. Tetrandrine was able to decrease the proliferation of HUVEC primary culture and LoVo cells (human colorectal carcinoma). Also, its in vitro activities on HUVEC included migration and tube formation impairment, apoptosis induction, and DNA synthesis suppression. Additionally, in vivo experiments using LoVo cells xenograft in nude mice indicated that tetrandrine significantly reduced the number of hot spots of neo-angiogenesis, which was measured by immunohistochemistry techniques [70].

In other experiments, tetrandrine exhibited inhibitory effect on tube formation of rat vascular ECs, which were stimulated by IL-1α (interleukin-1 alpha) and PDGF-ββ (platelet-derived growth factor subunits beta beta), and FBS (fetal bovine serum). Nanomolar concentrations of tetrandrine were more effective against tube formation stimulated by IL-1α and PDGF-ββ than FBS. In vivo experiments indicated that tetrandrine inhibited air-pouch granuloma angiogenesis, induced by Freund's complete adjuvant (FCA) with croton oil. Similarly to in vitro experiments, tetrandrine exhibited potency similar to the hydrocortisone. These pharmacological results support the traditional use of *S. tetrandra* as anti-inflammatory plant for chronic inflammations and **12** as its responsible biologically active compound [71].

Tetrandrine and its synthetic analogues (**13** and **14**) displayed potent inhibitory effect on FBS-stimulated angiogenesis of cultured choroidal tissues explanted of streptozotocin-diabetic Wistar rats and in vivo air-pouch granuloma angiogenesis in diabetic mice. This study indicated that *bis*[tetrahydroisoquinoline] unit connected by oxy-*bis*[phenylenemethylene] and 2,2-dimethyl groups was important structural feature for antiangiogenic activity. Analogue **13** may be considered as lead compound to treat diabetes-associated choroidopathy and retinopathy [72].

R^1= OMe **14**

2.2 Alkaloids Derived from Tryptophan

2.2.1 Brucine

Brucine (**15**) is a bitter substance closely related to strychnine, which is mainly isolated from the seeds of *Strychnos nux-vomica* L. (Loganiaceae). These compounds are monoterpenoid indole alkaloids and have been classified into type Ib category (or strychnines) [73]. Despite structural similarity between these compounds, brucine was not found be a potent toxic agent [74]. Brucine and strychnine exhibit distinguished historical relevance and have been extensively used as modern research tools, including their application as chiral deriving agents for racemic mixture resolutions [75].

Brucine inhibited tumor angiogenesis process, which was elucidated by in vitro and in vivo assays. It was able to inhibit human breast adenocarcinoma cell proliferation, when administered along VEGF polyclonal antibody, and reduced their pro-angiogenic factors secretion, including VEGF and tumor necrosis factor-alpha (TNF-α). This experiment suggests that brucine binds with VEGF receptors, inhibiting cell proliferation. In vivo experiments, using two Ehrlich tumor models, proved to confirm in vitro results, indicating that brucine downregulated VEGF and TNF-α levels, and increased interleukin-12 (IL-12), another antiangiogenic factor [76].

Brucine showed potent effects on inflammatory angiogenesis process, which was evaluated by in vivo cannulated sponge implant model in Swiss albino mice. It indicated that brucine decreased wet weight granuloma tissue and its hemoglobin content. Also, brucine exhibited inhibitory activity on inflammatory, angiogenic, and fibrogenic cytokines, such as cluster of differentiation 31 (CD-31), transforming growth factor beta 1 (TGF-β1), and VEGF [77].

2.2.2 Evodiamine

Evodiamine (**16**) is an indoloquinazoline alkaloid of mixed biosynthetic origin and possesses three nitrogen atoms arising from tryptophan and *N*-methyl-anthranilic acid residues [78]. It is chief alkaloid from fruits of *Evodia rutaecarpa* Bentham (Rutaceae), a plant widely used by traditional Chinese medicine [79].

Pharmacologically, evodiamine has been widely studied as innovative anti-obesity agent and was classified as a full TRPV-1 (transient receptor potential vanilloid-type 1) agonist. This receptor is a nonspecific ion channel and is activated by not only chemical compounds containing vanillyl moiety but also heat (≥45 °C) and acid (micromolar range) stimuli. It exhibited binding affinity similar to capsaicin in Chinese hamster ovary cell model. Despite similar in vitro and in vivo anti-obese activities between these compounds, evodiamine has not perceptible taste, including a peppery hot taste [80, 81].

Several evidences demonstrated that evodiamine possesses in vitro and in vivo anticancer properties, such as antiproliferative, anti-metastatic, apoptosis-inducing, and antiangiogenic activities [82]. Evodiamine was able directly to reduce HUVEC capillary tube formation and invasion, using Matrigel assay. In vivo assay, using

CAM of chick embryo and local administration of evodiamine, confirmed the suppression on tube formation process. Western blot and northern blot experiments, using HUVEC, indicated that evodiamine reduced VEGF and p42/p44 mitogen-activated protein kinases (p42/p44 MAPKs) expression and the mRNA expression of VEGF, respectively. In other experiments, using human lung adenocarcinoma cell lines (CL-1 cells), evodiamine inhibited markedly CL-1-induced tube formation in ECs and their VEGF expression [83].

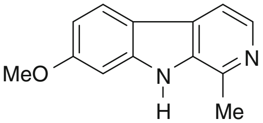
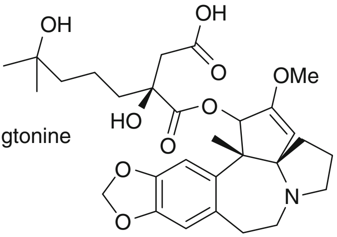
evodiamine
16



harmine
17



homoharringtonine
18

2.2.3 Harmine

Harmine (**17**) belongs to the β-carboline alkaloid class, which occurring in Malpighiaceae family, mainly in South American plants, such as *Banisteriopsis caapi* (Spruce ex Griseb) C. V. Morton [84]. This species is popularly known as "ayahuasca" (Ecuador, Peru), and "caapi" (Brazil) has been used in hallucinogenic preparations. *Banisteriopsis caapi* stems and *Psychotria viridis* Ruiz & Pav. leaves (Rubiaceae) have been widely used in mystic-religious ceremonies. Psychopharmacological and neuropharmacological properties of these infusions and decoctions were related to a complex alkaloid mixture, including harmine [85].

Harmine exhibits potent antineoplastic activity against tumors with high metastatic capacity, including HepA, Lewis lung cancer, and sarcoma 180. It has showed antiproliferative activity against cells of different histological origins, such as epidermoid carcinoma of nasopharynx, osteosarcoma, lung carcinoma, glioblastoma, and breast cancer [86].

Harmine proved to be a potent angiogenic inhibitor, which was extensively evaluated by in vitro and in vivo experiments. In vitro, it was able to reduce different steps of neo-vessel formation by VEGF-induced HUVEC, including proliferation, motility, invasion, and tube formation. Additionally, harmine showed inhibitory effect on transcription factors related to crucial tumor development and angiogenesis process. It reduced the translocation and activation of nuclear factor kappa B (NF-κB) subunits (p65, p50, and c-Rel) and nuclear translocation of important AP-1 (activator protein 1) factors, including c-fos, ATF-2 (activating transcription factor 2), and CREB-1 (cAMP response element-binding protein). Secretion of other factors by B16F-10 melanoma cells, which are involved in angiogenesis, including cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (iNOS), and matrix metalloproteinase was also reduced by treatment with harmine. Ex vivo assay, using rat aortic rings and conditioned medium from B16F-10 melanoma cells, demonstrated that harmine inhibited microvessel outgrowth. Experiments using B16F-10 cells intradermally injected on the shaven ventral skin and intraperitoneal administration of harmine (10 mg kg^{-1} body weight) in mice indicated potent reduction of tumor specific neo-vessel formation. The level of serum pro-angiogenic factors of VEGF and nitric oxide, as well as pro-inflammatory cytokines (IL-1β, interleukin-6 (IL-6), TNF-α, and granulocyte macrophage colony-stimulating factor (GM-CSF)), was effectively decreased by harmine treatment. Furthermore, harmine significantly enhanced the levels of interleukin-2 (IL-2) and tissue inhibitor of metalloproteinase (TIMP); both are important antiangiogenic factors [87].

2.2.4 Homoharringtonine

Homoharringtonine (**18**) is an alkaloid of unusual structure and belongs to harringtonine class, which is structurally characterized as cephalotaxine esters. These compounds have been exclusively isolated from *Cephalotaxus* plants, including *C. fortunei* Hook F and *C. harringtonia* K. Koch *var. harringtonia* [88].

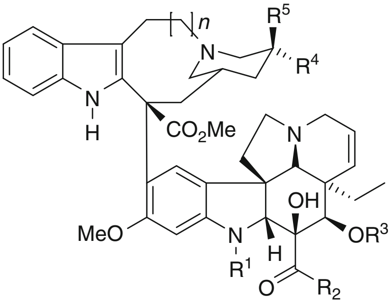
Cephalotaxine and its esters are of particular chemical and medical interest. Among these, **18** and harringtonine are most promising anticancer agents [89]. Homoharringtonine has been submitted to extensive phase I/II clinical studies in patients with different solid tumors, such as malignant melanoma, sarcoma, head and neck carcinoma, breast carcinoma, and colorectal carcinoma. Also, several clinical trials include studies efficacy in patients with acute leukemia, myelodysplastic syndrome (MDS), acute promyelocytic leukemia (APL), and chronic myeloid leukemia [90].

Homoharringtonine exhibited in vitro antiangiogenic effects on endothelial and leukemic cells, ECV304 and K562 cells, respectively. Its effects on ECV304 include proliferation inhibition and apoptosis induction. For leukemic cells, **18** downregulated VEGF mRNA expression and inhibited VEGF protein production, which were analyzed by reverse transcription-polymerase chain reaction (RT-PCR) and western blot, respectively [91]. Another in vitro study indicated VEGF antisense oligodeoxynucleotide increased the sensitivity of myeloid leukemia cells to **18** [92]. Experiments using gelatin sponges implanted on top of chick embryo CAM demonstrated that **18** significantly reduced microvessel density (MVD), confirming its in vitro antiangiogenic properties [93]. Studies involving RNA interference and transfected K562 cells suggested that inhibition of H1F-1α expression, at both mRNA and protein after RNAi H1F-1α, decreases VEGF, under hypoxic conditions. Moreover, this HIF-1α inhibition was able to increase K562 cell chemosensitivity to **18**. Altogether, these observations suggested that inhibition of H1F-1α expression is related to antiangiogenic activity through two complementary mechanisms, inhibition of VEGF expression and increase of leukemic cells susceptibility to **18**, an antiangiogenic agent [94].

2.2.5 Vinca Alkaloids and their Semisynthetic Analogues

Vinca alkaloids constitute a group of indole–indoline dimeric compounds from *Catharanthus roseus* (L.) G. Don. (formerly named as *Vinca rosea* L.). It is a pantropical species and belongs to the Apocynaceae family and is popularly known as Madagascar periwinkle [95]. Among these, vinblastine (or vincaleucoblastine, **19**) and vincristine (or leurocristine, **20**) are of clinical oncology interest [96]. Vincristine and vinblastine have been commonly administered in combination with other anticancer drugs in the treatment of hematological malignancies (leukemias and lymphomas) and solid tumors (bladder and breast cancers), respectively [97].

Soon after clinical impact of these phytochemicals in curative and palliative cancer chemotherapies, a number of studies focused on design of their semisynthetic derivatives were developed. These efforts led to important anticancer agents, including vindesine (**21**), vinorelbine (**22**), and vinflunine (**23**). Vinorelbine has been administered for treating non-small cell lung cancer (NSCLC), metastatic breast cancer, and rhabdomyosarcoma [98]. Vindesine is usually used to treat leukemia, lymphoma, melanoma, and breast and lung cancers. Vinflunine is a fluorinated vinblastine derivative and has been submitted to phase III clinical studies in patients with NSCLC and bladder cancer [99].



vinblastine **19** R^1= Me, R^2= OMe, R^3= COMe, R^4= Et, R^5= OH, *n* = 1

vincristine **20** R^1= CHO, R^2= OMe, R^3= COMe, R^4= Et, R^5= OH, *n* = 1

vindesine **21** R^1= Me, R^2= NH_2, R^3= H, R^4= Et, R^5= OH, *n* = 1

vinorelbine **22** R^1= Me, R^2= OMe, R^3= COMe, R^4= Et, R^5= H, *n* = 0

vinflunine **23** R^1= Me, R^2= OMe, R^3= COMe, R^4= CF_2Me, R^5= H, *n* = 0

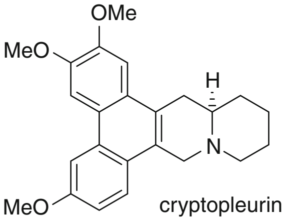
Vinblastine exhibited in vitro antiangiogenic activity. It was able to interfere in HUVEC angiogenic phenotype, at noncytotoxic concentrations, including proliferation, chemotaxis, adhesion, and abnormal vessel morphology. These features were observed when HUVEC was cultured in optimal growth medium alone or supplemented with angiogenic growth factors. Electron microscopy experiments demonstrated morphology alterations caused by **19**. They indicated that the HUVEC elongation was related to thin disturbance of cytoskeleton, in the form of slight depolymerization and addensation, as well as accumulation of microfilaments [100]. In other experiments, **19** inhibited adrenomedullin-induced angiogenesis, using in vitro and in vivo experiments, such as Matrigel tube formation and CAM of chick embryo, respectively [101]. The combination between **19** and rapamycin has exhibited in vitro and in vivo synergistic effects on angiogenesis [102, 103]. Differential proteomic analysis of this combination on ECs indicated crucial variations in protein contents, which were related to angiogenesis process. Among these, downregulation of ATP synthase, annexin A2, heat shock p70 (Hsp70), glucose-6-phosphate dehydrogenase (G6PDH), vasodilator-stimulated phosphoprotein (VASP), proteasome 26S, tryptophanyl-tRNA synthetase (TrpRS), and stathmin/Op18, as well as the up-modulation of carbonyl reductase, RhoGDP-dissociation inhibitor (Rho-GDI), and histone H1.0, was observed [104]. In another in vivo experiment, metronomic vinblastine chemotherapy inhibited VEGF-A-induced-angiogenesis. The continuous vinblastine treatment with an apparently nontoxic dose was able substantially to inhibit vascularized area and microvascular length, which were evaluated by microscopy morphometry and computerized image analysis, respectively [105]. Also, **20** and **23** have been intensively investigated as antiangiogenic agents, including their synergistic effects when combined with other drugs [106–108].

2.3 Alkaloids Derived from Lysine

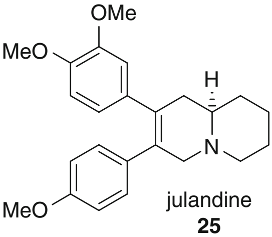
2.3.1 Cryptopleurine, Julandine, and their Synthetic Analogues

Cryptopleurine (**24**) and julandine (**25**) are phenanthroquinolizidine alkaloids. Together with phenanthroindolizidine alkaloids, they are constituted by over 70 compounds. These alkaloids are commonly isolated from plants of Asclepiadaceae and Moraceae families [109, 110]. They have exhibited similar biological activities, which include antiviral, antifungal, cytotoxic, and vesicant [111].

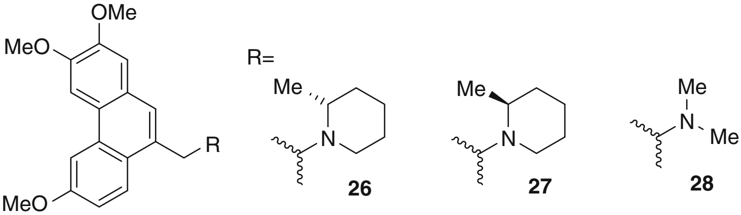
Cryptopleurine inhibited hypoxic HIF-1 activation in human gastric cancer cells (AGS cells), which were induced by hypoxia using a HIF-mediated reporter gene assay. Furthermore, **24** blocked HIF-1α protein accumulation in AGS cells, but not HIF-β protein, confirming its inhibitory effect on HIF-1 activation under hypoxic conditions [112]. Several C8c–C15 monoseco-analogues of **24** and **25** exhibited antiangiogenic activity, using rat aorta assay. Quinolizidine-ring opened analogues of cryptopleurine **26**–**28** inhibited 100% of blood vessel growth, at 100 μg mL^{-1}, and were more potent than PI-88, a heparin sulfate mimetic used as positive control [113, 114].

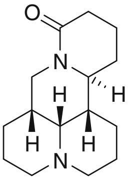


cryptopleurine
24



julandine
25





matrine
29

2.3.2 Matrine

Matrine (**29**) is a quinolizidine alkaloid isolated from several species of the genus *Sophora* (Fabaceae), mainly *S. alopecuroides* L. and *S. flavescens* Aiton. The latter has widely been used by traditional Chinese medicine, and its pharmacological properties were correlated to matrine contents [115, 116].

Matrine possesses potent antitumor activities in vitro and in vivo. It exhibits cytotoxic activity on cancer cell lines of different histological origins, including cervical cancer, gastric cancer, glioma, HCC, leukemia, lung cancer, and melanoma. Also, matrine administration reduced the growth of HCC and gastric tumor in mice [117–120].

Matrine showed potent in vivo antiangiogenic effect. Experiments, using breast cancer cell implanted in Balb/c mice, indicated that **29** reduced tumor MVD, which is measured by immunostaining techniques using anti-CD31 antibodies. Corroborating these findings, western blot assays demonstrated that **29** downregulated VEGF and VEGFR-2 expression [121].

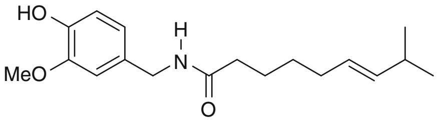
2.4 Capsaicin and its Natural Ester Analogues

Capsaicin (**30**) is an amide belonging to capsaicinoid class, which is formed by condensation between branched-chain fatty acids (C_8–C_{13}) and vanillylamine unit.

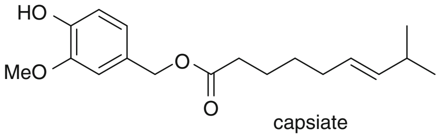
They are isolated from several varieties of *Capsicum annuum* L. and *C. frutescens* L. (Solanaceae), which are commonly named as hot peppers. Their physiological effects, such as lachrymation, coughing, and burning sensation, are directly correlated to capsaicinoid contents [122].

Pharmacologically, **30** has been intensively studied due to high TRPV-1 affinity. After TRPV-1 activation, **30** causes its long-lasting desensitization and loss of pain sensitivity. This unusual analgesia mode became **30** as valuable lead compound for design of innovative painkiller agents. The main therapeutic application of **30** is in cream-topical formulations, used to treat several algias associated with neurological origin, such as osteoarthritis, painful neuropathy linked to the trigeminal nerve, neuralgia caused by herpes infections, and painful diabetic neuropathy [123].

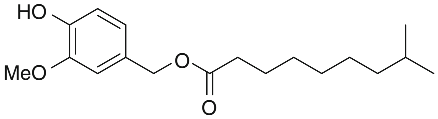
Capsaicin exhibited potent effect on cancer and inflammatory angiogenesis processes. In vitro assays demonstrated that **30** was able to inhibit the proliferation of HUVEC primary culture, which was not related to high TPRV-1 affinity. In other experiments, using HUVEC, capsaicin inhibited their migration and capillary tube formation. Further studies showed that **30** was able to inhibit DNA synthesis in HUVEC, causing G1 phase arrest. Its effect was attributed to downregulation of cyclin D1 expression, leading to inhibition of phosphorylation of retinoblastoma protein (pRb), mediated by CDK-4. Signaling experiments showed that capsaicin inhibited VEGF-induced activation of p38-MAPK (p38 mitogen-activated protein kinase), p125^{FAK} (p125 focal adhesion kinase), and Akt, suggesting its possible antiangiogenic molecular mechanism. Ex vivo assay, using art aortic ring, **30** significantly reduced VEGF-induced microvessel sprouting. Two in vivo experiments confirmed the potential antiangiogenic activity of **30**. It was capable of blocking angiogenesis induced by Matrigel plug containing VEGF, subcutaneously implanted into C57BL/6 mice. In another experiment, using CAM of chick embryo assay, **30** inhibited angiogenesis induced by primate fibrosarcoma (HT1080 cells) [124]. In vivo experiments, using acetic acid-induced kissing gastric ulcer, **30** strongly inhibited the microvessels formation in the granulation tissue at the ulcer margin. Additionally, **30** decreased epidermal growth factor (EGF) levels in salivary gland, serum and gastric mucosa, suggesting its potential antiproliferative activity on several epithelial cells [125].



capsaicin
30



capsiate
31



dihydrocapsiate
32

Capsinoids, which include capsiate (**31**) and dihydrocapsiate (**32**), are esters naturally occurring in red peppers. Although they are structurally similar to capsaicin and its amide-type analogues, capsinoids were not found to be potent pungent compounds. Capsiate and dihydrocapsiate showed in vitro and in vivo antiangiogenic properties closely related to capsaicin performance [124]. Additionally, these compounds blocked VEGF-induced endothelial permeability and loss of endothelial cell–cell junctions facilitated by vascular endothelial cadherin (VE-cadherin). Capsiate was able to suppress not only VEGF-induced activation of Src kinase but also the phosphorylation of its downstream substrates, including p125^{FAK} and VE-cadherin. Molecular modeling studies indicated the binding mode of **31** in Src tyrosine kinase, which interacted to its ATP-binding pocket [126].

2.5 Halofuginone

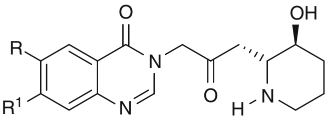
Halofuginone (**33**) is not plant-derived alkaloid. It is halogenated synthetic compound, which shows structural features based on febrifugine (**34**), a *N*3-substituted quinazolin-4-one alkaloid [127].

Febrifugine was first isolated from roots of *Dichroa febrifuga* Lour. (Saxifragaceae), a Chinese medicinal plant traditionally used to treat malaria fevers. This alkaloid showed potent anti-*Plasmodium* activity, which was superior to quinine, and unacceptable side effects, such as hepatotoxicity and severe emesis [128, 129]. Its properties not only precluded its use as drug but also encouraged the synthesis of safer analogues [127].

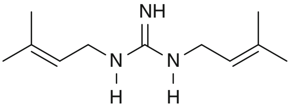
Halofuginone is of particular interest as a drug orphan candidate to treat scleroderma [130, 131]. It has been intensively investigated for control of diseases involving collagen biosynthesis and some cancer types [131, 132]. The main application of its hydrobromide salt is as a curative and prophylactic agent, used to treat protozoan veterinary infections, mainly in commercial poultry and cattle production [131].

Halofuginone was effective in critical steps of in vitro angiogenesis process, which was evaluated on bovine aortic endothelial cells (BAEC). These events include (1) antiproliferative activity, (2) inhibition of MMP-2 gelatinolytic activity, (3) decrease of invasion capacity through Matrigel containing medium conditioned by 3 T3 fibroblasts, (4) inhibition of capillary tube formation, and (5) inhibition of subendothelial extracellular matrix (ECM) deposition. Ex vivo assay, using rat aortic ring, indicated that **33** markedly reduced vascular sprouting. The most relevant antiangiogenic property was evidenced by in vivo experiments, using mouse corneal micropocket experiments. This assay revealed that **33** inhibited bFGF-induced neovascularization, both after intraperitoneally or diet administration [133].

In other studies, **33** exhibited biological activities closely related to key antiangiogenic effects. A potent inhibition on MMP-2 gene transcription activity was demonstrated in human and murine bladder carcinoma cell lines [134]. Highly specific suppression of collagen type α1 gene expression was observed in a broad panel of different cell types, including chicken, mouse, rat, and human origin [135]. Furthermore, **33** showed antiangiogenic properties in several in vivo models [136, 137].



halofuginone **33** R = Cl, R^1= Br
febrifugine **34** R = R^1= H



pterogynidine
35

2.6 Pterogynidine

Pterogynidine (**35**) belongs to guanidine alkaloid class, a quite rare plant-alkaloid category, which is most common in marine organisms. It is formed by guanidine core substituted by two isoprenylated units [138]. This compound was first isolated from *Pterogyne nitens* Tul. (Fabaceae), an ornamental species, which occurs only in South America regions [139].

Pterogynidine has showed cytotoxicity against several human cancer cell lines, including myeloblastic leukemia, glioblastoma, and malignant breast [140]. Its cytotoxic effect has been related to apoptosis-inducing activity, which was evaluated by several in vitro assays, such as Hoechst-propidium iodide, cytometry-based annexin-V, and caspase-Glo 3 and 7 [141].

Pterogynidine showed in vitro antiangiogenic properties, using HUVEC. Among these, **35** was able to decrease proliferation and invasion capacity, which was evaluated by bromodeoxyuridine (BrdU) and double-chamber assay, respectively. The terminal transferase dUTP nick end labeling (TUNEL) experiments indicated that **35** increases HUVEC apoptosis index, corroborating with the effects on cancer cells. In addition, **35** drastically reduced the number of capillary-like structures formation using HUVEC cultured on growth factor reduced-Matrigel (GFR-Matrigel) coated plates. In addition, **35** was shown to act through the inhibition of NFκB [26].

3 Conclusion

Plants are well known to be a rich source of bioactive constituents, and they can provide high potential for discovery of new and effective antiangiogenic agents. Angiogenesis is a process regulated by a balance between pro- and antiangiogenic molecules, and the inhibition of pathological angiogenesis can be important in several diseases. Rapid advances were made in the field of angiogenesis over the past years, and, more importantly, a great attention has been given to angiogenesis as a therapeutic target. The application of this strategy in the treatment of several diseases, including cancer and chronic inflammatory disorders, has now become a reality. At the moment, there are a growing number of alkaloids obtained from plants that may have antiangiogenic properties, suggesting that these naturally occurring compounds may provide significant approaches in treatment or prevention of diseases where excessive angiogenesis is part of the pathology. It can be concluded that antiangiogenic activities can be derived from alkaloids obtained from plants; however, most of the studies using antiangiogenic alkaloids were focused on in vitro studies, and there is a need to carry out in vivo studies to establish their efficacy and evaluate their toxic potentials. Besides that, it is still necessary to continue the search for novel molecules for drug development.

Abstract

Effective prevention and/or treatment strategies for neurodegenerative and other brain disorders have, so far, not been successful. For example, a number of drugs are available for management of Alzheimer's disease; however, these agents

produce only transient palliative results that often come with a wide variety of untoward effects. Therefore, there is an urgent need for new therapeutic strategies with better efficacy and fewer side effects. Many plant origin compounds possess properties that can be useful in preventing or retarding neurodegenerative and other neurological diseases. One such compound is nicotine, which has astonishingly varied actions including inhibition of apoptosis and cell cycle progression, stimulation of neurogenesis, restoration of calcium homeostasis, reduction of metal ion overload in the brain, support of mitochondrial respiratory chain, and the possession of substantial anti-inflammatory and antioxidant effects. In this chapter, we summarize some of the published literature on the beneficial effects of nicotine and its potential for the treatment of cognitive deficits associated with selected neuropsychiatric and neurodegenerative disorders.

Keywords

ADHD • aging • Alzheimer’s disease • hypothyroidism • molecular deficit • parkinson’s disease • PTSD • schizophrenia • sleep deprivation • stress • synaptic plasticity

Abbreviations

5-OHDA	5-hydroxydopamine
6-OHDA	6-hydroxydopamine
Ach	Acetylcholine
ACI	Adenylyl cyclase I
AD	Alzheimer’s disease
ADHD	Attention deficit/hyperactivity disorder
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazole
AMPAR	α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors
APP	Amyloid precursor protein
Aβ	Amyloid-beta
BACE	Beta-site amyloid precursor protein [APP]-cleaving enzyme
BDNF	Brain-derived neurotrophic factor
CA	Cornu ammonis
CaMKIV	Calcium-calmodulin-dependent protein kinase IV
CRE	cAMP response element
CREB	cAMP-responsive element-binding protein C
CSF	Cerebrospinal fluid
DG	Dentate gyrus
DMTS	Delayed matching-to-sample
E-LTP	Early-phase LTP
ERK1/2	Extracellular signal-regulated kinase 1 and 2
fEPSP	Field excitatory postsynaptic potential
FGF-2	Fibroblast growth factor-2
GABA	γ-aminobutyric acid

HFS	High-frequency stimulation
icv	Intracerebroventricular
iNOS	Inducible nitric oxide
L-LTP	Late-phase LTP
LTD	Long-term depression
LTP	Long-term potentiation
MAPK	Mitogen-activated protein kinase
MHFS	Multiple train high-frequency stimulation
MLA	Methyllycaconitine
MWM	Morris water maze
nAChR	Nicotinic acetylcholine receptor
NFT	Neurofibrillary tangles
NGF	Nerve growth factor
NMDA	n-methyl-D-aspartate
NS-DA	Nigrostriatal dopaminergic
p-CaMKII	Phosphorylated-Ca^{2+}-calmodulin (Ca^{2+}-CaM)-dependent protein kinase II
PD	Parkinson's disease
PKC	Protein kinase C
PP1	Protein phosphatase 1
PTSD	Post-traumatic stress disorder
RAM	Radial arm maze
RAWM	Radial arm water maze
REM	Rapid eye movement
SUD	Substance use disorders
TM	Transmembrane
TrkB	Tyrosine-related kinase B

1 Introduction

Nicotine, the major alkaloid found in tobacco plant leaves and the prototypical nicotinic acetylcholine receptor (nAChR) agonist, is known to reduce memory impairment associated with chronic stress [1–3], aging [4–8], brain lesions [9], and cognitive disorders, including Alzheimer's disease (AD) [3, 10–14], schizophrenia [14], attention deficit/hyperactivity disorder (ADHD) [15, 16], Parkinson's disease [13, 17], post-traumatic stress disorder (PTSD) [18], sleep deprivation [19, 20], and hypothyroidism [21, 22]. Moreover, nicotine is a potent scavenger of hydroxyl and superoxide free radicals. In fact, it has been reported that nicotine is more of an antioxidant than vitamin C [23].

Craving for nicotine is, perhaps, a form of self-medication and may account for the higher proportion of smokers among people with mental disorders. Individuals with mental disorders have a higher smoking incidence (e.g., up to 60 % of PTSD sufferers; [24]) than the general population (25 %), and about 30 % of the total smokers in the United States suffer from some form of mental illness [25]. For example, up to 90 % of schizophrenic patients [26] and more than 90 % of alcoholics [27] are tobacco users.

The effects of nicotine in the brain basically mimic those of the endogenous neurotransmitter acetylcholine (ACh), which activates nAChR. Acetylcholine itself has a fascinating role as a neuromodulator in memory consolidation in the hippocampal formation [28]. The importance of ACh in cognitive function is indicated by the observation that this neurotransmitter increases significantly in the hippocampus of rats that have learned a memory task [29].

Nicotine produces a variety of effects in the brain by interaction with nAChR. The drug is believed to enhance cognitive function by activating presynaptic nAChR in crucial areas of the brain, facilitating the release of neurotransmitters including those implicated in learning and memory such as ACh, glutamate, dopamine, norepinephrine, γ-aminobutyric acid (GABA), and serotonin [30–34].

Structurally, nAChRs are comprised of homologous or heterologous combinations of five polypeptide subunits. Each subunit is composed of four transmembrane (TM 1–4) domains arranged around a central, water-filled pore. The extracellular N-terminal domain of each of the five subunits makes up the agonist binding site [35]. The pentameric nAChR, formed by various combinations of α and β subunits, is widely distributed in mammalian brain [36, 37]. Eight forms of the α subunit (α2–α10) and three forms of the β subunit (β2–β4) have been identified. The mechanism for the neuroprotective/trophic effects of nicotine is not known but seems to be multifaceted, as the reader will appreciate throughout this chapter.

The cationic selectivity of nAChR arises from the presence of three rings of negative charge, located along the inner pore of the channel. The nAChR belong to a family of ligand-gated ion channels that mediate fast synaptic transmission in the central nervous system (CNS). nAChRs can be classified into three major groups, based on their pharmacological and physiological properties: (a) the heteropentameric nAChRs (subunits α, β, δ, σ, and ε), which exist in endplates of skeletal muscles; (b) the standard neuronal nAChRs formed from α and β combinations; and (c) the homopentameric nAChRs, formed from α_7–α_9 subunits [38]. The hippocampus is highly enriched with a number of nAChR subtypes; however, based on electrophysiological and in situ hybridization studies, the $\alpha_4\beta_2$- and α_7-nAChR subtypes are the most abundantly expressed receptor subtypes in the hippocampus [39, 40]. Receptor subtypes formed with α4β2 subunit combination and those with α7 subunits have been implicated in learning and memory functions [37]. The α4β2 receptor is found in areas that bind nicotine with high affinity (e.g., the cortex, hippocampus, and interpeduncular nucleus [36, 41]). The α7 receptor is distributed in areas with high-affinity binding sites for α-bungarotoxin [42]. Most hippocampal neurons respond to nicotine with a current, characteristic of α7 nAChR [40] that desensitizes rapidly and is blocked by the antagonist methyllycaconitine (MLA) [43]. Outside the central nervous system, in autonomic ganglia, the α3β4 subtype is the most abundant nAChR, and even within the autonomic nervous system, there seems to be differences in the nAChR distribution. For example, the number of neurons containing α3, α4, α5, and α7 subunits in sympathetic ganglia is about three times higher than in parasympathetic ganglia. This may explain the differential effects of certain drugs on neurotransmission in sympathetic and parasympathetic ganglia.

1.1 Effect of Nicotine on Structure and Function of the Brain

Chronic nicotine treatment increases the number of [^{3}H]ACh binding sites in rat brain [44, 45] even though this treatment desensitizes nAChR. This seems paradoxical, but prolonged desensitization may result in an enhanced synthesis rate of nAChR or a reduction in its rate of internalization. However, the seemingly increased number of receptors, indicated by the increase in binding sites, may include a low proportion of functioning receptors [44, 46].

Nicotine has been shown to improve normal memory performance in clinical [16] and animal studies [47, 48]. Furthermore, in vitro electrophysiological studies in brain slices have shown that acute or chronic nicotine treatment facilitates the induction of long-term potentiation (LTP) in area CA1 by lowering its threshold of induction [49–51]. In general, nicotine promotes LTP induction by producing changes in the nAChRs of the hippocampus, which in turn alters local circuit interactions and lowers LTP threshold in the hippocampal area CA1. Later, however, the same group reports that nicotine enhances long-term depression (LTD) as well in area CA1 of hippocampal slices from young rats [52].

The effects of nicotine on memory and LTP are prevented by mecamylamine, a nonselective nAChR antagonist, suggesting that most likely nicotine induces its effects on memory and LTP by acting on nAChRs in the hippocampus [6, 51, 53–55].

Nicotine is known to have neuroprotective and neurotrophic effects as it delays ischemia-induced neuronal death in area CA1 of the hippocampus [56], and it also reverses the effects of proinflammatory cytokines on LTP [57]. Furthermore, nicotine reverses impairment of spatial memory and working memory induced by lesioning of the fimbria [9, 53], hypothyroidism, and chronic stress [2, 58], as well as sleep deprivation [19, 20]. Additionally, clinical and epidemiological studies suggest a neuroprotective/trophic effect of nicotine in AD and Parkinson’s disease [13]. In fact, earlier reports show that the incidence of AD is lower among tobacco smokers and that nicotine treatment improves cognitive function of AD patients [59–61]. Interestingly, chronic nicotine treatment improved working memory performance of young adult rats in the radial arm maze, whereas aged rats treated with the same dose showed no significant improvement [6]. Therefore, depending on the dose, stressor, and individual variation in reaction to the drug, nicotine can reduce or enhance stress-related effects [62].

The role of α_7-nAChRs in memory and LTP is controversial. While blocking α_7-nAChRs by the antagonist methyllycaconitine (MLA) impairs memory and blocks the effect of nicotine on memory in radial arm maze [63], MLA facilitates the induction of LTP in hippocampal slices [49]. The facilitation of LTP by MLA is supported by the finding that chronic nicotine treatment induces desensitization of α_7-nAChRs in GABAergic interneurons [64, 65]. The desensitization of α_7-nAChRs reduces the release of GABA from these interneurons, thus indirectly increasing pyramidal cell excitability [64, 65]. This, in turn, facilitates LTP induction by decreasing its threshold for induction [49, 50]. Thus, changing the dynamics of nAChRs activation and distribution influences the release of neurotransmitters and affects memory and activity-dependent synaptic plasticity. Furthermore, in addition to modulating the activity of neuronal circuits in hippocampal and cortical brain regions, nAChRs appear to be involved equally in neuronal survival. For example, β_2-nAChR knockout old mice exhibit neocortical hypertrophy, hippocampal neuron loss, and astrogliosis and microgliosis, which are correlated with impaired spatial learning [66].

Tobacco smokers indicate that smoking is a way to cope with stress; however, adolescent smokers reported a reduction of stress on smoking cessation [67]. Adolescent exposure to nicotine seems to have gender- and brain region-selective effects that differ substantially from those in adults. Chronic nicotine treatment uniformly produced a longer-lasting upregulation of nAChR in the brain of adolescent rats than in adult rats where receptor upregulation was differential with the highest being in the hippocampus [68].

Nicotine administration has also been reported to improve attention and enhance learning and memory in ADHD as well as schizophrenic patients [14]. These effects are most probably the result of reported enhanced dopamine release [69]. In this report, we reviewed the effect of nicotine on various brain disorders. The number of reports on the neuroprotective action of nicotine is vast; however, due to the restricted space we have, we are only able to cite a limited number of relevant articles.

2 Alzheimer's Disease

Dementia of the Alzheimer's type (AD) is a progressive neurodegenerative disease characterized by a gradual deterioration of memory and other cognitive functions, leading to total incapacity and death within few years after diagnosis [70]. The major pathological hallmarks of AD are marked neuronal loss and the presence of extracellular senile plaques and intracellular neurofibrillary tangles (NFT) in the brain [70].

Dysfunctional cholinergic mechanisms are common in dementia disorders, including AD [71, 72]. The brains of AD patients exhibit marked losses of α_7- and $\alpha_4\beta_2$-nAChRs [73–75] and of presynaptic terminals in neocortical and hippocampal regions that are correlated with progressive cognitive decline [76, 77]. Immunohistochemical, biochemical, and pharmacological data suggest that the high-affinity binding of $A\beta_{1-42}$ to α_7- and $\alpha_4\beta_2$-nAChRs plays a critical role in AD pathogenesis, e.g., formation of AD plaques and degeneration of cholinergic neurons [78, 79]. It is suggested that chronic stimulation of α_7-nAChRs by $A\beta_{1-42}$ facilitates (a) derangement of ERK1/2-MAPK signaling [80], (b) internalization and intracellular accumulation of $A\beta_{1-42}$ [81], (c) modulation of GABAergic signaling [64], and/or (d) excessive glutamate receptor stimulation [82]. Experiments using exogenous Aβ administration, transgenic mice, and gene-targeting mouse models demonstrate correlations between excessive Aβ accumulation, impaired nAChR function [75], and deficits in learning, memory, and LTP [e.g., 3, 83–87].

Numerous epidemiological studies have reported a highly significant negative correlation between cigarette smoking and AD [88; but see 89]. In laboratory and clinical studies, nicotine in cigarette smoke has been shown to improve cognitive function in AD patients [11, 88, 90] and also attenuate Aβ-induced amnesia in animal models [91, 92]. It is well known that chronic exposure to nicotine causes desensitization and upregulation of its receptors [68]. Although the mechanism by which nicotine achieves this is not well understood, several possible mechanisms have been proposed. In the following, we discuss the effects of nicotine on various aspects of AD pathology.

2.1 Effect of Nicotine on Learning and Memory in AD

Nicotine and its metabolites (e.g., cotinine) inhibit β-amyloidosis [93–95]. Several studies have suggested that chronic treatment with nicotine may delay the onset and/or progression of AD by slowing down cognitive decline [93]. Behavioral tests in rodents are consistent with these findings and support the notion that chronic nicotine treatment, if administered prior to Aβ-infusion, inhibits impairment of learning and memory in Aβ-infused animals [3, 86, 87; Fig. 47.1]. Under our experimental conditions, the performance of nicotine-treated animals in the RAWM was not significantly different from that of untreated control animals, which supports previous findings from this lab, indicating that the nicotine dose we used, although completely prevented Aβ and/or stress-induced cognitive decline, had no effect on memory in normal animals [1–3, 96]. This finding is in contrast to that of Levin et al. [14] who reported that the performance of nicotine-treated normal animals was enhanced in the radial arm maze (RAM). However, the improvement of normal spatial memory reported by Levin et al. [14] involved the use of high doses of nicotine (>5 mg/kg/day), whereas the dose used in our studies (2 mg/kg/day) resembles the concentration of nicotine in the blood of chronic smokers [97, 98].

2.2 Synaptic Plasticity: The Physiological Correlate of Learning and Memory

Although LTP has been demonstrated in many parts of the mammalian CNS, hippocampal LTP is the most studied form. Hippocampal LTP requires synaptic glutamate NMDA (n-methyl-ᴅ-aspartate) receptor activation to constitutively activate key protein kinases and/or phosphatases [99]. There are two mechanistically distinct phases of LTP: early-phase LTP (E-LTP; related to short-term memory) and

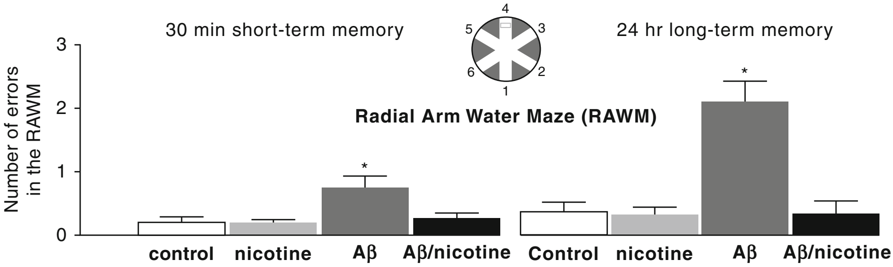

Fig. 47.1 Effect of nicotine on Aβ-induced deficits in spatial short-term memory and long-term memory performance in the RAWM. On days 6–8 of testing, chronic nicotine treatment (1 mg/kg s.c. twice/day for 6 weeks prior to and during Aβ infusion) prevented the Aβ-induced cognitive decline. All values are mean ± S.E.M. (n = 12 rats/group); $*p < 0.05$ compared to all groups

late-phase LTP (L-LTP; related to long-term memory). E-LTP is a transient, protein synthesis-independent phase, which requires constitutive activation of phosphorylated-Ca^{2+}-calmodulin (Ca^{2+}-CaM)-dependent protein kinase II (p-CaMKII) to phosphorylate and enhance the conductivity of postsynaptic glutamate α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPAR) [100–102], which in turn, initiates activation of glutamate NMDA receptors [99].

L-LTP is an enduring, protein synthesis-dependent phase, which requires (a) activation of CaMKIV and mitogen-activated protein kinase (MAPK) to phosphorylate cAMP-responsive element-binding protein (CREB) and (b) cAMP response element (CRE)-mediated transcription of target genes [103]. CRE-mediated gene transcription is absolutely necessary for synapse formation, neuronal survival (brain-derived neurotrophic factor, BDNF), and long-term memory formation [104]. For example, in AD brains, decreased CREB phosphorylation is correlated with decreased neuronal growth and survival, suggesting that Aβ acts through this transcription factor [105].

Altered synaptic plasticity is believed to be an early event that contributes to the cognitive deficits characteristic of AD [76, 106, 107]. Acute and chronic nicotine treatment has been shown to enhance LTP in rat and mouse DG in vivo [108]. The same group reported that co-application of nicotine with 500 nM Aβ prevented Aβ-induced deficits in LTP [108]. In anesthetized rat model of AD, in vivo recording of population spikes consistently showed severely suppressed E-LTP and L-LTP in hippocampal CA1. In contrast, Aβ animals chronically treated with nicotine showed alleviation of LTP impairment [3, 86, 87; Fig. 47.2].

Contrary to the majority of published reports, some labs reported that nicotine neither enhanced nor depressed HFS-induced LTP in normal animals [85, 109]. For example, Itoh et al. [109] found that in slices from Aβ-infused (300 ρmol/day $Aβ_{1-40}$, 11–12 days) rats, 50 μM of nicotine, perfused for 10 min, decreased population spike amplitude in area CA1 of control rats. Similarly, studies by Freir et al. [85] found that coinjection of 3 mg/kg nicotine with 1 or 10 nmol $Aβ_{1-40}$, 1 h prior to HFS, significantly depressed LTP, measured 1 h post-tetanus, more than $Aβ_{1-40}$ alone.

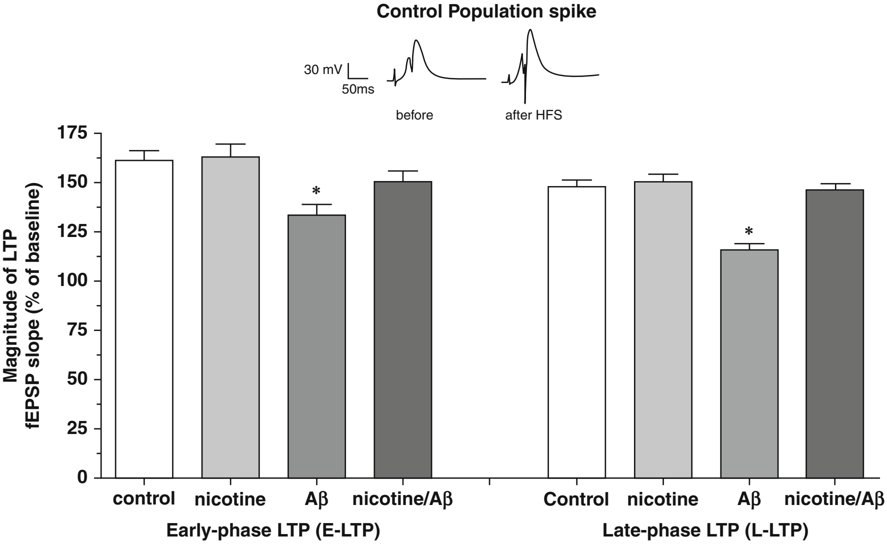

Fig. 47.2 Nicotine prevents Aβ-induced deficits in E-LTP and L-LTP. LTP of the hippocampal area CA1 evoked by repetitive stimulation of the Schaffer collaterals/commissural pathway, measured as increases in the slope of fEPSP. Each bar is mean ± S.E.M. from six anesthetized rats. * indicates significant difference from other groups ($p < 0.05$). Insets are representative pspikes from a normal rat before and after stimulation

2.3 Molecular Deficits in AD and the Beneficial Effect of Nicotine

The molecular processes underlying the expression of LTP in the hippocampus involves a cadre of signaling molecules that are believed to model the consolidation of information storage by this brain region. These signaling molecules play a pivotal role in synaptic plasticity and the processes of learning and memory. Calcineurin and CaMKII play integral roles in converting the initial entry of Ca^{2+} through the NMDA receptor channel, into persistent changes in synaptic activity. Gene-targeting experiments and transgenic animal studies have consistently demonstrated impairment of learning, memory, and hippocampal LTP following altered gene expression of selected protein molecules [110]. In AD, progressive accumulation of Aβ peptides in the brain impairs spatial learning and LTP in area CA1 of the hippocampus. Experiments suggest that Aβ impairs memory and disrupts LTP by perturbing the balance between protein kinase and protein phosphatase activity. Findings from this lab strongly suggest that Aβ interferes with the process of phosphorylation of kinases, downregulates nAChR but increases the levels of the phosphatase calcineurin [3, 86, 87; Table 47.1]. The levels of neurotrophic factors, including BDNF, are initially increased in specific brain regions in response to various types of insults, including AD, ischemia, seizure, traumatic brain injury, and neurotoxins. Consistent with its neuroprotective effects on learning and memory and synaptic plasticity, nicotine shows striking effects in normalizing the levels

Table 47.1 Basal levels of signaling molecules. Summary of the effects of nicotine on the basal levels of signaling molecules in area CA1 of the hippocampus compared to the control. ⇓ significantly decreased; ⇑ significantly increased; ⇔ no change (similar to control)

of the signaling molecules in Aβ-infused animals. The drug even reduced the levels of Aβ in these animals [3, 86, 87; Table 47.1].

2.4 Possible Mechanisms of Neuroprotective Effect of Nicotine

It has been suggested that nicotine and cotinine delay or inhibit β-amyloidosis by nonspecifically binding to Aβ and preventing an α-helix to β-sheet conformational conversion [93, 95]. It is postulated that nicotine binds to histidine residues (His6 and His13) on the α-helix [95], or to small, soluble β-sheet aggregates [94] and increases the average separation between Aβ monomers in solution, thus delaying the onset of aggregation [94, 111]. Similarly, studies using nornicotine, a nicotine metabolite, demonstrated that nornicotine-based covalent glycation of lysine-16 on the Aβ peptide occluded the Aβ polymerization domain and thus, delayed formation of the oligomeric β-sheet structure [95]. It is unclear whether nicotine-mediated inhibition of Aβ deposition, aggregation, and/or β-amyloidosis is due to altered processing (toward a non-amyloidogenic Aβ sequence), decreased synthesis, or increased clearance of Aβ peptides. However, a recent study found that chronic nicotine treatment (1 mg/kg/day and 8 mg/kg/day) reduced rat CSF levels of APPγ, which contains the amyloidogenic Aβ fragment, without significantly altering total soluble APP levels [74]. This suggests that nicotine exerts its effects, in part, by altering the processing of APP away from an amyloidogenic route, toward increased production of APP-carboxyl-terminally truncated forms, which do not contain the pathogenic $A\beta_{1-40}$ and/or $A\beta_{1-42}$ fragments.

Furthermore, whereas no single mechanism for nicotine-mediated protection has been determined, studies have shown that nicotine increases the levels of neuronal growth factors [112, 113], decreases the levels of nitric oxide generated in response to neuronal injury [114], and inhibits glutamate-evoked arachidonic acid release from cultured striatal neurons [115]. These and other possible mechanisms are discussed in the following sections:

Overload of metal ions: It has been reported that Aβ interacts with metal ions as indicated by the presence of copper and zinc in the senile plaques of AD brains [116] a finding that implicates these ions in the process of deposition of Aβ and formation of the plaques [117–120]. Nicotine significantly lowered the copper and zinc concentration in senile plaques and in hippocampal area CA1 in the brains of transgenic mice model of AD [121]. The effect of nicotine on metal homeostasis seems to be independent of nAChR activation [121].

Prevention of apoptosis: Shrinking of brain tissue in AD is due to cell death (apoptosis), which may be caused by combination of factors including increased intracellular calcium, oxidative stress and inflammation [122–127]. The caspases are enzymes essential for many cellular functions including growth and development and are crucial in apoptosis for which they have been termed "executioner" proteins. In cultured hippocampal neurons, nicotine effectively inhibited Aβ-induced caspase activity and apoptosis. This protective effect of nicotine is antagonized by mecamylamine indicating the involvement of nAChR.

Mitochondrial dysfunction: Mitochondrial dysfunction in AD is believed to be a major contributing factor that causes Aβ deposition, formation of NFTs and synaptic degeneration [128]. A number of studies have shown impaired mitochondrial dynamics and biogenesis in brains from AD patients, AD mouse models, and APP cell lines [129–131].

It has been suggested that nicotine maintains the intra-mitochondrial redox state and decreases the electron leak at the site of respiratory chain complex I [132, 133]. Therefore, the beneficial effects of nicotine in AD may be related in part, to its supportive actions on mitochondrial function [133].

Nitric oxide (NO) production: Emerging evidence suggests a role for NO in neurodegenerative diseases indicated by the increased expression of the enzymes that catalyze NO synthesis in brain tissue of patients with these disorders [134].

Nicotine treatment decreases the production of NO by downregulating the activity and expression of inducible iNOS in the cortex and hippocampus of APP(V717I) transgenic mice, a model for AD [135]. It is suggested that nicotine, by upregulating and activating α7nAChR, downregulates nitric oxide synthase (iNOS) activity and consequently the production of NO, by preventing activation of NF-κB and c-Myc through inhibition of the activation of MAP kinases (MAPKs). Support for this finding is obtained by the fact that nicotine markedly decreased the expressions of p65 and p50 subunits of NF-κB in the cortex and hippocampus of mice [135]. Incidentally, chronic nicotine treatment of AD rat model prevented Aβ-induced reduction of α7nAChR and impairment of learning and short-term memory [3].

Oxidative stress: Another important aspect of AD, which bespeaks the complexity of this disease, is oxidative stress. Oxidative stress is among the early events in the pathogeny of the disease and has been implicated in the synaptic dysfunction and neuronal loss in AD [136–139]. Moreover, it has been reported that nicotine is a potent antioxidant that can act as a scavenger of hydroxyl and superoxide free radical [23]. Therefore, a possible mechanism for the neuroprotective effect of nicotine in neurodegenerative diseases is its considerable antioxidant effects that may prevent oxidative stress.

Decreased Aβ production: Nicotine treatment effectively lowers the levels of amyloidogenic Aβ in the brains of rodent models of AD [3, 23, 140, 141]. In Aβ-infused rats, chronic nicotine treatment normalized the elevated levels of Aβ and that of BACE, the enzyme responsible for its production [3]. The same report shows that nicotine markedly upregulates the protein levels of α7- and α4β2-nAChR [3], which may suggest the involvement of these receptors in the ability of nicotine to curtail the production of pathogenic Aβ peptides.

In brains of APPs transgenic mice, which show substantial brain Aβ deposits, chronic nicotine treatment produces a significant (80 %) reduction in Aβ 1–42 positive plaques [140]. The same group later reports that the decrease in Aβ peptides is not accompanied by changes in brain α, β, or γ secretase-like activities, NGF (nerve growth factor) or BDNF protein expression [141].

3 Parkinson's Disease (PD)

Parkinson's disease is a debilitating progressive neurodegenerative disorder, which is characterized by a selective loss/damage of dopaminergic neurons that project from the substantia nigra to the caudate nucleus and putamen causing profound dopamine depletion in the striatum [142]. Although the precise cause of this cellular destruction in PD remains unclear yet, several suspected causal mechanisms have been proposed such as; apoptosis, depletion of ATP production by disruption of mitochondrial respiratory chain by endogenous neurotoxins or xenobiotics and production of oxidative stress caused by excessive free radical generation or disruption of antioxidant systems [143–145]. Actually, damage to dopaminergic neurons is proposed to occur through oxidative stress and/or mitochondrial impairment causing activation of an apoptotic, presumably p53-dependent cascade; some neurons experiencing energy failure may not be able to complete apoptosis and end up in necrosis and inflammation [146]. While oxidative stress seems an attractive target, whether it is a causal factor in PD etiology or an outcome of a secondary phenomenon remains to be sorted out. Nicotine has received much attention in the context of this disease primarily due to the fact that smoking, which is considered as a risk factor for most cardiovascular and other diseases, has been identified unexpectedly as a negative risk factor for PD [147]. In fact, since initial epidemiological findings in the early 1960s, several other studies have reported reduced occurrence of PD in smokers [148, 149]. This inverse relationship was revealed from studies that have shown that cigarette smokers are 50 % less likely to develop PD than appropriately matched nonsmoking counterparts [147]. The apparent neuroprotection against PD is reduced with smoking cessation and occurs with different types of tobacco products [148, 149] suggesting that the decline in PD with smoking is a true biological effect. Nicotine, the primary pharmacologically active compound in tobacco, is considered to be responsible for this protective effect. Furthermore, nicotine patches and gum have been reported to relieve some symptoms of PD [13]. Several studies have tested whether nicotine directly improves motor symptoms in PD. Although the etiology of PD is unknown, the symptoms are caused by a loss of dopamine-producing neurons in the pars compacta of the substantia nigra and in the ventral tegmental area of the midbrain. Administration of nicotine to rodents stimulates presynaptic release of dopamine, resulting in activation of dopaminergic receptor postsynaptically [150, 151]. Since nicotine modulates dopamine release from striatum [152], enhanced synaptic dopamine levels could ameliorate motor deficits that arise because of a nigrostriatal dopaminergic deficiency in PD. There is evidence for both in favor and against its role [153–156]. Moreover, works on different PD animal models indicate that nicotine exposure improves dopaminergic markers and function in lesioned striatum, the brain region predominantly affected in PD [144, 157–159]. Additionally, nicotine administration is reported to reduce side effects of L-dopa, the primary treatment for PD [160]. Several mechanisms responsible for the protective effects of smoking on PD have been proposed. The notion of involvement of central nAChR is popular [143, 161], and there is multiple preclinical evidence to support that nicotine is neuroprotective via its action on these receptors [143], but it must be noted that not all of nicotine's effects are receptor mediated [143], and thus neuroprotection via receptors may be partly responsible for the neuroprotective action. Involvement of monoamine oxidase and nitric oxide synthase also has been suggested [143]. The hypothesis that smoking reduces the risk of PD by increasing activity of the ubiquitin–proteasome system, thereby preventing damage associated with aberrant activity of this system, also has received some attention. The idea of nicotine-mediated neuroprotection has led to many hypotheses including that of antiapoptotic effects, regulation of intracellular calcium levels, and release of growth factors like fibroblast growth factor-2 [143, 161]. Whether one, some, or all of these mechanisms act together to afford neuroprotection remains unknown and studies examining the neuroprotective effects of nicotine remain controversial.

Some in vivo studies have reported antioxidant and protective role of nicotine [162, 163], while others have reported a pro-oxidant and deleterious effect [164, 165]. Other studies suggest nicotine might play dual effects: high doses induce neurotoxicity and stimulate oxidative stress, while low concentrations act as an antioxidant and may be neuroprotective. Furthermore, administration of nicotine is reported to reduce, enhance, or can even be ineffective on nigrostriatal degeneration in animal models of PD [162, 166, 167]. Thus, nicotine-independent mechanisms in the protective effects of smoking against PD have not been ruled out [168]. Exactly how nicotine might exert its antioxidant protective effect in PD is unclear. But a consensus is developing regarding its mechanism of action within the framework of oxidative stress. Linert et al. [169] proposed that nicotine may have antioxidant properties due to its Fe^{2+}-binding property and its ability to reduce transferrin-mediated Fe uptake and chelate Fe^{2+} to block the Fenton reaction [170]. Actually, increased levels of Fe accumulate within the substantia nigra of PD brains, which could be a cause of degeneration of nigrostriatal dopaminergic (NS-DA) neurons, a characteristic of PD. It is well known that most NS-DA neurons contain neuromelanin deposits, which bind excessive Fe in PD and increase the vulnerability of NS-DA neurons to degeneration in PD [171]. One mechanism via which nicotine might exert its protective effect on NS-DA neurons involving the above reactions could be its ability to form complexes with Fe(II), perhaps via the pyridine nitrogen although pyrrolidine nitrogen might also be involved. Consistent with this hypothesis, many studies have reported that nicotine inhibits thromboxane synthase enzyme by directly binding to the iron ions of this enzyme [172] and that nicotine reduces transferrin-mediated Fe uptake by reticulocytes and placental cells [173]. Thus, the proposition that nicotine may be protective against PD through complex formation with Fe(II), thus yielding Fenton-inactive Fe(II) and less oxidative stress, seems more convincing. The chemistry involving the reactions of dopamine, 5-hydroxydopamine (5-OHDA), and 6-hydroxydopamine (6-OHDA), with molecular oxygen, with and without the addition of catalytic amounts of iron (Ill) and other metal ions, and the implication of these reactions with respect to the progression of PD have been described. Basically 6-hydroxydopamine (6-OHDA) which is a neurotoxin present in both human brain [174] and urine of PD patients [175] is formed from the oxidation of DA in the presence of free (solvated) Fe(II) ions and H_2O_2 (i.e., Fenton's reagent). In normal brains, most of the Fe is stored as ferritin (Fenton-inactive). However, it has been shown that 6-OHDA is able to free Fe(II) from storage in ferritin [176], thus facilitating the Fenton reaction, which in turn leads to further production of 6-OHDA. Thus, under physiological conditions, 6-OHDA is oxidized by molecular oxygen to give hydrogen peroxide (H_2O_2) and the corresponding *p*-quinone. The *p*-quinone then undergoes a cascade of oxidative reactions, which finally results in the formation of an insoluble polymeric pigment related to neuromelanin [176, 177]. Evidently, the H_2O_2 resulting from the autoxidation of 6-OHDA may generate hydroxyl radicals (-OH) through a metal-catalyzed Fenton-type reaction. Although the precise molecular mechanism of neurotoxicity of 6-OHDA remains uncertain, its neurotoxicity is often related to the oxidative stress caused by the production of (OH) during its autoxidation [178–182]. Furthermore, the stereotaxic injection of 6-OHDA into the medial forebrain bundle or substantia nigra has been long used to produce animal models of PD [183]. Linert and colleagues [169] proposed that in NS-DA neurons, this cycle is continuous, forming strongly oxidizing radicals, which destroy cellular components. However, it has also been reported that 6-OHDA can act directly by inhibiting the mitochondrial respiratory chain at the level of complex I [184, 185]. The antioxidant properties of nicotine may be intracellular through the activation of the nicotinic receptors or extracellular by acting as a radical scavenger in that it binds to iron. The possibility that nicotine might be used to treat some symptoms of certain neurodegenerative diseases underlies the necessity to determine whether nicotine has pro-oxidant, antioxidant, or properties of both.

4 Attention Deficit/Hyperactivity Disorder (ADHD)

Nicotinic systems are vital for cognitive functions, hence, nicotinic system-based therapeutic interventions may be useful for the treatment of a variety of cognitive disorders including attention deficit hyperactivity disorder (ADHD). Although

ADHD is generally regarded as a genetic disorder, environmental and psychosocial factors may aggravate the symptoms but are not considered to be underlying causes of ADHD [186]. The core symptoms are difficulty concentrating, hyperactivity, and impulsivity [187] with prevalence of the disease estimated to be 5–10 % in children and adolescents and 4.4 % in adults. Interestingly, it is reported to be more common in boys than girls [186]. Some observations critical to the present discussion are provided. It has been repeatedly observed that people suffering from ADHD are more likely to become regular smokers [188], begin smoking earlier, become habitual smokers [189], and experience greater quitting difficulty [190] compared to normal subjects. Unexpectedly, it has been noted that cigarette smoking is more common in children [191] and adults with ADHD compared to the general population and/or controls [188]. Moreover, ADHD is not only associated with earlier onset of cigarette smoking [191] but has more severe nicotine dependence [192]. In fact, children with ADHD are at high risk to develop substance use disorders (SUD) in their adolescence and adulthood [193]. Nicotine, consciously or otherwise used as self-medication [194], has been suggested to function as a gateway drug [195, 196]. Actually, prevalence rates for SUD in adolescent and adult ADHD patients range from 30 % to 50 % [197]. This is made even more convincing considering the Minnesota Twin sample study, showing the association between ADHD symptoms in childhood and SUD even when controlled for comorbid disorders [198]. These links however are quite controversial [199] with some researchers suggesting that stimulant treatment induces an increase of SUD [200] while others suggesting a reduced risk of SUD [193]. Moreover, adult ADHD, with a 4.4 % prevalence rate [192], recognizable by inattention, impulsivity, and hyperactivity is associated with poor performance in all spheres of life and also is associated with higher rates of other psychiatric and SUD comorbidity [201]. While adult ADHD is one of the most common mental health disorders of adulthood [202], treatment strategies remain limited [203]. Nicotine has been found to be effective in tackling some of the ADHD symptoms [204], and in fact, several nicotine-like agents are currently being considered as ADHD treatments. It is now generally accepted that nicotine attenuates inattentiveness and improves focus [205, 206]. Recently, in an interesting report, Berlin et al. [207] have highlighted the fact that the core symptoms of ADHD (inattention, hyperactivity, and impulsiveness) are clinically similar to nicotine withdrawal symptoms including lack of focus and restlessness. Some investigators have suggested that perhaps nicotine reduces ADHD-associated deficits in dopaminergic function [208] suggesting a “self-medication” rationale for greater nicotine use among ADHD patients [209]. Little or no mechanistic insights are available to provide a biological basis for such observations.

One interesting concept is the role of oxidative stress in the pathophysiology as well as the association between nicotine and ADHD. Oxidative stress is reported to play an important role in the pathogenesis of many psychiatric disorders. Changes in the oxidant and antioxidant indices have been reported to contribute to autism, developmental disorders, and ADHD [210]. Some investigators have reported a significantly low level of oxidative stress markers in children with ADHD [210, 211], and others have seen low antioxidant levels in children with ADHD [212]. Adult ADHD patients are reported to present with increased levels of oxidative stress and decreased antioxidant activity [213, 214]. More recently, lower level of oxidative stress was detected in ADHD group. The authors of this study suggest that perhaps decreased oxidant level is associated with the hypodopaminergic activity state in ADHD. This is based upon the fact that lower levels of dopamine and noradrenaline have been reported in the cerebrospinal fluid, blood, and urine in ADHD patients [215]. It is believed that the degradation products of these neurotransmitters are important for ADHD etiology. Relevant to this, decreased dopamine secretion in the prefrontal cortex and decreased dopamine turnover and vesicular storage in the substantia nigra, ventral tegmental area, and frontal cortex have been reported in an animal model of ADHD [216]. Additionally, an abnormally active dopamine transporter, which could have increased the reuptake of dopamine and thus depletion of dopamine in the synaptic cleft, has been speculated. Perhaps the antioxidant characteristic of nicotine facilitates the metabolism and excretion of free oxygen radicals and hence exerts a protective effect in ADHD.

4.1 Sleep Deprivation

The National Sleep Foundation reports that 64 % of American adults get less than the 8 h of sleep that experts recommend is required to maintain optimal physical and mental health. One-third of the US population says they get less sleep now than they did 5 years ago. One-half of Americans have experienced insomnia (sleeplessness). Drowsiness due to a lack of a proper night sleep interferes with the daily activities of 37 % of all adults. Due to these pressing demands of modern society, more and more people are tending toward self-medication. While smoking is considered the most important behavioral health risk, its use for coping with anxiety and depression, and increasing focus and alertness is popular. Nicotine, by acting on various neurotransmitter systems, is purported to influence sleep and mood. However, the data regarding a *pro*- or an *antisleep* action of nicotine in both animals and humans is far from being in conformity.

For example, increase in sleep latency, sleep fragmentation and decreased slow-wave sleep with reduced sleep efficiency and increased daytime sleepiness are observed during nicotine consumption. Nicotine-induced rapid eye movement (REM) sleep suppression is also known. Some researchers have not detected any effect of nicotine on sleep [217]. In contrast, when administered intravenously [218], subcutaneously [219], or into the medial pontine reticular formation [220], nicotine is reported to increase REM sleep in cats. Moreover, some human studies employing transdermal nicotine report a decreased total sleep time, sleep efficiency, and REM sleep and an increase in wakefulness [221, 222]. On the other hand, depressive nonsmokers experience a mood improvement under nicotine administration comparable to the effect of antidepressants. Actually, transdermal nicotine patch improves mood in nonsmoking depressed patients. Animal studies using rodent models of depression also have shown that nicotine has antidepressant properties [223–225]. It has been proposed that the improvement in symptoms of depression by nicotine affects sleep architecture and is related to sleep deprivation, especially the deprivation of REM sleep [226]. The inconsistency in findings arguing for a pro- or antisleep role of nicotine is largely a result of different methodologies used, absence of appropriate controls, comorbidity status in human studies, and other criteria.

Clearly, a more unified approach is needed for a better understanding of the role of nicotine in sleep. Simply branding nicotine as a rogue substance and dismissing it on ethical grounds may not be productive. We will have to consider whether it is more important to avoid the severe consequences of debilitating diseases or to fear nicotine dependence. In the absence of other effective therapies for these debilitating diseases, nicotine ought to be taken seriously. Despite its promise, developing nicotine as a treatment is fraught with pitfalls. Regardless of a controversial role of nicotine in this regard, some very interesting data have emerged. For example, during sleep deprivation, the frequency of nicotine consumption is increased among smokers [227]. Nicotine is reported to alleviate impairment of memory associated with psychosocial stress [1, 228], aging [229], hypothyroidism [21, 230], and Alzheimer's disease [12, 231]. In the hippocampus, nicotine facilitates the induction of LTP in the CA1 region of rat hippocampal slices [3, 12] and induces long lasting potentiation in intact mouse dentate gyrus region [232]. In addition, nicotine treatment prevents impairment of hippocampal LTP associated with psychosocial stress [228], hypothyroidism [230], aging [233], as well as other mental diseases. Thus, the reported increase in nicotine consumption among smokers and the initiation of smoking among nonsmokers during sleep deprivation [227, 234] could be a form of self-medication to offset impairment of cognition and synaptic plasticity. Minimal mechanistic insights are currently available regarding the biological underpinnings of these observations. As far as the beneficial effect of nicotine on sleep deprivation is concerned, we suggest a hypothesis that centers on the long debated antioxidant role of nicotine. Recently we and others have reported that SD causes increased oxidative stress in the brain [235], and it also is known that nicotine has antioxidant characteristics. Thus, it is reasonable to suggest that antidepressant-like effects of nicotine perhaps are due to its oxidative stress quenching property.

4.2 Stress

Normal structure and function of the brain are altered by severe and/or long-term stress [reviewed in 236]. The hippocampus is among the brain's regions most vulnerable to stress-related adverse changes [reviewed in 237]. Stress negatively impacts hippocampal neuronal excitability, neurochemistry, and structural and functional plasticity [236, 238]. This has been demonstrated in both animal models [1, 228, 238–240] and in humans [241], where learning and memory are impaired during chronic stress. In addition, memory impairment induced by hypothyroidism [239] and in animal models of Alzheimer's disease [86, 87], is exacerbated during chronic stress conditions. Long-term potentiation (LTP), a cellular correlate for learning and memory in the CA1 area of the hippocampus, is significantly suppressed by chronic stress in adult anesthetized rats [1, 2, 86, 242–246] and freely moving animals [247]. Similar findings have been reported in hippocampal slices from stressed animals [e.g., 248]. At the molecular level, the protein signaling molecules important for memory and LTP including phosphorylated CaMKII [86, 244, 245] and BDNF [245] are reduced during stress.

Nicotine has been shown to attenuate chronic stress-induced impairment of short-term memory [1], and LTP [2, 245], and facilitation of long-term depression (LTD) [96, 249] in area CA1 of the hippocampus in adult anesthetized rats. Thus, the increase in tobacco smoking rate during stress may be a self-medication to counteract the harmful effect of stress on memory [250, 251].

The precise molecular mechanism by which chronic nicotine treatment prevents the effects of stress on memory and synaptic plasticity is not clearly understood. It is known that stress and/or stress hormones downregulate nAChRs [252–254] and that this effect is prevented by treatment with chronic nicotine [254]. This suggests that nicotine is, perhaps, acting through nAChRs to prevent stress-induced impairment of memory. Support for this proposal comes from the finding that the effects of nicotine on memory are prevented by mecamylamine, a nonselective nicotinic receptor antagonist [see 255 for review].

Chronic stress impairs the hippocampus-dependent spatial memory and blocks LTP in area CA1 of the hippocampus possibly by interfering with the function of key signaling molecules involved in memory and LTP including reduction of phosphorylated CaMKII [P-CaMKII], PKCγ, and calmodulin and increase in calcineurin levels [Table 47.2; 244, 245]. These changes are prevented by chronic nicotine treatment during stress [245]. Another important signaling molecule that is markedly impacted by stress is BDNF. The expression of BDNF mRNA [256–258] and protein levels [245, 259] is decreased after stress. Chronic nicotine treatment restores the protein levels of BDNF in CA1 area of the hippocampus of chronically stressed animals [245].

The presence of chronic psychosocial stress in Aβ-infusion rat model of AD induces impairment of short-term and long-term memory that is more severe than either stress or AD alone [86, 260, 261]. This also correlates with more intense suppression of hippocampal CA1 E-LTP and L-LTP by the combination than either condition alone [86, 87, 260]. Chronic nicotine treatment prevents the effects of the combination of these two conditions on memory and LTP [87, 260, 261]. Furthermore, the magnitude of LTD of area CA1 of the hippocampus is higher in the chronically stressed Aβ animals compared to animals with either condition alone [87, 260]. Here again, chronic nicotine administration prevented the effect of the combination of stress and Aβ on LTD and restored the synaptic signal to a magnitude comparable to that of control animals [87, 260].

Table 47.2 Basal levels of signaling molecules. Summary of the effects of nicotine and/or stress on the basal levels of P-CaMKII, CaMKII, BDNF, calmodulin, PKCγ, and calcineurin in CA1 area of the hippocampus. "Decrease/increase"; significantly different from control, "*No change*"; not significantly different from control

Basal levels of signaling molecules in CA1		Stress	Nicotine	Nic/Sts
P-CaMKII (total homogenate)		*Decrease*	*No change*	*No change*
CaMKII (total homogenate)		*Decrease*	*No change*	*No change*
P-CaMKII/CaMKII ratio		*Decrease*	*No change*	*No change*
BDNF (total homogenate)		*Decrease*	*Increase*	*No change*
Calmodulin	Homogenate	*Decrease*	*No change*	*No change*
	membranous	*Decrease*	*No change*	*No change*
	Cytosolic	*No change*	*No change*	*No change*
PKCγ	Homogenate	*Decrease*	*No change*	*No change*
	Membranous	*Decrease*	*No change*	*No change*
	Cytosolic	*No change*	*No change*	*No change*
Calcineurin (total homogenate)		*Increase*	*No change*	*No change*

To elucidate potential mechanisms by which stress exacerbated Aβ-induced impairment of cognitive abilities and synaptic plasticity, the levels of signaling molecules important for these processes have been evaluated. Results show that combination of chronic stress and Aβ reduced the basal levels of P-CaMKII and P-CREB in area CA1 of the hippocampus, more markedly than either condition alone [86, 87, 261]. Chronic nicotine treatment, on the other hand, completely prevents the effect of the combination on P-CaMKII and P-CREB levels [87, 261]. The combination of chronic stress and Aβ also elevates the basal levels of calcineurin in area CA1 of the hippocampus [86, 87, 260]. This elevation is also prevented by chronic nicotine treatment [87, 260]. Combination of chronic stress and Aβ suppresses the expected E-LTP-induced increase in CaMKII phosphorylation and L-LTP-induced increase in CREB phosphorylation and CaMKIV protein expression in area CA1 [86, 87]. These E-LTP- and L-LTP-induced expression of signaling molecules are restored by chronic nicotine treatment [87]. Furthermore, chronic stress has been shown to intensify the increase in protein levels of Aβ and beta-site amyloid precursor protein [APP]-cleaving enzyme [BACE] in area CA1 of Aβ-treated rat. This elevation is normalized by chronic nicotine treatment [262]. Additionally, the levels of the α7, β4, and β2 subunits of nAChRs are significantly decreased in Aβ rats, but these are also normalized in Aβ rats chronically treated with nicotine.

4.3 Hypothyroidism

Hypothyroidism causes a wide range of central nervous system [CNS] dysfunctions, including impairment of cognition [21, 230, 239] and synaptic plasticity in adult onset [21, 22, 229, 230, 243, 246, 263–266] as well as in developmental hypothyroidism [267–270]. In addition, hypothyroidism reduces the basal levels and activity of P-CaMKII and blocks HFS-induced P-CaMKII activation in the CA1 area of the hippocampus, which may, at least partially, explain hypothyroidism-induced impairment of LTP [22, 265]. Hypothyroidism also reduces the basal levels of signaling molecules upstream of CaMKII such as PKCγ, calmodulin, and neurogranin and increases the protein levels and activity of calcineurin in the CA1 area of the hippocampus [22, 265].

Chronic nicotine treatment reverses hypothyroidism-induced impairment of hippocampal learning and short-term memory [21]. It also prevents hypothyroidism-induced impairment of E-LTP and facilitation of LTD in area CA1 [21, 22]. At the molecular level, nicotine normalizes the reduction of basal activity of CaMKII and levels of P-CaMKII in area CA1 [22]. One hour after the induction of E-LTP in CA1, the failure of HFS to increase the levels of P-CaMKII in hypothyroidism is reversed by chronic nicotine pretreatment, suggesting that nicotine by restoring the ability of HFS to activate CaMKII and by normalizing the basal activity and levels of CaMKII reverses hypothyroidism-induced LTP impairment [22]. In addition, chronic nicotine treatment prevents hypothyroidism-induced reduction in protein levels of molecules upstream to CaMKII such as PKCγ, neurogranin, and calmodulin [22].

Calcineurin reduces postsynaptic activity [271], blocks LTP [272], induces and maintains LTD [273], and impairs hippocampus-dependent memory formation in mice [274]. It indirectly activates protein phosphatase 1 (PP1) by inactivating its natural inhibitor "inhibitor 1" [275], thus enabling PP1 to dephosphorylate many molecules including P-CaMKII [271, 276]. During hypothyroidism, calcineurin activity and basal protein levels are increased in CA1 area of the hippocampus [1, 229, 265]. This increase is normalized in nicotine treated hypothyroid rats [22]. It is likely that the increase in the activity and levels of calcineurin in hypothyroid rats may account for the reduced CaMKII activity and consequent impairment of short-term memory and LTP. By normalizing activity and levels of calcineurin in hypothyroid rats, nicotine may have prevented impairment of LTP during hypothyroidism.

Chronic nicotine treatment has been shown to reverse adult-onset hypothyroidism-induced impairment of long-term memory and late-phase long-term potentiation (L-LTP) in area CA1 [21, 263]. In the same area, chronic nicotine treatment of hypothyroid rats prevents the reduction in the basal protein levels of signaling molecules important for long-term memory such as adenylyl cyclase I (ACI), mitogen-activated protein kinases (MAPKp44/42 "ERK1/2"), calcium-calmodulin-dependent protein kinase IV (CaMKIV), and cyclic-AMP response element-binding protein (CREB; phosphorylated (P-) and total) [263]. The expected marked elevation in the levels of P-CREB, P-MAPKp44, P-MAPKp42, and BDNF is not seen in hypothyroid animals after multiple train high-frequency stimulation (MHFS); however, in nicotine-treated hypothyroid, the expected elevation of these molecules is similar to that seen in control animals after MHFS [263]. These findings suggest that prevention of impairment of basal level of CaMKIV, MAPKp44/42, and CREB by nicotine along with the regained ability of MHFS to induce MAPKp44/42 and CREB phosphorylation in nicotine-treated hypothyroid animals may be responsible for the reversal of long-term memory and L-LTP impairment by chronic nicotine treatment during hypothyroidism [263].

Owing to their diversity and multiple combinations, NMDA receptor subunits are differentially regulated in LTP or LTD. Evidence for that comes from pharmacological blockade of certain subunit-containing receptors indicating that selective blockade of the NR2B subunit-containing NMDA receptors abolishes LTD, but not LTP [277, 278]. On the other hand, LTP is impaired, while LTD stays intact when NR2A subunit-containing NMDA receptors are preferentially blocked [277–280]. Recently, it has been shown that NR2B subunit-containing NMDA receptors function by putting an inhibitory restrain on NR2A subunit-containing receptor via activation of calcineurin [280], thus enhancing LTD. Moreover, increased protein levels of NR2B subunit-containing receptor in the membranes of neurons of area CA1 of the hippocampus in hypothyroid rats have been reported [58]. This is accompanied by increased calcineurin activity and facilitated LTD in hypothyroid rats [58]. Therefore, the increase in the levels of NR2B-containing NMDA receptors may be responsible for the enhanced LTD observed in area CA1 of hypothyroid rats. However, in chronic nicotine-treated hypothyroid rats, these increase in the levels of NR2B-containing NMDA receptors, and calcineurin do not take place, which may explain occurrence of normal LTD in these animals [58].

Functional NMDA receptors contain at least one NR1 subunit [281–286]. It has been shown that NR1 transcript [287] and protein [58] levels are reduced in the hippocampus of adult hypothyroid rats. This reduction in the basal protein levels of NR1 in area CA1 is normal in chronic nicotine-treated hypothyroid rats [58]. Chronic nicotine treatment has also been shown to increase NMDA receptor binding sites in area CA1 of the hippocampus [288]. Additionally, nicotine reduces NMDA-induced toxicity in hippocampal cell cultures and slices [289, 290], by increasing calcium buffering capacity in the cells [291]. BDNF, which is increased by nicotine treatment [58], induces NMDA receptor subunit NR1 activation [phosphorylation] in an ERK and PKC-dependent mechanism in rat neuronal tissues and in cell culture [292–296]. It has been suggested that BDNF-induced tyrosine phosphorylation of the AMPA receptor subunit GlutR1 is regulated through NMDA receptor subunits [293]. In addition, BDNF enhances the magnitude of NMDA-mediated synaptic currents [297, 298], an effect that occurs through TrKB receptors [298]. BDNF also restores declining peak amplitude of NMDA-evoked currents in cultured hippocampal pyramidal neurons in a cAMP-dependent manner [299]. Recently, it has been shown that maximal neuroprotection for neuron is achieved by convergence of both NMDA receptor pathway and TrKB pathways to activate MAPKp44/42 [300, 301]. To that end, it has been shown that nicotine, which increases BDNF, normalizes reduction in MAPKp44/42 activation and restores changes in active NMDA receptor subunits induced by hypothyroidism [58]. Thus, nicotine seems to provide maximum neuroprotection for hippocampal neurons, which helps in restoring cognitive impairment during hypothyroidism.

4.4 Aging

Aging is often viewed as a progressive decline in physiological competence with a corresponding inability to adapt to stressful stimuli [302]. Aged animals have increased morbidity and mortality during prolonged exposure to stressful stimuli [302]. The aging process is associated with memory impairment [303, 304], which is alleviated by nicotine treatment [305]. Results from a double-blinded, placebo-controlled, crossover study show that 4-weeks transdermal nicotine patch usage (dose range 3–10 mg/day) in older subjects results in a sustained improvement of age-associated memory impairment measured as improved clinical symptoms and objective scores of computerized tests of attention [8]. In aged monkeys of both sexes, pretreatment with low doses of nicotine improves performance in the delayed matching-to-sample (DMTS) test [306, 307]. Subcutaneous administration of nicotine (0.1 or 0.4 mg/kg) significantly improves accuracy of performance in aged rats on a delayed nonmatching to position paradigm in a T-maze [308]. Additionally, nicotine pretreatment (15 min prior to testing) improves the acquisition and/or memory retention of aged rats in one-way active avoidance pole jumping over 12 days of testing [4, 309]. Moreover, in Lashley III maze training, aged animals are reported to make more alteration errors compared to adult controls, but these errors are prevented by prior nicotine administration in aged animals [4, 309]. In the 17-arm radial maze, both reference and working memories are reported to be impaired in aging. Acute nicotine pre-administration corrects reference, but not working memory performance in aged animals [4, 309]. In agreement, similar experiments in the eight-arm radial maze reveal that chronic nicotine administration (approximately 5 mg/kg per day using osmotic minipump for 4 weeks) does not improve working memory in aged rats. In the Morris water maze (MWM), it has been shown that nicotine administration 3 days prior to the onset of testing and 15 min prior to daily testing improved memory performance in aged rats [5, 310]. However, in the MWM, acute nicotine administration (15 min prior to testing) shows no beneficial effects on reference memory in aged Fischer 344 Rats [311]. Additionally, acute challenge with the nicotinic receptor antagonist, mecamylamine (subcutaneous 0.04–0.16 mg/kg), does not further impair working memory in aged rats [6]. The resistance of aged rats to nicotine-induced working memory improvements and mecamylamine-induced working memory deficits may be the result of the decline in hippocampal cholinergic functions seen in aging [312]. However, using a 5-choice discrimination paradigm, designed to test spatial working memory, Taylor et al. [313] report that chronic nicotine administration (subcutaneous 0.3 or 0.7 mg/kg daily for 5 weeks) improves working memory performance, whereas mecamylamine (subcutaneous 2–8 mg/kg) reverses this impairment in a dose-dependent manner [313]. Another report show that chronic nicotine treatment (0.1 or 0.7 mg/kg daily for 4 weeks in osmotic minipump) improves both working and reference memory in aged rats [314]. The discrepancies in the reported findings concerning the effect nicotine on working memory results may be related to differences in memory testing paradigm, animal strain, route and method for nicotine administration, and doses of both nicotine and mecamylamine.

Interestingly, in aged animals, LTP induction becomes rather difficult. In fact, age-associated decline in LTP induction becomes apparent with minimal stimulation protocol [315, 316], but not with high-frequency tetanic stimulation [315, 317, 318]. Acute nicotine treatment reduces the threshold for LTP induction in hippocampal slices from aged rats. The α7nAChR antagonist methyllycaconitine mimics the effect of nicotine, whereas the non-α7nAChR antagonist dihydro-β-erythroidine blocks nicotine's effect on LTP induction [233]. These results suggest that both nicotine-mediated desensitization of α7nAChRs and activation of non-α 7nAChRs contribute to the effect of nicotine on LTP during aging. The non-α 7nAChR agonist, A85380, facilitates LTP induction in the hippocampus in adult animals; however, it has no effect on LTP in aged animals [233]. This suggests at least one pathway involving non-α7nAChRs is altered during the aging process.

The exact mechanism for the neuroprotective effect of nicotine on aging-induced memory impairment is unknown. Acute nicotine protective effect on memory in aging is reversed by NMDA receptor antagonists or by nicotine antagonist, mecamylamine [310, 319], indicating the involvement of both nAChR and NMDA receptor systems in the effect of nicotine during aging. Additionally, chronic nicotine administration (subcutaneous 0.45 mg/kg twice daily for 4 weeks) prevents aging-induced reduction in the hippocampal protein levels of NR2A and NR2B NMDA receptor subunits [320]. It has also been suggested that nicotine-induced upregulation of fibroblast growth factor-2 (FGF-2) and nerve growth factor (NGF) proteins in several brain areas of rat including the hippocampus [314, 321] may be, at least in part, involved in the neuroprotective effect of nicotine during aging.

4.5 Schizophrenia

The rate of smoking among schizophrenia patients is much higher than the general population [322–324], and smoking withdrawal is associated with worsening of schizophrenia symptoms [325]. Several lines of evidence indicate the possibility of self-medication with nicotine against the disease's symptoms and/or adverse effects of antipsychotic drugs used in schizophrenia [326, 327]. The schizophrenia-induced impairment in visuospatial working memory and attention worsens in schizophrenics with overnight abstinence from smoking [328–330] but is enhanced to pre-quitting levels on smoking reinstatement [328]. Enhancement of visuospatial working memory and attention by smoking reinstatement is blocked by mecamylamine treatment [328], indicating the involvement of nicotine and nAChRs in the effects of smoking on cognitive functions in schizophrenia. However, smoking cessation for 7 days among schizophrenia patients is associated only with slowed motor speed but has no effect on attention, verbal learning and memory, working memory, or executive function [331].

Administration of nicotine nasal spray, although does not affect noncognitive symptoms of schizophrenia, it improves performance on a spatial organization task and working memory and attention, but not verbal memory among smoker schizophrenic patients [332, 333]. Acute nicotine administration also improves smooth pursuit eye movements and visual attention among schizophrenia patients [334] and enhances delayed recognition memory in schizophrenic patients who smoke, but similar performance enhancement is not observed for working memory or for patient who do not smoke [335]. In another study among smoker schizophrenic patients, who are switched from smoking to either nicotine patch or placebo, nicotine improves verbal working memory and selective attention by enhancing activation of and functional connectivity between brain areas that mediate task performance [336]. Similarly, nicotine gum is reported to improve antisaccade tasks performance, which reflects cognitive and neurological functions among schizophrenic patients [337]. Moreover, among nonsmoker schizophrenia patients, nicotine patch application for 4 h results in improved novelty detection and episodic memory [338]. In rat models of cognitive impairment of schizophrenia, nicotine improves working memory span [339]. Therefore, nicotine seems to correct most cognitive aspects among schizophrenia patients.

The α7nAChRs are known to be deficient in brain areas, especially, the hippocampus of patients with schizophrenia [340, 341]. The deficit in α7nAChR is likely to be related to defective sensory gating mechanism often seen among schizophrenics [342, 343]. This defect in the sensory gating mechanism is normalized by cigarette smoking among schizophrenia patients [344]. Acute nicotine can normalize temporal aspects of sensory memory processing in patients with schizophrenia, an effect that may be mediated by activation of α7nAChRs, the function of which is diminished in schizophrenia [345]. Studies in schizophrenia monkey model of memory impairment have shown clear beneficial effects of nAChR agonists [346], especially, the α4β2 and α7nAChRs agonists [347–349].

5 Concluding Remarks

Although nicotine is commonly associated with the stigma of addiction, emerging evidence argues for a potentially "good side" of this often maligned substance. For example, nicotine and nicotine-like compounds have been proposed as treatments for AD, PD, ADHD, and other neuropsychiatric conditions. It has been reported that smokers have a lower risk of developing AD, PD, and ADHD and that schizophrenic patients seemingly relieve the symptoms of their disorder with smoking. These observations however raise serious ethical issues. Obviously pure nicotine is a potentially toxic substance and, as part of tobacco smoke, is a major risk factor for heart and lung disease, but at the same time, it also begs the question of how nicotine can be managed to utilize its therapeutic potential.

The commonly known major psychological effects of nicotine include raising alertness, enhancing attention and information processing while providing a sense of relaxation and calmness of thought. Thus, for someone who is agitated (as in ADHD or schizophrenia), this calming effect might seem therapeutic. For someone who is lethargic and unfocussed (PD or AD), it might serve to increase alertness and focus and sharpness of thought. The fact that the majority of individuals with mental disorders use tobacco products is interesting. Whether this is coincidental or a biologically relevant phenomenon is a debatable issue, and thus causality is assumed but unproven. Relevant to this, nicotine is also known to have antidepressant-like effects in both rats and humans. The reasons behind these observations remain unknown and the scientific relevance unclear, but new research aimed at understanding the biochemical basis for these key observations has provided some persuasive clues into the biological underpinnings of the beneficial effects of nicotine on some of these conditions. Surprisingly, very few studies have examined the effects of nicotine on the CNS with regard to oxidative stress or its role as an antioxidant. This seems even more surprising considering the proposition of using nicotine as a future drug for certain neurodegenerative diseases and some cognitive disorders.

Abstract

Plants of the *Aconitum* genus have a long-lasting history of use both for their biological and toxicological properties. Most of *Aconitum* plants used in traditional medicine are being extensively explored and their chemical constituents and pharmacological effects are being evaluated.

This chapter summarizes the results of the most recent research works on the pharmacological and toxicological characteristics of alkaloids from various *Aconitum* species and highlights the analgesic, antiarrhythmic, and anticancer effects, attributed to various diterpenoid alkaloids. Diester diterpenoid alkaloids have been characterized as the most toxic compounds because of the presence of acetyl and benzoyl esters in the structures. Their capacity to bind to the sodium channels and activate permanent influx of Na^+ ions through cell membranes was

1 Introduction

Plants of *Aconitum* genus, known by various names such as aconite, monkshood, wolf's bane, women's bane, Devil's helmet, or blue rocket, have been used since antique civilizations in Ayurvedic, Chinese, Tibetan, and Greco-Roman medicines for their diverse pharmacological effects [1, 2]. Due to their extreme toxic nature, they have been widely used to eliminate wild animals or enemies and for criminal intents, and have attracted the particular interest of physicians, chemists, and legacy representatives from ancient world to modern times [3, 4]. During Greco-Roman civilization, *Aconitum* species underwent special restrictions to their growth, storage, and use under death penalty [5]. They are still an object of exhaustive investigation in the field of Forensic Sciences [6–8]. Nevertheless, the *Aconitum* species are widely used in Asian traditional medicine; they remain one of the most intriguing genera of plants both for their toxic and curative properties, and the interest to their pharmacological and toxicological characteristics is continuously growing. Their therapeutic potentials originating from traditional medicine are being extensively studied: multiple data on the analgesic and anti-inflammatory activity, the effect on the central nervous system, the arrhythmogenic and antiarrhythmic, antiparasite and anticancer properties of molecules from various *Aconitum* species are continuously reported.

In this chapter, we will overview the pharmacological properties and the therapeutic action and toxicity profile of compounds derived from the different *Aconitum* species in order to determine promising areas for therapeutic applications.

2 Occurrence and Chemical Classification

Plants of the *Aconitum* genus originate from the Northern hemisphere: they grow in the temperate mountainous areas of Europe, Asia, and North American continents. The *Aconitum* genus belongs to the family *Ranunculaceae*; the most known species are *A. napellus, A. lycoctonum* growing in Europe [9, 10], *A. carmichaelii* characteristic for Asian countries [11], *A. ferox* endemic to Himalaya, and *A. columbianum* growing in North America [12]. Presently, the *Aconitum* genus includes over 350 species and varieties [13], and more than 600 molecules isolated from *Aconitum* genus have been characterized [14].

Aconitum species are generally herbaceous perennial plants, with a tall leafy stem (70–130 cm) bearing violet, blue, or yellow (rarely white, rose, or bicolor) zygomorphous flowers in the form of a cylindrical helmet on long, packed racemes. The colors of the flowers and their intensity can vary from pale to deep, depending on the species or intraspecies varieties. The underground part of the plant is represented by tubers, whose size and form depend on the species, or by fibrous roots (*A. lycoctonum*).

The principal group of chemical compounds present in *Aconitum* species consists of diterpenoid alkaloids, detected in all parts of the plant. The maximal accumulation of alkaloids is observed in tubers. Other chemical substances found in plant are flavonol and kaempferol glycosides detected in aerial parts [15–17], polysaccharides, organic acids, etc. [18].

The alkaloids of *Aconitum* genus are divided into three categories: C_{20}, C_{19}, and C_{18} -diterpenoid alkaloids.

C_{20}-diterpenoid alkaloids are classified into four groups according to Wang et al. [19]:

1. The atisane class of alkaloids is based on the pentacyclic atidane **1** skeleton. Atisine **2** is an example of this class.
2. The kauran class of alkaloids consists of four 6-atom rings and one 5-atom ring D. The typical representative of this class is veatchine **3**.
3. The class of rearranged alkaloids, which possess four 6-atom and three 5-atom rings, is considered as rearranged product of hetisine. Delnudine **4** is an example of these type of alkaloids.
4. Bis-diterpenoid alkaloids, which are rare products of dimerization of two diterpene alkaloids.

Delnudine **4**

The C_{19} diterpenoid group comprises the most toxic alkaloids and can be classified into four groups on the basis of their structural variations [20]:

1. The Aconitine type, where the carbon at position 7 of the skeleton does not possess a hydroxyl function: this group is represented by aconitine **5**, condelphine, and delphinine.
2. The Lycoctonine **6** type, where the carbon at position 7 of the diterpene skeleton is hydroxylated.
3. The Heteratisine type, where a δ-lactone moiety is present in the ring C, for example, heteratisine **7**.
4. The Pyroaconitine type, where a double bond is present between the C_{18} and the C_{15} positions, for example, falaconitine **8**.

The C_{18}-diterpenoid alkaloid group is represented by lappaconitine **9** or ranaconitine, which are derivatives of C_{19}-alkaloids devoid of the benzoyl moiety at position 14 [21].

3 Pharmacological Activities

Preparations from *Aconitum* plants have been used in traditional Chinese medicine as cardiotonics, febrifuges, sedatives, and antirheumatics [22]. They have also been used in traditional medicine of some ex-USSR countries for the treatment of cancer, rheumatism, etc. [18, 23]. *Aconitum* plants were introduced in the medicine of European countries in the nineteenth century. Leaves and roots of *Aconitum* and aconitine powder were included in the British Pharmaceutical Codex (01911) [24], *French Pharmacopoeia* (9th edition) [25], and *USSR Pharmacopoeia* (8th edition) [26] and were applied to relieve neuralgic pain, especially in the face, to allay the pain of sciatica and acute rheumatism. Because of extreme toxicity, aconitine was replaced later by less-toxic anti-inflammatory and analgesic agents in European countries; presently, the use of *Aconitum* plants is limited to the homeopathic medicine [27, 28]. On the contrary, in many Asiatic countries, aconitine-containing plants still remain one of the most popular remedies, and more and more new, naturally occurring or semisynthetic molecules from *Aconitum* species are introduced in medical use. For example, lappaconitine found in several *Aconitum* species, bulleyaconitine isolated from *A. bulleyanum*, and crassicauline A isolated from *A. crassicaule* were introduced in the official Chinese medicine for the treatment of chronic pain, rheumatoid arthritis, and for local anesthesia [29, 30].

3.1 Analgesic and Anesthetic Activities

Various species of *Aconitum* are reported to possess analgesic and anesthetic activities. During the last 30 years, numerous diterpenoid alkaloids originating from plants and used in traditional medicine for the treatment of pain, rheumatisms, and neuralgia have been explored by a number of international groups of researchers for analgesic, anesthetic activities, arrhythmogenic–antiarrhythmic properties, and toxicological characteristics [31–35]. The analgesic activity of substances derived from *Aconitum* is evaluated on the basis of their capacity to relieve the pain produced by chemicals (formalin, acetic acid, and bradykinin), or by acting on thermoreceptors (tail-flick or hot plate test) or on mechanoreceptors in mouse models after s.c., p.o., or i.v. administration of alkaloids. The anesthetic activity of aconitum alkaloids is generally evaluated on mice models by the capacity of alkaloids to block the sensitivity of sciatic nerves [34, 35]. Simultaneously, they are studied for toxicological properties on animals in order to compare their therapeutic versus toxic potentials. The comparative data on analgesic, anesthetic activities and efficacy/toxicity ratios of various aconitum alkaloids obtained from different sources are given in Table 48.1. The therapeutic indices of alkaloids are calculated from the LD_{50} (lethal dose for 50% of animals tested) and ED_{50} (the dose inducing 50% of the pharmacological effect) values, determined by the same route of administration on experimental animals.

Comparing the anti-nociceptive activity of various compounds allows to conclude that there are two groups of *Aconitum* alkaloids exhibiting strong and moderate analgesic effects.

The first group includes aconitine-like diester alkaloids having strong analgesic activity: aconitine, hypaconitine, mesaconitine, 3-acetylaconitine, bulleyaconitine, and yunaconitine. The anti-nociceptive ED_{50} values of these alkaloids are within 0.028–0.097 mg kg^{-1} by i.v. and 0.025–0.14 mg kg^{-1} by s.c. route. The analgesic effect of these substances is about 10–50 times more important than that of morphine in suppressing formalin-induced or tail-flick nociceptive behavior [32]. The opioid receptor antagonist levallorphan does not interfere with the pharmacological effect of mesaconitine. The same results are obtained in experiments attempted to antagonize the effect of 3-acetylaconitine by naloxone. Moreover, in contrast to morphine, daily administration of 3-acetylaconitine in mice neither induced tolerance, nor physical dependence after a sudden withdrawal. These results prompted to suppose, that the anti-nociceptive activity of aconitine-like alkaloids is not mediated by stimulation of opioid receptors [33].

The second group includes less-toxic alkaloids with moderate analgesic effect. One of them, lappaconitine, is a well-studied compound already used in practical medicine, with analgesic ED_{50} of 2.7 mg kg^{-1} (i.v.). It is generally assumed that lappaconitine and its deacetylated analogue have lower toxicity than aconitine and, therefore, can be safely used as analgesic or anesthetic agents. However, the comparison of their analgesic and toxic properties has shown that even lappaconitine is about 40 times less toxic; its LD_{50}/ED_{50} ratio does not differ from that of aconitine, which characterizes it as an unfavorable drug candidate.

Table 48.1 The analgesic and anesthetic activities of *Aconitum* alkaloids

	Anti-nociceptive effect ED_{50} (mg kg^{-1})	LD_{50}/ED_{50} (analgesic effect) ratio	Local anesthetic effect ED_{50} (mg kg^{-1})	LD_{50}/ED_{50} (anesthetic effect) ratio	References

6-Benzoyl-heteratisine	i.v. 2.0	1.58	–		[31]
Songorine	i.v. 46.4	2.284	–		[31]
Napelline	i.v. 68.1	>2.158	–		[31]
1-Benzoyl-napelline	i.v. 21.5	2.158			[31]

All data in table were obtained in experiments with mice.
The routes of administration of substances were i.v.-intravenous and s.c.-subcutaneous.
The same route of administration was used for calculation of LD_{50}/EC_{50} (analgesic effect) values.

After evaluation of the analgesic versus toxic potential of some *Aconitum* alkaloids, Gutser et al. [32] have arranged the therapeutic indices (LD_{50}/ED_{30}) of molecules in the following order: aconitine (6.0)>hypaconitine (2.4)> 3-acetylaconitine (2.0) and lappaconitine (2.0). They reported that, because of their high toxicity, these alkaloids cannot be considered as effective anti-nociceptive agents. Friese et al. [31] and Ameri [33] have reached the same conclusions, emphasizing that the therapeutic indices of *Aconitum* alkaloids remain quite low, which characterizes them as unfavorable to become effective analgesic agents.

More recent studies on new *Aconitum* alkaloids allowed to identify a range of molecules possessing analgesic activity on different pain models [34–36]. Among them, four alkaloids, bulleyaconitine, *N*-deacetyllappaconitine, yunaconitine, and

8-*O*-cinnamoylneoline, may be selected as favorable candidates having better therapeutic indices of anti-nociceptive effect with LD_{50}/ED_{50} ratios of 18.8, 15.83, 9.25, and 13.8 respectively.

Evaluation of anesthetic versus toxic properties of diester diterpenoid alkaloids revealed that they possess good anesthetic potential and high therapeutic indices, with LD_{50}/ED_{50} ratios of 510 for 3-acetylaconitine, 479 for *N*-deacetyllappaconitine, 303 for bulleyaconitine, 292 for lappaconitine, and 274 for *N*-deacetylranaconitine.

The less-toxic groups of C_{19}- and C_{20}-diterpenoid alkaloids have been reported to possess no analgesic activity [31, 33].

3.2 Anti-inflammatory Activity

The anti-inflammatory activity of diterpenoid alkaloids has been determined experimentally on various inflammation models: acetic acid–induced edema, carrageenan-induced hind-paw edema, etc. Both mesaconitine and 3-acetylaconitine have been shown to inhibit the increased vascular permeability induced by acetic acid in the mouse peritoneal cavity and by histamine in rat intradermal sites. They were both reported to exert anti-inflammatory action in sham-operated mice as well as adrenalectomized mice, confirming that the anti-inflammatory effect was not mediated via stimulation of the hypophysis-adrenal system. Mesaconitine did not interfere with prostaglandin biosynthesis in either guinea-pig lung homogenate, or rat peritoneal-activated macrophages, thus excluding the hypothesis about similarity of their mechanism of action with that of nonsteroidal anti-inflammatory agents. It prevents hind-paw edema induced by injection of carrageenin, or by subplantar injection of histamine, serotonine, or prostaglandine, indicating that it is effective at an early, exudative stage of inflammation [33]. However, diterpenoid alkaloids are less effective than nonsteroidal anti-inflammatory drugs. For example, aconitine is 400–500 times less active than phenylbutazone, and the efficacy of 3-acetylaconitine is reported to be 50–100-fold less than that of indomethacin and 1,000–2,000-fold less than that of salicylic acid [37].

3.3 Arrhythmogenic–Antiarrhythmic Activity

The most toxic alkaloids of aconite, such as aconitine, mesaconitine, hypaconitine, etc., are known to possess arrhythmogenic effect. Aconitine itself has long been used to induce arrhythmia in experimental models [38, 39]. Aconitine and its structural analogues induce ventricular ectopics, ventricular tachycardia, torsades de pointes, and ventricular fibrillation in a dose-dependent manner. Aconitine has a positive inotropic effect on the heart. It has hypotensive and bradycardic actions [40]. Another group of diterpenoid alkaloids possessing C_{18} and C_{19} skeleton, such as lappaconitine, *N*-deacetyllappaconitine, heteratisine, and 6-benzoylheteratisine, are

Table 48.2 Antiarrhythmic activity of alkaloids from plants of *Aconitum* genus

	ED_{50} (mg kg^{-1})	LD_{50}/ED_{50}
Lappaconitine	i.v. 0.05	118
N-deacetyllappaconitine	i.v. 0.05	146
Ranaconitine	i.v. 0.05	124
6-Benzoylheteratisine	i.v. 0.035	142.9

known to exert antiarrhythmic action on the heart muscle. Lappaconitine is a well-studied compound in China and ex-USSR countries, introduced into medical use as an antiarrhythmic agent [41–43].

The data on the antiarrhythmic effect of some alkaloids isolated from various *Aconitum* species are presented in Table 48.2 [41].

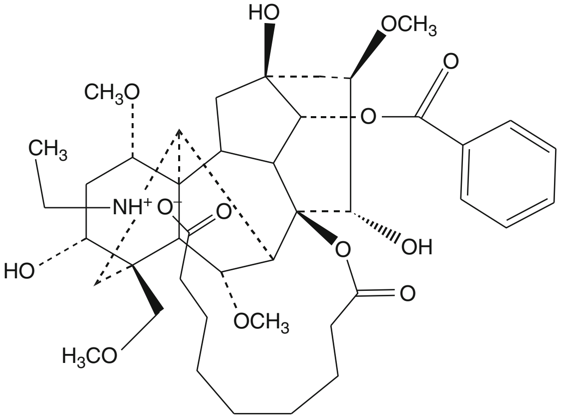
Experimental studies of the effect of lappaconitine and *N*-deacetyllappaconitine on guinea-pig-isolated atria have shown that these substances exert an antiarrhythmic effect on ouabain- and aconitine-induced arrhythmia in a dose-dependent manner. These substances decrease the contractile force of atria, increase excitation threshold, cause bradycardia at low doses (0.2 and 0.06 μM respectively), and can provoke asystolia of right atria at higher doses (4.5 and 10 μM respectively) [44]. 6-benzoylheteratisine, the main alkaloid of *A. tanguticum*, incubated with guinea-pig-isolated atria, exerts a negative inotropic effect on left atria and reduces the contractile force to about 50% at 0.6 μM, elevates the excitation threshold and causes bradycardia at the dose of 1 μM. It reduces significantly the maximum rate of action potential rise as well as the action potential amplitude of guinea-pig papillary muscle. Preincubation of atria with 6-benzoylheteratisine suppresses arrhythmia induced by aconitine, ouabain, and veratridine at a dose 0.06 μM [45]. It can be concluded that 6-benzoylheteratisine is a naturally occurring class-I antiarrhythmic substance. On the basis of the information that *A. tanguticum* has been used in Chinese and Tibetan folk medicine as a poison antidote, it can be inferred that the antidote effect might be at least due to antiarrhythmic property of 6-benzoylheteratisine, which antagonizes with the arrhythmogenic action of aconitine, ouabain, and veratridine.

3.4 Anticancer Activity

In spite of various and detailed studies of *Aconitum* alkaloids, very little information is available on their antitumor activity. De Ines et al. [46] have screened 43 C_{19}-diterpenoid alkaloids on CT26 (murine colon adenocarcinoma), SW480 (human colon adenocarcinoma), HeLa (human cervical adenocarcinoma), SK-MEL-25 and SK-MEL-28 (human melanomas), and on the non-tumor cell line CHO (Chinese hamster ovary cells). Several compounds (neoline, 8-*O*-methylcolumbianine, 18-*O*-demethylpubescenine, lycoctonine, acetylajadine, etc.) exhibit a selective cytotoxic effect to cancer versus non-cancer cells. Dasyukevich and Solyanik [47] have studied the anticancer activity of an *Aconitum* extract on in vivo experimental models using mice with ascites and solid form of Erlich's carcinoma. The product tested has no effect on the ascites form of tumor, but has shown substantial growth inhibition effect on the solid form of Erlich's carcinoma with 77.3% decrease of the tumor size compared to control. Hazawa et al. [48–50] reported that semisynthetic derivatives of C_{20}-norditerpenoid alkaloids, 11-veratroylpseudokobustine, 11-(*m*-trifluoromethylbenzoyl)kobustine, 11-(*m*-trifluoromethyl-benzoyl) pseudokobustine, and 11,15-dianisoylpseudokobustine, exhibited cytotoxic activity against A172, A549, HeLa, and Raji cell lines. Certain *Aconitum* alkaloids have been screened for anticancer activity at the Developmental Therapeutic Program of National Cancer Institute, NIH, USA.

Ajaconine, aconine hydrochloride, dehydroheteratisine, and heteratisine have been tested on the P388 leukemia model and isoatisine on the L1210 leukemia model in mice. Atisine has been studied on a yeast anticancer drug screen. Aconitine, jaconine, 8-*O*-ethylaconine, 8-*O*-ethyl-14-benzoylaconine, and delphinine have been screened on the panel of 60 human tumor cell lines. Among these, only two compounds exhibited cytotoxic activity: 8-*O*-ethyl-14-benzoylaconine was active against 786–0 (human renal cancer) with IC_{50} of 7.9 μM and delphinine was moderately cytotoxic on SK-OV-3 (ovarian cancer) with IC_{50} of 39.8 μM [51–53].

Aconitum karakolicum is widely used in traditional medicine against cancer in Kyrgyzstan. In order to explore its anticancer activity, we undertook a project aimed to isolate alkaloids from this plant and tested them on human tumor cell lines. Extraction and purification of alkaloids guided by in vitro cytotoxicity assay has resulted in the isolation of the compound 8-*O*-Azeloyl-14-benzoylaconine **10**. It is active against three human tumor cell lines with IC_{50} of 16.8 μM on HCT15 (colon cancer), 19.4 μM on A549 (lung cancer), and 10.3 μM on MCF7 (breast cancer). The comparison of IC_{50} values of this molecule with that of some clinically used anticancer drugs has shown that it is more active than melphalan (Table 48.3) [54].



8-*O*-Azeloyl-14-benzoylaconine **10**

Further, the naturally occurring 8-*O*-azeloyl-14-benzoylaconine was used as a basis for the design and hemisynthesis of new structural analogues [55]. A series of mono- and bifunctional acyl compounds, centered around the 8-*O*-azeloyl-14-benzoylaconine scaffold and differing by the length of the acyl chain, were synthesized and evaluated against three human tumor cell lines: A-549 (lung cancer), MCF-7 (breast cancer), and HCT-15 (colon cancer). Among bis-[*O*-(14-benzoylaconine-8-yl)]esters, only three molecules linked by azelaic, suberic, and pimelic acids presented a noticeable in vitro cytotoxic activity (IC_{50} ranging from 4 to 28 μM) (Table 48.4). The length of the linker chain in the structure seems to be important; a compound having a suberic acid moiety between two benzoylaconine skeletons was the most active, while shortening or lengthening of the diacid chain decreased the activity of compound.

The most active compound, bis-[*O*-(14-benzoylaconine-8-yl)-suberate **11**, was selected for further in vivo studies with breast cancer (MCF-7) and colon cancer (HCT-15) cells. It was evaluated for anticancer activity in immunodeficient mice xenografted subcutaneously with human tumor cells, at the dose of 10 mg kg^{-1} injected i.v.

bis[-O-(14-benzoyl-8-yl)]-suberate **11**

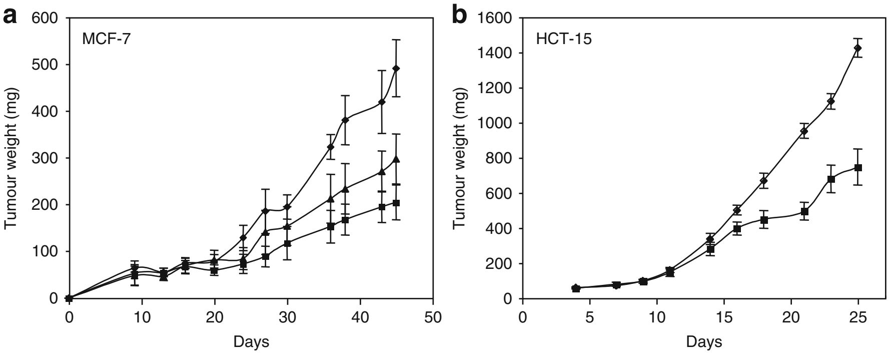

Fig. 48.1 In vivo antitumor activity of bis[*O*-(14-benzoylaconine-8-yl)]suberate on MCF-7 (**a**) and HCT-15 (**b**) tumor models grown in immunodeficient NOG mice. Two schedules were used for MCF-7 tumors

Antitumor activity was clearly detected at the dose of 10 mg/kg, a dose largely below the maximum tolerated dose (15 mg/kg). For MCF-7 cells, administration of five doses every 4 days, as well as weekly administration of four doses, resulted in T/C percent values of 36% ($p = 0.001$) and 56% ($p = 0.02$) on day 45, respectively (Fig. 48.1a). For HCT-15 cells, administration of five doses every 3 days resulted in 49% tumor regression on the 25th day (Fig. 48.1b, $p = 0.00001$).

3.5 Other Biological Activities

Lappaconitine has been shown to possess antiepileptic activity on rat hippocampal slices [56].

Gonzalez et al. have reported that three molecules of the C_{20}-diterpenoid alkaloid group: 15,22-*O*-diacetyl-19-oxo-dihydroatisine, azitine, and isoazitine exerted antiparasitic activity on promastigotes and intracellular amastigotes of *Leishmania infantum* [57, 58].

4 Mechanism of Action

The mechanism of action of aconitine-like alkaloids has been studied by many researchers [31, 33, 44] on synaptosomes of rat cerebral cortex and on guinea-pig-isolated atria. It was established that aconitine and its structural analogues have strong affinity to the voltage-gated Na^+ channels at epitope 2. Their binding to the open sodium channel provokes activation of this channel and permanent influx of Na^+ ions through the cell membrane, which finally results in prolonged depolarization of neurons and inhibition of neuronal conductivity. Consequently, the intracellular concentration of Ca^{2+} increases, resulting in transient enhancement of the contractile force of isolated atria. This mechanism underlying analgesic, local anesthetic, and arrhythmogenic properties is also responsible for the extreme toxicity of diester alkaloids. The arrhythmogenic action of aconitine is in part due to its anticholinergic effect, mediated by vagus nerve. Through binding to the axonal Na^+ channel site, aconitine inhibits also neuromuscular transmission by decreasing the release of acetylcholine [40].

The quantitative structure-activity relationship analysis has established a strong correlation between the toxicity and analgesic activity ($r = 0.96$), toxicity and local anesthetic activity ($r = 0.71$) of aconitine and its analogues [35]. These results are in line with the conclusions made by various authors [31–33]. It is obvious that the local anesthetic activity of these alkaloids is conditioned by a direct action on the receptors in the administration site. However, the mode of their anti-nociceptive action and the details of signal-ascending and/or signal-descending mechanisms participating in the pain-inhibition process are being explored. Ameri [33] hypothesizes that aconitine-like alkaloids are centrally acting analgesic agents. It was established that they do not interact with opioid receptors, which allows to suspect that they use a pain-suppressing pathway different from that of narcotic opioid analgesics [58]. Various experimentations on pain models using α- and β-adrenoreceptor agonists and antagonists together with aconitine-like alkaloids helped to determine that the anti-nociceptive effect of *Aconitum* alkaloids is potentiated by β-adrenoreceptor agonists, and on the contrary, inhibited by antagonists. Moreover, the mesaconitine-induced anti-nociception is potentiated by 3′,5′-cyclic monophosphate and phosphodiesterase inhibitors [59]. It was reported that the analgesic effect of mesaconitine is blocked by selective α_2-adrenoreceptor antagonists, as well as by 5-hydroxytryptamine receptor antagonists [60]. Taken together, these results suggest that the nociceptive effect of mesaconitine is exerted via stimulation of β-adrenoreceptors. It activates also descending inhibitory signals of α-adrenoreceptors and serotonergic neurons in nociception transmission pathways from the brain stem to the spinal cord [33, 61].

In contrast to aconitine, the less-toxic diterpenoid alkaloids with antiarrhythmic action, such as lappaconitine, its N-deacetylated analogue, and 6-benzoylheteratisine, selectively block the tetrodotoxin-sensitive Na^+ channels, decrease the intracellular concentration of Ca^{2+}, increase the activation threshold of Na^+ channels, resulting in bradycardia and significant negative inotropic action on the heart right atrium [44, 45]. The capacity of 6-benzoylheteratisine to prevent arrhythmia induced by aconitine prompted to conclude that these compounds compete for the same receptors, the former being characterized as a blocker, and the latter as a stimulator of Na^+ channels. The mode of anti-nociceptive and, probably, antiepileptic action of lappaconitine is due to its inhibitory action on inward tetrodotoxin-sensitive sodium currents, which is quantitatively and qualitatively different from the effect of aconitine [33, 56].

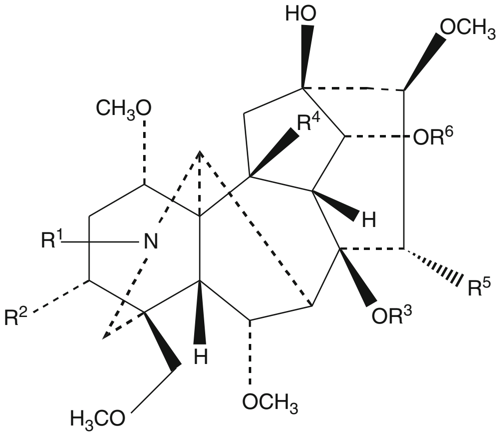
5 Toxicity

The onset and intensity of clinical symptoms of intoxication with *Aconitum* alkaloids usually depend on the quantity ingested. The first sign of poisoning may appear within 10 min after administration as paresthesia, numbness in the area of contact with poison (perioral, skin, then face, and limbs), followed by weakness, nausea and vomiting, dizziness, palpitation, hypotension, arrhythmia, systemic paralysis, shock, and coma. The death can occur within 2–6 h, or immediately, if a high dose of alkaloid is introduced. The main causes of death are ventricular arrhythmias, and paralysis of cardiovascular and respiratory systems [40].

Treatment of intoxication is supportive. No specific antidote is presently known. M-cholinoblockers (atropine) are indicated to treat bradycardia. Amiodarone and flecainide can be recommended for the treatment of aconitine-induced arrhythmia. Ventricular arrhythmias provoked by aconitine are often refractory to direct current cardioversion and antiarrhythmic drugs. In refractory cases of ventricular arrhythmias and cardiogenic shock, the cardiopulmonary bypass is recommended.

Even if all the plants of the *Aconitum* genus are considered to be poisonous, the toxicity of different species varies depending on the qualitative and quantitative content of alkaloids, plant origin, times of harvest, etc. There are multiple investigations that have been made by Japanese and German researchers to determine the toxicity of various alkaloids found in *Aconitum* genus. The toxicological characteristics of some alkaloids and related products given in Table 48.5 have shown that C_{19}-diterpenoid alkaloids can be divided into three groups depending on their toxicity.

The first group consists of the most toxic alkaloids such as aconitine, mesaconitine, hypaconitine, 3-acetylaconitine, jesaconitine, yunaconitine, beiwutine, bulleyaconitine, etc. Their molecular structures are relatively similar (**12**, Table 48.6). The common feature of all these alkaloids is the presence of two ester groups on position C-8 formed by acetyl moiety and on position C-14 formed by benzoyl or anisoyl moiety.



12

Numerous studies on the toxicological properties of these alkaloids have shown that the presence of these two ester groups is indicative of their toxicity; de-esterification drastically reduces the toxicity of all compounds, the LD_{50} of monoesterified benzoylaconine being about 200-fold less than that of aconitine. The same tendency is observed for benzoylmesaconine and benzoylhypaconine (210- and 49-fold less toxic than mesaconitine and hypaconitine, respectively). Elimination of both acetyl and benzoyl groups from the molecule of aconitine by alkaline hydrolysis results in the formation of the least toxic product aconine, with LD_{50} of 120 mg kg^{-1} (1,000-fold less than that of aconitine).

Indeed, *Aconitum* roots used in traditional medicine of many Asian countries should undergo a special processing in order to decrease their toxicity. Even if the methods of processing vary from one country to another (e.g., soaking in saline solution, heating, or autoclaving [62]), they are all intended to hydrolyze highly toxic alkaloids, transforming them into nontoxic products. These so-called processed tubers lose their toxicity by 65–90% in comparison with raw tubers, and are designed for internal administration [41]. Recent investigations of Chinese and Korean researchers have shown [63, 64] that processing of tubers gives not only the products of hydrolysis, but also by-products of trans-esterification. These reactions might give the lipo-alkaloids formed by replacement of the acetyl moiety on the C-8 position of aconitine, mesaconitine, hypaconitine, neoline,

Ac acetyl, *Bz* benzoyl, *As* anisoyl

or bikhaconine, by palmitoyl, linoleoyl, stearoyl, or oleoyl moieties. Examples of such lipo-alkaloids are 8-linoleyl-14-*O*-benzoylmesaconine, 8-nonadecenoyl-14-*O*-benzoylhypaconine, 8-palmitoyl-14-*O*-benzoylaconine, 8-stearoyl-14-*O*-anisoylbikhaconine, etc. Mixtures of lipo-aconitines are reported to be less toxic than aconitine, hypo- or mesaconitine [62].

The second group of diterpenoid alkaloids comprises moderately toxic C_{19}-alkaloids having a benzoyl moiety on the C-6, C-4, or C-14 positions, and without an acetyl moiety on the C-8 position. The representatives of alkaloids with a C-6 or a C-4 benzoyl moiety are 6-benzoylheteratisine, lappaconitine, and ranaconitine. Even if the LD$_{50}$ values of lappaconitine and 6-benzoylheteratisine found in the literature are not identical [32, 33, 35], these compounds remain about 20–50 times less toxic than diester alkaloids. However, they are more toxic than the de-esterified derivatives of aconitine-like alkaloids having a benzoyl group at C-14, such as benzoylaconine, benzoylmesaconine, and benzoylhypaconine, which indicates the importance of the position of the benzoyl moiety for toxicity.

The third group of C_{19}-diterpenoid alkaloids comprises lycoctonine, neoline, and heteratisine. They are devoid of any ester group on C-8 or C-14 positions; consequently, they have been reported to be among the least toxic of all *Aconitum* alkaloids.

The LD$_{50}$s of songorine, napelline, and karakoline presented in Table 48.5 allow to conclude that C_{20}-diterpenoid alkaloids are among the least toxic alkaloids.

6 Conclusions

The interest to the pharmacological activities of alkaloids extracted from the *Aconitum* genus is continuously growing. Most of *Aconitum* plants used in traditional medicine are being extensively explored and their therapeutic versus toxic potentials are being evaluated. Numerous investigations on the chemical constituents of raw and processed tubers of *Aconitum* plants allowed to explain the nature of the "Processed *Aconitum* preparations" used in traditional medicine: high-temperature treatment of *Aconitum* roots destroys highly toxic diester alkaloids to less-toxic derivatives by hydrolyzing or transforming them to lipo-alkaloids. The structure-toxicity relationship studies clarified the role of acetyl and benzoyl esters in the structure of diterpenoid alkaloids.

The pharmacological activities of *Aconitum* alkaloids principally have been evaluated in three axes: analgesic, antiarrhythmic, and anticancer effects. Aconitine-like alkaloids possess strong analgesic activities. They were determined as centrally acting anti-nociceptive agents, more potent than narcotic analgesics. However, there is a strong correlation between analgesic, arrhythmogenic activity and toxicity of diester diterpenoid alkaloids, which limits their use in medicine. More recent studies allow to find a number of alkaloids having wider therapeutic interval, for example, yunaconitine, *N*-deacetyllappaconitine, bulleyaconitine with LD_{50}/ED_{50} ratios of about 10–18. Among diterpenoid alkaloids evaluated for antiarrhythmic activity, three compounds, lappaconitine, *N*-deacetyllappaconitine, and 6-benzoylheteratisine, were characterized as the best antiarrhythmic agents. It was supposed that their antiarrhythmic action is due to the block of Na^+ channels, which is antagonistic in relation to the effect of aconitine-like alkaloids.

Interesting results were obtained on the cytotoxic activity of semisynthetic derivatives of C_{20}-diterpenoid alkaloids: 11-(*m*-trifluoromethylbenzoyl)kobustine, 11-(*m*-trifluoromethylbenzoyl)pseudokobustine, and 11,15-dianisoylpseudokobustine. The anticancer activity of synthetic bis [*O*-(14-benzoylaconine-8-yl)-suberate has been demonstrated on xenografted tumor models in mice with two human tumor cell lines: MCF7 (breast cancer) and HCT15 (colon cancer). The diverse biological activities of alkaloids from various *Aconitum* species are very encouraging and warrant further investigations.

Abstract

Alkaloids are one of the largest natural products with low molecular weight found in plants, fungus, animals, and microorganisms. Many reports have confirmed that alkaloids have a desired therapeutic potential against human diseases. Acetylcholinesterase (AChE, EC 3.1.1.7) is an enzyme that has ability to inhibit the hydrolysis of the neurotransmitter called acetylcholine and elevate its level in the synaptic cleft, associated with several neurological disorders such

as mostly Alzheimer's disease (AD) and myasthenia gravis. AChE inhibition in addition to butyrylcholinesterase (BChE) has been the most widely accepted treatment strategy against AD, which is characterized by shortage of acetylcholine in the brain. The current AChE inhibitors used in clinical application (rivastigmine, donepezil, and galanthamine) are classified under alkaloids, and consequently, alkaloids have become a popular target in discovery of novel cholinesterase inhibitors. In this chapter, current cholinesterase-inhibiting alkaloids of natural origin (physostigmine, galanthamine, and huperzine A) will be mentioned in addition to some promising ones with marked cholinesterase inhibition.

Keywords
Acetylcholinesterase • alkaloid • Alzheimer's disease • cholinesterase • plant

Abbreviations

ACh	Acetylcholine
AChE	Acetylcholinesterase

BCh	Butyrylcholine
BChE	Butyrylcholinesterase
FDA	Food and Drug Administration
IC	Inhibitory concentration
PD	Parkinson's disease

1 Introduction

Neurodegeneration is a term describing progressive loss in structure or malfunctioning of nerve cells called neurons. Neurodegenerative diseases have quite complex pathogenesis and therefore, the full pathology has not been elucidated for most of them up to date. The prevalence of neurodegenerative disorders such as Alzheimer's disease (AD) and Parkinson's disease (PD) is on the increase as they activate neuronal cell death through endogenous suicide pathways [1]; however, effective treatments are still lacking. Although AD was discovered more than a century ago by the German physician Alois Alzheimer, the precise physiologic changes that trigger the development of AD largely remain unknown [2]. At the moment, approximately 33.9 million people worldwide are suffering from AD and, unfortunately, prevalence is expected to triple over the next 40 years [3]. PD, the second most common neurodegenerative disorder especially beyond the age of 60, was firstly described in 1817 by James Parkinson, a British physician. In the United States, PD has been estimated to affect at least 500.000 people, and is expected to double in the next 20 years [4].

Thus far, two hypotheses have been proposed for AD pathogenesis: "cholinergic hypothesis" and "amyloid hypothesis" [5]. Cholinergic hypothesis describes the biochemical and histopathological changes of neurotransmitter acetylcholine (ACh), whose shortage has been found to occur in the brains of patients with AD [6, 7]. Cholinesterase inhibitors provide a great contribution to elevation of ACh levels by inhibiting the enzymes implicated in its degradation, namely, acetylcholinesterase (AChE) and butyrylcholinesterase (BChE) [8]. BChE (EC 3.1.1.8), also known as pseudocholinesterase, nonspecific cholinesterase, or simply cholinesterase, preferentially acts on butyrylcholine (BCh), in addition to its ability to hydrolyze ACh [9]. However, AChE is distinguished from BChE by its greater specificity toward ACh. Needless to say, the selectivity of cholinesterase inhibitors for AChE *versus* BChE may have an impact on both therapeutic and adverse effects of these compounds [10]. Consequently, inhibition of AChE, the key enzyme which catalyzes hydrolization of ACh into acetic acid and choline, is critical and AChE inhibitors have become the most prescribed drug class for the treatment of AD [11]. PD is often associated with dementia with Lewy bodies and, therefore, use of AChE inhibitors is also suggested for PD treatment [12].

An extensive research has been going on finding new cholinesterase inhibitors, whose efficacy has been confirmed in delaying the deterioration of symptoms of AD, a valuable treatment target considering the progressive nature of the disease. On the other hand, alkaloids that are nitrogen-containing natural compounds have been an attractive target for anticholinesterase drug research due to their structural similarity to all of the clinically approved anticholinesterase drugs (physostigmine, tacrine, rivastigmine, donepezil, and galanthamine) which also contain nitrogen in their structures. In consistent with this fact, the PubMed search using “alkaloids with anticholinesterase activity” as the keyword yields 2,562 results which underlines the popularity and efficacy of alkaloids in cholinesterase inhibition [13].

In this chapter, the main three alkaloids with cholinesterase inhibitory activity which have become approved drugs (physostigmine, galanthamine, and huperzine A) will be highlighted and some examples of promising alkaloids (lycorine, dehydroevodiamine, visoltricin, narciprimine, and berberine) with marked cholinesterase inhibition that may have potential in both therapy and drug development will be given.

2 Physostigmine

Physostigmine (also known as eserine) (Fig. 49.1) is a parasympathomimetic alkaloid isolated in 1864 by Jobst and Hesse from the calabar bean *Physostigma venenosum* Balf. (Fabaceae) growing in tropical forests of Africa [14]. The first therapeutic use of this drug was in 1877 in the treatment of glaucoma, which is still one of its clinical uses. Besides, it was the first discovered AChE inhibitor, which led to start practice of AChE inhibitors in clinical conditions in 1980s. Physostigmine [1,2,3,3a,8,8a-hexahydro-1,3a,8-trimethyl-*N*-methylcarbamate,(3a*S*,8a*R*)-pyrrolo(2,3-b)indol-5-ol] is a pyrroloindole type of alkaloid having a carbamate moiety which has been considered to be responsible for cholinesterase inhibition [15]. Due to its reversible inhibitory effect toward AChE, physostigmine has been used to treat myasthenia gravis, glaucoma, AD, atropine-induced coma along with delayed gastric

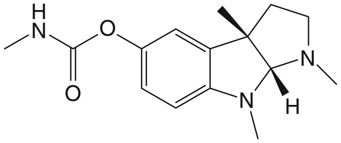

Fig. 49.1 Physostigmine

emptying [16]. In the late 1800s, physostigmine was utilized against atropine intoxication and glaucoma while its total synthesis was achieved in 1935 by the chemists Percy Lavon Julian and Josef Pikl [11]. The compound having lipophilic features has ability to pass blood-brain barrier that is probably due to its tertiary structure.

However, short half-life (30 min) of physostigmine and unsolicited side effects has put a limit to its widespread use as anticholinesterase agent. A number of clinical studies investigated efficacy of physostigmine in dementia patients by oral and intravenous applications, which was due to its cholinesterase-inhibiting properties. Development of an oral form with extended-release formula of the compound afforded sustainable blood levels [17]. Relevantly, a multicenter, double-blind, and large study showed efficacy and safety of extended-release formula of physostigmine salicylate after following 6 weeks use at the doses of 18, 24, and 30 mg *per* day [18]. In a later multicenter, double-blind, and placebo-controlled clinical trial, extended-release formula of physostigmine salicylate was evaluated in 850 subjects diagnosed with mild to moderate AD with dose-enrichment phase [19]. In the end of total 16 weeks, physostigmine salicylate was modestly effective in the AD patients at the daily doses of 12 and 15 mg according to body index. On the other hand, 204 patients with AD diagnosis were given the patches containing 30 mg and 60 mg of physostigmine with a placebo patch in a double-blind, randomized, multicenter study performed in Germany [20]. The evidence after a treatment period of 24 weeks showed that the efficacy of physostigmine was not superior to that of placebo and physostigmine did not cause any significant alteration in plasma cholinesterase activity. Therefore, it was concluded that the physostigmine patch application in doses of 30 mg and 60 mg actually did not lead to sufficient level of physostigmine concentrations in plasma that were to compensate for cholinergic deficiencies in affected brain areas and produce clinical benefits.

Despite its efficacy as a cholinesterase inhibitor, physostigmine has a narrow therapeutic index, short duration of action, and side effects such as nausea, dizziness, vomiting, headache, diarrhea, etc., and hence, it is not in clinical application any more for the treatment of neurological disorders [21]. Nevertheless, novel derivatives and analogs of physostigmine have been synthesized by many researchers and the structure of this compound has been a starting molecule for design of new anticholinesterase drug candidates. One of the earliest derivatives of physostigmine was neostigmine [3-(dimethylcarbamoyloxy)-*N*,*N*,*N*-trimethylbenzenaminium], which was used in the 1930's to treat gastrointestinal or urinary bladder atony and afterward approved for treatment of myasthenia gravis and glaucoma [11, 22, 23]. Later on, some other carbamate analogs of physostigmine have been synthesized including phenserine, tolserine, cymserine, and phenethylcymserine, which possess longer durations of action concerning cholinesterase inhibitory effect compared to their parent molecule; physostigmine as well as the other derivatives, neostigmine and pyridostigmine [24]. Eptastigmine (heptyl physostigmine; heptylcarbamic acid [(3aS,8aα)-1,2,3,3a,8,8a-hexahydro-1,3aα,8-trimethylpyrrolo [2,3-b]indol-5-yl] ester), a carbamate derivative of physostigmine in which the carbamoylmethyl group in position 5 of the side chain has been substituted with a carbamoylheptyl group [25]. The evidence underlined that eptastigmine is also a long-lasting reversible inhibitor of both AChE and BChE. Phenserine and tolserine are among the third generation cholinesterase inhibitors derived from physostigmine, entering in clinical trials.

Briefly, physostigmine representing the first generation of cholinesterase inhibitors has been a good model molecule for designing new derivatives with stronger cholinesterase inhibitory action with specific advantages over the earlier ones.

3 Galanthamine

Galanthamine [(4a*S*,6*R*,8a*S*)-5,6,9,10,11,12-hexahydro-3-methoxy-11-methyl-4a*H*-[1]-benzofuro[3a,3,2-ef][2]benzazepin-6-ol] (Fig. 49.2) is an alkaloid firstly isolated from *Galanthus woronovii Losinsk* (Amaryllidaceae) (snowdrop) and it is also known to be present in *Leucojum aestivum* L. (summer snowflake) and *Narcissus pseudonarcissus L.* from the same plant family, found widespread in the eastern parts of Europe mainly including Bulgaria and Turkey [5, 26]. Presence of galanthamine was also shown in *Lycoris radiata (L'Hér.) Herb.* and *Ungernia victoris Vved.* growing naturally in Asian countries [27]. The first work on discovery of AChE-inhibiting properties of galanthamine was published in 1951 by the Russian scientists Mashkovsky and Kruglikova-Lvova, who used an *ex vivo* system and smooth muscles (isolated rabbit small intestine and guinea pig uterus) [28]. Galanthamine is a central acting reversible AChE inhibitor, which has a good ability to penetrate into the blood-brain barrier and acts by dual mechanisms that can inhibit AChE and allosterically modulates human α3β4, α4β2, and α6β4 nicotinic ACh receptors [29, 30]. (-)-Galanthamine was developed as a drug for AD treatment and has been clinically used in Europe and the USA approved by FDA. Total synthesis of galanthamine that can yield in kilogram scale was achieved [31] and has been marketed as its hydrobromide salt (Razadyne®, Reminyl®) for the treatment of AD. Although nausea and vomiting are the common side effects of galanthamine, it is possible to eliminate these effects by increasing the galanthamine dose gradually and besides, no liver toxicity has been reported for galanthamine up to date [32, 33].

Galanthamine was reported to exert 50-fold selectivity against AChE than BChE by in vitro and in vivo experiments [28] and shown to inhibit AChE activity in human brain 10-fold less potent than that in human erythrocytes [34]. The pharmacokinetic data obtained from human subjects revealed that application of galanthamine hydrobromide at doses of 5 and 10 mg caused first-order pharmacokinetics, complete oral bioavailability, and a mean terminal half-life of 5.68 h [35].

The comparatively weakest one of the three clinically available cholinesterase inhibitors (rivastigmine, donepezil, and galanthamine) is galanthamine with IC_{50}

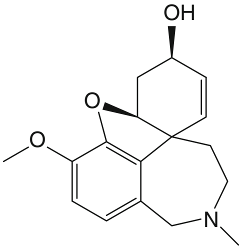

Fig. 49.2 Galanthamine

value of ~ 2.8–3.2 μM for the frontal cortex and the hippocampus [36]. However, the galanthamine dose should be escalated to 16 and 24 mg/day at 4-week intervals to achieve maximal tolerability [37]. Clinically, cognitive improvements are observed following 8-week treatment with galanthamine, which characteristically continues for 3–6 months [38]. Galanthamine was also shown to provide neuroprotection through antioxidant mechanisms, which was assessed by an in vitro model of H_2O_2-induced oxidative stress [39]. It reduced the release of reactive oxygen species (up to 50 %) and prevented loss in mitochondrial activity.

Many researchers have put effort in synthesizing novel analogs of galanthamine in order to obtain higher efficacy on cholinesterase inhibition. Those studies also furnished some key points for structure and activity relationship for galanthamine. For instance; new bis-interacting ligands of galanthamine were synthesized and length of the alkyl linkers was stated to play an important role to promote inhibitory potentials of these derivatives [40]. In this series, the highest inhibition was observed with the twelve methylene (-CH_2-) groups-containing derivatives. Moreover, *N*-alkylammonium derivatives exerted stronger inhibition than *N*-phthalimido derivatives. The results indicated that iminium moiety and *N*-alkylation of the nitrogen atom in galanthamine molecule enhanced inhibitory effect of these compounds against AChE. In several similar studies [41, 42], it was concluded that the alkylene moieties attached to galanthamine improved AChE inhibitory action due to lipophilicity of the alkyl and alkylene groups. Conversely, the anticholinesterase activities of new glucosyl and nitroxy derivatives prepared from galanthamine were shown to be lower as compared to the parent molecule (100 %), which was found below 70 % of inhibition [43].

From the evidence obtained with galanthamine, it can be pointed out to the fact that unique combination of AChE inhibition and nicotinic ACh receptor modulation for galanthamine provides an extra advantage and more significant benefit for this drug as compared to other cholinesterase inhibitors.

4 Huperzine A

(−)-Huperzine A [(5*R*, 9*R*, 11*E*)-5-amino-11-ethylidine-5,6,9,10-tetrahydro-7-methyl-5,9-methanocycloocta-[*b*]-piridin-2 (1H)-one] Fig. 49.3 is an alkaloid isolated

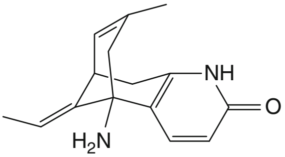

Fig. 49.3 (−)-Huperzine A

from *Lycopodium serratum* Thunb. (*syn. Huperzia serrata* (Thunb. ex Murray) Trevis.) (Lycopodiaceae/Huperziaceae), a Chinese plant used in traditional medicine for memory enhancement [11]. It was discovered in 1986 by the Chinese scientists at Shanghai Institute of Materia Medica [44]. It is an alkaloid with sesquiterpene skeleton that exhibits a potent and reversible inhibition toward AChE and has been shown to be effective against AD in preclinical and clinical studies [45, 46]. Huperzine A has been demonstrated to display a powerful, highly specific, and reversible inhibition against AChE [47, 48]. A tablet formulation with huperzine A, called as shuangyiping in China, was licensed in 1996 by the Chinese Health Authority for the treatment of AD [49]. Huperzine A was reported to improve memory deficits significantly in elderly people with benign senescent forgetfulness and in patients with AD or vascular dementia in phase IV clinical trials in China along with the findings of minimal peripheral cholinergic side effects and no unexpected toxicity [50–52]. Phase I studies in the United States indicated efficacy of increasing doses up to 400 μg twice daily in healthy older individuals [53]. In a phase II study under randomized, double-blind, placebo-controlled, dose-escalation conditions to investigate safety, tolerability, and efficacy of huperzine A in mild to moderate AD patients, the compound was generally well tolerated at doses of up to 400 μg for 24 weeks [54]. The results pointed out to the fact that huperzine A at dose of 200 μg is ineffective in the treatment of AD, whereas at a higher dose (400 μg) may improve cognition to some extent.

Huperzine A has a good penetration into the blood-brain barrier, higher oral bioavailability, prolonged half-life, and longer duration of AChE inhibitory action as compared to other cholinesterase inhibitors [55]. Total synthesis of huperzine A was achieved [56] and, using this compound as the parent molecule, a good number of analogs have been synthesized and compared with that of huperzine A. Among several novel fluorinated derivatives of huperzine A containing one, three, and six fluorine atoms in the molecule, one-fluorine containing analog; (±)-12-fluorohuperzine A was revealed to be the most active with IC_{50} value of 0.2 mM, whereas synthetic (+)-huperzine A and natural (−)-huperzine A had the IC_{50} values of 10 and 0.05 mM in the same experiment [57]. Among the new derivatives (±)-7-ethylhuperzine A as well as its two regioisomeric derivatives, (±)-7-ethyl derivative exhibited the highest inhibition although its effect was approximately 12-fold less than (−)-huperzine A [58]. In this regard, it definitely needs to be mentioned that ZT-1, a Schiff base derivative from natural huperzine A. ZT-1, *N*-[2-hydroxy-3-methoxy-5-chlorobenzilidene] huperzine A, is a pro-drug and rapidly transformed into the active huperzine A [59]. Because of its optimal profile and potency, ZT-1 was selected out of approximately 100 derivatives of huperzine

A identified at Shanghai Institute of Materia Medica, Chinese Academy of Sciences. It is currently being developed as a new drug candidate for AD treatment by Debiopharm S.A. (Switzerland) and also in China. On the other hand, the development of novel huperzine A-tacrine hybrids (huprins) led to discovery of a new class of very potent and selective AChE inhibitors [60–62].

On the basis of the reports on huperzine A, it seems to be most promising drug molecule with cholinesterase action as the last generation of this class.

5 Examples of Other Promising Alkaloids with Anticholinesterase Effect

5.1 Lycorine

Alkaloids are a large chemical class of bioactive compounds from natural sources. Various alkaloids including galanthamine, isolated especially from several members of Amaryllidaceae family, have been identified with remarkable cholinesterase inhibitory features [63–68]. Lycorine (1,2,4,5,12b,12c-Hexahydro-7*H*-[1, 3]dioxolo [4,5-j]pyrrolo[3,2,1-*de*]phenanthridine-1,2-diol) (Fig. 49.4), an isoquinoline alkaloid, isolated from the bulbs of *Crinum jagus* (J. Thomps.) Dandy (swamp lily) and *C. glaucum* A. Chev. (Amaryllidaceae) that are used in traditional medicine in southern Nigeria for memory loss and other mental symptoms, was reported to be a notable inhibitor of AChE with IC_{50} 450 μM and two free hydroxy groups in this structure was suggested to be associated with AChE inhibitory activity [69]. McNulty et al. synthesized a number of analogs of lycorine and stated that the effect of lipophilic substitution at C2 and polar H bond acceptor groups at C1 is additive in that the most potent analogs have both of these functionalities, which may help to design novel derivatives from the lycorine series [70].

5.2 Dehydroevodiamine

Dehydroevodiamine (21-methyl-3,13,21-triazapentacyclo[11.8.0.$0^{2,10}$.$0^{4,9}$.$0^{15,20}$] henicosa-2(10),4,6,8,15,17,19-heptaen-14-one) (Fig. 49.5) is a quinazolinocarboline alkaloid isolated from the fruits of *Evodia rutaecarpa* Bentham (Rutaceae), a well-known plant that has been used for a long time in Chinese traditional medical practice. It was identified as the active principal of the extract from *E. rutaecarpa* that was shown to have strong anti-AChE activity [71]. Dehydroevodiamine displayed a potent inhibition towards AChE in a concentration-dependent and noncompetitive manner with IC_{50} value of 37.8 μM. Anti-amnesic effect of dehydroevodiamine was also demonstrated by the same research group in scopolamine-induced amnesia model of the rat using the passive avoidance and eight-arm radial maze tests [72]. An in vivo pharmacokinetic study revealed that dehydroevodiamine is transported from the systemic circulation to the brain *via* the blood-brain barrier by linear kinetics [73]. Efficacy of this compound has been partially attributed to its AChE inhibitory

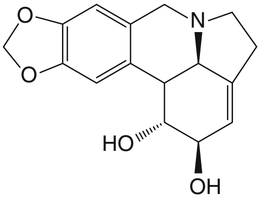

Fig. 49.4 Lycorine

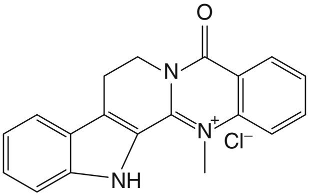

Fig. 49.5 Dehydroevodiamine

effect, but also to long-lasting facilitation of synaptic transmission due to activation of both muscarinic and NMDA receptors [74].

In a study that investigated whether the indole moiety was essential for AChE inhibitory activity of dehydroevodiamine [75], a series of compounds were synthesized, in which the indole was replaced by a benzene moiety. In some compounds of this series, the amidine structure was found to be responsible for moderate to strong AChE-inhibiting properties.

5.3 Visoltricin

Visoltricin (2-propenoic acid, 3-[1-methyl-4-(3-methyl-2-buten-1-yl)-1 H-imidazol-5-yl]-methyl ester) (Fig. 49.6) is an alkaloid isolated from the microfungus *Fusarium tricinctum* [76]. It was reported to have potent AChE-inhibiting properties with IC_{50} values of 2.6×10^{-4} M and 4.0×10^{-4} M in human serum and erythrocyte AChE, respectively [77]. Kinetic studies indicated that visoltricin is a reversible inhibitor of AChE with a mixed-type inhibition in concentration-dependent manner, but independent of time.

5.4 Narciprimine

Narciprimine (Fig. 49.7) is the known phenanthridone alkaloid isolated from *Cyrtanthus contractus* N.E. Br. (fire lily) (Amaryllidaceae). In in vitro experiments [66], it exhibited strong AChE inhibition with IC_{50} value of 78.9 μM. In that study, presence of narciprimine was shown for the first time in the genus

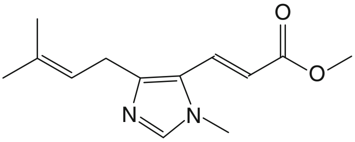

Fig. 49.6 Visoltricin

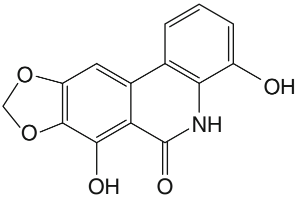

Fig. 49.7 Narciprimine

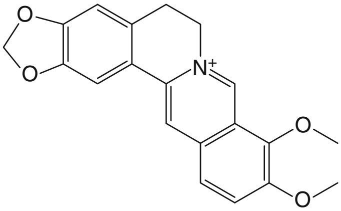

Fig. 49.8 Berberine

of *Cyrtanthus*, in addition to its known sources such as *Zephyranthes*, *Narcissus*, and *Lycoris*, the genera endemic to the Americas, Europe, and Asia, respectively.

5.5 Berberine

Berberine (Benzo[g]-1,3-benzodioxolo[5,6-a]quinolizinium, 5,6-dihydro-9,10-dimethoxy-chloride) (Fig. 49.8) is from the protoberberine group of isoquinoline alkaloids isolated from many plant sources such as some *Berberis* sp. (Berberidaceae) such as *Berberis vulgaris* L. (barberry) and *B. aristata* D.C. (tree turmeric) [78, 79], *Mahonia aquifolium* (Pursh) Nutt. (oregon grape) (Berberidaceae) [80], *Hydrastis canadensis* L. (goldenseal) (Ranunculaceae) [81], *Phellodendron amurense* Rupr. (Amur Cork Tree) (Rutaceae) [82], *Coptis chinensis* Franch. (Chinese goldthread, Huang-Lian, Huang-Lien) (Ranunculaceae) [83], *Tinospora cordifolia* (Thunb.) Miers (Menispermaceae) [84], as well as to a smaller extent in *Argemone mexicana* L. (prickly Poppy) (Papaveraceae) [85] and *Eschscholzia californica*

Cham. (californian poppy) (Papaveraceae) [86]. One of the earliest records on AChE inhibitory activity of berberine obtained from *Macleaya microcarpa* (Maxim.) Fedde (plume poppy) (Papaveraceae) growing in Ukraine was reported by Kuznetsova et al. [87]. Berberine isolated from the aerial parts of *Corydalis speciosa* Maxim. ex Regel of Korean origin (Papaveraceae) was shown to inhibit AChE strongly at IC_{50} value of 3.3 μM in concentration-dependent manner [88]. The tuber methanol extract of *Corydalis yanhusuo* W.T. Wang of Chinese origin also afforded berberine as the active principle of this plant with a high anti-AChE effect ($IC_{50} = 1.01$ μM) [89]. In a recent study, a new derivative of berberine identified as (-)-2,9-dihydroxyl-3,11-dimethoxy-1,10-dinitrotetrahydroprotoberberine displayed a potent inhibitory activity against AChE with IC_{50} value below 10 μM [90].

In a series of 9-N-substituted berberine derivatives synthesized, (o-methyl-phenethyl)amino derivative linked at the 9-position of berberine was demonstrated to possess a very high AChE-inhibiting feature ($IC_{50} = 0.027$ μM) [91]. Jiang et al. also reported that, among the benzenediol-berberine hybrids synthesized, berberine-pyrocatechol hybrid ($IC_{50} = 0.123$ μM) exerted a much higher inhibition against AChE than the parent molecule berberine ($IC_{50} = 0.374$ μM) [92].

6 Conclusion

Great number of alkaloids has been discovered from natural sources, especially the plant kingdom. The literature survey clearly points out to the fact that a good number of alkaloids possess remarkable anticholinesterase effect and some of them made it to clinical application as the approved drugs. The research going on finding new cholinesterase inhibitors has given to an assumption that many more alkaloids are waiting to be discovered for this purpose. Therefore, alkaloids need a special emphasis in the design and discovery of cholinesterase inhibitors.

Abstract

"Plant phenolics" and "polyphenols" are secondary natural metabolites arising biogenetically from either the shikimate/phenylpropanoid pathway, which directly provides phenylpropanoids, or the "polyketide" acetate/malonate pathway, which can produce simple phenols, or both, thus producing monomeric and polymeric phenols and polyphenols, which fulfill a very broad range of physiological roles in plants. Higher plants synthesize several thousand known different phenolic compounds. The ability to synthesize phenolic compounds has been selected throughout the course of evolution in different plant lineages, thus permitting plants to cope with the constantly changing environmental challenges over evolutionary time.

Plant phenolics are considered to have a key role as defense compounds when environmental stresses, such as high light, low temperatures, pathogen infection, herbivores, and nutrient deficiency, can lead to an increased production of free radicals and other oxidative species in plants. Both biotic and abiotic stresses stimulate carbon fluxes from the primary to the secondary metabolic pathways,

thus inducing a shift of the available resources in favor of the synthesis of secondary products. An interesting link between primary and secondary metabolism couples the accumulation of the stress metabolite proline with the energy transfer toward phenylpropanoid biosynthesis via the oxidative pentose phosphate pathway. The alternating oxidation of NADPH by proline synthesis and reduction of $NADP^+$ by the two oxidative steps of the oxidative pentose phosphate pathway lead to the simultaneous accumulation of phenolic compounds.

Secondary metabolism • plant phenolics • phenolic classes • ecological and physiological role • trade-off

1 Introduction

There are approximately 300,000 documented species of higher plants on the planet, which synthesize an enormous number of chemicals of diverse structure and class (more than 200,000 isolated and identified individual chemical entities). These compounds can be further divided into primary and secondary metabolites. The primary metabolites include metabolites such as sugars, fatty acids, amino, and nucleic acids, as well as chemicals considered ubiquitous to all plants for growth and development [1, 2]. Secondary metabolites are structurally and chemically much more diverse than the primary metabolites and refer to compounds present in specialized cells that are not directly essential for basic photosynthetic or respiratory metabolism but are thought to be required for plants' survival in the environment. Plants have metabolic pathways leading to tens of thousands of secondary products capable of effectively responding to stress situations imposed by biotic and abiotic factors. These pathways, often recruited from essential primary metabolism pathways upon initial gene duplication leading to duplicated genes showing new functions and optimized and diversified roles in new pathways, are an integral part of the developmental program of plants. Accumulation of secondary metabolites often marks the onset of developmental stages. A strict spatial and temporal control of gene expression ensures the correct accumulation pattern of various secondary products. The required transport of metabolic intermediates constitutes an additional level of regulation. Ontogeny and circadian clock-controlled gene expression are also important features of plant secondary metabolism, as are master regulatory transcription factors [3–8]. Secondary metabolites apparently act as defense (against herbivores, microbes, viruses, or competing plants) and signal compounds (to attract pollinating or seed dispersing animals), as well as protecting the plant from ultraviolet radiation and oxidants. The pattern of secondary metabolites in a given plant is complex; it changes in a tissue- and organ-specific way; differences can be seen between different developmental stages (e.g., organs important for survival and reproduction have the highest and most potent secondary metabolites), between individuals, and between populations. These secondary metabolites are classified into several groups according to their biosynthetic routes and structural features [9–14].

Phenolic compounds are the most widely distributed secondary metabolites, ubiquitously present in the plant kingdom, even if the type of compound present varies according to the phylum under consideration. Phenolics are uncommon in bacteria, fungi, and algae. Bryophytes are regular producers of polyphenols including flavonoids, but it is in the vascular plants that the full range of polyphenols is found [15, 16]. It is estimated that about 2% of all carbon photosynthesized by plants is converted into flavonoids or closely related compounds [17]. Higher plants synthesize several thousand known different phenolic compounds, and the number of those fully characterized is continually increasing. Leaves of vascular plants contain esters; amides and glycosides of hydroxycinnamic acids; glycosylated flavonoids, especially flavonols; and proanthocyanidins and their relatives. Lignin, suberin, and pollen sporopollenin are examples of phenolic-containing polymers. Some soluble phenolics are widely distributed, for example, chlorogenic acid, but the distribution of many other structures is restricted to specific genera or families, making them convenient biomarkers for taxonomic studies.

The ability to synthesize phenolic compounds has been selected throughout the course of evolution in different plant lineages when such compounds addressed specific needs, thus permitting plants to cope with the constantly changing environmental challenges over evolutionary time [18–21]. For example, the successful adaptation to land of some higher members of the Charophyceae – which are regarded as prototypes of amphibious plants that presumably preceded true land plants when they emerged from an aquatic environment onto the land – was achieved largely by massive formation of "phenolic UV light screens" [9, 15, 22, 23]. The phenylpropanoid pathway leading to lignins involves a common set of biochemical reactions in vascular plants already present 400 million of years ago with the emergence of erect vascular land plants. From an evolutionary point of view, these metabolic backbones have been progressively enriched to provide specific adaptations to different plant families and the remarkable biochemical diversity we can observe [21]. Accounting for about 40% of organic carbon circulating in the biosphere, these phenolic compounds are biosynthetically formed by way of either the shikimic acid pathway or the malonate/acetate pathway, also known as the polyketide pathway, and related biochemical pathways. Furthermore, it is their reassimilation back to carbon dioxide during biodegradation (mineralization) that presents the rate-limiting step in recycling biological carbon [24, 25].

Plant phenolics are, in themselves, a fascinating group of substances and have attracted some of the most distinguished of the Nobel-Prize-winning organic chemists, including Emil Fischer, who studied chemical substances used in tanning; Richard M. Willstätter, who in 1913 proposed the first chemical hypothesis concerning blue flower color development; Robert Robinson (copigmentation theory); Richard L.M. Synge (interested in interactions of tannins with proteins); and Alexander R. Todd who worked from 1931 to 1934 on anthocyanins and other coloring matters together with Sir Robert Robinson [26–29]. The continuing fascination of polyphenols for chemists involved with plant constituents is shown by the fact that a "plant phenolics group" was established in France (Narbonne 1970: the first meeting; Avignon-Montfavet 1971: the first International Conference on Polyphenols). This "Groupe Polyphénols" was constituted in an international society in Narbonne (France) in 1972 with the aim of promoting research on plant polyphenols, while providing members worldwide with a unique forum to exchange information on all aspects of these fascinating natural products, from their most basic and fundamental biophysicochemical properties to their most diverse applications in food and agricultural, pharmaceutical, and cosmetic sciences and technologies (http://www.groupepolyphenols.com/).

Broadly, as far as the definition of plant phenolics is concerned, the term 'phenol' is a chemical term that defines a phenyl ring bearing one or more hydroxyl substituents. The term 'polyphenol' could thus be used to define natural products featuring at least two phenyl rings bearing one or more hydroxyl substituents, including their functional derivatives (e.g., esters and glycosides), but in the context of plant phenolics such a definition is not satisfactory, since it would include compounds such as the gossypol, the phenolic carotenoid 3-hydroxyisorenieratene (I) or the phenolic female sex hormone oestrone (II), which are principally terpenoid in origin [30]. Thus, as a general rule recently proposed by Quideau et al. [31], the terms 'plant phenolics' should be strictly used to refer to secondary natural metabolites arising biogenetically from either the shikimate/phenylpropanoid pathway, which directly provides phenylpropanoids (Scheme 50.1), or the 'polyketide' acetate/malonate pathway, and which fulfill a very broad range of physiological roles in plants [30, 31]. In fact, although the bulk of these compounds play cell wall structural roles, plant tissues synthesize a vast array of nonstructural constituents that have various roles in plant growth and survival. Thus, the expression "plant phenolics" embraces a highly diverse group, the chemically known members of which can be counted in several thousand with a large range of identified structures: monomeric, dimeric, and polymeric phenolics have been identified. Several classes of phenolics have been categorized on the basis of their basic skeleton: C_6 (simple phenol, benzoquinones), C_6—C_1 (phenolic acid), C_6—C_2 (acetophenone, phenylacetic acid), C_6—C_3 (hydroxycinnamic acid, coumarin, phenylpropanes, chromones), C_6—C_4 (naphthoquinones), C_6—C_1—C_6 (xanthones), C_6—C_2—C_6 (stilbenes, anthraquinones), C_6—C_3—C_6 (flavonoids, isoflavonoids, neoflavonoids), $(C_6$—C_3—$C_6)_{2,3}$ (bi-, triflavonoids), $(C_6$—$C_3)_2$ (lignans, neolignans), $(C_6$—$C_3)_n$ (lignins), $(C_6)_n$ (catechol melanins), and $(C_6$—C_3—$C_6)_n$ (condensed tannins). Low-molecular-weight phenolics occur universally in higher plants; some of them are common in a variety of plant species and others are species specific. Higher-molecular-weight proanthocyanidins (also called condensed tannins) are the most abundant polyphenols in woody plants but are usually absent in herbaceous plants. Hydrolyzable tannins have a more restricted occurrence than proanthocyanidins, being found in only 15 of the 40 orders of dicotyledons [16, 32–40].

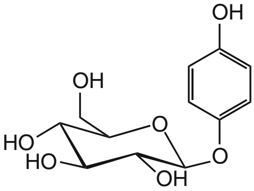
2 The Major Classes of Phenolics in Plants

Examples of simple phenols (C_6) include catechol and phloroglucinol. Although most of the more complex plant polyphenols contain these two simple phenols as a parts of their structures, catechol and phloroglucinol are uncommon in plant tissues. Catechol has been found in leaves of *Gaultheria* species, while phloroglucinol has been found as glucoside in the peel of various *Citrus* fruits. Arbutin (**III**) is found in leaves of various *Vaccinium* spp., such as blueberry, cranberry, cowberry, and pear trees (*Pyrus communis* L., *Rosaceae*) [41–43].

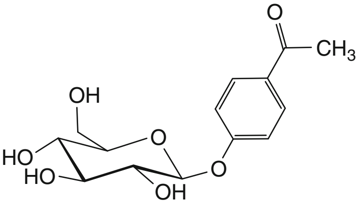


III

Phenolic acids (C_6—C_1) are commonly represented by gallic, *p*-hydroxybenzoic, protocatechuic, vanillic, and syringic acids. Phenolic acids are usually present in the bound soluble form conjugated with sugars or organic acids and are typically components of complex structures such as lignins and hydrolyzable tannins. Gallic acid is the base unit of gallotannins, whereas gallic acid and hexahydroxydiphenoyl moieties are both subunits of the ellagitannins, which are classified as hydrolyzable tannins. Free and bounded phenolic acids are found in cereals. Hydroxybenzoic acid glycosides are also characteristic of some herbs and spices. Aldehydes related to C_6—C_1 acids are also found in plants. Salicylaldehyde, *p*-hydroxybenzaldehyde (*Sorghum* spp.), *p*-anisaldehyde (*Vanilla*, *Mimosa*), and *p*-protocatechualdehyde

(*Cichorium intybus*) are also quite common in plants. Vanillin, the odor principle occurring in *Vanilla* pods, is certainly of very widespread origin [42, 44]. Ellagic acid has been reported to be present in berries, particularly raspberries (*Rubus idaeus*), strawberries, and blackberries. However, free ellagic acid is normally present in low levels in berries that more commonly contain ellagitannins [38, 45].

Among the less common C_6—C_2 compounds, phenolic ketones have occasionally been found as plant constituents. Picein (**IV**) the main component of all investigated spruce needles (*Picea abies* (L.) Karst.), also occurs in *Larix decidua* Mill., *Populus balsamifera*, and *Salix* spp. *p*-Hydroxyphenylacetic acid occurs free and as a glucoside in bamboo shoots. Xanthoxylin, a phloroacetophenone derivative, has been found in *Xanthoxylum* spp. [42, 46–48].



IV

A ubiquitous phenolic unit in plants is one with an aromatic ring attached to a C_3 aliphatic side chain. Such phenylpropanoids occur universally in plants and are also the precursors of many other classes of plant phenolics. For example, by *o*-hydroxylation and subsequent cyclization, *p*-coumaric acid can give rise to hydroxycoumarins. On reduction, it yields *p*-coumaryl alcohol, which is one of the monomeric building rocks of the lignin. β-Oxidation of *p*-coumaric acid yields *p*-hydroxybenzoic acids. Dimerization of *p*-coumaryl alcohol can give rise to a lignin. Finally, the *p*-coumaric moiety is an important unit in the structure of flavonoids, stilbenoids, and xanthones. The most widely distributed hydroxycinnamates (C_6—C_3) are *p*-coumaric, caffeic, ferulic, and sinapic acids, which usually occur in various conjugated forms and are seldom found in the free state except as artifact due to chemical or enzymic hydrolysis during tissue extraction. In aqueous solvents, they isomerizes from the more stable *E* (*trans*) form to the *Z* (*cis*) form, especially under the action of UV light. Hydroxycinnamates frequently accumulate as their respective tartrate esters, coutaric, caftaric, and fertaric acids. Quinic acid conjugates (Fig. 50.1) of caffeic acid, namely, 3-, 4-, and 5-*O*-caffeoylquinic acid, are commonly found in fruits and vegetables. Green coffee beans (*Coffea arabica*) are one of the richest dietary sources of caffeoylquinic acids. Chlorogenic acid (5-*O*-caffeoylquinic acid) (**V**) is the dominant caffeoylquinic derivative accounting for 50% of the total [49, 50]. Coumarins, which are also C_6—C_3 derivatives, are benzo-α-pyrones (lactones) formally derived from *o*-hydroxycinnamic acids by cyclization and ring closure between the *o*-hydroxy and carboxyl groups. This group of phenolic compounds can be found free in nature or in combined form with sugars as heterosides and glycosides in many dicotyledonous

families, including the *Apiaceae*, *Asteraceae*, *Fabaceae*, *Moraceae*, *Rosaceae*, *Rubiaceae*, and *Solanaceae*. Although mainly synthesized in the leaves, coumarins occur in high levels in fruits, roots, and stems. Coumarins can be roughly categorized as (i) simple hydroxycoumarins, the most common ones being umbelliferone, esculentin, and scopoletin (**VI**), which occur naturally as their β-O-glucosides; (ii) furanocoumarins (bergaptene, (**VII**)) that consist of a five-membered furan ring attached to the coumarin nucleus; and (iii) finally the pyranocoumarins (calanolide B, (**VIII**)) that are analogous to furanocoumarins but contain a six-membered pyran ring [51, 52]. Chromones are isomeric with coumarins but differ in the biosynthesis and position of the keto group. Their biosynthesis seems to proceed *via* the polyketide pathway by the condensation of five acetate units and subsequent *O*- and *C*-methylation. Most naturally occurring chromones contain a methyl group or an alkyl group at C-2 and hydroxyl or alkoxyl groups at C-5 and C-7. Only few simple chromones are known to occur naturally. Eugenin (**IX**) is an example of a simple 2-methyl-chromone present in *Eugenia aromatica* [49].

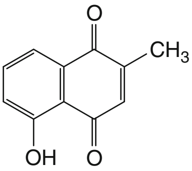
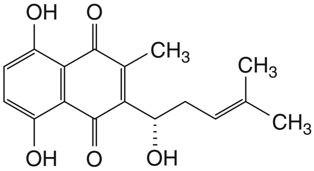
Naphthoquinones (C_6—C_4) represent a class of quinone pigments widespread in nature. The most important higher plant families containing naphthoquinones are *Avicenniaceae*, *Bignoniaceae*, *Boraginaceae*, *Droseraceae*, *Ebenaceae*, *Juglandaceae*, *Nepenthaceae*, and *Plumbaginaceae*. They are biosynthesized *via* a variety of pathways including polyketide pathway (plumbagin, **X**) shikimate/ succinyl-CoA combined pathway [lawsone (2-hydroxy-1,4-naphthoquinone)], and shikimate/mevalonate pathway (alkannin, **XI**). Although intensely colored naphthoquinones are not often apparent as plant-coloring matters. They are often present in heartwood or bark, where their presence is masked. When present in living tissues, leaves, and roots, they are usually in colorless form, and color is produced only after extracts have been treated with acid to bring about hydrolysis of sugar linkages and oxidation of quinol to quinone as observed for plumbagin, an orange pigment identified in *Plumbago capensis* [16, 53–55].



X



XI

Xanthones (C_6—C_1—C_6) are a class of plant phenolics occurring in a few higher plant families (Gentianaceae, Guttiferae, Loganiaceae, Podostemaceae, and Polygalaceae); therefore, they have a high taxonomic value in such families. The majority of natural xanthones have been found in just two families of higher plants, Guttiferae and Gentianaceae. Xanthones may be classified into five major groups: simple oxygenated xanthones (this group can further be subdivides into six groups according to the degree of oxygenation), xanthone glycosides, prenylated and related xanthones, xanthonolignoids, and miscellaneous. As far as the biosynthetic pathways to xanthones is concerned, ring A and attached carbonyl group are provided by the shikimic acid pathway, whereas ring B arises via the acetate-malonate polyketide route. Mangiferin is unique among the natural xanthones in having a much wider natural occurrence than that of any of the others. This 2-*C*-glucoside of 1,3,6,7-tetrahydroxyxanthone was first found in the leaves of *Mangifera indica*. It has since been found in many ferns and angiosperms such as *Asplenium* spp., *Hypericum* spp., *Cratoxylum pruniflorum*, *Senecio* spp., and *Dahlia* spp. [56–59].

The members of the stilbene family have the C_6—C_2—C_6 structure and are widely distributed in the plant kingdom, although some structures are characteristic of particular plant families. They are found in liverworts, in some ferns, in gymnosperms, and in many dicotyledonous angiosperms, ranging from the unsubstituted *trans*-stilbene from *Alnus* and *Petiveria* to the hexasubstituted combretastatin A-1 from *Combretum caffrum* [60]. There are also increasing numbers of reports of prenylated stilbenes, stilbene glycosides, and polymeric stilbenes. Stilbenes are biosynthesized via phenylpropanoid-polymalonate pathway. The first part of the pathway is common to both stilbenoids and flavonoids, the two biosynthetic routes diverging at the point of cyclization of a styryl-3,5,7-triketoheptanoic acid (Scheme 50.2). A C-acylation produces a chalcone, and subsequent modifications lead to the flavonoids, while an aldol condensation of the same intermediate polyketide produces a stilbene-2-carboxylic acid that is an unstable intermediate in pathways to a range of stilbenoids [61]. The main physiological roles of stilbenes include those of phytoalexins and growth regulators. Preexisting stilbenes may help to protect plant tissues from the attack by fungi, insects, and other organisms. In addition, synthesis of a number of antifungal stilbenes can be induced by infections by appropriate organisms, or by a number of abiotic stimuli such as UV light. These stilbene phytoalexins include resveratrol and its derivatives (**XII**) in *Trifolium*, *Arachis*, and members of Vitaceae [54].

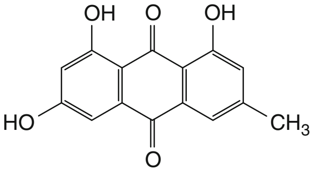
The tricyclic C_6—C_2—C_6 anthraquinones represent the largest group of natural quinones, and a wealth of structures with varying numbers of hydroxyl groups and other substituents have been identified. More than half of the natural anthraquinones are found in lower fungi, particularly in *Penicillium* and *Aspergillus* species, and in lichens. Over 200 structures have been found in flowering plants, especially in the families of Leguminosae, Liliaceae, Polygonaceae, Rhamnaceae, Rubiaceae, and Scrophulariaceae. Anthraquinones have been encountered in all parts and organs of plants. Thus, they have been isolated from leaves and stems, pods, seed coats, and embryos of *Cassia* plants and from leaves and roots of *Digitalis* spp. Anthraquinones may either be formed via the acetate-malonate pathway in Polygonaceae and Rhamnaceae or *O*-succinylbenzoic acid in the Bignoniaceae and Verbenaceae. In plants, anthraquinones are mostly present as glycosides but the free aglycones are widely distributed as well. Among the most common naturally occurring anthraquinone aglycones in higher plants are emodin (**XIII**), rhein, chrysophanol, aloe-emodin, and physcion. The anthraquinone emodin (1,3,8-trihydroxy-6-methylanthraquinone), mainly reported in three plant families, Fabaceae

(*Cassia* spp.), Polygonaceae (*Rheum*, *Rumex*, and *Polygonum* spp.), and Rhamnaceae (*Rhamnus* and *Ventilago* spp.), is present in both vegetative organs (stem, foliage) as well as in reproductive organs (flower, fruit, seeds, pods) [16, 62, 63].



XIII

Flavonoids and their conjugates form a very large group of natural products; over 8,000 different flavonoids have been identified. They are found in many plant tissues, where they are present inside the cells or on the surfaces of different plant organs. The chemical structures of this class of compounds are based on a C_6—C_3—C_6 skeleton. Depending on the position of the linkage of the aromatic ring to the benzopyrano (chromano) moiety, this group of natural products may be divided into three classes: the flavonoids (2-phenylbenzopyrans), the isoflavonoids (3-benzopyrans), and the neoflavonoids (4-benzopyrans). In addition, these chemical structures may differ in the saturation of the heteroatomic ring C and in the overall hydroxylation patterns. All these groups usually share a common chalcone precursor and, therefore, are biogenetically and structurally related. The flavonoids may be modified by hydroxylation, methoxylation, or *O*-glycosylation of hydroxyl groups as well as *C*-glycosylation directly to carbon atom of the flavonoid skeleton. In addition, alkyl groups (often prenyls) may be covalently attached to the flavonoid moieties, and sometimes additional rings are condensed to the basic skeleton of the flavonoid core. Various subgroups of flavonoids are classified according to both the substitution pattern and the degree of oxidation and saturation present in the heterocyclic C-ring. The flavonoids *sensu stricto* may be divided into 13 subgroups (Fig. 50.2), while isoflavonoids are subdivided into 11 subgroups (Fig. 50.3). The neoflavonoids, structurally and biogenetically closely related to the flavonoids and the isoflavonoids, comprise the 4-arylcoumarins (4-aryl-2*H*-1-benzopyran-2-ones), 3,4-dihydro-4-arylcoumarins, and neoflavenes [35, 39, 64–69].

Together with the proanthocyanidins, the bi- and triflavonoids constitute the two major classes of complex C_6—C_3—C_6 plant phenolics. These compounds arise from the oxidative coupling of various flavonoid structures and thus predominantly possess a carbonyl group at C-4 or its equivalent in every constituent unit. Anyhow, it should be emphasized that the terms bi- and triflavonoids are used loosely and that there is no commonly accepted trivial nomenclature for these classes of flavonoids. A multitude of compounds that do not arise via the phenol oxidative coupling of monomeric flavonoid structures possessing C-4 carbonyl functional groups are also classified as bi- and triflavonoids. For example, the bichalcone (**XIV**) isolated from *Dorstenia zenkeri* is a biflavonoid generated via an intramolecular Diels-Alder process [70].

Lignans and neolignans (C_6—C_3)$_2$ are a large and varied group of plant phenolics produced by the oxidative dimerization of two phenylpropanoid units, which occur in a wide range of plant species. For the purpose of numbering the various parent structures, the C_6—C_3 unit is numbered 1–9 where the α position is the 9, β is the 8, and γ is the 7. When the two C_6—C_3 units are linked by a β,β′-bond (or 8,8′-bond), the parent structure lignane is used as the basis for naming the lignan. If the two C_6—C_3 units are linked by a bond other than a β,β′-bond, the parent structure, neolignane, is used as the basis for naming the neolignan (Fig. 50.4) [71]. (+)-Pinoresinol (**XV**), for example, is a lignan derived by a tail-to-tail linkage in the β-position of two coniferyl alcohol residues, which has been extracted from various plant sources such as *Saussurea medusa*, *Pinus*, and *Picea*. Related dimers, called neolignans, can be formed by other condensations between two C_6—C_3 units, for example, joining head-to-tail

The plant *tannins* are a unique group of phenolic compounds of relatively high molecular weight which have the ability to complex strongly with carbohydrates and proteins. The name “tannin” is derived from the French “tanin” (tanning substance) and is used for a range of natural polyphenols. Probably the most acceptable definition of vegetable tannins is still that of Bate-Smith and Swain, formulated in 1962. They adopted the earlier ideas of White and classified these higher plant metabolites as “water-soluble phenolic compounds having molecular weights between 500 and 3,000 and, besides giving the usual phenolic reactions, they have special properties such as the ability to precipitate alkaloids, gelatin and other proteins.” In higher plants, tannins consist of two major groups of metabolites: the hydrolyzable tannins and condensed tannins. More recently, a third class of tannin, the phlorotannins, has been isolated in several genera of algae. Hydrolyzable tannins are split by acids, bases, and in some cases by hydrolytic enzymes (tannase) into sugars (usually D-glucose) or related polyols and a phenolic acid. In the case of gallotannins, this is gallic acid, and the vegetable tannins are simply polygalloyl esters. Ellagitannins (**XVII**) can be defined in a narrow sense as hexahydroxydiphenoyl esters of carbohydrates or cyclitols. When the hexahydroxydiphenoyl group is cleaved from the molecule, the parent acid rapidly lactonizes to yield the insoluble dilactone ellagic acid. The oligomeric and polymeric proanthocyanidins (*syn*. condensed tannins) (**XVIII**) constitute one of the most ubiquitous groups of all plant phenolics.

The proanthocyanidins usually originate by coupling at C-4 (C-ring) of an electrophilic flavanyl unit, presumably generated from a flavan-3,4-diol or a flavan-4-ol, most commonly to C-8 or C-6 (A-ring) of a nucleophilic flavanyl unit, for example, a flavan-3-ol. This classification of the two major groups of tannins suggested by Freudenberg, based on structural considerations, also represents a subdivision based on biogenetic origins: proanthocyanidins are products of the flavonoid pathway of biosynthesis (polyketide and cinnamate) and gallo- and ellagitannins are both derived from the shikimate pathway. Phlorotannins consist of phloroglucinol units linked to each other in various ways and are of wide occurrence among marine organisms, especially brown and red algae. Based on the means of linkage, phlorotannins can be classified into four subclasses, namely, phlorotannins (i) with an ether linkage (fuhalols and phlorethols), (ii) with a phenyl linkage (fucols), (iii) with an ether and a phenyl linkage (fucophlorethols), and (iv) with a dibenzodioxin linkage (eckols and carmalols). 3-Phloroeckol (**XIX**), isolated from *Eisenia arborea*, is an example of phlorotannins with a dibenzodioxin linkage [37, 74–81].

Lignin (Latin: *lignum* = wood) [$(C_6—C_3)_n$], the essential structural polymer of wood and second only to cellulose as the most abundant organic substance in plants, is found as an integral cell wall constituent of all vascular plants including herbaceous species. Gymnosperm lignins are primarily derived from coniferyl alcohol and, to a lesser extent, *p*-coumaryl alcohol, whereas angiosperms contain coniferyl and sinapyl alcohols in roughly equal proportions. As a biomacromolecule, lignin is unusual in having a complex network-type structure that at a first glance appears chaotic. In fact, it is optically inactive. "Normal" biomolecules, such as cellulose and proteins, generally are synthesized in the active site of an enzyme (or enzyme complex) in nucleotide triphosphate-driven condensations, and the polymers formed have very defined structures. It is unlikely that lignin is synthesized in this way. First, lignin polymerization from monolignols is not a condensation. Second, many different types of bonds connect the monolignol residues in a somewhat random pattern. Third, lignin is racemic, which does not accord with enzyme-controlled biosynthesis.

As far as in vivo formation of lignins is concerned, investigators originally proposed that monolignols were transported into the cell walls and that the only subsequent enzymatic requirement for biopolymer formation was the one-electron oxidation of the monolignols to give the corresponding free radical intermediates. The free radical intermediates formed by oxidation were initially believed to couple together in a manner requiring no further enzymatic control or input. These nonenzymatic free radical coupling reactions were thought to generate dimeric lignan structures that underwent further reoxidation and coupling to yield the lignin biopolymer. Freudenberg [82] demonstrated in a classic work that a polymer with the same types of chemical bonds as those in lignin could be obtained through the oxidation of coniferyl alcohol to resonance-stabilized radicals by a peroxidase. He suggested that the coupling of two unpaired electrons formed the covalent bonds. The polymerization could continue if a phenolic group on the lignin polymer became oxidized to a radical, either by a peroxidase or by a peroxidase-generated monolignol radical, and the phenolic radical on the polymer underwent coupling to a second monolignol radical. According to this model, nature's second most abundant substance is the only natural product for which its formation is not under enzymatic control. However, although it is rarely recognized, natural and synthetic lignins differ in terms of bonding frequency, bonding type, and macromolecular size. For example, for lignins in vivo, the 8–*O*–4′ interunit linkage predominates (more than 50%), with the 8–5′ substructure found in much lower amounts (about 9–12%). In contrast, in synthetic *in vitro* preparations, the 8–*O*–4′ substructure is present to only a very small extent, and the 8–5′ and 8–8′ linkages predominate [83–85]. Currently, there are two models for coupling radicals to produce a functional lignin molecule. One, the random coupling model, which emerged during the early studies on the structure of lignin, centers on the hypothesis that since lignins are not optically active, the optical centers must be generated randomly, that is, under simple chemical control, and then lignin formation proceeds through coupling of individual monolignols to the growing lignin polymer in a near-random fashion. In this view, the amount and type of individual phenolics available at the lignification site and normal chemical coupling properties regulate lignin formation (Fig. 50.5) [86, 87]. The second model, the dirigent protein model proposed by Lewis group, is more recent and suggests that a protein putatively harboring an array of dirigent (monolignol radical binding) sites assembles primary lignin chains. Such chains are then hypothesized to act as templates for replication of the chain. The rationale for this new model is the belief that nature would not leave the formation of such an important molecule as lignin "to chance." It is argued that the only way to explain the high proportion of 8—*O*—4 linkages in lignin would be through regulation by specific dirigent proteins [88, 89].

Suberin is an example of hydroxycinnamic acid-derived polymer that comprises both a poly(aliphatic) and a poly(aromatic) lignin-like domain. Suberized tissues are formed as multilamellar domains consisting of alternating polyaliphatic and polyaromatic layers. The aliphatic domain (aliphatic suberin) consists of a glycerol-based fatty acid–derived polyester that, on transesterification, releases small amounts of p-hydroxycinnamic acid (mainly ferulic) together with aliphatic monomers and glycerol. The major aliphatic constituents are esterified ω-hydroxy fatty acids and 1,ω-dicarboxylic acids. Structural knowledge of the aromatic part is not well established. Although it has been reported that esterified hydroxycinnamic acids are the major constitutive components, a lignin-like polymer of oxidatively cross-linked phenolics has also been postulated for the polyaromatic domain. Suberin is an abundant, complex, intractable plant cell wall polymeric network that forms both protective and wound-healing layers. Suberin is found in specialized plant cell walls (e.g., in dermal tissues of most underground plant organs, the periderm of aerial tissues that undergo secondary thickening, and the Casparian band of the endodermis), where it is laid down between the primary wall and plasmalemma. It is essential for water retention by plants and functions in the overall control of water movement through the apoplastic stream, as well as in providing a physical barrier to opportunistic pathogens. From an evolutionary perspective, suberization was of utmost importance in plant adaptation to living on land and may even have preceded lignifications [90–93].

Finally, melanins are pigments of high molecular weight formed by the oxidative polymerization of phenolic compounds and usually are dark brown or black. They are widely distributed in the living world. In general, they are conjugated polymers of ortho-dihydroxyphenols. The individual residues of polymeric melanin likewise contain two *ortho* oxygens. Melanins are among the most stable, insoluble, and resistant biochemical materials, and they enhance the survival and competitive abilities of organism in certain environments. Melanins constitute a mechanism of defense and resistance to stress such as UV radiations, free radicals, gamma rays, dehydration, and extreme temperatures and contribute to the fungal cell wall resistance against hydrolytic enzymes in avoiding cellular lysis. It has also been shown to chelate metal ions, to function as a physiological redox buffer, to provide structural rigidity to cell walls, and to help to store water and ions. The more general

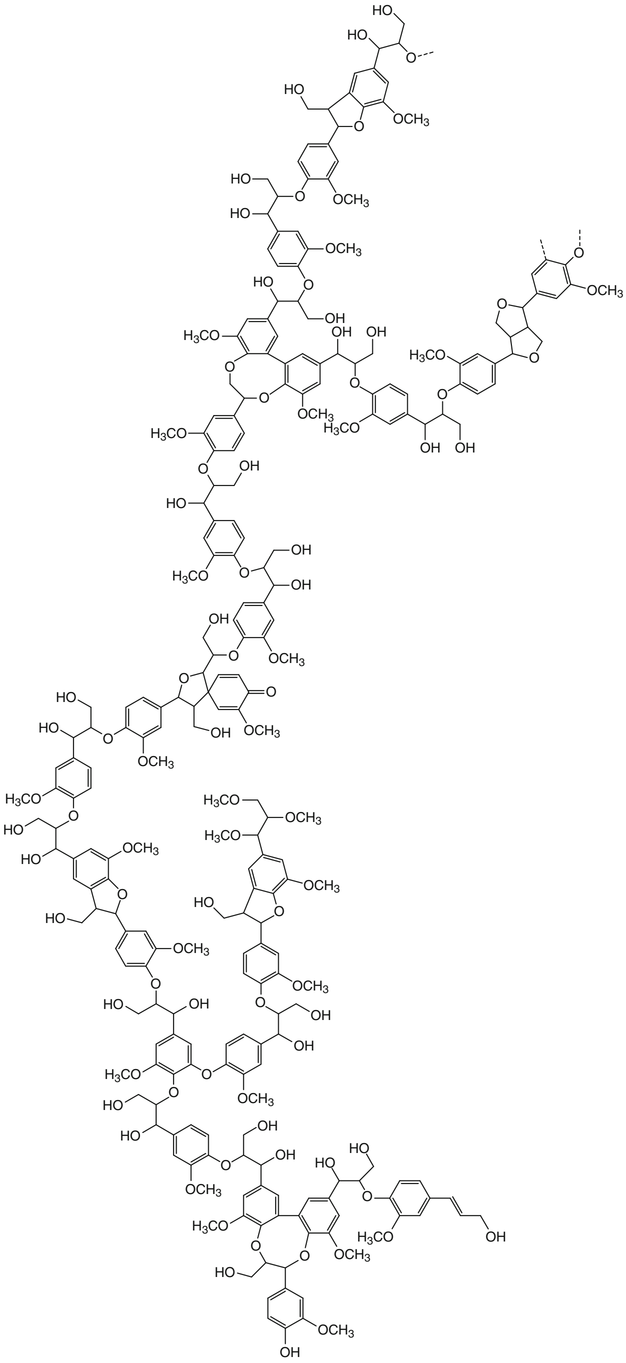

Fig. 50.5 Spruce lignin model (Redrawn from [87])

classification of such compounds, including all their types in pro- and eukaryota, contains three main types of such polymers:

1. Eumelanins (black or brown) that are produced in the course of oxidation of tyrosine (and/or phenylalanine) to 3,4-dihydroxyphenylalanine (DOPA) and dopaquinone, which further undergoes cyclization to 5,6-dihydroxyindole or 5,6-dihydroxyindole- 2-carboxylic acid
2. Pheomelanins (yellow, red, or brown) that are initially synthesized just like eumelanins, but DOPA undergoes cysteinylation, directly or by the mediation of glutathione, then polymerizes
3. Allomelanins (black), the most heterogeneous group of polymers, which emerge through oxidation/polymerization of dihydroxynaphthalene or tetrahydroxynaphthalene, homogentisic acid, γ-glutaminyl-4-hydroxybenzene, 4-hydroxyphenylacetic acid, as well as of catechols

The eumelanins and pheomelanins are found mainly in animal species, whereas the allomelanins are found in plants. For example, they constitute an important part of the black protective coating of many ripe seeds, such as seeds of sunflower and watermelon, and fungi, where they are found primarily in the gills and spores, as in mushrooms or in the black hyphae of molds. The characteristic feature of allomelanins is that they appear to be polymers of simple phenols, such as catechol, and their quinones and are considered as catechol melanins [$(C_6)_n$]. The available evidence indicates that, in the presence of the enzyme polyphenol oxidase (PPOs, EC 1.14.18.1 and EC 1.10.3.1), extensive condensation may occur between catechol units in various stages of oxidation to give polymeric structures in which the monomeric units are joined by C—C and C—O linkages, for example, partial structures such as (**XX**). Broadly, since the polymerization does not follow a precise pattern, as does the synthesis of most other biopolymers, a given sample of melanin contains molecules with various structures; therefore any diagramed structure represents an oversimplification. However, catechol also appears to be the main degradation product of plant allomelanins. The allomelanin of the fungi *Aspergillus niger*, *Ustilago maydis*, and *Daldinia* appears to contain perylene (**XXI**) units derived from 1,8-dihydroxynaphthalene (**XXII**) [94–99].

XXII

Unless they are completely esterified, etherified, or glycosylated, plant phenolics are normally soluble in polar organic solvents. Most phenolic glycosides are water-soluble, but the corresponding aglycones are usually less so. With a few exceptions, water solubility increases with the number of hydroxyl groups present. Some phenolics are solubilized by sodium hydroxide and sodium carbonate, but in alkaline media their oxidation is enhanced, and therefore treatment with alkaline solvents should either be performed under N_2 or, preferably, avoided. Phenolics with only a few hydroxyl groups are soluble in ether, chloroform, ethyl acetate, methanol, and ethanol. Methanol, ethanol, water, and alcohol–water mixtures are most commonly used for dissolving phenolic compounds for analytical purposes. All phenolic compounds exhibit intense absorption in the UV region of the spectrum and those that are colored absorb strongly in the visible region as well. Each class of phenolic compounds has distinctive absorption characteristics. For example, phenols and phenolic acids show spectral maxima in the range 250–290 nm, cinnamic acid derivatives have principal maxima in the range 290–330 nm, flavones and flavonols exhibit absorption bands of approximately the same intensity at about 250 and 350 nm, chalcones and aurones have an absorption peak of high intensity above 350 nm and a much less intense band at 250 nm, and anthocyanins and betacyanins show rather similar absorption in the visible region (475–560 nm and 535–545 nm, respectively) and a subsidiary peak at about 270–275 nm [14, 100–102].

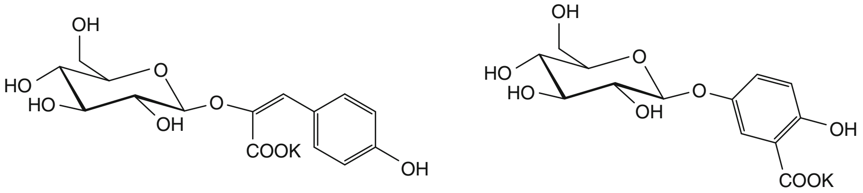
3 Physiological and Ecological Role of Plant Phenolics

The highly ordered interactions between plants and their biotic and abiotic environments have been a major driving force behind the emergence of specific natural products. In this connection, the accumulation of phenolics in plant tissues is considered a common adaptive response of plants to adverse environmental conditions, therefore increasing evolutionary fitness. Plant phenolics are considered to have a key role as defense compounds when environmental stresses, such as high light, low temperatures, pathogen infection, herbivores, and nutrient deficiency, can lead to increased production of free radicals and other oxidative species in plants. A growing body of evidence suggests that plants respond to these biotic and abiotic stress factors by increasing their capacity to scavenge reactive oxygen species. The induction of secondary metabolism gene expression by biotic and abiotic stress is often mediated by integrating signaling molecules such as salicylic acid, jasmonic acid, and their derivatives [8, 103, 104].

Nonfreezing low temperature stress on phenolics metabolism has been considered in several papers. These studies have shown that the phenolic metabolism is enhanced under chill stress and that the behavior of the same metabolism is further dependent on the storage temperature. There is a low critical temperature below which an increase of phenolic metabolism is stimulated, and this temperature is related to the threshold temperature at which chilling injury is also induced. It has been also observed that the low temperature effect involves a cold-induced stimulation of the phenylalanine ammonia-lyase activity (PAL, EC 4.3.1.5) as well as other enzymes important in the phenolic biosynthetic pathway. Cold treatments caused an increase in levels of hydroxycinnamic acid derivatives in artichoke heads (*Cynara cardunculus L.* subsp. *scolymus (L.) Hayek*) as well as of phloretin and quercetin glycosides in Golden Delicious apples (*Malus domestica* Borkh). These responses in phenolic metabolism to low temperature (increase in the activity of the enzymes, as well as in the level of phenolic compounds) could combine with the temperature-dependent phase changes in the cellular membrane, to affect the shelf life of stored fruit and vegetables by providing an adequate substrate to the browning reactions [105–107].

Plant growth depends on the supply of recycled nutrients; external nutrient inputs generally contribute only with a minor proportion to the total requirement. Nutrient mineralization by soil microorganisms is generally viewed as the rate-limiting step in the nutrient cycle, and the factors involved in the control of this process include climate, substrate (litter) quality, and decomposer organisms. Polyphenols, which enter the soil mainly as leachates from above- and belowground parts of plants and/or within above- and belowground plant litter, have been recognized as regulators of soil processes, where it has been suggested that they could control the pool and the form of nutrients available for plants and/or microbes. For example, phenolic compounds can directly affect the composition and activity of decomposer communities, thus influencing the rates of decomposition and nutrient cycling. Different types of soluble polyphenols, such as ferulic acid, gallic acid, or flavonoids, have been found to either stimulate or inhibit spore germination and hyphal growth of saprotrophic fungi. Plant mycorrhizal infection, nutrient uptake, and plant growth can be impaired by specific phenolics released by competitors in a process referred to as allelopathy [10]. Furthermore, plants depend on the ability of roots to communicate with microbes. The converse is also true; many bacteria and fungi are dependent on associations with plants that are often regulated by root exudates. For example, isoflavonoids and flavonoids present in the root exudates of a variety of leguminous plants activate the rhizobium genes responsible for the nodulation process and might be responsible for vesicular–arbuscular mycorrhiza colonization. Nodule formation is initiated by the host plant roots exuding phenolic flavonoid compounds into the rhizosphere. The exudate partly determines the specificity of the symbiotic relationship as each rhizobia species responds to specific flavonoids. The flavonoid perception attracts the bacteria to the root and activates the rhizobia *nod* (nodulation) gene expression, leading to the production and secretion of strain-specific lipo-chito-oligosaccharides, also known as nod factors (NF). NFs have an oligosaccharide backbone of *N*-acetyl-D-glucosamine units with a fatty acyl group attached to the nonreducing sugar. A major determinant of host–symbiont specificity is attributed to the different NF substituents attached to the oligosaccharide backbone. The presence of compatible rhizobia species and their corresponding NF is generally sufficient to trigger nodule development [108–111].

In general, plants are rooted and are unable to demonstrate mobility. However, a variety of plants are able to move in certain ways. Some plants are known to open their leaves in the daytime and "sleep" at night with their leaves folded. This circadian rhythmic leaf movement known as nyctinasty is widely observed in



Potassium lespedezate
(Leaf-opening compound)

Potassium 5-*O*-β-D-glucopyranosyl gentisate
(Leaf-closing compound)

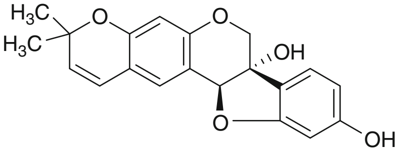
Fig. 50.6 Leaf-movement factors from nyctinastic plants

leguminous plants. Nyctinastic leaf movement is induced by the swelling and shrinking of motor cells in the pulvinus, an organ located in the joint of the leaf. A flux of potassium ions across the plasma membranes of the motor cells is followed by a massive water flux, which results in the swelling and shrinking of these cells. At the heart of such a mechanism is the regulation of the opening and closing of the potassium channels involved in the nyctinastic leaf movement, a process which is under metabolic control. Many attempts have been made to isolate the endogenous bioactive substances that control nyctinasty. It has been found that nyctinastic plants have a pair of endogenous bioactive substances that control the nyctinastic leaf movement. One of these is a leaf-opening factor that “awakens” the plant leaves, and the other is a leaf-closing factor that reverses this process so that the plant leaves “sleep.” Figure 50.6 shows a pair of bioactive substances showing a phenolic structure. Five sets of leaf-closing and -opening factors in five different nyctinastic plants have been identified. All the leaf-opening factors have a common structural feature, the *p*-coumaroyl moiety, and this result suggests that this structural feature would be deeply involved in the common mechanism for leaf-opening [112–114].

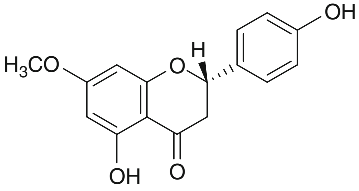
Anthocyanins represent a class of flavonoids providing the red and blue/purple colors familiar in many flowers and fruits. These compounds are synthesized as visual cues, to attract pollinators and other animals for seed dispersal, as well as molecular cues protecting plants from various stress conditions, and are stored in the acidic vacuole of specialized cells. Anthocyanins are also the pigments responsible for spectacular displays of variable red to reddish-orange color in the leaves of deciduous trees. Leaf color change is not simply a side effect of leaf senescence, and, in the past decade, several hypotheses have emerged to explain the evolution of autumn colors. Autumn colors are due mainly to carotenoids (yellow-orange) and anthocyanins (red-purple). Although carotenoids are present all year round in the leaves, they are masked in mature leaves by the green of chlorophyll; in autumn, they become visible because of the breakdown of green chlorophyll molecules into colorless metabolites, but there is no evidence for a de novo synthesis. Anthocyanins, by contrast, are newly generated in autumn, shortly before the leaf fall. Thus, red is produced actively in autumn and is not simply the side effect of leaf senescence. Why leaves that are about to be shed turn red? The adaptive value of the autumn colors of leaves is still a matter of controversy. Red may protect the leaf from the damaging effects of light at low temperatures (photoinhibition and photooxidation), allowing a more efficient resorption of nutrients, especially nitrogen (“photoprotection theory”). Alternatively, red might be a warning signal of the status of the tree (indicating high levels of defenses or low nutritional capacity) to animals, particularly feeding insects like aphids (“coevolution theory”). During winter, the combination of cold, dry, and bright sunlight conditions can result in excess energy capture relative to processing, photoinhibition of photosynthesis, formation of ROS, and greater photooxidative damage. Red pigments are thought to alleviate these stress factors by intercepting green sunlight (light attenuation) and/or neutralizing ROS directly as antioxidants. On the other hand, recent studies on autumn and juvenile leaves suggest that red pigments reduce the leaf damage either by making leaves less palatable or less visible to animals lacking a red visual receptor (camouflage) or by signaling a low leaf quality. According to the coevolution theory, red is a signal of the status of the tree to insects that migrate to (or move among) the trees in autumn. Migrating insects avoid red leaves and colonize preferentially green leaves. Trees with red leaves have better chemical defenses or a worst nutritional capacity that induces a lower fitness in the insects. In this scenario, therefore, color and preference coevolve in an arms race: autumn colors are an adaptation of the trees to reduce their parasite load, and insect preference for green is an adaptation to find the most suitable host trees [115–120].

Plants encounter numerous pests and pathogens in the natural environment. An appropriate response to the attack by such organisms can lead to tolerance or resistance mechanisms that enable the plant to survive. Resistance mechanisms refer to traits that inhibit or limit attack, while tolerance strategies do not limit attack but reduce or offset consequences on the plant fitness by adjusting its physiology to buffer the effects of herbivory or diseases. In this connection, plants produce a broad range of phenolic metabolites that serve a dual function of both repelling and attracting different organisms in the plant’s surroundings. The role of plant phenolics in chemoecology, especially on the feeding behavior of herbivores, has been recognized since 1959 when Fraenkel [121] described phenolic compounds as “trigger” substances, which induce or prevent the uptake of nutrients by animal herbivores. They act as protective agents, inhibitors, natural animal toxicants, and pesticides against invading organisms, that is, herbivores, nematodes, phytophagous insects, and fungal and bacterial pathogens [54, 122, 123]. Preformed antibiotic compounds that occur constitutively in healthy plants are likely to represent inbuilt chemical barriers to herbivorous and fungal enemies and may protect plants against attacks by a wide range of potential pests and pathogens. In contrast, induced defense compounds are synthesized in response to biotic stresses as a part of the plant defense response. These induced defense mechanisms are expressed at the site of attack (hypersensitive response) as well as at a distance (signaled by salicylates, jasmonates) from the site of primary infection and protect the plant from the spread of infection and future attacks. Induced resistance is regulated by a network of interconnecting signal transduction pathways in which phenolic acids are key signaling molecules [124, 125].

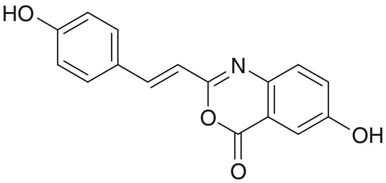
In an environment rich in potentially harmful microbes, plant survival depends on an efficient microbe perception and fast defense responses. Plant immunity relies on the ability of each cell to recognize pathogens. A first level of microbe recognition is performed by membrane proteins termed pattern recognition receptors (PRRs), which perceive the molecular signatures characteristic of a whole class of microbes, termed pathogen-associated molecular patterns (PAMPs). Phenolics are synthesized when plant PRRs recognize potential pathogens by conserved PAMPs, leading to a PAMP-triggered immunity [126–132]. The plant's recognition of pathogens induces its endogenous multicomponent defense system. The multicomponent defense response induced after the pathogen attack requires a substantial commitment of the cellular resources, including extensive genetic reprogramming, because the induced expression of a large number of defense-related genes is essential for plants to counter the pathogen attack. Many defense-related genes encode enzymes that catalyze defense metabolites, known as phytoalexins, for example, antimicrobial, low-molecular-weight secondary metabolites that are both synthesized by and accumulated in plant cells as a result of the interaction between the metabolic systems of the host and a fungal parasite. The structures of the phytoalexins are often unique at the family level: the majority of phytoalexins produced by the members of the family Leguminosae are isoflavonoids, and the commonest isoflavonoid subclass is the pterocarpans such as medicarpin and glyceollin II (**XXIII**), whereas phytoalexins from Vitaceae seem to constitute a rather restricted group of molecules belonging to the stilbene family, the skeleton of which is based on the *trans*-resveratrol structure (3,5,4′-trihydroxystilbene). Dicotyledonous species represent the majority of plants from which such compounds have been identified. Some monocotyledonous species producing phenolic phytoalexins are rice (*Oryza sativa*) (sakuranetin, **XXIV**), oat (*Avena sativa*) (avenalumin I, **XXV**), and sorghum (*Sorghum bicolor*) (3-deoxyanthocyanidins). Sorghum phytoalexins have been identified as 3-deoxyanthocyanidins: luteolinidin, 5-methoxyluteolinidin, apigeninidin, caffeic acid ester of arabinosyl 5-*O*-apigeninidin (**XXVI**), and 7-methoxyapigeninidin [36, 54].



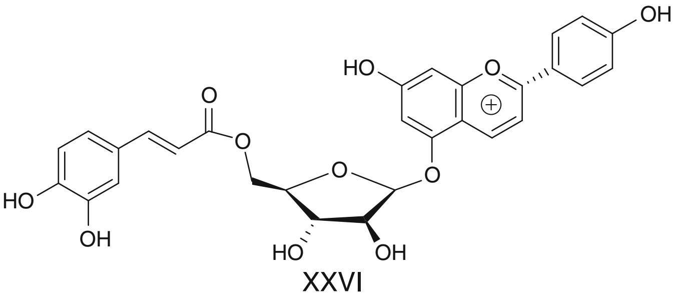
XXIII



XXIV



XXV



XXVI

The ecological relationship between plants and insects is a complex one with physical as well as chemical interactions. This relationship is also affected by plant factors, insect factors, and by some insect–plant factors, including hypersensitive reaction and plant resistance to insect-borne diseases. Plant constituents that make unpalatable a host are secondary metabolites in sufficient concentration to exert an undesirable physiological effect. It is now generally accepted that plant phenolics play a role in protecting plants from insects. For example, some cotton flavonoids are feeding stimulants for the boll weevil, *Anthonomus grandis* [133], or oviposition stimulants of a *Citrus*-feeding swallowtail butterfly, *Papilio xuthus* L. [134] or, finally, antibiotics effective against phytophagous insects [135]. Tannins, also, may affect the growth of insects in three main ways: they have an astringent taste which affects palatability and decreases feed consumption; they combine with proteins to form complexes of reduced digestibility; and they act as enzyme inactivators. Recent work by Raymond Barbehenn and coworkers about tannin oxidation in insects suggests that tannin activity cannot be explained quite this simply, as tannin oxidation should also be taken into account as a defense mechanism for plants [136–138].

4 Carbon Fluxes from the Primary to the Secondary Metabolic Pathways

Chemical defenses represent a main trait of the plant innate immune system. Besides regulating the relationship between plants and their ecosystems, plant phenolics are involved both in resistance against pests and pathogens and in tolerance toward abiotic stresses. Both biotic and abiotic stresses stimulate carbon fluxes from the primary to the secondary metabolic pathways, thus inducing a shift of the available resources in favor of the synthesis of secondary products, for example, reallocation of host resources. Therefore, defensive chemicals are considered to be costly for plants, reducing the fitness of the host in the absence of disease, because resistance genes might impose metabolic costs on plants (e.g., lower growth rates than their sensitive counterparts) [18]. When resistant genotypes have relatively low fitness in the absence of pests, it is often assumed that their poor performance must be explained by the energetic drain involved in building and maintaining a chemical or structural defense, metal hyperaccumulation, and temporal or spatial escape: all these mechanisms include allocation costs (the costs due to diversion of limited energy and resources away from primary metabolism), storage costs, ecological (i.e., environmental) costs (negative effects of resistance on one of the myriad of interactions between a plant and its environment that affect a plant's fitness under natural growing condition), etc. One way for a plant to reduce these costs is to synthesize defense compounds only after there has been some degree of initial damage by a pathogen or insect: this strategy is inherently risky because the initial attack may be too rapid or too severe for an effective defense response. Therefore, plants that are likely to suffer frequent and/or serious damage may be better off investing mainly in constitutive defenses, whereas plants that are attacked rarely may rely predominantly on induced defenses [139–142].

The negative correlation between concentrations of secondary metabolites and plant growth rate is assumed to indicate a trade-off between plant growth and the production of defensive compounds. Plants, in fact, have limited resources to support their physiological processes; hence, all requirements cannot be met simultaneously and more carbon is diverted from growth toward secondary metabolism when plant growth is restricted by any physiological and/or ecological constraint.

An interesting link between primary and secondary metabolism has been recently proposed by Lattanzio et al. [143] which couples the accumulation of the stress metabolite proline with the energy transfer toward phenylpropanoid biosynthesis via the oxidative pentose phosphate pathway [144] (Fig. 50.7). In many plants, free proline accumulates in response to the imposition of a wide range of biotic and abiotic stresses, such as water deprivation, salinization, high/low temperature stress, heavy metal toxicity, pathogen infection, nutrient deficiency, atmospheric pollution, and UV irradiation. In this connection, it has been also suggested that the value of stress-induced proline accumulation may be mediated largely *via* the effects of its synthesis and degradation on cellular metabolism [145–148]. Proline synthesis is accompanied by the oxidation of NADPH. An increased $NADP^+$/NADPH ratio is likely to enhance the activity of the oxidative pentose phosphate pathway providing precursors for the phenolic biosynthesis via the shikimic acid pathway. The alternating oxidation of NADPH by proline synthesis and reduction of $NADP^+$ by the two oxidative steps of the oxidative pentose phosphate pathway serve to link both pathways and thereby facilitate the continuation of high rates of proline synthesis during stress and lead to a simultaneous accumulation of phenolic compounds.

Furthermore, it has been also shown that an exogenous application of proline to the nutrient medium of *in vitro* grown oregano plants elicited the accumulation of rosmarinic acid and other phenolic compounds in that plant. This suggests that mitochondrial proline oxidation could drive the oxidative pentose phosphate pathway by recycling glutamic acid into the cytosol to generate a proline redox cycle.

5 Conclusions

(Poly)phenols are plant secondary metabolites that constitute one of the most common and widespread groups of substances in plants. They constitute a large reservoir of natural chemical diversity that encompasses an enormous range of compounds and enzymes and a wide spectrum of mechanisms of gene regulation and of transport of metabolites and enzymes. Levels of phenolic compounds in plants are both environmentally induced as well as genetically controlled. Despite a basic knowledge of the main biosynthetic pathways, some open questions, such as the biosynthesis, the intracellular transport, and functions of plant phenolics, need additional study. Until now, it appears that the phenolic patterns of higher plants have been shaped by a dialog between plants and their environment for the benefits of plants and their better adaptation to external conditions. Plants adapt themselves their phenolic patterns to a changing environment through the emergence of new genes brought about by gene duplication and mutation and subsequent recruitment for adaptation to specific functions. Plants also have the ability to synthesize specific chemical compounds which can act as toxins and deterrents to pathogens/herbivores and other competitors and are also able to attract needed symbionts for procreative purposes. Primary metabolism is an important source of precursors for the synthesis of secondary phenolic metabolites. Central metabolism requires high levels of limited plant resources, and during intense growth, the synthesis of phenolic metabolites may be substrate- and/or energy-limited. On the other hand, either abiotic or biotic stresses divert substantial amounts of substrates from primary metabolism into secondary defensive product formation, and this could lead to constraints on growth. Adjustments in resource allocation are the major mechanism by which plants respond to environmental constraints. The allocation pattern of a plant defines its ecological roles and is therefore an important factor in understanding plant distribution and adaptation. On the other hand, as far as the development of a new strategy to enable the production of useful secondary metabolites on a commercial scale is concerned, any progress made in the basic understanding of metabolic pathways and regulatory mechanisms may be addressed to exploit the plant cell and tissue culture potentials to produce food additives, such as antioxidant phenolics.
