Therefore, it has been suggested that ecdysteroids could be taken as an indicator for taxonomic purposes, even when fluctuations due to organ type, season, and geographical location may be confounding factors. Presence or absence of phytoecdysteroids may be of help in the taxonomic study of mushrooms (e.g., *Paxillus* and *Tapinella*) [17]–[19]. Presence of phytoecdysteroids in parts of higher plants has been linked to their survival efforts. For annual plants depending upon wind pollinating, this means that ecdysteroids will be present in the pollen-containing parts, the seeds, and the young leaves [20].

3 Diversity of Phytoecdysteroids

Several large-scale surveys have been conducted in the past, yielding hundreds of phytoecdysteroid structures. Imai et al. [21] did the first large-scale survey on 1,056 diverse well-identified species. They identified ecdysteroids in 61 of them. Hikino et al. [22] concentrated their efforts on Japanese ferns. Their screening was based upon less specific biological activity testing (instar larvae). This may be the explanation for the high number of positives: 170 of 283 species tested gave positive reactions.

The findings of these screenings are incorporated in the Ecdybase (http://www.ecdybase.org): ecdysteroid agonist as well as antagonist containing plants is listed. In July 2012, the database contained 463 ecdysteroids. Apart from the geographical distribution, also the ecological distribution has been focused upon [13]. The search for phytoecdysteroids in a large variety of plant species remains a research target. Publications about isolation of new entities or known ecdysteroids in newly investigated plant species are published in a large variety of scientific journals. We include here recent examples. *Limnanthes alba* or the white meadowfoam is an established oilseed crop and originated from southern Oregon. Ecdysone, 20-hydroxyecdysone, ponasterone A, and muristerone A were identified by LC-MS/MS in the plant seeds by Stevens et al. [23]. Ecdysteroids were already reported from other species of the *Limnanthaceae*, more particularly *Limnanthes bakeri*, *L. douglasii*, *L. floccosa*, *L. gracilis*, and *L. montana* [24]–[26]. Some other plant genera like *Ajuga* have been particularly studied as a rich source of structurally different phytoecdysteroids. Castro et al. [27] isolated three new phytoecdysteroids from the roots of *Ajuga macrosperma var. breviflora*: ajugacetalsterones C and D and breviflorasterone. Another new phytoecdysteroid, ajugatide E, was isolated from *Ajuga taiwanensis* [28]. New compounds reptanslactone A, reptanslactone B, and sendreisterone were isolated from *Ajuga reptans* as well as the known dehydroprecyasterone and breviflorasterone [29]. Also in *Ajuga remota*, 20-hydroxyecdysone is present. *Ajuga remota* is used as an herbal remedy against malaria in Kenya [30].

Wang et al. [31] isolated five new phytoecdysteroid glycosides from the whole plant *Froelichia floridana*. They were tested against human DNA topoisomerase, but did not show any inhibitory activity. Kumpun et al. [32] recently studied their presence in *Chenopodium quinoa*, an ancient Andean crop with high nutritional value. Besides large amounts of 20-hydroxyecdysone, they found also lower amounts of makisterone A, 24-*epi*-makisterone A, 24(28)-dehydromakisterone A and polypodine B. They also identified three new natural compounds, more particularly 24,25-dehydroinokosterone, 25,27-dehydroinokosterone, and 5β-hydroxy-24(28)-dehydromakisterone A. Ecdysteroids were concentrated in the bran of *Chenopodium quinoa* [32]. Tan et al. [33] identified a less common phytoecdysteroid with a 5α-cholestane skeleton in *Cyanotis arachnoidea*. New phytoecdysteroids were also found in the roots of *Achyranthes bidentata*. These steroids contain a furan ring on an acetonide moiety and are named niuxixinsterone A, B, and C [34]. Brainesterosides A–E were isolated as phytoecdysteroid glycosides from the rhizomes of *Brainea insignis*, along with three known phytoecdysteroids

*Galactoside

(ponasteroside A, ponasterone A, and 20-hydroxyecdysone) [35]. In *Serrulata wolffii*, a wide variety of structurally different ecdysteroids were found: compounds with an extra double bound at position 20(22) (1-hydroxy-20,21-didehydrotaxisterone and 20,22-didehydrotaxisterone), with a furan ring in the side chain (serfurosterone A and B) or with an intramolecular ether function in the side chain (shidasterone derivatives) [36]–[39]. In *Serrulata wolffii*, Ványolós et al. [40] identified still new ecdysteroids with an α-hydroxyl group, structures that are relatively rarely seen among the class of ecdysteroids (3-epi-shidasterone and 3-epi-22-deoxy-20-hydroxyecdysone), as well as ponasterone-22-apioside [40].

All these investigations confirm the position of phytoecdysteroids as important secondary metabolites in plants. The same Hungarian research group found also three new ecdysones in *Polypodium vulgare*: 5-hydroxyecdysone, 20-deoxyshidasterone, and polypodine B 2-β-D-glucoside [41].

The diversity of C27 phytoecdysteroids is illustrated in Tables 127.1 and 127.2 and examples of C28- and C29-phytoecdysteroids are shown in Tables 127.3 and 127.4.

Phytoecdysteroids have common structural features such as C24 to 29C atoms, several hydroxyl substituents, a Δ^7-6-keto grouping in the B ring, a cis junction of the A/B rings, and a side chain usually containing a (R)-C22-OH group. In most cases, phytoecdysteroids are isolated in the free state, although many derivatives such as ethers, esters, and glycosides have been isolated as well.

Most commonly, 1–3 major ecdysteroids will represent about 95 % of the total ecdysteroid in one plant species. As shown in the tables, the minor ecdysteroids form a mixture of ecdysteroid structural analogues.

Tóth and Báthori M [42] described a relatively simple separation procedure for phytoecdysteroids from *Silene viridiflora*. By a purification procedure in four steps, phytoecdysteroids were made available in adequate amounts.

4 Biosyntheses of Phytoecdysteroids

At present, the pathway for the biosynthesis in plants may differ from that in animals. The large number of ecdysteroids found in plants makes it unlikely that we are dealing with a single pathway. In *Polypodium vulgare*, cholesterol is converted to ecdysterone, α-ecdysone, and 5-β-OH-ecdysterone [43]. It is approved that the Δ^7-6-keto grouping and the A/B-cis junction arise at the first stages of the biosynthesis of cholesterol, the hydroxylation in position 14-α proceeding next [44]. It is suggested that in the few ecdysteroids with trans-A/B junctions, an isomerization of the chiral center 5 has occurred [16]. The order of the subsequent introduction of hydroxyl groups into the steroidal moiety and side chain, as well as the side-chain alkylation, does not seem to be strictly determined and changed from one plant family to another [45] (Fig. 127.1).

The *Ajuga* genus is unique for the great variety of phytoecdysteroids, with a broad spectrum of biological and pharmacological actions. They accumulate in various plant organs such as flowers, stems, leaves, roots, and fruits, usually present in small quantities of the order of 0.01–0.1 % of the plant dry weight. The major phytoecdysteroid is 20-hydroxyecdysone, which is also the active molting hormone of insects [46–48].

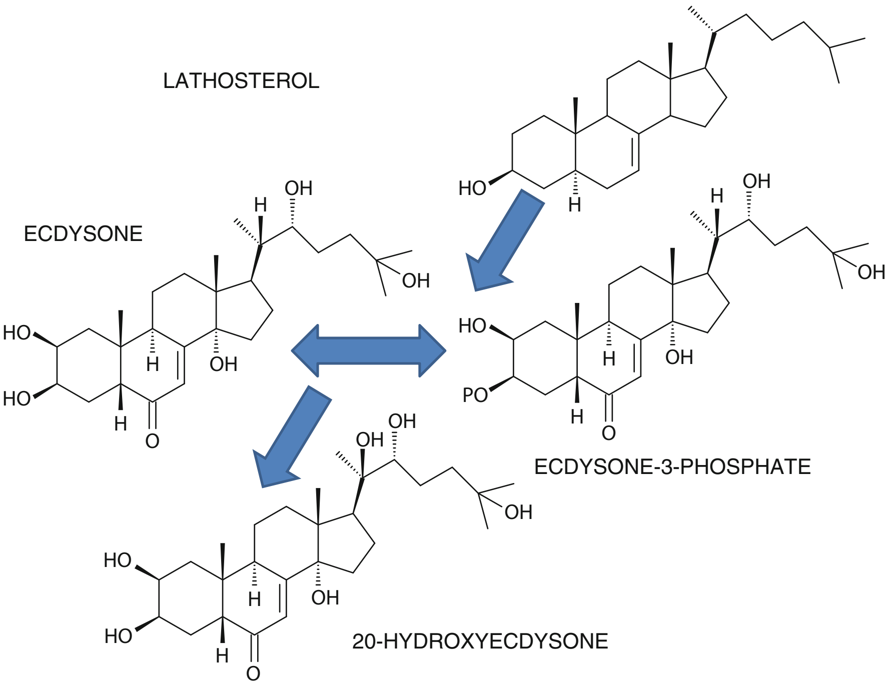

Fig. 127.2 Biosynthesis of spinach (*Spinacia oleracea*) ecdysteroids: the endogenously biosynthesized ecdysone and ecdysone-3-phosphate are converted to 20-hydroxyecdysone [49]

In this biosynthetic scheme, both cholesterol and lathosterol are involved and produce the ecdysteron moiety via 7-dehydro-cholesterol. The intermediate 5,6-epoxide would then be a plausible explanation for the formation of the 6-keto group (Fig. 127.1). Recent evidence suggests that phosphate conjugates are important in the processing or targeting of sterols and ecdysteroids in their biosynthesis in spinach. In animals, ecdysteroids are phosphorylated for excretion for the parent ecdysteroid from the animal gut. In plants, the phosphorylated ecdysteroids appear to be involved in the biosynthetic pathway as shown in Fig. 127.2.

Devarenne et al. [50] incubated radiolabeled [22,23-^{3}H]ecdysone with *Zea mays* leaves. Post-incubation, between 57 and 75 %, of the radiolabeled material recovered was present as unmetabolized [^{3}H]ecdysone. The remaining radioactivity was recovered as [^{3}H]ecdysone diphosphate, [^{3}H]ecdysone phosphate, and polyphosphorylated ecdysone. The same authors found lathosterol and not cholesterol as the preferred precursor to the ecdysteroids in spinach (*Spinacia oleracea*) and hypothesized it being the same situation in *Zea mays*, because it took considerable more time to convert cholesterol into ecdysteroids. Ecdysteroid polyphosphates have a downregulatory effect on the biosynthesis of ecdysteroids. This may lead to a sequestration of lathosterol into the steryl ester pool and subsequently the slow release of this lathosteryl ester for additional biosynthesis of ecdysteroid polyphosphates [50].

5 Functions of Phytoecdysteroids

A number of suggestions have been put forward, but the hypothesis that phytoecdysteroids act as potent deterrents and anti-feeding agents against insects received probably the greatest support.

As secondary plant metabolites, phytoecdysteroids stimulate protein synthesis in plants, activate cell mitosis, and possibly act as plant growth regulators. Ecdysteroids influence signal transduction pathways, similarly to anabolic steroids. They should not bind to cytosolic steroid receptors, but act by membrane-bound receptors [51].

They also protect plants against phytophagous insects either by feeding deterrence or endocrine disruption upon ingestion, which leads to death. The Indian meal moth *Plodia interpunctella* can be taken as an example. A concentration of 200 ppm of phytoecdysteroids in their diet manifested signs of toxicity as a decrease in larval weight, induction of cannibalism, and an increase in mortality, as well as a disruption of development. Minimal structural differences significantly affected the toxicity of phytoecdysteroids, makisterone A being the most toxic [52]. *Bombyx mori* or the silkworm is an example on which phytoecdysteroids have detrimental effects like inhibition of growth and death with or without promoted molting and prothetely. Strangely enough, when silkworms are exposed to low doses of 20-hydroxyecdysone at particular times during their development, improved synchrony of cocoon formation and higher silk yield could be seen. Also in honeybees fecundity of wax improved by the same effect. The mode of action is unknown. It is hypothesized that low levels of phytoecdysteroids may enhance the resistance against stress [46, 48, 53].

However, some insect species remain unaffected by phytoecdysteroids present in their food even at concentrations of 400 ppm and more (e.g., *Heliothis virescens* or the tobacco budworm, *Heliothis armigera* or the cotton bollworm/corn earworm, *Locusta migratoria* or the migratory locust, *Manduca sexta* or a moth known as the tobacco hornworm, *Spodoptera littoralis* or the African/Egyptian cotton leafworm, *Lacanobia oleracea* or a moth called the bright-line brown-eye, *Acherontia atropos* or the death's-head hawk moth). As shown in Figs. 127.3 and 127.4 the following detoxification and inactivation mechanisms, respectively in insects and mice, have been described to detoxify phytoecdysteroids:

- Conjugation to fatty acids, thereby blocking the C-22 hydroxyl group. This mechanism is dependent on the amount of fatty acids in the environment. In case of low concentration, insects will be exhausted sooner by spending their own energetic capacity.
- Instead of fatty acids, glycosidation (C-22, C-25), phosphorylation (C-2 or C-22), acetylation (C-3), and 3-oxo/3-epi derivatization can take place.
- Side-chain cleavage is done between C-20 and C-22.
- Excreting unmetabolized hydroxyecdysone is also seen.

The phytophagous behavior of the insect plays also an important role. Insects tolerant to phytoecdysteroids will not change their phagous behavior. Polyphagous insects can avoid plants containing higher levels of phytoecdysteroids, whereas insect monophagous for ecdysteroid-containing plants will be the most sensitive. Insects can even defend themselves by developing taste receptors, which facilitate avoiding ecdysteroid-containing plants in their diet, at least when they have the choice [53, 54].

Overall, the above-described metabolizations weaken considerably the position of plant ecdysteroids as exogenous pest control agents and divert the attention to possible therapeutic applications in higher species.

6 Pharmacology of Phytoecdysteroids

6.1 Pharmacology of Phytoecdysteroids

The literature reporting the effects of ecdysteroids on mammals has been reviewed by several researchers and summarized by Dinan [56] and Lafont and Dinan [53], and it can be concluded that beneficial pharmacological activities can lead to possible therapeutic applications. They have a higher safety margin as compared to chemical steroid derivatives [51].

6.2 Toxicology of Phytoecdysteroids

Although detailed toxicological data are lacking for phytoecdysteroids, their acute toxicity to mammals seems to be extremely low [46]. In mice, LD_{50} values of 20-hydroxyecdysone after i.p. injection and oral application were 6.4 g/kg body weight and 9 g/kg body weight, respectively. Furthermore, 20-hydroxyecdysone was not embryotoxic when injected into developing chicken eggs [55], [56].

6.3 Adaptogenic Activities

Ecdysteroids are believed to possess adaptogenic, antidepressive, tonic, and roborant properties, i.e., they enhance the ability to cope with stress and enhance resistance to tiredness. Certain plants (*Achyranthes* spp., *Cyathula* spp., *Leuzea carthamoides*) have been used as tonics, diuretics, and adaptogens in traditional Chinese and Asiatic medicines long before they were known to contain large amounts of ecdysteroids [57].

Koudela et al. [58] studied adaptogenic activity in Japanese quails. The animals were fed with a diet containing different amounts of pulverized seeds of the plant species *Leuzea carthamoides*. These seeds contain 1.8 %–2.1 % of 20-hydroxyecdysone and some smaller amounts of other ecdysteroids. In an additional experiment, the quails were administered whole seeds of *L. carthamoides* ad libitum. The basic experimental setup involved testing of (0) a standard diet (SD), (1) SD supplied with 0.2 % *L. carthamoides* seed powder, (2) SD supplied with 1 % *L. carthamoides* seed powder, (3) SD supplied with 5 %

L. carthamoides seed powder, (4) SD supplied with 5 % *L. carthamoides* seed powder + 5 % Biostrong (= biostimulating preparation for birds), (5) SD supplied with 5 % *L. carthamoides* seed powder + 5 % Ecovit (= biostimulating preparation for birds), and (6) SD supplied with whole seeds of *L. carthamoides* ad libitum.

After 37 days, the living mass increase was measured and expressed toward the control group (= 100 %) as follows: (1) 102.8 %, (2) 109.5 %, (3) 120.4 %, (4) 101.9 %, (5) 104.9 %, and (6) 103.5 %. These results show a dose-dependent anabolic effect in the birds. Anabolic effects of *L. carthamoides* were also seen in in vitro studies with preparations from liver and other organs of mice. However, it cannot be excluded that other secondary metabolites are also contributing to the effect. The results of radioimmunoassay analyses revealed that the amount of 20-hydroxyecdysone circulating in the blood of Japanese quails was proportional to the amount of dietary ecdysteroid. However, a direct correlation between these circulating levels and the anabolic effect remains unsure, as the highest concentrations were found in the quails which consumed the whole seeds of *L. carthamoides*, whereas this group did not have the highest increase in living mass [58].

Leuzea carthamoides is the basis of a green "tea," maralan, consumed extensively in Central Europe and said to improve general well-being, increase appetite, and improve digestion. Although these effects have been repeatedly ascribed to the ecdysteroid content of the plant, there is little evidence to directly associate them with this particular class of compounds [56].

6.4 Stimulation of Protein Synthesis

Otaka et al. [59] investigated the effect of 20-hydroxyecdysone on protein synthesis in mouse liver. The ecdysone increased markedly the incorporation of ^{14}C-chlorella hydrolysate into hot-acid insoluble protein, within 2 h after treatment. This effect is comparable to 4-chlorotestosterone. The effect was exerted on microsomes or polysomes. The stimulation induced by 20-hydroxyecdysone was partly insensitive to inhibitors of DNA-dependent RNA synthesis like actinomycin, whereas the stimulation by 4-chlorotestosterone was completely repressed by the same actinomycin. This may indicate other mechanisms involved or a partial protection against actinomycin.

6.5 Effect on Hyperglycemia

Ecdysterone, isolated from *Achyranthes fauriei*, has been recognized to have a suppressive effect on induced hyperglycemia. The administration of ecdysterone did not alter the blood glucose of normal animals, but pretreatment with ecdysone prior to hyperglycemic agents suppressed the hyperglycemia induced by glucagon at low levels. The effect of ecdysterone was also shown in alloxan-diabetic mice, with blood glucose levels reduced to about one-half of the value observed before the administration of ecdysterone. Ecdysterone stimulated the incorporation of ^{14}Cglucose into protein of normal mice liver and into glycogen of normal and mildly diabetic mouse liver [60]. Ecdysterone had a positive influence on insulin resistance induced by injections of hydrocortisone or insulin insufficiency caused by alloxan treatment in rats. The sensitivity toward intravenous administration of insulin was enhanced, but this enhancement was only indirectly measured by nonspecific synthesis of total proteins in cells, rather than by an increase in insulin secretion [61].

Sundaram et al. [62] more specifically described the influence of 20-OH-ecdysone on hepatic key enzymes of carbohydrate metabolism. The ecdysone was isolated from the plant species *Vitex negundo*. Oral administration of 5 mg ecdysone per kg body weight per day to streptozotocin diabetic rats for 30 days decreased the plasma glucose with more than 50 % and the glycosylated hemoglobin (HbA1c) with about 40 %. At the same time, the levels of insulin doubled and the hemoglobin normalized as compared to the control rats. The glycogen content of the liver and the skeletal muscles was enhanced, but not completely normalized by 20-OH-ecdysone. There was also an increase in the enzyme activity of hexokinase and glucose-6-phosphate dehydrogenase. These activities point to an interesting molecular mechanism of 20-OH-ecdysone, altering hormone secretion in case of induced hyperglycemia [62].

6.6 Cholesterol Homeostasis

The influence of phytoecdysteroids on cholesterol biosynthesis is more speculative. It is known that there exist negative feedback control mechanisms by steroids. Possible targets are the hydroxymethylglutaryl-CoA reductase or cholesterol catabolism. The presence of hydroxyl groups may play an important role in the activity [63].

6.7 Immunomodulatory Activity

Ecdysterone is able to stimulate the primary immune reaction. The activity is based upon a cellular activity, with enhanced T cell immunity and phagocyte activity when doses between 5 and 20 mg/kg are given to mice. When the dose is increased to 50 mg/kg, the number of antibody cells in the mouse spleen was marked [64]. These doses, however, are huge when calculated as the amount of extract to be made of phytoecdysteroid-containing plants.

In *Ajuga remota*, they can contribute to a possible antiplasmodial activity by their anabolic, adaptogenic, and immunoprotective activities. According to Dinan [56], ecdysteroids may show some immunomodulatory effects in mice and rats and have anti-inflammatory activity in rodents.

The immunomodulatory effect of 20-hydroxyecdysone has been studied in humans. It acts as a lymphocyte and neutrophil modulator in vivo. In vitro, it activates T cell CD2 presentation that is suppressed both in secondary immunodeficient persons and pharmacologically by increased cAMP levels [65].

6.8 Antiradical/Antioxidative Properties

Studying of and reporting on antioxidative properties of plants and their components are very popular. So it seems quite obvious also to investigate phytoecdysteroids in this field. Several ecdysterone concentrations (10^{-6}–10^{-3} M) were tested in a photochemical system, containing phosphatidylcholine liposomes challenged with Fe^{2+} and Fe^{3+}. The antioxidative activity of ecdysterone was comparable to diethylparaphenylenediamine and ethylenediamine tetra-acetate, both known as inhibitors of peroxide oxidation of lipids [66].

6.9 Synergism with Vitamin D

Experimental vitamin D hypovitaminosis induces changes in the structural and functional characteristics of liver nuclear chromatin fractions. DNA-polymerase activity increases, as well as the activity of the fraction enriched with RNA-polymerase I. Free-radical lipid peroxidase-mediated reactions are preferentially modified in the chromatin fraction with low activity. Moreover, the protein and lipid components of chromatin are changed. Administration of ecdysterone preparations partially restores the structural and functional organization of chromatin, whether it is separately or concomitantly given. Lipid peroxidase is normalized. In general, administration of ecdysterone mimics the activity of vitamin D3 with regard to the normalization of the biochemical indices [67].

Dittrich et al. [68] sought a suitable dosage form with continuous release of 20-hydroxyecdysone from a device implanted in animals. They made a binary mixture of poly-lactic acids and the ecdysone. Release of the active compound was tested in static in vitro conditions, comparable with those at the site of possible implantation. Prolonged drug release of nearly zero-order kinetics was obtained with hollow implants. These types of implants appear most appropriate for testing in vivo [68].

6.10 Antitumoral Activity

A lipophilic root extract of *Leuzea carthamoides* (Maral root), as well as 20-hydroxyecdysone, was tested in human breast adenocarcinoma MCF-7 cells. Cell proliferation was inhibited by the extract with an IC_{50} of 30 μg/mL; 20-hydroxyecdysone did not show inhibitory activity. It is not clear to what extent phytoecdysteroids from *Leuzea carthamoides* were responsible for the activity. Products derived from the roots of this plant are promoted as dietary supplements with adaptogenic and anabolic activity, because of their ecdysteroid content [69].

6.11 Dermatology and Cosmetology

Use of phytoecdysteroids in dermatology seems to be most promising. This sector offers perspectives by its more easy therapeutic access, especially in the field of topical applications.

Meybeck et al. [70] took a patent on the use of ecdysteroids as active substances incorporated into liposomes. The patent contains a non-limitative list of plants that can be used: *Achyranthes aspera*, *Achyranthes bidentata*, *Ajuga decumbens*, *Ajuga iva*, *Bombyx mori*, *Cyanotis arachnoidea*, *Cyathula officinalis*, *Cyathula capitata*, *Leuzea carthamoides*, *Lychnis flos-cuculi*, *Paris axialis*, *Paris dunniana*, *Paris fargesii*, *Paris polyphylla*, *Paris vietnamensis*, *Pfaffia iresinoides*, *Pfaffia paniculata*, *Polypodium vulgare*, *Rhaponticum integrifolium*, *Serratula sogdiana*, *Serratula tinctoria*, *Sesuvium portulacastrum*, *Silene brahuica*, *Silene dioica* (*Melandrium rubrum*), *Silene nutans*, *Silene otites*, *Silene scabrifolia*, *Silene tatarica*, *Silene traemixta*, *and Vitex glabrata*. Preferential plant extracts are those of *Achyranthes bidentata*, *Ajuga decumbens*, *Cyanotis arachnoidea*, *Leuzea carthamoides*, and *Polypodium vulgare*. The species *Rhaponticum integrifolium* and *Serratula sogdiana* have the advantage that they can be cultivated. Extraction procedures are described according to Imai et al. [71]. Examples of formulations are given with different indications: restoring the water barrier of the epidermis, treatment of psoriatic skin, hydration of the epidermis, re-equilibration the desquamation of the cornified layer of the epidermis and restoring the smoothness of the epidermis, and preventive treatment of dry skin treatment of ichthyotic skins. The formulations are prepared with pure ecdysterone, ecdysterone esters, or plant extracts [70]. Some of the properties are documented in the public domain, like experimental findings on in vitro keratinocyte differentiation by 20-OH-ecdysone [72].

Inaoka et al. [73] studied the effects of 80 herbs on hair growth, using normal C-3H/He mice from which telogen hair on the back had been removed. *Polyporus umbellatus* emerged as one of the active species that promoted hair regrowth. A 50 % ethanol extract of *Polyporus umbellatus* was fractionated by consecutive column chromatography. Testing of the fractions on the hair regrowth assay resulted in the isolation of three active principles: acetosyringone, polyporusterone A, and polyporusterone B [74]. The structure of the hair regrowth polyporusterone A was further studied. The NMR data indicated that the side chain has the same conformation in both the crystalline state and solution [75].

Meybeck and Yang [76] took a patent on compositions containing an ecdysteroid, an ecdysteroid derivative, or a natural plant or animal extract containing the same compounds used in cosmetics, pharmaceutics, or as a natural supplement. The patent is related to the use of the compositions to stimulate the natural defenses of cells, such as protein p53, against the consequences of being exposed to ultraviolet rays, in particular solar radiation.

6.12 Anabolic Effects

The backbone of phytoecdysteroids is identical to that of steroid hormones, which led to the comparison of their anabolic effects. As summarized by Sláma and Lafont [57], 20-hydroxyecdysone increased physical performance without training in a forced swimming test in mice and also caused anabolic increase of body mass. Stimulation of protein synthesis by up to 20 % in mouse and human skeletal muscle cells by ecdysteroids (20-hydroxyecdysone, polypodine B, and ponasterone) has been demonstrated [77].

According to other researchers, 20-hydroxyecdysone increased body mass and muscle fiber size in rats and may provide an alternative to anabolic–androgenic steroids in the treatment of muscle atrophy [42]. In contrast to anabolic vertebrate steroid hormones, the anabolic actions of 20-hydroxyecdysone are supposedly not associated with the adverse androgenic, antigonadotropic, or thymolytic side effects. Phytoecdysteroids also appear not to have androgenic or (anti)estrogenic effects [57].

Increase in muscle size is one of the most cited aspects of phytoecdysteroids on the Internet [78]. However, stringent research is needed, as in a double-blind, placebo-controlled trial 30 mg/day of 20-hydroxyecdysone did not significantly affect anabolic or catabolic response to resistance training, body composition, or training adaptations [79]. On the other hand, it cannot be excluded that phytoecdysteroids may have an anabolic influence on the long term. Kumpun et al. [80] found that they are concentrated in the bran of *Chenopodium quinoa*, an Andean crop plant. Most of the 20-hydroxyecdysone was recovered undegraded from the seeds, even after 20 min boiling. Humans who eat quinoa regularly could have some anabolic benefit from their eating habits [80].

7 Conclusions

Although promising therapeutic agents, phytoecdysteroids remain in the experimental pharmacological field. The steroid skeleton is a basic template on which nature continuously varies to make new entities. This may be a hampering factor for chemically synthesizing new substances that can be patented.

Abstract

Brassinosteroids are endogenous plant polyhydroxysteroids that are essential for normal plant growth and development. They induce cell elongation and division, increase DNA and RNA polymerase activity, interact synergistically with

auxins, stimulate ethylene production, and increase tolerance to temperature, water, and salinity stress. They are observed in many plant species and are present in nearly every part of the plant, although the highest concentrations occur in the reproductive organs. In mammalian cells, brassinosteroids inhibit cell growth and affect cell cycle progression; as such, they have potential for development as anticancer agents. Moreover, brassinosteroids and their synthetic derivatives possess antiangiogenic properties that could be effective in the treatment of any carcinoma. As such, they are an interesting source of lead compounds for developing novel natural product-derived anticancer drugs, and their properties have attracted the attention of many specialists in the fields of chemistry, biochemistry, pharmacology, plant physiology, and agriculture.

1 Introduction

The role of steroids as mammalian hormones has been known since 1930, and steroidal hormones have also been found in insects and fungi. Plants can biosynthesize a large variety of steroids, but it was not known until 1979 that steroids with plant growth-promoting activity were discovered. In that year, Grove et al. [1] reported the discovery of a new steroidal lactone called brassinolide from the pollen of *Brassica napus* L. To date, more than 70 structurally and functionally related steroids have been isolated from plant materials [2]. These compounds have been identified as members of a new group of plant hormones – the brassinosteroids (BRs).

BRs have been detected in all plant organs, including pollen, anthers, seeds, leaves, stems, roots, flowers, and grains. They have also been found in other interesting tissues such as insect and crown galls, notably the galls of *Castanea crenata, Distylium racemosum*, and *Catharanthus roseus*. Pollen and immature seeds in particular tend to be especially rich source of BRs, whereas their concentrations in vegetative tissue are very low compared to other plant hormones. Pollen and immature seeds contain about 1–100 $ng.g^{-1}$ FW of BRs, while shoots and leaves usually have lower amounts (0.01–0.1 $ng.g^{-1}$ FW) [3].

BRs control many developmental and physiological processes in plants, including regulation of gene expression, cell division and expansion, germination, vegetative and reproductive development, vascular differentiation, root growth, programmed cell death, and homeostasis [4, 5]. In addition to their growth-regulating activities, BRs have been shown to have dynamic roles in protecting plants against biotic and abiotic stresses [6, 7]. Treatment with exogenous BRs raises the inner potential of treated plants, which promotes survival under stressful conditions and also reduces biotic stress caused by pathogens [5, 8].

The physiological concentrations of BRs in plants are extremely low ($ng.Kg^{-1}Fw$), and it can be very difficult to analyze their abundance in plant tissues. A wide range of methods are currently employed for the determination and quantification of brassinosteroids in plants, including bioassays, diverse chromatographic procedures, radioimmunoassays [9], and enzyme-linked immunosorbent assays [10–13]. The most widely used bioassays are the second bean internode bioassay and rice–lamina inclination test. These bioassays have been used in the isolation of brassinolide from rape pollen [1] and castasterone from chestnut insect galls [14]. Gas chromatography–mass spectrometry (GC–MS) analysis is the current standard technique for instrumental analysis of BRs [15–17].

Some medically oriented applications of BRs have been reported [8, 18, 19]. Wachsman et al. [8, 20] observed that some natural BRs (28-homoCS, 28-homoBL) and their synthetic analogs exhibit antiviral activity in vitro against several RNA and DNA viruses, including herpes simplex virus type 1 (HSV-1), arenaviruses, and measles virus (MV). Moreover, natural and synthetic brassinosteroids have been reported to cause growth inhibition, cell cycle arrest, and initiation of apoptosis in many different cancer cell lines. It has also been demonstrated that BRs can inhibit the proliferation and migration of human endothelial cells, and there is evidence that BR treatment triggers the initiation of cell death by apoptosis. Brassinosteroid analogs have proven to be more effective than natural BRs in this context. Importantly, BRs inhibit cell migration and tube formation, suggesting they may possess antiangiogenic activity [21–23].

2 Chemical Structures of the Brassinosteroids

All known brassinosteroids have a 5α-cholestane, 5α-ergostane, or 5α-sitostane steroidal skeleton with mono- to trioxygenation on ring A and 22α-, 23α-dihydroxylation in the side chain. Ring B may be fully saturated or may contain a ketone or lactone at carbon 6 (Fig. 128.1).

All natural BRs consist exclusively of carbon, hydrogen, and oxygen and have:

1. A normal or B-homo cholestane, ergostane, or sitostane steroidal skeleton
2. An oxygen-containing functional group at carbon 3 (α- or β-hydroxyl, ester, ether, or ketone)
3. An all-*trans* fusion between rings A/B, B/C, and C/D

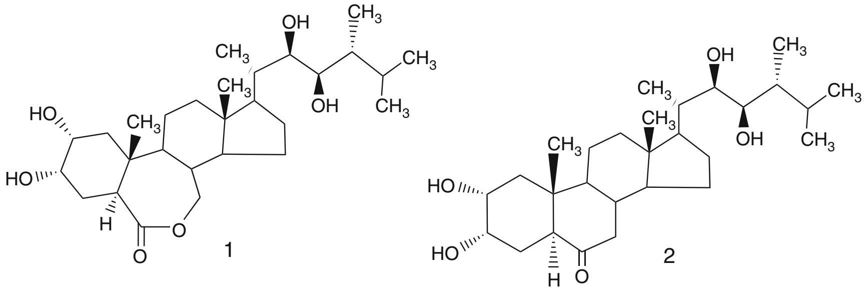

Fig. 128.1 Structures of brassinolide (1) and castasterone (2)

4. A 20R (or 20 β) configuration
5. α –*cis* (R,R) vicinal hydroxyls at carbons 22 and 23

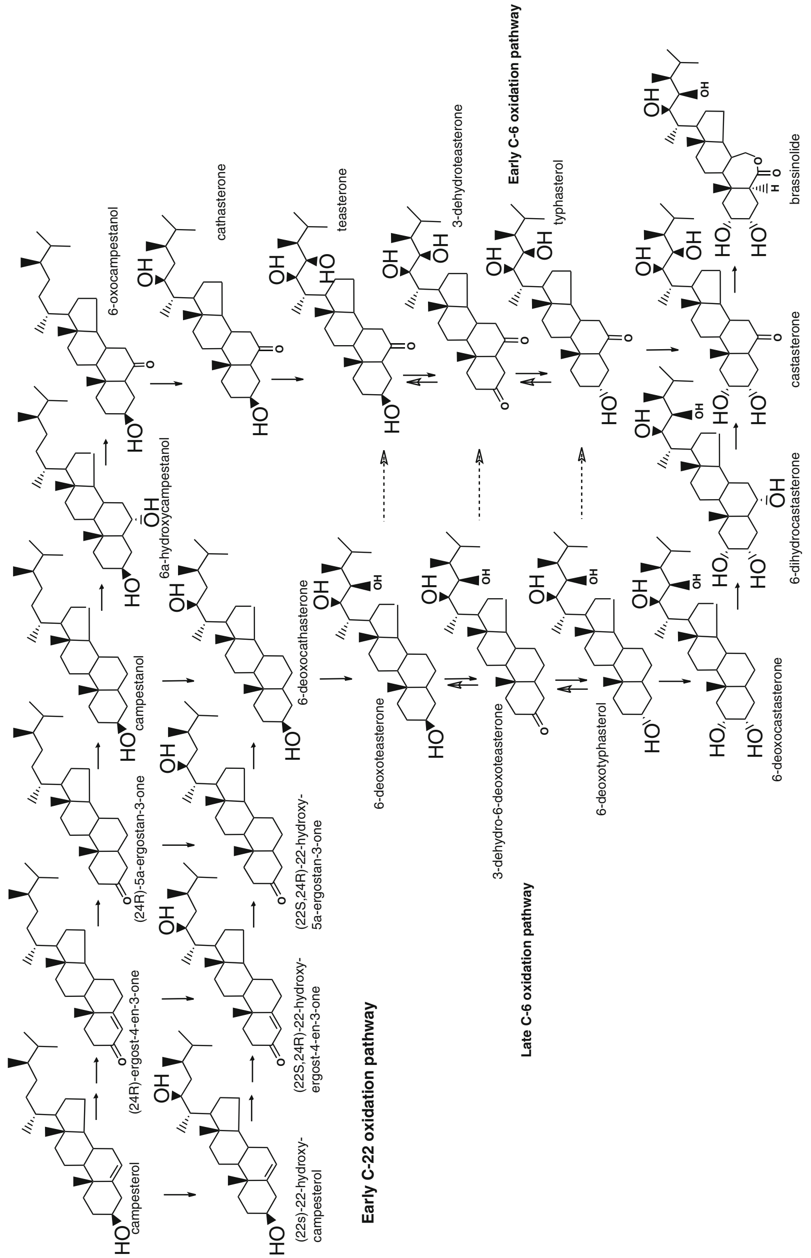
All of these compounds have an oxygen-containing functional group at carbon 3, none exhibit A/B *cis* ring fusion or have a carbon–carbon double bond between rings A and B, and all have at least 27 carbon atoms [24, 25].

3 Biosynthetic Pathway

BRs belong to the class of molecules known as triterpenoids. Because BRs are a group of modified sterols, the BR biosynthetic pathway can be divided into two major parts: the sterol-specific pathway (which converts squalene to campesterol) and the BR-specific pathway (which converts campesterol to the BR). In the sterol-specific pathway, mevalonic acid (which is the starting material in terpenoid biosynthesis) is condensed and cyclized to produce 2,3-oxidosqualene. This precursor is further modified to form the major plant sterols such as sitosterol and campesterol. To become bioactive BRs, sterols must be processed by the BR-specific pathway.

The biosynthetic pathways leading to brassinolide were initially elucidated using cultured *Catharanthus roseus* cells. Extensive metabolic studies suggested the operation of a series of parallel branched biosynthetic pathways that were named the early and late C-6 oxidation pathways (Scheme 128.1) [26–28]. Recent studies suggest that there is cross-talk between these parallel pathways, implying that they are not totally autonomous. The existence of an early C-22 oxidation branch in the BR biosynthetic pathway has also been demonstrated. It thus appears that BR biosynthetic pathways are highly networked [29–31].

As shown in Scheme 128.1, campesterol is first converted to campestanol, which is then converted to castasterone via either early or late C-6 oxidation. Finally, castasterone is converted to brassinolide. However, some of the steps involved have only recently been clarified. One such step, the conversion of 6-oxocampestanol to cathasterone, was demonstrated in cultured *Catharanthus roseus* cells [32], fully substantiating the pathway from campestanol to



campesterol

Scheme 128.1 Pathways of brassinosteroid biosynthesis (Modified by Fujioka S, Yokota T [105]) brassinolide via early C-6 oxidation. The campestanol → 6-deoxocathasterone → 6-deoxoteasterone sequence in the late C-6 oxidation pathway has also been established in *Arabidopsis* [31, 33], completing the elucidation of the late C-6 oxidation pathway. Ohnishi and coworkers proposed a novel shortcut in BR biosynthesis in *Arabidopsis*, which allows the direct conversion of early 22-hydroxylated intermediates to 3-dehydro-6-deoxoteasterone and 6-deoxotyhpasterol via C-23 hydroxylation [34]. In tomato and tobacco, the late C-6 oxidation pathway appears to be the primary route used because the only endogenous BRs in these species are produced via the late C-6 oxidation pathway [35, 36].

4 Brassinosteroid Signal Transduction

The perception of signals at the cell surface and the transduction of these signals to the cell's interior are essential in all life forms. In plants, this process is mediated by membrane-integral receptor kinases [37]. Brassinosteroid signaling (Fig. 128.2) and the resulting genomic response is initiated by the binding of a BR molecule to a receptor kinase, brassinosteroid-insensitive 1 (BRI1), which is localized in the plasma membrane. BRs bind to the extracellular leucine-rich repeat receptor kinase (LRR-RK) domain of BRI1. This triggers the phosphorylation of the intercellular serine–threonine kinase domain of BRI1, which in turn causes BRI1 to dissociate from the membrane-bound BRI1 kinase inhibitor 1 (BKI1) and to form a complex with a second receptor kinase, BRI1-associated receptor kinase 1 (BAK1). The active BRI1/BAK1 receptor kinase pair then propagates the signal downstream by inactivating a soluble kinase, brassinosteroid-insensitive 2 (BIN2), which is a negative regulator of BR signaling [39–42]. BKI1 is phosphorylated at a tyrosine residue in response to brassinosteroid perception; this mechanism is conserved in higher organisms and controls protein localization. The phosphorylated residue is part of a membrane-targeting motif and its modification releases BKI1 into the cytosol, allowing it to form an active signaling complex [43]. The structure of the *Arabidopsis thaliana* BRI1 ligand-binding domain has recently been published; it features a superhelix of 25 twisted leucine-rich repeats (LRRs) that is strikingly different to the assembly of LRRs in animal Toll-like receptors [37, 44]. A 70-amino-acid island domain between LRRs 21 and 22 folds back into the interior of the superhelix to create a surface pocket that contains the binding site for the plant hormone brassinolide. It seems that steroid binding to BRI1 generates a docking platform for a coreceptor that is required for receptor activation [37]. Irani et al. [45] used chemical and genetic approaches to interfere with the trafficking of the BRI1–BR complexes and examined their effect on BR signaling. They developed a bioactive, fluorescent BR analog (AFCS) and used it to visualize the endocytosis of BRI1–AFCS complexes in living *Arabidopsis* cells. These studies revealed that interference with clathrin- or ARF-GEF-mediated endocytosis of BRI1 enhanced BR signaling [45].

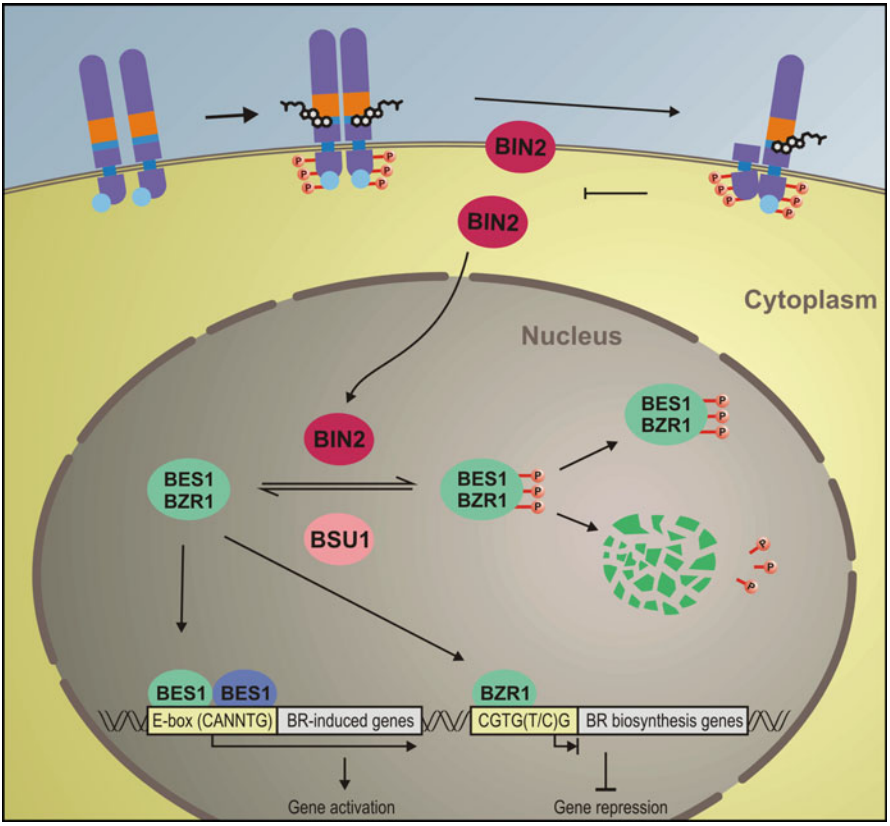

Fig. 128.2 Brassinosteroid signaling in the plant cell. BRs bind to the extracellular domain of brassinosteroid-insensitive 1 (BRI1), a leucine-rich repeat receptor kinase (LRR-RK) that is localized in the plasma membrane. This leads to phosphorylation of the intracellular serine–threonine kinase domain of BRI1, causing it to dissociate from the membrane-bound BRI1 kinase inhibitor 1 (BKI1) and to form a complex with a second receptor kinase, BRI1-associated receptor kinase 1 (BAK1). The active BRI1/BAK1 receptor kinase pair then propagates the signal downstream by inactivating a soluble kinase, brassinosteroid-insensitive 2 (BIN2), which is a negative regulator of BR signaling. BES1 (bri1-EMS-suppressor 1) and BZR1 (brassinazole-resistant 1) are phosphorylated by BIN2 and are closely related transcriptional activators of BR-induced genes. BSU1 (bri1 suppressor 1) counteracts the effects of BIN2 [38]

24-Epibrassinolide (24-epiBL) has also been shown to upregulate the transcription of an important positive cell cycle regulator gene, cyclin D3, which is involved in the activation of cell division by cytokinins in *Arabidopsis thaliana* L. [46]. No plant gene encoding an intracellular BR receptor has yet been identified in plants, although a chaperone heterocomplex that resembles an animal intracellular steroid receptor has been identified in wheat germ lysate [47]. Nevertheless, it is likely that there is an intracellular steroid hormone signaling pathway in plants that regulates gene transcription in a similar way to that found in animals [46].

5 Biochemical Analysis of Natural Brassinosteroids

5.1 Bioassays

The development of bioassays for isolating bioactive compounds from natural sources has played an important role in recent studies of natural BR phytochemistry. The development of highly sensitive and specific bioassays was essential for the isolation and purification of BRs from plant tissues because of the very low physiological concentrations of these hormones. The bean second internode assay was used to isolate BL from rape pollen [1], and the rice–lamina inclination test was used to isolate CS from chestnut insect galls [14]. Following the publication of these results, the rice–lamina inclination test has been widely used to isolate many BRs from various plant sources because of its simplicity, high sensitivity, and specificity for BRs [25].

5.1.1 The Bean Second Internode Bioassay

This test was first used for monitoring the biological activity of separated fractions during the isolation and purification of the "brassin-complex" [48–50] and later also for isolating pure BL [1]. Both gibberellins and BRs are active in this test, but the former cause only elongation, whereas BRs also cause swelling, increased curvature, and splitting of the internodes. Responses of this kind are considered indicative of "brassin activity" and are only observed for fractions containing BRs. The effect depends on the amount of BR applied. For example, swelling and increased curvature are only observed after treatment with at least 0.01 μg BL per plant. The sensitivity of the assay can be increased by omitting nitrate from and adding Ca^{2+} or Mn^{2+} to the solution in which the bean seedlings are grown [51].

5.1.2 The Rice-Lamina Inclination Bioassay

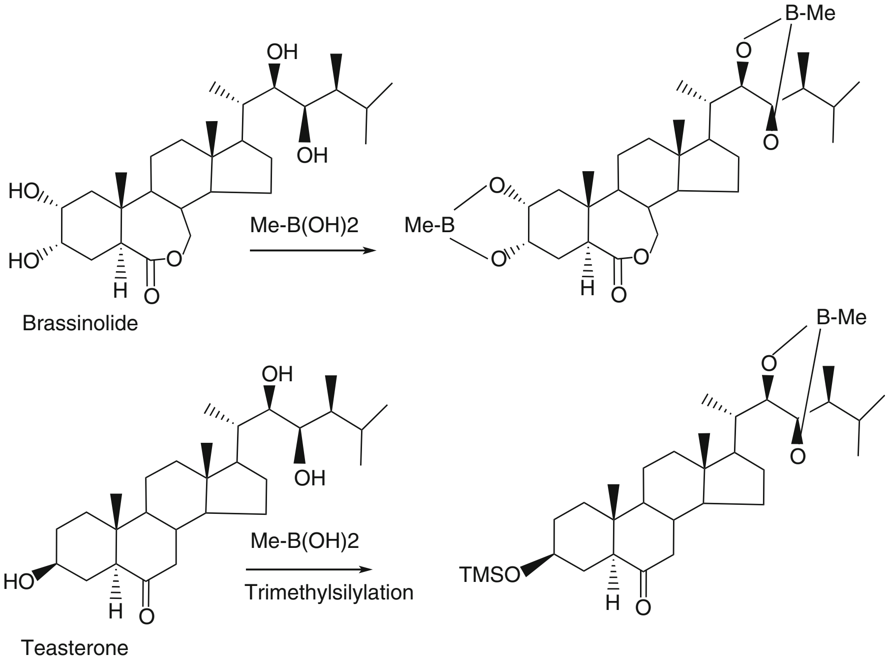
This bioassay is one of the most popular and useful tests for evaluating brassinosteroid activity. It was originally developed by Maeda [52] for gibberellins and indole-3-acetic acid (IAA). Two modifications were developed for use with brassinosteroids, one involving intact plants [53] and the other involving cuttings [54]. The assay is based on measuring the angles between the laminae and the sheaths after a period of incubation with the tested fraction; in the control segments, these angles are approximately 90°. In the presence of 0.0005 μg/ml BL, the angles between laminae and sheaths increased to around 140°; 0.005 μg/ml BL caused pronounced bending at the lamina joints to the abaxial side to the extent that some of the laminae came into contact with the sheaths. The activity of 28-homobrassinolide in this assay was comparable to that of BL, but the response induced by IAA was very modest even at 50 μg/ml [54]. Gibberellins also have only a modest effect on the inclination of the lamina in rice seedlings at a concentration of approximately 100 μg/ml. The sensitivity of the test depends on the rice cultivars used; out of 60 cultivars that were tested during its development, Arborio J-1 and Nihinbare were found to be the most reliable [55].

5.2 Gas Chromatography–Mass Spectrometry (GC–MS)

Brassinosteroids are highly polar and nonvolatile compounds. As such, it is generally necessary to convert them into more volatile derivatives prior to conducting gas-phase analyses. One such gas-phase analytical procedure that has proven useful when trying to identify BRs in a partially purified bioactive fraction is gas chromatography coupled to mass spectrometry in selected ion-monitoring mode (GC–MS-SIM). To facilitate their analysis by gas chromatography, BRs are typically converted into volatile bismethaneboronate (BMB) derivatives by treating them with methylboronic acid, which reacts specifically with vicinal diols (Scheme 128.2). This derivatization process makes it easy to separate the target compounds from contaminants that do not contain vicinal diols. The BMB derivatives are suitable for gas-phase analysis and also for the analysis of fragment ions in electron impact (EI) mass spectra. Furthermore, 24-epimers of BL and CS are also completely separated by capillary GC [15, 16]. In the case of 2-deoxy BRs such as teasterone and typhasterol, which have a vicinal diol in the side chain and single hydroxyl group on the A-ring, the diol moiety is first converted to the methaneboronate and then the remaining 3-hydroxyl group is trimethylsilylated with an appropriate silylating reagent to give a methaneboronate–trimethylsilyl (MB–TMS) derivative [56] (Scheme 128.2). The MB–TMS derivatives of teasterone, typhasterol, and their 28-homo and 28-nor analogs are well separated by capillary GC [56]. These derivatives have limit of detection (LOD) values in the nanogram range for full-scan EI-MS analyses and subnanogram LOD values for analyses by EI-GC in SIM mode.

5.3 High-Performance Liquid Chromatography (HPLC)

HPLC is one of the most frequently used analytical methods for the separation and analysis of BRs [57]. Because BRs have no suitable chromophore for detection, they are derivatized with prelabeling reagents that are suitable for use with ultraviolet (UV), fluorometric, or electrochemical detectors. Several boronic acid reagents that react with the vicinal diol groups of BRs have been used as prelabeling reagents, including naphthaleneboronic acid for UV detection [58], 9-phenanthreneboronic acid [59], 1-cyanoisoindole-2-m-phenylboronic acid [60] and (dansylamino)phenylboronic acid [61] for fluorometric detection, and ferroceneboronic acid for electrochemical detection [62]. The limits of detection for these methods range from 25 to 100 pg per injection, depending on the derivative used. The most effective of these reagents seems to be (dansylamino) phenylboronic acid because its chromophore can be detected at longer wavelength (excitation 345 nm/emission 515 nm) than other boronates, and so its signal is less susceptible to interference from matrix contaminants. The derivatized BRs are effectively separated by HPLC using ODS columns with acetonitrile–water as the mobile phase.



Scheme 128.2 Conversion of brassinolide to its bismethaneboronate derivative and teasterone to its methaneboronate–trimethylsilyl ether

Gamoh et al. [63] developed a HPLC method based on a combination of precolumn labeling and postcolumn fluorescence detection that can be used to separate and detect 24-epimers of BL and CS. Related reverse-phase HPLC methods have also been used successfully to analyze BRs in the pollen of broad bean, corn, sunflower, buckwheat, and orange [64–66].

5.4 Liquid Chromatography–Mass Spectrometry (LC–MS)

Microanalytical LC–MS methods for the analysis of BR-derived boronates have also been developed, using either atmospheric pressure chemical ionization (APCI) or electrospray ionization (ESI). APCI-based LC–MS has been used to analyze naphthaleneboronate derivatives of BRs; in this case, optimal results were obtained by using a reverse-phase HPLC acetonitrile–water gradient to elute a C18 column [67]. Typical ions observed in the positive-ion spectra of the naphthaleneboronates included a pseudomolecular ion $[M + H]^+$ and a fragment ion $[M + H\text{-}H_2O]^+$. The most abundant ion from the fragmentation of BL derivatives is the parent ion, while the $[M + H\text{-}H_2O]^+$ ion is the most abundant in the mass spectra of CS, teasterone and typhasterol. Full-scan mass spectra were readily obtained from 400 ng of free BRs, whereas the limit of detection in SIM mode was around 2 ng. The most effective mobile phase for naphthaleneboronates was found to be a mixture of acetonitrile and water (9:1) containing 0.5 % HCOOH. Svatoš et al. [68] reported a highly sensitive and selective LC–(ESI)-MS method that was developed for analyzing BRs in plant extracts. The method involves using a microbore C18 column (1.0 mm) in conjunction with chemical derivatization of free BRs to dansyl-3-aminophenylboronates. This gives it a much lower limit of detection than can be obtained with previous analytical methods: its limit of detection for derivatized BRs in selected ion-monitoring (SIM) mode is 125 attomoles. The practical utility of the method was demonstrated in *Arabidopsis thaliana* plants that were fed with a deuterium-labeled precursor of CS and converted it to BL [68]. A highly sensitive electrospray ionization mass spectrometry (MS) technique (LOD 50 fmol) has been developed and used for direct analysis of natural brassinosteroids in different plant tissues [12]. This method was successfully used to detect and quantify brassinolide and castasterone in rape pollen and seedlings of *Daucus carota, Phaseolus vulgaris*, and *A. thaliana* [12]. Despite these advances, there is considerable scope for further improvements upon existing analytical methods and for reducing their LODs by using capillary LC systems coupled to a nano-ESI source. Additional improvements could be made by using ultra-performance liquid chromatography (UPLC) or by developing brassinosteroid-specific immunoaffinity chromatography techniques for the analysis of natural plant samples.

6 Biological and Pharmacological Activities

The best known and the most widely studied biological effect of BRs is their ability to stimulate plant growth in a variety of systems such as whole plants, excised segments, cuttings, and seedlings.

Brassinosteroids have been observed to stimulate seedling elongation in many assay systems, including normal and dwarf pea epicotyls, dwarf bean apical segments, mung bean epicotyls, and cucumber and sunflower hypocotyls [69]. In general, BRs stimulate elongation in the light but not in the dark [70]. Kamuro and Inada [71] examined the effects of light on the growth-promoting effects of BL using mung bean (*Vigna radiata)* epicotyls. Cuttings with attached cotyledons underwent epicotyl elongation in the dark and also under monochromatic blue light (452 nm) or far-red light (722 nm). BL did not promote epicotyl growth under any of these conditions. Epicotyl growth was retarded by white light (400–700 nm) and monochromatic red light (660 nm), and the growth-promoting effects of BL were clearly observed under these light regimes. Cuttings that were alternately irradiated with red and far-red light exhibited retarded epicotyl growth if the treatment ended with exposure to red light; BL treatment overcame this retardation. These results indicated that the effects of BRs are related to phytochrome-mediated growth regulation.

Brassinosteroids have also been observed to inhibit adventitious root development in mung bean hypocotyls [72]. Subsequent work reviewed by Roddick et al. [73] indicated that this inhibition might not be a primary action of BRs and may instead be due to differences in the optimal concentration of BRs for adventitious root development and shoot elongation. When soybean (*Glycine max* L.) hypocotyl segments were produced under photoperiods of 16-h light and 8-h darkness, adventitious roots were induced by treatment with 24-epiBL at the very low concentration of 0.0001 μg/ml during the dark periods. There is also evidence that BRs may regulate root hair development: Kappusamy et al. [74] reported that the levels and patterns of expression for two master epidermal patterning regulators (WEREWOLF and GLABRA2) are regulated by BRs and that plants with BR-related mutations exhibit abnormal root hair development.

The effect of BRs on cell division is somewhat controversial. In carrot (*Daucus carota* L.) and tobacco cell cultures, BRs induced cell enlargement without any effect on cell division [75, 76]. In a culture of *Zinnia elegans* L. mesophyll cells, the inhibition of endogenous GA_3 and BR biosynthesis by treatment with uniconazole retarded tracheid differentiation, which could be restored by treatment with BL or 28-homoBL (but not by GA_3) [77]. BL is essential for entry into the final stage of tracheary element differentiation, where secondary wall formation and cell death occur [78]. Using tuber explants of *Helianthus tuberosus*, Clouse and Zurek [79] also showed that BL stimulates xylem differentiation. Under normal conditions, xylem differentiation occurred only after 3 or 4 days' incubation of the explant on xylem-inducing media. However, when BL was added at a concentration of $6.8.10^{-9}$ M, significant xylem differentiation was observed after 24 h. This evidence suggests that BRs may influence cytodifferentiation in plants [80]. While investigating the potential role of BRs in regulating cell division, Hu et al. [46] found that treating *Arabidopsis* seedlings with 24-epiBL can upregulate the expression of CycD3, a D-type plant cyclin gene that may promote cell division.

Many studies have suggested that BRs play essential roles in responding to various stresses such as abnormal temperatures, drought, high osmotic pressure, and pathogen attacks [81, 82]. The occurrence of cross-talk between BRs and stress-responsive hormones such as abscisic acid, jasmonic acid, and ethylene is consistent with the suggestion that BRs play an important role in plant stress responses [83].

The ability of BRs to enhance plant resistance to various external stresses has been investigated with a view to finding applications for them in agriculture. Because temperature changes are likely to occur more rapidly than other stress-causing factors in nature, many studies in this area have focused on temperature stress. Maize seedlings are highly sensitive to chilling stress during germination and the early stages of growth. Treatment with BRs promoted growth recovery in maize seedlings that had previously been chilled. BRs also promoted the greening of etiolated leaves at low temperature in light [84]. Schilling et al. [85] examined the effects of 28-homoBL on sugar beet (cv. Ponemo) under drought stress. Treatment with 28-homoBL caused an increase in taproot mass, sucrose content, and sucrose yield under drought stress; no such effect was observed under non-stress conditions. Brassinosteroids have also been shown to activate total protein synthesis in wheat leaves under high-temperature stress. BR-treated leaves that were maintained at 43 °C exhibited protein synthesis levels similar to those observed at 23 °C.

However, in untreated leaves maintained at 43 °C, protein synthesis decreased by a factor of 2.5 relative to control samples at 23 °C [86]. In plant cells under heat stress, small heat shock proteins aggregate to produce highly ordered cytoplasmic complexes known as heat shock granules (HSGs). In wheat leaf cells, HSGs aggregate further to form small clusters. The average number of HSGs in the clusters and the average cluster size were both higher in BR-treated leaves than in untreated leaves [86].

The ability of BRs to enhance plant resistance to infection by fungal pathogens has also been investigated [87]. It was demonstrated that potato plants sprayed with BR solution were less prone to infection by *Phytophthora infestans*. The increase of resistance in BR-treated potato tubers was associated with elevated abscisic acid and ethylene production as well as increased levels of phenolic and terpenoid substances. In some investigations, BRs proved to be more effective than standard fungicides at protecting against fungal infection. However, certain concentrations of BRs and treatment with BRs at certain plant developmental stages can stimulate fungal growth and disease progression. As such, it would be necessary to carefully consider the timing of BR application, the concentration applied, and the method of application when developing a potential BR-based fungicidal treatment [88].

The brassinosteroids are essential for many growth and development processes in plants. However, relatively little is known about the effects of BRs and their synthetic analogs on animal cells [89]. It has been reported that cultured hybridoma mouse cells treated with 24-epiBL exhibit certain interesting effects, including an increase in the mitochondrial membrane potential, a decrease in the abundance of intracellular antibodies, an increase in the fraction of the cells in the G_0/G_1 phase, and a corresponding decrease in the proportion of cells in S phase. Moreover, treatment with 24-epiBL at concentrations of 10^{-13} and 10^{-12} mol/l significantly increased the density of viable cells relative to controls [90].

It has recently been reported that the natural BRs 24-epiBL and 28-homoCS have significant effects on the growth and viability of various normal and cancerous cell lines [23]. 28-HomoCS and 24-epiBL were shown to affect the viability of human cancer cell lines of various histopathological origins, but not human fibroblasts (BJ). Cell lines tested included the T-lymphoblastic leukemia CEM, breast carcinoma MCF7, lung carcinoma A-549, chronic myeloid leukemia K562, multiple myeloma RPMI 8226, cervical carcinoma HeLa, malignant melanoma G361, and osteosarcoma HOS. Treatment with 28-homoCS and 24-epiBL resulted in potent, dose-dependent reductions in the viability of CEM and RPMI 8226 cells, although the severity of these effects differed between the two compounds.

Estrogen- and androgen-sensitive and -insensitive breast and prostate cancer cell lines were shown to respond differently to treatment with natural BRs. Most breast cancers consist of a mixture of estrogen-sensitive and estrogen-insensitive cells, and it seems that it is necessary to eliminate both cell types in order to control breast cancer. Hormone-sensitive cell lines were more susceptible to BR treatment. This finding may indicate that natural BRs are capable of modulating the steroid receptor response in human cancer cells. Natural BRs were found to be cytotoxic to cancer cells but not to untransformed human fibroblasts, suggesting that they induce different responses in cancerous and normal cells. As such, these plant hormones may be useful leads for developing novel anticancer drugs [23]. There is also evidence that brassinosteroids may perturb cell cycling in breast and prostate cancer cell lines. Using flow cytometry, it was shown that treatment with 28-homoCS and 24-epiBL [104] induced a blockage in the G_1 phase of the cell cycle in breast and prostate cell lines, with concomitant reductions in the percentage of cells in the S phase of the cell cycle [23]. In the MCF7 breast cancer cell model (which is the most widely studied experimental system in this context), this response mirrors the typical response to antiestrogens, which also reduce the proportion of cells that are actively synthesizing DNA (i.e., cells that are in the S phase) and concomitantly increase the proportion of cells in the G_0/G_1 phase [91].

Angiogenesis, i.e., the growth of new blood vessels in animals, is essential for organ growth [92] and for the growth of solid tumors and metastasis [93]. Potent angiogenic inhibitors capable of blocking tumor growth are thus promising leads for the development of a new generation of anticancer drugs [94]. Recently, several steroids (i.e., 2-methoxyestradiol, progestin, medroxyprogesterone acetate, and glucocorticoids such as dexamethasone and cortisone) have been shown to have antiangiogenic activity [95]. Until recently, nothing was known about the effects of natural BRs on angiogenesis or other processes in endothelial cells. A study was therefore conducted to investigate the effects of naturally occurring BRs and their synthetic analogs on cell proliferation and cycling in human microvascular endothelial or umbilical vein endothelial cells, with a particular emphasis on the migration and formation of tubes within these cells [89]. Although the antiangiogenic activity of natural BRs was weak, it was found that the synthetic BR-derivative cholestanone significantly inhibited angiogenesis in endothelial cells in vitro. At a concentration of 30 μM, cholestanone reduced migration to 38 % relative to untreated cells and decreased the number of tubes by 34 % relative to the control treatment. As such, the BR-derivative cholestanone was a significantly more potent inhibitor of migration and tube formation than natural brassinosteroids [96].

Brassinosteroids seem to exert their effects on growth and the cell cycle effects via the cell cycle machinery and apoptosis and may thus be useful leads in the development of novel agents for managing cancer. The antiangiogenic effects of BRs may also prove useful for controlling tumor growth and metastasis, potentially paving the way for the development of multiple novel phytohormone-derived anticancer drugs [89, 96].

7 Agronomical Uses

BRs have strong effects on plant growth and possess a unique combination of physiological actions that have considerable potential for practical applications. Their potential economic value as agents for increasing crop yields has been discussed previously [97]. Their applications in agriculture and horticulture would be based on their ability to stimulate plant growth and enhance plant

Table 128.1 Selected results from brassinosteroid field trials

Plant	BR applied, dose, mode of treatment	Yield enhancement (%)	References
Wheat	24-epiBL, 4 mg/ha, spraying at flowering	16	[100]
Corn	24-epiBL, 50 mg/ha, spraying at emergence of tassel	10	[101]
Soybean	24-epiBL, 50 mg/ha, spraying at flowering	5	[100]
Potato	24-epiBL, 20 mg/ha, spraying at budding	18	[102]
Tomato	24-epiBL, 25 mg/ha, spraying at flowering	33	[103]
Sugar beet	24-epiBL, 50 mg/ha, spraying at 2–3 leaves	7	[102]

resistance to various external stresses. These effects could make it possible or attractive to grow crops under otherwise-unfavorable conditions such as in areas that have high salinity, are undergoing drought, or have an insufficient nutrient supply. Moreover, BRs have some specific properties that could be very valuable in practical applications [87]. These include:

1. BRs are natural products and are ubiquitous in the plant kingdom. As such, they are a long-standing component of the food chains of men and mammals; the biosynthetic and metabolic pathways of plants and mammals have coevolved over a long period of time and are heavily interconnected.
2. Plants respond to very small doses of BRs (5–50 mg/ha) that are comparable to those that occur naturally.
3. As plant growth-promoting substances, BRs have a broad spectrum of stimulatory and protective activities, all of which should have positive effects on the quantity and quality of crop yields.
4. BRs increase plant resistance to phytopathogens and can be used as substitutes (total or partial) for some traditional pesticides. Their use in this way would reduce the need to use pesticides that interact unfavorably with the environment.
5. BRs can be easily applied to plants and seeds using existing equipment and technologies.

The most commonly used BR in field trials is 24-epibrassinolide because of its high biological activity and relatively simple and synthesis. Treatment with 24-epiBL has been reported to increase yields of wheat, tobacco, rape, orange, grape, and sugar beet [98, 99]. Moreover, the application of 28-homoBL and 24-epiBL to potato plants at a dosage of 10^{-20} mg.ha^{-1} increased yields by 20 % and improved the quality of the crop by decreasing its nitrate content and increasing its content of starch and vitamin C [87]. Some other selected results from BR trials with different agricultural plants are presented in Table 128.1.

The influence of BRs on development and crop yield in different crop plants such as cereals, legumes, vegetables, and fruits has been tested under both laboratory and field conditions. For large-scale field applications, there are two viable methods for applying BRs: soaking seeds and foliar spraying. The performance of these two methods has been investigated in depth; the results obtained with foliar spraying proved to be very dependent on the stage in the plants' development at which it was applied. In general, the best results were obtained when young plants were treated [87].

8 Conclusion

Brassinosteroids are now firmly established as essential regulators of plant growth and development that affect a broad spectrum of processes at the molecular, cellular, and physiological levels. BRs are natural nontoxic, non-genotoxic, biosafe, and eco-friendly plant products and can therefore be used in agriculture and horticulture to improve the growth, yields, quality, and tolerance of various plants to biotic and abiotic stress.

Over the past decade, genetic screening has been widely used for identifying and characterizing major components and genes involved in the BR signaling pathway. However, the molecular mechanisms of these processes remain largely unknown. As such, there is a need for additional research to understand the mechanisms by which BRs affect plant and animal cells on the molecular level.

Abstract

Lycopene, a red-colored carotenoid, present in many fruits and vegetables, including tomatoes and their processed products, watermelon, guava, carrots, pink grapefruit, and sweet potatoes, is inversely associated with the risk of many cancers. Unlike beta-carotene, lycopene lacks a beta-ionone ring and therefore has no provitamin A activity. However, the 11 conjugated and two nonconjugated double bonds in lycopene make it highly reactive toward oxygen and free radicals. Lycopene has been proposed to protect against cancer through various properties including decreased lipid oxidation, inhibition of cancer cell proliferation, and most notably potent antioxidant properties, apoptosis, increased gap-junctional communication, interferences in insulin-like growth factor 1 receptor signaling pathways, and cell cycle progression. Preclinical studies and clinical trials show that lycopene has potent in vitro and in vivo antitumor effects, suggesting potential preventive and therapeutic roles for lycopene. Further mechanistic studies and randomized controlled clinical intervention trials with lycopene in cancer patients are warranted. In this chapter, cancer prevention using lycopene is reviewed and the possible mechanisms of action are described.

Keywords

IGF-1	Insulin-like growth factor
IGFBP-3	Insulin-like growth factor binding protein 3
IL	Interleukin
Keap-1	Kelch-like ECH-associated protein 1
LEC	Long-Evans Cinnamon
LXRα	Liver X receptor alpha
MCF-7	Human breast adenocarcinoma cell line
MMP	Matrix metalloproteinase
MNNG	*N*-methyl-*N′*-nitro-*N*-nitrosoguanidine
MNU	*N*-methyl-*N*-nitrosourea
NASH	Nonalcoholic steatohepatitis
NF-kB	Nuclear factor kappa-light-chain-enhancer of activated B cells
NHANES	National Health and Nutrition Examination Survey
NNK	4-(*N*-methyl-*N*-nitrosamino)-1-(3-pyridal)-1-butanone
Nrf2	Nuclear factor-E2-related factor 2
NSAIDs	Nonsteroidal anti-inflammatory drugs
ORs	Odds ratios
PanIN	Pancreatic intraepithelial neoplasias
PCB	Polychlorinated biphenyls
PCNA	Proliferating cellular nuclear antigen
PGIS	Prostacyclin synthase
PGST	Placental glutathione-*S*-transferase
PPAR	Peroxisome proliferator-activated receptor
PPARγ	Peroxisome proliferator-activated receptor gamma
PSA	Prostate-specific antigen
RAR	Retinoic acid receptor
RCC	Renal cell carcinoma
RR	Relative risk
SOD	Superoxide dismutase
TE	Tomato extract
TF	The metal-binding protein transferrin
THP1	Human acute monocytic leukemia cell line
TNF-α	Tumor necrosis factor-alpha

1 Introduction

There is a link between nutritional factors in the diet and carcinogenesis in humans [1, 2]. Dietary risk factors have ranked higher than smoking and much higher than pollution or occupational hazards in their association with death due to cancer [3]. Intake of a number of compounds naturally occurring in foods, particularly antioxidant compounds in plants, is associated with a lower risk of cancer [4]. However, it is not clear which dietary chemical compounds account for this benefit. Most epidemiological studies suggest that vegetable and fruit consumption has constantly been associated with a reduced incidence of a variety of cancers [1, 2, 4], and dietary carotenoid intake from these sources has similarly been correlated with a reduced cancer risk [4]. Vegetables contain carotenoids such as β-carotene, lycopene, lutein, zeaxanthin, β-cryptoxanthin, and capsanthin. Citrus fruits contain β-cryptoxanthin and marine carotenoids include astaxanthin, β-carotene, lycopene, zeaxanthin, canthaxanthin, and fucoxanthin (Fig. 129.1) [4].

2 Lycopene

Lycopene is a carotenoid, an acyclic isomer of beta-carotene. It is a non-provitamin A carotenoid which gives tomatoes their red color. Humans and animals do not synthesize lycopene and, thus, depend on dietary sources. Tomatoes and tomato products, watermelon, pink grapefruit, apricots, guava, and papaya are the dietary sources of lycopene [5, 6]. Lycopene, one of more than 600 carotenoids synthesized by plants and photosynthetic microorganisms, is a tetraterpene hydrocarbon containing 40 carbon atoms and 56 hydrogen atoms [7]. Lycopene contains 11 conjugated and 2 nonconjugated double bonds, which make it highly reactive toward oxygen and free radicals [8]. The latter feature makes it exist in both the cis- and trans-isomeric forms (Fig. 129.2). In natural plants, it exists predominantly in an all-trans configuration. However, induced by light, thermal energy, and chemical reactions, it can also form cis–trans isomers including 15-, 13-, 11-, 9-, 7-, 5-cis isomers [9]. A recent finding showed that the 5-cis isomer of lycopene is the most stable one followed by the all-trans, 9-cis, 13-cis, 15-cis, 7-cis, and 11-cis isomers [5]. It is absorbed better from heat-processed food sources and lipid-rich diets than from raw food. Lycopene is permitted as a food colorant in the EU and was also approved for use as a food supplement in the USA in July 2005. The only permitted source is tomatoes (*Lycopersicon esculentum*, Lycopersicon, meaning wolf peach). Besides lycopene, tomato oleoresin also contains appreciable amounts of β-carotene, phytoene, and phytofluene [4].

2.1 Mechanism of Lycopene in Cancer Prevention

The mechanisms underlying the chemopreventive activities of lycopene may involve changes in pathways leading to cell growth or cell death (Fig. 129.3 and Table 129.1).

(5-LOX) [39], (h) modulation of carcinogen-metabolizing enzymes [40], and (i) modulation of immune function [41] (Fig. 129.4).

Lycopene has been demonstrated to be the most potent antioxidant with the ranking: lycopene > α-tocopherol > ß-carotene > ß-cryptoxanthin > zeaxanthin = ß-carotene > lutein [42]. Lycopene's oxygen-quenching ability protects against oxidative DNA damage in vitro and in vivo, thereby preventing potential mutations that may be associated with cancer initiation and progression [43]. Due to its extended system of conjugated double bonds, lycopene can quench singlet oxygen and free radicals and has been reported to be the most effective singlet oxygen quencher among

approximately 600 naturally occurring carotenoids [8]. In addition, lycopene can upregulate the antioxidant response element (ARE) and thereby stimulate the production of cellular enzymes such as superoxide dismutase, glutathione-*S*-transferase, and quinone reductase that protect cells from reactive oxygen species and other electrophilic molecules [8]. In human hepatocellular liver carcinoma cell line (HepG2) and human breast adenocarcinoma cell line (MCF-7), lycopene upregulates the ARE through the Nuclear factor-E2-related factor 2 (Nrf2) nuclear transcription pathway [44] (Figs. 129.4 and 129.5). Goo et al. used quantitative proteomics to show that lycopene upregulates the expression of proteins regulated by the ARE in the androgen-sensitive human prostate cell line LNCaP [45]. These proteins included epoxide hydrolase 1 (EPHX1), superoxide dismutase-1 (SOD-1), catalase (CAT), and the metal-binding protein transferrin (TF).

One of the mechanisms of action of lycopene is to increase gap-junctional intercellular communication (GJC) by increasing expression of a widely expressed gap-junctional gene, connexin 43 [32–34, 46] (Fig. 129.4). Increased expression of Cx43 and resulting increases in GJC have previously been shown to occur after treatment of human and murine cells in culture with diverse carotenoids, including lycopene [34]. This action correlates strongly with the ability of these carotenoids to suppress neoplastic transformation in model cell culture systems [32, 34], an action which is shared by retinoids [31]. Decreased expression of connexins, including Cx43, has been reported in human tumors in comparison to normal tissue [47], and connexins are regarded by many as putative tumor suppressor genes [48, 49]. Upregulated junctional communication has in turn been linked to decreased proliferation in normal and preneoplastic cells [50]. This action of

References	Cancer	Mechanism	Findings
Ettorre et al. [19]	Leukemia	Trigger apoptosis	Lycopene phytocomplex triggered apoptosis via a mitochondrial pathway. Redox state of cells was measured in terms of glutathione (GSH) content, but only a small percentage of cells showed GSH depletion, suggesting that the loss of GSH may be a secondary consequence of ROS generation. Moreover, LycoC pretreatment effectively increased apoptosis induced by photodynamic therapy
Palozza et al. [20]	Prostate cancer	Apoptosis and cell growth inhibition by altering mevalonate pathway and Ras signaling	Lycopene may alter mevalonate pathway through inhibition of HMG-CoA reductase. This may induce a decreased prenylation of Ras, which, in turn, may modulate redox-sensitive molecular pathways responsible for NF-κB activation and consequently, for cell cycle arrest and apoptosis induction, as evidenced by decreased cyclin D1 and pAKT levels; increased p21, p27, and p53 levels; and changes in Bax:Bcl-2 ratio
	Colon cancer		
Salman et al. [21]	Colon cancer	Anti-proliferative and apoptotic effect	Lycopene exerted on the proliferation capacity of K562, Raji and HuCC lines, whereas this effect was observed in EHEB cells
	Lymphocytic leukemia		
	Erythroleukemia		
	Burkitt lymphoma		Increased apoptotic rate was found after incubation of HuCC cells with 2.0 and 4.0 μM of lycopene and in Raji cells following incubation with 2.0 μM

carotenoids has been proposed to have mechanistic significance by enabling the transfer of growth-regulatory signals between normal growth-inhibited cells and preneoplastic cells. Indeed, when neoplastic cells were forced into junctional communication with quiescent normal cells, the neoplastic cells became growth arrested in direct proportion to their extent of junctional communication [30]. Furthermore, recent studies have shown that in human carcinoma cells, genetically engineered to be inducible for Cx43 expression, gene induction leads to decreases in their neoplastic potential as measured by changes in anchorage-independent growth and by growth as tumors in the nude mouse [51]. hypothesis of growth control via junctional communication, first proposed by Loewenstein [52], have been multiple reports that connexin expression and/or junctional communication is severely impaired in most solid tumors [47]. Progressive decreases with disease severity in the expression of Cx43 have been reported in the human prostate [53], implying that Cx43 expression is negatively selected during tumor progression. Similar reductions have been seen in tumor versus normal prostate cells [54]. When functional communication was restored in a human prostatic carcinoma cell line, cells had more normal differentiation, reduced proliferation, and suppressed tumorigenicity [55]. There is evidence in prostatic carcinoma cell lines that some of this loss of junctional communication may result from defects in assembly of Cx43 protein into gap junctions [56].

Another mechanism of action of lycopene is the modulation of the IGF-1/IGFBP-3 system (Fig. 129.4). Several studies show that lycopene administration to humans with colon cancer for 1–5 weeks prior to surgery significantly reduces serum IGF-1 levels [57]. Insulin-like growth factors have mitogenic and antiapoptotic effects on normal and transformed prostate epithelial cells [27, 58, 59]. As mitogens and antiapoptotic agents, IGFs may be important in carcinogenesis, possibly by increasing the risk of cellular transformation by enhancing cell turnover. Whereas IGF-1 is an important mitogen for prostate cells, IGFBPs have opposing actions, in part by binding IGF-1, but also by direct inhibitory effects on target cells [27]. In recent epidemiologic studies, relatively high IGF-1 and low IGFBP-3 plasma levels have been independently associated with greater

risk of prostate cancer [28, 29]. A two- to fourfold elevated risk has been observed for prostate cancer in men in the top quartile of IGF-1 relative to those in the bottom quartile, and low levels of IGFBP-3 were associated with an approximate doubling of risk [28]. Siler et al. tested lycopene (200 ppm) and vitamin E (540 ppm) in the MatLyLu Dunning prostate cancer model to gain insight into their in vivo action in humans for 4 weeks [38]. They reported that both compounds accumulated in tumor tissue and macroscopic evaluation of the tumors by magnetic resonance imaging showed a significant increase in necrotic area in the vitamin E and the lycopene treatment groups. Microarray analysis of tumor tissues revealed that both compounds regulated local gene expression. Lycopene interfered with local testosterone activation by downregulating 5-alpha-reductase and consequently reduced steroid target genes expression (cystatin-related protein 1 and 2, prostatic spermine-binding protein, prostatic steroid-binding protein C1, C2, and C3 chain, probasin). In addition, lycopene downregulated prostatic IGF-I and IL-6 expression.

Lycopene may suppress nonphosphorylated β-catenin protein levels and Akt activation, and augment the phosphorylated form of β-catenin, which were associated with reduced protein expression of cyclin D1 [60]. Hence, lycopene may inhibit Wnt/β-catenin signaling via the connection along the Akt/GSK3β/β-catenin [17]. Another potential target for the anticancer activity of lycopene is the 5-LOX pathway. Hazai et al. tested the acyclic tomato carotene lycopene (in all-trans and 5-cis isomeric configurations), its natural dihydroxy analogue lycophyll (also present in tomato fruit), and two bioactive oxidative metabolites of lycopene (4-methyl-8-oxo-2,4,6-nonatrienal and 2,7,11-trimethyl-tetradecahexaene-1,14-dial) and subjected them to molecular modeling calculations in order to investigate their predicted binding interaction(s) with human 5-LOX [39]. Lycopene and lycophyll were predicted to bind with high affinity in the superficial cleft at the interface of the beta-barrel and the catalytic domain of 5-LOX. Carotenoid binding at this cleavage site provided the structural rationale by which polygenic compounds could modify the 5-LOX enzymatic function via an allosteric mechanism, or by radical scavenging in proximity to the active center. In addition, the two bioactive metabolites of lycopene were predicted to bind to the catalytic site with high affinity, suggesting potential direct competitive inhibition of 5-LOX activity that should be shared by both lycopene and lycophyll after in vivo supplementation [61]. Simone et al. reported that lycopene regulates cigarette smoke-driven inflammation in human macrophages, THP-1 [62]. They have shown that lycopene inhibits the production of the proinflammatory cytokine IL-8 induced by cigarette smoke. Yang et al. [14] demonstrated that the anti-proliferative effect of lycopene on human prostate cancer cells (LNCaP) involves the activation of the peroxisome proliferator-activated receptor gamma (PPARγ)-liver X receptor alpha (LXRα)-ATP-binding cassette transporter 1 (ABCA1) pathway.

3 The Protective Role of Lycopene in Cancer Prevention

3.1 Lung Cancer

Lung cancer is one of the most common cancers in the world. The important risk factors for lung cancer are smoking, air pollution, and diet. Several studies have indicated that smokers and lung cancer patients tend to have lower plasma concentrations of retinol, α-tocopherol, β-carotene, lycopene, β-cryptoxanthin, selenium, and zinc [63]. This observation was explained by cigarette smoking impairing the uptake of the fat soluble antioxidants or that smokers have differing diets compared to nonsmokers, smoke being an appetite suppressant [64]. In a study, authors have treated lycopene solutions, human plasma, and isolated LDL with cigarette smoke and monitored all-(E)-lycopene, 5(Z)-lycopene, and beta-carotene depletion. In plasma, the depletion of all-(E)-lycopene (15.0+/−11.0%, $n = 10$) was greater than 5(Z)-lycopene (10.4+/−9.6%) or beta-carotene (12.4+/−10.5%). In LDL, both all-(E)- and 5(Z)-lycopene were more susceptible than beta-carotene (20.8+/−11.8%, 15.4+/−11.5%, and 11.5+/−12.5%, $n = 3$ respectively). The effects have been compared with Sin-1 reactions and isomerization of all-(E) lycopene is common to both treatments [64]. Consumption of tomato or tomato products such as lycopene has been associated with a lower risk of lung cancer [5]. Additionally, Choi et al. reported that Hel299 lung cells, A549 lung cancer cells, and HeLa cervical carcinoma cells were highly susceptible to inactivation by glycoalkaloid-rich green tomato extracts [65].

Recently, in vitro and in vivo experimental data have demonstrated lycopene's notable anticarcinogenic effect in lung carcinogenesis. Results from the combination of the Nurses' Health Study and Health Professional Follow-Up Study [66] and from the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study [67] showed that high intake of lycopene was associated with an approximately 20–30% lower risk of lung cancer. Cohort studies failed to show an inverse relation between lycopene intake and lung cancer prevalence [68, 69]. However, in almost all case–control studies, odds ratio of developing lung cancer with high lycopene or tomato intake was below one [70–74]. A case–control study on lung cancer in Spanish women matched 103 cases to 206 hospital controls by age and residence. High intake of lycopene was the carotenoid with the strongest, although not significant, inverse association with the risk of lung cancer (Odd ratio [OR] = 0.56, confidence interval [CI] = 0.26–1.24, trend $p = 0.15$) when adjusted for smoking status, total pack-years smoked, vitamin E and vitamin C intake, total flavonoid intake, and intake of other specific carotenoids [75]. These results were confirmed by Ito et al. [76]. In their nested case–control study, a marginally significant inverse association between serum lycopene level and lung cancer death was found (0.46, 95% CI 0.21–1.04) after adjusting for smoking and serum levels of other carotenoids. Furthermore, a 40% reduction in risk of mesothelioma was observed for those consuming tomato or tomato juice 16 or more times a month versus nonconsumers [77]. Only 1.7% of control subjects reported not consuming tomatoes or tomato juice as opposed to 9% of case subjects, suggesting that people who do not consume tomato products are at a high risk for mesothelioma.

In a cell culture study, Lian et al. observed that apo-10′-lycopenoic acid inhibited the growth of NHBE normal human bronchial epithelial cells, BEAS-2B-immortalized normal bronchial epithelial cells and A549 non-small cell lung cancer cells [78]. This inhibitory effect of apo-10′-lycopenoic acid was associated with decreased cyclin E, inhibition of cell cycle progression from G(1) to S phase, and increased cell cycle regulators p21 and p27 protein levels. In addition, apo-10′-lycopenoic acid transactivated the retinoic acid receptor beta (RARβ) promoter and induced the expression of RARbeta. They also examined the effect of apo-10′-lycopenoic acid treatment on 4-(*N*-methyl-*N*-nitrosamino)-1-(3-pyridal)-1-butanone (NNK)-induced lung tumorigenesis in the A/J mouse model.

They found that the lung tumor multiplicity was decreased dose-dependently from an average of 16 tumors per mouse in the NNK injection alone group, to an average of 10, 7, and 5 tumors per mouse in groups injected with NNK and supplemented with 10, 40, and 120 mg/kg diet of apo-10′-lycopenoic acid, respectively. Lian et al. also reported that treatment with apo-10′-lycopenoic acid, in a time- and dose-dependent manner, results in the nuclear accumulation of transcription factor Nrf2 protein in BEAS-2B human bronchial epithelial cells [79]. The activation of Nrf2 by apo-10′-lycopenoic acid is associated with the induction of phase II detoxifying/antioxidant enzymes including heme oxygenase-1, NAD(P)H:quinone oxidoreductase 1, glutathione-*S*-transferases, and glutamate-cysteine ligases in BEAS-2B cells. Furthermore, apo-10′-lycopenoic acid treatment increased total intracellular glutathione levels and suppressed both endogenous reactive oxygen species generation and H(2)O(2)-induced oxidative damage in BEAS-2B cells. Animal experiments also showed that lycopene might play a role in prevention of lung cancer. In a study, the incidence of lung adenoma and carcinoma in male mice that received 50 ppm lycopene in addition to diethylnitrosamine (DEN), *N*-methyl-*N*-nitrosurea (MNU), and 1,2-dimethylhydrazine (DMH) was found to be lower than the incidence in those that did not receive lycopene (75.0% vs. 18.8%) [80]. It was also reported that lycopene supplementation prevented downregulation of apoptosis in ferrets exposed to smoke while increasing the IGFBP-3 levels [81]. Taken together, these findings demonstrated that lycopene could suppress the proliferation and promote the lung cancer cells, which may be involved in the action mechanisms of lycopene in the prevention of lung cancer.

3.2 Gastric Cancer

Gastric cancer is the fourth most frequent cancer and the second leading cause of cancer death worldwide. Epidemiologic, experimental, and animal studies indicate that diet plays an important role in the etiology of gastric cancer. High intake of fresh fruits and vegetables, lycopene, and lycopene-containing food products may reduce the risk for gastric cancer [82]. In the meta-analysis of cohort studies, the summary relative risks of gastric cancer were 0.82 (95% CI 0.73–0.93) for fruits and 0.88 (95% CI 0.69–1.13) for vegetables [83]. There is great interest in lycopene in gastric cancer because it is a leukotriene inhibitor [61] and the products of the arachidonic acid–metabolizing enzyme, 5-LOX, stimulate the growth of several cancer types. Inhibitors of 5-LOX and 5-LOX-activating protein (FLAP) induce apoptosis in some cancer cells. Fan et al. [84] investigated the effect of a FLAP inhibitor, MK-886, on the inhibition of proliferation and induction of apoptosis in gastric cancer. They found that MK-886 inhibited cell growth in a dose- and time-dependent manner. Apoptosis was induced in gastric cancer cells and was characterized by upregulation of p27kip1 and Bax, with release of cytochrome c from mitochondria into cytosol, which initiated caspase-3 activation. Specific caspase-3 inhibitors partially blocked MK-886-induced apoptosis.

In a large cohort of 120,852 men and women, no association was found between lycopene intake and gastric carcinoma [85]. However, in at least six case–control studies to date, an inverse association between lycopene or tomato intake and gastric carcinoma incidence was reported [86–91]. In a case–control study conducted in Italy with 723 cases of stomach cancer and 2,879 matched controls, a significant trend in decreased risk associated with raw tomato intake consumption was demonstrated (odds ratio for quartiles: 1.00, 0.59, 0.45, 0.43) after adjusting for age, sex, study center, education, caloric intake, alcohol consumption, and smoking [88]. In another case–control study recently published including 191 cases and 570 age-, neighborhood-matched controls from China, odds ratio for gastric carcinoma in the highest versus lowest quartile of prediagnostic lycopene levels was found to be 0.55 (95% CI 0.30–1.00) [92]. Serum lycopene levels were significantly different between two groups. Pelucchi et al. found decreased odds ratios for the highest versus lowest quartile of vitamin E (OR = 0.50), alpha-carotene (OR = 0.52), and beta-carotene (OR = 0.42) intake [93]. They also reported that gastric cancer was directly associated with sodium, with ORs of 2.22 for the second, 2.56 for the third, and 2.46 for the fourth quartile of intake. However, no significant relation emerged with iron, calcium, potassium, zinc, vitamin C, thiamin, riboflavin, niacin, vitamin B6, folate, vitamin D, retinol, beta-cryptoxanthin, lycopene, and lutein plus zeaxanthin.

Several studies reported that lycopene was shown to inhibit gastric carcinogenesis induced by *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine and saturated sodium chloride [94–96]. In that studies, lycopene's chemopreventive activity was suggested to be due to modulating the expression of apoptosis-associated proteins Bcl-2, Bax, Bim, caspase 8, and caspase 3 and its antioxidant activity [94–96]. Study by Luo and Wu investigated the chemopreventive effect of lycopene on the oxidative injury and immunity activities of *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG)-induced gastric cancer rats [18]. Administration of lycopene (50, 100, and 150 mg/kg body weight) to gastric carcinoma-induced rats largely upregulated the redox status and immunity activities to decrease the risk of gastric cancer. In an animal model, the effects of lycopene administration on cigarette-smoke-induced changes in protein levels of p53 tumor suppressor gene, p53 target genes (p21 $^{\mathrm{Waf1/Cip1}}$ and Bax-1), cell proliferation, and apoptosis in the gastric mucosa were examined [97]. In that study, lycopene levels were significantly elevated in a dose-dependent manner in the gastric mucosa of ferrets supplemented with lycopene alone, but were markedly reduced in ferrets supplemented with lycopene and exposed to smoke. It was also found that total p53 and phosphorylated p53 levels were higher in ferrets exposed to smoke alone than in all other groups. However, smoke-elevated total p53 and phosphorylated p53 were markedly attenuated by both doses of lycopene. p21(Waf1/Cip1), Bax-1, and cleaved caspase 3 (an index for apoptosis) were substantially decreased, whereas cell proliferation indices like cyclin D1 and proliferating cellular nuclear antigen (PCNA) were increased in ferrets exposed to smoke alone, while lycopene prevented smoke-induced changes in p21(Waf1/Cip1), Bax-1, cleaved caspase 3, cyclin D1, and PCNA in a dose-dependent fashion. In contrary to these results, Persson et al. found no significant association between plasma levels of lutein/zeaxanthin, lycopene, retinol, alpha- or gamma-tocopherol, and gastric cancer risk [98].

3.3 Breast Cancer

Breast cancer is by far the most frequent cancer among women. Environmental factors, particularly dietary factors, have been postulated to play important roles in the etiology of breast cancer. An overall benefit of consumption of fruits and vegetables has been suggested for breast cancer in women in the USA [99]. Carotenoids such as lycopene are hypothesized to reduce the risk of breast cancer due to their capacity for scavenging DNA damaging free radicals, inhibit cell proliferation, induce apoptosis, and suppress angiogenesis [100]. Several case–control and prospective cohort studies have conducted the relationships between the lycopene and breast cancer. However, the results remain inconsistent. Comparing the highest with the lowest intake, dietary intake of lycopene did not significantly reduce the breast cancer risk (RR = 0.99; 95% CI: 0.93–1.06; I2 = 0.00%) when data from cohort studies were pooled [100]. Furthermore, no significant association was observed in further subgroup analyses. When data from case–control studies were pooled, dietary intake of lycopene significantly reduced the breast cancer risk by 29.0% (OR = 0.71; 95% CI: 0.56–0.92; I2 = 84.71%) [100, 101]. A nested case–control study was also done in the same cohort with 508 breast cancer cases and 508 controls and their plasma lycopene levels were not different (10.8 vs. 10.3 mcg/dl). Another nested case–control study including 1,452 breast cancer cases mice and 5,239 women showed that age-adjusted relative risks for breast cancer in increasing quintiles of lycopene intake were 1.0, 1.15, 0.93, 0.97, and 1.01 [102]. In another nested case–control study with 295 cases and 295 matched controls, the risk of developing breast cancer in the highest fifth quintile of plasma lycopene level was approximately half of that in the lowest fifth [103]. In a study comparing lycopene levels in breast adipose tissue between 46 cases and 63 benign controls, lycopene levels were inversely associated with breast cancer risk when adjusted for age, smoking status, and menopausal status [104]. Dorjgochoo et al. prospectively investigated the associations of plasma levels of tocopherols, retinol, and carotenoids with the risk of developing breast cancer among Chinese women [105]. They conducted a study of 365 incident breast cancer cases and 726 individually matched controls nested within a large cohort study of women aged 40–70 years at baseline. They observed no associations between breast cancer risk and any of the tocopherols, retinol, and most carotenoids. However, high levels of plasma lycopene other than trans, 5- and 7-cis, or trans alpha-cryptoxanthin were inversely associated with the risk of developing breast cancer. Moreover, Wang and Leung lycopene administration slightly reduced the 7,12-dimethyl-benz[a] anthracene (DMBA)-induced ethoxyresorufin-*O*-deethylase activity by 20% in MCF-7 cells [106].

Lycopene has been shown to inhibit the incidence and growth of the chemically induced breast tumors in laboratory animal studies [12, 107]. A protective effect of lycopene was found on DMBA-induced rat mammary tumors. When compared with placebo or control rats, the lycopene fed rats had the smallest average size of tumors, but the difference was not statistically significant. The number of tumors that developed over 135 days was much lower in the lycopene-treated group than the control group [107]. In a study, using rats, we have demonstrated that inhibition of mammary cancer incidence by lycopene (70%), genistein (60%), and their combination (40%) was observed [12]. In the same study, tumor weight decreased by 48%, 61%, and 67%, and mean tumor volume decreased by 18%, 35%, and 65% with lycopene, genistein, and lycopene + genistein, respectively. Animals administered DMBA developed breast cancer, which was associated with increased expression of Bcl-2 and decreased expression of Bax, caspase 3, and caspase 9 in mammary tissues. Administration of genistein and lycopene in combination was more effective in inhibiting DMBA-induced breast tumors and modulating the expression of apoptosis-associated proteins than the administration of each agent alone [12]. Moselhy and Al-mslmani [108] reported protection against DMBA-induced carcinogenesis was 66.5% in animals that received lycopene, whereas it was 80% in animals that received lycopene with melatonin as compared with nontreated rats. However, Cohen et al. reported that neither pure lycopene nor lycopene in the form of a mixed carotenoid oleoresin exerted an inhibitory effect on tumor incidence, latency, multiplicity, volume, nor total tumors per group compared with unsupplemented controls [109]. Differences in routes of administration (intraperitoneal injection, gavage, intra-rectal instillation, drinking water, and diet supplementation), species and strain differences, form of lycopene (pure crystalline, beadlet, and mixed carotenoid suspension), varying diets (grain-based and casein based), and dose ranges (0.5–500 ppm) resulted in no prevention effect on development of chemically induced mammary cancer. Additionally, Hu et al. reported that no significant association between dietary intake of β-cryptoxanthin, lutein/+zeaxanthin, and lycopene and breast cancer was observed in a comprehensive study [100]. In an another study, the combination of lycopene and tocopherol treatment showed a potential reduction of malondialdehyde and nitric oxide more than lycopene alone in serum and breast tissues of DMBA-injected rats. Formation of tumor and angiogenesis in DMBA-induced rats and these abnormal changes were ameliorated by combined treatment with combination of lycopene and tocopherol [11].

In a cell study on breast tumor cell lines, cells were cycle-arrested at G1/S phase after treatment with 10 microM lycopene for 48 h [110]. Expressions of breast cancer-1 (BRCA1) and breast cancer-2 (BRCA2) genes were increased in estrogen receptor (ER)-positive cell lines (MCF-7 and HBL-100) and were decreased in ER-negative cell lines (MDA-MB-231), suggesting an indirect effect of lycopene on the estrogen pathway [110]. In another cell study on MCF-7 cell line, bcl-2 mRNA expression was decreased by 88% and cell cycle progression was blocked at G(2)/M phase after treatment with lycopene [111]. Nahum et al. suggested that lycopene inhibited cell cycle progression via reduction of the cyclin D level and retention of p27 in cyclin E-cdk2, leading to inhibition of CDK activities [112]. Uppala et al. have shown that lycopene inhibits cell proliferation in MCF-7 human breast cancer cells but not in the MCF-10 mammary epithelial cells [10]. Lycopene was shown to modulate cell cycle proteins such as beta tubulin, CK8/18, CK19, and heat shock proteins.

3.4 Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is the fifth leading cause of death from cancer in males and the eighth leading cause in females in the USA [113]. Worldwide, liver cancer is the third leading cause of death from cancer [114, 115]. The incidence of and mortality from HCC are variable worldwide, with the Far East and sub-Saharan Africa having the highest incidences. The primary risk factors for HCC are infection with hepatitis B and hepatitis C viruses, and long-term exposure to aflatoxin. Chronic alcoholism leading to chronic liver disease is a significant risk factor [115, 116].

Phytochemicals have been examined for their effects including anticancer with its single oxygen-quenching ability on carcinogenesis in the liver [115, 117]. Lycopene is known to have a significant anticancer effect with its single oxygen-quenching ability. Several studies have reported that lycopene exhibits multifunctions in inhibition of metastasis in hepatoma SK-Hep-1 cells both in vitro and in nude mice [118, 119], upregulation of kelch-like ECH-associated protein 1 (Keap1)-Nrf2-antioxidant response element system in HepG2 cells [44]. Although experimental evidence from in vitro studies has suggested a beneficial effect of lycopene against hepatocarcinogenesis, [117, 120], results from human and animal studies are inconsistent. For example, Tharappel et al. found that lycopene decreased the number of placental glutathione-*S*-transferase (PGST)-positive foci induced by diethylnitrosamine/polychlorinated biphenyls-77 (DEN/PCB-77) but slightly increased their volume [121]. A case–control study has examined the relationship between lycopene and aflatoxin B_1 (AFB_1) initiated hepatocellular carcinoma. Lycopene was thought to influence the binding of AFB_1 to hepatic DNA. The urine level of the major in vivo AFB_1-DNA adduct, AFB_1-N^7-guanine, was significantly higher in subjects with HCC than in controls (HCC OR = 7.52). Plasma lycopene level was inversely related to the presence of AFB_1-N^7-guanine in urine [122]. However, lycopene (1.5 g/kg of 5% lycopene oleoresin) administered during the initiation phase did not show any effect on the size or number of AFB_1-induced rat liver tumors [123]. A separate mouse study gave 30 C3H/He male mice lycopene (0.005% in drinking water) for 40 weeks. Lycopene reduced the number of liver tumor-bearing mice by 49.7% (88.2% for control vs. 38.5% for lycopene-treated mice) and reduced the average number of tumors per mouse by 88% (7.65–0.92) [124]. In an animal model of hepatocarcinogenesis in rats, lycopene decreased the size of preneoplastic foci in liver induced by DEN, but did not reduce the number of lesions [125]. Anticarcinogenic effects of lycopene were demonstrated with the inhibition of toxic effects of aflatoxin B1 [126]. Reddy et al. demonstrated that hepatocytes pretreated with lycopene and beta-carotene are protected from the effects of the carcinogen aflatoxin at both cellular and molecular levels. In contrast, in another study with Long-Evans Cinnamon (LEC) rats, lycopene administration (50 mg/kg diet) for 70 weeks did not reduce the risk of spontaneous liver carcinogenesis [127]. These discrepant observations could be related with different models or lycopene dosages used in these studies.

In a study using Hep3B human hepatoma cell lines, Park et al. have demonstrated that lycopene induced G0/G1 arrest and S phase block and inhibited cell growth in a dose-dependent manner by almost 40% [128]. In another study on SK-Hep1 human hepatoma cell line, lycopene's antimetastatic properties were shown by adhesion and migration assays. Invasiveness of the cells was reduced by 62% after treatment with 10 microM lycopene [118]. It has been recently reported that antimetastatic effects of apo-8′-lycopenal (1–10 μM) in comparison with lycopene (10 μM) in SK-Hep-1 cells were determined by Yang et al. [14]. They found that both apo-8′-lycopenal and lycopene inhibited the invasion and migration of SK-Hep-1 cells, and the effect of apo-8′-lycopenal was stronger than that of lycopene at the same concentration (10 μM). They also reported that apo-8′-lycopenal: (1) decreased the activities and protein expression of metalloproteinase-2 (MMP-2) and -9; (2) increased the protein expression of nm23-H1 and the tissue inhibitor of MMP (TIMP)-1 and -2; (3) suppressed protein expression of Rho small GTPases; and (4) inhibited focal adhesion kinase–mediated signaling pathway, such as ERK/p38 and PI3K-Akt axis. On the other hand, Takahashi et al. also demonstrated that contrary to previous reports of the inhibitory effects of lycopene and EGCG on the development of various carcinogen-induced animal tumors, these compounds exert no chemopreventive effects on spontaneous liver tumorigenesis in C3H/HeN mice [129]. Wang et al. investigated the efficacy of an equivalent dosage of dietary lycopene from either a pure compound or a tomato extract against high-fat diet (HFD)-induced nonalcoholic steatohepatitis (NASH)-promoted hepatocarcinogenesis in a rat model for 6 weeks [130]. They found that both lycopene and tomato extract supplementations significantly decreased the number of altered hepatic foci expressing the placental form of glutathione-*S*-transferase in the livers of HFD-fed rats. This was associated with significantly lower proliferating cell nuclear antigen–positive hepatocytes and cyclinD1 protein, as well as decreased activation of ERK and nuclear NF-κB. Although both lycopene or tomato extract supplementations reduced HFD-induced lipid peroxidation in the livers, they observed significantly decreased cytochrome P450 2E1, inflammatory foci, and mRNA expression of proinflammatory cytokines (TNF-α, IL-1β, and IL-12) in the HFD + tomato extract–fed group but increased nuclear NF-E2-related factor-2 and heme oxygenase-1 proteins in the HFD + lycopene–fed group, relative to HFD feeding alone.

3.5 Pancreatic Cancer

Chronic pancreatitis has long been thought to be mainly associated with immoderate alcohol consumption, tobacco smoke, and obesity, diets high in animal protein and fat, as well as antioxidant deficiencies. Diets high in processed or red meat, diets low in fruits and vegetables, phytochemicals such as lycopene and flavonols, have been proposed and refuted as risk or protective factors in different trials [131]. In a case–control study of 462 cases and 4,721 controls, there was a significant inverse association between lycopene intake and pancreatic cancer, after adjustment for age, body-mass index, smoking status, total energy intake, education, and dietary folate [132]. However, no difference was found in women. Another prospective case–control study comparing frozen serum samples from 22 pancreatic cancer cases to 44 matched controls demonstrated that mean levels of lycopene were significantly lower in cases (0.70 ± 0.07 μmol/L) than in control subjects (0.93 ± 0.06 μmol/L), after adjusting for smoking status, educational level, and serum levels of other carotenoids and retinoids [133]. Seo et al. investigated whether lycopene protects oxidative stress–induced cell death of pancreatic acinar AR42J cells by preventing the loss of Ku70 in the nucleus [134]. The cells received oxidative stress caused by glucose oxidase acting on beta-D-glucose (glucose/glucose oxidase) and were cultured in the absence or presence of various concentrations of lycopene. Lycopene inhibited glucose/glucose oxidase–induced cell death by preventing nuclear loss of Ku70 and a decrease in Ku-DNA-binding activity of AR42J cells.

3.6 Colorectal Cancer

Colorectal cancer is one of the most common causes of cancer-related mortality in Western societies, and the death rate from colon cancer has also been stably increasing in Asia [135]. According to American Cancer Society, more than 50,000 people die from colorectal cancer each year. Although the causes are not completely understood, it is generally accepted that the hereditary genetic component combined with low intake of fibers, proteins, fruits, and vegetables as well as diets with high red and processed meat and fat levels are among the greatest risk factors [136]. Although many people are diagnosed with colorectal cancer every day, there is no reported preventative treatment for this deadly disease. However, it has been suggested that a diet loaded with natural antioxidant-rich foods may reduce the risk of developing colorectal cancer [137]. Malila et al. reported that no significant association was found between colorectal cancer risk and dietary lycopene intake in a large cohort study of middle-aged male smokers during an 8-year follow-up [138]. However, case–control studies reported about a 60% reduction in risk of colorectal cancers associated with higher tomato consumption [139, 140]. In an Italian case–control study with 955 colon cancer and 629 rectal cancer patients, a significant trend in decreased colon and rectum cancer risk associated with raw tomato intake consumption was identified [141]. In another study, when subjects who had colorectal adenomas were compared to those who had no adenomatous polyps, the median plasma lycopene level was 35% lower than that in the adenoma group [142]. Also, plasma lycopene concentration <70 mcg/l was found to be a risk factor for adenomatous polyps in logistic regression (OR: 2.31, 95% CI: 1.12–4.77). Tissue lycopene level in colon, along with levels of lutein, tocopherols, carotenes, and beta-cryptoxanthin, was found to be significantly lower in 10 patients with adenomatous polyps than in 15 patients with normal colonic mucosa [143]. In cell culture study, Lin et al. demonstrated that lycopene significantly inhibited leptin-mediated cell invasion and matrix metalloproteinase-7

(MMP-7; matrilysin) protein expression in human colon cancer HT-29 cells [17]. Lycopene could augment the expression and stability of E-cadherin proteins. They showed that MAPK/ERK and PI3K/Akt signaling pathways played important roles in leptin-mediated MMP-7 expression and cell invasion. Lycopene could effectively inhibit the phosphorylation of Akt, glycogen synthase kinase-3β (GSK-3β), and ERK 1/2 proteins.

Several studies have evaluated the protective effects of lycopene supplementation against rat and mouse colon carcinogenesis induced by carcinogens such as azoxymethane (AOM), 1,2-dimethylhydrazine (DMH), or *N*-methyl-*N*-nitrosourea (MNU) with some contradictory results. In rats pretreated with MNU, those who were treated with a daily intragastric lavage of lycopene had a significant reduction in both size and number of colonic aberrant crypt foci (ACFs), precursor lesions of colon cancer [144]. Furthermore, ACFs following treatment with AOM were reduced by 58% in rats treated with lycopene compared to the controls [145]. However, in another study, addition of lycopene into drinking water had no effect on number of ACFs in mice treated with DMH [146]. In male Fischer 344 rats initiated with AOM, treatment with this carotenoid during the initiation phase inhibited the early formation of ACF, but not during the post-initiation phase [147]. Also, post-initiation treatment with lycopene did not reduce the development of ACF in male B6C3F1 mice initiated with MNU or in male and female B6C3F1 mice initiated with a combination of the carcinogens DEN, MNU, and DMH [148]. In contrast, treatment with lycopene during the post-initiation phase reduced ACF development but not colon tumors in female Fischer 344/NSlc rats, respectively [149]. A rat study evaluated whether a synergy exists for the combined treatment with lycopene (300 mg/kg) and symbiotic (*Bifidobacterium lactis* plus oligofructose/inulin) on early biomarkers of colon carcinogenesis by DMH. Treatment with lycopene, symbiotic or their combination, significantly increased apoptosis, reduced the PCNA and p53 labeling indexes, and the development of classical ACF and mucin-negative ACF. Furthermore, a lower genotoxicity of fecal water was also detected in the groups treated with the chemopreventive agents. An additive/synergistic effect of the combined treatment with lycopene/symbiotic was observed only for the fecal water genotoxicity and mucin-negative ACF parameters [150].

Study from our laboratory has shown that tomato powder added to feed at 5% rate decreases the rate of ACF and reduces the development of adenocarcinoma and growth of AOM-induced colorectal cancer in rats (Fig. 129.6). In addition, we demonstrate that tomato powder supplementation shows its chemopreventive activities through inhibition of cyclooxygenase-2 (COX-2) expression via NF-κB pathway and promotion of apoptosis, as well as regulating Nrf2/HO-1 signaling pathway in colorectal tissue of AOM-treated rats (Fig. 129.7). Our findings identify an intimate connection between dietary supplementation of tomato powder and the decreased risk of colorectal cancer in rats, and suggest that consumption of tomato powder would be a natural candidate for the prevention of colorectal cancer in men [151]. Tang et al. investigated whether consumption of lycopene could prevent the growth and progression of colorectal tumor in a mouse xenograft model [152].

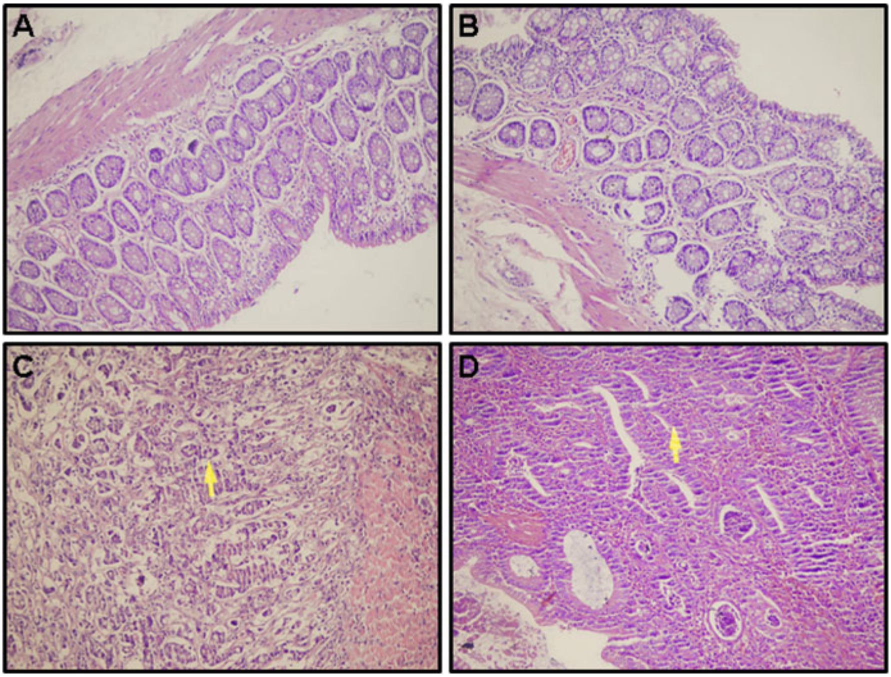

Fig. 129.6 Representative histopathology of H&E stained colorectal tissue sections (**a**) control group fed with a standard diet (**b**) control group + tomato powder fed with a standard diet +5 % tomato powder (**c**) AOM-treated group fed with a standard diet (**d**) AOM + tomato powder group fed with a standard diet +5 % tomato powder (×400 magnification) [151]

The results indicated that lycopene could effectively suppress the growth and progression of colon cancer in tumor-bearing mice. They also demonstrated that lycopene significantly suppressed the nuclear expression of PCNA and β-catenin proteins in tumor tissues. Consumption of lycopene could also augment the E-cadherin adherent molecule and nuclear levels of cell cycle inhibitor p21(CIP1/WAF1) protein. The chemopreventive effects of lycopene were associated with suppression of COX-2, PGE(2), and phosphorylated ERK1/2 proteins. Furthermore, the inhibitory effects of lycopene were inversely correlated with the plasma levels of matrix metalloproteinase 9 (MMP-9) in tumor-bearing mice.

3.7 Bladder Cancer

A relative risk of 1.40 (95% confidence interval = 1.08–1.83) was reported for a diet low in fruit intake in a meta-analysis of diet and bladder cancer [153]. However, no associations were observed for intakes of total fruits or vegetables [154, 155]. In a nested case–control study of 569 bladder cancer cases and 3,123 controls, relative risk for bladder cancer was 1.08 comparing highest to lowest

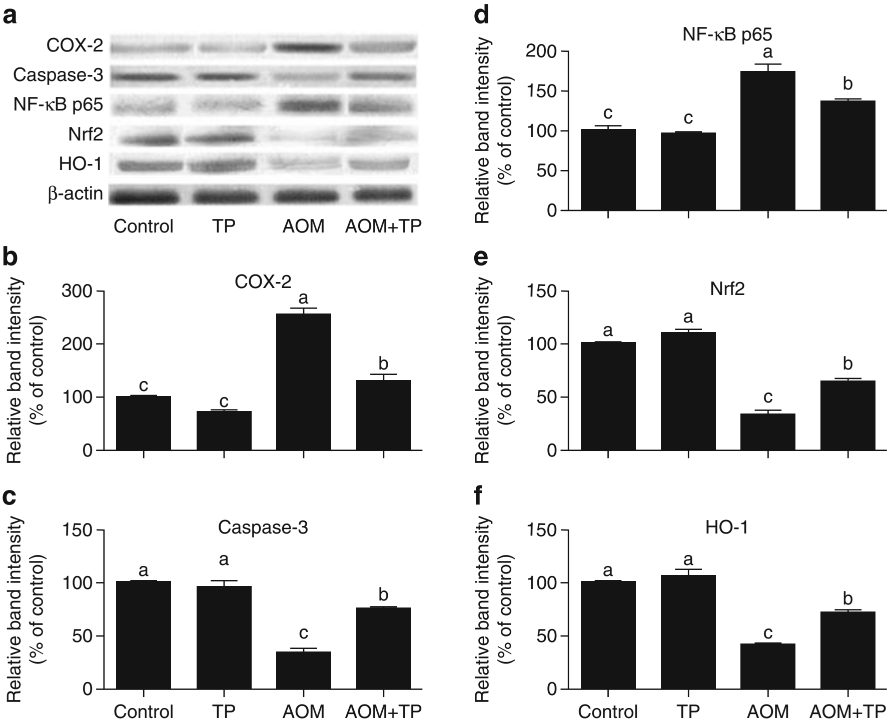

Fig. 129.7 The effects of tomato powder on COX-2, Caspase-3, NF-κB, Nrf2 and HO-1 expressions in the colon of rats [151]

quintile of lycopene intake [156]. However, in a previous cohort study, serum lycopene level was found to be lower in bladder cancer cases than in matched controls [157]. In another case–control study with 84 cases and 173 controls, OR for bladder cancer was found to be 0.94 (95% CI 0.89–0.99) in the highest quartile of plasma lycopene intake when compared to the lowest after controlling for age, sex, education, and pack-years of smoking [158]. None of the other case–control studies found statistically significant associations with risk of bladder cancer, although tendencies for inverse associations were reported [159–161]. In an animal study, lycopene administered in drinking water exhibited a nonsignificant tendency to decrease the number of transitional cell carcinomas of the bladder in rats after the administration of *N*-butyl-*N*-(4-hydroxybutyl) nitrosamine [162].

3.8 Head and Neck Cancer

Epidemiologic studies, in vitro, and in vivo animal studies have suggested that tomato and lycopene have beneficial effects in the treatment of head and neck cancer [9, 163–165]. Mayne et al. evaluated the association between plasma b- and a-carotene, lycopene, lutein⁄zeaxanthin, total carotenoids, retinol, a-tocopherol, and subsequent mortality in a cohort of 259 patients with prior oral, pharynx, or larynx cancers [164]. They reported that only plasma lycopene was significantly inversely associated with total mortality and mortality in nonsmoking patients. In a case–control study including 754 oral cancer cases and 1,775 controls, dietary lycopene measured by food frequency questionnaires was not found to be significantly associated with oral cancer risk [166]. Another case–control study including 201 larynx cancer cases failed to show an association between cancer risk and tomato intake [167]. A similar result was found in another case–control study in Italy, in which reduced risk of cancers of oral cavity and pharynx emerged in subjects reporting more frequent consumption of fresh tomatoes [168]. However, Zheng et al. reported in a case–control study that OR for oral cancer was 0.49 (95% CI 0.26–0.94) in subjects with high tomato intake [169]. Additionally, lycopene strongly and dose-dependently inhibited proliferation of a human oral cancer cell line KB-1 while upregulating expression of gap-junctional protein connexin 43 [165].

Animal experiments also showed that lycopene might play a role in prevention of oral cancer. In a study, an inverse association was observed between lycopene (2.5 mg/kg lycopene orally) and buccal pouch squamous cell carcinomas in hamsters [170]. It was also reported that the daily lycopene intake improved oral leukoplakia lesions in a group of patients [171]. The chemopreventive efficacy of lycopene with regard to oral carcinogenesis was investigated using 4-nitroquinoline-1-oxide (4-NQO)–induced tongue squamous cell carcinoma in rats by El-Rouby [172]. Lycopene treatment at a dose of 2.5 mg/kg body weight by intragastric intubation once a day significantly decreased the incidence of 4-NQO induced tongue carcinogenesis. A decreased percentage of PCNA-positive nuclei was associated with lycopene treatment. Increased E-cadherin and β-catenin immunoexpression was recorded in the lycopene-treated group in comparison to the carcinogen group [172]. Cheng et al. investigated the chemopreventive effect of lycopene and other carotenoids in betel quid extract–induced hamster oral cancer model [173]. They reported that no carcinoma was found in the lycopene or mixed carotenoid groups, whereas apparent ones appeared in the control group. In dysplastic lesions, the expressions of PCNA by the lycopene were less than that of control group. In order to study the relationship between tomatoes, tomato products, and lycopene and cancers of the upper aerodigestive tract (oral cavity, pharynx, larynx, and esophagus), De Stefani et al. conducted a case–control study in Uruguay [174]. Two-hundred and thirty eight cases and 491 hospitalized controls were frequency matched on age, sex, residence, and urban/rural status. Both series were submitted to a detailed questionnaire, including tobacco smoking, alcohol drinking, and queries on 64 food items. Tomato intake was associated with a reduction in risk of 0.30 (95% CI, 0.18–0.51), whereas tomato sauce–rich foods displayed a protective effect of 0.57 (95% CI, 0.33–0.96 for the highest quartile of intake). The food group composed of raw tomato and tomato-rich foods showed a strong inverse association with head and neck cancer (OR, 0.23; 95%

CI, 0.13–0.39 for the highest quartile of intake). Lycopene was also strongly associated with a reduced risk of 0.22 (95% CI, 0.13–0.37). Adjustment of tomato intake for several phytochemicals explained almost completely its protective effect, which disappears in this model.

3.9 Prostate Cancer

Prostate cancer is the second leading cause of cancer deaths in males in the USA. It accounts for about 30% of all cancers that are diagnosed in men. The incidence of prostate cancer has increased dramatically in the last decade mainly due to the increase in screening using prostate-specific antigen. The prevalence of the precursor lesion, high-grade prostatic intraepithelial neoplasia (HGPIN), and carcinoma of the prostate increases with aging, starting in men in their early 30s. Lycopene has been postulated to be the protective compound against prostate cancer [175–178]. The epidemiologic studies on dietary lycopene intake or level and prostate cancer based on observational studies have been inconsistent overall. Several studies had appeared more promising but some studies are not supportive [163, 176, 177, 179–181]. In a review, Ilic and Misso reported that meta-analysis of four studies identified no significant decrease in the incidence of benign prostatic hyperplasia (RR =0.95, 95% CI 0.63, 1.44) or prostate cancer diagnosis (RR = 0.92, 95% CI 0.66, 1.29) between men randomized to receive lycopene and the comparison group [182]. Meta-analysis of two studies indicated a decrease in PSA levels in men diagnosed with prostate cancer, who received lycopene (mean difference = −1.58, 95% CI −2.61, −0.55). A strong inverse dose–response relationship between lycopene intake and prostate cancer risk was reported in a case–control study of Chinese men [183]. For lycopene intakes of 1,609–3,081, 3,081–4,917, and >4,917 μg/day, the relative risks of prostate cancer compared with lycopene intake <1,609 μg/day were 0.47 (95% CI: 0.25–0.86), 0.40 (95% CI: 0.21–0.77), and 0.17 (95% CI: 0.08–0.39), respectively. A significant inverse association between tomato intake and prostate cancer was similarly reported in a case–control study of 617 Canadian men with prostate cancer and 636 age-matched controls conducted between 1989 and 1993. The RR of prostate cancer was 0.64 (95% CI: 0.45–0.91) for tomato intake >73 g/day compared with <24 g/day. However, there was no significant association reported for lycopene intake and prostate cancer [184]. As per results from a recent meta-analysis [180], high serum lycopene levels were associated with significant decreased risk of prostate cancer: RR = 0.78 (95% CI: 0.61–1.00). Subsequent studies on serum lycopene levels conducted in the post-PSA era [185, 186] have not reported significant inverse associations with total prostate cancer risk. Rao et al. observed significantly lower serum and prostate tissue lycopene levels (44%, 78%, respectively) in patients with PCa than in controls in a case–control study [37]. Lycopene and beta-carotene were the predominant carotenoids in human prostate glands obtained by radical prostatectomy from patients with PCa [187]. Also, some preliminary data suggest that persons with a variant in the XRCC1 gene are at higher prostate cancer risk if their lycopene intake is low [188]. This may suggest that effects of lycopene intake can differ by an individual's genetic characteristics [189].

In in vitro studies, using PCa LNCaP and PC-3 cells, Ivanov et al. [190] reported that treatment of cells with lycopene-based agents (100 nM) resulted in mitotic arrest, with cells accumulating in G0/G1 phase. There was block in G1/S transition mediated by decreased levels of cyclins D1, E, cdk-4, and suppression of retinoblastoma phosphorylation. These responses correlated with decreased IGF1R expression and activation, increased IGFBP-2 expression, and decreased AKT activation. Exposure to lycopene also induced a profound apoptotic response in LNCaP cells.

Several studies have been published supporting an inhibition of prostate tumorigenesis by lycopene in transplantable model systems [191]. Remarkably, few carcinogenesis studies have been reported [192]. Siler et al. studied the effects of lycopene consumption in the MatLyLu Dunning prostate tumor model on rats. The three treatment groups were fed diets containing 200 mcg lycopene, 540 mcg vitamin E, or both. The other two groups were control groups [193]. After 4 weeks of supplementation, tumors were induced by injection of 10^5 MatLyLu prostate tumor cells into the ventral prostate lobe. Both vitamin E and lycopene single treatment substantially increased the necrotic area of the tumors which were examined in vivo by MRI, to 36.4% and 36.0%, respectively, compared to 20.0% and 23.3% in the two control groups. There was no significantly increased necrosis rate (27.5%) in the vitamin E and lycopene combination group. Also, the influence of lycopene and/or vitamin E on gene expression in prostate tumors was investigated. The hallmark of both lycopene and vitamin E effect was suppression of genes involved in steroid metabolism and signaling, mechanisms known to be important in prostate cancer development. Moreover, a set of androgen target genes was consistently downregulated in both lycopene-treated groups**.** These investigators also showed more pronounced anti-androgen and anti-inflammatory effects of lycopene in normal prostate tissue compared to prostate tumor tissue. In a xenograft model of BALB/c nude mice implanted with DU145 prostate cancer cells, administration of 100 and 300 mg/kg of lycopene reduced tumor growth to 55.6% and 75.8%, respectively [191], while, in a different model represented by PC-346 C orthotopic mouse, no effect was observed at a lower dose (5 or 50 mg/kg) [194]. In other study using rats, Boileau et al. did not observe any anticancer effect of lycopene compared to the control group, but risk of death was lower for rats fed with the tomato powder diet than for rats fed with the control diet [195]. Although there is considerable interest in the role of lycopene as a therapeutic agent in prostate cancer, only a few small clinical trials have been reported. For example, in a randomized two-arm clinical trial, patients with a diagnosis of prostate cancer who were scheduled to undergo radical prostatectomy were randomly assigned to either 30 mg of oral lycopene supplementation or no intervention for 3 weeks prior to surgery. The study reported that the plasma PSA level decreased by 18% in the intervention group, while it increased by 14% in the control group over the study period. In the intervention group, 11 of 15 patients (73%) had no involvement of surgical margins and/or extra-prostatic tissues with cancer, compared to 2 of 11 patients (18%) in the control group. Twelve of 15 patients (80%) in the lycopene group had tumors that measured 4 cc or less, compared to 5 of 11 (45%) in the control group [196]. In the same study, Kucuk et al. noted that the expression of Cx43, in the malignant part of the prostate glands, was higher in the lycopene group than the control group. Prostatic tissue lycopene levels were 47% higher in the intervention group compared to control group, which was significantly different [196]. Chen et al. conducted a similar clinical trial to examine the effects of consumption of tomato sauce–based pasta dishes in patients with prostate cancer [197]. Thirty-two patients with localized prostate adenocarcinoma consumed a lycopene-rich diet for 3 weeks (30 mg of lycopene per day) preceding their scheduled radical prostatectomy. After the dietary intervention, serum and prostate lycopene concentrations were significantly increased. Serum PSA levels decreased from 10.9 ng/mL (95% CI = 8.7–13.2 ng/mL) to 8.7 ng/mL (95% CI = 6.8–10.6 ng/mL). Furthermore, leukocyte oxidative DNA damage was significantly reduced, from 0.61 8-OHdG/10^5 dG to 0.48 8-OHdG/10^5 dG. Prostate tissue oxidative DNA damage was significantly lower in men who had consumed the lycopene-rich diet than in the randomly selected patients (0.76 8-OHdG/10^5 dG and 1.06 8-OHdG/10^5 dG, respectively). The efficacy of lycopene plus orchiectomy with orchiectomy alone in 54 patients with metastatic prostatic cancer was investigated by Ansari and Gupta [198]. After 6 months of follow-up, there was a significant reduction in PSA level in both groups, but more marked in the lycopene plus orchiectomy group (mean 9.1 and 26.4 ng/mL). After 2 years, these changes were more consistent in the lycopene group (mean 3.01 and 9.02 ng/mL). Eleven (40%) patients in orchiectomy and 21 (78%) patients in the lycopene plus orchiectomy group had a complete PSA response. Bone scans showed that in the orchiectomy arm, only four (15%) patients had a complete treatment response, whereas in the lycopene plus orchiectomy group, eight (30%) patients had a complete response. Additionally, there was a significant improvement in the peak urine flow rate in the lycopene group. Twelve (22%) patients in the orchiectomy group and seven (13%) in the lycopene group died of prostate cancer.

In a study, total of 40 patients with high-grade PIN (HGPIN) were randomly assigned to receive 4 mg of lycopene twice daily for 1 year or no treatment [199]. The serum PSA level in the treatment group changed from a mean level of 6.07–3.5 ng/ml, while in the control group, PSA increased from a mean value of 6.55–8.06 ng/ml. During follow-up, six patients had increased PSA in treatment group and nine in control group. Subsequent prostate biopsy in these patients with increased PSA showed four patients with benign prostate hypertrophy (BPH) and two with adenocarcinoma in study treatment group, whereas the total was three with BPH and six with adenocarcinoma in the control group. In a non-randomized dietary intervention study, patients with histological diagnosis of BPH and plasma levels of serum PSA between 4 and 10 ng/ml had a decrease of 11% in their serum PSA levels after consuming 50 g of tomato paste daily for 10 weeks [200]. In the same way, Clark et al. conducted a phase I–II trial of lycopene supplementation in 36 men with biochemically relapsed prostate cancer after definitive local therapy [201]. Six consecutive cohorts of six patients each received daily supplementation with 15, 30, 45, 60, 90, and 120 mg/day for 1 year. The primary endpoints were PSA response (defined as a 50% decrease in serum PSA from baseline), pharmacokinetics, and the toxicity/tolerability of the regimen. No serum PSA responses were observed and 37% of the patients had PSA progression. The plasma levels of lycopene were similar for a wide dose range (15–90 mg/day) and reached a plateau by 3 months. In a case–control study, an inverse association was found for *cis*-lycopene-1 only. *cis*-Lycopenes 2 through 5 individually and in sum as total *cis*-lycopene and trans-lycopene were not associated with prostate cancer risk [202]. The authors suggest that the structural type of lycopene measured may influence the ability to detect an association, as one cis isomer but not total cis- or trans-lycopene was associated with decreased prostate cancer risk. The multicenter case control Third National Health and Nutrition Examination Survey (NHANES III) of US Caucasian and African-American men aged 40–79 years reported a significant inverse association between serum lycopene and aggressive prostate cancer (highest compared with lowest quartile RR = 0.37; 95% CI: 0.15–0.94; Ptrend = 0.04) and nonsignificant association between serum lycopene and prostate cancer (highest compared with lowest quartile RR = 0.65; 95% CI: 0.36–1.15; Ptrend = 0.09) [203]. In a double-blind randomized placebo-controlled trial, 105 African-American male veterans recommended for biopsy to detect prostate cancer were administered tomato sauce containing 30 mg/day of lycopene or placebo over 21 days [204]. The group randomized to lycopene had an increase in serum lycopene and decrease in PSA while the placebo group had the reverse, with a decrease in serum lycopene and increase in PSA. This study did not report a significant decrease in prostate cancer risk for individuals administered lycopene, but the study duration of 21 days was likely inadequate to significantly influence prostate cancer risk. Yang et al. demonstrated that lycopene can inhibit the proliferation of androgen-dependent prostate LNCaP cancer cells through the activation of the peroxisome proliferator-activated receptor gamma (PPARγ)-liver X receptor alpha (LXRα)-ATP-binding cassette transporter 1 (ABCA1) pathway [14]. They also showed that lycopene significantly increased protein and mRNA expression of PPARγ, LXRα, and ABCA1 and cholesterol efflux (i.e., decreased cellular cholesterol and increased cholesterol in culture medium). Lycopene (10 μM) in the presence of a specific antagonist of PPARγ (GW9662) or of LXRα (GGPP) restored the proliferation of DU145 cells and significantly suppressed lycopene-induced protein and mRNA expression of PPARγ and LXRα and cholesterol efflux. Liver X receptor α knockdown by siRNA against LXRα significantly promoted the proliferation of DU145 cells, whereas si-LXRα knockdown followed by incubation with lycopene (10 μM) restored the proliferation to the control level [14].

3.10 Renal Cancer

Renal cell carcinoma (RCC), the most common type of kidney cancer in adults, has been increasing worldwide, at least until the mid-1990s. RCC will account for approximately 3.8% of adult malignancies and 90–95% of neoplasms arising from the kidney in 2010 [205]. There will be an estimated 58,240 new cases of and 13,040 deaths from renal cancer in 2010 in the USA, accounting for 2.3% of all cancer deaths in the USA [205]. Dietary factors have been linked to RCC [206]. For example, several studies indicate an increased risk of RCC with increased consumption of meat [207], fried meats [208], dairy products [209], margarine, and oils [210]; reduced risks of RCC have been observed with increased intake of vegetables and fruit [207]. On the other hand, micronutrients with anticancer and antioxidant capacities such as carotenoids were associated with a reduced risk of renal cancer [208]. In Eker rats, we found that presence of tumor ranged from 94% to 65% among the experimental group, which was independent of dietary lycopene, but the differences were not significant. Mean numbers of renal carcinomas were decreased in lycopene-treated rats when compared to untreated control. Moreover, tumor numbers linearly decreased and tumor number tended to decrease linearly as supplemental lycopene increased from 0 to 200. Control rats fed only with basal diet had a greater length of smooth muscle tumors (23.98) than rats fed with lycopene supplement groups (12.90 and 11.07). Moreover, tumor length linearly decreased and tumor length tended to decrease linearly as supplemental lycopene increased from 0 to 200. All tumors showed strong staining with antibodies against mTOR, phospho-S6, and EGFR [211].

3.11 Leiomyoma

Uterine leiomyomas arise from the uterine myometrium and are the most common benign tumors in women of reproductive age and are the leading cause of hysterectomy in the USA, accounting for 1.2 billion dollars in hospital expenditures annually [212, 213]. Clinically significant leiomyoma occurs in 30% of these women [214], resulting in a menorrhagia/anemia, pelvic pain/pressure, dyspareunia, and, in some cases, reproductive dysfunction**.** Etiology of fibroids is not well understood although studies have shown that these tumors are hormonally dependent, similar to breast and ovarian cancers [215]. Treatment options depend on the size and location of the tumor, patient's symptoms, age, and future reproductive plans. Medical treatment involves gonadotropin-releasing hormone (GnRH) agonists, GnRH-antagonists, oral contraceptive pills whereas surgical approaches are myomectomy, hysterectomy, endometrial ablation, or uterine artery occlusion [214]. Terry et al. reported that total lycopene intake was not associated with diagnosed uterine leiomyoma risk [213]. They reported that compared to women in the lowest quintile of cumulative average lycopene intake, the corrected HRs for women in the second, third, fourth, and fifth quintiles of cumulative lycopene intake were 1.01 (95% CI = 0.86–1.18), 1.11 (95% CI = 0.94–1.31), 0.90 (95% CI = 0.75–1.08), 0.97 (95% CI = 0.79–1.20) and with regard to baseline intake of lycopene, women in the highest quintile had a 7% lower risk of diagnosed uterine leiomyoma of borderline significance, but there was no association with other levels of lycopene use and no trend in the association. However, in a previous study [216], we reported that tomato powder and lycopene supplementation decreased the number of leiomyoma compared with control subjects in quail. We also found that no measurable lycopene could be detected in the serum of control birds, whereas a dose-dependent increase was observed in the serum of lycopene-supplemented birds. Similar to tumor size results, we reported that the administration of a lycopene supplement to quail results in reduced size of leiomyoma in the oviduct compared to quail who did not receive the lycopene supplement. In Eker rats, we found that the incidence of leiomyoma in control and lycopene-treated uteri were 39%, 48%, and 21%, respectively, but the differences were not significant. The presence of tumor was 7/18 in the control, while the presences were 10/21 in 100, and 4/19 in 200 groups, respectively. Lycopene did not significantly reduce the mean numbers of leiomyoma compared to the control value. The average diameter of tumors was smaller in the group supplemented with higher dose compared to the group supplemented with lower dose of lycopene, indicating a dose response. The mean diameter of tumors was 7.00 mm in the control, while the diameters were 5.00 in 100, and 2.80 cm in 200 groups, respectively [217].

4 Chemotherapy and Lycopene

Chemotherapy is a common method of treatment for many types of cancer. The side effects of chemotherapy come about in part because cancer cells are not the only dividing cells in the body. Chemotherapeutic agents cause increased production of free radicals that can be harmful for normal cells, and these free radicals can be bound by antioxidant vitamins and supplements, including lycopene. A large number of studies have reported the beneficial effects of a variety of antioxidants in antineoplastic agents-induced nephrotoxicity, hepatotoxicity, ototoxicity, and peripheral neuropathy [218, 219]. Chemoprotective activities of lycopene [219, 220], and other dietary components that scavenge free radicals induced by exposure to antineoplastic agents [218, 220] have been well documented (Table 129.2).

Administration of antineoplastic agents during cancer chemotherapy causes oxidative stress as evidenced by increased lipid peroxidation products but decreases total radical-trapping capacity of blood plasma, plasma levels of antioxidant vitamins, and glutathione levels and activity of antioxidant enzymes [218, 219, 221]. In a study, Erhola et al. showed that anthracycline-based chemotherapy caused decreased plasma total antioxidant capacity after chemotherapy treatment in small cell lung cancer patients [222]. The high level of oxidative stress during chemotherapy may overcome the antioxidant defenses of cancer cells, with the resulting lipid peroxides reducing or halting cancer cell proliferation and interfering with antineoplastic activity. Thus, the antioxidant status of cancer patients may play an important role in their response to chemotherapy, with individuals having an impaired status being relatively unresponsive. However, supportive nutritional therapy with antioxidants during chemotherapy, which reduces the generation of lipid peroxides that results from the treatment [218], may overcome the growth-inhibiting effects of oxidative stress and maintain responsiveness to antineoplastic

Table 129.2 Potential mechanisms of action of lycopene in chemotherapy [219]

Observed effect	Potential mechanisms
Reduced lung coefficients as well as the extent of alveolitis and pulmonary fibrosis	Decreased oxidative stress and inflammation markers and expression of TNF-a in lung
	Increased antioxidant enzymes activities
Protective effects against cisplatin-induced nephrotoxicity and adriamycin-induced cardiotoxicity	Decreased oxidative stress and expression of renal Bax, HSP60, and HSP70 proteins
	Reduction in the number of abnormal metaphases

agents. Block et al. have previously reviewed randomized controlled trials in which antioxidants were given with chemotherapy and survival and tumor response outcomes were measured [223]. They reported that no indication was found that antioxidants were associated with decreased survival or tumor response, although further research with very large sample sizes would be required to definitively reject the hypothesis of interference. Their analysis suggested, in fact, that concurrent use of supplements and chemotherapy treatments might produce better tumor response rates and increased chances of survival, although small sample sizes and low quality of studies precluded firm conclusions. It is reported that antioxidants might protect cancer cells against the oxidative damage induced by chemotherapy, which would mitigate against their use or they may enhance drug-induced cytotoxicity by blocking reactive oxidant species [224].

Several studies have demonstrated that lycopene, a strong antioxidant, can influence the response to chemotherapy as well as the development of adverse side effects that results from treatment with antineoplastic agents (Table 129.3) [225, 229, 230]. Zhou et al. reported that lycopene can partially reduce the extent of pulmonary fibrosis induced by bleomycin in rats [227]. They found that the lung coefficients in group lycopene were reduced (day 14) as well as the extents of alveolitis (day 7 and 14) and pulmonary fibrosis (day 14 and 28) compared with bleomycin group. The concentrations of TNF-alpha (day 7, 14, and 28), NO (day 14), and malonyldialdehyde (day 3) in plasma as well as the expression of TNF-alpha in lungs decreased, whereas the plasma superoxide dismutase activities increased (day 28) in lycopene-supplemented group compared with bleomycin group. Lycopene supplementation has also been shown to enhance the antitumor activity of cisplatin and ameliorate cisplatin-induced renal oxidative stress in rats [225]. To test the protective effect of lycopene against cisplatin-induced oxidative damage in renal tissue, we treated cisplatin-administered rats with tomato lycopene complex (6 mgkg^{-1}, daily; 6% lycopene, 1.5% tocopherols, 1% phytoene and phytofluene, 0.2% b-carotene). Cisplatin administration (7 mgkg^{-1} i.p., single dose) resulted in a significant increase in serum urea-N (171 vs. 37 mg/dl) and creatinine (1.80 vs. 0.42 mg/dl) and decrease in body weight in comparison with the control rats. Serum creatinine and urea-N levels were lower in rats treated with tomato lycopene complex + cisplatin compared with rats treated with cisplatin alone. Significantly higher malondialdehyde (172 vs. 93 nmol/g) and 8-isoprostane levels (1,810 vs. 610 pg/g) was observed in the renal tissue of cisplatin-treated rats in comparison to the control rats. Tomato lycopene complex prevented the rise of >malondialdehyde and 8-isoprostane. No measurable lycopene could be detected in the serum of animals that are not supplemented while lycopene was detected in the serum of rats supplemented with tomato lycopene complex (0.19 and 0.11 µmol/L). Expression of Bax protein in renal tissue was significantly higher in cisplatin-treated rats compared with control rats, and tomato lycopene complex treatment significantly reduced the levels of Bax in renal tissue. Tomato lycopene complex did not affect the level of Bcl-2 expression in cisplatin-administered rats.

Table 129.3 In vivo and in vitro studies with lycopene and chemotherapy [219]

First author (References)	Agents	Toxicity	Treatment	Results
Dogukan et al. [225]	Cisplatin	Nephrotoxicity	Male Wistar rats; groups: control rats, tomato lycopene complex rats (6 mg kg^{-1}, daily); cisplatin-injected rats (7 mg kg^{-1} i.p., single dose); cisplatin-injected + tomato lycopene complex–treated rats	*Cisplatin*
				Increased serum urea-N and creatinine, MDA production, 8-isoprostane levels
				Increased renal Bax protein expression
				Lycopene supplementation
				Decreased serum creatinine and urea-N levels
				Prevented the rise of MDA and 8-isoprostane
				Reduced the levels of Bax
				No difference in the level of Bcl-2 between tomato lycopene complex–treated/cisplatin-administered rats and cisplatin-injected rats
				Lowered the expression of renal HSP60 and HSP70
Rios et al. [226]	Cisplatin	Human DNA	Cell-free experimental model by the bixin and lycopene	Inhibition of ROS generation by DNA–cisplatin interaction by both lycopene and bixin in a concentration-dependent manner
				At a concentration of 100 lM, lycopene inhibited superoxide anion generation at 90 %, the total ROS generation at 44 %

Table 129.3 (continued)

First author (References)	Agents	Toxicity	Treatment	Results
Zhou et al. [227]	Bleomycin (BLM)	Pulmonary fibrosis	Sixty Sprague–Dawley rats; groups; control group, BLM-treated (intratracheal instillation) group, lycopene group (administered at a dose of 5 mg/kg body weight once a day) + BLM-treated group	Reduced by lycopene
				Lung coefficients as well as the extents of alveolitis and pulmonary fibrosis
				Decreased by lycopene
				TNF-alpha ($P < .001$),
				NO (day 14, $P < .05$),
				MDA (day 3, $P < .01$)
				Expression of TNF-alpha
				Increased plasma superoxide dismutase
Ferreira et al. [228]	Doxorubicin	Cardiac myocyte	Wistar male rats, groups: control (C), lycopene (L; tomato oleoresin 5 mg/kg body wt. day for a 7-week period), doxorubicin (D; 4 mg/kg body wt., i.p. at the 3rd, 4th, 5th, and at 6th week) and doxorubicin + lycopene (DL) groups	Higher cardiomyocyte levels of SBs, SBs FPG, and SBs Endo III in rats from D when compared to other groups
				No differences in DNA damage levels in cardiomyocytes from DL when compared to C and L groups
				The viability of cardiomyocytes from D or DL was lower than C or L groups
				Similar lycopene levels (mean+/−S.D.nmol/kg) in hearts between L (47.43+/−11.78) and DL (49.85+/−16.24) groups
Sendão et al. [229]	Cisplatin	Chromosomal aberrations	Rats, three lycopene doses in the acute treatment (2, 4, and 6 mg/kg b.w.), three lycopene doses in the subacute treatment (0.5, 1.0, and 1.5 mg/kg b.w.) with and without cisplatin (5 mg/kg b.w. i.p.)	Lycopene is neither cytotoxic nor clastogenic when compared with the negative controls
				Cisplatin-treated animals submitted to acute and subacute treatments with different lycopene doses and showed a significant reduction in the number of abnormal metaphases when compared with the animals treated only with cisplatin

Table 129.3 (continued)

First author (References)	Agents	Toxicity	Treatment	Results
Karimi et al. [230]	Doxorubicin	Cardiotoxicity	Mice; doxorubicin toxicity(15 mg/kg; i.p) tomato extract (1.2 and 2.4 g/kg, i.p.) and lycopene (1.7 and 3.5 mg/kg, i.p.)	Lycopene supplementation Prevented the rise in serum creatine kinase-MB Ameliorated cardiac cell injury
Puri et al. [231]	Radiotherapy + Paclitaxel	High-grade gliomas	50 patients with anaplastic astrocytoma or GBM. All of them received RT to a dose of 60 Gy in 30 fractions over 6 weeks with concomitant Paclitaxel, 60 mg/m^2 i/v weekly. Two groups: Group A: (n = 25) received 8 mg of oral lycopene daily, Group B: (n = 25) received placebo; along with RT	Lycopene levels in patients of Group A were 152 and 316 ng/ml and in Group B were 93 and 98 ng/ml Among Group A (lycopene group): 10 (40 %) patients had complete response (CR), 10 (40 %) had partial response (PR), 1 (4 %) had stable disease (SD), 3 (12 %) had progressive disease (PD) while response was not available for 1 patient (4 %) Among Group B (placebo group); 5 (20 %) patients had CR, 6 (24 %) had PR, 1 (4 %) had SD, 8 (32 %) had PD while response was not available for 5 patients (20 %)

The expression of renal HSP60 and HSP70 was significantly lower in tomato lycopene complex + cisplatin-treated rats compared with rats treated with cisplatin alone [225]. The protective effect of tomato extract (1.2 and 2.4 g/kg, i.p.) and lycopene (1.7 and 3.5 mg/kg, i.p.) to reduce acute doxorubicin (15 mg/kg)-induced myocardial toxicity has been demonstrated in mice by preventing the rise in serum CPK(MB) and ameliorate cardiac cell injury [230]. Sendão et al. investigated the cytogenetic effects of a single acute and four daily gavage administrations of lycopene, and to examine possible protective effects on chromosomal damage induced by the antitumor drug cisplatin in rat bone marrow cells and reported that lycopene is neither cytotoxic nor clastogenic when compared with the negative controls [229]. Cisplatin-treated (5 mg/kg b.w. i.p.) animals subjected to acute (2, 4, and 6 mg/kg b.w.) and subacute (0.5, 1.0, and 1.5 mg/kg b.w.) treatments with different lycopene doses showed a significant reduction in the number of abnormal metaphases when compared with the animals treated only with cisplatin. Ferreira et al. has shown that tomato oleoresin at 5 mg/kg body weight enhances the chemotherapeutic effect of doxorubicin [228]. Lycopene reduced the cardiotoxic effect of doxorubicin. They also found that cardiomyocyte levels of SBs, SBs FPG, and SBs Endo III were higher in rats from doxorubicin when compared to other groups. DNA damage levels in cardiomyocytes from doxorubicin+lycopene were not different when compared to control and lycopene groups. The viability of cardiomyocytes from doxorubicin or doxorubicin + lycopene was lower than control or lycopene groups. In another study, Rios et al. tested the modulation of reactive oxygen species produced by the cisplatin–human DNA interaction in a cell-free experimental model by the carotenoids bixin and lycopene, extracted from natural dietary sources and purified through luminol- and *Cypridina* luciferin methoxy-analogue (MCLA)–enhanced chemiluminescence assays and reported that results showed that the ROS generation by DNA–cisplatin interaction was inhibited by both lycopene and bixin in a concentration-dependent manner [226]. At a concentration of 100 μM, lycopene and bixin inhibited superoxide anion generation at 90% and 82%, respectively, and the total ROS generation at 44% and 42%, respectively. We also showed that cisplatin-induced decrease in the levels of Nrf-2 and HO-1 was counteracted by lycopene. On the other hand, cisplatin-mediated increase in NF-kappaB p65 was brought down by lycopene [221].

5 Radiation Therapy and Lycopene

An ideal radioprotective agent would be easily administered, inexpensive, nontoxic, and would selectively protect normal tissues, but not the tumor, from radiation. Prevention of radiation toxicities may improve patient's quality of life and may allow higher doses of radiation administered, which may lead to higher disease response and/or cure rates. In a randomized placebo control study [231], 50 patients with high-grade gliomas were treated with surgery followed by adjuvant radiotherapy and concomitant paclitaxel. Patients were randomized to receive either oral lycopene 8 mg daily with radiotherapy or placebo. They found that pre- and posttreatment plasma lycopene levels in the patients in lycopene A were 152 ng/ml and 316 ng/ml and in the patients in control group were 93 ng/ml and 98 ng/ml ($P = 0.009$). There were nonsignificant differences in favor of lycopene between Group A and Group B with higher overall response at 6 months, response at last follow-up, and time to progression (40.83 vs. 26.74 weeks). Andic et al. evaluated whether lycopene could reduce acute gastrointestinal side effects in Wistar albino rats receiving abdominopelvic irradiation [232].

They reported that rats receiving radiotherapy, using 8 Gy single fractions, lost weight within 4 days after radiotherapy and weight loss rates were significantly higher in the radiotherapy-only group compared to lycopene + radiotherapy group. Diarrhea ratio was 72.7% (8/11) in the radiotherapy-only group and 46.7% (7/15) in lycopene + radiotherapy group. Plasma TBARS levels, 4 and 6 days after radiotherapy, were significantly higher in radiotherapy-only group than in lycopene + radiotherapy group. As a result, lycopene reduced oxidative stress, diarrhea, and weight loss seen after abdominopelvic irradiation in Wistar rats. Since lycopene has activity against prostate cancer, it may be particularly beneficial in prostate cancer patients receiving pelvic radiation therapy by preventing radiation toxicity in the bowel and bladder while exerting an anticancer effect on the prostate.

6 Conclusion

In this chapter, we have summarized the potential effects of lycopene in prevention and treatment of cancer. Lycopene intake and plasma levels of lycopene have been inversely associated with cancer risk in most of the case–control studies and animal studies. Clinical trials need to be conducted to investigate lycopene in prevention of cancer and as an adjunct to standard cancer therapy. Until more data is available regarding lycopene supplementation, it is suggested that the potential health benefits of lycopene can best be achieved through a diet rich in a variety of fruits and vegetables, which include tomatoes.

Acknowledgments The authors would like to thank Prof. Dr. Nurhan Sahin, Dr. Mehmet Tuzcu, and Dr. Cemal Orhan for much valuable collaboration.

Abstract

Lutein (L) and zeaxanthin (Z) are the only carotenoids found within the retina, and although they are not essential micronutrients, they have antioxidant and photoprotective functions that are thought to be useful in the prevention of onset or progression of age-related macular degeneration (AMD). This condition is the leading cause of visual loss in the developed world, and the number of people affected by it is predicted to increase dramatically as the proportion of the population aged over 65 years increases. Epidemiological studies suggest that people who consume high levels of L and Z are at lower risk of AMD than those who consume low levels. Intervention studies have shown that increasing dietary intake of foods that contain L and Z or consuming L and Z supplements can increase serum and retinal levels of L and Z. L and Z supplementation is thought to increase macular pigment optical density (MPOD, the amount of L and Z within the macular region of the retina), although clinical methods for MPOD assessment can be unreliable. Small randomized controlled trials have demonstrated improvements in visual function in people who have age-related macular disease and have taken nutritional supplements that contain more than 10 mg L. The results of a large multicenter trial, AREDS 2, are due in December 2012. These results will inform clinical practice with regard to the recommendations that are made about L and Z supplementation for the prevention of progression of AMD.

Keywords

Age-related macular degeneration • lutein • macula • meso-zeaxanthin • retina • xanthophylls • zeaxanthin

Abbreviations

AMD	Age-related macular degeneration
ARM	Age-related maculopathy
ARMD	Age-related macular disease
HFP	Heterochromatic flicker photometry
L	Lutein
MP	Macular pigment
MPOD	Macular pigment optical density

MZ	Meso-zeaxanthin
ROS	Reactive oxygen species
RPE	Retinal pigment epithelium
Z	Zeaxanthin

1 Introduction

Carotenoids are a family of pigments that are divided into two main groups: carotenes and xanthophylls. They are introduced to the human body through dietary means alone, and although not considered to be essential micronutrients, they have important antioxidant and photoprotective properties. These functions have prompted interest in their potential role in prevention of disease.

Oxidative damage may be an important factor in the development of age-related diseases [1, 2]. Chemically, oxidation refers to the removal of electrons, and when it occurs within the body, it can result in the formation of cytotoxic chain reactions. Reactive oxygen species (ROS) is a term used to describe some types of free radicals, hydrogen peroxide, and singlet oxygen, which are all capable of damaging membrane lipids, proteins, nucleic acids, and carbohydrates via oxidation [3].

The eye is particularly prone to ROS damage. The transparency of the cornea, aqueous humor, lens, and retina allows continuous exposure to light, which along with aging, inflammation, air pollutants, and cigarette smoke has been shown to increase production of ROS [4, 5]. Polyunsaturated fatty acids are abundant in the retina, predominantly found in photoreceptor outer membranes, and are readily oxidized [4, 6, 7]. Phagocytosis, a process that produces ROS, occurs within the retinal pigment epithelium.

Lutein (L) and its stereoisomers, zeaxanthin (Z) and meso-zeaxanthin (MZ), are xanthophylls. They are relevant to human ocular health and as they are the only carotenoids present in the lens [8] and retina [9]. It has been suggested that they play a similar role in humans as in plants, as antioxidants and screeners of high-energy blue light [10]. Within the central retinal area, these xanthophylls are known as the macular pigment (MP). The MP may prevent some of the biological processes within the retina that can result in the development of sight-threatening macular diseases [11–16] and subsequent visual loss. In addition, it has been shown that those at very high genetic risk of macular disease may not exhibit retinal conditions that promote the accumulation and stabilization of MP [17] (Figs. 130.1–130.3).

1.1 Retinal Anatomy

The retina is a highly differentiated neuroectodermal tissue that can be divided into the central retina (the macula), which is specialized for detailed vision, and the peripheral retina, which is specialized for night vision. The human retina is

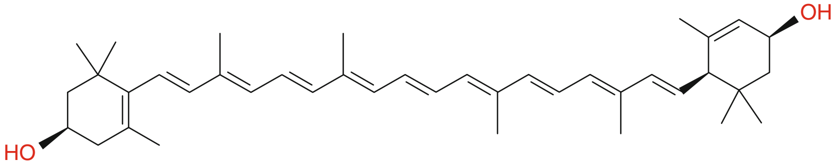

Fig. 130.1 Chemical structures of lutein

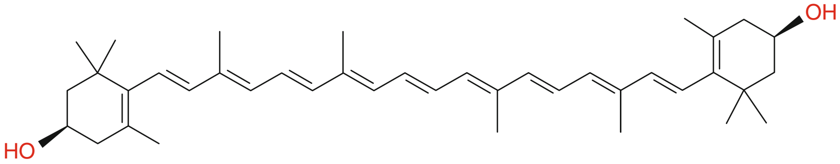

Fig. 130.2 Chemical structures of zeaxanthin

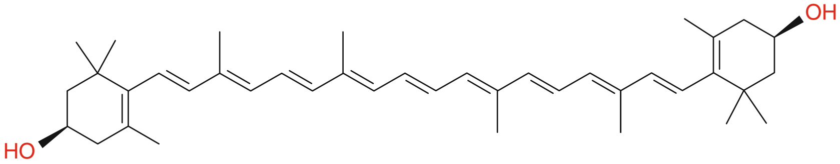

Fig. 130.3 Chemical structures of meso-zeaxanthin

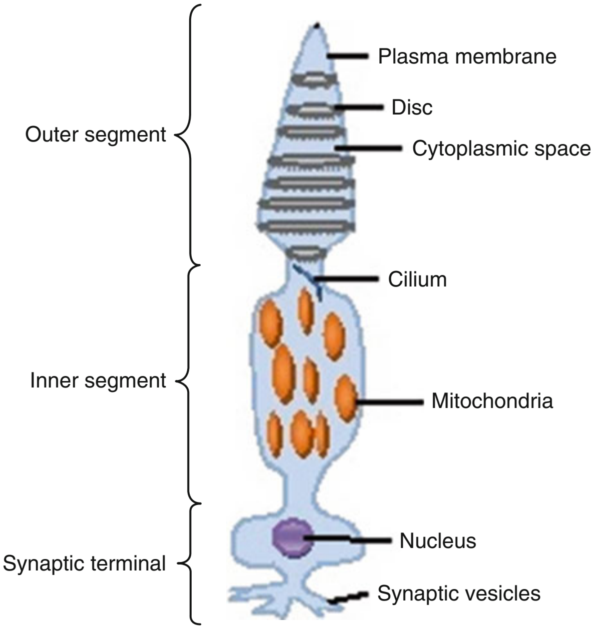
comprised of three layers of nerve cell bodies and two layers of synapses. The outer nuclear layer contains photoreceptor cell bodies. The inner nuclear layer contains bipolar, horizontal, and amacrine cell bodies. The ganglion cell layer contains ganglion cells and displaced amacrine cells [18].

1.2 Structure and Function of the Photoreceptors

Within the human retina, there are two types of photoreceptors – rods and cones. There are approximately 92 million rods, predominantly found at the periphery of the retina, which contain the visual pigment rhodopsin and are required for night vision. There are approximately 4.6 million cones found predominantly in the macula, which contain the red, green, or blue opsin pigments necessary for color vision and sharp visual acuity [19]. These visual pigments are located within the outer segment discs of the photoreceptors and are essential for light absorption (Fig. 130.4).

Fig. 130.4 Schematic diagram of a cone photoreceptor (kindly provided by Dr. Emma Berrow)



1.3 The Retinal Pigment Epithelium, Bruch's Membrane, and Choriocapillaris

The retinal pigment epithelium (RPE) plays an important role in maintaining the health and efficiency of the tissues within which phototransduction occurs [20]. Each RPE cell is associated with around 30 photoreceptor cells. One important function of the RPE is the phagocytosis of outer segments that are shed by photoreceptors, allowing for constant turnover of photoreceptor membrane discs [21]. The RPE consists of a nonrenewing monolayer of cuboidal-shaped cells, positioned between the photoreceptors and the Bruch's membrane. The correctly functioning RPE also provides an outer blood-retinal barrier [22].

The RPE cells contain melanosomes that provide pigment to absorb stray light – essential for image sharpness by minimizing light scatter [23].

Within the visual cycle, the RPE is involved in the processing of the vitamin A derivative, retinal, which is transported to the photoreceptors and combined with opsin to form the visual pigments. Retinal pigment epithelial cells reduce uniformly over time with increasing age within the retina and at a greater rate equatorially than centrally [24]. Melanosome number also consistently decreases with increasing age, possibly through the damaging effects of blue-light irradiation [25].

Bruch's membrane lies between the RPE and the choriocapillaris. It provides a semipermeable membrane through which major metabolic transfer occurs [26].

The choriocapillaris is directly adjacent to Bruch's membrane and is comprised of an intricate network of blood vessels which provide oxygen and nutrients to the RPE. It is among the most highly perfused tissues in the body [27].

1.4 The Macula

The macula is the central portion of the retina. If you were to look straight through an individual's pupil toward the back inner surface of their eye, you would be looking at the macula. Within the macular region, photoreceptors are densely packed in order to facilitate high-detailed vision. The macula is defined as the portion of the posterior retina that contains xanthophylls and two or more layers of ganglion cells [28]. The macula is approximately 6 mm in diameter and is centered on the cone-dominated fovea, which is a depression in the inner retinal surface in the center of the macula measuring 0.8 mm in diameter. The parafovea encircles the fovea and is dominated by rod photoreceptors [19]. The central floor of the fovea is called the foveola, and this is 0.35 mm thick. The foveola lies within a capillary free zone and thus has no retinal circulation [28].

1.5 Lutein, Zeaxanthin, and Meso-zeaxanthin: The Macular Pigment

Lutein and Z are two of around 600 plant pigments in the carotenoid group and are both xanthophylls. They have the structural formula $C_{40}H_{56}O_2$, are not made within the body, and so can only be obtained from the diet. Carotenoids are synthesized in plants, where they are essential for photosynthesis [29] and photoprotection. L and Z are found in most fruits and vegetables, although Z is found in much smaller quantities than L [30, 31]. The highest mole percentages of L and Z are found in egg yolk and maize [30], although good sources are also spinach [32], collard greens, and kale [33]. A full list of L- and Z-containing foods can be found via the US Department of Agriculture website (www.nutriton.gov) by clicking on the "What's in food" link.

Although humans consume a wide range of carotenoids, L, Z, lycopene, beta-carotene, alpha-carotene, and beta-cryptoxanthin account for 90 % of circulating carotenoids [34]. Carotenoids are water-insoluble molecules and are transported around the body by water-soluble lipoproteins. Inside cells, they are solubilized in membranes or lipid vesicles, or bound to proteins. The transport and localization of L and Z is thought to be mediated by carrier proteins [35–37]. The human retina, and more specifically the macula, is the single richest site of carotenoid accumulation within the human body. Postmortem retinal analysis has shown that the total L and Z concentration at the macular is 100 times more than at the peripheral retina. The assumption that L and Z within the retina is of dietary origin is supported by fundus photographs of rhesus monkeys on carotenoid-depleted diets that demonstrate an absence of macular pigmentation [38].

In the foveal region of the macula, L and Z concentrations are at their highest [39], and in this location, they are known as the MP. The MP acts as optical filter, filtering out incoming blue light. The absorbance spectrum of MP peaks at 460 nm, which is the same as short-wavelength blue light. This is thought to protect the retina against the actinic effects of blue light that include damage to the RPE and overlying photoreceptors [40, 41].

1.6 Lutein and Zeaxanthin Uptake and Bioavailability

Although possible binding proteins have been identified, the mechanism for uptake of xanthophylls into the bloodstream is still not clear. The efficacy of absorption from the gut depends on its original source, for example, L from egg yolk [42] is more readily absorbed than that derived from green leafy vegetables [43]. This relatively low absorption from green leafy vegetables may be caused by complexing with proteins in chloroplasts within cell structures [44]. Xanthophylls that are associated with oil or fat, such as those found in egg yolk, may be more readily extracted during digestion [44].

Unesterified xanthophylls such as lutein in its pure form are absorbed by mucosal cells and subsequently appear unchanged in the circulation and peripheral tissue. Esterified xanthophylls must be de-esterified to their pure form before uptake [34, 45]. The xanthophylls are packaged as plasma lipoproteins by the liver, released into the systemic circulation, and absorbed by a range of tissues including liver, lung, adipose, skin, prostate, and macula [34, 46]. Their major storage site is adipose tissue [34, 47], so much so that a negative correlation between the adipose tissue L concentration and the amount of L and Z in the retina has been reported in women [48].

Although some tissues, such as the skin, are not particularly selective about carotenoid uptake and compositions (they are determined by serum levels), other tissues such as the macula are highly selective [49–51]. It is likely that specific binding proteins are involved when tissues exhibit such highly selective uptake and deposition of biological molecules.

Primates fed with carotenoid-free diets have no detectable yellow pigmentation of the macula [38], and studies have shown that macular pigment levels can be raised in humans using dietary supplementation [52–54]. Serum concentrations of L and Z are also reported to be responsive to dietary modifications [48, 53, 54].

1.7 Meso-zeaxanthin

Lutein and Z are produced as a single stereoisomer by plants [55]. However, the central retina also contains a high concentration (between 25 % [56] and 30 % [57]) of MZ. Meso-zeaxanthin has been found in the human macula, retina, and RPE but has not been detected in the plasma or liver [49]. Within the central macula, L, Z, and MZ are found in equal quantities, but the ratio of MZ to

Z decreases with increasing eccentricity [56]. This forms the basis for the assumption that MZ is formed via isomerization of L [56], and it is thought that the conversion mechanism is concentrated at the macula. The xanthophyll-binding protein may also act as an enzyme for the conversion of L to MZ. Supplementation with 16 mg MZ and 4 mg L is reported to increase MPOD levels by 18 % in 120 days [58]. This percentage increase is similar to that found when supplementing with only 20 mg L daily. This further supports the L to MZ conversion theory.

Meso-zeaxanthin is a xanthophyll that is not found within most foods but is present in some types of seafood [30, 55]. It is found to reach a maximum level in the central macula, where L levels reach a minimum [9]. This suggests that it may have some specific function at the macula. There may be a functional relationship between L and MZ within the central macula, as there is an inverse relationship between the two xanthophylls in terms of concentration at that location. Meso-zeaxanthin may be more effective than L at some essential role within the central macula and may not be needed in the peripheral retina. This suggests some kind of protective function in ARMD. It may also be that L is oxidized within the central retina, and then reduction results in its conversion to MZ [9]. The evidence suggests that there are specific mechanisms or biological pathways in place for the conversion of L to MZ within the central macula.

1.8 Spatial Profile and Distribution of Xanthophylls and Macular Pigment

The concentration of L, Z, and MZ is higher at the macula than anywhere else in the human body [39]. The distribution of MP generally peaks at the central macula (the fovea) [51, 59, 60]. The ratio of L to Z and MZ within 0.25 mm of the fovea is approximately 1:2.4 [60, 61], but the situation reverses at the retinal periphery, where the ratio is 2:1 [60]. In other words, Z and MZ are present in higher concentrations within the fovea, whereas L predominates in the more peripheral macula. It is proposed that retinal L is converted to MZ in the central macula [62].

Macular pigment has been located in the inner axons of the photoreceptors and the rod outer segments. Within the central fovea, the carotenoids are most concentrated within the photoreceptor axons of the Henle nerve fiber layer [59]. It may be that L and Z are transported here from the choroid, passing across the RPE and the photoreceptor outer segments.

In the perifoveal region, L and Z are present in the outer segments of rod photoreceptors [63, 64], where there is a high concentration of polyunsaturated fatty acids. These are particularly prone to oxidative attack. Within the rod outer segments, the concentration of L and Z is highest in the perifoveal region, where it is approximately 2.5 times higher than in the peripheral retina [64] (Fig. 130.5).

There is a 100 fold drop in the concentration of MP in the peripheral retina compared with the fovea, although levels vary considerably between donors [51, 65]. The MP is optically undetectable at a distance of 2 mm from the fovea,

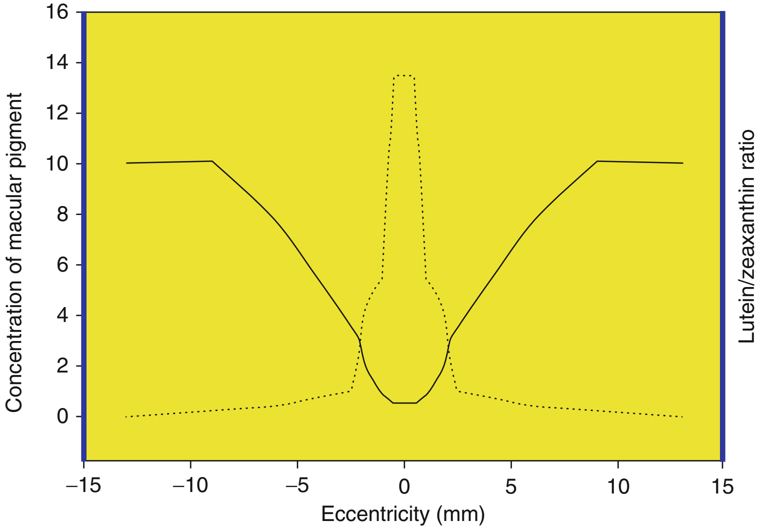


Fig. 130.5 Graph showing spatial profile of xanthophylls within the macular region (Adapted from [9])

although L and Z are present in very small quantities beyond this eccentricity (their combined concentration beyond 8.7 mm from the fovea is 1/300 of that within 0.25 mm of the fovea) [60]. The ratio of L to Z and MZ varies linearly with the ratio of rods to cones with increasing eccentricity up to approximately 6° from the fovea [60]. The hypothesis that Z is only found in the rods is refuted by the fact that the fovea contains predominately cones, as well as by the fact that squirrel monkey and macaque retinae have their highest concentration of L and Z in the central fovea [61].

1.9 Measurement of Macular Pigment

The measured amount of MP within a retina is known as macular pigment optical density (MPOD). The measurement of MPOD can be divided into two categories: subjective psychophysical techniques and objective optical techniques. Objective techniques include fundus reflectance and autoreflectance, and subjective techniques are psychophysical in nature. Heterochromatic flicker photometry (HFP) is the best known and most widely used subjective technique and involves the calculation of MPOD based on the luminance ratio of short-wavelength blue light presented in the central retina (where it is assumed to be partly absorbed by the MP) compared to that presented at a more peripheral retinal point (where MP levels are assumed to be minimal). When the short-wavelength light is alternated at an appropriate frequency with a wavelength that is not absorbed by MP and luminance of the two wavelengths is not perceived to be equal, then the combined stimulus will appear to flicker [66–70] (Fig. 130.6).

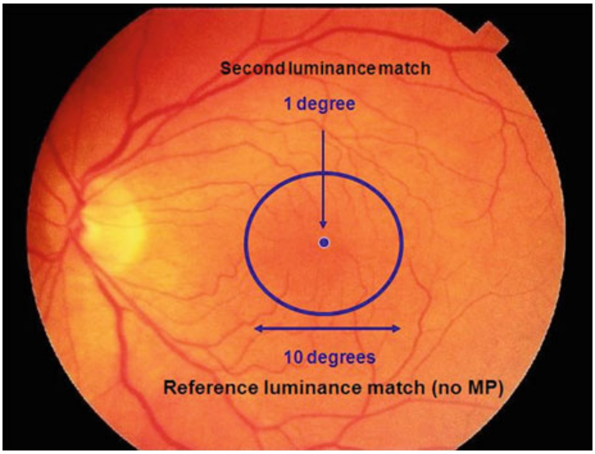

Fig. 130.6 Luminance matches in heterochromatic flicker photometry

Although there are various ways in which HFP can be used to measure MPOD, in all techniques, the observer is required to flicker match using one wavelength of light that is absorbed by MP and one wavelength of light that is not. These flicker matches are made in the central macula and at a peripheral point at which the MP is assumed to be absent. Conventional HFP requires the observer to adjust the luminance ratio of the two wavelengths of light at both retinal locations until the flicker is perceived to disappear, or be reduced to a minimal amount [71–74]. This can be conceptually difficult to achieve, and so more recent variations of HFP involve the subject indicating when the flicker is first noticed, which may be more intuitive, particularly for naïve subjects [75]. Comparison of HFP with objective measurement of MP using spectral fundus reflectance reports a high correlation between the two techniques ($r = 0.72$, $p < 0.001$) [76].

1.10 Normal Values of Macular Pigment

Studies that used HFP to measure MPOD have reported average central values in normal cohorts of 0.211 ± 0.13 (n = 280, age range 18–50 years) [77], 0.28 ± 0.21 (n = 280, age range 18–50 years) [78], 0.289 ± 0.156 (n = 46, age range 21–81 years) [79], 0.319 (n = 100, age range 22–60 years) [80], 0.43 ± 0.23 (n = 1,648, age range 53–86 years) [81], 0.47 ± 0.14 (n = 38, age range 19–46 years) [82], 0.50 ± 0.24 (n = 76, age range 18–74 years) [83], and from 0.58 ± 0.29 to 0.72 ± 0.27 (n = 24, mean age 38.1 ± 10.6 years) [84]. The wide range of mean MPOD values may be the result of differing test protocols and stimulus characteristics.

The relationship between MPOD and age has also been investigated using HFP; some studies have reported a negative correlation between the two variables [82, 85, 86], while others reported no relationship [60, 78, 83, 87, 88].

Ethnic differences in MPOD have also been reported, with South Indians displaying higher mean MPOD values (0.64 ± 0.23) [86] than Africans (0.59 ± 0.14) [89], Asian Chinese (0.48 ± 0.23) [90], and white non-Hispanics (0.36 ± 0.13) [89].

The relationship between gender and MPOD is also conflicted within the literature with several studies reporting no difference [77, 79, 82, 83, 90–93] and others reporting that females have lower MPOD than males [88, 94–96].

1.11 Functions of Macular Pigment

Carotenoids are also able to quench singlet oxygen (a potent oxidant) [97], scavenge reactive oxygen species [98], limit peroxidation of membrane phospholipids [99], and reduce lipofuscin formation [100]. The presence of MP in the rod outer segments and RPE [63, 64] is suggestive of a ROS-quenching function. The fact that L and Z have been found in higher concentration in the rod outer segments of the perifoveal retina than the peripheral retina lends support to their proposed protective role in age-related macular disease [63].

The absorbance spectrum of MP peaks at 460 nm, and it is purported to act as a broadband filter, reducing the sensitivity of the macular region to short-wavelength light which is most damaging in the 440–460 nm range [101, 102] (see Fig. 130.3). The presence of MP in the inner retinal layers [66] supports a photoprotective role (Fig. 130.7).

Blue light is the highest energy form of visible light and is known to induce photooxidative damage by generation of ROS. Lutein is reported to be a superior filter [103] due to the fact that it is orientated both parallel and perpendicular to the plane of the membrane [104]. Zeaxanthin is orientated perpendicular to the membrane plane only and so may not be able to absorb the excitation beam from all directions. Zeaxanthin, however, is reported to be a superior photoprotector during prolonged light exposure; the shorter timescale of protective efficacy of L has been attributed to oxidative damage of the carotenoid itself [104].

As well as reducing the potential for photooxidation, the blue-light filtering by MP may also reduce glare, increase contrast reduce chromatic aberration, and improve visual acuity.

1.12 Effect of Nutritional Supplementation or Dietary Modification on MPOD

Several studies have provided information about the relationship between dietary intake of L and Z and MPOD. Macular, peripheral retina, and crystalline lens levels of L, Z, and their metabolites were chemically measured in 228 eyes of 147 human donors in one study [105]. The results were then correlated with retrospective supplement histories from families of selected members of the study population. Investigators found that those eyes with unusually high levels of macular carotenoids tended

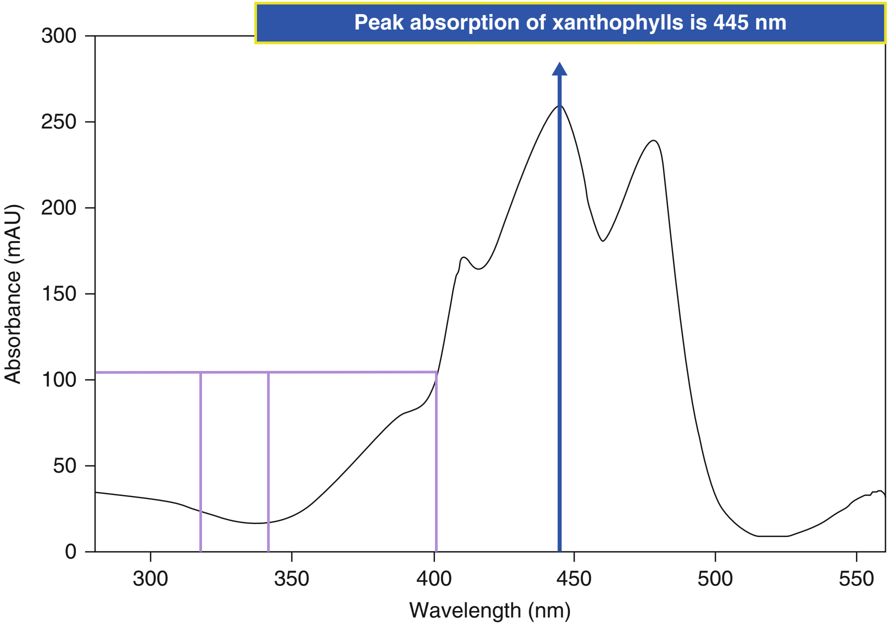

Fig. 130.7 The absorbance spectrum of xanthophylls

to come from donors who consumed high-dose L supplements before death and that in these eyes, carotenoid levels were also unusually high in the peripheral retina and lens. Lutein supplementation was less common in the eyes of donors whose macular carotenoids were at normal levels [106]. The investigators concluded that their findings support the hypothesis that L supplementation can increase levels of MP.

A study of dietary, serum, and retinal carotenoids in couples found that of 20 male-female married couples between the ages of 29 and 70 years who had been married for an average of 21.6 years (SEM = 2.4), the dietary intake and serum concentrations were correlated between partners but that MPOD levels (measured using HFP) were not [107]. There was, however, a statistically significant relationship between dietary intake and serum levels of carotenoids, and MPOD for the cohort.

Another study investigated the effect of consumption of two and four egg yolks per day on MPOD measured using HFP. Of 37 participants, those with low MPOD (defined as MPOD $\leq$0.50 at 0.25°, $\leq$0.4 at 0.5°, and $\leq$0.35 at 1°) showed increases of $\leq$50 % ($p < 0.05$) at the three retinal eccentricities when consuming four egg yolks per day for 5 weeks. Those consuming two egg yolks per day demonstrated a nonsignificant increase of 31 % in MPOD at 0.5° [108].

More recently, supplementation for 6 months with a combination of L, Z, and MZ was found to significantly increase MPOD in healthy subjects [109].

The results of these studies support the hypothesis that MPOD can be augmented by supplementation with L and Z, or by increasing dietary intake of these carotenoids by consuming foods rich in L and Z. Having said this, there is some variability in retinal response between subjects [48, 53, 110]. Short-term feeding studies have reported increases in retinal L and Z levels following a diet of L- and Z-rich foods [48, 53] and supplements [52, 110–112] for at least 3 months. The variability in retinal response may be related to differences in the bioavailability of carotenoids from different foods [113]. Cooking, chopping, or ingesting carotenoid-containing foods with dietary fat can all increase bioavailability of L and Z [114]. In other words, eating chopped spinach leaves with a little olive oil would make it easier for L and Z to be extracted during digestion than eating whole spinach leaves without oil. Also, choosing a nutritional supplement that contains L and Z bound in oil may also be more beneficial than choosing a dry powder formulation.

It has also been suggested that retinal levels of L and Z may be more easily affected by dietary modification and nutritional supplementation in men than women. Higher MPOD levels in men have been reported in some studies [94, 96, 115] but not others [80, 91]. MPOD levels are also reported to be lower in those people with higher levels of body fat [77, 96, 116]; this may be explained by the fact that adipose tissue is a preferred storage site for L and Z, and so the retina has to compete for the xanthophylls. MP is known to be lower in those with lighter iris color [116] and in those who smoke [77, 80, 115, 117]. Cultural differences in L and Z intake have been reported; for example, Hispanic and White Americans consume around half as much L as African Americans [118].

There have been no large-scale studies looking at the effect of L and Z supplementation in MPOD. The results of several small studies suggest that MPOD can be modified by nutritional supplementation and dietary modification but only for some people. For example, MPOD increased by 4–5 % in eight males supplementing with 10 mg L daily [111]. Additionally, an average increase in MPOD of 19 % was found in people supplementing with spinach (providing 10.8 mg L and 0.3 mg Z) or sweet corn (providing 0.4 of L and 0.3 mg Z) for up to 15 weeks, although three out of 13 participants were nonresponders [53]. The fact that some people do not appear to have a retinal response to L and Z supplementation may be related to the xanthophyll-binding protein [36]. It could be that some people are genetically predisposed not to have the binding protein, which would mean that they are unlikely to respond to any amount of supplementation or dietary modification.

A recent review found that supplementation with 10 mg or 20 mg of L does not increase MPOD by a value of more than 0.1 in either healthy or diseased eyes [119]. The same review found a wide range of reliability values for clinical MPOD assessment devices. It was concluded that the chance of eliciting an increase in MPOD during 6 months of daily supplementation with between 10 and 20 mg L that is of sufficient magnitude to be detected by using HFP techniques on an individual basis is small.

2 Xanthophylls and Normal Visual Function

The specific uptake of L and Z at the macula may also be suggestive of a functional role in normal visual function. The macula is specialized for high spatial resolution and also for color vision, and so it may be that L and Z play a part in these processes.

With respect to healthy eyes, the blue-light filter effect of L and Z may reduce longitudinal chromatic aberration [120–123]. In addition, the acuity hypothesis states that these nutrients may improve visual acuity for images that are illuminated by white light by absorbing poorly focussed short wavelengths before this light is processed by the retina [124–128]. In theory, if an emmetropic eye views a mid-wavelength object (approximately 550 nm) in blue-dominated sunlight, shorter wavelengths will focus in front of the retina and longer wavelengths will focus behind such that there is a range of focus of approximately 1.20 diopters [122]. The fact that images are not degraded may be explained in part by the preretinal filtering effect of L and Z.

2.1 Chromatic Aberration

When any optical system defects in the formation of the image occur, these aberrations can be classified as either chromatic or monochromatic. In the human eye, longitudinal chromatic aberration results from the dispersion characteristics of the ocular media, and a dioptric interval of around 0.9 D between the paraxial foci for 656.3-nm red light and 486.1-nm blue light has been reported [129]. Transverse chromatic aberration results in long-wavelength light being deviated less than short-wavelength light, which has the effect of producing a red blur around the edge of an image. When viewing white light, the combined effect of transverse and longitudinal chromatic aberration would be to create a purple penumbra to the image.

In 1866, it was proposed that MP might reduce longitudinal chromatic aberration through absorption of short-wavelength light [130]. It has since been shown that a filter covering a similar spectral range to MP can reduce the radiance of the short-wavelength blur circle to a subthreshold value [102]. The hypothesis that the MP reduces short-wavelength chromatic blur and therefore enhances spatial vision has been termed the acuity hypothesis by Wooten and Hammond [126]. Trials provide conflicting evidence for the use of optical filters in enhancement of spatial vision and varying effects across different individuals. It could be that in those with low levels of MP, the filter does improve spatial vision, whereas the effect is less in those with high levels of MP [131]. It has more recently been suggested that image quality is independent of wavelength [132] and is not degraded by longitudinal chromatic aberration for shorter wavelengths [133]. Further work is required to confirm the role of MP in reducing the effect of chromatic aberration and therefore improving visual function, as current evidence is largely associative.

The acuity hypothesis has more recently been tested by resolution acuity and hyperacuity under two different illumination conditions. One condition consisted of mid-wavelength yellow light that is not absorbed by MP, and the other consisted of a perceptual white light that was subject to chromatic aberration because the blue portion would be absorbed by MP [134]. There was no relationship between MP and resolution acuity or between MP and hyperacuity in either the white or yellow conditions.

2.2 Visibility

Short-wavelength light is scattered more than long-wavelength light by air molecules and larger atmospheric molecules. This scattering effect results in the blue coloration of the sky, as well as the blue haze seen around objects viewed in the distance. Wooten and Hammond [126] hypothesize that MP may increase visibility by reducing the luminance of the background with respect to the object itself. This means that the contrast of the object is increased. A person with a MPOD of 0.0 would only be able to see an object at 10 km that a person with an MPOD of 0.5 would be able to see at 11.9 km.

3 Relating the Function of Macular Pigment to Retinal Structure and Disease Pathogenesis

The MP is thought to reduce the amount of light reaching the RPE by 40–90 %, and in turn, this should reduce the rate of formation of A2E and ROS. Lutein and Z have been shown to reduce lipofuscin formation in cultured RPE cells (111). A2E is toxic, appears to reduce mitochondrial integrity, and also exhibits phototoxic behavior when exposed to blue wavelengths of light (112, 113, 114). The phototoxicity of A2E is reduced by L, which suggests that some of the protective effects of carotenoids may occur at the level of the RPE.

It is thought that the carotenoids are transported from the choroid, across the RPE and the photoreceptor outer segments and that L and Z molecules are preferentially orientated to absorb plane polarized light incident perpendicular to the nerve axons.

UV light is a source of potential damage for the cornea and the lens but very little reaches the retina. However, the retina is prone to photochemical damage from visible light between the wavelengths of 400 and 500 nm. The retina is most at risk from blue light between the wavelengths of 430 and 470 nm [40].

In summary, the fact that L and Z are selectively absorbed at the macula and the fact that L is likely to be converted to MZ at the fovea suggest some specific roles and have prompted interest in the possible functions of these carotenoids at that location. These functions may include screening of photooxidation inducing blue wavelengths of light, scavenging of free radicals, and also protection of RPE cells.

4 Age-Related Macular Degeneration and the Xanthophylls

Age-related macular degeneration (AMD) is the leading cause of irreversible visual loss in the developed world [135–140]. In the UK, half of those registered as blind or partially sighted every year (approximately 30,000) have AMD [141]. This pattern in the registered population is reflected in the rest of Europe, North America, and Australia [136, 142–146].

There are estimated to be nearly one million visually impaired people in Britain, 90 % of whom are over 65 years of age [147]. AMD is the most frequently occurring disease that results in permanent vision loss in this age group [137, 148].

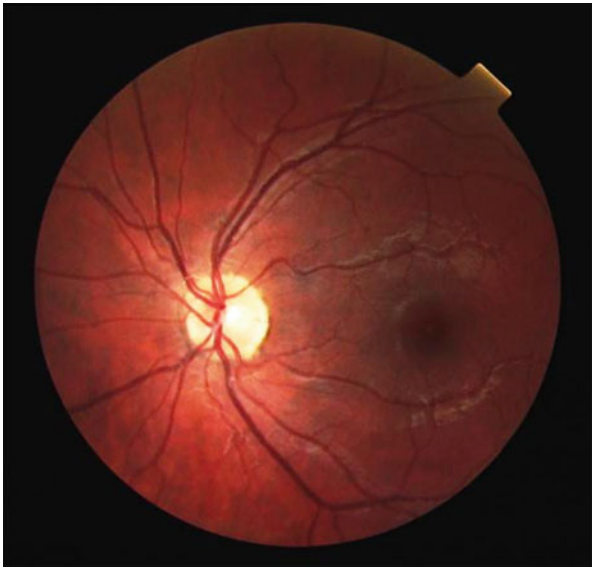

Fig. 130.8 Healthy retina

The proportion of blindness attributable to AMD is expected to increase during the twenty-first century as a result of the aging population [147, 149]. People over the age of 65 represent the fastest growing segment of the US population, and between 2000 and 2020, this group is expected to increase by 53 %. This age group will then make up 16.5 % of the entire US population [150].

Information about risk factors for AMD is limited, and there are no treatment options for most people, despite the prevalence of the condition. It is thought that the condition becomes manifest subject to genetic predisposition and exposure to certain risk factors, including lifestyle and environmental factors [151]. Aging, smoking, and having a positive family history are now undisputed risk factors [152]; other factors such as dietary deficiency of antioxidants thought to be beneficial to retinal health and light exposure are also proposed. Treatments, such as laser photocoagulation and photodynamic therapy, can delay the progression of visual loss in the small proportion with exudative AMD [153] but are unlikely to significantly reduce AMD-related blind- and partial-sight registrations. Developments in genetic methods and molecular biology have been used more recently for the identification of risk factors and may play an important role in reducing the incidence of AMD in the future [154] (Figs. 130.8 and 130.9).

4.1 Terminology

Classification of age-related macular degeneration is required for studies investigating the condition in order to make reliable comparisons between findings. For this reason, the international classification and grading system for

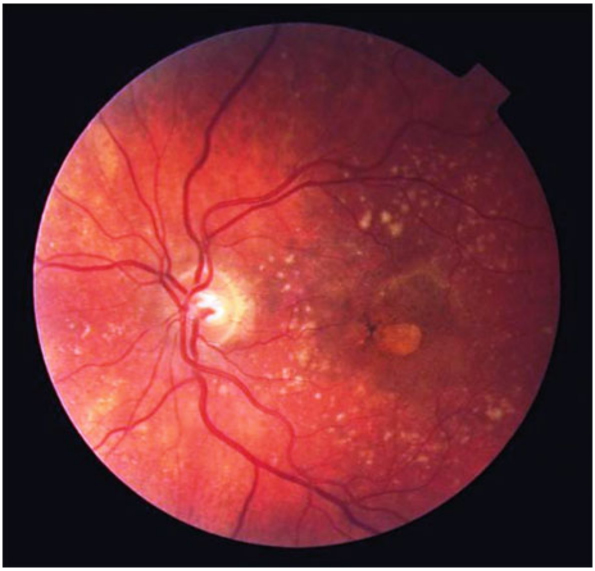

Fig. 130.9 Dry age-related macular degeneration

age-related maculopathy (ARM) and age-related macular degeneration (AMD) has been developed in an attempt to standardize terminology. ARM refers to large soft drusen and pigmentary abnormalities of the retinal pigment epithelium (RPE) and the retina, and AMD refers to later stages of the disease such as geographic atrophy (GA), choroidal neovascularization, pigment epithelium detachment, and fibrous scaring of the macula [155]. This review will use the terms ARM and AMD according to this classification. The term "age-related macular disease," or ARMD, will be used as an umbrella term for all stages of the disease.

4.2 Pathogenesis of AMD: Retinal Pigment Epithelium Structure

The RPE consists of a single layer of cells and is positioned between the photoreceptors and Bruch's membrane. The RPE cells perform several functions, including absorption of light, enabling the turnover of photoreceptor outer segments, and formation of visual pigments by storing and releasing vitamin A. The RPE cells also absorb light and prevent incident light being reflected back to the neural retina, which result in loss of image sharpness. The number of RPE cells per eye can range from 4.2 to 6.1 million, and in younger eyes, these form a highly organized hexagonal pattern. In older eyes, the regular pattern is lost as a result of the low regenerative ability of these cells. Cell loss prompts hyperplasia (abnormal multiplication) of adjacent cells. Interestingly, monkeys that were fed diets free of L and Z had a significantly lower RPE cell density than those fed normal diets [156].

The RPE cells are joined by tight junctions forming a barrier that limits the flow of ions and prevents diffusion of large toxic molecules from the choriocapillaris to the photoreceptors. Each RPE cell supports around 50 photoreceptors. A breach in the connection between photoreceptors and RPE cells, as well as damage to RPE cells, will result in visual loss.

The basal end of each RPE cell rests on a basement membrane that forms part of Bruch's membrane, and the apical end has multiple microvilli measuring 5–7 μm that project between the outer segments of the rods and cones. The apical microvilli continuously erode the outer segments of the rods. Lysozymes within the microvilli contain hydrolytic enzymes that break down the photoreceptor outer segments. In this way, the RPE cell phagocytoses the discs of broken-down visual pigment within the outer segments. Lipofuscin granules are the final products of this process. As we age, lipofuscin collects within the RPE cells [157], and this continual increase in the lipofuscin content of RPE cells between the age of 20 and 70 years has been described as "physiological" [158].

4.3 Pathogenesis of AMD: Lipofuscin Formation

The RPE progressively accumulates a brown-yellow, autofluorescent, electron dense material called lipofuscin. It is a chemically and morphologically polymorphous waste material, originating from a variety of intracellular structures and which accumulates at the primary site of waste disposal, the lysosome. It accumulates within postmitotic cells primarily because it is undegradable and cannot be removed from the cells via exocytosis. Lipofuscin is often called age pigment because the amount of lipofuscin increases with age, and it is composed from a variety of compounds, mainly of protein and lipid origin (30–70 % and 20–50 %, respectively) [159]. The lipofuscin found in the RPE is different to that found in other body tissues because it is mainly derived from the chemically modified residues of incompletely digested photoreceptor outer segments [160].

The accumulation of lipofuscin in the liposomes of the RPE can adversely affect RPE function and may be involved in the development of ARMD. If the RPE is not able to phagocytose the photoreceptor outer segments completely, then remnants of the outer segments accumulate on the inner collagenous layer of Bruch's membrane [161]. These remnants have been morphologically described as basal linear deposit [162] and are clinically recognized as large drusen [158]. Age-related macular disease may also be related to the effects of A2E, which is a lipofuscin-associated chromophore. Chromophore is the name given to a molecule that can exhibit color within a compound. The A2E chromophore requires light for its formation (109, 110), is found within lipofuscin, and is derived from photoreceptor outer segments [163]. A2E is likely to interfere with mitochondrial respiration within RPE cells [164], which is likely to compromise cellular survival. Apoptosis (self-destruction of damaged cells) is four times higher in the center of the macula than in the periphery [165], which supports a role for this mechanism in the development of ARMD. Interestingly, it has been reported that quail that were exposed to bright light and supplemented with Z demonstrated significantly less photoreceptor apoptosis than quail that were exposed to light and fed diets low in carotenoids [166, 167].

Drusen represent the first clinical appearance of ARM. They result from the accumulation of insoluble, lipophilic material between the Bruch's membrane and the RPE. The RPE deforms and thins as it stretches to cover the bulge formed by druse. The thinning of the light-absorbing layer of cells results in more light being reflected back from the retina in these areas and permits the physical examination of drusen [168, 169]. The deformation of the RPE layer compromises the contact between the microvilli of RPE cells and the photoreceptors. Photoreceptor death follows the complete separation of photoreceptors and the RPE. The timescale for this process can vary from individual to individual [168].

Wet or neovascular AMD results when the separation of the RPE and Bruch's membrane is associated with growth of new blood vessels into the subretinal space. These new blood vessels develop from the choriocapillaris, which is responsible for the nutrition and oxygenation of the outer retina.

4.4 Clinical Evidence Regarding the Proposed Role of Macular Pigment in the Prevention of Age-Related Macular Disease

Several studies have investigated possible links between the amount of L, Z, and MZ within the retina (MPOD) and ARMD, using a variety of measurement techniques. Some of these studies have shown that increased levels of MP may delay, avert, or modify the course of ARMD [79, 170, 171] and some have not [11, 78]. However, the fact that MPOD is modifiable means that ongoing research into its role in prevention of the onset or progression of ARMD is important.

Serum concentrations of L and Z and MPOD are reported to be responsive to dietary modifications [48, 53, 54]. A cross-sectional study reported that people with plasma concentrations of L in the lowest third of the distribution have a significant OR for risk of ARMD of 2.0 (95 % CI, 1.0–4.1) compared with those in the highest third after adjustment for other risk factors [172]. In other words, subjects in the study with low-plasma L had a much greater chance of developing ARMD than those with high-plasma L. There were no significant trends between plasma concentrations of L or L combined with Z.

A study of retinal levels of L and Z in donor eyes found an 82 % lower risk of AMD in retinae among the 25 % with the highest L and Z levels compared to the 25 % with the lowest levels [170]. A 70 % reduced risk of AMD has been demonstrated with high (>0.67 μmol/L) versus low (0.25 μmol/L)-L/Z plasma levels [173]. Measurement of MPOD in healthy eyes showed an age-related decline, and healthy eyes considered to be at risk for AMD had significantly less MP than healthy eyes not at risk [79]. This evidence suggests that there is an increased risk of AMD with lower plasma and retinal levels of L and Z.

The research that has been done in this area seems to suggest that the dose of L that is used in supplements is important. Generally speaking, a dosage of

10 mg/day or higher is associated with an increase in MP and, in some cases, an improvement in visual performance. Conversely, supplementation with lower doses does not bring about these changes. A brief overview of the literature follows.

Early work on L and Z supplementation suggested that both serum and macular response is dose dependent [52]. This finding is supported by more recent studies that investigated the impact of supplementation of L and Z in lower doses and did not find a significant increase in MP. For example, daily supplementation with 6 mg L for 1 year did not increase MPOD in a Japanese cohort of 43 adults, some of whom had macular disease. However, the supplementation was associated with an improvement in visual function [174]. Similarly, daily supplementation with 6 mg L as part of a randomized controlled trial did not improve contrast sensitivity in people with ARM [175] and did not improve visual function in young healthy adults [176].

However, L supplementation at achievable dietary levels increased and maintained serum levels, and this was associated with an improvement in glare recovery and VA [177]. A pilot study found that short-term intervention including 15 mg lutein was associated with statistically significant changes in macular focal electroretinogram parameters, suggestive of an improvement in retinal function in ARM [178].

A 35 % increase in L serum levels and a 20 % increase in MPOD were demonstrated in a study supplementing 11 subjects daily with 11 mg of L from 60 g of spinach and 150 g or corn/maize [53]. Supplementation with 10 mg/day of L esters for 12 weeks was shown to increase serum lutein levels by five times and MPOD by approximately 20 % [111]. Serum levels of L doubled over 24 months of taking 15 mg lutein three times weekly [177].

The lutein and antioxidant supplement trial (LAST) was a 12-month RCT designed to evaluate the effect of daily supplementation with 10 mg alone or lutein combined with additional carotenoids and antioxidants/minerals on MP optical density and objective visual outcome measures in 90 subjects with ARMD. Glare recovery and contrast sensitivity significantly improved with both interventions, although it is worth noting that 95.6 % of the study population was male [179].

The Carotenoids in Age-Related Maculopathy (CARMA) Study was a multicenter RCT that investigated intervention with 12 mg L and 0.6 mg Z in combination with other antioxidants in people with AMD. A total of 433 participants were recruited, and at 36 months from baseline, corrected visual acuity was improved in the treated arm of the study compared to the placebo arm. However, it should be noted that the sample size had reduced to 41 at this stage in the study [180].

No positive effect of supplementation with 6 mg in combination with other antioxidants was reported from an RCT that included participants with and without AMD. The outcome measure was contrast sensitivity, which is a "real-world" measure of visual function. However, the sample size was small (25 with AMD0), and it should also be noted that the level of lutein included in the intervention was low (6 mg) compared with other studies [175].

The Age-Related Eye Disease Study (AREDS) 2 is currently underway and is investigating the effect of supplementation with L and Z, with and without omega-3 essential fatty acids, on progression to AMD (www.areds2.org). This is a large multicenter trial, enrolling around 4,000 subjects, that is due for completion in December 2012. The results will undoubtedly inform clinical practice regarding the recommendations for nutritional supplementation and/or dietary modification for the prevention of progression of ARMD.

5 Macular Pigment as an Antioxidant

5.1 In Vitro Studies on Lipofuscin

An in vitro study was carried out to determine whether lipofuscin was detrimental to lysosomal and antioxidant function in cultured human RPE cells. It was concluded that lipofuscin inhibited lysosomal function and reduced antioxidant capacity in RPE cells. It occurred in an in vitro cellular system with its full complement of antioxidants and repair systems and therefore demonstrated the potential for such action inside the eye. The lysosomal system of the RPE is integral to the degradation and turnover of intracellular organelles and ingested photoreceptor outer segments. A decline in the efficiency of this system leads to the buildup of nondegradable material and cellular congestion, culminating in cell dysfunction [181].

A further in vitro study was carried out on cultured RPE cells in order to investigate the involvement of oxidative reactions in lipofuscin formation, the effect of antioxidants on lipofuscin formation, and the effect of lipofuscin accumulation on the phagocytic capacity of RPE cells. The involvement of oxidative reactions in lipofuscin formation was studied by culturing RPE cells fed with photoreceptor outer segments in 8 % and 40 % oxygen [182]. It was shown that significantly more lipofuscin was formed in cells cultured in 40 % oxygen than in cells cultured in 8 % oxygen, indicating an involvement of oxidative mechanisms in lipofuscin formation. When antioxidants were added to the RPE, there was a significant reduction in lipofuscin formation. The antioxidants were found to act as free radical scavengers and chain-breaking agents in peroxidation reactions. The phagocytic capacity of lipofuscin-loaded RPE cells was significantly reduced in comparison to unloaded control RPE cells. The reduced capacity of the lipofuscin-loaded RPE to cope with the needs of the photoreceptors in terms of phagocytosis of their outer segment tips may contribute to the development of AMD [183].

Another in vitro experiment investigated if lipofuscin formation in RPE cells was reduced by antioxidants. It was shown that α-tocopherol and the macular carotenoids, L and Z, have chain-breaking properties in peroxidation reactions of lipid membranes and also play a part in the quenching of free radicals. It was reported that formation of lipofuscin was significantly reduced as a result of the antioxidant substances in the RPE [100].

L, Z, and MZ all contain a high number of double bonds and therefore a high number of free electrons [57]. This means that they form part of a defense mechanism against the production of ROS within the retina. Oxidative stress occurs when the level of ROS overwhelms the antioxidants within a system [184]. The production of ROS occurs as a by-product of oxygen metabolism but can also be promoted by aging, inflammation, smoking, alcohol consumption, and atmospheric pollution. ROIs are unstable molecules that interact with and damage cells and tissues in order to achieve stability. They include singlet oxygen, hydrogen peroxide, and free radicals.

Macular pigment is able to quench or deactivate ROS such as singlet oxygen and free radicals [104, 185, 186]. As such, it has been shown to protect the macula against oxidative stress [50, 187]. Both L and Z are orientated perpendicular to the surface of cell membranes, which means that they are soluble, stable, and can infer significant effects on the membrane itself [104]. It has been proposed that this orientation may also enhance to antioxidant properties of the MP, by changing the properties of the membrane so that it is less sensitive to oxidative damage [188]. In addition, L and Z have been shown to protect RPE cells by increasing the viability in cells exposed to an acute oxidative stress induced by hydrogen peroxide [189]. In the presence of tocopherol and ascorbic acid, zeaxanthin is reported to protect RPE photosensitized cells [189]. L, Z, and MZ are all able to quench singlet oxygen, but when combined in the ratio 1:1:1, they were able to quench 2.4 times more than when L is in isolation [190].

Supplementing with Z has also been shown to reduce light-induced photoreceptor apoptosis in quail [167]; L, Z, and DHA supplementation was found to reduce oxidative stress-induced apoptosis in photoreceptors [191].

The studies above have indicated a potential link between lipofuscin and oxidative reactions which can lead to the dysfunction of RPE cells. This could in turn lead to AMD, with RPE damage being a fundamental part of the onset of AMD. Increased oxygen levels fuel the oxidative stress induced on the RPE; antioxidants help relieve this stress as they act as free-radical scavengers and chain-breaking agents in photoreceptor outer segment peroxidation reactions [3]. However, further research is required to investigate whether this is the case in vivo, as most studies have been carried out in vitro. A potential mechanism is however available, in order for oxidative stress to lead to AMD.

6 Macular Pigment as a Blue-Light Filter

6.1 Filtering Characteristics of the Eye

Light consists of electromagnetic particles which travel in the form of waves. Visible light is the portion of the electromagnetic spectrum which is visible to humans, and a typical eye will respond to wavelengths from 400 to 700 nm [192]. The human eye has unique filtering characteristics that determine in which area of the eye each wavelength of light will be absorbed. Wavelengths $\leq$295 nm are absorbed by the cornea, that is, some of the shortest, most energetic wavelengths of light (all UVC and some UVB) are filtered out before they reach the crystalline lens. In adults, the lens absorbs the remaining UVB and all UVA (295–400 nm), and therefore, only visible light reaches the retina. However, the very young human lens transmits a small window of UVB light (320 nm) to the retina, while the elderly lens filters out much of the short blue visible light (400–500 nm) [193].

6.2 Retinal Effects of Blue Light

There are three types of radiation insult in the spectral range 400–1,400 nm that cause damage to the retina. These are mechanical disruption of retinal structure such as shock waves produced by extremely short pulses of radiation which are absorbed in the RPE and choroid. The second is thermal insult resulting from absorption of energy in the RPE and choroid sufficient to produce temperatures greater than 10 °C above ambient temperature in the RPE, neural retina, and choroid. The final is actinic insult from the photochemical effects of extended exposure to the short wavelengths in the visible spectrum (400–550 nm). The effects produce temperatures of only a few degrees Celsius above ambient [194]. Photooxidative damage, usually simply referred to as photochemical damage, is associated with long-duration exposures to wavelengths of 550 nm or shorter and low to moderate tissue irradiance because of the requirement for relatively energetic photons to drive the chemical reactions which causes the underlying damage [195].

In one experiment, it was established that photochemical damage to the RPE was related to wavelength, with the damage threshold being lowest for short-wavelength blue light and continued to decrease into the UV region of the electromagnetic spectrum [196]. In another experiment by the same researchers, rhesus monkeys were exposed to blue light (441 nm). It was found that the exposure needed to produce the photochemical lesion was much less than that needed to produce a retinal burn. Also, mild photochemical lesions show uniform damage across the entire exposed area and require 48 h to become funduscopically visible. A nonthermal type of photochemical lesion originating in the RPE was found on monkey retina which led to hypopigmentation of the RPE which resembled that seen in the human aging retina [197]. Recent in vitro experiments investigated whether blue light damaged RPE cells. It was concluded that damage induced by blue light to cultured RPE cells may originate in the mitochondria, and the type of cell death seems to be determined mainly by the intensity of the light but is also related to the duration of exposure. Also, the RPE cells can be damaged directly by blue light after excluding the possible influence of phagosomes and lipofuscin [198, 199].

The experiments mentioned show that irradiation to high-intensity short-wavelength light and particularly blue light can accelerate aging of the retina. UV is more damaging to the retina than blue light as the photons of light contain more energy, but most of the UVs are filtered out by the components of the eye, so blue light from the visible spectrum is the most damaging to the human eye. The blue light can induce photochemical damage to the RPE as shown from the studies and lead to hypopigmentation which is a characteristic sign of AMD, hence indicating a potential link between blue light and AMD.

6.3 The Role of Photooxidation in the Onset of Disease

In the retina, the generation of ROS can occur as the by-products of cellular metabolism or as a result of photochemical reactions [41]. Photooxidative damage results when incident light interacts with an endogenous chromophore in the eye, causing a chemical change that is not related to a thermal increase in the irradiated tissue [195]. A chromophore is a substance that absorbs light, and an endogenous chromophore is a chromophore present in the eye [193]. Lipofuscin is an example of an intraocular chromophore in the RPE. Short-wavelength blue light of the visible spectrum is strongly absorbed by lipofuscin, which is photoexcitable. The extent of the photochemical reaction depends on the amount of blue light absorbed in the lipofuscin. When lipofuscin absorbs a photon of blue light, it is typically excited to a triplet state. Triplets are reactive species and readily undergo chemical reactions with other molecules [195]. These chemical reactions can result in damage to the RPE and photoreceptors.

It was concluded from early studies that elevated blood oxygen increases retinal sensitivity to blue-light damage; it lowers the damage threshold and increases the severity of damage at a given radiant exposure [200]. There have been numerous studies carried out indicating how blue light, ROS, and lipofuscin induce RPE cell death, therefore leading to AMD.

An in vitro experiment was carried out to determine whether human RPE exhibits any substantial photoreactivity that may lead to retinal phototoxicity. It was found that illumination of human RPE cells induced a significant uptake of oxygen that was both wavelength and age dependent. It was observed that photoreactivity of human RPE cells was significantly determined by their lipofuscin content. Lipofuscin irradiated with blue light, under aerobic conditions, generates several ROS. It was also established that lipofuscin photosensitized aerobic reactions leading to enhanced lipid peroxidation. It was postulated that lipofuscin is a potential photosensitizer that may increase the risk of retinal photodamage and contribute to the development of ARM [201].

Lipofuscin is known to accumulate with age in secondary lysosomes of RPE cells. The autofluorescent lipofuscin pigment has an excitation maximum within the range of visible blue light, while it is emitting in the yellow-orange area. This property of the pigment indicates it may have a photooxidative capacity and destabilize lysosomal membranes of blue-light-exposed RPE. Thus, an in vitro study was conducted in order to find out if lipofuscin accumulation in cultured RPE cells caused enhanced sensitivity to blue-light irradiation. The cultured lipofuscin-loaded RPE cells exposed to blue light showed a considerably enhanced loss of both lysosomal stability and viability. It was concluded that accumulation of lipofuscin within secondary lysosomes of the RPE sensitizes these cells to blue light by inducing photooxidative alterations of the lysosomal membranes, resulting in a presumed leakage of lysosomal contents to the cytosol with ensuing cellular degeneration of an apoptotic type [202]. The leakage of lysosomal content into the cytosol may indicate a potential system for which RPE cell death can occur. This in turn can lead to photoreceptor death and hence can result in early ARM and ultimately AMD.

N-retinylidene-*N*-retinyl-ethanolamine (A2E) is the major photosensitizing chromophore in lipofuscin that causes reactive oxygen species production [203]. This chromophore is known to strongly absorb in the blue region of the visible spectrum; therefore, a study was carried out to utilize the known susceptibility of the RPE to blue-light damage, in order to investigate A2E as a fluorophore involved in blue-light toxicity. The investigation implicated A2E as a mediator of blue-light damage in the RPE. It was deduced that healthy RPE cells that have amassed A2E at critical concentrations and that are subsequently exposed to blue light can undergo an apoptotic form of cell death. No damage was found in RPE cells irradiated with blue light in the absence of internalized A2E [204]. A further investigation was carried out by the same researchers to evaluate the role of oxidative mechanisms in mediating cell damage. The augmentation of cell death in the presence of a singlet-oxygen enhancer and the protection afforded by quenchers and scavengers of singlet oxygen indicated that the generation of singlet oxygen may be involved in the mechanisms leading to the death of A2E containing RPE cells after blue-light illumination. In the presence of a singlet-oxygen quencher, the photooxidative changes in A2E were diminished. Therefore, it was postulated that singlet oxygen may not only mediate the cellular damage directly but may also serve in the photooxidation of A2E with the products generated from the photochemical changes in A2E, being the ravaging agents [204].

6.4 Photooxidation and the Role of Antioxidants

Both oxygen and blue light in the visible light spectrum are strong oxidative agents; therefore, lipid peroxidation by light and/or free radicals produces damaged photoreceptors that are indigestible by the RPE cells and accumulate as lipofuscin [205]. Strong evidence has been presented that lipofuscin and its major photosensitizing chromophore A2E are responsible for blue-light-induced RPE cell damage. Blue light also results in enhanced ROS in the RPE, thus causing oxidative stress on the RPE. The degree of oxidative stress is restricted by a range of potent antioxidants and the repair of damaged elements [206]. With age, however, the RPE loses its antioxidant protection [207–209], and ROS production in the aging RPE can lead to apoptosis and cell death [193]. The functions of the RPE are to transport nutrients to the photoreceptor cells and phagocytose the outer segments of photoreceptors. With the death of the RPE cells, the photoreceptors are no longer nourished and the outer segments of the photoreceptors cannot be phagocytosed; therefore, they die off, and waste products accumulate near Bruch's membrane [193]. The death of RPE and photoreceptors thus leads to loss of vision and hence AMD.

It has been shown that antioxidants can protect against blue-light damage to inhibit the death of RPE cells, [210] therefore reducing the risk of developing AMD.

7 Conclusion

Although the exact etiology of AMD is unknown, there is substantial evidence confirming a plausible mechanism by which blue light, oxidative stress, and AMD can interrelate. As the buildup of lipofuscin increases with age [159], circumstantial evidence has shown that it may initiate events in the macula that are central to the development of AMD. The main photosensitizing chromophore of lipofuscin A2E has shown that it generates numerous harmful ROS in the presence of blue light, which seems likely to trigger the events leading to AMD.

Lutein (L) and its stereoisomers, zeaxanthin (Z) and meso-zeaxanthin (MZ), are xanthophylls. They are relevant to human ocular health and as they are the only carotenoids present in the lens [8] and retina [9]. It has been suggested that they play a similar role in humans as in plants, as antioxidants and screeners of high-energy blue light [10]. Within the central retinal area, these xanthophylls are known as the macular pigment (MP). The MP may prevent some of the biological processes within the retina that can result in the development of sight-threatening macular diseases [11–16] and subsequent visual loss.

Antioxidants such as L and Z have been shown to have a protective effect over the macular area suppressing the oxidative stress induced by blue light and lipofuscin. However, further research needs to be carried out as the previous studies and experiments performed have remained contentious. Comprehensive in vivo experiments need to be carried out in order to investigate whether blue light and ROS can cause damage to the same extent in the eye, as to that seen from in vitro experiments. Furthermore, additional research needs to be conducted in order to find out if L and Z can help reduce oxidative damage in vivo and whether any systemic or ocular side effects may be caused by increasing macular levels of these xanthophylls. The results of the large multicenter randomized controlled trial, AREDS 2, is likely to inform clinical practice with regard to recommendations about L and Z supplementation for ARMD.

Abstract

Triterpenoid centellosides of *Centella asiatica* (CA) have been used as an ingredient in a wide range of applications that include healthcare. The triterpenoid centellosides' specific constituents, namely, asiatic acid, asiaticoside, madecassic acid, and madecassoside, have been extensively researched and reported to have many health and therapeutic benefits.

Its pharmacology in vitro and in vivo presents potential remedies in antioxidant, anti-inflammatory, anticancer, antidiabetic, hypertension protection, anti-rheumatoid arthritis, wound healing, brain improvement and neuroprotective effect, gastric ulcer prevention, cardioprotection, anxiolytic activity, and venous hypertension improvement. The clinical study of triterpenoid centellosides has shown its potential in venous hypertension-related improvements. Due to its great prospect and potential, this chapter will present the recent application of triterpenoid centellosides in healthcare covering the pharmacological (in vivo and in vitro) and clinical studies as well as its chemical composition and safety.

TTF	Total triterpenic fraction
TTFCA	Total triterpenoid fraction of *Centella asiatica*
WHO	World Health Organization

1 Introduction

Medicinal herbs and their phytochemical components used for pharmacological application have raised interest in research all over the world. One such important medicinal herb is *Centella asiatica* (L.) Urban, belonging to the family Apiaceae or Umbelliferae. The *Centella asiatica* (CA) is a small herbaceous, creeping plant with kidney-shaped green leaves. It is being used as a medicinal herb in Ayurvedic medicine and traditional herbal medicine in Malaysia, China, and other parts of Asia for hundreds of years [1]. The herb is commonly known as pegaga in Malaysia, Indian pennywort and gotu kola in the Western world, and mandookaparni in the Ayurvedic system of medicine in India. This plant is commonly used in these countries for various applications such as traditional medicine, vegetables, salad, and drinks as in tea or juice [2]. CA is widely used mainly as an extract and has been known for many years in treating all kinds of diseases such as wound healing, headache, body ache, insanity, asthma, ulceration, and eczema [1]. It is believed that the biologically active triterpenoids of CA also known as triterpenoid centellosides are responsible for the health benefit claims [3, 4]; the most important are the asiatic acid (AA), madecassic acid (MA), asiaticoside (AS), and madecassoside (MS) [5, 6]. Previous studies reported that triterpenoid centellosides had various health benefits such as memory-enhancing property [7], antidiabetic [8], anti-inflammatory [9], antioxidant [2, 10], wound healing [11, 12], anticancer [13], as well as tonic drinks for general health and blood circulation. The titrated extract of CA (TECA) is a mixture of three triterpenoids containing 40 % of AS and 60 % of AA and MA, which produces a wide range of preventive and therapeutic effects [14, 15]. HMPC [14] has reported that total triterpenoid fraction of CA (TTFCA), TECA, and total triterpenic fraction (TTF) are different acronyms to designate the same extract, commercially known as Madecassol® or Centellase®, containing 40 % of AS and 60 % of AA and MA. TECA is being used in Europe in wound healing drugs and to treat inflammatory skin problems (leprosy, lupus, varicose ulcers, eczema, atopic dermatitis, and psoriasis), intestinal problems, fever, anxiety, and mental diseases [15]. Due to triterpenoid centellosides' importance and wide applications, this chapter will cover the advances achieved in research works of CA triterpenoid centellosides as potential source of treatment and prevention of illness (healthcare). The compilation of recent findings on numerous pharmacological studies on various in vitro, in vivo, and clinical test models as well as the chemical composition and safety of CA is also included.

2 Chemical Composition

The medicinal herb CA is rich in phytochemical components such as alkaloids, tannins, triterpenoid centellosides, flavonoids, and phenols. Among these compounds, triterpenoid centellosides are the primary components of CA with the most potential of preventive and therapeutic effect. Based on previous reports, the concentration of triterpenoid centellosides is in the range of 0.01–2.20 % [10, 16, 17]. It comprises mainly of AA, MA, AS, and MS [5, 6]. Figure 131.1 shows the structure of the triterpenoid centellosides; the difference of the glycosides and the aglycones (AA and MA) is the sugar glucose-glucose-rhamnose; meanwhile for the aglycones, the sugar molecule is replaced by an OH group. The similar triterpenoid centellosides are also found and identified in Malaysian accession [10, 16]. These compounds have been used as biomarker to determine the quality of the plant [18]. However, the triterpenoid centellosides' components are

varied with regard to its content based on location and diverse environmental conditions [19]. Therefore, it is required to check the source of the plant for their consistent efficacy and quality [20]. Other triterpenoids of CA are composed of brahmoside, brahmic acid, brahminoside, thankiniside, isothankunisode, centelloside, madasiatic acid, centic acid, and cenellic acid [18].

3 Pharmacological Studies for Healthcare Applications (In Vivo and In Vitro)

Healthcare is the treatment and prevention of illness. The CA triterpenoid centellosides provide many health and medicinal benefits. As its primary application has been in promoting wound healing, today, it is being used in many preparations and, hence, is becoming an important compound. The use of triterpenoid centellosides in healthcare applications has become increasingly important in our integral health system today.

3.1 Antioxidant Activity

Studies on the triterpenoid centellosides demonstrated its strong antioxidant properties and can prevent oxidative damage which leads to promoting health benefits.

Antioxidant is useful as it offers an effective and a safe way of increasing the body defense system against free radicals [21] and keeps the reactive oxidative stress (ROS) in a state of balance [22]. The antioxidant in CA (84 %) is comparable to vitamin C (88 %) and grape seed extract (83 %), which may be due to its triterpenoid centellosides and flavonoids [10]. The AS has been proven to affect the levels of certain antioxidants in the wound healing process as it enhanced the production of antioxidant levels at the early stage of healing [23]. During the application of 0.2 % (topical) AS, twice daily for 7 days to excision-type cutaneous wounds in rats, an increase in enzymatic and nonenzymatic antioxidants in newly formed tissue was detected, which included 36 % superoxide dismutase (SOD), 67 % catalase, 49 % glutathione peroxidase, 77 % vitamin E, and 36 % ascorbic acid, whereas lipid peroxidation level decreased by 69 %. Beside flavonoids and selenium, the triterpenoid centellosides in CA might contribute to its powerful antioxidant properties to increase cell rejuvenation and improve mental and physical health [24].

3.2 Anti-inflammatory

CA herbal plant extract has been used in Ayurvedic medicine for the treatment of inflammation. MA, one of the components in triterpenoid centellosides, has been identified to possess antioxidant and anti-inflammatory activities in collagen-induced arthritis (CIA) mice [9]. The anti-inflammatory effect of MA (3, 10, 30 mg kg^{-1}) on CIA mice may be related to its inhibition of tumor necrosis factor-alpha (TNF-α), interleukin-6 (IL-6), prostaglandin E_2, expression of cyclooxygenase-1, and upregulation of anti-inflammatory molecule IL-10. The anti-inflammatory study in rat model using alcoholic and aqueous extracts of CA (100 mg kg^{-1}) inhibits edema after 3 h at 71 % and 46 %, respectively. It appears from the study that the carrageenan-paw-induced inflammatory method and the effect may be due to the presence of AS, MA, and triterpenes [25]. The results strongly justify the traditional use of this plant for improvement of inflammatory conditions.

3.3 Anticancer and Cytotoxic Activity

There are several in vitro studies using various cancer cell lines that demonstrated the potential cytotoxicity and anticancer properties of CA triterpenoid centellosides. The protection against chemical-induced carcinogenesis was demonstrated in phenobarbital-induced rat liver microsomes in vitro using the CA233 extract containing 80 % triterpenoid glycoside (43 % MA and 39 % AS). The findings indicate that the components of MA and AS in CA233 exerted an inhibition effect on hepatic xenobiotic drug/metabolism enzymes, particularly cytochrome P459 in a dose-dependent manner with a median inhibition of IC_{50} 523 μg mL^{-1} [26]. In other studies, AA was used to inhibit cell proliferation by the induction of apoptosis, which is a process of programmed cell death [13]. In the studies, AA demonstrated potent cytotoxicity to squamous carcinoma cells SCC4 and SCC5 (oral cancer cells), SK-BR3 breast cancer cells, and HeLa cells as compared to Taxol (commercial leading chemotherapeutic agent). Studies by Lee et al. showed that AA was effective to decrease the viability and induce apoptosis of HepG2 human hepatoma cells through increased intracellular calcium (Ca^{2+}) which led to enhancement of p53 expression in HEpG2 cells [27]. These results demonstrate that AA may exert as potential preventive agent for human hepatomas. Meanwhile, AA also exhibited its ability as candidate for prevention of human skin cancer. It inhibited cell proliferation and induced apoptosis in human melanoma SK-MEL-2 cells through generation of ROS, alteration of Bax/Bcl-2 ratio, and activation of caspase 3, but p53 independent [28]. The latest study on AA also indicated that this triterpenoid centelloside exerts anticancer property by inhibiting breast cancer cell line MCF-7. AA at a concentration of 10 μM induced 95 % cell death in 48 h as compared to 10 μM of tamoxifen, an antiestrogen drug used in breast cancer [29]. These results further suggest that AA may be a good candidate for therapeutic intervention of human cancer.

3.4 Antidiabetic and Hypertension Protection

Diabetes mellitus is a chronic hyperglycemia caused by insufficient insulin in the body and is estimated about 4 % of global health problems today [8]. There is an increasing demand of oral intake of hypoglycemic agents from herbal plant preparations with antidiabetic activity and with hypertension protection for hypertensive people. The latest potential of these triterpenoid centellosides is antidiabetic and hypertension protection. After 14 days, the AS-administered rats showed significantly lower blood glucose level and higher sugar absorption inhibitory effect and decrease in the systolic blood pressure [30]. The activity was lower than the control drug for angiotensin-converting enzyme (ACE) inhibitors, captopril. In this study, AS may be candidates for antidiabetic and hypertensive protection.

3.5 Anti-rheumatoid Arthritis Effect

The intake of MA (20 and 40 mg kg^{-1}) in CIA mice claimed to be useful for rheumatoid arthritis by decreasing joint swellings and erythema (reduced clinical score), increasing infiltration of inflammatory cells and synovial hyperplasia, and protecting the destruction of the joints [31]. In addition, MA at 20 and 40 mg kg^{-1} decreased the serum level of anti-CII IgG antibody by 21 % and 62 %, respectively, and significantly reduced the delayed type hypersensitivity against CII in mouse ears by 21.4 % and 33.3 %, respectively, while the control (dexamethasone) inhibited 56.8 %. It moderately suppressed CII-stimulated proliferation of lymphocytes from popliteal lymph nodes in CIA mice. Moreover, MA exhibited its ineffectiveness in the activation of macrophages caused by lipopolysaccharide. Therefore, the study proved that MA was responsible in preventing mouse CIA and it might be the major clinical uses in rheumatoid arthritis, mainly by regulating the abnormal humoral and cellular immunity as well as protecting the joint.

3.6 Wound Healing

Wounds are physical injuries that cause openings or cuts of the skin. There are many processes in wound healing that involve cell-matrix interactions and overlapping phases, inflammation, cellular proliferation, and skin remodeling [32]. It is also known that angiogenesis plays a very important role in wound healing, whereby the newly formed blood vessels assist the hypoxic wounds to attain normal levels of oxygen, known as normoxic conditions [33]. The CA extract and its triterpenoid centellosides have been used for wound healing applications and many skin disorders for decades as topical agent and oral supplements. It has been reported that AA is the active ingredient in Madecassol®, which is recognized as a medicinal effector and commercially available for the treatment of keloids and the proliferation of connective tissues and hypertrophic scars [13, 34]. Its medicinal effect is to restore a damaged tissue by modifying the fibrosis progress and protect the cells in the tissue. Oral intake of MA, the major triterpenoid centelloside of CA, at 6, 12, and 24 mg kg^{-1} was seen to speed up the healing of burn wound in a time-dependent manner due to the involvement of several mechanisms such as antioxidative activity, collagen synthesis, and angiogenesis [35]. During the burn healing process, MA assists in dermal proliferation of fibroblast by increasing infiltration of inflammatory cells and stimulating epithelization process, decreasing nitric oxide (NO) and malondialdehyde (MDA) in burn skin tissue, but increasing the reduced glutathione and hydroxyproline content, and, hence, facilitates the healing process. The collagen is the key component in wound healing as it involves in the extracellular matrix composition and granulation of wound. The in vitro studies using fibroblast cells on CA ethanol-aqueous extract containing triterpenoid centellosides showed significant stimulation of collagen production in a dose-dependent manner [10]. At 50 mg mL^{-1}, the extract stimulated collagen threefold as compared to the control. The results demonstrated are in agreement with several studies conducted on TECA, wherein the triterpenoids consisting of 40 % of AA and 60 % of AS and MA stimulated collagen synthesis and increased tensile strength of tissues [11, 36]. In other studies, similar constituents of TECA stimulated extracellular matrix accumulation in rat experimental wounds, and these results were demonstrated in vitro by gene expression changes in the human fibroblast [12]. AA was the component responsible for the stimulation of collagen synthesis, whereas MS increased the collagen III production.

Studies by Bian et al. showed that MA exerted a healing effect on myocardial ischemia-reperfusion injury by significantly decreasing the infarct size, lactate dehydrogenase and creatine phosphokinase, SOD, MDA, and C-reactive protein [37]. Previous studies on AS also exhibited that this compound was able to enhance wound healing activity by stimulating collagen synthesis and angiogenesis as well as increasing cell strength of the newly formed skin [23, 38]. It is able to promote fibroblast cell proliferation and extracellular matrix synthesis in wound healing [39]. Application of 0.2 % solution of AS led to a 56 % increase in hydroxyproline and 57 % increase in tensile strength, increased collagen content, and improved epithelization, thereby facilitating the healing process [23]. The AS is said to have curative effect, including wound repair, whereby the treatment of keratinocyte cell line (HaCaT) at 2 × 10^5 cells with AS (10 pg, 1 ng, 100 ng per wound area), after 24 h, significantly increased monocyte chemoattractant protein-1, vascular endothelial growth factor, and IL-1β levels in burn area [40]. The application of AA and AS and its derivatives have shown to be effective to treat pulmonary fibrosis induced by bleomycin in rats [41]. The protective effect of AS (45 mg kg^{-1}) has been studied on septic lung injury induced by cecal ligation and puncture (CLP) in mice [42]. The AS exerted effective protection from septic lung injury induced by CLP. It significantly decreased CLP-induced mortality, lung pathological damage, infiltration of mononuclear and polymorphonuclear leucocytes, and total proteins. The underlying mechanisms might be related to upregulation of peroxisome proliferator-activated receptor-Y, which facilitate the wound closure by inhibits, mitogen-activated protein kinases, and NF-κB pathway.

3.7 Brain Improvement and Neuroprotective Effect

CA extract has been used as herb in Ayurvedic medicine as a nerve tonic in stimulating learning and memory [7]. The intake of the CA extract containing triterpenoid centellosides has been reported to act as micronutrients which could retard brain aging and assist in renewal of neural tissue. It also helps as an effective antistress, is adaptogenic, enhances memory and revitalizes the brain, and increases attention span and concentration [43]. Phospholipase A2 (iPLA2) is an enzyme group that causes irregularity of the central nervous system activity and commonly relates to neuropsychiatric diseases. The in vitro study using brain cells exhibited the CA aqueous extract (500 μg mL^{-1}) containing 84 % AS and inhibited iPLA2 and cytosolic phospholipase (cPLA2) by 96 % and 77 %, respectively [44]. The inhibition of these PLA2 enzymes in the brain by AS demonstrated that it can be useful for prevention of epilepsy, stroke and multiple sclerosis, and other neuropsychiatric disorders. Hence, AS is suggested to be a key component and potentially responsible for brain protection. The study by Krishnamurthi revealed the potential use of AA as a neuroprotective agent in the treatment of cerebral ischemia [45]. In a mouse model of focal cerebral ischemia, AA significantly reduced the infarct volume to 60 % at day 1 and 26 % at day 7 postischemia and improved neurological outcome at 24 h postischemia. It is claimed that the neuroprotective effect of AA might be due to the decrease in blood–brain barrier permeability and mitochondrial injury. The AA (30 mg kg^{-1} of body weight) treatment in male Sprague–Dawley rats showed significant results on memory and learning improvement by prolonging the latency on retention trial [7].

The AA and AS derivatives including AS6 and SM2 demonstrated very promising results in protecting the brain against beta-amyloid neurotoxicity [46]. At 1 μM, they were shown to decrease hydrogen peroxide-induced cell death, reduce free radical concentration, and inhibit beta-amyloid cell death, hence suggesting their potentials in the treatment and prevention of Alzheimer's disease and beta-amyloid neurotoxicity. Following nerve damage or disease-induced axonal degeneration or transaction in the peripheral nervous system, axonal regeneration is very important for functional recovery. However, the recovery is slow because the rate of axonal elongation is slow. In vitro studies using CA extracts and its AA fractions (1 μM) significantly increase in neurite elongation in human SH-SY5Y cells, whereas in vivo, these extracts had shown more rapid functional recovery and increased in axonal regeneration (larger caliber axons and thicker myelin sheaths), indicating that the axons grew at a faster rate [47]. This findings indicate that the components in CA particularly the AA may be responsible for accelerating repair for damaged neurons.

3.8 Gastric Ulcer Prevention

Many studies demonstrated that triterpenoid centellosides exhibited significant protection as anti-gastric ulcers. The CA water extract and its AS exhibited the healing effects on acetic acid-induced gastric ulcers in rats by significantly increasing the activity of myeloperoxidase, promoting epithelial cell proliferation and angiogenesis, and upregulating expression of fibroblast growth factor in the ulcer tissues, which led to the strengthening of the mucosal defensive factors [48]. Meanwhile, Guo et al. also demonstrated that CA water extract and AS possessed an anti-inflammatory property that enables the inhibition of NO synthesis and facilitates the healing of ulcers [49]. The ulcer protection effect may be due to the reduction in edema and leucocyte infiltration of submucosal layer.

3.9 Cardioprotection

MA, the major triterpenoid component of CA, has been found to have cardioprotective activity in lipopolysaccharide-mediated sepsis through the blocking of extracellular signal-regulated kinase 1/2 and p38 and NF-κB [50]. The intakes of MA (20 mg kg^{-1} of body weight) in male Sprague–Dawley demonstrated that the extract inhibits the lipopolysaccharide (LPS). The disturbance caused the inhibition of plasma TNF-α, slowed down the drop of the mean arterial blood pressure, and diminished the tachycardia induced by LPS, while, in vitro, the MA significantly inhibited LPS-induced TNF-α in neonatal rat cardiomyocytes in a dose-dependent manner. These results showed that MA can be a potential protective agent in cardiovascular diseases.

3.10 Anxiolytic Activity

CA has been used for centuries in Ayurvedic medicine for psychoactive purposes to control anxiety and help in relaxation and mental calmness. Various studies and evaluations by human and animal models have confirmed the potential claim of CA and its triterpenoid centellosides in anxiolytic activity. In animal studies, the methanolic and ethyl acetate extract of CA as well as the AS of the plant have been reported to possess anxiolytic activity in rat behavioral models [51]. In elevated plus maze study, CA methanol extract (3,047 mg kg^{-1} of body weight) and AS (3 and 5 mg kg^{-1}) significantly reduced the number of closed arm entries and increased the time spent in protected head dips, whereas both CA ethyl acetate extract (111 mg kg^{-1}) and AS (3 and 5 mg kg^{-1}) significantly increased the number of protected head dips and the time spent for this activity. For the open-field test, AS (3–10 mg kg^{-1}) significantly increased the rat spent time (41.3 s) at the center of the arena, while the social interaction test treatment with 1 and 3 mg kg^{-1} of AS significantly reduced the number of non-interaction activity by 29.8 s and 35.0 s, respectively.

3.11 Venous Hypertension Improvement

Restoring tissue firmness and elasticity is also a very important criterion to venous wall. The CA extract containing triterpenoid centellosides is used as venous tonic in the treatment of venous-lymphatic disorders [3]. It improves and maintains the connective tissue by strengthening the weakened veins [33]. The TTFCA, containing 40 % of AS and 60 % of AA and MA, enhanced microcirculatory effect by reducing the capillary filtration rate and increasing the oxygen and carbon dioxide transcutaneous partial pressure [52]. Consequently, due to its modulating action, it improves the connective tissue modulation, stimulates the synthesis of collagen and other tissue protein by modulating the action of fibroblast in the vein wall, and increases collagen remodeling in and around the venous wall [38]. As such, the TTFCA is effective to treat venous wall alterations in chronic venous hypertension and in protecting the venous endothelium.

4 Clinical Studies

To date, very few clinical studies have been conducted using the triterpenoid centellosides of CA. Most of the studies that have been realized with the CA extracts do not determine the concentration of the active components of the triterpenoid centellosides. In some studies, TTFCA showed its effectiveness on microcirculation and capillary permeability, while AS stimulates angiogenesis both in vitro and in vivo [23, 52]. A study with TTFCA combined with the use of vacuum suction chamber device improved the microcirculation and capillary permeability in patients with venous hypertension [53]. In a similar treatment, placebo-controlled, randomized trial, TTFCA improved the microcirculation in venous hypertension microangiopathy [54]. Oral administration of TTFCA (30 and 60 mg day^{-1}) taken for 60 days that was conducted in a double-blind study in 87 patients with chronic venous hypertensive microangiopathy confirmed the results that TTFCA was effective in the treatment of venous hypertensive [55]. In a 3-week treatment with 90 mg TTFCA on patients with post-phlebetic syndrome (PPS), a reduction in circulating endothelial cells was noted compared to the normal patients [56]. An increase in the circulating endothelial cell number was observed in vascular injury, thrombosis, acute myocardial infarction, and other peripheral venous diseases. As such, the reduction of epithelial cell number was indicated by the effectiveness of TTFCA to protect the integrity of vascular intima. In another study involving 52 patients with venous hypertension (pressure greater than 42 mmHg), patients were treated with 60 and 30 mg day^{-1} of TTFCA [57]. After a 4-week treatment, there was significant improvement in the filtration rate, ankle edema, and ankle circumference. Studies on 94 patients suffering from venous insufficiency of the lower limb were conducted for 2 months using 120 and 60 mg day^{-1} of TECA [58]. These results also confirmed the significant improvements of the lower limb and edema for the TECA groups compared to the placebo.

5 Safety and Toxicology

The safety and nontoxicity effect of CA were reflected by its use in traditional Indian Ayurvedic, Asian, and Chinese medicines for hundreds of years [1]. World Health Organization (WHO) recommendation stated that no toxic effects due to the oral administration of CA have been reported so far, and WHO recommends oral dosage for scar healing is 1–2 g day^{-1}, divided into three parts, taken as such or as an infusion [59]. However, concern on safety should be on the use of its triterpenoid centellosides in pure form. The oral administration of standardized CA extracts and AS was safe in experimental animal model [33]. The AS has shown nontoxicity effect even at 1 mg kg^{-1} in oral administration. Meanwhile, the toxic dose by intramuscular application on rabbit and mice was reported at 40–50 mg kg^{-1} [60]. In oral application, AS at 1 g kg^{-1} of body weight has proven to be nontoxic [61]. Studies on CA triterpenoid active components (AS, AA, and MA) with human cytochrome P450 2C9 (CYP2C9) enzymes have shown moderate to strong inhibition with the strongest ($K_i = 9.1$ μg mL^{-1}) being AA [62, 63]. Therefore, these results demonstrated the potential risk of drug-herb interactions when these CA products, particularly when high AA, were taken together with CYP2C9 isoform substrates.

6 Conclusion

The in vitro and in vivo studies and clinical evaluations have shown the healthcare potential of triterpenoid centellosides' bioactivities and uses. However, the clinical evaluation in human is still limited. As such, it is important to substantiate its healthcare claim clinically, especially on the possible interaction with other drugs. With all these claims in healthcare applications, the prospect of triterpenoid centellosides as an alternative to standard drugs should be further explored.

Abstract

During the last decades, the limit of microbial diseases and infections has been exceeded dramatically. Several types of pathogenic microbes have been reported; however, some are being less infection responsible. Increase in disease infections in human and plants caused by pathogenic bacteria and fungi mainly occurs due to the development of new specific features in microbial majority, making them to adapt in any environmental condition. Resistance of these pathogens to commercial antibiotic drugs has emerged as a great health concern to the consumers. Diseases caused by bacteria and fungi and their resistant nature to antibiotics have played a vital role to increased rate in plant and

human infectious diseases. Extensive use of antibiotics in several industries against hazardous bacteria and fungi has resulted in additional antibiotic resistance to these pathogens, which has become a matter of great concern to the public health. There has been an increasing concern worldwide on therapeutic values of natural products including essential oils. Hence, there are multitudes of potential useful bioactive substances to be derived from plants. With the recent trend of high percentage of resistance in microorganisms to the present-day antibiotics, search for new and effective drugs is a challenging task. This chapter discusses antimicrobial efficacy and suitability of plant essential oils against diverse range of microbial pathogens causing several diseases in human and agricultural industry. Also, a brief description of the chemical nature of essential oils, mode of antimicrobial action, their legal use in various beneficial industries, and the area for future research has been laid out.

Keywords

Antibiotic resistance • antimicrobials • essential oils • microbial pathogens

1 Introduction

Microbial pathogens including bacteria and fungi have become the major cause of human and plant diseases which has raised a great safety concern to public health. In several geographic regions, a large proportion of bacterial and fungal diseases have been confirmed by the hazardous pathogens [1, 2]. Diseases caused by microbial pathogens including bacteria and fungi can affect human health and economically important plants [3, 4]. In this respect, the infection may initiate and spread dramatically to various body or plant sites if the person or plant is not treated with suitable antibiotics. There are many examples of plant diseases that have made a major impact on society and have even changed human history. More than 70% of all major crop diseases are caused by fungi. The disease cause of fungi as an agent of plants, human diseases, and decomposers has spurred scientists worldwide to control such pathogens through plant-based natural antimicrobials including essential oils [5]. The impact that fungi have in agricultural industry with regard to plant health, food loss, and human nutrition is staggering. Some of the world's great famines and human suffering can be blamed on plant pathogenic fungi. Similar to all other groups of plant pathogens, fungal pathogens have developed ways to survive periods of unfavorable environmental conditions or in the absence of a susceptible host, spread, infect, grow, and reproduce on and within plants [6].

Food industry, although having a number of food preservatives, is also experiencing a lack of potent food preservative agents to secure the safety of food or food products [7]. Although antimicrobial drugs have supported to control the food-borne pathogens or diseases in food system, however, acquired resistance to these antimicrobial agents is a major drawback due to their several side effects [8]. Hence, certain effective antimicrobial drugs are needed for their practical applications to control food-borne bacterial pathogens.

The essential oils are plant secondary metabolites which are biosynthesized in glandular structures of a plant cell. Essential oils are potential antimicrobial agents because of the presence of bioactive volatile components by which they control several pathogenic bacteria and fungi [9–11]. Use of essential oils in several industries has been exploited since decades [9, 12]. Chemistry of essential oils also supports the phenomena that these oils containing volatile components serve as the most potent antimicrobials [13, 14]. The major drawback of food products is that they are easily deteriorated by food-borne pathogens during their processing [15]; this warrants search for new and effective food preservatives for food and agricultural industries [16, 17]. It has been reported that various factors are responsible for the biological efficacy of essential oils to serve as potent antibacterial agents in food system which include temperature, appearance, pH, load of microbial flora, and favorable environment [18]. Essential oils find practical application as potent food preservatives in meat production than commercial antimicrobials [19]. Several essential oils have been used effectively to control the load of microbial pathogens in various food products [20, 21]. Hence, addition of essential oils can serve as green preservatives to food industry against pathogenic bacteria [12, 22]. Due to these findings, focus on the research related to essential oils has changed from their biological efficiency [23–25] to the activity against various pathogenic bacteria [26–28].

In general, the biological efficacy of essential oils is confirmed due to their chemical components that include phenolics or the components from terpene origin [12, 29]. Although all the essential oils have been shown to exert antimicrobial efficacy, variations in their chemical nature and the amount of their volatile components have been observed. This is attributed to variations in the collection time of sample, abundance or lack of mineral components, distribution, changes in genetic levels, environmental conditions, and portion of the plant used for distillation [30, 31]. Although several essential oils, as a whole, show potent biological efficacy [27, 32], the antimicrobial efficacy of essential oils has been credited to the components present in higher amount. Besides, the components present in lower amount have been shown to exert synergistic effect with the major components of the oil [33].

Several concerns have been raised to minimize the load of chemical preservatives in food or agricultural food products. Recently, the use of essential oils has become a focal area of research for their practical applications to control the hazardous pathogens in food and agricultural systems [2, 34–36]. Pathogenic microbes in storage food or food products are responsible to degrade or deteriorate the quality of food or agricultural products, resulting in the emerging plant and human diseases in various regions of the world [7]. In this regard, applications of essential oils, being potent antimicrobials and low toxic in nature, can be a good strategy to control or inhibit the pathogenic bacteria and fungi in marketable food or processed food or agricultural products with higher percentage of consumer acceptability [37, 38].

2 An Overview of Essential Oils

Although food and agricultural industries have been enriched with several modern practices, consumers are still aware about the health problems caused by pathogenic bacteria and fungi [11, 39]. A large proportion of population is suffering from the diseases caused by pathogenic bacteria and fungi in several geographical regions of the world [11, 39]. This has requested an urgent need to develop new and effective natural antimicrobials to combat with the diseases caused by pathogenic microbes including bacteria and fungi as the western society has appeared to experience the concern that corporates the chemical preservatives with a lesser amount of environmental impact [5, 39–43].

In nature, essential oils having aroma and flavor are isolated from the various parts of the plants [39]. The essential oils for commercial utilization can be isolated using various methodologies which include steam distillation, solvent extraction, and expression [39, 44]. As reported previously, most of the plant essential oils exert potent biological efficacy [11, 35, 39, 45–47]. The antimicrobial or other biological activities of essential oils are directly correlated to the presence of their bioactive volatile components [11, 43, 48].

The use of essential oils was exploited in several industries; however, the extreme utilization rate of essential oils was reported to have in aroma and flavor industries [39]. Essential oils have been used widely in industries [39, 44, 49, 50]. Also, the role of essential oil components has been exploited vigorously in several beneficial industries to secure the antimicrobial efficacy in food and agricultural industries [43, 51]. Combinations of various essential oils with natural and herbal forms are also available in the market for their practical utilization [39, 52, 53].

Extension of life span of food or agricultural products for human utilization is needed from the contamination caused by pathogenic bacteria and fungi. Traditional preservative practices cannot control the microbial contamination; hence, other new methodologies are required to maintain the shelf life of food and agricultural products [54]. Besides, concerns on reducing chemical preservatives in food and agricultural industries have been raised due to the adversary effects of chemical preservatives, resulting in the release of toxic materials in food and agricultural systems. Use of essential oils can be effective application in food and agricultural industries naturally due to their potent antimicrobial nature. The essential oils have been thoroughly screened for their potentials using various test assays, and the inhibitory effect is defined directly or by measuring the physical properties [39, 54–57]. Although variations in the antimicrobial activities of the essential oils have been observed, the less sensitivity of negatively charged bacteria is attributed to the extrapolysaccharide layer as compared to positively charged bacteria lacking this outer cell wall coverage. The antimicrobial efficacy of some of the selected essential oils as minimum inhibitory concentrations against bacteria and fungi has been summarized in Table 132.1.

3 Chemistry of Essential Oils

Plant essential oils are the low molecular weight volatile mixtures, biosynthesized in various plant organs. The chemical nature of essential oils belongs to the composition of terpene compounds (mono-, sesqui-, and diterpenes), which are mainly obtained as hydrocarbon compounds or the derivatives of oxygen molecule. A few components of the essential oil are nitrogenous or sulfury in nature which are found as alcohols, acids, esters, epoxides, aldehydes, ketones, amines, and sulfides [58]. The components of the essential oil are divided in two groups: (1) compounds from terpene origin and (2) aroma compounds [59].

Terpene compounds have natural occurrence in plants found as major components of most of the plant essential oils. Based on their structural and functional properties, terpene compounds have been classified according to their basic structural unit isoprene containing five carbons. In the formation of terpenes, prenyldiphosphate serves as a precursor. The terpene compounds exist in the form of mono-, sesqui-, hemi-, di-, tri-, and tetraterpenes. The monoterpenes containing two isoprene units are responsible to construct the major portion of all the essential oils. These compounds work as carbure, alcohol, aldehyde, ketone, ester, ether, peroxyde, and phenols [58]. The sesquiterpene compounds contain three isoprene units, and the functional properties are very close to monoterpene compounds.

The aromatic compounds are the derivatives of phenylpropane, which are aldehydes, alcohols, phenols, methoxy, and methylenedioxy in nature. A few nitrogen and sulfur compounds present in essential oils are also characterized as plant essential constituents. A list of selected and important antimicrobial components of essential oils has been presented in Fig. 132.1.

4 Action Mechanism of Essential Oils

Though a large volume of data is available on biological effect of essential oils, the mechanism of antimicrobial effects is not clearly understood till recently as essential oils are a complex mixture of several diverse components. Besides, different essential oils or their different components show antimicrobial mode of action not only at a particular location but also at different cell sites [21, 60]. Hydrophobic nature of essential oils makes them interact too well with lipid membrane of bacterial pathogens, resulting in the leakage of the inner cell components of the cell as well as affecting potassium ion reflux and eventually leading to cell death [24, 32, 61, 62]. Generally, phenolic nature of essential oils makes them to work effectively against pathogenic bacteria [32] by disrupting the cell membrane as well as effectively inhibiting the functional properties of the cell and eventually leaking the inner materials of the cell [62, 63]. Besides, phenolics contain an OH group, hence working effectively against pathogenic bacteria [22, 64].

Volatiles from the essential oils not only work on a single target site in the cell, but also they bind to protein structures of the cell. Bacterial cell membrane contains the enzymatic proteins to maintain the functional properties, and storage of hydrocarbons to lipid membrane can make the changes in the building block of lipids and proteins, resulting in the permeability of the cell components [62, 65]. Some of the essential oils and their volatiles are found responsible in inhibiting the enzymatic proteins in some bacterial pathogens [66].

In addition to this, terpene compounds have been well known to affect the bacterial and fungal cell membrane by inserting themselves between the fatty acyl chains that make up the membrane lipid bilayers [62]. This results in changes in cell functions, leakage of cell components making starving conditions

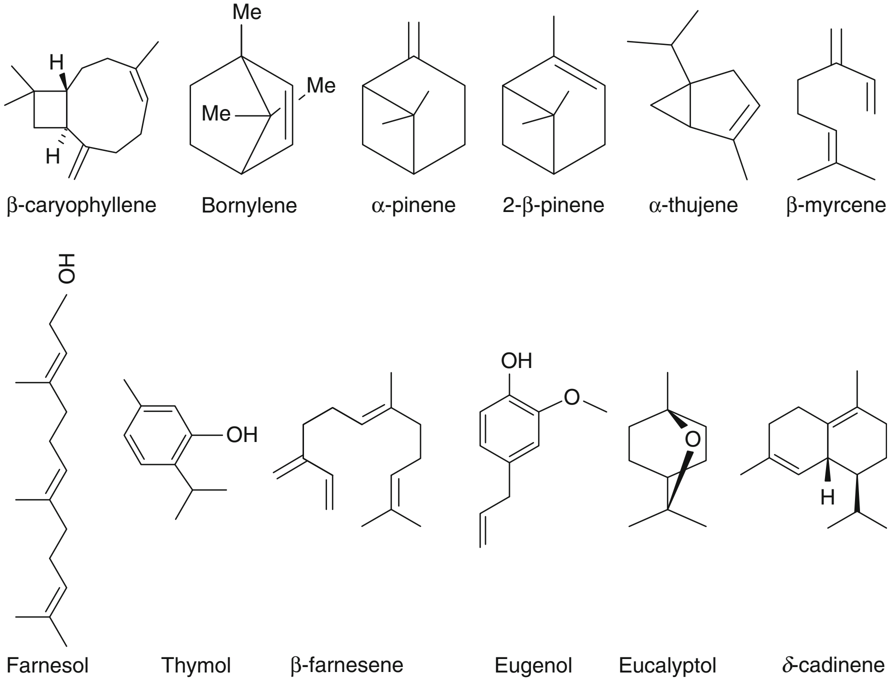

Fig. 132.1 Chemical structures of some selected antimicrobial principles of essential oils

of the cell [67]. In particular, the fungal plasma membrane ATPase may protect cells by maintaining cell homeostasis and by countering the permeabilizing effects of essential oils. On the other hand, the essential oils and their terpene composition have been shown to inhibit respiration in fungal pathogens, suggesting adverse effects on mitochondria [24, 68]. Also, the sesquiterpene dialdehyde polygodial has been shown to inhibit the yeast mitochondrial ATPase, affecting medium acidification indirectly by reducing or eliminating the large amounts of cellular ATP required to fuel the plasma membrane ATPase in fungal pathogens [69]. Hence, the functions of cell components including nucleus can be reduced by the effect of essential oil or their volatiles due to the permeability changes occurring in the membrane of fungal and bacterial cell [67, 70].

5 Synergism and Antagonism

The antimicrobial efficacy of essential oils can be attributed to the volatile majority of essential oil, volatile ratio, as well as their mode of action [22, 34, 39]. Antagonistic efficacy can be visualized upon the supply of two compounds where the sample mixture has low antimicrobial efficacy as compared to using them separately [39]. Additional antimicrobial efficacy can be visualized upon the supply of two compounds where the sample mixture has similar antimicrobial efficacy while using them separately [39]. However, when combinatory effect of two compounds is higher than the effect of individuals, it is known as synergism [39, 71]. Literature survey has demonstrated that an oil as a whole showed better antibacterial efficacy than only a combination of major volatiles of the oil [39, 72]. Hence, it might be said that the minor elements of the oil have crucial role in increasing the biological effectiveness of the oil, resulting in the synergism. Previously, we reported that cone essential oil of *Metasequoia glyptostroboides* exerted potential synergistic effect along with nisin against gram-positive bacteria at varied concentrations in whole, low, and skim milks [73]. Combined fractions of different essential oils such as cilantro, coriander, dill, and eucalyptus have been shown to exert synergistic and additive mode of action [39, 74]. Although proportions of volatile compounds of essential oils have been found to exhibit a complete inhibitory action to some of the bacterial pathogens, however, these volatiles could not be able to exert antibacterial efficacy when applied individually against the tested organisms [39, 75]. The biological efficacy of essential oils not only corresponds to the volatiles present in a higher quantity but also the volatiles present in low amount can influence the biological efficacy of whole essential oil.

6 Legal Regulations on the Use of Essential Oils

The European Union (EU) has laid down recommendations and laws for using plant volatiles and essential oils to retain the quality of the food or food products which are easily hampered by the pathogenic microbes. FDA is very likely to follow the EU over these issues. Several essential oils and volatiles in their marketable forms are sold as flavoring agents. The registration of oil or oil components at EU and FDA is considered the products to be nonhazardous as well as safe to the health of consumers. Besides, a new registration to serve as natural flavoring agent can only be considered if the concerned metabolic and toxicological researches have been performed in order to confirm its daily purpose use in the USA so as to call approved food additives [39]. Interestingly, it will be more beneficial economically to the people of the developing countries to use herbal plant or the plant parts as a whole or a whole essential oil as an ingredient as well as herbal drug than using an individual component of the essential oils [39, 42].

7 Future Perspectives

The most diverse and interesting area of the essential oils and their volatiles for their proper utilization is to suppress hazardous pathogens including bacteria and fungi. The improvement in the quality of food or agricultural products as well as control of multidrug-resistant pathogens might be an important area of further research. The essential oils can also be used in the food stuffs which have not been associated previously with any flavor, if one or more components of the oil together can exert desired antimicrobial efficacy at the particular amount, having no deteriorating effect on the quality of food or agricultural products [39]. In fact, the consumer goods are experiencing an increased influence of essential oils or their volatiles in order to develop new and effective natural antimicrobials of plant origin [39, 41]. These products can also be served as natural in other related industries for their safe use. For large-scale production of essential oils, biotechnological approaches of their synthesis may be useful to obtain the desired volume of essential oils. In addition, standardization of the chemical nature of commercial essential oils will be needed for their safe and practical applications.

In addition to this, the mechanism of action of plant essential oils and volatiles on proteins associated with cytoplasmic membrane as well as on lipid structure has not been completely studied. Therefore, it might be an important aspect of future studies [39]. Moreover, evaluation of the mechanism of action of essential oils will potentially strengthen their practical applications and significance in future research in antimicrobial therapy [39]. In order to optimize the antimicrobial efficacy, synergistic, antagonistic, and additive effects, essential oils can be explored so as to optimize the lowest concentration required for the inhibition of any pathogenic bacteria or fungi which will indeed be a helpful strategy in the practical application of essential oils. Besides, experimental data on various direct or indirect consequences of using essential oils and their volatiles will confirm whether the essential oil or its volatiles are safe for using human purposes.

8 Conclusion

Microbial pathogens including bacteria and fungi are getting hazardous to human society in various aspects of utilization. Food or agricultural products including ready-to-eat products and vegetables are the major source of microbial contamination resulting in various human diseases. Practical applications of essential oils are needed for the complete elimination of hazardous pathogens. Several essential oils and their volatiles have shown a great potential to exert antimicrobial efficacy in several in vitro and in vivo model systems to control the harmful and pathogenic microbes. The volatiles of essential oils from terpene origin are most likely to affect the target pathogen. Based on selectivity and specificity, essential oils or their volatiles can be applied as potent and natural antimicrobial agents to control the pathogenic microbes including bacteria and fungi.

Abstract

Natural products are still been explored to provide new molecules that could interact with known and unknown pharmacological targets. Medicinal chemists have put a lot of effort in order to validate highly selective and potent biological agents. The studies focusing on the understanding of how these molecules act are very important and relevant to the field. A number of studies have shown that menthol possesses a large spectrum of biological activities. Interestingly, menthol has been implicated in the generation of an inward cationic current related to temperature sensing and this fact has been the focus of attention of various research groups around the world. In this chapter, we will provide information of menthol's pharmacological profile in different tissues. We also discuss the cytotoxic effects that have been attributed to menthol and many groups have provided evidence to confirm that this cytotoxicity is somehow related to the activation of TRPM8 ion channels and it seems to be dependent on intracellular calcium handling.

Keywords

Natural products • menthol • cytotoxicity • ion channels • TRP channels • voltage-dependent ion channels

1 Introduction

Over the last years, research on natural products have contributed enormously not only to the development of important therapeutic drugs used currently in different areas of modern medicine, but these compounds have also been used as molecular tools to explore new pharmacological targets and uncover intracellular signaling mechanisms involved in their distinct biological functions. However, the still unexplored potential of natural products as sources for new drugs relies on the fact that only a small fraction of plants, animals, and microorganisms have been so far investigated phytochemically or biologically [1]. The goal of this chapter is to collect basic information available in the literature related to menthol and its effects.

Menthol is a plant-derived cyclic terpene alcohol that gives plants of the *Mentha* genus their typical minty smell and flavor. The plant oil, often referred to as peppermint oil (from *Mentha piperita*) or cornmint oil (from *M. arvensis*), is prepared by steam distillation from the fresh parts of the plant or synthesized from other essential oils such as citronella oil, eucalyptus oil, and Indian turpentine oil. Among the optical isomers, (−)-menthol is the predominant chemical form present in nature and it is considered as a fragrance and flavor compound. For this reason, it is widely used as a flavoring for toothpaste, other oral hygiene products, and chewing gum [2]. Either *Mentha* herbs or menthol are mentioned in the Japanese Pharmacopeia, British Herbal Pharmacopeia, and US Pharmacopeia.

In this chapter, we will bring to attention some of the published studies that actually implicate menthol as an important pharmacological agent in different tissues.

2 Menthol Effects on Nonvascular Smooth Muscle

Menthol has been characterized in the literature mainly as an agonist on TRP channels, particularly as an activator of TRPM8, the receptor that makes the transduction for cool sensation [3–5]. Experimental work, however, has demonstrated that menthol has several additional pharmacological activities [6, 7]. Concerning smooth muscles, menthol is reported to act directly on their contractility, either via activity on excitation-contraction coupling or via intracellular signaling mechanisms.

Menthol blocks the excitation-contraction coupling that is mediated via cytoplasmic membrane depolarization (electromechanical coupling) and opening of voltage-operated Ca^{2+} channels (VOCC). On the experiments performed to investigate the effect of menthol on electromechanical coupling high concentrations of extracellular K^+ (20–60 mM) were used to induce depolarization of the cytoplasmic membrane and provoke VOCC opening, which causes increase in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) [8]. Blockade of electromechanical coupling has been demonstrated on the tracheal [9], bronchial [10], intestinal [11], urogenital [12–14], and vascular smooth muscles. This inhibition of electromechanical coupling has been attributed to menthol-induced blockade of VOCC [12–14].

Menthol is also described to block the excitation-contraction coupling that is mediated via the cascade of phenomena triggered by combination of agonists with cytoplasmic membrane receptors, also known as the pharmacomechanical coupling. Blockade of pharmacomechanical coupling has been demonstrated on tracheal [9], bronchial [10], urogenital [13, 14, 15], and vascular smooth muscles. Pharmacomechanical coupling include activity of receptor-operated calcium channels (ROCC) as one of the initial steps of the cascade of events leading to contraction, which causes increase in ($[Ca^{2+}]_i$) [8]. Menthol is also reported to act on the TRP channels located on the sarcoplasmic reticulum with implications on the contractility of the smooth muscle [12, 14]. Due to the diversity of parameters related to contractility that were investigated below, we will give the relevant details of menthol activity on each smooth muscle type.

3 Respiratory Smooth Muscle

The contractions of tracheal muscle of guinea pig induced by high concentrations of extracellular K^+ (20–60 mM) and methacholine (MCh, 0.01–10 μM) on the bath solution were inhibited by menthol [9]. The temperature dependence of this inhibitory effect was tested for the MCh-induced contraction: increase in temperature decreased menthol effect on contraction. Menthol also inhibits the increases of $[Ca^{2+}]$ induced by MCh or high K^+. This diminished increase in $[Ca^{2+}]_i$ was interpreted to be caused by inhibition of Ca^{2+} influx, which was concluded to be an important role on menthol-mediated inhibition of smooth muscle contraction [9].

On bronchial muscle of guinea pig, in experiments done in vitro, menthol caused dose-dependent relaxation of bronchial contraction induced by high concentrations of K^+ and ACh. In experiments in vivo, menthol also attenuates both capsaicin and NKA-induced bronchoconstriction. These effects were interpreted to be, in part, explained by a direct action of menthol on bronchial smooth muscle tissue [10].

4 Gastrointestinal Smooth Muscle

Menthol blocks the contractions induced by high concentrations of K^+ in guinea pig ileal smooth muscle (IC_{50} 7.7 μg/ml). Based on the similarity of IC_{50} for menthol-induced blockade of ileal contraction and Ca^{2+} uptake by synaptosomes it was concluded that menthol blocks Ca^{2+} channels. Additionally, it was suggested that this channel blocking property is one of the mechanisms contributing to the blockade of electromechanical coupling in ileum [11].

5 Genitourinary Smooth Muscle

In vitro experiments demonstrated that menthol (0.1–1.0 mM) inhibited carbachol-induced contraction of the detrusor smooth muscle of rat. Intravesical infusion of menthol (3.0 mM) facilitated the micturition reflex since it caused a reduction in voided volume (by 20%), volume threshold for inducing micturition (19%), and pressure threshold for inducing micturition (31%). This effect on micturition reflex was not modified by pretreatment with capsaicin. This was interpreted to suggest that intravesically infused menthol cannot relax detrusor muscle, and acts on capsaicin-resistant afferents (probably through TRPM8 in urothelium or sensory nerve endings) to facilitate the micturition reflex [15].

In rat vas deferens in vitro experiments menthol (0.1–1.0 mM) inhibited contractions induced by high concentration of K^+, carbachol, or noradrenalin. It was suggested that menthol acts via two mechanisms: partial blockade of Ca^{2+} entry via the voltage-gated, L-type calcium channels and a decrease of the calcium storage capacity of the sarcoplasmic reticulum (SR). It was also suggested that the effect on SR at least in part was mediated by menthol-induced activation of the SR-resident TRPM8 channel, which would lead to the enhancement of passive leak of Ca^{2+} from the SR and reduction in the amount of the releasable calcium during activation of contractions [12]. Investigation of the same research group reported that in the prostatic portion of smooth muscle cells of rat vas deferens higher TRPM8 protein targeted specifically the SR and cytoplasmic membrane, while in the epididymal portion it targeted only the plasma membrane [13]. Based on its localization on membrane of SR, TRPM8 was suggested to be capable of modulating the contractile activity [13]. Comparing the results obtained in normal versus castrated rats and in epididymal versus prostatic portions of the vas deferens it was suggested that TRPM8 modulates contractility of the prostatic portion by primarily decreasing Ca^{2+} storage in the SR, while in the epididymal portion by both decreasing the Ca^{2+} storage in SR and supporting Ca^{2+} entry. It was also suggested that castration and its resultant drop in the circulation of androgens changes the modulation of the rat vas deferens SM contractility mediated by menthol and icilin via the decrease of expression of L-type VOCC and increase in expression of TRPM8 [14].

6 Actions of Menthol in Vascular Smooth Muscle

Despite the use of menthol in culinary and medicinal preparations [2], relatively little is known about its actions on the human cardiovascular system, particularly in vascular smooth muscle. Studies in blood vessels evaluating the effects of menthol demonstrated different actions, particularly related to the precontractile state of the vasculature prior to menthol administration.

In studies using thoracic aorta from rat, menthol induced relaxation in precontracted vessels. This effect was significantly greater when the endothelium was left intact (by 15–20%), compared with denuded vessels suggesting that endothelium mediators participate in menthol-elicited relaxation. However, in relaxed tail artery with endothelium removed menthol addition caused a small but consistent contraction that peaked in the first minute of application. These evidences demonstrate that menthol induces a moderate vasoconstriction in vessels that have low vasoconstrictor tone and a marked vasodilatation when vasoconstriction is set at a high level [16].

Menthol actions in other vessels have also been characterized. As in the aorta, menthol induced relaxation in precontracted femoral, renal, mesenteric, and tail arteries, revealing no significant differences between potency and magnitude of effect between tissue beds. Therefore, menthol causes relaxation of vascular smooth muscle through intracellular Ca^{2+} concentration regulatory mechanisms [16].

However, it is well described that topical menthol application produces an innocuous cooling sensation at low concentrations and a burning pain sensation at high concentrations. Studies have indicated that menthol stimulates membrane depolarization and increased action potential firing on a subpopulation of primary afferent neurons. This depolarization results, as mentioned before, from activation of channels considered to be the main molecular thermosensors in sensory neurons belonging to the family of transient receptor potential (TRP) channels. TRPM8 (Transient receptor potential melastatin 8) is a Ca^{2+} permeable nonselective cation channel [17], predominantly expressed in a subpopulation of thermoceptive/nociceptive neurons found in the dorsal root ganglia and in trigeminal ganglia.

The expression of TRPM8 channels has also been described in the vascular smooth muscle cells [16, 18–20]. TRPM8 mRNA and protein were detected in rat tail, femoral and mesenteric arteries, and thoracic aorta [16, 20]. Additionally, this was confirmed in single isolated vascular myocytes by immunocytochemistry [16]. It has been demonstrated that the vascular effects induced by menthol seems to be related to the activation of TRPM8 channels, and this monoterpene is vastly used as a TRPM8 agonist. The major effect was observed in precontracted vessels, where

TRPM8-specific agonists, including menthol, caused a profound dilatation. These effects were predominantly attributable to direct stimulation of TRPM8 channels associated with vascular smooth muscle cells [16].

Studies using rat aorta demonstrated that the relaxation effect of menthol was abolished in the absence of extracellular Ca^{2+} or in the presence of Ni^{2+} but not in the presence of nifedipine, an voltage-dependent L-type Ca^{2+} channel blocker, suggesting that, at least in part, TRPM8 proteins are functional Ca^{2+} influx channels in vascular myocytes [20].

Additionally, it was found that in human forearm cutaneous vessels, menthol caused a profound dilatation in an assay where cutaneous red cell flux (RCF) was recorded from the ventral surface of the left forearm using a laser Doppler perfusion monitor. The delay in action (8–18 min) in relation to what was observed in other vessels may simply reflect the time taken for menthol to passively diffuse into blood vessels from which RCF measurements were taken, 1 mm below the skin surface [16]. This observation is of particular relevance to demonstrate that experiments conducted in humans seems to reflect similar vasorelaxation effects observed in rats.

In summary, these findings suggest that menthol disturb Ca^{2+} homeostasis on smooth muscle cells and help to reveal that as the common mechanism by which menthol affects various cell properties, although the effects of menthol on $[Ca^{2+}]_i$ are opposite in different tissues and species.

7 Assessment of Cytotoxic Effects Caused by *d, l*-Menthol

It has been reported that the monoterpene menthol presents a variety of biological actions including antibacterial, antifungal, antioxidant, and radical scavenging properties. Moreover, some studies have shown menthol effects on ion channels, the voltage-gated sodium channels [21], and transient receptor potential channels, specifically Transient Receptor Potential Melastatin 8 subfamily (TRPM8) channels, which is a member of the TRP ion channel superfamily [22] and these effects on TRPM8 channels have been associated with menthol's cytotoxic actions. By using a number of experimental approaches different research groups demonstrated that menthol could cause cell death [23, 24].

The relationship between the pharmacological effects elicited by menthol and ion channel dysfunction depends on the interaction of this monoterpene with distinct types of ion channels. In this way, the reported local anesthetic effects attributed to menthol and for some of its structural chemical homologues, such as thymol, carvacrol, and carveol, might be caused by a blockade of voltage-gated sodium channels [21, 25, 26]. On the other hand, a pronounced cytotoxic effect of menthol is correlated with the action of menthol in TRPM8 channels [22, 27]. At this point, we will make a short introduction to TRPM8 channels to further discuss the putative cytotoxic effects of menthol in various cell types.

The TRPM8 channel is a cold- and menthol-sensitive ion channel, as was shown by Reid and Flonta in 2001 [28]. TRPM8 is a nonselective cation channel and calcium permeable which is activated by temperatures below 26°C. This channel has six transmembrane domains and the functional channel is formed by assembly of four identical subunits, homotetrameric protein [29] and its structure is reasonably conserved although evolution from invertebrates to vertebrates. These channels play a key role in regulation of cell cycle and calcium handling [30]. Furthermore, it has been demonstrated that some substances, including menthol has the ability to activate the TRPM8 channel [22, 31].

TRPM8 has been found in neurons although its expression is low, moreover this channel is also expressed in smooth and skeletal muscle, prostate, bladder, genital tract, and lungs [21, 32, 33]. However, it has been shown that there is greater expression of these channels in cancer cells than the corresponding noncancer cells and it could be addressed as a marker for diagnosis and also suggests the possibility of target-directed drug design studies [22, 31, 33].

As the TRPM8 channel seems to be related to events such as proliferation, apoptosis, and cell differentiation, it is reasonable to think of TRPM8 contribution to modulate important cellular processes. It was shown by Thebault and colleagues [33] a TRPM8 channel restrict to the endoplasmatic reticulum (ER) membrane of human prostate cancer epithelial cells (also known as LNCaP an androgen-dependent prostate cancer cell lineage). This menthol-activated channel at subcellular localization provoked calcium release from ER which was associated with the entry of calcium through plasma membrane store-operated channels. These calcium handling processes might be important for cell fate decision (p.ex. apoptosis or proliferation). Menthol also triggered the TRPM8 channel in another human prostate cancer cell, DU145 which is androgen-independent cells and has significant TRPM8 protein expression. It was shown that menthol decreased both, proliferation and motility of DU145 cells [34].

It was also reported that menthol suppressed the viability of human malignant melanoma cell line, G-361 and was proposed that the influx of calcium through activation of TRPM8 channels may be responsible for the regulation of cell cycle events leading to cell death in such melanoma cells [27].

Various authors have demonstrated that menthol acts not only by activating the TRPM8 channel but also in other cellular mechanisms. In line with this statement, human gastric cancer SNU-5 cells menthol reduced the cell proliferation rate by inhibiting the expression of topoisomerase I [24]. In murine WEHI-3 and human promyelocytic HL-60 leukemia cells menthol decreased the Mac-3 and CD11b markers which are involved in processes, such as leukocyte adhesion and migration, phagocytosis and cell-mediated cytotoxicity, and in HL-60 menthol–stimulated cell death [35, 36] Another study showed that menthol was able to change tubulin polymerization as well as apoptosis inhibiting human epithelial colorectal adenocarcinoma cells [37].

In general, some studies have addressed several issues mentioning that menthol has the potential to become a new drug active on cancer cells. However, caution should be exercised here because menthol has a number of different biological actions which could be an actual problem in terms of developing a new class of drugs. Clearly more in vivo and in vitro studies are essential to better certify this prospective.

8 Menthol Effects on Voltage-Gated Channels

Voltage-gated channels have fundamental roles in many cells, excitable or not. Alteration in the regular function of these molecules alters excitability in muscle and neuronal cells and secretory pattern in endocrine cells, for example. Despite the stimulatory action of menthol on TRPM8 channels, in general the reports so far show menthol as an inhibitory molecule on voltage-gated channels.

Voltage-gated calcium channels mediate calcium influx that controls many functions such as contraction, secretion, neurotransmission, and gene expression in different cell types. In neurons and neuroblastoma cells, menthol inhibits calcium currents measured from low voltage-activated (LVA) and high voltage-activated (HVA) calcium channels in the concentration range of 0.1–1 mM [38, 39]. Additionally, menthol also accelerates inactivation phase of the calcium current from HVA calcium channels in a concentration-dependent manner and without major calcium influence [39, 40].

Similar to that observed in neurons, menthol can inhibit cardiac L-type calcium channels. However, another well-known TRPM8 agonist, icilin, had only a minimal effect on these channels suggesting that menthol-induced modification on cardiac voltage-gated calcium channels is independent of activation of TRPM8 [41].

Voltage-gated sodium channels are crucial for the initial phase of action potential in excitable cells and inhibition of these channels is one of the primary mechanisms implicated on local anesthetic effects [42]. Menthol was reported as local anesthetic in vivo and in vitro experiments, strengthening the notion that menthol acts on voltage-gated sodium channels [43]. Corroborating with this study, two more recent reports demonstrate menthol inhibitory effect on tetrodotoxin-sensitive (TTX-S) and tetrodotoxin-resistant (TTX-R) voltage-gated sodium channels [21, 44].

Menthol inhibits sodium inward currents generated by heterologously expressing in HEK293 cells rat neuronal (rat type IIA) and human skeletal muscle (hSkM1) sodium channel isoforms [21]. Also, the inhibitory potency of menthol on these channels increases when maintaining the holding potential in more depolarized levels. This fact, per se, indicates that menthol could have more affinity for channels in inactivated state [21].

Menthol also inhibits native TTX-R sodium channel isoforms (Na_V 1.8 and 1.9) in dorsal root ganglia neurons independent of TRPM8 ion channel activation. Similarly, TTX-S sodium channel isoforms inhibitory potency increases at more depolarized holding potentials [44]. In TTX-R and TTX-S sodium currents, menthol induced a negative shift in steady-state inactivation curve indicating a change in inactivation kinetics without major changes on the voltage-dependence of the steady-state activation [44]. Menthol inhibited firing at high-frequency stimulation with minimal effects on normal neuronal activity and, in low concentrations, menthol also cause analgesia in mice alleviating pain produced by Amm VIII, a sodium channel-targeting toxin which slows down sodium channel inactivation [44].

Despite these reports, until now menthol effects on voltage-gated potassium channels were not well explored. Menthol-activated large-conductance

Ca^{2+}-activated K^+ (MaxiK) channels by increasing intracellular calcium levels and stimulated cell migration on human glioblastoma cells [45]. However, in inside-out patch clamp experiments (using pituitary GH3 cells as a model), to avoid any influence of intracellular calcium, menthol did not increase MaxiK channels activity [46].

In a recent review, Araújo and colleagues [26] have pointed out some of the pitfalls and promises in this exciting field of research that is worth reading. The authors argued that we are far from a complete set of experimental approaches that lead us to actually investigate the biotechnological potential of substances isolated from natural sources.

9 Conclusion

Menthol is a natural compound isolated from a variety of plants and it has been mostly used as analgesic. Recently, it was demonstrated by a number of studies that menthol produces cool sensation which is mediated by the activation of TRPM8 channels. Experimental work from different laboratories has demonstrated that menthol has several additional pharmacological activities that compose its pharmacological features. In this chapter, we have pointed out a scenario where menthol is posed as the main actor toward the understanding of its biological and toxicological effects.

Abstract

Eugenol is an active ingredient of essential oil extracted from cloves and other herbs. Eugenol is used extensively in dentistry for its analgesic and anti-inflammatory activities. However, the molecular mechanism underlying the pharmacological action of eugenol is only recently investigated. This chapter discusses eugenol's abilities to modulate various ion channels that are responsible for nociception, generation of neuronal spikes, and synaptic transmission. Therapeutic use of eugenol as antibiotic, anti-inflammatory, antitumor, and antioxidant agent is described and then followed by other aspects of eugenol

Eugenol • analgesic • anesthetic • anti-inflammatory • antibiotic

1 Introduction

Eugenol (4-allyl-2-methoxyphenol) is an active ingredient of several herb plants that are well known and widely used in traditional medicines, especially for analgesic and antiseptic purpose in treatment of toothache [1]. For example, eugenol is a major constituent of clove oil, which was rubbed on the gums in treatment of toothache [2]. Its therapeutic use in dental clinic is documented in as early as 1873 in its mixture form with zinc oxide [3]. It was more than a hundred years later that the anodyne [4] and the antibacterial effects [5] of the zinc oxide eugenol were assessed by modern scientific method. Eugenol was commonly used as dressings after periodontal surgery in the 1960s [3]. In present days, eugenol is extensively used in dentistry, as an active ingredient of filling materials, endodontic sealers, dental cements, periodontal dressing materials, and dry socket dressings. However, traditional use of eugenol was not limited to analgesics and antiseptics but as versatile as anesthetic, antiemetic, antiseptic, antispasmodic, antiparasitic, healing, and disinfectant effect [1]. The application of eugenol is growing fast as modern scientific methods have revealed antifungal[6], anticarcinogenic [7], antimutagenic [8], antiallergic [9], antioxidant [10], and insecticidal activity [11] of eugenol. This review mainly focuses on the recent advances on the understanding of mechanism underlying the neuronal modulation by eugenol and then discusses other pharmacological effects of eugenol.

2 Definition with Chemical Examples

Eugenol is a member of the phenylpropanoids, a large family of organic chemicals that contain a phenyl ring and a C_3 side chain. Phenylpropanoids are synthesized in plants from the phenylalanine, an essential amino acid, to serve various important roles such as an antibiotics, natural pesticides, signal substances, protective agents against ultraviolet light, an essential component of a cell wall, attractants for pollinators [12]. Other bioactive phenylpropanoids include carvacrol, thymol, cinnamaldehyde, salicylic acid, vanillin, and coumarin [2].

Eugenol is also a phytochemical, meaning it is a naturally occurring compound in plants. While cloves (*Syzygium aromaticum* or *Eugenia caryophyllata*) have the highest percentage of eugenol in its oil extract, eugenol is also found in allspice

(*Pimenta dioica*), sweet basil (*Ocimum basilicum*), holy basil (*Ocimum tenuiflorum*), bayrum tree (*Pimenta racemosa*), carnation (*Dianthus caryophyllus*), and cinnamon (*Cinnamomum verum*) [13].

3 Biosynthetic Pathway and Regulation

The first step of phenylpropanoid biosynthesis is conversion of phenylalanine into cinnamic acid by cleavage of ammonium group by the enzyme phenylalanine ammonia-lyase (PAL). Reduction of carboxylic acid from the cinnamic acid leads to cinnamaldehyde, which is then acylated with acetate from acetyl-CoA to form coniferyl alcohol [14]. Reductive cleavage of coniferyl alcohol by eugenol synthase yields eugenol [15].

4 Biological and Pharmacological Activities

4.1 Analgesic Activity

Historically, eugenol was used primarily as an analgesic agent. However, its molecular mechanism underlying the analgesic effect was studied only in recent years [16–22].

4.1.1 TRPV1 Channels

Transient receptor potential (TRP) channels are large family of cation channels that play roles from insects to humans as key transducers of various physical and chemical stimuli [23]. Among over 30 members of mammalian TRP family, several have been implicated in transduction of nociception. The most extensively studied TRPV1, or transient receptor potential vanilloid 1, is of particular interest because it is activated by noxious heat and algogenic chemicals. The chemical activators of TRPV1, such as capsaicin, resin feratoxin, and olvanil, are called vanilloids because they share vanillyl functional group in their structure [24]. Interestingly, the vanillyl moiety is also included in the structure of eugenol. Based on the vanilloid structure of eugenol and observation of calcium-permeable current induced by eugenol in dorsal root ganglion neurons [25], it was tested and demonstrated that eugenol activates TRPV1 [26] and TRPV3 channels [27].

Activation of TRPV1 induces a robust inward cationic membrane current, but repetitive or prolonged exposure to the activating condition leads to desensitization, and TRPV1-induced currents are gradually reduced [28]. Therefore, the analgesic mechanism of eugenol, especially in its ability to alleviate thermal hyperalgesia after nerve injury [29], might be partly attributed to the desensitization of TRPV1. However, because eugenol does not induce a strong response of TRPV1 as capsaicin, and because desensitization of TRPV1 by repetitive application of eugenol has not been observed, this is yet to be proved in future study.

4.1.2 HCN Channels

Hyperpolarization-activated cyclic-nucleotide-gated (HCN) channels depolarize cell membrane in response to membrane hyperpolarization. The current produced by HCN channels, hyperpolarization-activated current, or I_h, was first identified as a pacemaker current in cardiac muscle cells [30]. I_h in dorsal root ganglion (DRG) neurons, particularly in medium- and large-size neurons, evokes spontaneous firing of action potentials and induces ectopic discharges after peripheral nerve injury [31, 32]. The role of HCN channels in development of neuropathic pain was further confirmed by that pharmacological blockade of I_h reversed both pain behavior and the spontaneous discharge in injured nerve fibers [33]. It was recently shown that eugenol abolished mechanical allodynia induced by chronic constriction injury of infraorbital nerve [16]. The mechanism of the subsidized mechanical allodynia could not be attributed to inhibition of voltage-gated sodium channels because mechanical allodynia was reversed by much lower dose of eugenol than thermal hyperalgesia [16]. Because upregulated HCN channels in neuropathic pain condition contribute more to mechanical allodynia than thermal hyperalgesia, the effect of eugenol on I_h was tested in rat trigeminal ganglion neurons. Whole-cell patch-clamp recording revealed that I_h was successfully inhibited by eugenol at much lower dose than voltage-gated sodium channels. The mechanism underlying inhibition of I_h by eugenol does not seem to be mediated by $G_{i/o}$-protein activation, although intracellular cAMP concentration is somehow related. Although the molecular mechanism is yet to be discovered, it was proposed that eugenol could be potentially used for treatment of mechanical allodynia in neuropathic pain patients [16].

4.1.3 Purinergic Receptors

P2X receptors are cation channels that are activated by extracellular adenosine 5′-triphosphate (ATP). Among seven members of P2X receptor family, $P2X_3$ is predominantly expressed in subpopulation of IB4-positive nociceptive sensory neurons [34, 35]. Since $P2X_3$ is also expressed in trigeminal ganglion neurons that innervate tooth pulp [36], eugenol used in dental treatment might play its analgesic action through inhibition of $P2X_3$ channels expressed in tooth pulp neuron [21].

4.2 Anesthetic Activity and Inhibition of Nerve Impulses

Eugenol has been shown to be effective in anesthetizing fish including rainbow trout (*Oncorhynchus mykiss*) [37, 38], channel catfish (*Ictalurus punctatus*) [39], and rats [40]. A low dose of eugenol as 65 mg/L induced anesthesia successfully and safely in juvenile tambaqui fish (*Colossoma macropomum*) [2]. The anesthetic mechanism of eugenol might involve its ability to block nerve impulses as demonstrated in sciatic nerve of the bullfrog prepared in nerve chamber. Eugenol of 0.01% to 100% concentration extinguished the compound action potential in irreversible manner within time frame of 3 h [41]. Another study observed that eugenol slowed nerve conduction in crayfish and made it less excitable [42]. Reversible inhibition of nerve impulse and compound action potentials by eugenol was recorded in tooth pulp nerve of adult cats [43] and phrenic nerve [44], sciatic nerve, and superior cervical ganglion neurons of rats [45]. A study on rat vagus nerve suggested that eugenol is more effective than lidocaine in inhibiting compound action potential of C nerve fibers [46]. These in vivo and ex vivo results suggest that eugenol might have a direct effect on ion channels in peripheral sensory nerve fibers.

4.2.1 Voltage-Gated Sodium Channels

Sodium channels depolarize cell membrane to initiate action potential [47]. Therefore, it is possible that voltage-gated sodium channels are the molecular targets of eugenol in its analgesic action. When tested in dental primary afferent neurons [18] and dorsal root ganglion neurons [48] of rats, eugenol successfully inhibited voltage-gated sodium channels [18]. The magnitude of inhibition was similar between TTX-resistant and TTX-sensitive sodium channels, suggesting that eugenol might block action potentials in both nociceptive and non-nociceptive afferent fibers. The molecular mechanism underlying the inhibition of sodium channels is not clear. The inhibitory action of eugenol was comparable between neurons with and without transient receptor potential vanilloid 1 (TRPV1) channel expression, suggesting that eugenol does not modulate sodium channels through activation of TRPV1. Eugenol might bind to voltage-gated sodium channels and modulate directly, but the supporting evidence is yet to be found. However, it is clear that modulation of voltage-gated sodium channels is a mechanism that contributes to the analgesic action of eugenol [17].

4.2.2 Voltage-Gated Potassium Channels

In addition to above voltage-gated channels, voltage-gated potassium channels are also inhibited by eugenol [22]. However, voltage-gated potassium channels play roles in repolarization of cell membrane after action potential firing. Therefore, inhibition of voltage-gated potassium by eugenol might result in enhanced neuronal activity. It is not clear how action potential spikes are modified by eugenol together with its inhibition of voltage-gated sodium channels. The inhibition of voltage-gated potassium channel was similar between capsaicin-sensitive and capsaicin-insensitive neurons.

4.3 Inhibition of Synaptic Transmission

The potential use of eugenol in the treatment of epilepsy and cephalic has been proposed. Eugenol reversed epileptiform field potentials and spreading depression induced by KCl microinjection, presumably by inhibition of synaptic plasticity [49]. Depression of synaptic transmission by eugenol is also reported in CA1 region of hippocampal slices [50]. Molecular mechanism underlying reduced synaptic transmission is yet to be discovered.

4.3.1 Voltage-Gated Calcium Channels

Voltage-gated calcium channels play a critical role in exocytosis of neurotransmitter by promoting fusion of synaptic vesicle and presynaptic terminal membrane. Therefore, the molecular mechanism underlying reduced synaptic transmission might be partly explained by inhibition of calcium channels by eugenol [19, 20]. The structural similarity of eugenol to capsaicin might contribute to the inhibition of calcium channels, since capsaicin has been demonstrated to inhibit high-voltage-activated calcium channel (HVACC) currents [51, 52]. However, the inhibition does not seem to be mediated by activation of TRPV1, because calcium current was also inhibited by eugenol in neurons where capsaicin response was negative.

4.3.2 NMDA Receptors

N-Methyl-ᴅ-aspartic acid (NMDA) receptor is an NMDA-sensitive ionotropic glutamate receptor that plays an important role in synaptic modulation and memory function. Antagonism of NMDA receptor by eugenol [53] might result in its presumed inhibition of synaptic plasticity [49] or contribute to its anesthetic ability.

4.3.3 GABA$_A$ Receptors

GABA$_A$ receptor is a receptor channel that takes γ-aminobutyric acid (GABA) as its ligand. The pore of GABA$_A$ receptor channel conducts chloride ion into cell upon activation, making membrane potential hyperpolarized and less excitable in central nervous system. Therefore, GABA$_A$ receptor-mediated synapses are called inhibitory, and pharmacological activation of GABA$_A$ receptor causes sedation or general anesthesia. Interestingly, eugenol has been shown to potentiate GABA$_A$ receptor activation [54], which might be another mechanism that contributes to its ability to cause anesthesia.

4.4 Therapeutic Effects

In addition to the modulation of ion channels in nervous system, eugenol displays a broad spectrum of biological activities.

4.4.1 Anti-inflammatory Activity

Anti-inflammatory action of eugenol is mostly attributed to its ability to inhibit cyclooxygenase (COX) [55]. COX converts membrane phospholipid arachidonic acid to prostanoids, biological mediators that mediate inflammation and pain. Therefore, anti-inflammatory and analgesic effect can be achieved by pharmacological inhibition of COX. Nonsteroidal anti-inflammatory drugs such as aspirin and ibuprofen are the best examples of COX inhibitor. It was reported that prostaglandin and thromboxane production after an intentional damage to incisal teeth of rats was markedly reduced immediately with application of zinc oxide eugenol paste [55]. Inflammatory mediators such as interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), and prostaglandin E2 in LPS-activated macrophage were reduced after eugenol application [56]. An in vivo study with rat liver showed reduced inflammatory cells and necrosis following administration of eugenol [57].

4.4.2 Antitumor Activity

Anticarcinogenic [7] and antimutagenic [8] effect of eugenol has been reported. Reactive-oxygen-species-mediated cytotoxic effect of eugenol on human promyelocytic leukemia cell line HL-60 has been reported [58]. Eugenol in volatile gas form was cytotoxic against human tumor cell lines PC-3 [59]. In vivo effect of eugenol on amelioration of gamma-radiation-induced clastogenic effects [60] and DNA damage induced by genotoxin [61] was also reported. Enhanced activity of the detoxifying enzymes, glutathione S-transferase, by dietary administration of eugenol was observed in rat liver [62]. A recent study of rats revealed that eugenol restricted skin carcinogenesis by attenuation of c-Myc and H-ras and modification of p53-associated gene expression [63].

4.4.3 Antioxidant and Prooxidant Activity

Many plant phenolic molecules found in the fruits, seeds, and leaves serve as natural antioxidants [64], which apply to eugenol as well [10]. The mechanisms by which eugenol and other natural or synthetic phenolic compound act as antioxidants are attributed to their ability to reduce superoxide to H_2O_2 [65] or to scavenge the free radicals through chelation of metal ions [2, 66]. Eugenol showed strong chelating potential against Fe^{3+}, thereby inhibiting the initiation of hydroxyl radicals [67]. Antioxidant effect of eugenol was suggested to be one of the mechanisms by which eugenol rescued liver damage caused by carbon tetrachloride. Coadministration of eugenol with liver-damaging drugs might provide beneficial effect [68]. The antioxidant action, along with its anti-inflammatory and antimutagenesis effect, suggested eugenol as potential liver drug [57].

However, phenolic compounds are double-edged swords. High concentration of eugenol generates free radicals and acts as prooxidant agent that causes tissue damage [66, 69–72]. Photochemical reduction of eugenol might play a role in its prooxidant effect [73]. The joint FAO/WHO committee has permitted daily intake of eugenol of 2.5 mg/kg body weight for humans [69].

4.5 Antimicrobial Activities

4.5.1 Antibacterial Activity

Antibacterial activity of eugenol is well documented by Chaieb et al. [2]. Pathogenic bacteria influenced by eugenol include *Campylobacter jejuni*, *Salmonella enteritidis*, *Escherichia coli* and *Staphylococcus aureus, Staphylococcus epidermidis, Listeria monocytogenes, Bacillus cereus* [2, 59, 74–79]. Bactericidal effect of eugenol on coagulase-negative Staphylococci (CoNS) is of particular interest since CoNS are known to survive on medical devices which can be hazardous for patients with poor immune responses [80]. Eugenol was reported to be effective against both Gram-positive and Gram-negative strains [81, 82]. Bactericidal effect of eugenol against oral bacteria that cause periodontal disease and dental caries is also described [83].

4.5.2 Antifungal Activity

Antifungal activity of eugenol against *Candida albicans*, that causes serious health problem in immunocompromised patients, was demonstrated by in vitro and in vivo experiments [84, 85]. It is also shown that eugenol inhibited growth of a number of dermatophyte fungi that cause onychomycosis, such as *Trichophyton rubrum, Trichophyton mentagrophytes* var. *interdigitale*, and *Epidermophyton floccosum* [1]. Eugenol was also effective in inhibition of several food-borne fungal species including *Fusarium graminearum* [86], *Penicillium islandicum*, *Aspergillus flavus* [87], and *Aspergillus niger* [88]. The antifungal activity seems to be exerted by disruption of cellular membrane [89], which was confirmed by scanning electron microscope image of significant morphological deformity of *Saccharomyces cerevisiae* by clove oil [6].

4.5.3 Antiviral Activity

Viruses are generally sensitive to essential oils [2]. In a research that investigated antiviral activity of several plant extracts that were used in traditional medicine of Sudan, extract of *Syzygium aromaticum*, whose main ingredients is eugenol, showed over 90% inhibition on replication of the hepatitis C virus [90].

4.6 Other Aspects

4.6.1 Olfactory G-Protein-Coupled Receptor

Olfactory system is unique in that there are numerous receptors for each specific kind of odorants [91]. It is very peculiar compared to other sensory systems like vision, touch, or taste in which only a few kinds of receptors exist. Eugenol has a very distinctive odor that is usually remembered as dental clinic scent. The olfactory receptor that eugenol binds was identified in mice and named mOR-EG or Olfr73, a G-protein-coupled receptor with a seven-transmembrane domain that increases intracellular cAMP concentration upon activation [92].

4.6.2 Allergic Reactions

Eugenol is a well-known contact allergen in dermatology [3]. Majority of patients who experienced stomatitis after dental treatment with eugenol-containing dressings were shown to be allergic to eugenol by patch testing [93]. Subsequent study found that as high as 10% of patients who were insensitive to eugenol prior to dental treatment with eugenol became sensitized postoperatively [94]. The allergic reaction to eugenol is usually in association with its use in surgical and periodontal packs [93], root canal sealers [95], mouth rinses [96], and impression pastes [3]. In rare cases, eugenol can induce severe allergic response when applied in the mouth [97]. In one most severe case, patient even experienced anaphylactic-like shock after receiving pulpotomy with zinc oxide eugenol cement [98]. Localized skin irritation and allergic contact dermatitis are also reported in dental professionals [3]. Allergic contact dermatitis reaction against eugenol is increasing and gained focus in perfume industry recently [99–102].

4.6.3 Cytotoxic Activity

Direct contact of tissue to high concentration of eugenol is cytotoxic and reported to have adverse effect on osteoblast-like cells [103], fibroblasts [104], and oral mucosa [105]. Uncontrolled concentration of eugenol can induce necrosis and reduce healing [3]. Application of eugenol in its mixture with zinc oxide is beneficial in terms of concentration control. Eugenol chelates zinc oxide and forms zinc eugenolate by hardening reaction. This compound readily undergoes hydrolysis with the presence of water. As a result, free eugenol is gradually released from the surface of the zinc oxide eugenol mixture, and the intraoral eugenol concentration stays relatively within certain range [106].

4.6.4 Insecticidal Activity

Eugenol has been shown to be effective against several parasites and insects such as larvae of common house mosquitos (*Culex pipiens*) [107], malaria mosquitos (*Anopheles dirus*) [108], head lice (*Pediculus capitis)* [109], red flour beetle (*Tribolium castaneum*), and maize weevil (*Sitophilus zeamais*) [110]. Acaricidal activity by direct contact or by vapor gas of eugenol was observed against a few species of mites including *Dermatophagoides farinae, D. pteronyssinus* [111], and *Psoroptes cuniculi* [112]. Eugenol could be used as a fumigant agent against Japanese termite (*Reticulitermes speratus*) [113]. A careful consideration has to come before using drugs to control parasitic insects in terms of environmental damage and drug resistance [114]. Using eugenol could be beneficial since it is a naturally available insecticidal agent.

5 Conclusion

Eugenol is a versatile natural compound with many beneficial effects and wide range of safe dose. It has been used most widely in dentistry as analgesic and anti-inflammatory agent. However, its usage is growing wide rapidly. Its greatest advantage is that it is a natural molecule that is already being used by plants as an insect attractant or repellent. Its ability to anesthetize fish can be used in aquarium for research and management. Eugenol can be used as supplementary additive to drugs that could harm liver because of its antioxidant, anti-inflammatory, and antimutagenetic effect. Its ability to inhibit growth of bacteria, virus, and fungi can be adopted in topical drugs that control appropriate infections, from dermatophytosis of a healthy human to opportunistic infection of an immunosuppressed patient. Further research on application and safety of eugenol will provide novel solutions to current problems involving health and environmental issue in many areas such as medicine and agriculture.

Abstract

Carotenoids, precursors of vitamin A, are natural pigments synthesized by plants and some microorganisms. Humans and animals are not able to synthesize and need to acquire them by alimentation. Beyond the health benefits promoted by vitamin A, these compounds have antioxidant capacity which gives protection for cardiovascular and degenerative diseases. The presence of conjugated double bonds in carotenoid structure contributes for their pigmentation, absorption of ultraviolet/visible radiation, and antioxidant activity but also is the main reason

of their chemical instability. Some factors such as heat, light, acids, organic solvent reflux, crystal melting, and iodine treatment can promote carotenoid *cis–trans* isomerization and oxidation. In the carotenoid qualitative and quantitative analysis, steps of extraction and storage are important to prevent degradation and total recovery. The extraction is generally realized using organic solvents in addiction or not a saponification step. The high-performance liquid chromatography is the most widely used technique, but others may be employed. The industrial production of carotenoids can be made by simple extraction or microbial process.

1 Introduction

Carotenoids are natural pigments synthesized by plants and some microorganisms. Humans and animals are not able to synthesize and need to acquire them by alimentation [1]. These compounds are widely distributed in fruits, flowers, roots, seaweeds, invertebrates, fishes, birds, bacteria, fungi, and yeasts [2–4]. They are responsible for the red, yellow, and orange colors, but green, purple, or blue color could be obtained when carotenoids are bound with some proteins [1]. Such molecules act as photosynthesis aid and for the photoprotection of their hosts [2–4]. Due to this, it is used in food and feed as colorant, flavoring, and nutritional supplement, being source of provitamin A.

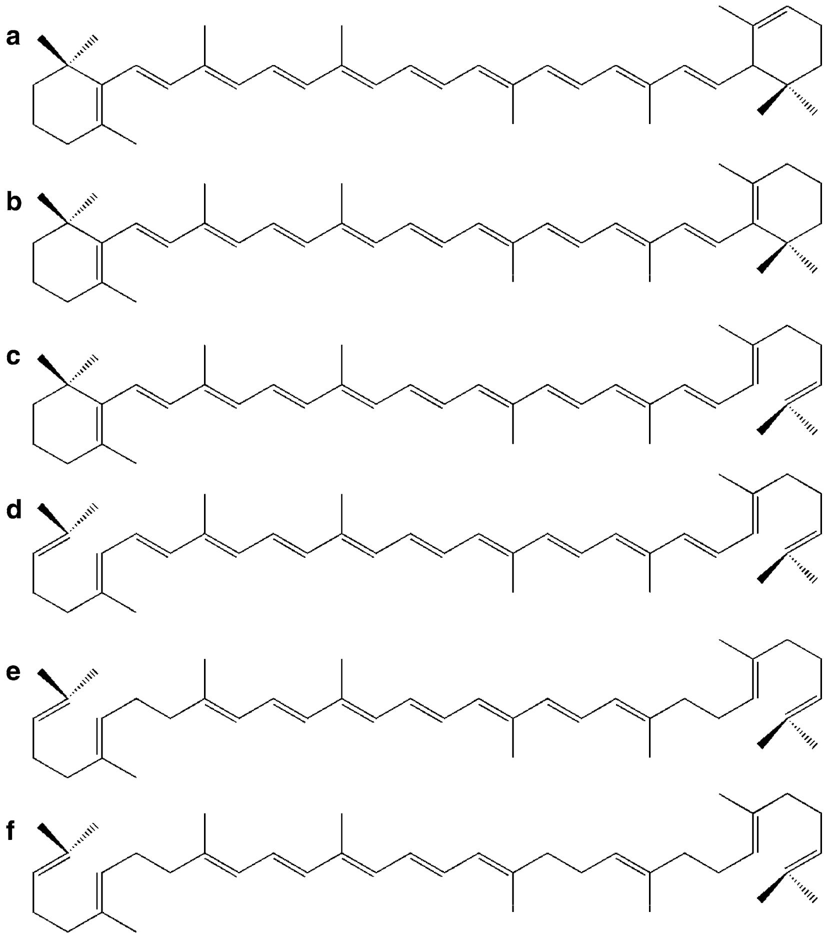

Fig. 135.1 Carotenes (**a**) α-carotene, (**b**) β-carotene, (**c**) γ-carotene, (**d**) lycopene, (**e**) ζ-carotene, (**f**) phytofluene

The structures of these compounds have numerous conjugated double-bonds and cyclic end groups; thus, carotenoids present a variety of stereoisomers with different chemical and physical proprieties [5]. Carotenoids can be divided in two groups: *carotenes*, constituted by polyunsaturated hydrocarbons C_{40} (Fig. 135.1), and *xanthophylls*; their oxygenated derivatives and main contain epoxy, carbonyl, hydroxy, methoxy, or carboxylic acid functional groups (Fig. 135.2).

Lycopene and ζ-carotene are the most common acyclic carotenes. *Lycopene* is the major pigment of many red fleshy fruits, such as tomato (*Lycopersicon esculentum*), watermelon (*Citrullus lanatus*), papaya (*Carica papaya*), guava (*Psidium guajava*), and grapefruit (*Citrus paradisi*). *ζ-carotene* is present in low quantities in many plants, but in starfruit (*Averrhoa carambola*) and passion fruit (*Passiflora alata*), this carotene becomes more significant as main pigment. Other

carotenes as phytofluene and phytoene are colorless and probably more widely distributed than the reported [2, 4]. Among cyclic carotenes, *β-carotene* is the most prominent orange pigment, being present in carrots (*Daucus carota*), mango (*Mangifera indica*), acerola (*Malpighia glabra*), apricot (*Prunus armeniaca*), medlar (*Mespilus germanica*), and Palmae/Arecaceae fruits. The *α-carotene* and *γ-carotene* are generally in minor concentration than β-carotene, which the former found in carrots and pumpkins (*Cucurbita* sp.) and the latter found in dog roses (*Rosa canina*) and Surinam cherry (*Eugenia uniflora*). *δ-Carotene* is less frequent but can be detected in tomatoes and pupunha (*Bactris gasipaes*) [6].

Among hydroxylated xanthophylls, β-cryptoxanthin, lutein, and zeaxanthin, derived from α- and β-carotenes, are the main yellow pigments. *β-cryptoxanthin* is the major pigment from orange fruits as peaches (*Prunus persica*), persimmon (*Diospyros kaki*), and hog plum (*Spondias mombin*). *Lutein* is the prevailing carotenoid in green leaves and vegetables and yellow flowers such as marigold (*Tagetes erecta L.*), and *zeaxanthin* is the main pigment in maize (*Zea mays*) and in piqua (*Caryocar villosum*). Epoxidized xanthophylls as *violaxanthin* and *antheraxanthin* are degradation products from other carotenoids, like zeaxanthin, and their presence is underestimated in many foods [6–8]. There are some uncommon xanthophylls, as *capsanthin*, present in chili pepper (*Capsicum frutescens*), *bixin*, major pigment in annatto (*Bixa orellana*), and *crocetin*, which is predominant in saffron (*Crocus sativus*) [2, 4].

In green vegetables, these compounds are located in chloroplasts with the xanthophylls non-unesterified and have the same qualitative pattern and relative proportions, with lutein, β-carotene, violaxanthin, and neoxanthin as the principal carotenoids, but the absolute concentrations differ considerably. However, there are two exceptions: lettuce, which also has lactucaxanthin as a major carotenoid and which α-carotene, α- or β-cryptoxanthin, zeaxanthin, antheraxanthin, and lutein-5,6-epoxide as minor pigments may be yet found; and kiwifruit (*Actinidia chinensis*), which remains green even when matured and the carotenoid esterification of which does not occur [7, 9]. In ripe fruits, the hydroxycarotenoids are found in chromoplasts, and carotenes are mostly esterified with fatty acids. The composition is highly complex and variable being affected by genetic and environmental factors, influenced by the cultivar, variety, maturity at harvest, climate, season, geographic site of production, part of the plant utilized, farming practices, harvesting and post-harvest handling, processing, and storage conditions [10].

Industrially, the carotenoids are used in nutrient supplementation, for pharmaceutical purposes, as food colorants and fragrances, and in animal feed [1]. The worldwide market of carotenoids is growing fast; in 2010, carotenoids were responsible for about USD 1.2 billion, mainly β-carotene and lutein, which accounts for 22 % and 19 % of this market, respectively, and was estimated to grow 2.3 % per year, reaching USD 1.4 billion in 2018. Currently, the international trade is dominated by private companies, such as Roche, BASF, Merck, Rhône-Poulenc, and DSM [11, 12].

2 Biosynthesis in Plant

Terpenoid biosynthesis is now well established in plants, which the major precursor isopentenyl diphosphate (IPP) can be synthesized in the plastids through 1-deoxy-D-xylulose-5-phosphate (DXP) pathway, generating monoterpenes, diterpenes, and carotenoids, and in the cytosol through the mevalonic acid (MVA) pathway, forming sesquiterpenes, triterpenes, and steroids [9, 13].

In the case of carotenoids, the main precursor phytoene is generated by action of phytoene synthase, strictly dependent upon Mn^{2+} enzyme, on geranylgeranyl pyrophosphate. Then, the desaturation of phytoene to lycopene involves four steps (Fig. 135.3) that are catalyzed by phytoene desaturase and ζ-carotene desaturase,

which promote the hydrogen removal alternately and thus become targets to photobleaching herbicides. Both α-carotene and β-carotene can be generated by lycopene cyclization, catalyzed by lycopene cyclases, as lycopene β-bicyclase, lycopene ε-bicyclase, lycopene β-monocyclase, lycopene ε-monocyclase, and bifunctional lycopene β, ε-bicyclase. These two carotenoids can be modified by hydroxylases, epoxydases, ketolases, and synthases forming xanthophylls as lutein and zeaxanthin (Fig. 135.2) [9,11,14].

Plants synthesize carotenoids to regulate the growth and development, which serve as accessory pigments in photosynthesis, photoprotectors, and precursors for the hormones abscisic acid and strigolactones. Carotenoid color further helps in attracting other organisms, such as pollinating insects and seed-distributing herbivores [1]. The composition of carotenoids is affected by the genetic and environmental factors. In food, the carotenoid composition is influenced by cultivar, variety, maturity at harvest, climate, season, geographic site of production, part of the plant, farming practices, harvesting and post-harvest handling, processing, and storage conditions [10].

With the knowledge of higher plants carotenoid biosynthesis and its regulation, it enabled new methods to obtain biofortified foods such as golden rice, tomato, potato, maize, and sweet potato, which can contribute significantly to reduce vitamin A deficiency in the world, since they represent cultivars widely adopted [11,15–20].

3 Health Benefits of Carotenoids

More than 700 carotenoids have been described in nature, but it is estimated that we only have access to about 40 carotenoids that can be absorbed, metabolized, and/or used in our bodies. That number is reduced to 6 if we consider the carotenoid profile that is usually detected in human blood plasma: α- and β-carotene, lycopene, β-cryptoxanthin, zeaxanthin, and lutein [21].

Nevertheless, carotenoids are known as vitamin A precursor (provitamin A), and this is its main nutritional function. Approximately 10 % of carotenoids meet the main structural requirement for acting as vitamin A precursors, that is, with at least one β-type ring, without oxygenated functional groups, along with one polyene chain containing at least 11 carbon atoms [21]. The main carotenoid with such characteristics is β-carotene, and it can be cleaved by a β-carotene-15,15′-dioxygenase, resulting in the formation of retinal [22]. The involvement of retinal (vitamin A) as visual pigments chromophore in the eyes is of paramount importance in the vision process. Hypovitaminosis A is still one of the major nutritional problems in least-developed regions of the world, presenting as frequent consequences the xerophthalmia (deficiency in the production of tears) and blindness, particularly in children, as well as premature death [23]. Vitamin A also presents important systemic functions in the growth and reproductive efficiency, besides the epithelial tissue maintenance and prevention of its keratinization. Thus, retinoids have been used in dermatological treatments, such as for the elimination of acne [4,24].

The antioxidant property of carotenoids is independent of provitamin A activity and is associated to its binding capacity with a singlet oxygen by conjugated double-bonds systems, mainly in the 5,6 and 5′,6′ double bonds in their cyclic end groups, which can undergo epoxidation with O_2, and the maximum protection is given by carotenoids with more than 9 double bonds. Due to this reason, lycopene shows higher antioxidant efficiency than β-carotene. In high oxygen partial pressure or high carotenoid concentration, however, lycopene and β-carotene can present prooxidant activity [25–28]. Due to its antioxidant capacity, β-carotene is utilized as oral sun protector to prevent skin from photoaging and sunburn, and must be consumed along several weeks to increase its content in the blood plasma and skin and increase its protection effect [25].

Carotenoids, mainly lycopene, have been used in the treatment of cardiovascular and degenerative diseases, besides prostate, stomach, and lung cancers acting on possible modulation mechanisms of carcinogens, inhibition of cell proliferation, increase of cell differentiation by retinoids, stimulation of intercellular communication, and high immunological response [11,21,28,29], whereas zeaxanthin and lutein presented high performance on prevention of age-related macular degeneration [7,11,25,28].

Lutein is an important carotenoid in the human macula. This compound is a blue filter at wavelengths around 450 nm with peak absorption at 446 nm, and these wavelengths are known to induce light-mediated damage to the retina. Damage in retina is also caused by the oxidation, reactive oxygen species have been shown to induce apoptosis of photoreceptors, and lutein has been shown to be able to block paraquat or H_2O_2-induced apoptosis of cultured retinal photoreceptors. Lutein show yet benefices in the immune response and in the inflammatory process [30].

However, only a fraction of carotenoids absorbed by the human body can effectively contribute to human health, reaches up to 10 % when a natural food is consumed [21]. A number of factors can affect the bioaccessibility and/or bioavailability, including the species of carotenoids, linkages at molecular level, amount of carotenoid, matrix, effectors, nutrient status, genetics, host-related factors, and interactions among these variables. In carrots, for example, β-carotene is located in the chromoplasts (surrounded by a double bilayer membrane) of the plant cells (surrounded by a cell membrane and a cell wall), where it is often associated with proteins and/or residual membranes. This fact results in several physical barriers that have to be broken to make β-carotene accessible for absorption.

In processed food, the maceration reduces the particle size and removes some barriers, increases the contact superficies for interaction with digestive. Effectors, such as the presence of oil, can also have an influence on the bioaccessibility and/or bioavailability of carotenoids: these compounds are lipophilic molecules, and they have to be incorporated in mixed micelles in the duodenum before they can be absorbed in the mucosa [31]. Certain structural differences may alter fat solubility and modify the efficiency of the micellization. One of them is the esterification of xanthophyll with fatty acids. Esterified xanthophylls exhibit increased fat solubility relative to their corresponding free xanthophylls and even against carotenes.

4 Carotenoid Modification

The presence of conjugated double bonds in carotenoids structure contributes for their pigmentation, absorption of ultraviolet/visible radiation, and antioxidant activity but also is the main reason of their chemical instability, since conjugated double bonds are very susceptible to oxidation and geometric isomerization. Some factors such as heat, light, acids, organic solvent reflux, crystal melting, and iodine treatment can promote carotenoids *cis–trans* isomerization (Fig. 135.4). *Trans*-carotenoid isomerization, which is the usual configuration of carotenoids in nature, to the *cis*-form enhances solubility and decreases color intensity, melting point, and provitamin A activity [4,6,7,10,32].

Oxidation, major degradation mechanism of carotenoids, can be accelerated by heat, light, unsaturated fatty acids, peroxides, iron, copper, manganese, and the presence of some enzymes, as lipoxygenases, phenoloxidases, and peroxidases [4,6,7].

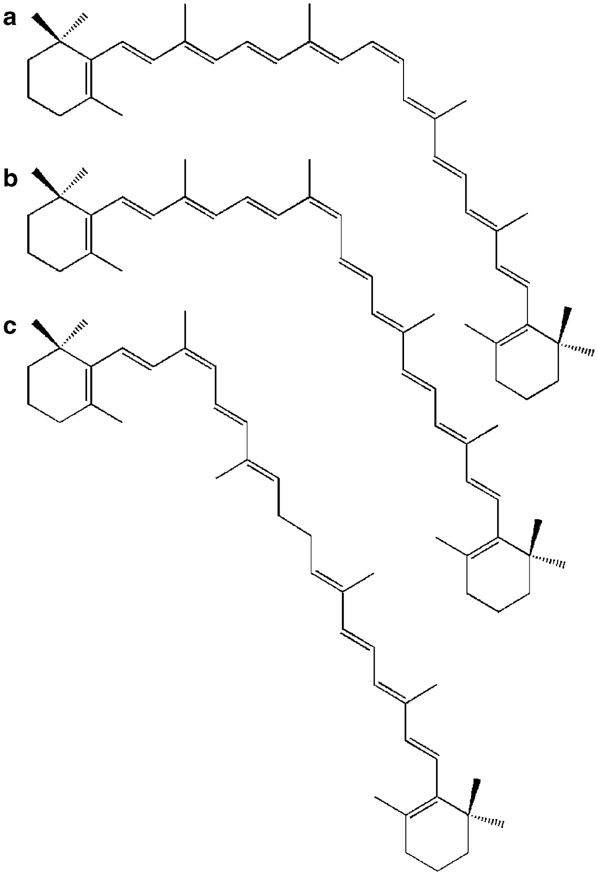

Fig. 135.4 β-*Carotene cis-isomers* (**a**) 15-*cis*-β-carotene, (**b**) 13-*cis*-β-carotene, (**c**) 9-*cis*-β-carotene

The major degradation by-products of carotenoids are epoxycarotenoids, apocarotenoids (Fig. 135.5), and volatile compounds, which, although having very low provitamin A activity, have metabolites that can be used as food dyes, in the case of apocarotenoids, or natural flavoring from volatiles compounds [33–35] These by-products are generated in many types of food processing, such as cooking, frying, pasteurization, extrusion, and dehydration, with losses around 25–35 % [33,36–38], and in vegetable oil refining, such as bleaching, deodorization, and deacification steps [39].

Norisoprenoids, responsible for the typical aroma of some grape varieties, could originate from direct degradation of carotenoid molecules such as β-carotene, lutein, neoxanthin, and violaxanthin. Some degradation carotenoid products have an important sensorial impact on wine, such as β-damascenone, β-ionone, 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN), and vitispirane. These aromatic molecules have very low olfactory perception thresholds [40].

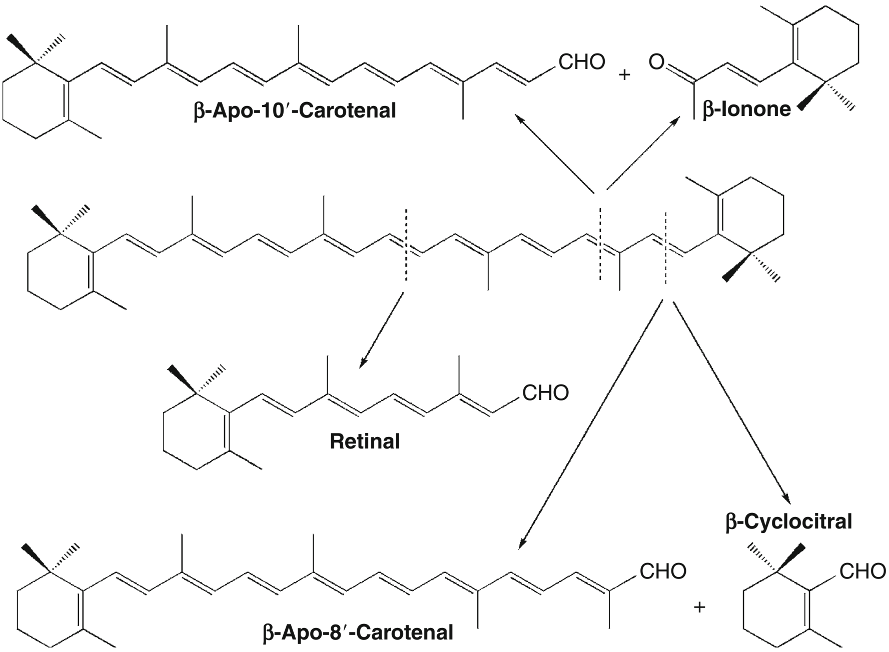

Fig. 135.5 Apocarotenoids derived from β-carotene

5 Analytical Methods

For a long time, quantification of only β-carotene or the major provitamin A carotenoids was considered sufficient. In the course of time, advances in studies have identified health benefits independent of the provitamin A activity, and this fact has encouraged the development of new techniques to quantify all-E- (*trans*) and Z-isomers (*cis*) [10].

Carotenoids have a long structure with alternating double and single bonds, constituting a conjugated system in which the π-electrons are delocalized along the entire polyene chain which gives carotenoids a unique molecular shape, chemical reactivity, and light-absorbing properties. These characteristics are the base of the analytical methods describes above [1].

An important point to emphasize is the difficulty to analyze the existence of a large number of carotenoids, concentration range, uneven distribution in the sample, varied nature of the matrix and susceptibility of carotenoids to isomerization and oxidation during analysis, and extraction and storage of samples and standards.

5.1 Sample Extraction and Storage

The procedure for the preparation of the analytical sample should be adapted to the nature of the food, analyte, and analytical method, as well as the distribution of the

Table 135.1 Carotenoids extraction solvents

Food	Extraction procedure	Detection method	References
Fruit and vegetables	50 % tetrahydrofuran, 50 % methanol/ saponification with 10 % KOH	HPLC and UV–Vis detector	[42]
Marigold	Methanol/ethyl acetate/light petroleum (1:1:1)/OCC	HPLC and MS detector	[8]
Red palm oil	Hexane	Spectrophotometry	[43]
Wine	50 % ether, 50 % hexane	HPLC and diode array detector	[40]
Grape	50 % hexane and 50 % diethyl ether	HPLC and MS detector	[44]
Pumpkin puree	Acetone/saponification with 10 % KOH	HPLC and diode array detector	[45]
Carrot roots	50 % hexane, 25 % acetone, 25 % ethanol	HPLC	[46]
Carrot puree	50 % hexane, 25 % acetone, 25 % ethanol, 0,1 % BHT	Spectrophotometry	[31]
Orange juice	50 % dichloromethane, 25 % methanol, 25 % acetone, 0.1 % BHT/saponification with 15 % KOH	HPLC and UV–Vis	[47]

analyte in the food [10]. In the cassava rot, for example, the concentration of carotenoids is higher in the part of the root closest to its attachment to the stem (proximal section) and is gradually decreasing toward the opposite end (distal section) [41].

Usually, carotenoid extraction has been carried out with acetone. This solvent penetrates the food matrix well and dissolves both carotenes and xanthophylls efficiently, and subsequent partitioning to an apolar solvent occurs more easily. Tetrahydrofuran (THF) has excellent solubility for β-carotene and lutein; however, it easily accumulates peroxides. Other solvents, such as hexane, petroleum ether, methanol, and ethanol, have also been utilized. The first two solvents readily dissolve carotenes but not the xanthophylls; on the other hand, methanol and ethanol dissolve the xanthophylls efficiently but not the carotenes. Thus, mixtures of solvents have been preferred [10]. Saponification with KOH is another procedure that can be applied to increase the extraction because some carotenes are esterified with fatty acids. Step of clean up may be made before analysis, such as open column chromatography (OCC) or solid-phase extraction (Table 135.1). The solubility of carotenoids depends on its molar mass, polarity, and solvent strength. Carotenoids are transported together with triglycerides, with large molar mass (807–885). Sometimes, a transesterification is necessary to reduce this weight, producing fatty methyl and ethyl esters [48].

The time between the storage of samples and analysis should be short. Ideally, the analysis should be planned to be realized after collection because it is difficult to avoid changes in carotenoid composition during storage, even at very low temperature. Lyophilization, an alternative method of storing used in some studies, however results in significant degradation of β-carotene and especially lycopene, and it increases sample porosity, consequently raising its exposure to oxygen during storage [10].

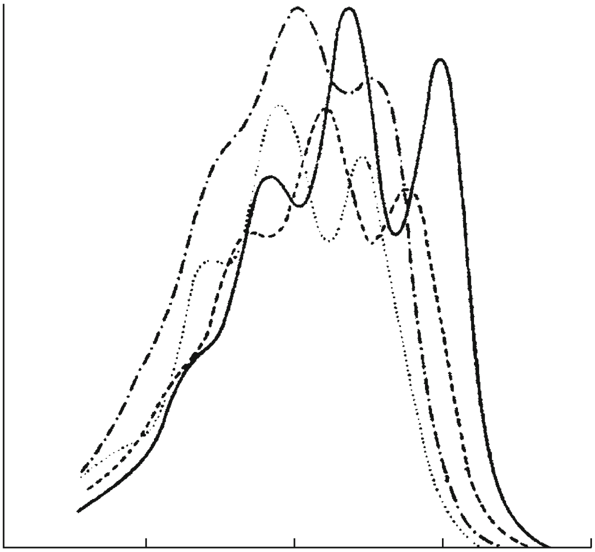

Fig. 135.6 Visible absorption spectra of lycopene (- - - -), γ-carotene (- - -), β-carotene (-.-.-.), and α-carotene (....) in petroleum ether [7]

5.2 Spectrophotometry

This method is based in the light-absorbing chromospheres and the visible absorption spectrum. The wavelength of maximum absorption (λmax) and the shape of the spectrum (spectral fine structure) are specific characteristics of each chromophore structure. In the past, most data on the amount of carotenoids found in foods were based on the total absorbance at a specified wavelength (450 nm). In some cases, a separation in an OCC was previously made followed by a spectroscopy.

Most carotenoids absorb maximally at three wavelengths, resulting in three-peak spectra (Fig. 135.6). The greater the number of conjugated double bonds, the higher the λmax values. Thus, the most unsaturated acyclic carotenoid lycopene, with 11 conjugated double bonds, is red and absorbs at the longest wavelengths (λmax at 444, 470, and 502 nm). At least 7 conjugated double bonds are needed for a carotenoid to have perceptible color. The introduction of hydroxy and methoxy substituent in the carotenoid molecule does not affect the chromophore and therefore has virtually no effect on the absorption spectrum.

Cis-isomerization of a chromophore's double bond causes a slight loss in color, small hypsochromic shift (usually 2–6 nm for mono-*cis*), and hypochromic effect, accompanied by the appearance of a *cis* peak in or near the ultraviolet region. The intensity of the *cis* band is greater as the *cis* double bond is nearer the center of the molecule.

The absorption spectra of carotenoids are markedly solvent dependent. The λmax values relative to hexane and petroleum ether are practically the same in diethyl ether, methanol, ethanol, and acetonitrile and higher by 2–6 nm in acetone, 10–20 nm in chloroform, 10–20 nm in dichloromethane, and 18–24 nm in toluene [4].

Table 135.2 Wavelength of maximum absorption and absorption coefficient $A^{1\%}{}_{1cm}$ of some carotenoids [7]

Carotenoid	Solvent	Λ_{max}, nm	$A^{1\%}{}_{1cm}$
Bixin	Petroleum ether	456	4,200
α-Carotene	Petroleum ether	444	2,800
	Hexane	445	2,710
β-Carotene	Petroleum ether	450	2,592
	Ethanol	450	2,620
	Chloroform	460	2,396
β-Cryptoxanthin	Petroleum ether	449	2,386
	Hexane	450	2,460
Lutein	Ethanol	445	2,550
	Diethyl ether	445	2,480
Lycopene	Petroleum ether	470	3,450
Violaxanthin	Ethanol	440	2,550
	Acetone	442	2,400
Zeaxanthin	Petroleum ether	449	2,348
	Ethanol	450	2,480
	Acetone	452	2,340

The absorption coefficient $A^{1\%}{}_{1cm}$ of a carotenoid (absorbance at a given wavelength of a 1 % solution in spectrophotometer cuvette with a 1-cm light path) used in the calculation of the concentration also varies pronouncedly in different solvents (Table 135.2).

5.3 High-Performance Chromatography Methods

Among the high-performance chromatographic methods available, gas chromatography (GC) is unsuitable for the analysis of carotenoids because of the inherent instability and low volatility of these molecules [1]. The high-performance liquid chromatography (HPLC) is a separation technique that coupled with some detector permits qualitative and quantitative analysis of small quantities of carotenoids in liquefied samples. Ultrahigh-performance liquid chromatography (UHPLC) has recently been developed; this is an improvement in HPLC. This technique uses narrow-bore columns packed with very small particles and mobile-phase delivery systems operating at high back pressures. UHPLC offers several advantages over conventional HPLC, such as faster analyses (shorter retention times), narrower peaks (giving increased signal-to-noise ratio), and greater sensitivity [1]. In the HPLC system, the chromatography column mostly applied in carotenoid separation was the polymeric C_{18}, but in recent years, the use of polymeric C_{30} column has grown (Table 135.3). Several solvents may be employed as mobile phase, but the mostly used are based on methanol and acetonitrile.

The detector based in the absorbance of ultraviolet–visible (UV–Vis) is currently the most common technique. Diode array detector (DAD) is a detector that can scan a variety of wavelengths, and it is widely used. A number of structurally related

Table 135.3 HPLC systems used in carotenoid analysis

Compound	Food	Column material	Detection	Mobile phase	Refernces
Lutein, zeaxanthin, β-cryptoxanthin, lycopene, α- and β-carotene	Vegetables	C_{18}	UV–Vis at 450 nm	Acetonitrile, methanol, dichloromethane, water, BHT	[42]
β-Carotene isomers	Standard	C_{30}	NMR	Acetone/D_2O	[49]
Lutein, zeaxanthin	Spinach	C_{30}	NMR	D_2O	[50]
β-Carotene, lutein	Wine	C_{18}	DAD at 270 and 550 nm	Ethyl acetate, acetonitrile, water	[40]
Violaxanthin, lutein isomers, α-, β-carotene	Grapes	C_{30}	MS	Triethylamine, methanol, water, methyl tert-butyl ether	[44]
Violaxanthin, lutein, zeaxanthin, α-, β-, and ζ-carotene	Pumpkin puree	C_{18}	DAD	Acetonitrile, triethylamine, methanol, and ethyl acetate	[45]
Trans and *cis* β-carotene	Carrot puree	C_{30}	DAD at 450 nm	MeOH, methyl t-butyl-ether, water	[31]
Violaxanthin, lutein, zeaxanthin, α-, β-, and ζ-carotene	Orange juice	C_{30}	DAD at 450 nm	Methanol, methyl tert-butyl ether and water	[47]
Lutein isomers	Marigold	C_{30}	MS	Methanol/tert-butyl methyl ether/water	[8]

molecules can coelute, and their analysis can be difficult because the spectra of many carotenoids are similar. The mass spectrometry (HPLC–MS) is another detector widely employed; this detector provides information about molecular mass and structural conformation, but does not distinguish stereoisomers. Other detectors have been used in accord with an interest in identifying carotenoids directly in the biological matrix (without preliminary sample preparation), such as near-infrared reflectance spectroscopy (HPLC–NIRS), Raman spectroscopy, and nuclear magnetic resonance (HPLC–NMR) spectroscopy; this last has the capacity to identify the geometric isomers, which are not distinguished by MS. These approaches allow a rapid overview of carotenoids while saving time and cost [1].

5.4 Other Techniques

The MS technique can be used without being coupled to HPLC; however, it requires steps of isolation and purification, such as thin layer chromatography, OCC, or preparative HPLC. The capillary electrochromatography (CEC) has been increasingly used in substitution of HPLC with good result to β-carotene, lycopene, and lutein. It is a technique that combines the versatility of HPLC and the high plate efficiency of capillary electrophoresis. The CEC use fused silica capillaries packed with a stationary phase that has fixed charges at the surface. The flow of the eluent across the column is produced and maintained by electroosmotic means by application of high electric field. The components are separated by the differences in their partitioning between the mobile and the stationary phases and the differences in their electrophoretic mobilities if they are charged [51]. Sander et al. quantified 17 carotenoids (such as *trans*-lutein, *trans*-zeaxanthin, β-cryptoxanthin, *cis*- and *trans*-β-carotene, *cis*- and *trans*-lycopene) in food by this technique using C_{30} as stationary phase and acetone/sodium borate buffer [52].

Near-infrared spectroscopy (NIRS) and resonance Raman spectroscopy are techniques with rapidity, simplicity, safety, and low operational costs and are nondestructive techniques. The results obtained were shown to have high equivalency with HPLC. Brenna and Berardo compared NIRS and HPLC in the quantification of 8 carotenoids in maize (α- and β-carotene, α- and β-cryptoxanthin, isolutein, lutein, violaxanthin, and zeaxanthin) and found good correlation between HPLC values and NIRS estimates [53].

6 Sources and Production Methods

A great part of carotenoids in the market are from synthetic processes, as, for example, β-carotene synthesis by Wittig condensation using β-ionone as precursor, but the natural carotenoid market is growing. Both synthetic and natural carotenoids have the same molecular polyenic structure; the natural compound contains several other carotenoids in low concentrations, which provides further health benefits and can be consumed in larger quantities.

Natural carotenoids can be produced by biotechnological processes using filamentous fungi, yeasts, bacteria, or microalgae or through extraction from vegetable resources [54]. For example, β-carotene and lycopene originated from vegetables are generally obtained by solvent extraction with, for example, hexane, acetone, ethyl acetate, ethanol, and ethyl lactate from carrot, palm, and tomato, which present small contents of α-carotene, γ-carotene, and some xanthophylls [55–57]. Lutein is industrially obtained from marigold petals by solvent extraction and saponification [30,58]. Additionally to those described above, several other technologies have been studied for the production, extraction, or concentration of carotenoids in vegetable matrices.

6.1 Supercritical Fluid Extraction

Carotenoid extraction with organic solvent generates a large amount of waste, and the extraction with supercritical fluids emerged as a good alternative with advantages of inertness, low toxicity, and reactivity. França and Meireles studied the extraction of carotenoids from palm oil retained in press cake using supercritical fluids [59], while França et al. reported the utilization of supercritical CO_2 in the extraction of carotenoids from buriti fruit [60]. However, in these works, although the extraction yields until 10,000 ppm, carotenoids were achieved, triglycerides and fatty acids were also obtained, and other step would be needed for their separation from carotenoids. Davarnejad et al., using supercritical CO_2 for the extraction of β-carotene from palm oil, obtained 174.1 ppm of β-carotene at a pressure of 75 bar, temperature of 120 °C, and time of extraction of 1 h, respectively. Nevertheless, temperatures above 60 °C promote degradation of β-carotene, and this probably influenced their results, which could be even better [61]. Jo et al. proposed the use of a supercritical fluid with acetone for β-carotene extraction from persimmon (*Diospyros kaki*) skin with conditions of 40–50 °C and 150–250 bar [62].

Some modifications were proposed by Chuang and Brunner in this supercritical fluid extraction process to contour the low selectivity that they have previously observed [63]. The authors utilized a process of transesterification of palm oil and subsequently after the three-step extraction obtains a product 200-fold concentrated in carotenoids but virtually absent of esters, fatty acids, and triglycerides. Nevertheless, the temperature used (60 °C) and the presence of O_2 in supercritical CO_2, conditions that lead to carotenoid degradation, require addition of antioxidants (such as butylated hydroxytoluene) to the process [64].

Other carotenoids such as lycopene from tomato and its industrial waste [65–68] and lutein esters from marigold (*Tagetes erecta*) petals [69–71] had been extracted with supercritical fluids, achieving better extraction yields when modifiers and cosolvents were used as acetone, chloroform, ethanol, and vegetable oils.

6.2 Membrane Separation

The membrane separation process was initially conducted in degumming vegetable oil and then was adapted for the recovery of carotenoids. Dense polymeric membranes are employed in this system and are very effective in the separation of xanthophylls, phospholipids, and chlorophyll, with retention of 80–100 %, producing an oil rich in carotenes [72,73]. This process, however, requires an additional step of hydrolysis or transesterification. Chiu, Coutinho, and Gonçalves examined the membrane technology as an alternative to concentrate carotenoids from crude palm oil in detriment of ethyl esters. A flat sheet polymeric membrane constituted by polyethersulfone was used and obtained a retention rate of 78.5 % [74]. Darnoko and Cheryan obtained similar results using nanofiltration with 2.76 MPa and 40 °C in red palm methyl esters [75]. Whereas Tsui and Cheryan combined ultrafiltration with nanofiltration to separate zein and xanthophylls from ethanolic corn extract [76].

6.3 Enzymatic Treatment

The enzymatic hydrolysis had also been tested as a pretreatment of chemical extraction in order to improve carotenoid recovery, and it was observed that it could replace successfully the traditional process of alkaline hydrolysis, without losses of the desired product, due to degradation or isomerization. Lietz and Henry tested the hydrolysis of palm oil using a lyophilized lipolytic preparation from *Candida rugosa*, at a dosage of 10 % (w/v) in relation to oil volume, solubilized in phosphate buffer 0.08 M. The volume ratio between oil and aqueous solution was maintained as 1/175, and the system was stirred in a N_2 atmosphere, at 35 °C, for 4 h. The authors obtained a yield of 96 % of fatty acids, without variations in carotenoid concentration [77]. Similar results were achieved by Fernandez et al., which only modified the ratio between oil and aqueous solution to 1/350, also showing in these conditions that the quantity of carotenoids remained virtually constant and equal to 330 ppm. When the authors tested an alkaline saponification, it was observed a reduction by 15 % in the carotenoid content. According to the authors, the decrease was even greater when the formed soap was removed by filtration [78].

You et al. used palm oil and immobilized lipolytic preparation from *C. rugosa* for improved carotenoid extraction, but in different conditions as cited above. In their work, the enzyme dosage used was 1 % w/v, the phosphate buffer was replaced by water, the oil/water ratio was changed to 1/1, and the temperature and the reaction time were increased to 50 °C and 24 h, respectively. The authors obtained a yield of 94 % of fatty acids and a reduction in the carotenoid content of 15 %, probably due to the temperature used [79].

Ribeiro et al. tested three different lipolytic preparations obtained from *Thermomyces lanuginosus* (immobilized), *Candida antarctica* (liquid), and *Yarrowia lipolytica* (liquid) for the hydrolysis of buriti oil, reaching values around 75 %, 35 %, and 18 % of yield of free fatty acids, respectively, without considerable losses in the total carotenoid content. After hydrolysis, carotenoids were concentrated up to 3,900 ppm by deacidification methods, such as partition using ethanol, as well as winterization, thus removing 70 % of the free fatty acids [80].

Other enzymes could be utilized if the vegetable matrix is non-oleaginous, as protease hydrolyzes corn gluten meal allowing the extraction of lutein, zeaxanthin and β-cryptoxanthin [81], and pectinases and cellulases to degrade cell wall polysaccharides from tomato skins to obtain more yields of lycopene in the extraction with hexane [82].

6.4 Other Methods

Molecular distillation process represents a type of vaporization at low pressure and low temperature. The transesterification can also be used as pre-step in molecular distillation process, like centrifuge distillatory. Batistella and Maciel studied the extraction in palm oil with 2,400 ppm of carotenoids applying a centrifugal distillator and a falling film distillator. The first process obtained a decomposition of 12 % at 155 °C and 25 % at 175 °C. The centrifugal distillator results in loss of 13 % at 190 °C and 14 % at 210 °C [83].

Other extraction methods have been used which regard a green approach besides supercritical fluid extraction, utilizing less solvent, lower extraction time, and higher efficiency and replacing thermal energy by microwave [84] or ultrasound [85, 86].

7 Conclusion

Carotenoids are an important group of natural pigments with pronounced antioxidant activity, provitamin A factor, and many health benefits. The structure with conjugated double bonds governs mainly the proprieties of color, stability, detection, and quantification. With an increase of natural carotenoid markets, more different sources will be necessary and new technologies will be developed greener and cleaner, showing how promissory and profitable industrial sector can be.

Abstract

Pine oleoresin is an abundant source of useful terpenes. It has two major fractions: turpentine, which is the volatile fraction, and rosin, which is the solid fraction. A key element of tree defense, oleoresin is an important non-wood forestry product because of the various conventional and potential uses of its terpenes. Oleoresin derivatives can be used by different industries, including pharmaceutical, cosmetic, and food industries, as well as by the chemical industry in the manufacturing of various products, such as paint, varnishes, adhesives, insecticides, and disinfectants. Biotic and abiotic factors that affect oleoresin production can be used to improve yields by promoting specific

Pine oleoresin applications • Pine oleoresin biosynthesis • Resin tapping methods • Terpenes • Wounding defense response

Abbreviations

IPP	Isopentenyl diphosphate
MEP	2-*C*-Methyl-D-erythritol 4-phosphate
DXP	1-deoxy-D-xylulose-5-phosphate
DMPP	Dimethylallyl diphosphate
FPP	Farnesyl diphosphate
GPP	Geranyl diphosphate
GGPP	Geranyl geranyl diphosphate
TPS	Terpene synthases
RDs	Resin ducts
TRDs	Traumatic resin ducts

1 Introduction

Pine oleoresin is probably one of the oldest natural products used in large scale by humans. In ancient times, oleoresin was used for lighting, to seal, and preserve wooden ships [1] and as sealant of Greek urns in religious ceremonies [2]. Presently, pine oleoresin has been widely applied as feedstock for chemical industries to produce several types of by-products, such as cleaners, insecticides, solvents, paper sizing, paint, printer ink, pharmaceuticals, cosmetics, aroma and flavor compounds, food additives, among others [3–5].

The oleoresin synthesized by *Pinus* species represents a copious source of terpenes, the largest group of natural products with more than 30,000 known structures [6–8]. Biosynthetically derived from isoprenoid units (IPP – isopentenyl diphosphate), [4, 9] terpenes of conifers are mostly biosynthesized in the cambium zone and associated vascular tissues [10], either through the classic mevalonic acid pathway (in the cytosol) from acetyl-CoA or through the plastid or MEP (2-*C*-Methyl-D-erythritol 4-phosphate) pathway [5]. In the MEP pathway, DXP (1-deoxy-D-xylulose-5-phosphate) is formed from condensation of glyceraldehyde-3-phosphate and two carbon atoms derived from pyruvate. Then, DXP is rearranged and reduced to form MEP, which leads to the basic unit of the terpene biosynthesis (IPP). Once available, IPP and its isomer DMPP (dimethylallyl diphosphate) undergo successive additions of other hemiterpene units catalyzed by prenyltransferases [11, 12], yielding the basic acyclic precursor units of the main terpene classes: geranyl diphosphate (GPP) – monoterpenes (C_{10}), geranyl geranyl diphosphate (GGPP) – diterpenes (C_{20}) and tetraterpenes (C_{40}), mainly through the MEP pathway; farnesyl diphosphate (FPP) – sesquiterpenes (C_{15}) and triterpenes (C_{30}), mainly via the mevalonate pathway. After the formation of the basic terpene units (acyclic), there are fusion reactions and unit attachments (e.g., GGPP+GGPP in carotenoid synthesis), cyclization reactions driven by terpene synthases, additional prenylations, and other modifying reactions involved in the final steps of terpene biosynthesis, including oxidations, methylations, and binding to phenolic or lipidic compounds [6, 9, 13, 14].

The immense diversity of terpene metabolites known today is especially due to the large terpene synthase (TPS) gene family evolution and the versatility of the enzymes encoded by it. Most gymnosperm terpene synthases form a different family from those in angiosperms. However, phylogenetic analyses support the fact that all plant TPS have evolved from an ancestral diterpene synthase implicated with primary metabolism [4].

Various genes encoding for TPS of conifer species have been isolated and characterized [2]. The TPS of *Pinus* spp., and specially those of *Abies grandis* (Grand fir), are among the best known enzymes due to the ease of adaptation of the species to greenhouses and for presenting oleoresin production inducible by injury, simulating the response to the attack of bark beetles [14, 15]. The monoterpene synthases of *A. grandis* are soluble monomeric proteins, with 50–70 kDa and optimum pH for activity between 6.8 and 7.8. Monoterpene synthases of conifers require a divalent metal ion for catalysis (Mn^{2+} or Fe^{2+}) [16, 17], and their activity is stimulated by monovalent cations (mainly K^{+}). Although angiosperm monoterpene synthases require Mg^{2+} or Mn^{2+} as cofactors, magnesium is ineffective as a cofactor for conifer monoterpene synthases [14, 17, 18]. TPS may synthesize unique or multiple products. Limonene synthase, capable of producing limonene, myrcene, α- and β-pinene [2], and *Pinus taeda* abietadiene/levopimaradiene synthase, which synthesizes levopimaradiene, abietadiene, palustradiene, and neoabietadiene, are examples of multiple product TPS [19].

Pine oleoresin probably constitutes the most important ecological trait as defense against highly aggressive conifer pests, the boring bark beetles, and their associated pathogenic fungi [6, 20–27]. The volatile portion of pine oleoresins is composed of turpentine, and the nonvolatile fraction is made of rosin [6, 28, 29], both showing equivalent ecological importance in the successful evolutionary history of pines. Turpentine is a complex mixture of mono (C_{10}) and sesquiterpenes (C_{15}) responsible for the earliest emissions of chemicals/olfactory signals to discourage insect predation. Turpentine also acts as an efficient solvent that facilitates the mobilization of resin acids to injury sites. Diterpene (C_{20}) resin acids are the major components of rosin. The ecological role of rosin is to entrap and kill the undesirable visitors (bark beetles and wood borers), by sealing wounds in stems, after the volatilization of turpentine [30].

In many species of Pinaceae oleoresin biosynthesis may occur as a constitutive pattern of growth and development (primary or preformed resin), or its formation may be inducible by external factors (secondary resin), such as mechanical wounding, or biological challenge, like insect or pathogen attack [13, 14, 26, 31–34].

In general, conifer oleoresins are mixtures of mono-, sesqui-, and diterpene resin acids that accumulate in resin blisters (pockets or cysts), resin cells, or resin canals (or ducts). In pines, both preformed and induced oleoresin are produced and stored in structures named resin ducts (RDs), the most elaborate reticular system of ducts distributed throughout the wood and bark of conifers [14, 35]. RDs are arranged both horizontally (radially) and vertically, often connected at different levels [36]. RDs are formed by the separation of clusters of epithelial cells at the schizogenous level [37–39], which delimits a lumen (or extracellular storage cavity) where the resins are stored. Similar to the patterns observed for oleoresins accumulation, RDs can be primary (constitutive), or originated in response to external stimuli, commonly classified as traumatic resin ducts (TRDs). TRDs are the main features observed in secondary xylem of other genera of the Pinaceae family, such as true firs (*Abies*), and spruces (*Picea*), since constitutive RDs are absent or sparse in unwounded trees of these taxa. In contrast to the origin site of preformed resin (secretory epithelial cells), the production of induced resin is carried out by parenchyma cells surrounding the site of injury [12].

1.1 Biological Aspects of Pine Oleoresin Production

The great international demand for by-products of pine resins in industry and the copious and long-term production of this feedstock by extensive commercial plantations [40] have transformed resin tapping operations in a very profitable business. Unlike agricultural crops, conifer native forests or plantations do not require intensive investments in maintenance [5], and are relatively more tolerant to conditions such as drought and low fertility soils. On the other hand, for commercial purposes, the establishment of resin tapping operations must take into account some important aspects of pine biology and chemistry.

In spite of the fact that all pines are capable of producing resin, the quality (composition) and quantity of both rosin and turpentine can be strongly determined by genetic traits, intrinsic of each species. For instance, *P. patula* (Schiede ex Schltdl. & Cham.), an exotic species widely cultivated in Africa, does not yield sufficient resin, and the quality of its resin is poor (less than 10% of pinenes in its turpentine composition versus approximately 90% observed in *P. elliottii* var. *elliottii* [41]). These features hinder the possibility of *P. patula* use in viable commercial tapping. Similarly, *P. kesyia* is not the first choice of species to be commercially tapped (except in regions where it can be tapped throughout the year, such as the Philippines [2]), since, in spite of its natural and widespread occurrence in Thailand, the species yields very low resin [42].

Trade parameters of by-products of pine oleoresins are also crucial when choosing the species to be tapped. For example, pinenes are the most versatile and widely used compounds of turpentine purchased by the chemical industry to produce mainly pine oil and food additives [3, 43–51]. Alpha-pinene is often the most abundant component of pine turpentine, whereas β-pinene is the isomer with highest value for the chemical industry. *Pinus radiata* D. Don (Monterey pine, insignis or radiate pine) synthesizes turpentine with a superior quality (rich in α- and β-pinenes); however, it does not produce sufficient resin to become economically viable. On other hand, the occurrence of undesirable compounds in turpentine, such as the monoterpene 3-carene (comprising 50 % of the Indian turpentine), can compromise trade values of this by-product in the international market of resin derivates [42].

Historically, the same pine species have been tapped all over the world [2, 42]: *P. elliottii* Engelm., which has reasonable oleoresin yields and good composition of turpentine – Slash pine (Brazil, USA, South Africa, Zimbabwe, Kenya, China); *P. pinaster* Aiton – Maritime pine (Portugal, Spain [52]; France); *P. halepensis* Mill. – Aleppo pine (Greece); *P. massoniana* D. Don – Masson pine (China); *P. merkusii* – Merkus, Tenasserim, or Mindoro pine (Indonesia, Thailand); *P. yunnanensis* Franch. (China); *P. caribaea* Morelet – Caribbean pine (South Africa, Kenya, Brazil, China).

Patterns of heritability of resin production and some important commercial traits (e.g., viscosity) have been investigated in southern pines (*P. palustris* Mill. – longleaf pine, *P. elliottii*, and *P. taeda* L. – loblolly pine) [53–58]. Repeatability estimates for oleoresin yields of loblolly, slash, and longleaf pines proved to be higher than 55% [59].

Besides the genetic control, both constitutive and inducible resin yields may be influenced by environmental conditions [32]. Several investigations have been performed to evaluate the effects of biotic and abiotic factors on oleoresin biosynthesis, including plant age [56, 60], plant physiological status [58, 61, 62], fungal inoculation, water availability [62–68], temperature [58, 60, 69–72] season [54, 58, 60, 73, 74], irradiance [29, 61, 62, 66], and site fertilization status [22, 72, 75]. Some examples of the main results reported are briefly described below.

One-year-old plants of slash pine had increased oleoresin production after flooding [63]. Site fertilization increased constitutive flow of resin in 6-year-old loblolly pine [72], but reduced it in 11-year-old plants [22]. Rates of monoterpenes emission increased exponentially with temperature in slash pine [70] and *P. halepensis* [66]. However, variable emission responses were observed in Aleppo pine plants after exposure to different irradiance levels and limited water availability [66]. Light and water stresses reduced the constitutive level of monoterpene cyclase activity in Grand fir saplings [62]. Highest production of oleoresin in slash pine was observed in spring [54, 73] when compared to other seasons examined.

1.2 Mechanical Wounding Methods and Physiological Treatments Used to Improve Pine Oleoresin Yields

Besides genetic and environmental influences, oleoresin biosynthesis may be physiologically modulated, at least in part, by means of mechanical wounding (extraction method, frequency of bark removal) and/or chemical stimuli [76].

In Europe, the initial aggressive methods of resin exploitation (*le gemmage à mort*) have led to a severe exhaustion of entire pine forests in France. After the establishment of a well-managed reforestation program in the 1800 s, the earlier resin tapping method was replaced by another one, more sustainable and less destructive (described below), to ensure the survival of trees and extend their useful life (*le gemmage à vie*) [2, 77].

Burning the base of the trunks was the first method used in North America to promote gum exudation by trees, followed by the "boxing" method, whereupon a cavity called "box" was cut at the base of trees and above it streaks were made, both highly destructive methods for the trees [2, 78]. Nevertheless, techniques of resin stimulation used worldwide currently (French, Chinese, Mazek, and American) [79] are variations of the "boxing method" briefly described above.

In general, from the outside to the inside of a pine trunk fully grown, the following main tissues (or cell layers), through which resin ducts are distributed, can be recognized: bark (confers protection against predators, by acting as the first barrier encountered by visitors), phloem (vascular tissue that conducts photosynthates, e.g., sucrose), vascular cambium (lateral meristem involved in secondary growth, by giving rise to secondary phloem and secondary xylem – wood), and xylem (vascular tissue for water and mineral nutrient transport) [80] (Fig. 136.1). The current commercial resin tapping operations are performed on trunks presenting a well-developed secondary growth by removing the bark and further tissues beneath it, at variable depths, according to the extraction method employed (Fig. 136.2).

The French (or Hugues) method, the first technique of resin stimulation developed by Pierre Hugues in 1844, (which became popular around 1860 [77]) consists in removing long vertical bark streaks (about 10 cm wide), deep enough to reach

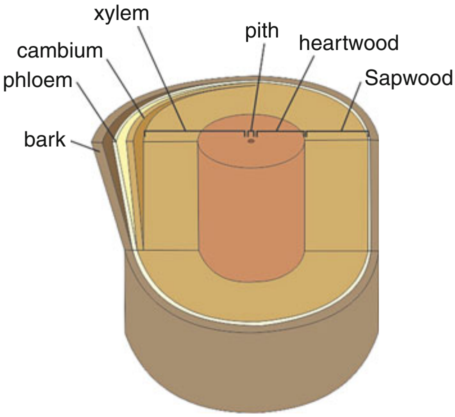

Fig. 136.1 Schematic section of a pine trunk showing the main layers that can be removed in resin tapping processes (Adapted from [185])

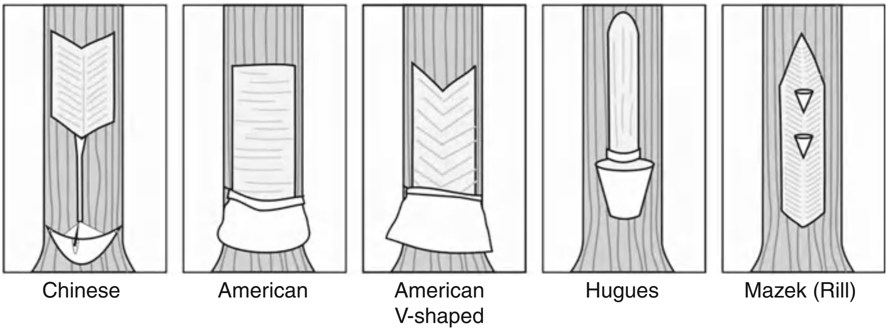

Fig. 136.2 Methods of resin tapping (Adapted from [79])

the secondary xylem of the trunks. This is the main method used in Indonesia, one of the major producers of crude gum resin today.

In the Chinese method, V-shaped streaks are daily removed in a downward direction, the starting point being about 1.2 m aboveground, to expose the secondary xylem. No chemical stimulation is used in French or Chinese methods of resin tapping operations.

The method known as "Mazek or Rill," today used in India, was adapted by Mazek Fialla in Europe (1950s) based on a US patent deposited by Steele in 1869, which describes the principle of the fish bone tapping system to stimulate and collect resin. In this system, V-shaped streaks (2–3 mm wide) are cut in variable intervals (every 24 h, 3 or 7 days) in upward direction, much like in the American method.

In the American method, horizontal (or V-shaped) strips of bark (2.5–3.0 cm wide) are removed every 14 days, from roughly one third of the tree circumference, exposing the cambium (only the bark and phloem are removed) or preferably the sapwood surface. This method is used in Brazil, Argentina, Portugal, and Spain [79]. The influence of mechanical wounding shape in resin production was tested on slash pines in southern Brazil, indicating that both horizontal and V-shaped streaks were equivalent for oleoresin yield [81].

Although mechanical wounding is well established as an efficient defense-response inducer in plants (especially in conifers) [33, 56, 61, 62, 82, 83], and this principle has been applied for centuries to obtain oleoresins, over the years numerous chemical stimulating treatments (Table 136.1) have been tested in order to enhance oleoresin yields in commercial pine plantations, including several US Patents [84–93]. For example, in the Rill method, a spray solution composed of an equal proportion mixture of hydrochloric (HCl) and sulfuric (H_2SO_4) acids is applied on the exposed "face" to improve resin yield. In the American method, a chemical stimulating paste containing sulfuric acid (20%) and CEPA (2-chloroethylphosphonic acid) (3.5–4.0%) in its formulation is placed on the sapwood or cambium surfaces [40, 73, 81]. This practice reduces the damaged area in pine trunks originally affected by the destructive traditional methods of mechanical injury.

Table 136.1 Treatments used to increase oleoresin production

Compound	Mode of action and responses observed in conifers (besides oleoresin yield enhancement)	Species tested	References
Sulfuric acid	Potential generator of free radicals; increases and prolongs gum resin yields by maximizing the effect of the wounding at the injury zone or "face"	*Pinus elliottii* Engelm., *P. palustris* Mill., *P. caribaea* var. *bahamensis, P. oocarpa, P. kesiya, P. caribaea* var. *caribaea, P. caribaea* var. *hondurensis, P. patula, P. ponderosa, P. pinaster*	[40, 41, 53, 69, 73, 76, 81, 86, 88, 89, 91, 94–99]
Ethephon, CEPA[a] or Ethrel®	Precursors of ethylene, signaling molecule involved in stress-induced responses; increases biosynthesis of mono- and diterpenes, induces radial growth, RDs formation in xylem, and alters the anatomical pattern of tracheids	*P. elliottii* Engelm. *P. palustris* Mill., *P. caribaea* var. *hondurensis, P. taeda* L., *P. resinosa*	[15, 81, 90, 93, 96, 98, 100–107]
Paraquat[b]	ROS[c] generator; increases ethylene synthesis, induces lightwood formation	*P. elliottii, P. taeda* L., *P. palustris*	[73, 90, 93, 102, 103, 108–111]
2,4-D[d] (Auxin)	Stimulates the cambial activity and RDs formation, and promotes the expression of ACC[e] synthase gene (enzyme involved in ethylene biosynthesis)	*P. elliottii, P. palustris*	[38, 73, 85, 97, 112, 113]
Salicylic acid (SA)	Mediator in pathogen-associated responses, acts to improve the defense performance of plants against their predators	*Pseudotsuga menziesii* (Douglas-fir) (Pinaceae), *Sequoiadendron giganteum* (Giant sequoia) (Taxodiaceae), *Picea abies, P. elliottii*	[73, 114–118]
Benzoic acid	Precursor of SA in pathogen-signaling pathways	*P. elliottii*	[73, 115]
Metal cofactors (Mg^{2+}, Mn^{2+}, Fe^{2+}, K^{+}, Cu) valence in Cu: Cu^{+}	Required as cofactor or stimulators of TPS activity or ethylene perception (Cu valence in Cu: Cu^{+})	*P. elliottii*	[9, 14, 16–18, 40, 119]
Yeast extract	Simulates pathogen attack	*P. elliottii, Abies grandis*	[73, 120]
Chitosan or fungal cell wall fragments[f]	Simulate pathogen attack; promote hyperoleoresinosis (transient increased accumulation of mono- and diterpenes) and increased monoterpene cyclase activity (limonene cyclase); promote formation of large lesion sizes on xylem	*P. contorta* var. *latifolia* (Lodgepole pine), *A. grandis, P. taeda, P. echinata* (Shortleaf pine), *P. palustris, P. virginiana*	[104, 120, 121]

(*continued*)

Table 136.1 (continued)

Compound	Mode of action and responses observed in conifers (besides oleoresin yield enhancement)	Species tested	References
Methyl Jasmonate (MeJA)[g]	Induces defense responses in conifers, induces the transcription of ACC oxidase gene involved in ethylene biosynthesis; increases biosynthesis of monoterpenes and diterpenes in needles and wood, promotes cell activation and TRDs formation on xylem, induces ethylene production, increases TPS transcripts	*Picea abies* L. (Karst) (Norway spruce), *Metasequoia glyptostroboides* (Dawn redwood), *Sequoiadendron giganteum*, *Sequoia sempervirens* (Coast redwood), *Cryptomeria japonica* (Japanese cedar), *A. grandis*, *Cedrus libani* (Cedar of Lebanon), *Tsuga heterophylla* (Western hemlock), *Pseudotsuga menziesii*, *Araucaria araucana* (Monkey puzzle), *Araucaria heterophylla* (Norfolk Island pine), *Podocarpus totara* (Totara), *Podocarpus lawrencei* (Mountain plum pine), *Cupressus macrocarpa* (Monterey cypress), *Picea sitchensis* (Sitka spruce)	[28, 29, 116, 122–127]
Fungal elicitors[h]	Induce hypersensitive responses in conifers; induce pronounced increase of ethylene production, monoterpene biosynthesis associated with increased ethylene production, increase systemic and traumatic resin accumulation in stems, induce expression of TPS genes (mono-, sesqui-, and diterpenes synthases), induce monoterpene cyclase activity (limonene cyclase)	*P. elliottii* Engelm. var. *elliottii, P. taeda* L., *P. nigra* Arn. (Austrian pine), *P. resinosa* Aiton (Redwood pine), *Picea sitchensis* (Sitka spruce), *P. echinata*, *P. palustris*, *P. virginiana, A. grandis*	[33, 72, 106, 107, 120, 121, 123, 128, 129]

[a] 2-chloroethylphosphonic acid
[b] *N*′,*N*′-dimethyl-4-bipyridinium dichloride
[c] reactive oxygen species
[d] 2,4-dichlorophenoxyacetic acid
[e] 1-amino-cyclopropane-1-carboxylic acid
[f,g,h] chemical stimuli or elicitors not used in large scale

2 Commercial Aspects of Oleoresin Production

In Europe, there is evidence of oleoresin exploitation predating 100 B.C. in France, albeit it is known that Greeks were the pioneers in production of resin from *P. halepensis* Mill. in ancient times. In spite of wide geographical spread of Aleppo

Table 136.2 Brazilian pine resin (and by-products) exportations and main international customers

Product	Year	Total annual (kg)	US$ per ton (FOB)	Customer
Gum resin	1989	6,653,978	496.18	India
	1999	10,420,534	420.64	Portugal

	2008	4,941,900	1,080.61	Netherlands
	2009	9,285,100	862.09	Netherlands

Pine along the Mediterranean coast, the maritime pine (*Pinus pinaster* Ait. syn. *P. maritima* Mill.) has been the main species used in France since at least the mid-1800s [2] for resin tapping commercial operations [77, 130]; today, resin tapping is practically nonexistent in this country.

In North America, the diversified industry of pine-based oleoresin, known as "Naval Stores," was the first and long-lasting industrial activity in the USA, which started roughly in the1600s, introduced by the English settlers during the Colonial period and nearly abandoned at the end of the twentieth century. The main species tapped to supply the Naval Stores industry in the 1900s were longleaf (*Pinus palustris* Mill.) and slash (*P. elliottii* Engelm.) pines [2, 78].

From 1987 to 1989, China, the former Soviet Union, and Portugal contributed, respectively, with about 55%, 12%, and 10% of the total crude resin produced in the world [42]. Currently, China, Brazil, and Indonesia are the major world producers of pine gum resins [79].

The international market of gum resin is quite variable, affecting the trade values of turpentine and rosin. Besides international standards usually required (particular chemical composition of turpentine, and specific physical properties of rosin, [76]), the prices of gum resin exported (and its by-products) may be subject to negotiation, depending on the type of customer (end user or fractionator) and the amount of tons purchased. For instance, in 2008, the average value of turpentine exported from Brazil was US$ 1,023.46/t Free on Board (FOB) however, the charged prices for France (the main customer of Brazilian turpentine, Table 136.2) and Spain (which acquired 584,600 kg in 2008) were US$ 848.85/t FOB and US$ 1,169.88/t FOB, respectively [131].

In the last 3 years, the average Brazilian total production of gum resin was more than 91,000 t. The largest Brazilian producers are the states of São Paulo (~50%)

and Rio Grande do Sul (~25%). Slash pine is the major species tapped in Brazilian plantations contributing 72% of the total oleoresin produced, followed by tropical pines (*P. caribaea* var. *caribaea, P. caribaea* var. *hondurensis*, *P. caribaea* var. *bahamensis*) [131]. Crude gum resin was initially the major feedstock purchased in large scale by the international market, but currently its by-products are preferable, with France and the Netherlands being the main customers of Brazilian turpentine and rosin, respectively (Table 136.2). In 2012, prices per ton of Brazilian resin, turpentine, and rosin reached US$ 638.50, US$ 1,658.11, and US$ 1,800.00, respectively.

2.1 Industrial Applications of Terpenes Obtained from Pine Oleoresin

Estimates indicate that terpenes represent 55% of all secondary metabolites in plants, whereas alkaloids and phenolics account for 27% and 18%, respectively [7]. Various important biological properties have been reported for plant essential oils and related terpenes [132]. A key aspect of using terpenes from plants is the fact that these represent renewable resources, yielding sustainable economic returns for longer periods of time. Moreover, terpene extraction from live trees provides a means to remove excess carbon dioxide from the atmosphere through forest plantations.

Different oleoresin terpenes have been identified in pine species (Table 136.3) [133–137]. Oleoresin obtained by tapping the bark in pine trees constitutes an important forestry product because of the chemical diversity of these secondary metabolites and their multiple possibilities of use. Oleoresin has two major fractions: rosin (diterpenes), which is the solid fraction, and turpentine (mono- and sesquiterpenes), which is the volatile fraction [6, 40].

Different types of industries can make use of oleoresins from pines: pharmaceutical and perfume industries, food additives, and other chemical industries (household cleaning products, paints, inks, varnishes, rubber, insecticides, aromatherapy). These various uses are due to their pleasant fragrance [140, 141], antimicrobial activity, among various other physical and biological properties. Examples of different terpenes obtained from pine oleoresin and their importance in distinct industrial segments are listed in Table 136.4.

2.2 Applications of Monoterpenes

Turpentine is mostly composed of monoterpenes and these can have different industrial applications. Borneol is used in cosmetics and in non-cosmetic products, such as household cleaners [145]. Carveol, linalool, myrcene, α- and β-pinene, phellandrene and terpineol are used in the food, perfume, and cosmetics industry as fragrance and to impart flavors to foods [133, 146–149]. Also, it has been reported that turpentine could be an interesting resource for the pharmaceutical industry due

Table 136.3 Examples of terpenes found in pine species

Compound[a]	References

Camphene	[40, 133, 135–137]
Carene	[135, 136]
Carvacrol	[136]
Carveol	[135, 136]
p-cymene	[135–137]
Limonene	[135–137]
Linalool	[133, 135]
Myrcene	[40, 135, 137]
Phellandrene	[40, 133, 135, 137]
α-pinene	[40, 133–135, 137]
β-pinene	[40, 133–135, 137]
Terpineol	[135, 137]
Aromadendrene	[135]
Isopimaric acid	[138, 139]
Bisabolene	[135–137]
Germacrene	[133, 135–137]
Longifolene	[133, 135, 136]

[a] These reports might not reflect all of the terpenes present in pine species because of differences in experimental analysis and biological conditions of plant growth

to its analgesic and antioxidant activities [150]. Linalool and myrcene were shown to have considerable protective effect against genotoxicity, due to their strong antioxidant activities, both in *Escherichia coli* and human hepatoma cultured cells [151]. Pathogenesis caused by *Staphylococcus aureus* and *Salmonella enterica* draw great medical attention. Efforts have been made to understand and inhibit the formation of biofilms produced by these two important bacteria [152, 153]. Carvacrol was capable of inhibiting the formation of *S. aureus* and *S. enterica* biofilms [154]. These results highlight the important potential of antioxidant and antimicrobial effects of compounds such as linalool, myrcene, and carvacrol for the pharmaceutical industry.

In the industry of insecticides, one of the central issues is to develop products that are not harmful to the environment and to human health. It has been shown that α-pinene, camphor and limonene can be good natural repellents for insects [155]. Besides the use of geraniol in the industry of fragrances, this compound has also proven effective as a mosquito repellent [156, 157]. Terpene halides, 3-carene, and toxaphene, a chlorinated camphene, are important for agriculture because of their use as pesticides [158, 159]. However, especially for toxaphene, several restriction issues have been raised because of its pollutant capacity and carcinogenic potential in humans [159–161].

Terpineol, which has a pleasant aroma, is one of the most common ingredients of Chinese black tea [162]. Camphor and menthol are also interesting for the

Table 136.4 Classes of different terpenes and specific components present in oleoresin of pine trees and their respective industrial applications

Category	Compound	Industrial use
Monoterpenes [136]	Borneol	Cosmetics, household cleaners
	Camphene	Fragrances, pharmaceuticals, plasticizers, repellents, explosives
	D-3-carene	Repellents, manufacture of menthol, pesticides
	Carvacrol	Pharmaceutical
	Carveol	Fragrances, cosmetics, household cleaners, detergents
	p- cymene	Pharmaceuticals, repellents, disinfectants, solvents, flavorings
	Limonene	Fragrances, solvents, cleaning agents, flavorings, insect attractants, perfume industry
	Geranyl Linalool	Perfume industry, cosmetics, household cleaners, pharmaceutical
	Myrcene	Perfume industry, pharmaceutical
	Phellandrene	Perfume industry
	α-pinene	Fragrances, repellents, plasticizers, solvents, perfumery, insecticides
	β-pinene	Pharmaceuticals, fragrances, repellents, plasticizers, solvents, perfumery, insecticides
	α-terpineol	Fragrances, cosmetics, household cleaners, detergents, repellents, perfumery
	Toxaphene	Pesticides
Diterpenes [142]	Abietic acid	Paints, varnishes, lacquers, pharmaceuticals
	Dehydroabietic acid	Pharmaceuticals
	Geranylgeraniol	Potential antibacterial agent
	Isopimaric acid	Paper industry, pharmaceuticals
	Levopimaric acid	Paper industry
Sesquiterpenes [143]	Aromadendrene [144]	Potential antibacterial agent, food industry
	Bisabolene	Food additive, biofuel industry
	β-Caryopphyllene	Cosmetics, biofuels, perfume industry, food safety
	Farnesene	Insect repellent, chemical industry
	Germacrene	Food industry
	Longifolene	Chemical industry
	Isolongifolene	Fragrance, pharmaceutical

pharmaceutical industry. Camphor is an active molecule in vapor-steam products and the application of ointments that contain camphor has been effective to treat cough in children [163]. Interestingly, in Phase I trial studies, *L*-menthol was used as smooth muscle relaxant and proved to be readily metabolized and excreted in urine [164].

Esters of pinic acid derived from pinenes, which are additives to increase plasticity and fluidity of a material, are used as plasticizers [165]. *P*-Cymene and *p*-menthane are used as disinfectants, solvents, and also as flavoring ingredients [166]. Terpene phenols and terpene polymers are important in the chemical industry to make adhesives [167].

2.3 Applications of Diterpenes

There is a large-scale industry involved in producing gum rosin. In 2005, for example, China produced 700,000 t of tall oil resin (TOR) derived from tapping oleoresin of pine trees [168]. Rosin is a highly valued derivative of pine oleoresin.

Resin acids, such as abietic acid, can be converted to ester gum and used to make varnishes. Also, it is rubbed on the surface of musical instruments to make them less slippery, and used in paints [169]. Although abietic acid and its derivatives have been used in the chemical industry and as household cleaning agents, they have also shown potential as antiobesity and antioxidant molecules [170–172]. Tuberculosis is a very important disease caused by *Mycobacterium tuberculosis*, which is increasing and resurging in various parts of the world, often with the development of chemotherapy-resistant strains. It has been reported that geranylgeraniol is a potent inhibitor of *M. tuberculosis* in vitro [173]. Other diterpenes found in *P. spez*, such as isopimaric acid and dehydroabietic acid, have been identified as potent anticancer and antiviral agents [138]. Although further research is necessary to investigate the biological potential of geranylgeraniol to fight tuberculosis, the antiobesity and antioxidant effect of abietic acid and its derivatives, and of the anticancer and antiviral potential of isopimaric acid and dehydroabietic acid, these readily available compounds may be lead molecules for the pharmaceutical industry.

Levopimaric acid and isopimaric acid are very important adjuvants for cellulose pulp production and the paper industry [168]. Another relevant aspect of isopimaric acid, extracted from immature cones of *P. nigra*, is that it showed activity against a multidrug-resistant bacteria strain of *S. aureus* [139].

2.4 Applications of Sesquiterpenes

Farnesene can be used as an insect repellent [174]. Also, there are many other applications for farnesene, which can be converted into lubricants, fuels, and polymers for the biofuel industry. In Brazil, a genetically modified organism was approved by the National Committee of Biosafety (CTNBio) to produce farnesene at large scale by the chemical industry [184].

Bisabolene is a sesquiterpene used in the flavoring industry to add fruity flavor to foods [166]. In South Asia, cucurmin, which is the main compound of turmeric, is used in tradicional medicine to treat epilepsy. A detailed investigation found that bisabolene sesquiterpenes were additional molecules responsible for anticonvulsant effects [175]. Interestingly, because of its physicochemical properties, bisabolene has been investigated as an alternative biofuel for replacing D2 diesel [176, 177].

Together with the monoterpenoid terpineol, the sesquiterpenoid longifolene has been characterized as one of the main components of the aroma of Chinese black tea [162]. Isolongifolene, obtained by isomerizing longifolene, has been used in the fragrance and pharmaceutical industry [178, 179].

Beta-caryophyllene has been detected as one of the most abundant terpenes in *P. caribaea* by spectrometric methods [133]. This sesquiterpene has long been used in the perfume and cosmetics industry. Recently, using biotechnological approaches, phototrophic organisms have been genetically transformed to produce β-caryophyllene to be used by the biofuel industry [180].

Another interesting application of caryophyllene and other terpenoids found in essential oils is for enhancing aroma and safety of fresh foods, such as fresh fruit-cuts [181, 182]. Plant extracts containing germacrene and aromadendrene had a strong growth inhibition effect on food-borne microorganisms such as *Bacillus cereus* and *Salmonella thyphimurium* [183].

3 Conclusion

The plantations of commercial and renewable pine forests are sources of biomass to the continued rational exploration and extraction of oleoresin [40]. As analyzed in this chapter, there is a large array of industrial applications of different terpenes present in pine tree oleoresins. The scope of traditional and new applications of terpenes is wide and broadening. Recent advances in the management of tapped forests, by means of low-cost physiological treatments stimulating signaling cascades and terpene biosynthetic activity, may further improve oleoresin yields. Genetic selection for oleoresin production in pine forests is an important venue to pursue. The growth of different markets, with considerable social, economic, and environmental impacts, depend on future research and technology generation for oleoresin production and pine terpene products.

Acknowledgments Research on pine oleoresin in the senior author laboratory (AGFN) is supported by a Consortium of Pine Forestry Companies (Palmares-Irani-Trevo, RS, Brazil), and by the Brazilian Research Funding Agencies CNPq (National Council for Scientific and Technological Development) and CAPES (National Committee for Graduate Personnel Improvement). The authors would also like to thank M.Sc. Vinícius de Abreu Waldow (Petrobrás, Brazil) for assistance in preparation of the figures.

Abstract

Pyrethrins and synthetic pyrethroids are used extensively as insecticides and acaricides for the treatment of a broad range of ectoparasites in large and small animals, as well as in nonmammalian species such as birds, fish, and honeybees. These compounds are used in veterinary medicine in different formulations including spot-on, sprays, ear tags, dips (immersion), soluble powders, and shampoos to control fleas, mite, lice, and ticks between other insect infestations both outside and inside the house. The synthetic pyrethroids have been classified in two classes: type I and type II; the addition of the alpha-cyano group to the 3-phenoxybenzyl alcohol group in type II has increased the insecticidal potency. The mode of action of these compounds suggests that the voltage-dependent sodium channel in the nerve membrane is the common target in insects and mammals. The pharmacokinetic/toxicokinetic properties of these compounds are also presented. This chapter also reviews the antiparasitic activities and the veterinary applications (uses) of pyrethrins and synthetic pyrethroids in several animal species. The clinical signs of poisoning in particular in the cats by permethrin are described. The chapter also provides the EU's maximum residue limits (MRLs) established for the pyrethroids as antiparasitic agents in food-producing animals; the MRLs are necessary to establish the withdrawal/withholding periods of the final veterinary drug formulations containing these chemical compounds.

1 Introduction

Pyrethrins are a group of closely related, naturally occurring compounds that are the active insecticidal ingredient of pyrethrum and have been used for centuries. Pyrethrum, which has been used as a pesticide in commercial applications since the early nineteenth century, is extracted from the flowers of *Chrysanthemum cinerariaefolium* and *Chrysanthemum cineum* [1]. Most of the insecticides derived from plants traditionally have been considered safe for use on animals, and pyrethrum is an example of such material. There are six active insecticidal compounds that comprise the natural pyrethrins: pyrethrin I and II, cinerin I and II, and

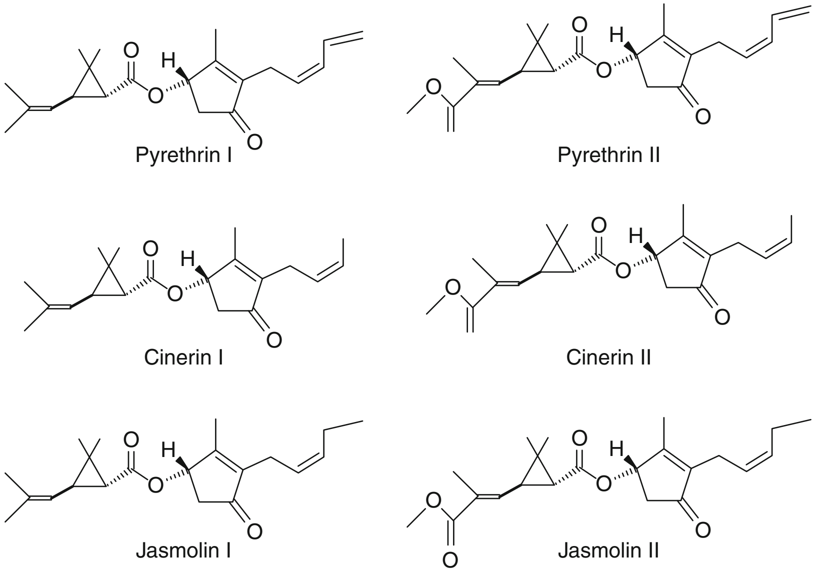

Fig. 137.1 Structure of natural pyrethrins

jasmolin I and II, the proportions being dependent on the extracts in questions. Most commercial preparations contain 20–25% pyrethrins with the ratio of pyrethrin: cinerin:jasmolin approximating 71:21:7. The structure of natural pyrethrins is shown in Fig. 137.1. Rapid knockdown of flying insects is a characteristic of the pyrethrin II compounds, but the pyrethrin I compounds possess greater insecticidal activity. Pyrethrins cause hyperexcitability with very little cytotoxicity. However, because the natural pyrethrins breakdown rapidly in the presence of moisture, air, light, and heat, they are rapidly biodegradable. The pyrethroids were developed to improve the stability of the pyrethrins, usually are biodegradable, but are sufficiently stable when exposed to air and light; the success of this chemical modification has led to widespread use of these agents as animal, agronomy, and industrial insecticides, providing excellent control of insects.

In the last century, the development of organophosphorus, carbamate, and organochloride insecticides was followed by synthetic pyrethroids. As a result, pyrethroids are now used frequently in the domestic milieu. Pyrethroid insecticides are synthetically derived from the molecular structure or sharing the same mechanism of action of natural pyrethrins that have broader spectrum of activity, more stability, and residual activity (persists longer than that of natural pyrethrins) and include the following: allethrin, cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, fenvalerate, flumethrin, fluvalinate, tau-fluvalinate, and permethrin (see structure in Fig. 137.2). They are lipophilic compounds and generally of low acute oral toxicity to mammals but are very toxic to aquatic organisms. When synthetic pyrethroids are administered to mammals parenterally, the synthetic pyrethroids are neurotoxic.

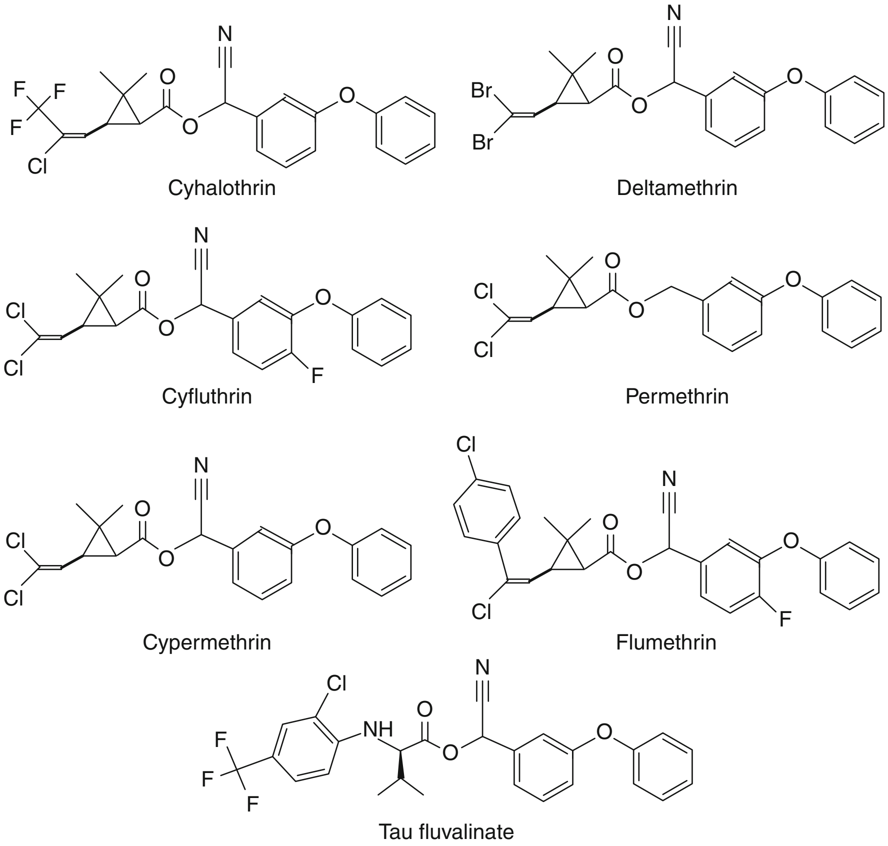

Fig. 137.2 Structure of synthetic pyrethroids

Pyrethrins and pyrethroids are used widely in numerous formulations for control of a broad spectrum of ectoparasites (i.e., fleas, lice, ticks, mites, and flies) affecting to the animals as well as in the home and garden and in agriculture to control insects for more than 45 years and account for approximately one-fourth of the worldwide insecticide market [2]. Many factors may influence the choice of product as active chemical ingredient, target parasite, efficacy and safety, regulatory status of the product, convenience, and aesthetic acceptability. In the EU and some other countries, these products are regarded as veterinary medicines, whereas elsewhere they are regulated as pesticides.

Pyrethroids have different pharmaceutical formulations and use varying solvents. Studies have shown significant differences in the efficacy of formulations with the same concentration of pyrethroids dissolved in diverse solvents since the solvent may play a role in the distribution of the active ingredient and therefore influence the efficacy of the active ingredient. Moreover, distinction between the effect of the pharmaceutical formulations in different areas of the animal body (i.e., close to and far away from the application site) could be observed.

Since pyrethrins are highly photolytic, antioxidants are often added to preparations to stabilize formulations; antioxidants adjoin include pyrocatechol, pyrogallol, hydroquinone, and 1-benzene-azo-2-naphthol. Practically, all pyrethrins and many pyrethroids are commonly combined to additives (including synergists), some formulations include additional insecticides, insect repellents, or both, and many contain hydrocarbon solvents [3] to enhance their insecticidal activity. Pyrethrin and pyrethroid sprays may also be water based or be alcohol or petroleum based, which increases the overall toxicity. It is known that concomitant use of pyrethrins and pyrethroids with synergists such as piperonyl butoxide, *N*-octyl bicycloheptene dicarboximide, sulfoxide, sesamin, sesame oil, sesamolin, isosafrole, and organophosphorus compounds or carbamates may increase toxicity by mechanisms involving inhibition of microsomal oxidation [4].

2 Classes of Pyrethroids

Pyrethroid insecticides are generally classified into one of two large groups on the basis of the central neurotoxic syndrome that they produce [5, 6]. Type I pyrethroids are esters of chrysanthemic acid and an alcohol, having a furan ring and terminal side chain moieties, and absence of a cyano moiety. Allethrin was the first pyrethroid identified in 1949. Allethrin and other pyrethroids such as phenothrin and permethrin with the basic cyclopropane carboxylic ester structure are type I pyrethroids. The insecticidal activity of these synthetic pyrethroids was enhanced further by the addition of a cyano group to give α-cyano type II pyrethroids such as deltamethrin, fenvalerate, cyfluthrin, cyhalothrin, and lambda-cyhalothrin (Fig. 137.2).

Type II pyrethroids have 3-phenoxybenzyl alcohol derivatives in the alcohol moiety and have had some of the terminal side chain moieties replaced with a dichlorovinyl or dibromovinyl substitute and aromatic rings. They are neurotoxic both for mammals and insects. In all species tested, pyrethroids show a pattern of toxic action typical of a strongly excitant effect on the nervous system. The type II pyrethroids, exerting their action on higher brain centers and interfering with the transmission of nerve impulses, act on the sodium channel of the axonal membrane; they induce a long-lasting prolongation of the membrane during excitation, leading to prolonged trains of impulses. The action on the nervous system of Type II pyrethroids is specific and tends to be reversible.

In mammals, two distinct toxic syndromes have been described: the T syndrome (characterized by tremor) induced by type I pyrethroids and the CS syndrome (characterized by choreoathetosis and salivation) induced by type II compounds [7]. Type I pyrethroids cause hyperexcitation, ataxia, convulsion, paralysis [7–9], and repetitive nerve firing [10]. In contrast, type II pyrethroid poisoning is characterized by hypersensitivity, profuse salivation, choreoathetosis, tremor, and paralysis [8, 9] but no repetitive nerve firing in sensory nerves [11]. Some pyrethroids produced tremors and salivation, classified as the intermediate TS-syndrome. In humans, the most prominent effect of the pyrethroids is paresthesia mainly in the face, and there is little evidence of any permanent effects.

3 Mode of Action

All pyrethroids share the same basic mode of action, but the different types cause somewhat different symptoms as described previously. Although the molecular aspects of pyrethroids action are not fully understood, detailed electrophysiological investigations strongly suggest that the voltage-dependent sodium channel in the nerve membrane is the common target in both insects and mammals, including humans [9]. Type II pyrethroids also depress resting chloride conductance, thereby amplifying any effects of sodium or calcium.

The mechanisms by which pyrethroids alone are toxic are complex and become more complicated when they are co-formulated with piperonyl butoxide, an organophosphorus insecticide, or both, as these compounds inhibit pyrethroid metabolism. The main effects of pyrethroids are on sodium and chloride channels. As a result, excitable (nerve and muscle) cells are the principal targets of pyrethroid toxicity, which is manifested as disordered function rather than structural damage. In that way, the major toxic effect of dermal exposure is paresthesia, supposable also due to hyperactivity of cutaneous sensory nerve fibers [12].

3.1 Effects on Sodium Channels

Pyrethroids act primarily on the nervous system. The primary mode of action of pyrethroids in both insects and mammals is disruption of voltage-sensitive sodium channel function, but chloride and calcium channels are also affected. Perturbation of sodium channel function by pyrethroids is stereospecific [13]. Using cell-attached patch-clamp electrophysiology recordings can be observed that individual voltage-gated sodium channels open for a few milliseconds and then fail to open again for an extended period due to channel inactivation. In the presence of pyrethroids (tetramethrin), the channels open with a long delay, and then often remain open for several seconds even after the termination of the depolarizing pulse. In conclusion, the pyrethroids that hold the sodium channel open the longest will cause the greatest amount of depolarization. There is marked stereospecificity of the action of pyrethroids on the sodium channel; some isomers are more toxic than others. This interaction with the sodium channel has the effect of slowing the activation and inactivation properties of the sodium channel leading to a stable hyperexcitable state in all excitable tissues. The proportion of sodium channels modified is dose-dependent, but the duration of their hyperexcitable state is determined by the structure of the pyrethroids and is not dose-dependent. The *cis*-isomers are usually more toxic than the *trans*-isomers. As an example, the 1*R* and 1*Scis*-isomers bind differently than the 1*R* and 1*Strans*-isomers that bind noncompetitively to another [14]. In mammals, the 1*R* isomers are toxic and the 1*S* isomers inactive, making the 1*S* isomers nontoxic. The stereospecificity, due to isomerism about the third carbon atom of the cyclopropane ring, accounts for the reported differences in toxicity of the pyrethroids available in isomeric mixtures. In general, type II compounds delay the inactivation of voltage-sensitive sodium channel substantially longer than type I compounds. Type I compounds prolong voltage-dependent sodium channels opening only long enough to cause repetitive firing of action potentials (repetitive discharge), whereas type II compounds hold the channels open for such long periods that the membrane potential ultimately becomes depolarized to the point making the generation of action potentials impossible (depolarization-dependent block). These differences in prolongation of channel open times are hypothesized to contribute to the differences in the CS and T syndromes of neurologic toxicity after exposure to type II and I pyrethroids, respectively. The depolarizing action results in a massive discharge of neurotransmitter at nerve terminals and hence severe disruption of synaptic transmission. Paresthesia results from the direct action of pyrethroids on sensory nerve endings, causing repetitive firing of these fibers, and they are more likely to follow exposure to type II than type I pyrethroids.

Finally, some differences have emerged between sodium channels of insects and vertebrates in terms of their intrinsic sensitivity to pyrethroids indicating that the selectivity of pyrethroids to insect is at least in part to their higher activity on insect sodium channels than vertebrate channels [15].

3.2 Effects on Chloride Channels

Pyrethroids also affect the voltage-dependent chloride channels. These channels are found in the brain, nerve, muscle, and salivary gland and are modulated by protein kinase C, and their function is to control cell excitability. There are many different functional types of chloride channels in contrast to sodium channels. Most pyrethroid-sensitive channels belong to the maxi chloride channels class [16]. Maxi channels are activated by depolarization, have high conductance, are calcium independent, and are inactivated by protein kinase C phosphorylation. Pyrethroids decrease maxi chloride channel current, which serves to increase excitability and therefore would synergize pyrethroid actions on the sodium channel. Of the pyrethroids that have been tested, only some of those producing type II poisoning syndrome (deltamethrin and fenvalerate) seem to affect maxi chloride channels. Since agents such as ivermectin and pentobarbital, which open chloride channels, antagonize pyrethroid-evoked salivation, choreoathetosis, and repetitive firing in skeletal muscle [17], it is probable that chloride channel actions contribute most to the features of poisoning with type II pyrethroids, such as salivation and myotonia.

The decrease in chloride-open channel state produced by type II pyrethroids serves to increase excitability and therefore to synergize pyrethroid actions on the sodium channel. At relatively high concentrations, type II pyrethroids have also been shown to interfere with the GABA-gated chloride channels [18] which may contribute to the seizures (the pyrethroids can act as "proconvulsants") seen in severe type II poisoning. These effects occur only at doses higher than those required to affect sodium flux. Several other reports have suggested a role for the $GABA_A$ receptor-ionophore complex in components of type II pyrethroid toxicity [11, 19]. The mechanism whereby pyrethroids interact with ion channels is not known, but type II pyrethroids (i.e., deltamethrin, fenvalerate, cypermethrin) stimulate protein kinase C-dependent protein phosphorylation at as low a concentration as 10^{-13} M in vitro by a direct mechanism [20]. Since both sodium- and chloride-ion channel activities are modulated by phosphorylation state, this could be an important mechanism of action although pyrethroids are also capable of acting directly in systems with no phosphorylation capacity, but at somewhat higher concentrations [21]. Diazepam (a GABA agonist) prevented the seizures associated with late-stage poisoning in experimental animals [22] but was ineffective in fenvalerate-poisoned humans. Thus, it appears that the undoubted potential of type II pyrethroids to act at the GABA receptor is of limited clinical significance, other than in severe poisoning [12]. Type II pyrethroids antagonize the $GABA_A$ receptor (decreased synaptic inhibition), resulting in a strychnine-like effect. This is similar to that of organochloride insecticides.

3.3 Other Actions

Other channel and receptor systems in neuronal tissues have been proposed to play a role in the generation of compound-specific clinical symptoms in mammals. The complex nature of the effects of pyrethroids on the central nervous system (CNS) has led various workers to suggest that they also act via modulation of nicotinic cholinergic transmission, reduce peripheral presynaptic adrenoceptor sensitivity [23] which leads to an enhancement of noradrenaline release [24], and affect the serotonin neurotransmission [25]. However, because neurotransmitter-specific pharmacological agents offer only poor or partial protection against poisoning, it is unlikely that any one of these effects represents an alternative primary mechanism of action of the pyrethroids.

Other possible mechanisms of pyrethroid toxicity have been investigated. Inhibition of Ca^{2+}, Mg^{2+}-ATPase, and calcium-binding protein calmodulin has been observed with some pyrethroids.

In the scientific literature, two characteristics have been mentioned which are allegedly typical of pyrethroids and responsible for the health risks involved: (a) due to their lipophilic properties, pyrethroids are supposed to be capable of accumulating in nerve tissue, and (b) there is no evidence indicating that the nervous system is reversible or irreversible [26].

4 Pharmacokinetics/Toxicokinetics

Only few studies have been conducted to analyze the toxicokinetic properties of types I and II in laboratory animals [27–29]. The lipophilicity of pyrethroids also enables rapid access to tissues, including the CNS. Non-cyano pyrethroids (permethrin) as well as cyano pyrethroids (deltamethrin and cyhalothrin) have an accumulation in the nervous tissues [25, 28, 29]. The toxicokinetic behavior of these pyrethroids revealed prolonged elimination half-lives (typically in the order of 10 h but may be larger) and high concentrations in several regions of the brain and other nervous tissues of the peripheral nervous system. For example, for lambda-cyhalothrin, the peak concentration in hypothalamus (C_{max} 24.12 μg/g) and myenteric plexus (C_{max} 25.12 μg/g) was about 1.5 times higher than in plasma (C_{max} 15.65 μg/mL) and 1.3 times higher than in liver (C_{max} 18.42 μg/mL).

The metabolic pathways for the breakdown of the pyrethrins and pyrethroids vary little between mammalian species but vary somewhat on structure. Essentially, pyrethrins and pyrethroids can be hydrolyzed in the gastrointestinal tract. Once absorbed, they are rapidly metabolized by oxidation of methyl groups and aromatic rings, hydrolysis of the ester linkage, and by conjugation reactions producing a wide range of metabolites that are excreted mainly in urine (conjugated metabolites with glucuronide, glycine, taurine, sulfate, and/or glutamate). The advantageous properties of the synthetic pyrethroids result from the fact that they are hydrolyzed relatively easily, both in the mammalian body and in the environment too; consequently, bioaccumulation in the latter does not occur, and they do not persist in soils. There is some stereospecificity in metabolism, with *trans*-isomers being hydrolyzed more rapidly than the *cis*-isomers, for which oxidation is more important metabolic pathway [30]. These metabolic reactions take place in the liver, kidneys, and other organs, as well as to a minor extent in nerve tissue. Cleavage of the ester bond results in substantial reduction in toxicity. The presence of α-cyano group will decrease the rate of hydrolysis of the ester bond. Cleavage of the α-cyano group results in rapid conversion of the cyano group to thiocyanate. As a rule, the metabolic reactions are exclusively detoxification processes, but there are exceptions. Epoxychrysanthemates are formed metabolically [31] and retain moderate insecticidal activity.

5 Antiparasitic Activity

Pyrethrins and synthetic pyrethroids are used extensively for the treatment of a broad range of ectoparasites in large and small animals, and in nonmammalian animal species (birds, fish, and honeybees). The "family member" of the pyrethroids is used in veterinary medicine to control fleas (*Ctenocephalides felis*, *Ctenocephalides canis*, *Haematobia irritans*, *Stomoxys calcitrans*, *Musca* species, *Hydrotaea irritans*, *Pulex irritants*), lice (*Trichodesctes canis*, *Damalinia bovis, Solenopotes capillatus, Linognathus vituli, Haematopinus eurysternus*, *Haematopinus suis*), ticks (*Ixodes ricinus*, *Ixodes hexagonus*, *Rhipicephalus sanguineus*, *Rhipicephalus turanicus*, *Dermacentor reticulatus*), and mites (*Otodectes cynotis*), between other infestations both outside and inside the house. Insects and acari [an order of the Class Arachnida (subphylum Chelicerata) comprising of mites and ticks] are distributed worldwide, and they are vectors of important diseases in animals and humans. Moreover, several of these insect- and acari-borne infections influence zoonotic potential and may produce serious infections in persons. The antiparasitic activity of pyrethroids has been linked to their ability to affect the sodium channel, but chloride and calcium channels are also affected. Specifically, electrophysiology studies have confirmed that pyrethroids slow the kinetics of opening and closing of sodium channels at the molecular level, thus impacting the insect's nervous system by slowing action potential decay [32]. The duration of the sodium action potential is much longer for type II pyrethroids than for type I. Type I pyrethroids result in primarily repetitive charges, and in type II, pyrethroid toxicity cell membrane depolarization is the main mechanism of action. Pyrethroids cause a phenomenon in insect called "knockdown" [10], which is caused by inhibiting the cell but not causing a lethal effect throughout ability of sodium channel to retain many of the functions such as selectivity for sodium ions and conductance after exposure to pyrethroids. The alliance of repellence and fast-kill of parasite is the most effective way of pyrethroids to reduce the risk of transmission of parasite vector and reservoir of infection.

Pyrethrins and synthetic pyrethroids have antiparasitic activities, but in general, pyrethroids have a broader spectrum than pyrethrins. The widespread and uncontrolled use of pyrethrins and pyrethroids might lead to environmental damage, insecticide and acaricide resistance in infected population, and a possible exacerbation of insect and arcari-borne population. The development of insect resistance can appear as a result of increased potency and especially increased persistence in the environment [33].

5.1 Ruminants

Insecticides and acaricides are periodically used to protect different ruminant species (cattle, sheep, and goat) from the attachment and blood sucking of various tick species which are known to be important vectors to transmit a broad spectrum of agents of diseases in particular cattle or sheep. Pyrethroid insecticides such as cyfluthrin, deltamethrin, fenvalerate, flumethrin, lambda-cyhalothrin, and permethrin had been successfully tested on their activity against a broad spectrum of insects, although their activity against ticks has been occasionally examined. Differences were found in the susceptibility of different species of insect and arcari (e.g., mites and ticks) certainly due to different long-reaching efficacy of insecticides on all treated species. One example is deltamethrin that is active against insects and ticks. The efficacy of deltamethrin pour-on against nymphs and adult ticks (*Ixodes ricinus* and *Rhipicephalus sanguineus*) in treated hair of cattle and sheep has been proven. *I. ricinus* adults and nymphs died from at least being exposed to hair taken even at 4 weeks after application (from backside to feet) of sheep; member of the species *R. sanguineus* may survive if ticks come into contact with treated hair beginning 3 weeks after treatment. While protection on the back is rather good for 3 weeks, the effects are less good if the hair of the feet comes into contact with the ticks. In cattle, the efficacy against *Rhipicephalus* is lower than in sheep. With respect to protection from insect vectors such as *Culicoides* species (vector of bluetongue disease), it was recommended to use deltamethrin at intervals of 3 weeks [34] although few insecticidal veterinary medicines have authorized claims regarding use against *Culicoides* species of insects. To control the *Culicoides*, alpha-cypermethrin has been used and applied to cattle and sheep against the biting midge *Culicoides nubeculosus* (Diptera: Ceratopogonidae). It is not known if commercial pour-on insecticides, which are most commonly applied along the dorsum of ruminant livestock, give sufficient coverage to protect animals from biting midge at potential sites of *Culicoides* feeding such as the belly and legs. Alpha-cypermethrin has shown convincing evidence that the commercial formulations tested on sheep and cattle will be at least partially effective in reducing onward transmission of bluetongue virus [35].

5.2 Horses

Culicoides biting midges can occur in large number on horses, and their bites have been linked to an immediate-type hypersensitivity reaction which causes a chronic skin disease (known as "sweet itch"). In general, *Aedes aegypti* and *Culex quinquefasciatus* appeared to be less susceptible to cypermethrin than *Culex nubeculosus*, and the attenuation of the toxic effect declined more quickly with time after treatment. There were differences in the toxicity of hair from different body regions, with hair from the back consistently inducing the highest mortality and hair from legs the lowest; this effect was more pronounced for *C. nubeculosus* than *A. aegypti* or *C. quinquefasciatus* [36].

5.3 Pet Animals

Fleas and ticks on dogs and cats usually have a widespread prevalence. For instance, ticks are known to transmit viruses, bacteria, fungi, protozoa, and nematodes, with every genus and species possessing its own specific germ flora. As blood sucking, adult fleas and all stages of ticks penetrate the skin of their hosts with their sucking mouthparts and inject saliva during the feeding process. This permit adult fleas and both immature and adult ticks to transmit disease agents throughout their saliva. One of the most important ticks in companion animals is *Dermacentor reticulatus* which achieves its main significance from being a vector of *Babesia canis* which produce the canine babesiosis. To minimize the risk of tick-transmitted diseases, a compound should ideally prevent tick attachment or should kill attached adult ticks larvae and nymphs rapidly, and permethrin has been used successfully for the prevention and control of many arthropod species.

Leishmaniasis is a group of zoonotic diseases transmitted to human and animals by the bite of phlebotomines and flies. *Leishmania infections* in dogs have great health importance as dogs are the reservoir hosts of zoonotic visceral leishmaniasis caused by *Leishmania infantum*. To control canine leishmaniasis, strategies have been proposed: cut transmission by treating domestic dogs with insecticides, lotions, or insecticide-impregnated dog collars originally developed for flea and tick control [37]. The anti-feeding and lethal effects of deltamethrin-impregnated dog collars have been tested, and this pyrethroid protects the dogs from sandfly-borne diseases when used topically [38]. For full efficacy, deltamethrin collar should be put on approximately 2 weeks before an anticipated sandfly challenge; the effects of deltamethrin on sandfly blood feeding and survival persisted for up to 8 months.

By contrast, sandfly blood feeding and survival rate of both feed and unfed flies were significantly reduced by permethrin-treated dogs after 1 week suggesting topical application of permethrin lotion can have a relatively immediate effect [38].

5.4 Birds

The northern fowl mite, *Ornithonyssus sylviarum* (Arcari: Macronyssidae), is an obligatory blood-feeding ectoparasite (hematophagous mite), which is considered to be one of the most important and common pests of poultry. This mite is sensitive to lambda-cyhalothrin, cypermethrin, fenvalerate, and permethrin. Due to short residue time, many registered compounds often need to be repeated after 2–4 weeks. Residue time of an insecticide on feather depends not only on the nature of but also on the formulation of the drug [39].

Most of the available pyrethroids applied in the northern fowl mite control are usually formulated as wettable powder or emulsifiable concentrate. For these two formulations, dilution with water before spraying is required. Since water has very low affinity to feathers, a great quantity of dilution of pyrethroids will fall on the ground, feed bin, or the cage, and some quantity will drift in the air during the process of spraying. An oil solution of pyrethroids applied has a higher affinity on the feathers of the birds and can stay on the feather for a longer time, and may provide a high efficacy and be effective for a longer, persistent period against the northern fowl mite. Lambda-cyhalothrin oil solution has a potential to become an effective and safe formulation to control northern fowl mite in breeders.

6 Veterinary Applications (Uses)

Pyrethrin and pyrethroid insecticides are effective against a variety of insect pests on companion animals and livestock, and are used on farms, in the home, and garden and have many public health implications because of the safety associated with these compounds. The great potential of pyrethroids for the control of flies, tsetse flies, fleas, and ticks is known.

Concentrations of pyrethrins range from 0.05% to 0.2% in the ready-to-use products. Concentrates are marketed for dilution as a pour-on and are not greater than 2%. A practical method of providing a pyrethrin spray for a large dog is the use of a pour-on concentrate diluted in a commercial lawn/garden pressure sprayer. Many of pyrethrin-based products incorporate the use of synthetic pyrethroids (permethrin, resmethrin, sumithrin, D-*trans*-allethrin) which are added predominantly for residual effects. Permethrin is by far the most common pyrethroid used [40] in a range from 0.2 to 71.5 [4].

Most chemotherapeutic agents registered and labeled for use as external parasiticides for large animals are pyrethroids. Pyrethroids used in veterinary medicines for domestic animals are listed in Table 137.1. For some spot-on products, particularly those intended for use on large animals and containing active ingredients

Table 137.1 Pyrethroids used in veterinary medicines for domestic animals

Pharmacologically active substance	Formulation	Animal species	Indications	Doses
Alpha-cypermethrin	Topically (spray, pour-on)	Bovine, ovine	Ectoparasites (ticks, fleas, lice, blowflies)	150 mg/animal
	Spray	Poultry	Ectoparasites	8–10 mg/bird
Cyfluthrin (8 enantiomers)	Topically (pour-on)	Bovine, caprine	Ectoparasites (horn fleas, horse flies)	100 mg/animal cattle
Cyhalothrin (contains two pairs of *cis*-isomers A and B (ratio 60/40)	Topically (pour-on, spray, dip tanks)	Bovine, pigs, and sheep (including dairy animals)	Ectoparasites (horn and face flies)	*Pour-on*: 0.2 mg/cattle, 0.1 mg/sheep or pigs
				Sprays (up to 250 mg/animal/treatment)
				Dip tanks (up to 50 g/100 L of water)
Cypermethrin (contains a mixture of 4-*cis* and 4-*trans*-isomers) (isomer ratio 40:60)	Topically	Cattle, sheep, goats, pigs, chickens including laying birds and lactating cattle, sheep, and goats	Ectoparasites (ticks, fleas, lice, blowflies)	
		Salmonidae	Treatment and control of parasites such as sea lice in *Salmonidae*	Seawater cage at a dose of 5 µg/L of seawater for a period of 1 h
Deltamethrin (90% *cis*-isomer)	Topically (dip, spray, pour-on)	Cattle, sheep, chickens	Ectoparasites (flies, including tsetse flies)	*Cattle*: 0.25–1.5 mg/kg bw as a single application or as repeated application (every 3–6 weeks)
				Sheep: 0.94–4.5 mg/kg bw as a single application, repeated 10 or 21 days later
				Chicken: 0.08 mg/kg bw
	Bath	Fin fish (Atlantic salmon, rainbow trout)	Ectoparasites treat sea lice (*Lepeophtheirus salmonis* and *Caligus elongatus*)	Bath dose 2 µg/L for 30 min in a closed container or 3 µg/L for 40 min in a particular closed sea cage

(*continued*)

Table 137.1 (continued)

Pharmacologically active substance	Formulation	Animal species	Indications	Doses
Flumethrin	Topically (pour-on, as a plunge dip)	Bovine, ovine	For control of ticks, lice, mites, and scab	*Pour-on*: 2 mg/kg bw *Plunge dip*: 1 L product in 900 L of water
		Honeybees	Diagnosis and treatment varroatosis in honeybees (3.6 mg are hung in beehives)	*Strips*: 4 strips/hive for mature colonies and 2 strips/hive for immature colonies
Permethrin (isomer ratios of *cis:trans*: 80:20, 40:60, or 25:75)	Spray (including udder spray), powders, pour-on, ear tag	Cattle, pigs, sheep, goats, poultry	Ectoparasites (horn and face fleas, mites, ticks, and lice)	4 mg/kg bw for cattle ≈6 mg/kg bw for pigs, sheep, and poultry
Tau-fluvalinate (contains two of four isomers of racemic mixture, fluvalinate)	Topically treatment	Honeybees	Parasitic mite *Varroa jacobsoni*	Polymer matrix strip (8 g in weight containing 800 mg tau-fluvalinate suspended midway for 6–8 weeks

such as synthetic pyrethroids, gloves are recommended as the quantities involved are larger than with companion animal products, and a large number of animals are likely to be treated.

6.1 Uses in Ruminants

The treatment and prophylaxis for cattle, sheep, and goat ectoparasites involves the use of ectoparasiticidal formulations containing insecticides/acaricides. There are several methods of applying these insecticides: plunge dipping (immersion) into water containing those chemical products, shower dipping, jetting races, pour-ons (actually sprays in common parlance) by application of chemical products along the vertebral column of the animals, and injection. Products available for use in sheep dips contain ectoparasiticidal solutions must to kill the larvae of green and blue bottle flies responsible for flystrike and to control sheep scab and keds. Up until 1985, lindane was the main substance used in sheep dips, but although it is less persistent in soil, lindane was banned throughout the EU, largely on environmental grounds. Dips containing synthetic pyrethroids (flumethrin and cypermethrin) have become more widely used, but the environment is targeted. Pour-ons containing pyrethroids are available and control a range of ectoparasites but not

Psoroptes ovis. None of the pour-on products provides protection against the range of ectoparasites that is achieved by plunge dipping.

In lactating dairy cows, only those veterinary medicinal products that are not excreted in the milk are approved for use in this category of animals. Fenvalerate, permethrin, and pyrethrins may be applied directly or throughout tags impregnated with permethrin or fenvalerate attached to the ears of lactating dairy cows. These pyrethroids usually need a withdrawal period when being used for human consumption, and the period may be as short as zero days or as long as several days. All parasiticides approved for lactating dairy cattle may also be used on non-lactating dairy cattle and beef cattle. The same restrictions are applied to their use on lactating dairy sheep and goats.

Sheep and goat (except when their milk is being used for human consumption) and non-lactating sheep and goats may be treated with products that contain the following: fenvalerate, permethrin, and pyrethrins. Minimum time from treatment to slaughter varies from 0 to 60 days. Fenvalerate and permethrin are marketed in spray and pour-on formulations and are used for control of the target parasites lice, mites, keds and flies, ticks, and blowflies, respectively.

In the cattle, the following pyrethroids are used:

- Cyfluthrin is approved as ear tag for use on beef cattle to control horn flies, face flies, Gulf Coast ticks, and ear ticks. The ear tags containing cyfluthrin should be removed at the end of fly season and before slaughter.
- Cyhalothrin is marketed as ear tag and pour-on formulations to control horn flies and face flies.
- Cypermethrin is a potent synthetic pyrethroid which is available as an ear tag in combination with chlorpyrifos. It is used on beef and dairy cattle to control horn and face flies, Gulf Coast ticks, and ear ticks and helps control stable flies, houseflies, and lice.
- Fenvalerate is characterized to be very photostable and potent being marketed as ear tag and pour-on formulations; the ear tags are used in dairy and beef for control of the target parasites (i.e., horn and face flies, Gulf Coast ticks, and ear ticks), and as an aid in the control of stable and houseflies, and lice. It can also be applied to livestock buildings for control of filth flies *Musca domestica* and *Fannia cannicularis*.
- Permethrin is marketed in spray (liquid or wettable powder), dust, ear tag, and pour-on formulations and is used in cattle being the target parasites horn flies, face flies, stable flies, back flies, houseflies, ticks, mites, and lice. Permethrin is available as ear tag formulation in combination with chlorpyrifos, and the target parasites are the same for permethrin.

The pyrethroids marketed as ear tags must be removed from the animals before slaughter.

6.2 Uses in Horses

Horses that are not to be used as food for human consumption may be treated with products that contain fenvalerate, permethrin, phenothrin, and pyrethrins.

Fenvalerate is marketed as spray formulation, and the target parasites are horn flies, face flies, stable flies, and houseflies. Permethrin is marketed as spray, wipe, and dust formulations, and the target parasites are horn and face flies, horseflies, stable flies, deer flies, mosquitoes, biting gnats, and ticks. Pyrethrins are marketed as spray, and the target parasites are the same than for permethrin. Ticks are capable of surviving in the environment for prolonged periods (e.g., more than 300 days without feeding), and some are not strictly species-specific and are adapted to several animal species being the control on the wet season and in some area throughout the year.

6.3 Uses in Swine

Pigs may be treated with products that contain fenvalerate, permethrin, and pyrethrins. Fenvalerate is marketed as spray and pour-on formulations and can be applied to control the target parasites lice (pour-on), mites, and flies, and permethrin is marketed in spray, paint, dip, and dust formulations, and the target parasites are lice, mites, ticks, and horn flies.

6.4 Uses in Nonmammalian Species

Fish. The only available pyrethroids intended for the treatment and control of parasites such as sea lice (*Lepeophtheirus salmonis* and *Caligus elongatus*) in *Salmonidae* are cypermethrin and deltamethrin. Usually, the diseased fish is treated with veterinary drugs either soluble or suspended in the water. The recommended doses (route and dose rate) for both pyrethroids are listed in Table 137.1.

Honeybees. Honeybee diseases are predominantly infectious and parasitic conditions accentuated by the close confinements in which they congregate, either in man-made hives or in colonies in a natural cavity. One of the most important parasitic diseases is the *Varroa* mite where pyrethroids such as flumethrin in the form of impregnated strips or tau-fluvalinate in topical application of honeybees is used. Two particularly important features of flumethrin thus formulated are the differential toxicity of the drug to the bees and their parasitic mites and the potential problem of drug residues in honey. In honey, we know there is massive variability not only between hives in the same apiary but also between frames in the same hive. Bees have a practice of moving honey around the hive as required, and this can lead to significant variations in residue concentration even across the same frame in all three dimensions. With regard to drug residues in honey, no migration of the acaricide from the plastic strip has been recorded, and levels in honey are below the limit of detection. The product may, however, be absorbed into the wax of the honeycomb [41]. If the product leaves residues in wax, it is generally assumed that honey and wax from the treated colonies are consumed in the proportions 9:1. Residues in both honey and wax need to be considered in exposure estimates (20 g honey for EU and 50 g for Codex Alimentarius, amounts assumed to be consumed daily by a 60-kg person).

6.5 Uses in Pet Animals

A wide variety of ectoparasiticides is available, and brand switching is frequent, which is an indication of the problems faced in achieving acceptable parasite control. Concentrated ectoparasiticidal dermal spot-on products are used for the control fleas and ticks and are commonly used on household pets such as dogs and cats. Synthetic pyrethroids such as permethrin and deltamethrin are extremely effective against fleas and other ectoparasiticides in the dog [42], but because of their adverse effects in cats, they are usually contraindicated for this species.

Pyrethrins are used noteworthy for rapid "knockdown," paralysis, and killing of arthropods, an effect of pyrethrin II that is further potentiated in a concentrated organic solvent such as alcohol. Unfortunately, alcohol sprays have disadvantages, particularly for use in animals with flea allergy already having dry, sensitive, and irritated skin and in cats [40]. Concern for product decay should be emphasized if solutions are left diluted for greater than 24 h. Concentrations of pyrethrins range from 0.05% to 0.2% in the ready-to-use products. Concentrates are marketed for dilution as a pour-on and are not greater than 2%. A practical method of providing a pyrethrin spray for a large dog is the use of a pour-on concentrate diluted in a commercial lawn/garden pressure sprayer. Many of pyrethrin-based products incorporate the use of synthetic pyrethroids (permethrin, resmethrin, sumithrin, D-*trans*-allethrin) which are added predominantly for residual effects. Permethrin is by far the most common pyrethroid used [40].

The following compounds are used in dogs and cats:

Pyrethrins: Some formulations contain piperonyl butoxide (synergist), *N*-octyl bicycloheptene dicarboximide (synergist), di-*n*-propyl isocinchomeronate (repellent), permethrin, carbaryl, or rotenone. The marketed formulations are spray, foam, dust, shampoo (0.2%), dip, or ear drops, and the target parasites are mainly fleas, ticks, mites, and lice (some products).

Allethrin: This first-generation pyrethroid is a mixture of several optical isomers. It is used in the control of flies, mosquitoes, ticks, and fleas in infested animal quarters.

D-trans-Allethrin: Some formulations contain piperonyl butoxide (synergist), *N*-octyl bicycloheptene dicarboximide, or sumithrin. The marketed formulation is shampoo, and the target parasites are fleas and ticks.

Permethrin: Is an extremely active insecticide with rapid "knockdown" effect against a variety of insects (fleas and ticks). Permethrin is marketed in a diversity of formulations such as collar (0.8–1.5%), topical concentrate (spot-on), spray (0.2–1%), shampoo (1%), dip, or cream rinse. Some formulations of permethrin contain furthermore piperonyl butoxide, *N*-octyl bicycloheptene dicarboximide, di-n-propyl isocinchomeronate, pyrethrins, pyriproxyfen, or butoxypolypropylene glycol (repellent).

Tetramethrin: This compound is available in a total release fogger in combination with permethrin to kill cockroaches and fleas in pet sleeping areas. Moreover, it is used in dogs as solution (at concentration of 0.6%) and as shampoo (at concentration of 0.2%).

Resmethrin: This pyrethroid shows excellent “knockdown” effect and is marketed for use in sprays and shampoo, fleas and ticks being the target parasites.

Other pyrethroids used in dogs and cats are cyfluthrin, cypermethrin (solution, 5%), deltamethrin (collar, 4–4.5%), fenvalerate (solution 6%, to dilute in water), flumethrin (collar, 4%), and phenothrin (shampoo, 0.25%) [4]. Flumethrin (4.5%) in combination with imidacloprid (10%) as a neonicotinoid has been introduced as insecticidal, acaricidal and repellent in collars for dogs (from 7 weeks of age) and cats (from 10 weeks of age); this combination is effective against fleas (*Ctenocephalides felis* and *canis*) and *Pulex irritants* of dogs and cats, ticks of dogs and cats and for treatment of biting/chewing lice (*Trichodectes canis*) infestation of dogs.

To reduce exposure, keep pets indoors during and for about 30 min after spraying. Pets that remain outdoors could be exposed to small amounts of pyrethroids, but would not be expected to experience adverse health effects from spraying. These compounds should not be applied to kittens less than 4 weeks old or the suckling puppies.

7 Toxicity

7.1 Toxicity in Domestic Animals

Dermal shampoos, spot-on type products, and collars containing insecticidal ingredients for the control of fleas and ticks are habitual on household pets. Cats are more likely than dogs to develop pyrethroid toxicosis. Cats, especially young animals less than 6 weeks of age, are particularly sensitive to the toxic effects of synthetic pyrethroids as they have low ability to conjugate these compounds through glucuronide conjugation. Most brands of permethrin spot-on products are restricted to use in dogs only. Inappropriate use of permethrin spot-on on cats can cause severe toxicity. These permethrin compounds may be obtained over the counter in grocery stores or pet stores. Permethrin toxicity usually occurs when the owner applies the dog spot-on product highly concentrated (45–65%) to the cat; however, cats which actively groom or engage in close physical contact with recently treated dogs may also be at risk of toxic exposure. The severity of permethrin toxicity varies with each individual animal. Some cats develop signs when only “one drop” is applied, while others show no clinical signs after an entire vial is used. Overall, overdosing small pets is easier than overdosing large pets due to the larger body surface to weight ratio of smaller pets [43]. Animals with small body mass and high hair density are more susceptible to poisoning due to the great surface area created by the hair. If dogs are accidentally sprayed in the mouth, the risk for poisoning increased from 60- to 150-fold. Onset of clinical signs is usually within a few minutes to hours after exposure but may be delayed up to 24 h (i.e., as a result of prolonged exposure from dermal absorption or grooming), and effects lasted in some cases for 3 days or more. The most common clinical signs of permethrin toxicity in cats are muscle tremors and seizures. Hypersalivation, depression, vomiting, anorexia, and even death may also be seen. Most cats affected by pyrethroid poisoning are presented as an emergency; the patient should be stabilized if hypothermia or hyperthermia is present [4].

In a retrospective study of 87 cases of pyrethrin and pyrethroid intoxication in cats, central neuropathies were reported to be the most common clinical signs [44]. Central neuropathies manifested primarily as hyperexcitability, tremors, or convulsions and occurred in 69% of intoxicated cats. Skeletal muscular weakness and fasciculations, which are signs of peripheral neuropathies, occurred in 28% of affected cats. Clinical signs were evident only in cats younger than 4 years of age, with more than half the intoxicated cats younger than 12 months. In a review of 286 cases reported to the Veterinary Poisons Information Service regarding inappropriate feline exposure to permethrin spot-on preparations, 96% were symptomatic. Increased muscular activity was common and occurred in 87% of cases. Death occurred in 10.5% of cases [45].

The clinical signs of pyrethroid acute toxicity are similar in dogs, cats, and large animals. The main circumstances of poisoning are excessive use of flea control sprays or dips which can lead to overdosed dermal exposure or accidental ingestion of concentrated pesticides by livestock. Clinical signs observed in pyrethroid intoxication include salivation, vomiting, hyperexcitability, hyperesthesia, tremor and seizures, dyspnea, prostration, and death. The signs begin in all animal species within minutes to hours (24–72 h) of exposure, depending on the route of exposure. Clinical signs generally last 2–3 days [4].

7.2 Toxicity in Aquatic Organisms

Pyrethrins and pyrethroid products are highly toxic for fish. It is known that the relatively high toxicity of pyrethrum and pyrethroids to fish and invertebrates is in part due to high density of specific binding sites that are much less prevalent in higher vertebrates. Moreover, toxicity of pyrethrum and pyrethroids was indirectly related to temperature (i.e., greater insecticidal effect when the temperature is lowered) and directly related to pH and water hardness [46]. However, the biological activity of several pyrethroids was not significantly altered by pH. In several countries, sheep are treated for various infestations of external parasites by immersion (plunge dipping). The practice of treating sheep in this way has been carried out for over 100 years. In EU, the number of active substances used in sheep dips has been reduced over the years. There were only two left on the market: diazinon, an organophosphorus compound, and cypermethrin. Both of these are acutely toxic to nontarget organisms in the environment particularly invertebrates and fish [47]. In general, pyrethrins and pyrethroids bind tightly to particulate organic matter, and also pyrethrins bind tightly to soil and rely, to a large extent, on photolysis for degradation. The pyrethroids in aquatic acute toxicity studies can reach LC_{50} values of less than 1 μg/L, and can cause chronic toxicity at concentration as low as 0.01 or even 0.001 μg/L. Pyrethroids dumped into dishes can kill fish and other water organisms.

8 Maximum Residue Limits and Drug Withdrawal/ Withholding Periods

A critical factor in the medication of all food-producing animals is the mandatory withdrawal/withholding period, defined as the time during which drug must not be administered prior to the slaughter of the animal for consumption. The withdrawal period is an integral part of the regulatory authorities' approval process and is designed to ensure that no significant drug residue is present in the animal at slaughter. Drug residues in food-producing animals should comply with the MRL values for their target tissues in the animal species. The withdrawal period is intended to ensure that no harmful residues remain in edible tissues (muscle, liver, kidney, skin + fat, milk, eggs, or honey) after slaughter, and it is usually established as the slaughter time when residue levels in all the edible tissues are below the MRL. Adherence to the withdrawal period provides assurance that food derived from treated animals will not exceed the MRL (termed "tolerances" in the USA) for the drug substance. Failure to keep the preslaughter withdrawal period while using animal drug is the major cause of violation of permissible drug residues in animal meat in the EU. Even if the withdrawal period involves only a few days or a few hours, the resulting residues can violate the national regulations against sale of adulterated foodstuffs which can originate distortions of competition between member states of the EU. Human food safety can have a significant impact on the withdrawal time of a drug which might make it unacceptable in the market [48].

Article 14(7) of Regulation (EC) No. 470/2009 [49] states "where it appears necessary for the protection of human health, the classification shall include conditions and restrictions for the use or application of a pharmacologically active substance used in veterinary medicinal products which is subject to a MRL, or for which no MRL has been set" (e.g., not for use in animals from which milk or eggs are produced for human consumption).

Under EU legislation (Article 14(2) of Regulation (EC) No. 470/2009) [49], the classification of pharmacologically active substances shall also establish, in relation to each such substance, and, where appropriate, specific foodstuffs or species, one of the following: (1) an MRL, (2) a provisional MRL (pending further data), (3) the absence of the need to establish an MRL, and (4) a prohibition on the administration of a substance. Those substances included in Annex I, II, or III of Council Regulation (EEC) No. 90/2377 [50] are listed in the Annex of Commission Regulation (EC) No. 37/2010 [51] (Table 137.1, allowed substances, where the pharmacologically active substance, marker residue, animal species, MRL value, target tissues, other provisions (according to Article 14(7) of Regulation (EC) No. 470/2009) [49], and therapeutic classification are listed, and Table 137.2 (prohibited substances) (where an MRL cannot be established)). This classification substitutes the four annexes of Council Regulation (EEC) No. 2377/90 [48].

The EU MRL values for pyrethroids in food-producing animals are listed in Table 137.2.

Table 137.2 EU MRLs for pyrethroids as antiparasitic agents [Regulation (EU) No 37/2010 of 22 December 2009]

Pharmacologically active substance(s)	Marker residue	Animal species	MRLs	Target tissues	Other provisions
Alpha-cypermethrin	Cypermethrin (sum of isomers)	Bovine, ovine	20 µg/kg	Muscle	For milk MRL further provisions in Commission Directive 98/82/EC are to be observed
			200 µg/kg	Fat	
			20 µg/kg	Liver	
			20 µg/kg	Kidney	
			20 µg/kg	Milk	
Cyfluthrin	Cyfluthrin (sum of isomers)	Bovine, caprine	10 µg/kg	Muscle	For milk further provisions in Council Directive 94/29/EC are to be observed
			50 µg/kg	Fat	
			10 µg/kg	Liver	
			10 µg/kg	Kidney	
			20 µg/kg	Milk	
Cyhalothrin	Cyhalothrin (sum of isomers)	Bovine	500 µg/kg	Fat	For milk further provisions in Council Directive 94/29/EC are to be observed
			50 µg/kg	Kidney	
			50 µg/kg	Milk	
Cypermethrin	Cypermethrin (sum of isomers)	All ruminants	20 µg/kg	Muscle	For milk further provisions in Commission Directive 98/82/EC are to be observed
			200 µg/kg	Fat	
			20 µg/kg	Liver	
			20 µg/kg	Kidney	
			20 µg/kg	Milk	
		Salmonidae	50 µg/kg	Muscle and skin in natural proportions	

(*continued*)

Table 137.2 (continued)

Pharmacologically active substance(s)	Marker residue	Animal species	MRLs	Target tissues	Other provisions	
Deltamethrin	Deltamethrin	All ruminants	10 μg/kg	Muscle	No entry	
			50 μg/kg	Fat		
			10 μg/kg	Liver		
			10 μg/kg	Kidney		
			20 μg/kg	Milk		
		Fin fish	10 μg/kg	Muscle and skin in natural proportions

	Not applicable	Bees	No MRL required	Not applicable	No entry	
Permethrin	Permethrin (sum of isomers)	Bovine	50 μg/kg	Muscle	For milk further provisions in Commission Directive 98/82/EC are to be observed	Antiparasitic agents/ agents against ectoparasites
			500 μg/kg	Fat		
			50 μg/kg	Liver		
			50 μg/kg	Kidney		
			50 μg/kg	Milk		
Tau-fluvalinate	Not applicable	Bees	No MRL required	Not applicable	No entry	No entry

9 Conclusion/Prospects

Pyrethrins and synthetic pyrethroids are considered as very effective insecticides and acaricides for the treatment of a broad range of ectoparasites in veterinary medicine such as fleas, flies, mite, lice, and ticks between other infestations both outside and inside the house. Insects and acari are distributed worldwide, and they are vectors of important diseases in animals and humans. Pyrethrins and synthetic pyrethroids are available in a large number of formulations, in particular spot-on, sprays, dusts, dips (immersion), shampoos, and ear tags. Pyrethrins and pyrethroids are neurotoxic as a result of their availability to bind to sodium channels in the nerve membrane and cause repetitive nervous discharges or membrane depolarization. All pyrethroids share the same basic mechanism of action, but the different types cause somewhat different symptoms. In general, pyrethroids have a broader spectrum, and their residual activity persists longer than that of the natural pyrethrins. Clinical signs associated with acute poisoning with pyrethroids are related to nervous system stimulation. These chemicals are generally of low toxicity to mammals and birds; however, they exert potent acute toxicity to arthropods and are highly toxic for fish. Fish and cats represent the most susceptible animals to pyrethroids. In fish, at the recommended doses, deltamethrin and cypermethrin can be safely used. The concomitant use of pyrethrins and pyrethroids with synergists may increase toxicity by mechanisms involving inhibition of microsomal oxidation. In addition, pyrethroids cause induction and/or inhibition of cytochrome P450 enzymes which may lead to an enhancement of the toxicity and drug interactions. Pyrethrins and pyrethroids should not be used in dogs and cats <6 weeks of age, and when both compounds are utilized as spray, formulations should be used in well-ventilated rooms because inhalation can cause serious adverse effects.

1 Introduction

Because they have a broad spectrum of uses, essential oils (EOs) have many industrial applications in perfumery, cosmetics and detergents, pharmacology, and fine chemistry as well as aromatics for the food industry. They also occupy a significant place to control insect pests and in fact are presently considered to be among most efficient botanicals used as alternative to chemicals. It exists today a societal claim for a friendly environmental use of pesticides that implicates to promote alternative solutions for a better and relevant using of chemicals. EOs take place in the market of biopesticides or BCAs which is expecting to increase to $3.3 billion in 2014 for a 5-year CAGR of 15.6 % (BCC Research; www.bccresearch.com). However, progress has to be done before biopesticides will share with synthetic pesticides the PPP (plant protection products) global market which is estimated at 38,318 billions of USD for 2010 with around 25 % represented by insecticides (9,985 billion USD) [1].

EOs play in fact an important role in the protection of the plants in agricultural and nonagricultural areas (e.g., orchards, gardens). They have a wide range of activities (insecticide, antifeedant, or repellent) against bacteria, virus, and fungi, and also against insects. This chapter is focused on the uses of EOs as biopesticides (BCAs) to control pest insect, the challenges they face, and the factors that nowadays impede their development. After defining the essential oils and their main chemical components, it details their relevant uses to control insect pest insects, including a discussion about their advantages for an ecological friendly approach. Trends and prospects conclude this overview.

2 Essential Oils: Very Complex Natural Mixes

The essential oils have been used since centuries. The first distillation of these products was mentioned during the thirteenth century in Andalusia after which their pharmacological properties induced their inclusion into the very early Pharmacopoeias of several European countries [2].

EOs are biosynthesized by aromatic plants belonging to a few families. They are particularly abundant in conifers, Rutaceae, Umbelliferae, Myrtaceae, Lamiaceae, and Lauraceae. Depending on the species and families, they are localized in specialized histological structures: glandular trichomes (Lamiaceae), secretory canals (Myrtaceae), or resin ducts (Apiaceae). They could be stored in different parts of the plant such as flowers (e.g., *Citrus bergamia*), leaves (*Citronella* spp.; *Eucalyptus* spp.), wood (*Santalum* spp.), roots (*Chrysopogon zizanioides*), or seeds (*Myristica fragrans*) [3].

Essential oils appear to be very complex natural mixes. Terpenoids are major constituents of EOs and, to a lesser amount, phenylpropanoids. EO constituents belong mainly to two phytochemical groups of terpenoids: monoterpenes and sesquiterpenes of low molecular weight. They generally consist of several tens of constituents of which the great majority possess an isoprenoid skeleton. Most of the compounds have ten atoms of carbon (monoterpenes) and 15 atoms of carbon (sesquiterpenes) or more rarely 20 atoms of carbon (diterpenes). Monoterpenes present in EOs may contain terpenes that are hydrocarbons (α-pinene), alcohols (menthol, geraniol, linalool, terpinen-4-ol, p-menthane-3,8-diol), aldehydes (cinnamaldehyde, cuminaldehyde), ketones (thujone), ethers (1,8-cineole e.g., eucalyptol), and lactones (nepetalactone). As the elongation of the chain to 15 carbons increases the number of possible cyclizations, sesquiterpenes have a wide variety of structures (over 100 skeletons). Aromatic compounds are less common and are derived mainly from the shikimate pathway. Some are typical of EOs of particular species, for example, vanillin (*Vanillia* spp.) or estragol (*Artemisia dracunculus* L.). Some compounds identified in EOs result from the degradation of fatty acids (jasmonic acid) or are glycosylated volatile compounds (e.g., linalool glucoside) [3].

The majority of EOs contains a limited number of main compounds, but some of the minor compounds play an important role as vectors of fragrance and make up the richness of an extract. It is thus well established that essential oil composition is very variable depending of the species and of chemotypes within the species and also physiological parameters. As examples, the EO of eucalyptus (*Eucalyptus globulus* Labill.) is characterized by a monoterpene 1,8-cineole and that of coriander (*Coriandrum sativum* L.) by another monoterpene linalool. Thyme (*Thymus vulgaris* L.) is a species with numerous chemotypes named according to the major compound, for example, thyme with chemotype thymol or chemotype carvacrol or terpineol or linalool. A typical EO may contain 20–80 phytochemicals. The analyses of EOs of the African basil *Ocimum canum* Sims contain no less than 80 compounds identified by GS-MS and GS-FID [4].

This complexity of EOs phytochemistry led to a certain inconsistency of the chemical composition of an essential oil. In fact, several factors influence the balance of the compounds within EOs. Terpenoids and isoprenoid are synthesized through secondary metabolism of the plant. Monoterpenes are biosynthesized in plastid via two 5-carbon precursors, that is, isopentenyl pyrophosphate and dimethylallyl pyrophosphate, which condense to give the monoterpenes (10-carbon). The sesquiterpenes (15-carbon) are formed via the mevalonate pathway in the cytosol. Phenylpropanoids are derived mainly from the shikimate pathway [5].

These metabolic pathways do not have the same importance at all stages of the plant development and in all the organs. The physiological development of the plant, its degree of maturity at the harvest, and the choice of the organ to be extracted play a role. Gershenzon et al. [6] showed that limonene and menthone are the major monoterpenes existing in the youngest leaves of peppermint, but limonene content declines rapidly with development of the plant, whereas menthone increases and then declines at later stages. Thus, menthol becomes the dominant constituent. External factors like the climatic and soil conditions or seasonal variations may also change the main compounds identified within an EO. Several studies confirmed that separated geographic areas led to observe different chemotypic races or populations [7]. Isman and Machial [8] reported that rosemary oil extracted from plants harvested in two different areas of Italy contained 1,8-cineole concentrations ranging from 7 % to 55 % and α-pinene concentrations ranging from 11 % to 36 %.

The variability of the composition of an EO is also impacted by the choice of the method of extraction of EOs. One characteristic of EOs is the volatility of their compounds which allows them to be easily extracted by water vapors, in contrast to fixed lipid oils and essences (concrete, absolute, oleoresins, and resinoids) which are extracted by solvents and alcohol. Guenther [9] distinguished three kinds of water and steam distillation methods for obtaining essential oils. These methods are far more restrictive than more recent extraction and separation methods which are mentioned in the European Pharmacopoeia [10] using supercritical fluids, steam distillation, dry distillation, or mechanical cold pressing of plants.

The diversity in the EOs phytochemical composition induces as a consequence that the production of a standardized product is a real challenge for their commercialization.

3 Insecticidal Activities of EOs

An abundant literature, more than 2,000 scientific papers, is devoted to study the EO-insect relationships. Among these, some major reviews would be mentioned [11–15].

3.1 Diversity of Activities on Insect Targets and Routes of Exposure

The insect control by EOs is the result of several kinds of modes of action and depends on the routes of the exposure. EOs develop toxicities by ingestion or contact through cuticle or inhalation for volatile compounds. Some EOs repel the insect or are deterrent or antifeedant. Others disturb oviposition or disrupt the larvae growth or modify the imago's behavior or physiology. In fact, the activities the EOs exert on an insect could impact several physiological targets at the same or at different stages of the insect development. This complexity in the way they act is illustrated by the numerous following examples.

Early studies were mainly focused to observe the activities of EOs and their volatile constituents on insects of the stored products. Twenty-two essential oils were extracted mainly from Lamiaceae and Umbelliferae families and showed a range of LC_{50} from 2 to more than 300 mg dm^{-3} air on the bruchid *Acanthoscelides obtectus* (Say) imagos [16]. Some EOs produced also ovicidal and larvicidal activities and consequently inhibited the reproduction of the insect [17]. From Lamiaceae were extracted the most efficient of those EOs, that is, thyme (*T. vulgaris*) and wild thyme (*Thymus serpyllum* L.), rosemary (*Rosmarinus officinalis* L.), summer savory (*Satureja hortensis* L.), oregano (*Origanum vulgare* L.), and sweet basil (*Ocimum basilicum* L.), which also had an antifeedant effect on larvae inside artificial seeds [18]. This beetle *A. obtectus* has been shown to be a convenient model to point out with accuracy which reproductive stage is targeted and which is the speed of the activity of essential oils. Table 138.1 shows that the fumigant toxicity of EOs on imagos and reproduction could be quite different. As an example, parsley *Petroselinum sativum* L. [Umbelliferae] did not have significant fumigant toxicity on the beetle adults but inhibited strongly its reproduction, whereas the *Satureja hortensis* presented a high toxicity on adults but inhibited poorly the bruchid reproduction. In the same way, some EOs produced fumigant toxicity and antifeedant effect with variable intensity (e.g., mint *Mentha piperita* L., bay tree *Laurus nobilis* L. or dill *Anethum graveolens* L.).

A lot of EOs protected stored grains against the damages of Coleoptera. EOs of sweet basil, of patchouli (*Pogostemon* spp.), of *Eucalyptus* spp., of thyme, and of African basil with its major component linalool were toxic to Mexican bean weevil *Zabrotes subfasciatus* Boheman, rice weevil *Sitophilus oryzae* L., lesser grain borer *Rhyzopertha dominica* Fab., drugstore beetle *Stegobium paniceum* L., bean weevil *Acanthoscelides obtectus* Say, red flour beetle *Tribolium castaneum* Herbst, and pulse beetle *Bruchus chinensis* L. [19–21]. The toxic effect of essential oils is not

only suitable for granary insects but also for flying insects. The Lamiaceae *Mentha* spp. and *Lavandula* spp. or *Pinus* spp. (Pinaceae) EOs were noted to be toxic against the green peach aphid *Myzus persicae* and the greenhouse white fly *Trialeurodes vaporariorum* as well as the pear bug *Stephanitis pyri* [22]. Greek aromatic plants, especially from genus *Satureja*, *Origanum*, and *Mentha* (Lamiaceae), prevented egg hatching and provoked prohibition or malformation of the puparium of the flies *Drosophila auraria* [23]. And some of these aromatic Mediterranean plant EOs tested on *A. obtectus* were also toxic to the Mediterranean fruit fly, *Ceratitis capitata*, and the cereal aphids *Rhopalosiphum padi* and *Metopolophium dirrhodum* [24]. More recent studies demonstrate that a wide range of insect taxa are affected by EOs. Park et al. [25] demonstrated the fumigant activity of EOs of *Schizonepeta tenuifolia* (Lamiaceae) against the sciarid fly *Lycoriella america*. Papachristos et al. extended the studies of the toxic effect of Mediterranean plants' EOs on *C. capitata* with this of citrus peel [26]. In the same way, Liu et al. [27] extended previous works observing the toxicity of EOs to the four major stored-product insects: *Tribolium castaneum*, *Sitophilus zeamais*, *R. dominica*, and sawtoothed grain beetle *Oryzaephilus surinamensis* [28]. They determined the fumigant toxicity of the water dropwort *Ostericum sieboldii* (Apiaceae) EOs with LC_{50} values of 27.4 mg dm^{-3}air (*T. castaneum*) and 20.9 mg dm^{-3} air (*S. zeamais*). Extracted oils from leaves and bark of Chilean laurel *Laurelia sempervirens* (Atherospermataceae) and *Drimys winteri* (Winteraceae) carried on fumigant activities of EOs against the aphid *Acyrthosiphon pisum* [29].

Besides fumigation, other routes of penetration of EOs are effective. Coleopteran insects, maize weevil *Sitophilus zeamaïs* (Motschulsky), *T. castaneum*, and larger grain borer *Prostephanus americana* (Horn) were very sensitive to topical applications of the *Citrus* spp. essential oils [30]. EOs decimated numerous agricultural pest insects and affected disease-vector insects as well. The Annonaceae *Dennettia tripetala* EOs decimated a wide range of agricultural pest insects, for example, the American cockroach *Periplaneta americana* and the grasshopper *Zonocerus variegatus* [31]. The Myrtaceae *Eucalyptus saligna* EOs killed lice *Pediculus capitis*, mosquitoes *Anopheles funestus*, bed bugs *Cimex lectularius*, and American cockroach *Periplaneta orientalis* within 2–30 min [32].

Antifeedant effects could decimate insects too, but the insects' decision to avoid feeding on a plant could be influenced by such factors as phagodeterrency of the substances, post-consumption physiological stress, or a repellent effect, and it is not always easy to discriminate them. Laboratory choice tests were conducted to evaluate the antifeedant effect of pine EOs and terpenes for the weevil *Hylobius pales* [33]. Discriminant assays were developed to observe the deterrent activity of EOs of *Minthostachys mollis* (Lamiaceae) and *Melaleuca quinquenervia* (Myrtaceae) essential oils on the flour beetle *T. castaneum* [34]. These assays were conducted to screen the antifeedant activity of Uruguayan plants that belonged to Bignoniaceae (*Clytostoma callistegioides*, *Dolichandra cynanchoides*, *Macfadyena unguis-cati)*, Sapindaceae (*Dodonaea viscosa*, *Allophylus edulis, Serjania meridionalis*), Lamiaceae (*Salvia procurrens*, *Salvia guaranitica*; Solanaceae: *Lycium cestroides*), and Phytolaccaceae (*Phytolacca dioica*) against the specialist Coccinellidae *Epilachna paenulata* and the larvae of the generalist Lepidoptera *Spodoptera littoralis* [35].

Since the last 25 years, repellent effects of EOs were also fully described with plants of all continents. The Indian plant *Adhatoda vasica* (Acanthaceae) EOs exhibited repellent activity ag*ainst S. oryzae and B. chinensis* [36]. Essential oils of Kenyan plants *Ocimum suave* (Lamiaceae) and *Lippia* spp. (Verbenaceae) repelled *S. zeamaïs* [37, 38], and *Acorus calamus* (Araceae) EOs *T. castaneum* [39]. Wang et al. [40] revisiting the traditional use of a very common weed in China *Artemisia vulgaris* to protect stored products showed the repellent activity of this EO to the Tenebrionidae *Tribolium castaneum*. In Europe, Kalemba et al. [41] demonstrated that EOs from the berries of the Cupressaceae *Juniperus communis* were a very good mosquito repellent. A review recently gathered the numerous studies published during the last 10 years on the repellent effect of EOs [42].

Nevertheless, if a lot of essential oils are repellent, some have been found to be highly attractive [10, 12]. The attractiveness of sandalwood oil, basil oil, and grapefruit oil in yellow sticky traps improved the number of trapped greenhouse whitefly *Trialeurodes vaporariorum* Westwood [43]. Cade oil, an essential oil produced by destructive distillation of juniper (*Juniperus oxycedrus L.*) twigs, synergized the attraction of alpha-ionol to tephritid fruit fly *Bactrocera latifrons* (Hendel) male [44].

Some essential oils develop a combined activity on the insects, for example, EOs of *Ocimum* spp. exhibited both a repellent and a larvicidal action [45]. *Acorus calamus* EO and its active ingredients, asarone and its analogues, were both antifeedant and potent growth inhibitors to the variegated cutworm *Peridroma saucia* (Lepidoptera: Noctuidae) [46]. It has also been shown that some essential oils exert quite opposite effects on different insect species. As an example, the tansy (*Tanacetum vulgare* L.) EOs impacted in different ways the following three beetles: it was attractive and paralyzing for *Rhizoperta dominica*, repulsive for *Tribolium confusum*, and toxic for *Sitophilus americana* [47].

A difference could be made between accurate and chronic toxicity. A short (24-h) exposure to tansy oil exerted an antifeeding activity in larvae and significantly decreased egg laying in adult females of obliquebanded leafroller (*Choristoneura rosaceana*), while the chronic (long-time exposure) of this EO mixed into the diet during 75 days decreased significantly larvae survival rate [48].

Besides the variability of the phytochemical composition of EOs mentioned above, the point is that insects vary enormously in their responses to secondary plant products. It is well known that the sensitivity of different insect species could be quite different for the same substance [11]. Oils from *Cymbopogon nardus* which killed quickly the bruchid *A. obtectus* [12] only knocked down and disabled the Angoumois grain moth *Sitotroga cereallela* [49].

From all these observations, it could be deduced that essential oils present a widespread range of activities on insects that necessitate to be sharpened by a case-by-case study before application in pest management. Because of the chemical complexity of essential oils and the variability of sensitivity of the insect species, to be significant, the comparison of the toxicity of essential oils necessitates an evaluation which must be (1) conducted with samples of an EO having a quite similar phytochemical composition at each test and (2) experimented on homogenous insect populations.

3.2 Mechanisms of Action

Although the effects of EOs for insect control are abundantly studied, a very few researches are devoted to understand the mechanisms of these observed effect. They involve both physical and chemical properties of EOs. An update was recently published on this point [15].

Because oils are lipophilic, a topical application of EOs laid a film on insect cuticle that modifies the physiology of the insect. The film changed the conditions of penetration inside the body of insect of the air and of substances because of the disruption of lipid bilayers of cell walls. A review on the biological and pharmacologic effects of EOs was recently documented [50].

The second point is linked with volatility of monoterpens. Because they are small volatile molecules, they are involved in the transmission of airborne signals from plants to insects. Detection of bouquets of fragrant and chemosensory-active compounds by insects involves different families of proteins, including OBPs and chemosensory proteins (CSPs). OBPs and CSPs are found on the periphery of the sensory receptors and function in the capture and transport of molecular stimuli [51]. In the sensilla of insects, specialized odorant binding proteins (OBPs) respond to volatile monoterpenes. For example, trichoid sensilla of the female silkworm, *Bombyx mori*, respond to linalool [52]. In moths, the OBPs include proteins that bind general odorants GOBPs (general odorant binding proteins) such as volatile compounds from plants. The protein identified in tobacco hornworm *Manduca sexta*, GOBP2, preferentially interacts with floral aromas and green plant odors such as [Z]-3-hexen-1-ol, geraniol, geranyl acetate, and limonene [53]. The different types of GOBPs serve to detect the different categories of odorants released by plants and play an important role in the response of the insect to an EO blend.

Several monoterpenoids (thymol, α-terpineol, linalool, geraniol, eugenol), which have been identified as important components of essential oils, induce a neurotoxicity. The mechanisms of this neurotoxicity have now been explored. They involve receptors of nervous system. Huignard et al. [54] described several different types of receptors which are playing a role. Thymol binds to GABA receptors associated with chloride channels located on the membrane of postsynaptic neurons and disrupts the functioning of GABA synapses [55]. Eugenol acts through the octopaminergic system by activating receptors for the neuromodulator octopamine which increases the concentration of cAMP. This AMPc increase was inhibited in the presence of a mixture of eugenol, α-terpineol, and cinnamic alcohol, but low doses of eugenol and octopamine lead to an increase in adenyl cyclase activity of cells in the nervous system of the cockroach *Periplaneta americana* [56]. Further studies on cultures of brain cells of *P. americana* and of *Drosophila melanogaster* demonstrated that eugenol mimics the action of octopamine with the consequence to increase intracellular calcium levels [57]. The cytotoxicity of EOs through the octopaminergic system was also demonstrated in cultures of epidermal cells of *Helicoverpa armigera* [58]. Thymol, carvacrol, and α-terpineol influence the production of cAMP and calcium at the cellular level in *D. melanogaster*. In this insect, tyramine receptors are involved in the recognition of monoterpenes (tyramine is a precursor of octopamine) [59].

Some EOs and their constituents also act on the transmission of the nervous impulse. Price and Berry [60] conducted electrophysiological experiments which showed that eugenol inhibits deeply neuronal activity, whereas citral and geraniol have a biphasic effect that is dose dependent. At low doses, these compounds induce an increase in spontaneous electrical activity but at high doses cause a decrease. Using a similar electrophysiological experimentation, Huignard et al. [54] observed that *O. basilicum* EOs have a complex neurotoxic activity. The neuronal electrical activity was fully inhibited by the EO which decreased the magnitude of nerve-action current and also reduced the post-hyperpolarization phase and the frequency of nerve-action current firing. The authors hypothesized that this effect could be the result of the combined action of linalool and estragole, two major components of the *O. basilicum* EO. The mere application of pure linalool in fact produced a reduction in the amplitude of nerve-action current and decreased the post-hyperpolarization while estragole specifically induced a reduction of post-hyperpolarization.

This activity of EOs on nervous system involves also another well known target for neurotoxicity, the enzyme acetylcholinesterase. Tea tree oil inhibited acetylcholinesterase [61]. Lopez and Pascual-Villalobos [62] demonstrated that several types of inhibition are involved with monoterpenes. It could be the result of a reversible competitive inhibition occupying the hydrophobic site of the enzyme's active site or of a mixed inhibition by linking to a different site from the active site where the substrate bounded.

These studies confirm that the insecticidal activity of EOs and monoterpenes, which are among the major components of EOs, is the consequence of several mechanisms that affect multiple cellular and physiological targets.

4 Trends for the Development of EOs as BCAs

One of the most attractive features of EOs is that they are, in general, low-risk products which provide a friendly environmental pest management. They develop many ecological advantages, but if the pros prevail, some unintended effects have to be mentioned.

4.1 Benefit-Risk Ratio for Environment

On an ecological point of view, EOs present several advantages that could consider them to be useful complementary or alternative method to the intense use of chemical insecticides. Because they are natural and most compounds they included are volatiles, they are biodegradable with short half-life. The AOPWIN Program for alpha-pinene, beta-pinene, camphene, and trans-pinane gave half-life in air ranging from 1.4 to 9.4 h [63]. One of the most common constituents of EOs, α-terpineol, has a short half-life of 4 h in air, 466 h in surface water, and 2 days in soil where it is degradable by soil microflora [64]. This biodegradability induces little persistence in the environment, and in contrast to some synthetic insecticides, no bioaccumulation or biomagnification has been reported to date. As a consequence, this could improve the biodegradability of insecticide treatments and therefore decrease the quantity of toxic insecticide residues not only in the environment but also for food and feed.

EOs generally affect very specific physiological and cellular target. Therefore, they increase insecticide selectivity, and most of the time, by comparison to classical pesticides, the hazards and unintended effects on nontarget species appear to be limited. Very few works, however, were devoted to study the environmental fate and pathways of EOs as well as their effects on agricultural nontarget arthropods. Requiem® is a *Chenopodium* EO-based biopesticide recently registered in the United States [65]. It is used as insecticide against thrips (*Frankliniella occidentalis*), green peach aphid, and the greenhouse whitefly (*Trialeurodes vaporariorum*) and as acaricide against the two-spotted spider mite and the European red mite *Panonychus ulmi* [66, 67]. Bostanian et al. [68] demonstrated that Requiem® is also operational against two beneficial arthropods used as BCAs, the anthocorid minute pirate bug *Orius insidiosus* and the micro-Hymenoptera *Aphidius colemani* which currently control thrips in flower and vegetable greenhouses and also the aphid *Rhopalosiphum padi*. In Africa, Huignard et al. [69] have shown that EOs of citronella and sweet basil were not only toxic to the bruchid *Callosobruchus maculatus* but also to its parasitoid *Dinarmus basalis*, thus compromising its biocontrol.

In same way but on plant species, phytotoxic and allelopathic effects have been described. EOs of wild marigold (*Tagetes minuta*) and pepper tree (*Schinus areira*) inhibited roots of maize (*Zea mays*) and thus have allelopathic effect [70]. Dudai et al. [71] observed that *Cymbopogon citratus* or *Origanum vulgare* EOs not only inhibited weed species such as amaranth (*Amaranthus palmeri*) and *Euphorbia hirta* but also the growth of crops such as wheat (*Triticum aestivum*) and tomatoes (*Lycopersicon esculentum*).

These examples demonstrate that in terms of ecotoxicology, EOs are safe to use but not without potential problems. Because of the variability of species sensitivity to EOs, unintended effects on nontarget species could be observed.

4.2 Benefit-Risk Ratio for Human and Animal Health

It is not because they are natural products that the EOs are without any toxicity when they are used in an inappropriate way. The toxicity of EOs is relatively well studied experimentally and clinically because of their use in human and veterinary medicine. This EOs toxicity may result from the mere toxicity of particular components included therein or from synergistic effects between these numerous compounds being in a same extract.

Their mammalian toxicity of EOs is generally low. Most of EOs (e.g., citronella, lavender, clove, eucalyptus, anise, marjoram, etc.) have an oral LD_{50} value ranging from 2,000 to 5,000 mg kg^{-1} in rats. Less than a dozen EOs (e.g., basil, tarragon, hyssop, oregano, savory, tea tree, and sassafras) have LD_{50} values ranging from 1,000 to 2,000 mg kg^{-1}. But a few are toxic to very toxic. EOs of Pennyroyal (*Mentha pulegium* mixed with *Hedeoma pulegiodes*) and *Thuja* spp. have LD_{50} values of 400 and 830 mg kg^{-1}. EO of Boldo (*Peumus boldus*) has LD_{50} value of 130 mg kg^{-1} but causes convulsions at a dose of 70 mg kg^{-1} in rats. The EO of rosemary is also convulsant and can cause epilepsy [2, 72].

Dermal toxicity was observed with some EOs. Tea tree oil is now described since near 15 years to cause skin allergies [73, 74]. Bergamot (*Citrus bergamia*) and angelica (*Angelica archangelica*) EOs are identified to be photosensitizing [75] and EOs of wintergreen (*Gaultheria procumbens*), eucalyptus, clove, and sage to be irritant [76].

In veterinary medicine, some EOs have demonstrated manifestations of toxicity. Dogs dermally exposed to pennyroyal oil at 2 g kg^{-1} exhibited diarrhea, hemoptysis, and epistaxis 30 h after exposure. A histopathologic examination of liver tissue showed massive hepatocellular necrosis caused by a bioactivation of the major component of this oil pulegone into its hepatotoxic metabolite menthofuran. Commercially available shampoos containing the tea tree (*Melaleuca alternifolia*) EO and the pure oil have been sold for use on dogs, cats, ferrets, and horses. Clinical signs of three cats dermally exposed to pure melaleuca EO for flea control were described. They included hypothermia, ataxia, dehydration, nervousness, trembling, and coma. Two cats recovered within 48 h following decontamination and supportive care, but one cat died within 3 days following exposure. Terpinen-4-ol, the main constituent of this EO, was detected in the urine of the cats [77].

These examples underline that some EOs need to be handled with caution despite most EOs are not particularly toxic. It is remarkable that these toxicities of some EOs do not coincide with that of the plant from which they are extracted and whose safety is generally recognized [78]. Because risk includes both hazard and exposure, the use of EOs for biocide or for plant protection effects requires that the applicators follow carefully the labeling recommendations given for each situation. EOs are most often delivered by spraying or fogging that may induce a dermal or respiratory exposure. The need of suitable equipment for handling EO products and the treated plant must be observed to avoid accident or chronic intoxication. The EO risk, whatever minimal is it, must not be ignored simply because EOs are natural products.

4.3 Commercial Prospects and Impediments

The insect control by EOs receives attention very soon. In the years 1980–1990, the patents involving essential oils showed that a majority of the inventions focused on household uses. Japanese companies understood very soon the interest to use EOs in such a way. To prevent reinfestation by Blattarias, particularly the German cockroach *Blatella germanica*, a cleaning solution including clove essential oils and pyrethrinoids [79] and adhesives containing acrylic polymers and high levels of essential oils [80] were commercialized as well as mixtures associated with essential oils and pyrethrinoids to control mosquitoes and flies [81, 82]. *Eucalyptus* spp. EOs were used as a synergistic insecticide in addition to growth inhibitors [83], and EOs of spearmint, bitter almond, and birch (*Betula lenta*) bark essential oils were incorporated into a formulation sold for acaricide, insecticide, and insect repellent properties [84]. Domestic uses prevailed. To prevent the clothes from moths and beetles, filter papers or tablets soaked with EO *Juniperus rigida* were placed in the wardrobe [85]. To protect pet dogs, a flea collar was manufactured by adding essential oils (eucalyptus, cedarwood, citronella, and peppermint) to ethylene-vinyl acetate polymer [86]. To improve resistance to insects, handicraft veneer-faced panels were impregnated with polymer layer and hiba or kinoki EOs [87, 88]. EOs also showed some usefulness for building and hand-manufactured materials. *Eucalyptus* spp. EOs were mixed with pyrethrinoids and borax in a solution to preserve wooden beams [89].

But the important sector in which EOs present applications as insect BCAs, still is the area of agriculture, the stored-product storage and feed. Mustard essential oil was used very soon into formulation containing insecticide, microbicide, and repellent substances absorbed onto silica used to prevent infestation of mites in feed [90]. In Europe, pine EOs were also incorporated in the 1990s with polymers into sheets to develop attractant adhesive films or coating materials to enhance the control of harmful insects in agriculture, livestock structures, and horticulture [91, 92].

Twenty years after, Arnason [93] underlined that essential oils are now considered to be the most important commercial application of botanical insecticides. He indicated that no less that 88 insect repellent products are actually sold in the United States market containing an essential oil as one of the active ingredients in the formulation. Eight EOs are distinguished. The most commonly used ingredient is citronella oil (45 products), followed by geranium oil-geraniol (33 products), lemongrass oil (24 products), cedar oil (22 products), peppermint oil (16 products), rosemary oil (15 products), soybean oil (15 products), and eucalyptus oil (14 products). According to this author, 57 of these 88 formulations contain a blend of two or more active ingredients. Among reasons that facilitate the use of EOs as BCAs, the need to replace methyl bromide, which is considered to deplete the ozone in the stratosphere, renews interest in essential oils as fumigants.

This enhancement of using EOs to control insect pests in orchards and to protect high-value crops is probably the result of the regulation rules in the USA. Because the procedure for regulatory approval of plant protection products is expensive and the market for BCAs appear to be presently a niche market (about 2 % of pesticides global market), industrial producers of BCAs need a simplified procedure for registration to achieve a reasonable return on investment. As indicated by Regnault-Roger et al. [15]: “A reduced regulation process for these products has existed in the United States since 1996 and it is particularly relevant to EOs. Biopesticides are subject to special procedures outlined in Title 40, Code of Federal Regulations, of FIFRA. A number of natural substances, such as EOs of mint, thyme, rosemary, and lemon grass that did not benefit from this simplified procedure, however, were classified as GRAS (generally regarded as safe). They were placed on a list (FIFRA Section 25 [b]), exempting them from the registration process [94].” Paulizt and Bélanger [95] confirmed that this simplified approval procedure has led to a large diversity of EO-based products available in the United States. Moreover, this exemption has become a marketing strategy to promote these products [96, 97]. The company EcoSmart^{TM} was a pioneer, 15 years ago, to develop a line of products on this exemption. These products now are named “EcoEXEMPT$^{®}$ Minimum-Risk & EcoPCO$^{®}$ Products” and are commercialized on a large scale by several suppliers [98].

Compared to United States, only few EO products are available in the European Union [EU] and Canada, where registration is stricter. Pest Management Regulatory Agency [PMRA, Canada] decided in 2004 to deregister citronella products due to a lack of safety data. However, since “Health Canada did not identify any imminent health risks, citronella-based personal insect repellents will remain on the market until a final decision is made” [99, 100], but strict recommendations accompany the use of these products.

In UE, the procedure for reevaluation of plant protection products (PPP) ended in 2008. To be authorized on market, all PPP derived from biological as well as chemical have to be listed in Annex 1. Because they meet the purposes of Directive 2009/128/CE to promote integrated pest management (IPM), some vegetable oils have been recently authorized but for uses that are not insecticidal [101]: tea tree oil for use as a fungicide, citronella oil as an herbicide, clove oil as a fungicide and bactericide, and spearmint oil as a plant growth regulator. The status of EOs extracted from thyme or marigold (*Tagetes* sp.) for insecticide use is presently pending and should be approved soon. Orange oil is now allowed in France for control of sweetpotato whitefly, *Bemisia tabaci*, on field pumpkin (*Cucurbita pepo*) and of greenhouse whitefly on tomato [102].

The situation for using EOs in developing countries is quite different. The tropical flora of many developing countries is remarkably diverse and can be a rich source of potent and valuable EOs. Aromatic plants are traditionally and widely used for stored-product insects or to repel harmful insects in fields. Currently, there is a move to enhance the use of steam-distilled EOs, but the lack of technologic resources leads to use crafty solution like a domestic pressure cooker for extracting EOs by steam distillation. Another point that impedes the proper development of EOs in Africa is that results most of the time are unsupported by scientific experimentation [15]. The promotion of BCAs in developing countries needs more consistent risk analyses as well as stricter regulatory systems.

5 Conclusion

The development of EOs as PPP and biocide to control insect is an alternative or a complementary approach to synthetic insecticides. They are environmentally friendly products, that is, they have natural origin and are biodegradable, and they have diverse physiological targets within insects that may delay the evolution of insect resistance. Thus, they are especially suited to organic farming as well as to integrated pest management. As a result, EOs have been embraced by the public.

Two key points impede their development as BCAs. Because the field of researches is widespread, there is a lack of data on environmental features of EOs and their components and also on plant-insect interrelationships and mechanisms. More fundamental and applied studies are needed; even the publications devoted to EOs improved the last years. The second key point is the difficulty to have a relevant registration both in developed and developing countries. Most of developing countries need to have appropriate and stronger regulation whereas many developed countries need to have adapted regulation. In some countries, it is difficult to meet the consumers demand because of registration requirements. Among the arguments used to seek reduced regulation for EOs is the fact that many active ingredients of EOs are used daily at home or in food. Therefore, it is rather logical to conclude that it would be unreasonable to request heavy and costly registration requirements for these products that have no history of adverse effects [97]. However, the safety of products which are used in a precise context sometimes led to the reality of unintended effects in a new context. As a consequence, an evaluation of the benefit-risk ratio on a case-by-case basis must be required to prevent this undesirable situation and to have a reasonable management of real risk if there is some.

Therefore, most of government policies are now seeking low-risk and alternative plant protection products. The US EPA is the only regulatory regime that has considered reduced risk seriously and, as a result, has allowed a significant number of EOs for commercial use more than 10 years ago. The results of this American position must be checked carefully to determine positive and negative inputs of using EOs in such a way. Because of the numerous advantages of EOs in controlling harmful insects, they certainly have a room in the BCAs approaches which promote sustainable development.

Abstract

Reports on the biological properties of mono- and sesquiterpenes (MTs and SQTs) have been on the increase. Although MTs and SQTs are already in wide use as flavoring and antimicrobial agents in cosmetics, perfumes, household and cleansing products, and food additives, many of their pharmacological properties are yet to be discovered. Studies report on their anticancer, antiinflammatory, antinociceptive, antidiabetic, and antimicrobial activities and effects on the central nervous system that make them potential targets for development of new therapeutics and for usage for medical purposes. This chapter provides an overview of the biological activities and aromatherapeutic uses of chemical classes of MTs and SQTs, compiling the scientific achievements mainly from 2010, 2011, and the first part of 2012. Because hundreds of MTs and SQTs and their derivates exist, only some prominent representatives of MT- and SQT-hydrocarbons, -alcohols, -oxides and -carbonyls are discussed.

Keywords

Abbreviations

AC	Adenylate cyclase
AUC	Area under the plasma level/time curve
cAMP	Cyclic adenosine monophosphate
CAT	Catalase
CB receptor	Cannabinoid receptor
CDK	Cyclin-dependent kinase
CNS	Central nervous system
COX	Cyclooxygenase
CREB	cAMP response element-binding
CYP	Cytochrome P450
E-BCP	(*E*)-β-Caryophyllene
EO	Essential oil
ER	Endoplasmic reticulum
ERK	Extracellular signal-regulated kinase
GABA	Gamma-aminobutyric acid
GI	Gastro-intestinal
HepG2	Human hepatocellular liver carcinoma
HMG-CoA	3-Hydroxy-3-methylglutaryl-coenzyme A
IL	Interleukin
JNK	C-Jun N-terminal kinase
K_{ATP+}	ATP-dependent potassium channels
L-NAME	*N*-(ω)-nitro-L-arginine methyl ester

LPO	Lipid peroxidation
LPS	Lipopolysaccharide
MAPK	Mitogen-activated protein kinase
MAPK p38	Mitogen-activated protein kinase p38
MDA	Membrane lipid peroxidation
MPO	Myeloperoxidase
MT	Monoterpene
NMDA	*N*-methyl-D-aspartate
NFkB	Nuclear factor "kappa-light-chain-enhancer" of activated B-cells
NO	Nitric oxide
NOS	Nitric oxide synthase
PG	Prostaglandin
ROS	Reactive oxygen species
SOD	Superoxide-dismutase
SQT	Sesquiterpene
TNF-α	Tumor necrosis factor alpha
TRP	Transient receptor potential
TRPA1	TRP Ankyrin 1
TRPM8	TRP Melastatin 8
TRPV1	TRP Vanilloid 1

1 Introduction

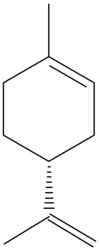
Monoterpenes and sesquiterpenes are small molecules compared with the majority of drugs used in classical pharmacotherapy. N-containing molecules cannot be found among them, which is one reason why terpenic medicines are not usually encountered, except for MT-ic alcohol menthol, which is used as a spasmolytic drug to treat bile problems, along with a few other examples. Nearly all naturally occurring MTs and SQTs are volatile and thus fragrant, rendering them suspicious to the majority of pharmacologists and physicians. Another fact hinders the entrance of these natural compounds into the pool of established medicaments, namely, that they occur as multi-component mixtures in EOs and are therefore not compatible with the so-called "-one-molecule-one-target-" dogma of classical pharmacotherapy (Hannelore Daniel, Oral presentation, entitled: Genetic and Nutrient Determination of the Metabolic Syndrome (Nutrigenomics), 59th Intern. Congress and Annual Meeting of the Society for Medical Plants and Natural Product Research, Antalya, Turkey, 4th–8th September 2011. See also S. Frantz, Nature (2005), 437:942). Thus, the medicinal uses of these terpenes remain in the domain of complementary and alternative medicinal therapies. But the question is offered: "Why should these fragrant, small molecules do not possess other biological, namely therapeutically usable properties?"

As already mentioned, MTs and SQTs are the major components – besides some phenylpropanes and small alkene derivates, the latter often the catabolic products from unsaturated fatty acids – in the EOs that are produced by plants mainly as protection against herbivores, insects, mites, fungi and bacteria, for use as pollinators, or for release when under attack to warn neighboring plants and/or to "cry for help" in order to lure the enemies of the attacking aggressors [1, 2]. The biological properties of EOs and thus also of their constituents have already been covered in reviews by one of the authors [3–7] and other colleagues [8, 9]. Therefore, to avoid a repetition of already discussed material, the present overview focuses on biological activities and aromatherapeutic uses of chemical classes of MTs and SQTs, specifically hydrocarbons, alcohols, oxides, and carbonyls. Because hundreds of MTs and SQTs and their derivates exist, only a few prominent representatives of each class will be discussed. Finally, the term *biological* must be defined, as has already been done in [4]. Therefore, in this treatise the following are not discussed: plant care, inter-plant communication (see also [1, 2]), pheromones (discussed in detail in [10]), veterinary therapeutics, cosmetic uses, perfumes, household and cleaning products, and flavors for food and drinks. Other activities will be partially discussed; they are also covered in [7]. The "penetration enhancement properties" of MTs and SQTs have been excluded here as they are discussed in ▶ Chapter 124, "Terpenes and Improvement of Transdermal Drug Delivery".

2 Hydrocarbons

2.1 (+)-Limonene

(Former: d-limonene, ᴅ-limonene)



One of the most prominent MT-hydrocarbons is (+)-limonene, which occurs in nearly every EO of the citrus oils and is a major compound (up to 97 % [11]) in sweet orange oil (from the peel of *Citrus sinensis* (L.) Osbeck, syn. *Citrus aurantium* var. *sinensis*). Its odor is reminiscent of the typical sweet orange flavor, whereas its antipode (–)-limonene possesses an odor that recalls turpentine [12]. Sweet orange oil achieves its main importance in the flavor and food industry because it is easily obtainable (yield: ~5 % [11]) and due to its pleasant odor, which is accepted by everyone and is caused by the "character impact compound" [13] (+)-limonene. In the past, the use of (+)-limonene has experienced a great expansion. Besides its use in the food industry, it is used as flavor and fragrance additive in cosmetics, soaps, and perfumes, and also in medicine to mask the bitter taste of alkaloids in pharmaceutical products. (+)-Limonene is consumed by people mostly as a natural ingredient in common foods such as oranges and other citrus fruits, juices, vegetables, coffee, meat, and spices [14]. (+)-Limonene is also realizing increasing use in cleaning and disinfection products in both industrial and household products.

There has been increasing interest in the use of EOs as plant-based antimicrobials in the food industry. They are an alternative to synthetic antimicrobials, attractive because of the growing resistance of foodborne microorganisms to synthetic chemicals, and also because these plant-based antimicrobials are less expensive and more environmentally friendly. Singh et al. [15] confirmed the use of (+)-limonene as a plant-based antimicrobial and, due to its antioxidative effects, a food preservative. They investigated the antifungal, antiaflatoxigenic, and antioxidant activity of EOs of the leaves of *Citrus maxima* Burm. and of the peels of *Citrus sinensis (L.) Osbeck*, and the 1:1 combination of them. The major components, analyzed by GC-MS, in the oil of in *C. maxima* were 31.8 % DL-limonene and 17.7 % *E*-citral; in the oil of *C. sinensis*, DL-limonene represented 90.7 % followed by 2.8 % linalyl acetate. The 1:1 combination contained 69.8 % of DL-limonene. An antifungal assay was first performed due because fungi are among the major destroyers of food that is being stored. The results showed, according to ANOVA and Tukey's comparison test, that the EOs were in all concentrations effective compared with a control. A broad fungitoxic spectrum was established. Furthermore, the efficacy of suppression of aflatoxin production was investigated and at 500 ppm the EOs of *C. maxima, C. sinensis*, and their combination, showed a complete inhibition of AFB1 production and AFB1.

The antioxidant activity was observed by DPPH radical scavenging assay on TLC, which proved the strong antioxidative effect. Tests on mice showed a high value for LD50, which confirmed the safety of oral consumption. (+)-Limonene is generally recognized as safe (GRAS) by the US FDA. By oral consumption it has a relative small toxicity, although when applied in high concentrations it may cause dermal irritation [16].

Because limonene possesses such strong antioxidant activity, it could potentially provide protection from diseases caused by oxidant damage, for example, cancer.

Previous studies in rats and mice showed that limonene prevented the growth of tumors in chemical-induced carcinogenesis models.

Roberto et al. [14] analyzed the effect of limonene on proliferation of normal lymphocytes and its connection to the H_2O_2 level and its effect on the cell antioxidant enzymes (catalase, peroxidase, and superoxide dismutase). H_2O_2 has a large impact on the process of growth and death of cells. In small concentrations it stimulates cell proliferation, whereas in higher concentrations proliferation is decreased. H_2O_2 also is connected with damaging the DNA and genetic mutations. The results showed that, at low concentrations, limonene decreased H_2O_2, whereas in higher concentrations the level increased.

The enzymes peroxidase and catalase reduce the concentration of organic hydroperoxides and hydrogen peroxides, whereas superoxide dismutase generates H_2O_2. Limonene presented its activity relative to the applied concentrations.

Limonene applied in low concentrations leads to an increase of catalase and peroxidase, which then leads to decrease of H_2O_2 and vice versa. In addition, limonene can stimulate cell proliferation through decreasing the level of H_2O_2 by increasing the activity of the enzymes catalase and peroxidase. Limonene also protected the cells from oxidative damage when H_2O_2 was exogenously added.

Chaudhary et al. [17] investigated the exact mechanism of how limonene provides its antitumor effects. The chemopreventive and chemotherapeutic effects of D-limonene were tested against chemically induced tumors in female Swiss albino mice. The development of the tumors was initiated by DMBA (7,12-dimethylbenz-[a]anthracene) and promoted by TPA (12-*O*-tetradecanoylphorbol-13-acetate). DMBA and TPA activate a few carcinogenesis pathways. One way is by triggering the Ras-ERK pathway; another is the genetic mutagenesis made by ROS that are generated by TPA. As mentioned in the study above, the activity of antioxidative enzymes is reduced and there is an up-regulation of proinflammatory genes such as COX-2. Limonene showed significant results: by reducing the edemas and hyperplasias that were chemically induced, it reduced COX-2 expression, the activity of ornithine decarboxylase while the level of antioxidant enzymes was increased, and the amount of [3H] thymidine incorporated in the genetic material reduced. A topical treatment with d-limonene, prior to TPA alleviated the TPA-induced increase of COX-2 enzymes, which implies that COX-2 might be a potential target for d-limonene.

A significant inhibition of the Ras/Raf/ERK signaling pathway can be confirmed, which is also connected to a suppression of the induced down-regulation of Bax and up-regulation of Bcl-2. Namely, when ERK is activated, it has activating effects on proteins such as transcription factors and other protein kinases. By its inhibition, it affects the expression of apoptotic proteins such as Bim, Bax, and Bcl-2, leading to an apoptosis. By attenuating the inflammatory process, oxidative stress, and Ras-cascade, limonene provided its chemopreventive effect and the induced skin tumorigenesis could be delayed.

One study showed that d-limonene alleviates insulin resistance and liver injuries induced by oxidative stress. Victor Antony Santiago et al. [18] performed their investigations on young, male Wistar rats that were previously fed a high-fat diet together with L-NAME for 8 weeks and subsequently with 2 % (+)-limonene in the last 4 weeks. They examined the effect of (+)-limonene against biochemical and histological alterations of the liver in a high-fat diet and L-NAME-induced metabolic syndrome. Dietary d-limonene supplementation improved the biochemical changes in the liver induced by HDF and L-NAME, especially the hepatic lipid accumulation, liver function indicators, circulatory antioxidants, hepatic histology, and insulin resistance. (+)-Limonene restored the pathological changes of liver and pancreas. These findings indicate the potential therapeutic efficacy of (+)-limonene against the development of NAFLD (nonalcoholic fatty liver disease), especially as a promising complementary treatment. NAFLD is most probably the hepatic manifestation of the metabolic syndrome (linked to obesity, insulin resistance, diabetes type 2, and hyperlipidemia).

> d-Limonene is known to inhibit lipid peroxidation, arrest the free radical-induced damage and prevent physical stress, psychological stress, stress-induced hypertension, and stress responses in stroke-prone spontaneously hypertensive rats. d-Limonene is also known to regulate the development of pulmonary hypertension, induce glutathione (phase II detoxification) and inhibit 3-hydroxy-3-methylglutaryl coenzyme A(HMG-CoA) reductase activity. In addition, d-limonene is reported to exert potent biological activities, such as antioxidant properties, chemopreventive or chemotherapeutic properties against many types of cancers, antiinflammatory properties, hepatoprotective activities and immunomodulatory effects. [18]

Limonene also shows other effects on the cellular metabolism. Park et al. [19] came, in their study, to the conclusion that limonene binds directly to the adenosine A2a receptor. This leads to the activation of receptor-mediated signaling pathways – the increase of the cytosolic cAMP concentration and activation of protein kinase A – and further to the phosphorylation of the CREB transcription factor. Through binding on the adenosine A2a receptor, limonene also increased the intracellular calcium level. Both these effects are typical for agonists of the receptor, which leads to the conclusion that limonene also acts as an agonist on the A2a receptor. The ligands of A2a receptors have, in general, an impact on the inflammation process through modulating the release of the pro- and anti-inflammatory cytokines, so they act as a potential protection of tissue injuries. Therapeutically, they can be used as potential sleep inducers due to their effects in sleep regulation. This holds implications for the possible sedative effects of limonene. The activation of the receptor has also influence on the cardiovascular system.

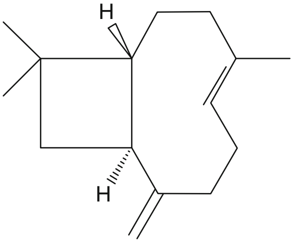
Fletcher [20] investigated the effects of (+)-limonene and its metabolites perillyl alcohol, perillaldehyde and perillic acid on the membrane lipid bilayer. The effect was assessed by bilayer-spanning gramicidin (gA) channels using two methods. The first was a fluorescence assay, which showed that at micromolar concentrations (+)-limonene decreased the gA channel activity and all its metabolites (except perillic acid, which had no effect) increased the activity. The second method, using single-channel electrophysiology, showed, however, that each terpene increased the lifetime and occurrence of the gA channel. Thus the disagreements appeared between (+)-limonene and perillic acid using these two methods; nevertheless, these terpens have been confirmed to have significant bilayer-modifying potential.

Limonene also has an effect on the central nervous system. Further studies have shown the relaxant properties and anxiolytic effect of EO of *Citrus sinensis*, suggesting a possible depressant activity of these constituents [21]. De Almeida et al. [22] analyzed the effects of (+)-limonene epoxide on the CNS of male Swiss mice.

(+)-Limonene epoxide is synthesized from (+)-limonene and is a mix of cis and trans-isomers that are found in many plants. It has been shown to have antitumor and antinociceptive activities. In the study, the acute toxicity of (+)-limonene epoxide in mice was examined, showing, dose-dependence and relatively good safety, though it fell into the group of slightly toxic substances. Furthermore, the anxiolytic, sedative, and motor coordination effects were investigated using diazepam as a positive control. (+)-Limonene epoxide was able to significantly decrease the number of crossings, grooming, and rearing. It increased the percentage of open arms entries and the time spent in those arms. At higher doses, it produced an inhibition of motor coordination, presented through a muscle relaxation effect. Flumazenil reversed the diazepam and (+)-limonene epoxide effect, suggesting that its mechanism might be involved in an action on the $\mathrm{GABA_A}$ receptor complex. These findings suggest (+)-limonene epoxide as a therapeutic approach in the treatment of anxiety inasmuch as it is relatively safe. The results also indicated that (+)-limonene epoxide might be responsible for the effects of limonene on the CNS.

2.2 β-Caryophyllene

Synonym: (−)-trans-Caryophyllene



Another prominent representative of the ST-hydrocarbons with significant scientifically proven biological activities is (*E*)-β-caryophyllene. It occurs in large amounts as a major plant volatile in the EOs of spice and food plants like *Origanum vulgare* L. (oregano), *Cinnamomum spp*. (cinnamon), and *Piper nigrum L.* (black pepper). *E*-BCP is in nature found together with small amounts of its isomers (*Z*)-β-caryophyllene (*Z*-BCP) and α-humulene (former name α-caryophyllene) or with its oxidation product β-caryophyllene oxide [23]. β-caryophyllene possesses a woody, spicy aroma, so traditionally it is used in the fragrance and cosmetic industry. Because its antibiotic, anesthetic, anti-inflammatory, antioxidant, and other effects have been established by scientific studies, there is great interest in the use of this natural product as a starting point for the development of new drugs. At the present time, β-caryophyllene is being isolated by various methods of purification from oleoresins extracted from huge amounts of plant materials. To avoid this wasteful means of production, Reinsvold et al. [24] engineered phototropic microorganisms with sesquiterpene-synthase genes. The β-caryophyllene synthase gene from *Artemisia annua* was inserted into the genome of the cyanobacterium *Synechocystis ssp.*

The experiment was successful and the synthesis of β-caryophyllene was confirmed in the transgenic strain using GC-FID and GC-MS analysis. This was an important step in developing alternative ways of synthesizing relevant terpenoids, both for pharmaceutical research and for biofuels.

(*E*)-BCP is a selective agonist of the cannabinoid receptor type 2. Investigations were performed in 2008 by Gertsch et al. [23] in the EO of *Cannabis sativa* L., which contains (*E*)-BCP up to 35 %. It was the first *Cannabis*-derived CB receptor ligand with a basically different structure than the one of typical cannabinoids. Traditional cannabinoids are agonists of CB_1- and CB_2-receptors, so, despite their potential therapeutic effect by activating the CB_1-receptor, they cannot be taken for a pharmacological development because of their central CB_1-receptor activity. In this study, a CB_2-receptor-selective agonist was discovered that provided all the potential therapeutic effects of a CB_2-receptor activator but without the psychoactive effects associated with the CB_1-receptor activation. This makes (*E*)-BCP an excellent candidate for the development of new drugs for treatment of inflammation and pain, atherosclerosis, and osteoporosis. (*E*)-BCP binding of the CB_2 receptor initiates a complete stimulation program:

- Inhibition of the adenylate cyclase, which leads to calcium transiency in the cell
- Weak activation of the mitogen-activated kinases ERK1/2 and p38 in primary human monocytes. Three major MAPK pathways are known, ERK1/2, JNK, and p38, which further on leads to the phosphorylation of cytoplasmic and nuclear targets. ERK is mostly activated by mitogenic factors, whereas JNK and p38 are usually activated by stress-inducing stimuli such as UV light. MAPKs have, in general, an important role in cell proliferation [25].
- Inhibition of LPS-induced proinflammatory cytokine expression in peripheral blood
- Alleviation of LPS-stimulated ERK1/2 and JNK1/2 phosphorylation in monocytes, because these pathways are critical for expression of IL-1 and TNF-α (both cytokines involved in inflammation processes in the body). The experiment confirmed that (*E*)-BCP also provides its effect in vivo.

After this discovery, interest in further investigations of (*E*)-BCP was awoken. Horváth et al. [26] investigated the possible therapeutic effects of BCP in a cisplatin-induced murine nephropathy model. Cisplatin is a chemotherapeutical agent often used in cancer therapy but with nephrotoxicity as a side effect. This side effect is probably caused by oxidative and nutritive stress and inflammation, so a solution for preventing or reducing these complications is in great demand. β-Caryophyllene attenuated cisplatin-induced kidney dysfunction and morphological damage, inflammatory response in the kidney, the increased oxidative and nutritive stress, and the enhanced cell death. All of these effects were provided in a CB_2-receptor-dependent manner, which was proven by the fact that the protective effect of BCP was absent in CB_2-knock-out mice.

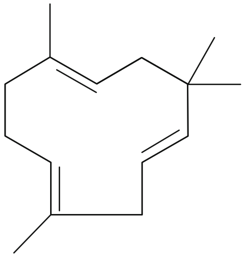
CB_2-receptors also exist, in low levels, in cells of the gastrointestinal and cardiovascular system, bone and neuronal cells, liver tissue, and other cell types [26]. CB_2 is up-regulated in inflamed colonic tissue of colitis patients. It is believed that the CB_2-receptors are in close interaction with the PPARγ-receptor, and both are considered targets for treatment of inflammatory bowel diseases. That was the motivation for Bento et al. [27] to investigate the effect of oral BCP in DSS (dextran sulfate sodium)-induced colitis experimental models. The results showed that BCP inhibited the influx of inflammatory cells, decreased damage to the colon, and reduced the production of inflammatory mediators and cytokine release from LPS-stimulated macrophages. It also inhibited the activation of transcription factors NFkB, CREB, and ERK ½ and activation of colonic caspase-3 but not claudin-4. The effects of BCP could be reversed by CB_2 and PPARγ selective antagonists. That leads to the conclusion that BCP activates the CB_2 receptor and reduces the inflammation of the colon by directly or indirectly interacting with the PPARγ-receptor. The examination showed, with small significant differences, however, that a preventive treatment was more effective than the therapeutic treatment, so BCP exhibits both preventive and therapeutic effects in DSS-induced colitis models. A preventive treatment with BCP also improved oxazolone-induced colitis by reducing weight loss and increasing the survival rate. Investigations also showed that applications of BCP in high concentrations induced an antiedematogenic effect in CB_2 knockout mice, which could suggest that BCP does not act on the CB_2 receptor exclusively.

β-Caryophyllene also showed antispasmodic activity. Leonhardt et al. [28] examined the effect of BCP as the main constituent of the EO of *Pterodon polygalaeflorus* F. on the isolated ileum from rats. Both BCP and the EO of *P. polygalaeflorus* F. showed a dose-dependent relaxant effect on the ileum and were able to inhibit the acetylcholine and KCl-induced contractions of the ileum and alleviate $CaCl_2$-induced contractions. This effect on muscle contractility is provided by an intracellular mechanism and is myogenic. This leads to the conclusion that BCP plays a crucial role in the relaxation and antispasmodic effect that the EO of *P. polygalaeflorus* F. provides in the ileum.

β-Caryophyllene shows a potential anti-cancer effect. Previous studies have demonstrated that BCP possesses strong antimutagenic activity against 2-nitrofluorene mutagene [29] and that it has a potentiating effect in the anticancer activity of α-humulene, isocaryophyllene, and paclitaxel against tumor cell lines [30]. To investigate whether BCP provides an antitumor effect and its possible mechanisms, di Sotto et al. [31] studied the in vitro effects of BCP at the chromosomal level by using human lymphocytes. The cultured lymphocytes were exposed to the genotoxic effects of two different mutagens: the alkylating agent EMS (ethyl methanesulfonate) and the aneugenic agent COL (demethylcolchicine). The treatment with BCP was performed three times: a pre-treatment before the treatment with the mutagenes (to examine the capability to prevent the damage), a co-treatment (to see whether BCP can directly interfere with the mutagene) and after the damage was made by mutagens, and a post-treatment (to see whether BCP is able to repair the genotoxic damage). The results showed that, compared with the control, BCP by itself did not provoke any cytotoxic or genotoxic effects. BCP's provision of its anticlastogenicity potential exclusively in the pre- and co-treatment with EMS was significant but not dose-dependent. The post-treatment could not assert any antimutagenc effect of BCP, which means that it could not promote a reversion of the damage made on the DNA. In addition, testing in the presence of COL could not confirm a protective effect. This could lead to the conclusion that BCP acts as a des-mutagen and is an active pre- or co-treatment antimutagen, which means that it deactivates mutagens before they attack the DNA. The exact mechanism is not yet clear. The anticlastogenic activity may be involved in the antioxidant effect that BCP provides, or a chemical interaction with the mutagens is possible; another hypothesis is that is has a destabilizing effect on the cellular membrane. Nevertheless, due to the lack of genotoxic effects and the anticlastogenic activity, BCP provides valid reasons for further investigations and interest as a potential chemoprotective agent.

2.3 α-Humulene

Synonym: Humulene, α-Caryophyllene



α-Humulene is a naturally occurring monocyclic sesquiterpene, with a structure built of three isoprene units. The name α-humulene is derived from *Humulus lupulus*, in whose EO it is found. Humulene and its oxidation products play an important role in the hoppy flavor of beer [32]. In plants it is often found together with its isomer β-caryophyllene, like in the EO of *Cannabis sativa* L., where they are the major sesquiterpenes [33], and it contributes to the characteristic odor of this plant.

α-Humulene is also an important constituent of *Cordia verbenacea*, which is used in folk medicine for its antirheumatic, anti-inflammatory, analgesic, and healing properties. It is believed that the oral-inflammatory actions that *C. verbenacea* provides are related to the presence of the SQTs α-humulene and β-caryophyllene.

α-Humulene showed rapid and relatively good absorption by oral and topical administration, which plays an important role in the topical and systemic anti-inflammatory and antinociceptive effects it provides. Chaves et al. [34] reported that the oral anti-inflammatory effects of α-humulene and β-caryophyllene, isolated from *C. verbenacea*, could be compared to the effects observed in animals treated with dexamethasone. They examined the inhibitory effects of these two compounds in different inflammatory models in mice and rats.

Fernandes et al. [35] reported that these SQTs were able to inhibit the activation and/or release of inflammatory mediators like bradykinin, platelet activating factor, histamine, IL, IL-1β, TNFα, and PGE_2. They also inhibited the up-regulation of the enzymes COX-2 and iNOS (inducible nitric oxide synthase). α-Humulene stood out in the study as it was the only compound that could, in a systematic treatment, reduce the histamine-induced mouse paw edema and largely prevent both TNFα and IL-1β generation in carrageenan-injected rats, whereas β-caryophyllene reduced only TNFα release.

Based on these findings, Rogerio et al. [36] investigated the anti-inflammatory properties of α-humulene, in order to identify potential targets that could prevent or treat inflammatory diseases like allergies or asthma. α-Humulene was applied preventively and therapeutically in a allergic airway inflammation murine model. The examination results revealed that SQT reduced the eosinophilic migration into the bronchoalveolar lavage fluid and lung tissue, similar to that reported with corticosteroids.

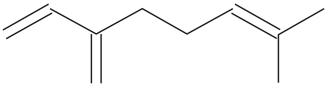
It is believed that the mechanism is related to a reduction of inflammatory mediators, adhesion molecule expression, and activation of transcription factors. Namely, by modulation of the Th1/Th2 (T-helper1/T-helper2) balance, reduced production of mucus, and inhibition of IL-5, CCL11 (chemokine (C-C motif) ligand 11 (eotaxin)) and LTB4 (leukotriene B4) levels and P-selectin expression, probably by inhibiting the NF-κB and AP-1 pathways. An interesting fact was that the animals treated with α-humulene gained weight similar to animals from the control, while dexamethasone-treated animals suffered weight loss. This implies a minor collateral effect of this compound. α-Humulene was successful, by oral or aerosol treatment, though application via aerosol was more effective.

It is reported that α-humulene also provides an antitumor effect. In the study, α-humulene inhibited the growth of MCF-7 breast cancer cells by about 50 %. This effect can be potentiated by β-caryophyllene by increasing the inhibition up to 75 % [30].

El Hadri et al. [37] investigated the cytotoxic effect of both α-humulene and β-caryophyllene from *Salvia officinalis* on breast cancer MCF-7, colon cancer HCT-116, and murine macrophage RAW264.7 cellular lines by the MTT assay (a colorimetric assay to assess viability and cell proliferation and also the cytotoxicity of substances). The results showed that the subfraction of *S. officinalis* EO, containing α-humulene, provided the highest activity at the RAW264.7 and HCT-116 cell line, whereas the subfraction with β-caryophyllene showed less activity on the same cell lines. This suggested that both SQTs were able to inhibit the growth of tumor cells.

2.4 Myrcene

Synonym: β-myrcene



Myrcene is an unsaturated acyclic MT, which exists in two isomeric forms: β-form, which can be found in nature, and the α-isomer, which does not occur naturally but can be easily synthesized. The EO has a pleasant odor of geranium, but in pure form it is not used as a flavor; a solution with at most 5 % would be recommended for smelling. Myrcene tends to polymerize, which is why it is unsustainable in the air [38]. It has a reactive diene structure, which makes it an eclectic starting material for flavoring agents and fragrances. It also is used in cosmetics, soaps, detergents, vitamins, and pharmaceuticals and as a flavoring agent in food and beverages. It is the main constituent of hop and bay oils, which are used in the production of alcoholic drinks [38, 39]. Myrcene can be found in *Humulus lupulus*, *Pimenta racemosa*, *Rosmarinus officinalis*, and *Salvia officinalis*.

Behr and Johnen reported [38] that myrcene is an important starting point for the synthesis of menthol, nerol/geraniol, and linalool. Further derivates are citral, citronellal, and citronellol, which are used because of their lemon-like smell. Based on the diene structural component, it can be used for Diels-Alder reactions with unsaturated structures, which leads to synthesis of amberlike flavors and anticancer therapeutics. By a C-C linkage, geranylacetone and β springene can be obtained, derivates which can be used to synthesize side chains of vitamin E.

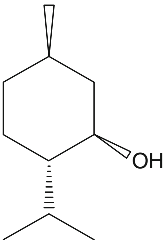
Another use of myrcene is the synthesis of pheromones that can be used as traps for insects. Myrcene can be found in many plants, but its extraction would not be economical, so industrially it is obtained by pyrolysis of β-pinene, which is contained in turpentine.

The National Institute of Environmental Health Sciences [39] studied myrcene for its cancerogenic activity, because it is heavily produced and shows structural connections to limonene, which induces tumors in male rat kidneys. The study was performed on male and female rats and mice by force-feeding with myrcene for either 3 months or 2 years. The results of the 2-year studies showed that myrcene possesses a carcinogenic effect based on increased incidence of renal tubule neoplasms in male rats and renal tubule adenomas in female rats. Increased incidence of hepatocellular adenoma, hepatocellular carcinoma, and hepatoblastoma was seen in male mice and marginally increased incidences hepatocellular adenoma and carcinoma were observed in female mice.

3 Alcohols

3.1 (−)-Menthol

Synonym: *Levomenthol*



Menthol belongs to the group of monocyclic terpenes, which can be found as a major compound in the EO of leaves of mentha species like *Mentha piperita* and *Mentha arvensis*.

Because of the presence of three asymmetric C-atoms in its structure, menthol occurs in four pairs of optical isomers, (−)- and (+)-menthol, (+)- and (−)-neomenthol, (+)- and (−)-isomenthol, and (+)- and (−)-neoisomenthol. (−)-Menthol is the isomer that mostly occurs in nature and, besides its characteristic odor, it possesses a cooling effect on the skin and mucosa. It can be obtained synthetically or from peppermint or other mint oils, or from essential oils such as citronella oil, eucalyptus oil, and Indian turpentine oil. Due to its minty smell and flavor, it is used in pharmaceuticals, soaps, hygiene products like toothpaste, cosmetics, chewing gum, teas, sweets, and tobacco products [40, 41].

Because of its antispasmodic, carminative, choleretic, and cholagogic effects it is traditionally used for treating gastrointestinal disorders and also in mucus-dissolving and broncholytic preparations. In pharmaceuticals it is a compound in antipruritic, antiseptic, and cooling preparations [40].

The cooling effect and tingling sensation of menthol by topical application is related to its stimulation of cold-receptors. This stimulation is caused by inhibiting Ca^{++}-currents of neuronal membranes, since Ca^{++}-channel blockers are connected to painkilling properties [40]. Both (+)- and (−)-menthol show equiactive local anesthetic activity, but only (−)-menthol also elicits an analgesic effect [40].

Kahner et al. [41] reported on the effects of menthol in tobacco-products. Approximately a quarter of worldwide use of menthol is in tobacco products. According to the tobacco industry, it gives the tobacco a more intense and pleasant taste. The addition of menthol actually has strong pharmacological effects, such as easing inhalation and increasing the addictive potential, which can further lead to numerous chronic diseases and death. The authors detail the mechanism by which menthol interacts in the body. Menthol interacts with channels responsible for perception of heat, cold and pain, the so-called TRP ion channels, particularly with TRPM8, which reacts with cold. Menthol inhibits TRPA1, responsible for pain perception, so it works as an analgesic and anesthetic. With long and recurrent consumption it causes a desensitization of the mouth, which affects the perception of irritant substances such as nicotine. Menthol also increases the transdermal and transbuccal absorption of substances and prolongs the time the breath can be held and suppresses the need to cough. Other studies reported that menthol inhibits the oxidation of nicotine to cotinine, so nicotine stays longer in the body,

Subsequently, there have been reports of menthol pyrolysis-products containing the cancerogenic agent benzopyrene and menthol inducing the absorption of benzopyrene.

In conclusion, menthol in tobacco products is not simply a flavor, increasing the tobacco taste; it affects sensoric perception, smoking habits, and addiction potential.

The mechanism of menthol interaction in the body, as mentioned above, is confirmed by other studies. Willis et al. [42] concluded that menthol in mentholated cigarettes acts as a counterirritant that diminishes the chemosensory responses of inhaled irritants. Irritations were elicited in mice by irritants that occur in cigarette smoke (acrolein, acetic acid, cyclohexanone) and menthol abolished the irritation responses caused by these irritants, which are agonists of the TRP channel family. Menthol effects could be reversed by a TRPM8 antagonist.

The effect of menthol in mentholated cigarettes on nicotine pharmacokinetics is an important topic for investigation for the tobacco industry. Abobo et al. [43] performed their examination by exposing rats to the smoke of mentholated and nonmentholated cigarettes, then collected blood samples and analyzed the nicotine and cotinine concentrations. The results showed that mentholated cigarettes decreased the maximum concentration (Cmax) of nicotine in plasma and the plasma AUC compared with nonmentholated cigarettes. The values for cotinine were reduced by menthol as well. These results showed that menthol in mentholated cigarettes decreased the absorption and increased the clearance of nicotine. Kreslake and Yerger [44] reported that menthol, besides its use as a flavor and to ease inhalation, also reduces the irritation from inhaling smoke and modulates the subjective effects, like smoke harshness and increased smoothness.

In addition to its use in the tobacco industry, menthol provides many biological activities, which make it extremely attractive in pharmacy and medicine. It has been reported that menthol showed anticancer effects by being effective in treating prostate cancer in vitro. Menthol induced cell death in prostate cells through TRPM8 activation and the resulting increase in Ca^{++} [45].

Bhadania et al. [46] reported that menthol had a protective effect on β-amyloid peptide–induced cognitive deficits in mice. Menthol's ability to interfere with cognitive actions opened another area of medical research on the effects of this MT. Young and aged mice were examined, using interceptive and exteroceptive memory models (modified elevated plus-maze test and Morris water maze test, which are used in behavioral neuroscience to study spatial learning and memory processes in rodents) and various biochemical parameters were assigned (brain glutamate, glycine, glutathione, and thiobarbituric acid reactive substances). The nootropic effect of menthol on learning and memory was evaluated with piracetam as a control. Menthol maintains the glutamate concentration in the mouse brain throughout its antioxidant activity. It triggers the glutamate release by acting directly on the presynaptic Ca^{++} stores of sensory neurons to release Ca^{++}. It is believed that the glutamate concentration plays an important role in cognitive functions. The results showed a significant enhancement in learning and memory. Menthol did not modify the level of glycine in the brain, but it increased the glutamate level, which leads to the conclusion that the effect is most probably based on the glutamatergic neuronal effect.

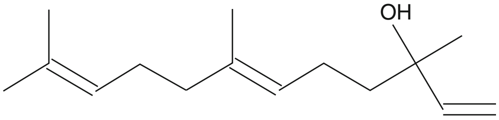
Menthol has been recognized for many years as a treatment for gastrointestinal disorders because it relaxes the GI smooth muscles. Thus, the use of menthol as an antispasmodic agent before GI endoscopy has been examined. The application of the EO in form of a spray on the gastric mucosa inhibited gastric peristalsis, having the advantage of being connected with fewer undesired drug effects than the substances typically used. Hik et al. [47] investigated the mechanism and pharmacokinetics of menthol used for GI endoscopy. Menthol showed fast absorption and was excreted mainly through the urine in form of menthol-glucuronide. It had good safety and only a few adverse effects, whose relation to the GI treatment cannot be excluded. The C_{max} and AUC of menthol increased dose-dependently, but the elimination half life showed it to be dose-independent. The study showed that the C_{max} can be obtained faster if sprayed on the gastric mucosa (0.17–1.00 h) rather than taken orally.

Menthol is traditionally used to relieve pain caused by exercise because of its cooling and relaxing effect. Topp et al. [48] examined the mechanism by testing the effect of menthol on blood flow and arterial diameter. The investigation was performed on a small group of eight males and eight females, and with two doses of menthol (3.5 % and 10 %), assessing the blood flow and arterial diameter before and after MVMC (maximum voluntary muscular contraction) were performed on the quadriceps and hamstrings. Exercise with high intensity and short duration increases the blood flow of the surrounding tissue and menthol acts by stimulating the thermoreceptors, leading to a vasoconstriction and localized cooling. The results showed that application of both doses decreased the local as well as the generalized blood flow after a MVMC. This effect may be attributed to an inhibition of local NOS and NO and also to an increase in systemic a_{2C} adrenergic tone.

The effects of ice and a menthol gel (3.5 % menthol) on blood flow and muscle strength of the lower arm were compared in another study [49]. The results suggested that menthol provides a fast-acting but short-lived reduction of the blood flow, while with topical application of ice a similar vasoconstrictive effect can be achieved only by a longer application of ice.

3.2 Nerolidol

Synonym: Peruviol



Nerolidol is a natural occurring aliphatic SQT-alcohol that possesses one chiral center in its structure; it prevails as a mixture of its cis and trans-form. It is an isomer of farnesol, from which it is distinguishable by a different position of one double bond and the hydroxyl-group. Nerolidol is a major component of EO extracted from many plants [50–52]. It has a woody aroma reminiscent of tree bark. It is used to enhance flavor and aroma and is also used as a fragrance in perfumes, cosmetics, shampoos, toilet soaps and, household products. [53].

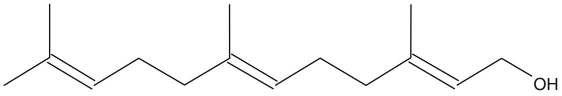
It has been reported that this long-chain SQT is an enhancer for the transdermal delivery of therapeutic drugs and for substances that permeate the human skin membranes in general [54]. It reinforces the bilayers, possibly by orientating alongside the lipids of stratum corneum [55]. Nerolidol also exhibits antineoplastic activity, probably by having an impact on protein prenylation or affecting the mevalonate pathway [56]. The antibacterial effect of nerolidol was confirmed in several studies, for example, on *Staphylococcus aureus*, reporting that the mechanism of this action is probably the damaging of the cell membrane [57]. Other studies accounted the antifungal effect against *Microsporum gypseum* [58] and its anti-Leishmania effect by inhibiting the growth of *Leishmania amazonensis, L. braziliensis*, and *L. chagasi promastigotes* and *L. amazonensis* amastigotes [59]. Nerolidol also displays an anti-ulcer activity. As a main constituent from the essential oil of *Baccharis dracunculifolia* DC, it inhibited the formation of ethanol-, indomethacin-, and stress-induced ulcer models in rats [60]. Nerolidol and farnesol were classified in 1986 as active ingredients in biochemical pesticides [61].

Ferreira et al. [62] investigated the effect of nerolidol in mitochondria and also correlated the results with its cytotoxic effect on HepG2 cells. The mitochondria might be a target for compounds of EO, provoking changes, possibly leading further on to enzyme inhibition or cell death. And nerolidol can, as a hydrophobic compound, cross the plasma membrane easily and interact with cellular proteins and intraorganelle sites. Nerolidol was shown to increase respiratory chain activity and decrease phosphorylative efficiency. The inhibitory effect in the phosphorylative system is related to a reduced concentration of ATP in cells, through inhibition in the ATP-ase enzyme activity. Nerolidol also was shown, dose dependently, to induce a decrease of the mitochondrial transmembrane electric potential. The permeability transition in the mitochondria was delayed, most probably as a result of a Ca^{2+}-uniporter reduced activity. The decrease of the calcium-induced permeability transition susceptibility can be a consequence of the decreased membrane potential and modifications of the mitochondrial membrane fluidity. In connection to the HepG2 cell line, nerolidol presented hepatic cell cytotoxicity. It induced cell death and inhibited cell growth.

Nerolidol is classified (as is farnesol) in “Toxicity Category IV” for acute oral toxicity, “Toxicity Category III” for acute dermal toxicity, primary eye irritation and primary dermal irritation, and “Toxicity Category II” for acute inhalation toxicity, according to the US Environmental Protection Agency (EPA) [61]. Considering this and the above-mentioned cytotoxicity, nerolidol may present a possible risk in use as a therapeutic agent, or as a flavor enhancer at high doses; therefore, differentiation between the therapeutic and toxicological effects is important.

Pículo et al. [63] assessed the in vivo gentoxicity of nerolidol. The authors investigated whether a single treatment with this compound was able to induce DNA damage in peripheral blood and liver cells of mice and micronuclei in polychromatic erythrocytes of their bone marrow cells. The comet assay was used to assess the genotoxicity, and *N*-nitroso-*N*-ethylurea was a positive control for the comet and micronucleus assay. In both peripheral blood and liver cells, nerolidol induced weak, dose-dependent DNA damage compared with the control. Nerolidol also induced a clastogenic effect on bone marrow cells of mice by enhancing the average number of micronucleated cells in high doses tested. In conclusion, the study pointed out the clastogenic and weak genotoxic effects of nerolidol.

3.3 Farnesol



Farnesol is an acyclic SQT-alcohol that possesses a floral odor; some people report it reminds them of *Convallaria majalis*. It is often used to enhance the odor and flavor of sweet floral perfumes and as an antibacterial compound in cosmetics. Farnesol has been shown to decrease biofilms of *Staphylococcus epidermidis*, which often causes infections and is resistant to antimicrobial agents. Thus, farnesol has been shown to be a potential therapeutic for clinical *S. epidermidis* biofilm infections [64]. There has been an increase in interest in the use of this compound as an antifungal agent. In *Candida albicans*, it caused a down-regulation of the expression of some aspartyl proteinase genes, provoking morphological changes [65]. Farnesol is believed to be endogenously produced by dephosphorylation of farnesyl-PP, a metabolite of the cholesterol biosynthetic pathway [66].

Hyuck Joo and Jetten [67] reported on the anti-cancer and chemoprotective effects of farnesol and summarized the mechanisms of its apoptosis-inducing activities. In vitro, farnesol was shown to inhibit cell proliferation and induce apoptosis in different types of malignant cells. It was notable that tumor cells were more sensitive to the growth inhibition induced by this compound than normal cells. Cells treated with farnesol were shown to have a G_O/G_1 cell cycle arrest, reduction in in CDK2 activity, and an increased generation of the cyclin-dependent kinase inhibitor $p27^{Kip1}$ with cyclin E/CDK2 complexes. The inhibitory effect of this terpene is suggested to be dependent on these CDK inhibitors ($p21^{Cip1}$ and $p27^{Kip1}$), because their down-regulation provided protection from the proliferation-inhibitory effect. Farnesol also proved its anti-tumor effects in vivo. Liver of farnesol-treated rats had an increased number of phase I and phase II enzymes, which metabolize drugs and carcinogens, so farnesol might interfere in the metabolism, toxicity, or carcinogenesis of drugs. A farnesol has inhibitory effects on HMG-CoA reductase can be related to its anti-cancer effect. Tumor cells need an increased cholesterol biosynthesis, so by inhibiting it, farnesol might provide its growth-suppressing activity. A farnesol-induced endoplasmatic reticulum stress is a major factor leading to cell death. It can activate ERK1/2 and MAPK p38, and by activating this MEK-ERK-pathway, the ER-stress is most probably induced. The authors also reported that farnesol inhibited phosphatidylcholine synthesis by changing the subcellular localization and activity of CCTα (CTP: phosphocholine cytidylyltransferase α), which catalyzes its biosynthesis. Phosphatidylcholine is important in maintaining the structure of membranes and it is a precursor of a few second messengers, which control several cellular processes, including proliferation and cell death. Namely, under treatment with farnesol, CCTα translocates to the inner nuclear envelope, following a further export to the cytoplasm and causing an inhibition of the phosphatidylcholine synthesis.

Apoptotic stimuli can lead to an assembly of an apoptosome, a protein complex that also includes caspase. Farnesol activates caspases 3, 6, 7, and 9, but not caspase 8, which leads to the conclusion that the apoptosis is mediated by the intrinsic, mitochondrial-dependent pathway and not the extrinsic pathway. A higher level of expression of the pro-apoptotic protein Bak and lower level expression of anti-apoptotic proteins BCL2 and BCL-X are also related to a farnesol-induced apoptosis. Farnesol activates the NF-κB signaling pathway and expression of inflammatory genes and increases the level of ROS. Studies in vivo demonstrated that this substance can reduce oxidative stress, inflammations, and injuries in rat lungs exposed to intratracheal installation of cigarette smoke extract. In conclusion, the anti-tumor effects probably involve a few mechanisms, and farnesol can act at the initiation phase (reducing the DNA strand breaks and formations of DNA adducts) or at the progression phase of tumor development.

Qamar et al. [68] investigated the chemopreventive effects of farnesol on rats what were intratracheally exposed to the cancerogene benzo(a)pyrene. Pretreatment with farnesol alleviated the inflammation, edema, surfactant dysfunction, and injuries caused by this cancerogene. Farnesol was shown to have an effect on the benzo(a)pyrene metabolizing enzymes (NADPH-cytochrome P450 reductase, microsomal epoxide hydrolase (mEH), and glutathione S-transferase (GST)) and it was able to normalize the reduced levels of the lung surfactants.

Farnesol is an interesting and promising compound due to its antioxidant, anti-inflammatory, and chemopreventive properties. Khan and Sultana [69] explored its anticipatory effect against DMH (1,2-dimethylhydrazine)-induced oxidative stress, inflammatory response, and apoptotic tissue damage in the colon of Wistar rats. The study showed that a prophylactic treatment with farnesol increased the antioxidant enzymes superoxide dismutase, catalase, glutathione peroxidase, glutathione reductase, glutathione-S-transferase, and quinone reductase and the cellular antioxidant-reduced glutathione. Farnesol was shown to have a protective effect against DMH-induced lipid peroxidation in colonic tissue. The pretreatment may also down-regulate caspase-3-activity, which was up-regulated by DMH, a colon-specific cancerogene. Farnesol was shown to suppress the initial stages of colon cancerogenesis, and the mechanism is, according to these findings, probably the amelioration of the oxidative damage, inflammatory processes, and apoptotic responses.

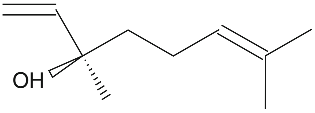
Because farnesol proved its antioxidant effect and and antioxidative agent can have a protective effect against neurotoxicity, de Oliveira Júnior et al. [70] investigated the antinociceptive effect of farnesol and its effect on the brain of adult mice. Mice were treated with doses of 50, 100, and 200 mg/kg, injected intraperitoneally. In the group treated with the highest dose, 16 % of the mice had a brain injury that affected 12 % of the hippocampus, but no lesions were found on mice treated with doses of 50 and 100 mg/kg. This leads to the conclusion that farnesol provides an antinociceptive effect, with no significant neurotoxicity.

A number of studies have previously shown that farnesol has an impact on the metabolism of lipids and can regulate serum lipid concentrations. This effect is a consequence of farnesol up-regulating the PPARα and genes of fatty acid oxidation, as well as down-regulating the synthesis of fatty acid in liver cells, which results from a decreased mRNA and protein level and activity of fatty acid synthase. Farnesol lowered serum triglyceride levels, and is potentially a protective factor to hypertriglyceridemia [71].

Goto et al. [72] made further investigations on farnesol being a ligand of PPARs and its effect on metabolic abnormalities. PPARs control energy homeostasis. Farnesol was shown to improve metabolic abnormalities by decreasing plasma glucose concentration, glucosuria, and the hepatic triglycerides. The study confirmed the previously mentioned mechanism of action, observing that farnesol could not up-regulate the mRNA expression of PPARγ target genes in adipose tissues. This showed that an up-regulation of fatty acid oxidation genes requires the function of PPARα, but farnesol was shown to act on two types of receptors: PPARα and FXR (farnesoid X receptor). FXR regulates genes important for bile acid homeostasis and lipid and glucose metabolism [65]. The decrease of the hepatic triglycerides is probably related to activation of both receptors, with FXR presenting a PPARα-independent way of acting.

3.4 Linalool

Synonym: β-linalool



Linalool is a MT-alcohol that possesses one chiralic C-atom, so it occurs naturally in the form of two enantiomeres: (–)-linalool and (+)-linalool. This compound is widespread in plants; the most commonly used *Lavandula* species are *L. angustifolia, L. latifolia, L. stoechas.* and *L. x intermedia* [73]. Other prominent linalool-producing species would be *Citrus bergamia* R., *Melissa officinalis* L., *Rosmarinus officinalis* L., *Cymbopogon citratu*s DC, and *Mentha piperita* L. [74]. Linalool is one of the best-examined terpenes. In ancient times it was used as a compound of these plants, providing sedative, analgetic, and anxiolytic effects, which has been later on proved in scientific studies. Studies also reported strong anti-oxidative, antibacterial, antifungal, anticonvulsive, and antihypercholesterinemic effects. Because of its pleasant scent, it is used as a flavor and fragrance; incorporated in soaps, cosmetics, and hygiene products; used in aromatherapy; and is a common compound of herbal essential oils and teas.

Linck et al. [74] investigated the effect of inhaled linalool on anxiety, aggressive behavior, and social interactions in mice. The results showed that inhaled 3 % linalool extended anxiolytic effects on mice, due to the fact that it increased the time spent in the lit area in the light/dark test. A step-down inhibitory avoidance test was performed, showing that linalool possesses amnesic effects. All results were compared with diazepam as a control. Linalool decreased aggressive behavior and increased social interactions at a concentration of 1 %. Three percent inhaled linalool showed a lack of effect in the social interaction test, most probably related to the fact that linalool acts as an antagonist on NMDA receptors, which is a common effect of NMDA antagonists in general. The same team of authors showed in a previous study that inhaled linalool can bolster pentobarbital-induced sleep and decrease body temperature and locomotion. These results can be taken as further proof of the psychopharmacological effects of inhaled linalool and EO containing this compound.

Takahashi et al. [75] compared the EO from six *Lavandula* species, investigating how the interspecies differences affect the expression of their anxiolytic activity. The result showed a qualitative as well as a quantitative compositional variance between the EOs, leading to significant differences in the provided anxiolytic effect. The authors also investigated the influence of the major constituents of the EOs of these species, suggesting that linalyl-acetate acts synergistically with linalool, and that the presence of both compounds is required for the anxiolytic effect of the inhaled EOs.

Linalool is, as already mentioned, a competitive antagonist of the NMDA receptor, and is believed to have an important role in the building of memory. Coelhoa et al. [76] evaluated the effect of (−)-linalool on the acquisition of long- and short-term memories using three types of behavioral models: recognition task, inhibitory avoidance test, and habituation in a new environment. With an open field test, the effect on motivation, locomotion, and exploration level was investigated. The test was performed on more than 200 male Wistar rats, using a glutamate antagonist as a positive control. (−)-Linalool showed different effects in the three types of tests. In the object recognition task, (−)-linalool impaired the formation of long-term memory without impacting short-term memory. The building of both STM (short-term memory) and LTM (long-term memory) was impaired in the inhibitory avoidance test, while in the habituation test, the LTM was impaired. In the open field test, the tested rats showed no difference in the crossing and locomotion, but higher concentrations of (−)-linalool decreased rearing behavior. The effect was different in each assay, but the compound still impaired memory acquisition in every assay. This suggests that (−)-linalool, probably due to its antagonistic effect on the NMDA receptor, affects the memory, like other antagonists of this receptor also do.

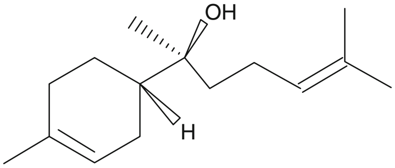
The anxiolytic and anticonvulsant effect of linalool is related to its mechanism of action in the CNS, blocking glutamatergic NMDA receptors, stimulating GABA receptors, and blocking voltage-dependent ion channels. Sampaio et al. [77] investigated the inhibition of adenylate cyclase by rosewood oil (*Aniba rosaeodora* Ducke), due to the fact that an increased cAMP concentration plays an important role in development of seizures in epilepsy, so inhibitors of the AC could be potential anticonvusant therapeutics. Rosewood oil, (−)-linalool, and the racemate (±)-linalool were tested against the increase of cAMP concentration, also involving the effect on adenosine receptors (adenosine decreases cAMP concentration through binding to the A1 receptor). Chick retinas were used as a CNS model and a phosphodiesterase inhibitor and an adenosine receptor antagonist as controls to determine the involvement of these receptors in the resulting effect. Rosewood oil and the linalool isomers inhibited the accumulation of cAMP but only when the AC was activated by a forskolin stimulus, suggesting that they act on the forskolin binding site of the AC. The effect was provided even when the adenosine receptor were blocked, showing that the antagonist did not interfere in the effect of the EO in the AC activity.

De Sousa et al. [78] investigated the difference in the anticonvulsant activity between the two linalool enantiomeres and the racemate. The results showed that a pretreatment with all types of linalool could increase the latency of convulsions, but rac-linalool was more effective, providing the effect at lower doses than the enantiomeres. In addition, all types of linalool could inhibit convulsive actions, with effects comparable to diazepam. (−)-Linalool was, in general, more potent than (+)-linalool, but still less potent than rac-linalool. When it comes to preventing tonic convulsions, both enantiomeres were equipotent and rac-linalool was even more effective than phenytoin. The study reported the presence of a chiral influence, observing that the two enantiomeres have similar anticonvulsant effects but different potencies.

Cho et al. [79] investigated the hypocholesterolemic effect of linalool in high-fat fed mice and in HepG2 cells. A treatment with linalool on high-fat fed mice reduced the total- and LDL-cholesterol level, with an accompanying reduction in the hepatic lipid concentration; the levels of HDL cholesterol increased. In hepatocytes, linalool extended a dose-dependent reduction of cholesterol and triglyceride concentration. Linalool decreased cholesterol by decreasing the expression of the sterol regulatory element binding protein-2 and an accompanying decrease of HMG-CoA reductase protein expression through transcriptional and posttranscriptional mechanisms. The reduction of expression of HMG-CoA reductase is a result of the reduced binding of SREBP-2 (sterol regulatory element binding protein-2) to its promoter and the induction of a ubiquitin-dependent proteolysis of HMG-CoA reductase.

Nevertheless, the antitumor effect of linalool should be mentioned. Gu et al. [80] investigated the antitumor effect of linalool on different hematopoietic tumor cell lines along with the effect on healthy blood cells. Linalool inhibited proliferation and induced rapid apoptosis on different human leukemia cells, but it spared normal blood cells. The effect is associated with an activation of the tumor suppressor gene p53 and cyclin-dependent kinase inhibitors.

3.5 Bisabolol



The name bisabolol includes both α- und β-isomeres of this compound, with each existing in two enantiomeric forms. In nature, the most common form is

(−)-α-bisabolol. (−)-α-Bisabolol is an unsaturated, optically active sesquiterpene alcohol that possesses a delightful floral odor [81]. It is part of the EOs of a variety of plants, the most commonly utilized source being *Chamomilla recutita* L, but it is also found in *Salvia runcinata*, *Plinia cerrocampanensis* [82], and *Vanillosmopsis erythropappa* [81]. (−)-α-Bisabolol is used in different formulations, and due to its antiseptic effect often in cosmetics, aftershave lotions, moisturizers, and creams for sensitive skin. Previous studies have reported on the anti-inflammatory, antibiotic, anti-ulcerative, anti-oxidative, anti-tumor, and other effects of this compound [82]; a few of them will be discussed here.

Rocha et al. [81] were among the first teams to examine the anti-nociceptive and anti-inflammatory potential of (−)-α-bisabolol as an isolated drug and not just as a plant containing this compound. The examinations were performed on male Swiss mice and male rats in classic models of pain and inflammation. The study showed that (−)-α-bisabolol reduced carageenan- and dextran-induced paw edemas, and at higher doses also reduced edemas produced by direct application of 5-HT. This suggests that the substance does provide anti-inflammatory effects. Bisabolol has been shown to be a peripheral anti-nociceptive and anti-inflammatory drug. This finding is supported by the fact that the anti-nociceptive test on hot-plate response did not suggest central analgesic activity and the formalin test also supported this conclusion. The formalin test includes two phases: the first phase confirmed the peripheric mechanism of action and the second phase proved the anti-nociceptive activity of the substance by influencing inflammatory mediators (histamine, serotonin, prostaglandins, and bradykinin). Pre-treatment with (−)-α-bisabolol decreased leukocyte migration, protein concentration, and myeloperoxidase activity in rats with peritonitis. It could also decrease TNFα in the peritoneal fluid of rats with carrageenan-induced peritonitis. The effects of (−)-α-bisabolol might be related to the effect on TNFα, but the effect of other inflammatory mediators cannot be excluded. The study proves the substance exhibits anti-inflammatory effects but without ulcerative potential like the commonly used analgetics and inflammation therapeutics (diclofenac, indomethacin). In contrast, (−)-α-bisabolol provides gastroprotective effects.

Moura Rocha et al. [83] investigated the gastroprotective effect of isolated (−)-α-bisabolol in ethanol and indomethacin-induced ulcers in mice. The substance showed anti-ulcerative activity in both ulcer models. The authors assessed the possible mechanisms involved in this action. (−)-α-Bisabolol was able to protect the gastric mucosa from lesions caused by NSAIDS, similar to ranitidine. To examine the role of prostaglandins in the effect of this substance in ethanol-induced ulcer models, mice were pretreated with indomethacine, but this did not prevent the effect of (−)-α-bisabolol. Therefore, an increased prostaglandin synthesis is not the mode of action. The involvement of K_{ATP+} channels and (−)-α-bisabolol in gastric functions was investigated, but it showed not to be related in the mechanism of action due to the fact that there was no difference in the gastroprotective effect of (−)-α-bisabolol in animals pre-treated with glibenclamide (glibenclamide closes the ATP-dependent potassium channels) or not. Also, the nitric oxide pathway is not involved, because the anti-ulcerative effects could not be reversed by L-NAME, an inhibitor of nitric oxide synthase. Finally, the effect was shown to probably be related to a decreased reduction of non-protein sulfhydryl groups, which leads to an increase of their occurrence and strengthening of their protective effects on gastric tissue, leading to a reduction of gastric oxidative injuries induced by ethanol and indomethacin. Namely, ethanol is able to diminish the levels of non-protein sulfhydryl groups, such as reduced glutathione in gastric tissue, which provides its gastroprotective effects by scavenging free radicals and preventing the gastric damage made by free-radicals' accumulation.

In a previous study, (−)-α-bisabolol was shown to have the ability to reduce gastric ulcer in response to absolute alcohol, but the way of acting was not clear, although a few mechanisms could be excluded. Moura Rocha et al. [84] have done further experiments, evaluating the gastroprotective effect in ethanol-induced lesions on the gastric mucosa. The methods they used were histopathological determination, measuring the membrane lipid peroxidation, myeloperoxidase, superoxide-dismutase, and catalase activity and the nitrite level. Ethanol produces characteristic necrotic gastric lesions, but the damage is also related to a massive production of free radicals. That is why the authors investigated the connection between the capability of (−)-α-bisabolol to reduce oxidative stress and inflammation, and the anti-ulcerative effect on ethanol-induced lesions.

The study showed that (−)-α-bisabolol prevented the ethanol-induced increase of MDA, showing its antioxidant activity. The substance increased the SOD activity and the dismutation of superoxide anion and it prevented the reduction in CAT activity. (−)-α-Bisabolol also reduced the influx of neutrophils in the gastric lesions. In agreement with the findings mentioned in the previous study, the pathway of nitric oxide is not related to the effect, because the substance did not significantly modify the nitrite levels.

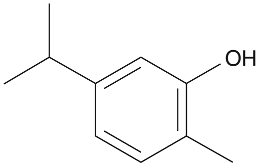
Seki et al. [82] reported that (−)-α-bisabolol is, in vitro, capable of suppressing cell proliferation which leads to death in pancreatic cell lines. The substance was effective and did not cause significant side effects. The mechanism of action includes the inhibition of Akt activation (one of the most often activated serine/threonine kinases in pancreatic cancer) and an up-regulation of the expression of the tumor suppressor early growth response-1 (EGR1). The authors did not exclude that other mechanisms, next to those two mentioned, are involved in the activity. They report that (−)-α-bisabolol might be a potential therapeutic in treatment of pancreatic cancer.

Cavalieri et al. [85] first gave evidence of α-bisabolol being a pro-apoptotic substance for primary human acute leukemia cells. The cells used in the study were Philadelphia-negative and -positive B acute lymphoid leukemias (Ph-/Ph + B-ALL), acute myeloid leukemias (AML), normal leukocytes, and bone marrow stem cells. α-Bisabolol was shown to be effective in ALL cells at all concentrations and duration of the treatment, and it spared normal leukocytes and bone marrow cells. At a bit higher concentration, it also acted as apoptotic against primary AML cells. The apoptotic activity was present even in imatinib mesylate-resistant Ph + B-ALL. The mechanism of action might involve the disruption of the mitochondrial membrane potential, which goes along with a decrease of oxygen consumption in the presence of glutamate/malate and the unpersuaded respiration levels in the presence of succinate/glycerol-3-phosphate.

De Siqueira et al. [86] investigated the pharmacological effect of (–)-α-bisabolol in various smooth muscle preparations of rats. The substance was shown to be biologically active in smooth muscle, but it had different effects depending on the tissue and applied concentration. For example, in preparations that were electromechanically or pharmacologically pre-contracted, (–)-α-bisabolol had a relaxing effect. At concentrations of 30–300 μmol/L, (–)-α-bisabolol relaxed duodenal strips; it contracted endothelium-intact aortic rings and urinary bladder strips, but relaxed the same tissues at higher concentrations (600–1,000 μmol/L). On tracheal or colonic tissue the effect was relaxing but with less potency than in mesenteric vessels. In vivo, (–)-α-bisabolol alleviated the increase of carbachol in tracheas of ovalbumin-sensitized rats challenged with ovalbumin, but it did not interfere with the decreasing responsiveness of urinary bladder strips in ifosfamide-treated mice. The authors suggested that a possible mechanism of action is the inhibition of voltage dependent Ca^{++} channels.

Alvesa et al. [87] studied the pharmacological effect of (–)-α-bisabolol on the peripheral nervous system of mice. The examination was performed ex vivo, observing the effect on the compound action potential characteristics, using a modified single sucrose-gap method. (–)-α-Bisabolol was dose-dependently able to decrease neuronal excitability. The effect was similar to lidocaine but not to 4-aminopyridine; both are known as inhibitors for sodium and potassium voltage-gated channels. In contrast to lidocaine, the (−)-α-bisabolol action showed an irreversible and non-use-dependent pathway. Based on this finding, the effect might be provided through irreversible inhibition of voltage-dependent sodium channels.

3.6 Carvacrol



Carvacrol is a member of MT phenols that occur in many EOs of the family *Labiatae*, including *Origanum, Satureja*, *Thymbra, Thymus*, and *Coridothymu*s species. This alcohol is generally recognized as safe, so it is commonly used as a flavoring substance. Carvacrol is described as having a pungent and warm scent similar to oregano. The EO from *Origanum vulgare* contains carvacrol at the highest naturally occurring concentration (up to 80 %) [88]. Carvacrol, in rat models, is metabolized and excreted very quickly. After 24 h, only small amounts could be found in urine, suggesting the excretion is almost complete in 1 day.

The substance is excreted mostly unchanged, but an oxidation of the methyl and isopropyl group can also occur, leading to benzyl alcohol and 2-phenylpropanol and their carboxylic acids [89].

Carvacrol was shown to strongly activate and sensitize TRPV3 channels, which are warm-sensitive Ca^{++}-permeable channels, often occurring in skin and neural tissues, causing the sensation of warmth. Carvacrol also activates and desensitizes TRPA1, a pain receptor, giving a possible explanation for the pungent taste of oregano [90]. Years after this finding, Parnas et al. [91] found carvacrol to inhibit the non-thermoTRPs, TRPL and TRPM7 channels. TRPM7 channels are mediators of anoxic neuronal death, so by inhibiting the expression, protection from ischemic cell death is provided.

Hotta et al. [92] reported on carvacrol acting on other receptors. They found that this substance, as a major part of the EO of thyme, is an activator of PPARα and γ, leading to an inhibition of COX-2 expression. This finding is a strong indicator for the anti-inflammatory effect of carvacrol since COX-2 is known to play important roles in inflammation processes and circulatory homeostasis.

Liu Y et al. [93] examined the in vitro anti-inflammatory effect of seven plant extracts, including carvacrol, on alveolar macrophages collected from pigs. Carvacrol was shown to significantly suppress TNFα and decrease IL-1β secretion from LPS-treated macrophages. Carvacrol also suppressed TGF-β from macrophages with LPS stimulation. An even more detailed report about the effect of this substance was given by Guimarães et al. [94]. The authors evaluated the effect of carvacrol on inflammatory hypernociception and inflammation on different mice models, and also on in vitro–stimulated murine macrophages. The inflammations were induced by carrageenan, TNFα, PGE2, and dopamine. The effect on leukocyte-accumulation and production of TNFα in carrageenan-induced pleurisy, as well as the effect on the NO building in murine macrophages, were also examined. A cavacrol-pretreatment was successful in reducing hypernociception and edema induced by carrageenan and TNFα, but there was no effect when induced by PGE2 and dopamine. In agreement with the study mentioned before, the TNFα concentration was decreased and an accumulation of leukocytes could be inhibited. Carvacrol inhibited LPS-induced nitrite production. The authors suggest that the suppression of TNFα production and NO release play the most important roles in the anti-inflammatory effect of carvacrol.

Carvacrol elicits an inhibitory effect on histamine receptors, as Boskabady et al. [95] report. They examined the effect of an aqueous-ethanolic extract of *Zataria multiflora* Boiss (Labiatae) and its constituent carvacrol on H1 (histamine 1) receptors in tracheal chains of guinea pigs. The results confirmed the inhibitory effect of both extract and carvacrol on H1 receptors with no significant difference when different concentrations of extract and carvacrol where applied.

Aristatile et al. [96] investigated the effect of carvacrol on mitochondrial enzymes, oxidative stress, and DNA damage in hepatic tissue in a model of D:-galactosamine (D:-GalN)-induced hepatotoxicity. The studies were performed on male Wistar rats and silymarin was used as a control drug. Carvacrol normalized the changes that were induced, providing antioxidant and defensive effects against mitochondrial enzymes and DNA damage. Carvacrol was able to bring the hepatic mitochondrial enzymes isocitrate dehydrogenase, α-ketoglutarate dehydrogenase, succinate dehydrogenase, malate dehydrogenase, NADPH dehydrogenase, and cytochrome C oxidase, after they were decreased by D:-GalN, to normal levels again. In addition, the increased concentration of thiobarbituric acid reactive substances was also decreased. Carvacrol was able to modulate the enzymatic antioxidants SOD and glutathione peroxidase and the non-enzymatic antioxidants vitamin C and vitamin E, and it and reduced glutathione back to higher concentrations. Carvacrol decreased DNA damage, probably due to the scavenging of free radicals before they caused the damage.

The effect of carvacrol on the mitochondrial pathways plays an important role in its anti-hepatocarcinogenic activity, as the study of Yin et al. [97] found. The study was performed on HepG2 cells showing that carvacrol was able to induce apoptosis and suppress further growth of cancer cells. The apoptosis mechanism involved an activation of caspase-3, PARP cleavage (a marker for apoptosis in tissue sections), and reduction of Bcl-2-gen expression. An important mechanism in the antitumor activity might be the influence in the mitogen-activated protein kinase pathway, by reducing phosphorylation of ERK1/2 and activating the p38 phosphorylation, but not interfering with JNK MAPK.

The effect of carvacrol on hepatocellular carcinoma has also been the subject of Jayakumar et al. [88]. The authors examined the preventive effect of the substance against carcinoma induced by diethylnitrosamine in rats. The main topic of research was the strong antioxidant effect and free radical elimination as an anti-cancer mechanism. Carvacrol modulated LPO levels and enhanced the endogenous antioxidant defense in cancerogenesis and decreased the high levels of serum markers.

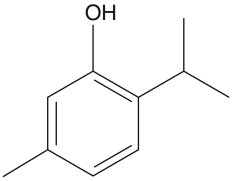
An interesting fact for the application of carvacrol and carvacrol-containing plants is that this substance exerts inhibitory properties on UGTs (UDP-glucuronosyltransferases). UGTs are responsible for metabolizing about 35 % of all drugs metabolized by phase II enzymes. Its inhibition could result in serious drug-drug interactions and cause metabolic disorders. Dong et al. [98] investigated the inhibition of main isoforms of UGT using a nonspecific probe substrate 4-methylumbelliferone and recombinant UGT enzymes as enzyme resources. Carvacrol was able to inhibit UGT1A9, one of the most important UGT isoforms, with an irrelevant effect on other UGT isoforms.

Yu et al. [99] investigated the neuroprotective potential of carvacrol against cerebral ischemia and/or reperfusion damage in mice using the middle cerebral artery occlusion model. The study showed the protective effect of carvacrol by decreasing the infarct volume and the level of neuronal cell death. Noticeably, a post-treatment was also able to provide protection. The authors' suggestion is that the PI3K/Akt pathway is related to the protective mechanisms of carvacrol on cerebral I/R damage. With intracerebroventricular treatment after cerebral I/R damage, carvacrol was shown to have a wide therapeutic window by still providing its protection even when applied 6 h after reperfusion. The therapeutic window was shortened when carvacrol was intraperitoneally applied, so this method might affect its protective efficiency. The authors suggest the use of carvacrol as a therapeutic drug, better yet as nanoformulations, which would make it even more efficient and easier to apply for an infarct treatment.

Carvacrol also improves cognitive activity. Azizi et al. [100] examined the effect of carvacrol and thymol in two rat models of dementia: deficits caused by amyloid β and by scopolamine. The method they used was the Morris water maze test and they also assessed the acute toxicity of both carvacrol and thymol. The result showed that both substances could reverse and alleviate the induced cognitive impairments, for example, the escape latency and reduction in target quadrant entries. Both substances also were shown to be relative safe, with LD50s of thymol (565.7 mg/kg) and carvacrol (471.2 mg/kg) that were significantly higher than the therapeutic concentration. The authors also suggest that the antioxidative, anti-inflammatory, and anti-cholinesterase activity could be involved in these activities.

Carvacrol possesses antibacterial, antifungal, and anti-insecticidal effects that are worth noting. The antibacterial potential of this substance has been ascribed to its effect on the structural and functional integrity of the cytoplasmic membrane. Due to this effect, carvacrol is used to extend the time before food becomes spoiled by bacteria [101]. For example, carvacrol inhibited, in sub-lethal concentrations, the virulence of *Salmonella typhimurium* by reducing the motility and invasion in porcine epithelial cells, which is an important finding inasmuch as carvacrol is commonly used in sub-lethal concentrations [102].

3.7 Thymol



Thymol is a MT-ic phenol derivate of cymene, which can be found in EOs of thyme, *Thymus vulgaris* or *Thymus zygis* L. *var. gracilis* Boissir. Thymol constitutes up to 80 % of the major compound of thyme EO, but it can be found in various citrus plants as well [103]. Thymol possesses a well-known antimicrobial and antiseptic activity, and because of its pleasant taste it has been used in mouthwashes and toothpastes for many years [104].

Thymol is a ligand of odorant receptors that are expressed in the intestinal mucosa, and by binding to those receptors, serotonin secretion is stimulated. These receptors belong to the group of chemical receptors that play an important sensoric role and can modulate functions of the GI system. Due to the fact that the ion transport, as a result of the binding, had not been previously evaluated, Kaji et al. [105] investigated the effect of thymol on ion transport in human and rat colonic epithelial cells by using a Ussing chamber (used to measure the short-circuit current to determine the ion transport taking place across an epithelium). The results showed that thymol can interfere in the permeability and anion secretion in colon cells. The mucosal application of thymol induced dose dependently an anion secretion that is probably related to an activation of TRPA1 channel. The authors came to this conclusion because the anion secretion could be reversed either under Ca^{++}-free conditions or application with a blocker of TRPA1.

Thymus vulgaris L. and/or *Thymus zygis* L. extracts from leaves and flowers have been traditionally used for diseases of the respiratory tract due to their broncholytic, secretomotoric, and anti-spasmodic effects. Thymol is known to relax the trachea and binds with α1-, α2, and β-receptors of smooth muscles, so this effect is believed to be related to the activity of thymol and carvacrol, the main phenolic compounds in the extract. To get evidence of this hypothesis, Engelbertza et al. [106] investigated the spasmodic effect of thymol-deprived thyme extracts and determined which compounds are responsible for the actual effect. The thyme extract was split into fractions, the compounds were isolated from them and the anti-spasmodic effect was determined on smooth muscle trachea model of rats with papaverin as a control. The results showed that thymol possesses an anti-spasmodic effect, but for the complete effect it was not responsible by itself alone but probably in synergistic effect with the flavone luteolin.

The pro-apoptotic and anti-cancer effects of thymol are reported in several studies. Xuan et al. [107] investigated the effect of thymol on the immune response, by examining the effect, survival, and function of dendritic cells. Dendritic cells are important for inducing an immune reaction against pathogens, but also to prevent unnecessary immune reactions against harmless antigens, and it plays important roles in the intestine. The study was performed on dendritic cells either from wild-type mice or from mice lacking acid sphingomyelinase, treated and untreated for 24 h with thymol. The treatment with thymol was shown to stimulate sphingomyelinase and formation of ceramide, down-regulation of Bcl-2 and Bcl-xL expression, activation of caspase-3 and -8, and suicidal death of the cells in the end. This finding is interesting because thymol was shown to protect from suicidal cell death in erythrocytes, which is also triggered by sphingomyelinase stimulation and ceramide formation. So, there is an opposite effect on erythrocytes and dendritic cells. The authors suggest, besides the fact that the thymol-induced apoptosis could induce anti-inflammatory actions, caution is necessary with use in infectious diseases because there is a possibility it might induce the pathway of an infectious disease.

Hsu et al. [108] examined the effect of thymol on Ca^{++} and the viability in human astrocytes, using glioblastoma cells for a model. The study showed that thymol induced a rise of the Ca^{++} concentration and cell death in the glioblastoma cells. The Ca^{++} rise was thymol-dose-dependent and realized through releasing Ca^{++} from the intracellular stores and inducing Ca^{++} entry from extracellular medium via non-store operated Ca^{++} channels. The mechanism is, according to the authors, related to the phospholipase C- and protein kinase C-dependent release from stores from the ER. Thymol induced cell death that was not triggered by the rise of Ca^{++} concentration. The cell death most probably involves apoptosis and necrosis.

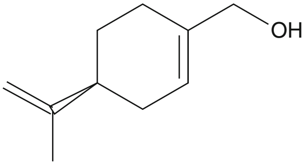
Chang et al. [109] investigated the same topic, using MG63 human osteosarcoma cells. The results were partially similar. Thymol provoked a Ca^{++} rise by triggering the phospholipase C-dependent release from the stores in the ER and the Ca^{++} entry through kinase C- dependent store-operated Ca^{++} channels. Thymol was also able to induce cell death, probably related to apoptosis via mitochondrial pathways.

Satooka and Kubo [110] investigated the inhibitory effect of thymol on the formation of melanin. They came to the conclusion that this effect is due to the radical scavenging activity of thymol. Thymol inhibits the redox reaction between dopaquinone and leukodopachrome without any interaction with tyrosinase, although, tyrosinase is the key enzyme in melanin synthesis. This finding is important due to the fact that a high melanogenesis produces free radicals and can be further on related with development of diabetes mellitus, cardiovascular diseases, or cancer. One year later, the same authors investigated [104], on basis of the previous findings, the effect of thymol on B16-F10 murine melanoma cells. They wanted to examine whether thymol is capable of inhibiting melanogenesis in cultured melanocytes, but without interfering the cell growth. Thymol exhibited moderate cytotoxity but not an antimelanogenic activity. With vitamin C and D, the moderate cytotoxic activity could be inhibited and cell viability enhanced. Actually, B16 melanoma cells cultured with thymol showed a significant increase of oxidative stress. In conclusion, at high concentrations, thymol acts as a pro-oxidant rather than an antioxidant, so the authors suggest rather caution when using it as a food additive.

The anti-cancer effect of thymol is related to its ability to scavenge free radicals, but besides these antioxidant properties, other effects exist. That is why Deb et al. [111] investigated the anti-cancer effect of thymol on acute promyelotic leukemia HL-60 cells. Thymol exerted a cytotoxic effect on HL-60 cells but not on normal human peripheral blood mononuclear cells. The authors suggest that the different effect on normal and cancer cells can be related to a different gene expression or an activity-modulation of thymol, and, in general, the case that a plant extract is pro-oxidative in vivo on one tissue and is antioxidative on another tissue is already known. The cytotoxic effect of thymol is related to an increase of ROS production, mitochondrial H_2O_2 generation, depolarization of the mitochondrial membrane potential, decrease in Bcl-2 protein and increase in Bax protein expression and activation of caspase. So, thymol was able to induce the cell death in HL-60 cells both caspase dependently and independently.

Archana et al. [103] investigated the role of thymol against radiation-induced DNA damage under in vitro conditions, determined by micronuclei and comet assay in Chinese hamster lung fibroblast cells. Radiation is commonly used for cancer treatment, but the DNA damage it causes can also affect normal tissue. That is one of the reasons the researchers were interested in finding new, effective substances as a protection against damage of healthy tissues while exposed to radiation. Thymol protected cells against genotoxicity and apoptosis induced by radiation. This effect is most probably related again to its antioxidant and radical scavenging properties. On basis of this in vitro information, the same team investigated the in vivo radioprotective effect of thymol in Swiss albino mice [112]. Besides the radioprotective effect, the anticlastogenic effect of thymol was investigated against a whole-body gamma radiation. The results showed that with a pre-treatment with thymol on gamma radiation-sensitized mice, a decrease in LPO levels and increase of the antigenotoxic, anticlastogenic, and radioprotective effects and an increase in viability of the animals could be caused. This effect is again due to the antioxidative and free radical scavenging activity, but the existence of other mechanism cannot be excluded.

3.8 Perillyl Alcohol



Perillyl alcohol is a MT-ic alcohol that can be found in the EOs of lemon, lavender, mint, ginger, and some vegetables. Perillyl alcohol is best known for its anti-cancer activities and several studies report on its mechanism of action.

For example, Garcia et al. [113] reported on the inhibitory effect of this substance on the Na/K-ATPase from guinea pig kidney and brain tissues, and from A172 human glioblastoma cells. They suggest that the anti-cancer activity could be related to its Na/K-ATPase binding properties, thus showing a non-competitive inhibition of perillyl alcohol to Na^+ and K^+ and an un-competitive inhibition towards ATP. The authors also suggest that the drug probably acts in the initial phase of the catalytic cycle of the enzyme, different from the standard inhibitor ouabain (binding and inhibiting on the plasma membrane Na^+/K^+-ATPase).

The results of many recently published studies point out the anti-cancer effect on glioblastoma cells. Those discoveries are important because glioblastoma multiforme is the most deadly primary brain tumor in humans. Da Fonseca et al. [114] investigated the efficacy of perillyl alcohol, when intranasally administered, on the survival rate of patients with recurrent malignant glioma. The study was performed in comparison to historical untreated patients. The intranasal administration was chosen due to the evidence that the substance takes its route through perineural and/or perivascular channels along the olfactory and the trigeminal nerves. The study showed that perillyl alcohol can increase the overall survival of recurrent glioblastoma patients, compared with the historical control group. The effects were outstanding in patients with secondary glioblastoma multiforme and patients who had tumors in deep areas of the brain. It is important to note that there were almost no side effects, even in patients who were treated for 4 years. The mechanism of action of perillyl alcohol is believed to be related to the inhibition of Ras/Raf/ERK pathways, NFkB, and also the isoprenylation of the Ras small GTPase superfamily of proteins that induce tumor-related angiogenesis. In the primary glioblastoma multiforme, the EGFR and its mutant EGFRvIII are overexpressed, so by alterations of the EGF/EGFR pathway, perillyl alcohol likely influences the development of the disease.

The previous study followed up on earlier findings of the same group. In 2008, their study proved that perillyl alcohol was able to extend average life by more than 8 months in recurrent glioblastoma patients, to decrease the tumor growth, and to reduce tumor size.

However, after 7 months, tumors became resistant to perillyl alcohol and continued to grow [115]. Based on these findings, de Saldanha da Gama Fischer et al. [116] investigated the molecular changes that finally lead to the resistance of the tumor to perillyl alcohol. For the purposes of the study, a new glioblastoma cell culture was generated heretofore as A172r, which was able to tolerate doses of perillyl alcohol from which the standard cell line would die. The result was a list of protein markers that are representative in the resistant or the non-resistant cell line. The proteins are related to cellular growth, negative regulation of apoptosis, ras-pathway, and other functions of the cell.

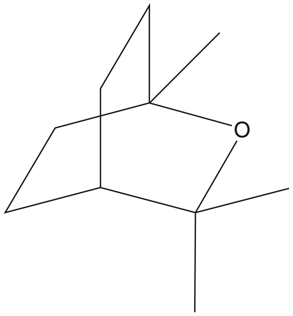
Malignant gliomas are related to alterations in EGF/EGFR signaling. Thus, da Silveira et al. [117] examined the influence of an EGF + 61A > G gene polymorphism on the development of the disease and the different responses to an intranasal administered perillyl alcohol therapy. The study showed that patients who had lower EGF levels survived longer after the perillyl alcohol treatment, probably due to the fact that high levels of EGF can be related to larger tumor sizes and greater degree of malignancy. Thus, EGF level in the serum may be predictive of treatment response. The authors also suggest that perillyl alcohol, as a lipophilic substance, can cross the blood-brain barrier and induce cell death even in cells with low rates of EGF/EGFR signaling.

Khan et al. [118] reported on perillyl alcohol exerting antioxidant effects and modulating TNFα release and NFκ-B activation. With these activities, which are related to inflammation processes and damaging of cells, perillyl alcohol showed protective effects in models of ethanol-induced liver injuries in Wistar rats. The study demonstrated that perillyl alcohol has the capability to prevent liver toxicity by boosting the endogenous antioxidant system, inhibiting lipid peroxidation, and suppressing the inflammatory cytokines and NFκ-B activation. The authors suggest this monoterpene has a possible role in the prevention of liver toxicities.

4 Ether

4.1 1,8-Cineole

Synonym: Cineole, Eucalyptol



The 1,8-cineole MT compound can be found abundantly in nature. It is the major compound of the *Eucalyptus* EO, with up to 80 %, but it can be also found in *Rosmarinus off., Salvia off., Mentha* ssp. and in other plants as well. It is used in different cosmetic products, like toothpaste, soaps, and creams, and also in household products like air fresheners and cleaning products [119]. The substance is a colorless liquid, which possesses a fresh, camphor-like odor. It is reported that with appropriate handling of 1,8-cineole, no toxic effects can be expected, but after admission of high concentrations, systematic effects such as blood pressure drop-down, CNS disturbance, and somnolence can be caused [120].

The pharmacological effects of 1,8-cineole, which have been documented in the past, are mostly focused on the therapeutic activity of this substance on the respiratory tract and inflammation in general. A long-term systematic treatment can have therapeutic, mucolitic effects in asthma, sinusitis, and COPD and in diseases of the lower and upper airways in general. The normalizing effect of the mucus hypersecretion by 1,8-cineole is related to its ability to inhibit the arachidonic acid metabolism and generation of cytokines in human monocytes. So, the substance exhibited a steroid-saving effect on steroid-dependent asthma [121]. 1,8-Cineole is also an inhibitor of TNFα and IL-1β [122].

Worth et al. [123] investigated whether 1,8-cineole can, due to its mucolytic, bronchodilating, and anti-inflammatory activity, reduce the exacerbation rate and improve the health status when applied as a concomitant therapy in COPD patients. The substance possesses positive effects on the beat frequency of the cilia in the mucus. 1,8-Cineole reduced the exacerbation rate and improved lung function by improving the airflow obstruction and reducing severity of dyspnoea. Due to its positive effect on the health status, lack of side effects, and relative low cost, concomitant therapy can be recommended with therapy of the rather costly COPD, in the opinion of the authors.

The antioxidant property of the EO as well as of methanolic extracts of *Eucalyptus loxophleba* Benth. ssp. were evaluated by Rahimi-Nasrabadi et al. [124], where 1,8-cineole presents, with 39.4 %, the major compound. For the examination, the DPPH, β-carotene/linoleic acid, and reducing power assays were used. The results showed that the methanolic extracts are very effective antioxidants in in vitro assays and that the compounds of *E. loxophleba* exhibit antioxidant activities.

It is recognized that EOs with MT compounds such as 1,8-cineole can be used to evoke epileptic seizures. For this reason, Ćulić et al. [125] investigated the effect of this compound in the camphor EO using wavelet and fractal analysis to quantify the electrocortical changes. Animals were intraperitoneally treated with camphor EO or 1,8-cineole, and then by wavelet analysis the frequency bands in pre-ictal, ictal, and inter-ictal stages were examined. The properties of the acute, epileptic-like seizures, caused by either the EO or 1,8-cineole, could be described through frequency bands in wavelet analysis. δ frequency bands dominated brain activity, with ≈45 % mean relative wavelet energy (MRWE) in the control group (no treatment) increasing up to ≈76 % MRWE after drug application. The effect seems to be concentration-dependent.

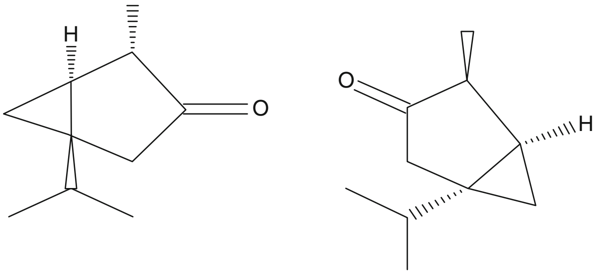
Kirscha et al. [119] investigated the flavor changes in breast milk after the oral intake of a preparation that contains 1,8-cineole. The background of this investigation was the fact that odorants in breast milk can potentially affect the breastfed child. Newborns are extremely sensitive to olfactory stimuli, and this influence is believed to affect food preferences in the years to come and may be a potential preventive of nutrition-related diseases. The study showed that after ingestion of a preparation containing 100 mg 1,8-cineole, the substance was transferred into the milk in a time-dependent manner. The change of the flavor of the milk could lead to rejection of the milk, and over the long term, might have an effect on food preferences later in life.

Yoshimura et al. [126] examined the influence of 1,8-cineole on proliferation and elongation in plant cells by using BY-2 suspension-cultured tobacco (*Nicotiana tabacum*) cells. 1,8-Cineole inhibited cell elongation more efficiently than cell proliferation. The authors suggest that the inhibitory effect of this substance is not specific, but it seemed to affect several cellular activities in an almost nonspecific way by direct contact with the cells.

Tomsheck et al. [127] found that 1,8-cineole can be produced in *Hypoxylon* sp., an endophyte of *Persea indica.* This novel source is easier to use and apply in medicine, industry, and even as a fuel additive, due to the fact that it is a derivate of octane.

5 Carbonyls

5.1 Thujone



Thujone belongs to the group of bicyclic MT ketones and it occurs in two stereoisomeric forms, the α-thujone and β-thujone. It is an ingredient of the EOs of *Salvia* spp.*, Thuja* spp.*, Artemisia* spp., and some others [128]. Thujone is a compound in aromatic plants that are used to flavor food and beverages. The substance is often associated with absinthe, the spirit flavored with *Artemisia absinthium* L. Much discussion has taken place regarding the possible role of thujone in causing adverse psychoactive effects in the “absinthism” syndrome. But the symptoms may have been wrongly attributed to thujone, and may rather be caused by ethanol or other toxic adulterants. Today, thujone-containing plants can be used in food without restrictions, but in pure form, it is still forbidden to directly add thujone to food. That decision was made in 2008 by the European Union Regulation on flavorings [129]. Thujone is believed to be neurotoxic, by providing a convulsant effect, with α-thujone being even more toxic than *β*-thujone. The EO of *Salvia off*., which is rich in thujone (35–50 %, mainly α-thujone) is known to be an abortifacient and an emmenagogue agent [130].

In 2010, Lachenmeier and Uebelacker [129] re-evaluated the toxicological evidence for thujone by making a new risk assessment using the benchmark dose (BMD) approach. The current limits set for thujone in food products are based on short-term animal studies from the 1960s, and they estimated the acceptable daily intake (ADI). As mentioned above, the restrictions for food were lowered in 2008, but the opposite happened for use in medicine when in 2009 the European Medicines Agency (EMA) introduced limits for the substance. *Artemisia absinthium* L. and *Salvia offinicinalis* L. are often used in medicine in various preparations. Due to the lack of toxicological data for thujone, it was not possible to set an accurate value for ADI for thujone, so the ADI for *A. absinthum* has been determined as 3.0 mg/person for maximum 2 weeks use and 5.0 mg/person for *S. officinalis*. The results of the evaluation were similar to previous short-term studies, thus, the authors proposed an ADI of 0.11 mg/kg bw/day, which would not be possible to reach even when consuming high levels of food containing thujone – between 2 and 20 cups of wormwood or sage tea would be required to reach this ADI.

In 2011, the National Toxicology Program [131] published the results of their study on the effect of α,β-thujone on male and female rats and mice. The aim was to determine the potential toxic and cancer-related activity of thujone. The rats receiving 50 mg/kg died; all other rats, which received 25 mg/kg, had seizures. Similar results were obtained dose dependently with mice. Male rats showed high frequency of preputial gland cancer and a slight increase of pheochromocytomas in the adrenal gland, but no increases in cancer were shown in female rats or male and female mice.

Abass et al. [132] described the metabolism of α-thujone using human hepatic preparations in vitro. Their aim also to determine the relevance of cytochrome P450 and the possible interference of other enzymes in the metabolization of α-thujone. The substance was shown to have two major metabolites (7- and 4-hydroxy-thujone) and two minor metabolites (2-hydroxy-thujone and carvacrol), and glutathione and cystein conjugates were also detected. CYP2A6 was responsible for 70–80 % of the metabolism, followed by CYP3A4 and CYP2B6.

To address the controversy regarding the psychoactive effects of thujone in absinthe, the thujone content in this alcoholic drink is too low to produce such effects. However, modern studies report that at high concentrations, thujone can indeed induce seizures, which is one of the symptoms of absinthism. Because this effect can be attenuated by benzodiazepines, an interaction with GABA_A receptors has been suggested. Because the effect of thujone on GABAergic synaptic transmission and also the mechanism of GABA_A modulation was unknown, Szczot et al. [133] investigated this effect. They used cultured hippocampal neurons and compared the effect of thujone and dihydroumbellulone on GABAergic miniature inhibitory postsynaptic currents and on responses caused by rapid exogenous GABA applications. α-Thujone reduced the frequency and amplitude of miniature inhibitory postsynaptic currents and also modulated their kinetics, suggesting both pre- and postsynaptic mechanisms. The current response on exogenous GABA showed reduced amplitude, modulated onset, desensitization, and deactivation, which indicates receptor gating. Dihydroumbellulone was ineffective or showed much smaller effects. α-Thujone was confirmed to exhibit a specific action on GABAergic activity, indicating the existence of a MT-recognition site on $GABA_A$ receptors. The authors suggest further systematical investigations.

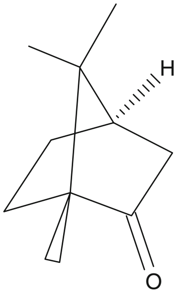
Thujone is a major compound in several plants that are believed to have antidiabetic properties. For this reason, Alkhateeb and Bonen [128] examined the use of thujone per se in the therapy of insulin resistance. In the study, insulin resistance was rapidly induced with high concentrations of palmitate in the skeletal muscle and the restoration of insulin sensitivity with thujone was assessed. The study showed that this substance was able to completely recover insulin sensitivity, even when palmitate was continuously present. This effect is related to the complete restoration of AS160 phosphorylation and palmitate oxidation. Thujone showed improvement in insulin-stimulated glucose transport and GLUT4 (glucose transporter type 4) translocation (an insulin-regulated glucose transporter), but those two effects were not totally parallel to each other. The authors suggested a possible improvement of the intrinsic activity of GLUT4 as a secondary mechanism, next to the modulation of GLUT4 translocaton. Thujone was able to activate AMP-activated proteinkinase (which usually stimulates fatty acid oxidation via inhibition of acetyl-CoA carboxylase activity), but not every restorative effect was related to this activation, such as the oxidation of palmitate, for example. The insulin-stimulated AS160 phosphorylation and glucose transport was shown, however, to be related to AMP-activated proteinkinases. The finding that thujone can improve insulin sensitivity in skeletal muscle suggests it as a, relatively cheap potential therapy, although the exact mechanisms and its safety should further examined.

Although, as already mentioned, thujone has been shown to induce cancer when applied in high doses, it seems that, in the opposite direction, it can also provide anti-cancer effects. The ethanolic extract of *Thuja occidentalis* is commonly used, in form of a mother tincture (TOΦ), in homeopathy and also in traditional medicine to treat moles and tumors. The EO of fresh leaves from this plant contains approximately 65 % thujone, related to the MT fraction. Biswas et al. [134] investigated the anti-cancer effect of the mother tincture and a thujone-rich fraction (TRF), which was separated from it, on the cancer melanoma cell line A375. TOΦ had four fractions, chromatographically separated, of which the TRF was shown to have the best anti-cancer and pro-apoptotic effect. The TRF might actually be the key-component for this effect in general. The anti-cancer activity was provided by inducing a pro-apoptotic pathway via activation of Bax, caspase-3, and cytochrome 3. Both TOΦ and TRF also caused a reduction in cell viability, induced DNA fragmentation, mitochondrial transmembrane potential collapse, and higher ROS production.

The study of Siveen and Kuttan [135] provided further proof for the anti-cancer and, more precisely, antimetastatic effect of thujone. The examination was performed on mice, where the metastasis was induced by injecting highly metastatic B16F-10 melanoma cells through the lateral tail vein. Administration of thujone, either prophylactic or parallel to tumor induction, suppressed the tumor nodule formation in lungs and increased the surviving rate. The parameters that thujone influenced where extensively discussed. The treatment led to an inhibition of pro-inflammatory cytokines (TNFα, IL-1β, IL6, GCSF), down-regulation of the matrix metalloproteinase 2 and 9, tissue inhibitor of metalloproteinase 1 and 2, VEGF, ERK-1, and ERK-2 in the lung of the animals. The invasion of the melanoma cells across the collagen matrix in a Boyden chamber was suppressed by thujone treatment, as well as the adhesion of the cancer cells to collagen-coated microtitre plate wells and the migration of the melanoma cells across a polycarbonate filter.

The possible antioxidative effect should be mentioned. Laciar et al. [136] tested the EO of *Artemisia echegarayi* for it antioxidant activity. It inhibited, with one exception, the growth of Gram-positive and -negative bacteria. It had the lowest minimal inhibitory concentration against *Listeria monocytogenes* and *Bacillus cereus*. Thujone and camphor are believed to be responsible for the antibacterial activity.

5.2 Camphor



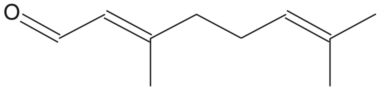
Camphor is naturally occurring in the camphor laurel tree (*Cinnamomum camphora*), but it can be obtained synthetically from turpentine oil. It possesses a cyclic turpentine structure, so it is very lipophilic, which is the reason why it is so well distributed in the body and can make crossings through mucus membranes and probably attract myelinated axons. Camphor is used in medicine for its local anesthetic, antipruritic, and antiseptic activities and as a expectorant in pharmaceutical preparations [137]. Camphor has been cherished for its medical uses for ages in Asia; it remains less known in other parts of the world. Camphor vapor is not irritating to the eyes, so it is used in cosmeticproducts and also in room fresheners or in food as a disinfectant [138].

In the eighteenth century, Leopold Auenbrugger reported on the use of camphor in the treatment of psychosis by inducing epileptic seizures. Camphor was considered to be similar to opium in pain treatment or quinine in treatment of malaria fever [139]. Indeed, camphor can cause seizures; camphor poisoning can also result in apnoea, renal insufficiency, high hepatic enzyme levels, and vomiting, which can end in pneumonitis due to the aspiration or even death. Many everyday products contain this substance. For example, several cases of camphor poisoning by ingestion of camphor mothballs for persistant headaches are known [140]. The most common symptoms in serious poisoning are neurological, such as irritability, hyperreflexia, tonic muscle, contraction, confusion, and coma. The only care is supportive help since no antidotes are available. During acute camphor toxicity, changes occur in axonal excitability. There is an excessive response to hyperpolarizing currents in the threshold electrotonus and the current-threshold relationship, which leads to a decrease in the conductance that was initiated by the hyperpolarization [137].

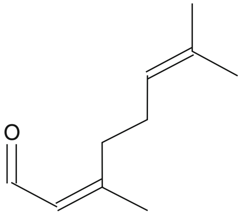
Camphor has been shown to act on two members of the TRP family, TRP vanilloid subtype 1 and subtype 3. That is the reason for the modulating sensation of warmth in humans by this substance [141]. Marsakova et al. [142] investigated the molecular mechanism of this action and the possible interaction site on TRPV1. The results showed that camphor acts on the channel by affecting the gating equilibrium of the outer pore helix domain of the channel. Camphor might also induce changes in the spatial distribution of phosphatidylinositol-4,5-bisphosphate on the inner leaflet of the plasma membrane, since it is known that the substance can decrease fluidity of the plasma membrane.

Worth mentioning is the finding of Nikolic et al. [143] that camphor (eucalyptol and thujone as well) can stimulate error-free DNA repair processes and act as a bioantimutagen. The studies were performed on prokaryotic and eukaryotic cells. The results showed the antimutagenic potential of these MT, although at higher concentrations these substances induced DNA strand breaks.

5.3 Citral



Geranial



Neral

Citral is a naturally occurring aliphatic aldehyde MT. The name citral stands for the mixture of the cis and trans-isomer called geranial and neral. With approximately 80 %, it is the major component of lemongrass oil (*Cymbopogon citratus*), but it can be found in all other citrus fruits as well. Citral possesses a fresh, intense lemony scent, which is why it is extensively used in food, cosmetics, and household products. *Cymbopogon citratus*, which is the most prominent source of this MT, is an evergreen plant growing widely in Asia and traditionally used in oriental households. Citral is believed to be non-toxic and does not induce cancer in animal models [144]. Reports on the pharmacological activities of citral are made continuously, so a few recent discoveries will be mentioned within the next lines.

C. citratus is traditionally used against GI disorders, and citral is believed to be responsible for most activities of this plant. For this reason, Devi et al. [145] investigated the extract of different parts of *C. citratus* (leaves, stems, and roots) and citral on the visceral smooth muscle in the rabbit ileum. The aim of the study was to examine the spasmolytic activity of citral, so the effect was tested on acetylcholine (ACh)- and KCl-induced contractions. The study showed that citral and the leaf extract (LE) were capable of inhibiting spontaneous contraction in a dose-dependent manner, while the extracts of the root and stem did not show results worth noticing. Citral and LE were also able to reduce the contractions induced by ACh, which was similar, although less strongly, to atropine, an antagonist of the muscarinic receptor, suggesting the possible mechanism of action. Citral was also able to inhibit contractions induced by high concentrations of K^+, very similar to verapamil (80 % inhibition with citral compared with 90 % by verapamil). The inhibitory effect of citral on the visceral smooth muscle was the strongest on spontaneous contractions, followed by KCl- and ACh-induced contractions. The mechanism of relaxation is probably by interfering in the NO-pathway and inhibiting calcium channels, due to the fact that the spasmolytic effect of citral could be reduced by L-NAME, an inhibitor of the nitric oxide synthase. Another possible mechanism is the blockage of muscarinic receptors, as mentioned above, and also inhibition of IP3, resulting in a relaxation of the smooth muscle.

It is believed that citral provides anti-inflammatory and analgesic activities, which was examined and proved in several studies. Katsukawa et al. [146] evaluated this effect using established assays for COX-2 and PPAR. Citral was shown to be a dual activator of PPARα and γ and also a PPARγ-dependent inhibitor of COX-2 expression. This finding was assessed by the fact that the NF-κB site of the COX-2 gene was involved in the inhibition of LPS-induced COX-2 promoter activity by 15d-PGJ2, a natural PPARγ ligand, as well as by dexamethasone. In U937, human macrophage-like cells, citral was able to inhibit both LPS-induced COX-2 mRNA and protein expression dose dependently. Citral is known to act on the TRP channels, particularly TRPM8 and TRPA1. The TRP channels are believed to be related to inflammation processes and even cancer, so this mechanism cannot be excluded. The authors suggest that this finding of citral is useful for consumption as a compound in the daily diet but not as a pharmacological drug, because the activity is, after all, lower compared with standard synthetic drugs.

Macrophages present an important source of inflammatory cytokines and have the potential to control an overproduction of these products, thus protecting against development of immunopathologies. Bachiega and Sforcin [147] investigated the effect of lemongrass and citral on the production of the cytokines IL-6, IL-1β, and IL-10 by peritoneal macrophages in vitro. The effect was determined before and after macrophages where incubated with LPS. The study proved the anti-inflammatory effects of citral, suggesting that the possible mechanism is involved with the inhibition of the transcription factor NF-κB. Citral inhibited the release of IL-1β, both before and after the LPS challenge; the same effect was seen with IL-6 and IL-10. Lemongrass, in comparison to citral, was not so effective; it could only inhibit LPS action after the macrophage challenge with LPS.

The synergistic action of a non-steroidal anti-inflammatory drug with plants that provide the same effects can increase the anti-nociceptive activity, with even lower rates of side effects and using lower doses. Ortiz et al. [148] investigated the anti-inflammatory effects and the gastric damage of the application of citral, naproxen, and their combination in rat models. The substances were orally administered and the effect was assessed on carrageenan-induced paw edemas and gastric damages, while the interaction type was assessed by isobolographic analysis. Naproxen, citral, and their combination exhibited anti-inflammatory effects. The advantage of their combination was that the gastric damage that naproxen significantly produced when administered by itself was not obtained when applied with citral, suggesting a potential of minimizing gastric damage in therapeutic use. Naproxen and citral were shown to have a synergistic interaction, which the isobolographic analysis demonstrated. This interaction is most probably provided by citral acting on TRP channels and inhibiting NO production, while naproxen, on the other side, suppresses the prostaglandin production.

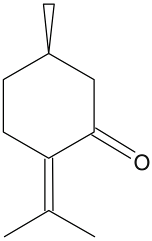
Another interesting pharmacological effect of citral is its antiadipogenic and antidiabetic activity, recently investigated by Modak and Mukhopadhaya [144]. This finding was based on the fact that citral acts as a competetive inhibitor of retinaldehyde dehydrogenase, leading to higher levels of retinaldehyde in adipocytes. Retinaldehyde is known to suppress adipogenesis and increase the metabolic rates and also influences the glucose tolerance. The study showed that citral was able to decrease the body weight gain and abdominal fat mass in rats, which were held on a high-energy diet. The effect was dose-dependent. The food intake of the rats has not changed while citral was administered suggesting that the lower weight gain is related to a lower fat absorption or higher energy expenditure. An increased metabolism is most probably the involved mechanism because an increased metabolic rate, temperature, and respiratory quotient were determined. Citral also was shown to affect insulin by decreasing its levels. which is related to an improvement in glucose tolerance and lower fasting plasma glucose levels. Taking these findings together, the authors suggest that citral has a possible role in alleviating lifestyle diseases like obesity or diabetes.

Chaimovitsh et al. [149] reported on the effect of citral on mitotic microtubules in models of tobacco BY2 cells and wheat roots. Citral disrupted mitotic microtubules and suppressed the cell cycle and also increased the occurrence of asymmetric cell plates in those cells. The effect seemed to be dose-dependent. The authors propose that at lower concentrations, citral influences cell division by disruption of the mitotic microtubules and cell plates; at higher concentrations it suppresses the cell elongation by disrupting cortical microtubules.

The antibacterial activity of citral should be briefly mentioned. Citral inhibits swarming and virulence factor expression of *Proteus mirabilis*, which can cause urinary tract infections, thus it is used to prevent development of these infections

[150]. Citral was also shown to be effective against four pathogene stains of isolated bovine mastitis, including *Staphylococcus aureus, Streptococcus agalactiae, Bacillus cereus*, and *Escherichia coli* and was also effective in destroying *S. aureus* biofilms [151]. The inactivation of *E. coli* cells is related to inducing damage in the cell envelope [152]. In addition, citral has been shown to be the responsible compound in the anti-Leishmania activity of *C. citratus*, by providing a significant inhibition of *Leishmania infantum, Leishmani tropica*, and *Leishmania major* [153].

5.4 Pulegone



Pulegone is a MT ketone that can be found as a compound in pennyroyal EO (*Mentha pulegium*). It is used in low doses as a flavoring agent in food, beverages, and hygienic products. In high doses, it is reported to cause gastritis, seizures, hepatic and renal damage, toxicity to the CNS, and coma. It has been used to induce menstruation and abortion. [154]. In 2011, the National Toxicology Program published the results of the toxicology and carcinogenesis gavage study of pulegone. The study was performed on rats and mice receiving pulegone, and data assessment was performed after 2 weeks, 3 months, and 2 years. Genetic toxicology studies have been performed on *S. typyhmurium, E. coli*, and mouse erythrocytes. The toxic effects of pulegone on rats and mice increased dose dependently. Even in the 2-week treatment group, several cases of animal death occurred when pulegone was applied in high concentrations. In the group of rats and mice treated for 3 months, besides changes in blood parameters, most damage or death was attributed to liver toxicity. The rats and mice treated for 2 years with pulegone showed symptoms like thinness, lethargy, and ruffled fur. In comparison to vehicle controls there was an increase in pathological developments in the liver (oval cell hyperplasia, bile duct hyperplasia, hypertrophy, hepatocyte necrosis, portal fibrosis), kidneys and urinary tract (hyaline glomerulopathy, nephropathy), osteoma and osteosarcoma, degeneration of the olfactory epithelium and inflammations, hyperplasia, and ulcerations of the forestomach [155].

Based on the findings of the above study, da Rocha et al. [154] investigated the mechanism of action of pulegone on the urinary bladder of female rats. It was concluded that female rats showed an increase of urinary bladder neoplasms, whereas male rats did not show an increased incidence of neoplasms of that type. The metabolism of pulegone includes hydroxylaton, reduction or conjugation with glutathione, and the metabolites identified are piperitone, piperitenone, menthofuran, and menthone. The results of the study were in agreement with those from the previous study, with rats losing body weight, bloody nasal mucus, and alopecia in the mouth and urogenital area. Scanning electron microscopy showed damage on the surface of the bladder induced by pulegone. The authors suggest that the tumors are induced due to chronic exposure to high doses of pulegone, its metabolism, excretion, and concentration and its toxic metabolites, especially piperitenone in urine, urothelial cytotoxicity, cell proliferation, and ultimately development of tumors.

De Sousa et al. [156] reported on the pharmacological effects of (R)-(+)-pulegone on the CNS. Pulegone was shown to have a central depressant effect, increased the latency of convulsions, and to inhibit both chemical and thermal models of nociception. The authors suggest, therefore, that pulegone is a psychoactive substance with activities of analgesic drugs.

De Cerqueira et al. [157] investigated the ionotropic effects of R(+)-pulegone in mammalian myocardium. They examined the effect of pulegone on L-type Ca^{++} channels, due to the assumption that it might decrease the Ca^{++} influx and thus change heart contractility. The results showed that pulegone was able to decrease myocardial contractility and reduce the intracellular Ca^{++} transient and L-type Ca^{++} current. The negative inotropic effect is similar to nifedipine, an L-type Ca^{++-}channel inhibitor, which indicates that this is the mechanism of action, but the authors do not exclude other mechanisms from possibly being involved. The effects of pulegone were almost reversible, so possible myocardial damage was unlikely.

Umezu [158] examined whether dopamine is involved in a pulegone-induced ambulation in ICR mice. The results indicate a possible involvement of dopamine and pulegone. A co-administration of pulegon and bupropion (a dopamine agonist) was shown to increase the effect on ambulation-promoting actions, and antagonists of dopamine (chlorpromazine, fluphenazine, haloperidol, and spiperone) were able to alleviate the effects of pulegone. A pretreatment with reserpine (a dopamine depletor) eliminated the sensitivity to the effect of pulegone, which implies that pulegone may not be a direct dopamine receptor agonist.

Xanthine oxidase, 968
Xanthium strumarium, 3528
Xanthohumol, 2154, 2162, 2343, 2346, 2452
Xanthones, 1553
Xanthophylls, 1730, 1732, 2787, 2860, 2868, 3369, 3925, 3928–3931, 3934, 3935, 3937, 3948, 4019, 4020, 4022, 4031
Xanthosine, 959
Xanthoxylin, 1549
Xanthoxylum spp., 1549
Xanthylium cation, 1784
Xenobiotics, 2450, 2472
Xeno-estrogens, 2386
Xenohormetic compounds, 2572
Xerostomia, 599, 877
Xiphophora gladiate, 27
Xylose, 2467

Y
Yamogenin, 3227, 3229, 3230
Yeast, 1705, 1707
Yeast extract, 4044
Yew, 2799
Yohimbine, 589, 596

Z
Zabrotes subfasciatus, 4091
Zanthoxylum, 721
Zanthoxylum limonella, 2998
Zapotidine, 864
Z-β-ocimene, 2979
Z-3-bromo-2-heptenoic acid, 2889
Z-3-bromo-2-nonenoic acid, 2889
Zearalene, 3125
Zeatin, 2737
Zeaxanthin (Z), 3369, 3925, 3926, 3928–3931, 3933–3937, 3939–3944, 3948, 4021
Zeinoxanthin, 3378
Zeta potential, 1155
Zetekitoxin AB, 54
[Z]-3-hexen-1-ol, 4096
Zieridium, 734
Zingiberaceae, 786
Zingiberene, 2985
Zingiber officinale, 2985
Zonocerus variegatus, 4094
Zooecdysteroids, 3828
ZR751, 3478
ZT-1, 1252, 1256
Zygophyllaceae, 800
