Abstract

The metabolic engineering of plants offers the opportunity to change the content of specific phytonutrients in plant – derived foods.

The plant polyphenol *trans*-resveratrol (3, 5, 4′-trihydroxystilbene), mainly found in grape, peanut, and other few plants, displays a wide range of biological effects. Numerous in vitro studies have described various biological effects of resveratrol. In order to provide more information regarding absorption, metabolism, and bioavailability of resveratrol, different research approaches

have been performed. In recent years, the induction of resveratrol synthesis in plants which normally do not accumulate such polyphenol has been successfully achieved by molecular engineering.

In this context, the ectopic production of resveratrol could have positive effects on the enhancement of the nutritional value of several widely consumed fruits and vegetables. This chapter focuses on the latest findings regarding on resveratrol bioproduction in tomato (*Solanum lycopersicum*) fruits.

STS	Stilbene synthase

1 Introduction

Because of resveratrol capacity to confer disease resistance in grapevine and given its clinically useful, most interest has centered, in recent years, on STS gene transfer from grapevine to the genome of numerous plants, with the objective of increasing their tolerance to pathogenic microorganisms and/or improving the of food products through the expression of resveratrol in plants incapable of synthesizing this compound. Studies have been published describing STS-encoding genes isolated from grapevine or other plant species and their use for plant genetic transformation. This chapter explores recent research on the gene transfer of grape STS-encoding genes to tomato plants.

1.1 Overview on Genetics, Biochemistry, and Molecular Biology of Stilbene Synthase

Bioactive ingredients of functional foods help to overcome nutritional deficiencies, and the demand of healthy food products will certainly increase in the future. Plant secondary metabolites are nutritional components of our daily diet.

Stilbenes are small naturally occurring phenolic compounds found in a wide range of plant – derived food – among which berries are important sources [1, 2]. Resveratrol is biosynthetically correlated to stilbenes, but its biosynthesis is restricted to only a few plant species commonly used for human consumption [3–9].

The most abundant levels of naturally occurring resveratrol are found in the roots of Japanese *Polygonum cuspidatum* which has been used in traditional Asian herb medicine, for hundreds of years, in the treatment of inflammation [5]. Grape (*Vitis vinifera* L.) is probably the most important source of resveratrol, since the compound is also found in wine. The economic importance of grapevine has encouraged many researchers to study the physiological and molecular basis of berry physiology, particularly those processes affecting wine quality [10]. In this species, a large array of STS genes has been identified thus suggesting the importance of stilbene metabolism [11].

Resveratrol and its 3-*O*-β-D-glucoside derivative share a chemical structure similar to that of other polyphenol-type stilbenes (Fig. 51.1a) and are controlled by the key enzyme, stilbene synthase (STS), which belongs to a multigene family of the type III group of the polyketide synthase superfamily [3, 4]. STS catalyzes the condensation of three molecules of coumaroyl-CoA to form resveratrol. Synthesis of resveratrol takes place in a single enzymatic step with CoA-esters of cinnamic acid derivatives and 3 malonyl-CoA units as starting blocks (Fig. 51.1b). STS and chalcone synthase (CHS) that are key enzymes of the flavonoid pathway share a high degree of homology and competing for the same substrates.

1.2 Stilbenes Functions in Plants and in Humans

In nature, the most abundant form of resveratrol would appear to be the 5,3,4′-dihydroxystilbene-3-*O*-*β*-D-glucopyranoside [12]. Resveratrol exists in two stereoisoforms with *cis*- or *trans*-configuration, the latter being the most widely studied, although *cis*-resveratrol may also possess health-promoting properties. The number as well as the position of moieties play an important role in the biological activity of the compound [13].

Synthesis of resveratrol in plants tissues is either constitutive or inducible being strongly enhanced by fungal attacks, UV irradiation, and other environmental stress conditions [3–5].

Resveratrol possesses numerous important bioactivities including anti-inflammatory, antioxidant, anti-aggregatory functions, and modulation of lipoprotein metabolism [14]. It has also been shown to possess chemopreventive properties against certain forms of cancer and cardiovascular disorders [15]. Subsequent work has shown that resveratrol extends the life spans of lower eukaryotes [16–18]. In mice, long-term administration of resveratrol-induced gene expression patterns that resembled those induced by calorie restriction

and delayed aging-related deterioration [19]. Resveratrol also decreased insulin resistance in type 2 diabetic patients [20], suggesting that the pathway targeted by resveratrol might be important for developing therapies for type 2 diabetes.

An important mediator of the metabolic effects of resveratrol [21, 22] is the peroxisome proliferator-activated receptor g coactivator, PGC-1α [23]. Consistent with the known ability of Sirt1 to deacetylate and activate PGC-1α [24, 25], resveratrol increased Sirt1 and PGC-1α activity in mice fed a high-fat diet [21, 22].

AMPK, an emerging key regulator of whole-body metabolism, has been shown to activate Sirt1 and PGC-1α [26–28]. Recently it was shown that AMPK-deficient mice are resistant to the metabolic effects of resveratrol, providing evidence that AMPK is a key mediator of the metabolic benefits produced by resveratrol [27]. Resveratrol directly inhibits cAMP-specific phosphodiesterases and the cAMP effector protein Epac1, which leads to the activation of AMPK and Sirt1 [27].

2 Resveratrol Synthesis in Transgenic Tomato Fruits

Plant metabolic engineering has provided a means to improve polyphenol composition and levels. For example, tomato plants with enhanced flavonols have been recently developed through the overexpression of a transcription factor able to activate flavonol biosynthesis [30–32].

STS structural genes have been transferred to a number of crops, either to improve the resistance to stresses or the nutritional value of the plant (for a review see ref. [33] and Table 51.1).

Few articles reported on the production of stilbenes in transgenic tomato, suggesting that it is indeed possible to introduce new branches of the flavonoid pathway, at least at its first step, by introducing foreign structural genes [34–36]. In order to further explore the possibilities of flavonoid engineering in tomato fruits, some authors [35] have targeted this pathway toward classes of flavonoids, which are normally not present in tomato. Using structural genes from several plant sources and combinations thereof, they were able to produce transgenic tomatoes accumulating stilbenes, deoxychalcones, or flavones. These fruits displayed altered antioxidant profiles and an up to threefold increase in total antioxidant activity of the fruit peel (Table 51.1).

Transgenic tomato plants (*Solanum Lycopersicum*, cv money maker), expressing stilbene synthase gene under constitutive 35S, and mature fruit-specific promoter (*TomLoxB*) were obtained by genetic transformation through *Agrobacterium* infection of cotyledons [34]. The phenotype of all transformed lines was similar to that of the wild-type plants, showing a regular development, flowering, and fruit maturation. However, high resveratrol-producing 35SS tomato fruits were seedless, whereas low resveratrol LoxS fruit showed a normal seed set, comparable to wild type (Fig. 51.2) [38]. Protein analyses revealed that the highest accumulation of stilbene synthase was at green stage in constitutively transformed 35SS tomato line [34] and at the red mature stage in the LoxS line [37]. Resveratrol accumulation showed some quantitative differences since the levels recorded in the LoxS were about 20 times lower than those found in 35SS fruits (Fig. 51.3a and b, respectively).

Qualitative and quantitative comparisons between the different transgenic plants synthesizing resveratrol and related stilbenes are difficult, as different analytical methods are used to assay these compounds. These analyses have shown various stilbene levels and spatiotemporal distributions, leading to a considerable variability in terms of relative amounts of different forms.

In particular, the glycosylation of polyphenolic compounds occurs frequently in plant to protect the cell from their potential toxic effects and to prevent their

oxidation and enzymatic degradation [13]. In the case of resveratrol, the free compound is first synthesized, before being glycosylated by endogenous glycosyl-transferases. Free resveratrol and its glycosylated forms have been both detected in transgenic plants [13]. Stilbenes content also depends strongly upon plant species, probably on account of different endogenous pools of enzymes or

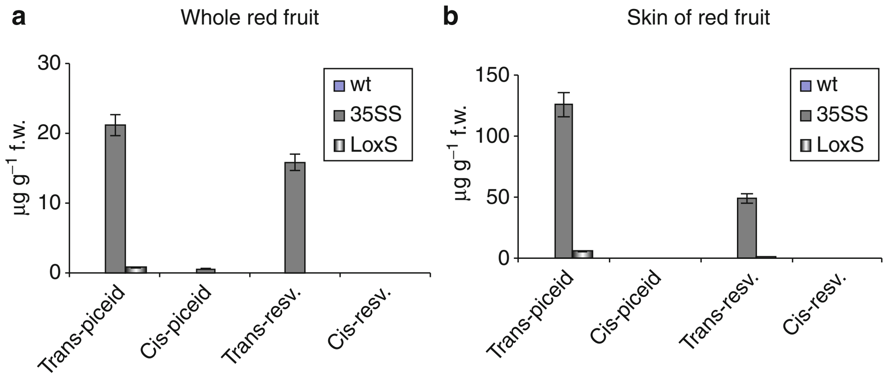

Fig. 51.3 Stilbenes accumulation in 35SS and LoxS whole mature red fruits (**a**) and skin (**b**). The amount of *trans*-resveratrol, *trans*-piceid, and their correspondent *cis*-forms were simultaneously detected on the basis of their retention time and UV spectra of the additional peaks observed after UV irradiation at λ: 366 nm of *trans*-resveratrol and *trans*-piceid, respectively

precursors, as well as differences in secondary metabolic pathways. In resveratrol synthesizing tomato lines, the free to glycosylated resveratrol ratio was related to the fruit ripening stage [34]. Furthermore, these related compounds accumulate differentially in different fruit tissues at the mature stage [36].

The comparison of different resveratrol levels in LoxS and 35SS fruits allowed the authors to study the effect of the differential depletion of substrates and, in the meantime, to clarify the effect of a novel metabolite as resveratrol on related and unrelated pathways committed to secondary metabolism.

2.1 Biochemical Analysis of Flavonoids in Fruit

The main flavonoids which had accumulated in tomato fruits were naringenin and rutin (quercetin-3-rutinoside), predominantly detected in the peel [43, 44].

Both these compounds, together with kaempferol-rutinoside (Kae rut), were quantified in the peel extracts from both the resveratrol synthesizing tomato lines (35S and LoxS lines; Fig. 51.4).

In order to clarify whether the novel biosynthetic pathway introduced in transgenic tomato caused competition for the utilization of the common substrates, levels of main flavonoids in tomato fruit were analyzed. The overall levels of these flavonoids were not impaired in either the transgenic lines. On the contrary, the 35SS line showed an increased level of Kae rut, whereas the LoxS line showed an increased naringenin content. The levels of the other flavonoids did not show any significant differences in comparison with the control tomato line. As far as the other soluble phenolics are concerned, HPLC analysis indicated that significant differences in coumaric and cinnamic acids content, which decreased in 35SS tomato fruit in all the ripening stages [34, 37].

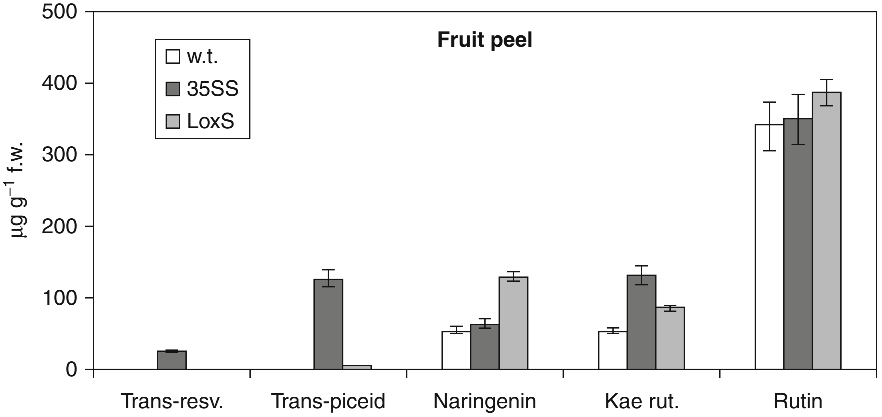

Fig. 51.4 Comparison of flavonoid levels in wild type and transgenic skin of fruit at the *red* stage of ripening. Naringenin levels (λ:.290 nm) in the wild type and transgenic skin (of almost three) red fruits. Outline of flavonols biosynthesis and profiles of accumulation of rutin and kaempferol-rutinoside (λ:.370 nm) in skin of transgenic tomatoes compared with those of wild type

3 Antioxidant Parameters

Fruit ripening has described as an oxidative phenomenon which requires a turnover of ROS, such as H_2O_2 and superoxide anion. A balance between the production of ROS and their removal by antioxidant systems has been proposed. It is likely therefore that the antioxidant system will play a crucial role in the ripening process.

3.1 Effect of Resveratrol Synthesis on the Level of ASA and GSH in Green and Red Tomato Fruits

The production of resveratrol in transgenic plants increased the levels of ASA and GSH in edible tissues thus improving the nutritional values of tomato fruit (Fig. 51.5a).

Given the importance of ROS in the ripening process, the authors have examined the changes in some oxidative parameters and in the antioxidant system during transgenic tomato fruit ripening. It is worth noting that the highest ASA and GSH contents were detected in fruits at green and red stage of ripening concomitantly to the highest level of resveratrol. In ripening tomato fruits, a transient increase in ROS production occurs during the intermediate phases of maturation. The relevance of antioxidant enzymes and metabolites during ripening has been widely investigated [45]. The acquisition, in tomato fruits, of a new biosynthetic pathway leading to the synthesis of resveratrol, which, as other phenolic compounds, has antioxidant properties, induces an increase in the ASA and GSH pools in the transformed fruits [34, 37]. In the red phase, the transformed plants (both 35S and LoxS) had ascorbate content higher than wild type. Therefore the ex novo synthesis

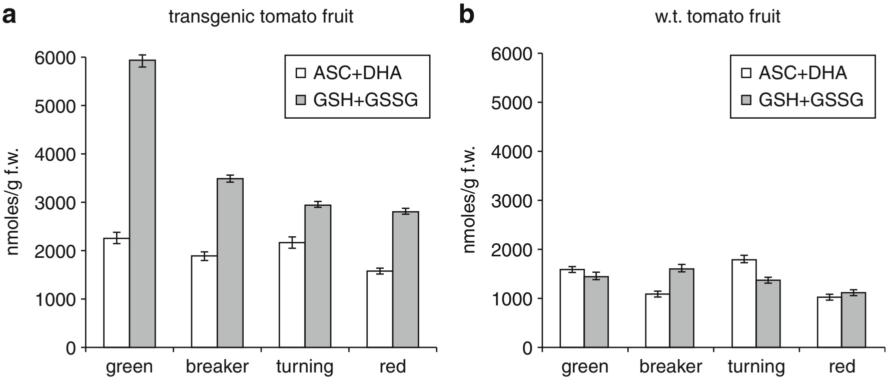

Fig. 51.5 Behavior of the ascorbate and glutathione redox pairs during tomato fruit maturation in transgenic 35SS (**a**) and wild type (**b**). Ascorbate pool (ascorbate plus dehydroascorbate) and glutathione pool (glutathione plus glutathione disulfide) were analyzed in the four different stages of fruit ripening

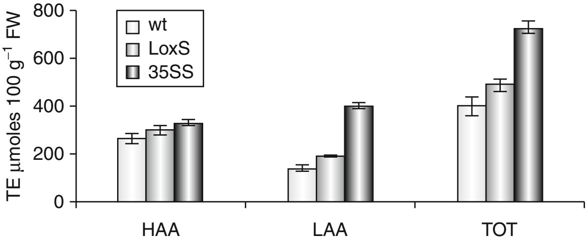
of resveratrol affected the biosynthesis/storage of other antioxidants although these molecules do not have any biosynthetic correlation. Interestingly, only the 35SS fruits, in which stilbene synthase was constitutively expressed, showed increased ascorbate level and enzyme activities altered in the green phase (data not shown). This was in agreement with the fact that stilbene synthase was under the control of *spatio*temporal-specific promoter (LoxS), which allowed gene expression preferentially in the late phase of fruit maturation [36, 37].

In transformed fruits, the increase in GSH levels was much higher than that observed in ASA levels at all the ripening stages analyzed, and the GSH redox state was at least twice that of the control [34, (Fig. 51.5b)]. The increase of glutathione biosynthesis could be a consequence of the presence, in the transformed cells, of the foreign molecules. Indeed, besides a role in ROS scavenging, GSH is also the co-substrate of glutathione transferase and is involved in phenol and xenobiotic conjugation and in their segregation into the vacuole [46, 47]. On the other hand, plant transformation with the STS gene does not seem to affect the level of membrane-associated molecules mainly present in the plastids, since their levels do not significantly differ in either transformed or non-transformed fruits, at any stage of ripening [34]. Since ASA and GSH are soluble antioxidants widely distributed in all cellular compartments, the different effect of resveratrol on these two types of metabolites could be the effect of their different cellular localizations.

3.2 Antioxidant Capability

In transgenic tomato, resveratrol synthesis was able to increase the overall antioxidant properties of the fruit, as well as the ascorbate/glutathione content with

Fig. 51.6 Antioxidant power of mature fruit of wild type, LoxS and 35SS tomato fruits. Antioxidant capability of hydrosoluble (HAA) and liposoluble (LAA) fraction of whole mature fruit



a consequent two to threefold increase in antioxidant activity of fruits and a correlation was found between resveratrol concentrations and antioxidant capacities in the ripening stages accumulating high resveratrol levels [34].

The higher antioxidant capability of resveratrol synthesizing fruits, compared to wild type, has also been confirmed by the analysis of total antioxidant activity (Fig. 51.6). Resveratrol contributes to such an increase since both hydrosoluble and liposoluble fractions have higher antioxidant activities in the transformed in comparison with wild-type fruits, whereas ASC and GSH only affect the hydrosoluble fractions. Interestingly, the increase in the antioxidant activity of the fruits affects lipid peroxidation, the value of which is significantly lower in transformed fruits in respect to that in wild types [34].

4 Anti-inflammatory Activity of Resveratrol-Producing Tomato

Several studies have reported that resveratrol has cardioprotective effects because of its ability to increase plasmatic antioxidant capacity, inhibit platelet aggregation and coagulation, reduce low-density lipoprotein oxidation, and suppress the pro-inflammatory response [48]. The anti-tumorigenic, anti-inflammatory, and cardioprotective effects of resveratrol seem to be related, at least in part, to its ability to suppress prostaglandin production through its interference with the expression and activity of COX-2, the rate-limiting enzyme in prostaglandin biosynthesis. In particular, macrophages are prominent producers of prostaglandin during inflammatory processes in response to signals that trigger macrophage activation, such as bacterial lipopolysaccharide or phorbol ester [49].

Altered COX-2 levels and consequent abnormally high prostaglandin secretion are thought to be involved in diverse pathological processes, and COX-2-specific inhibitors represent important challenges for cancer treatment, as well as chronic inflammatory diseases such as atherosclerosis [50]. The effects of resveratrol-enriched tomato extracts on COX-2 expression induced by phorbol ester in monocyte–macrophage U937 cells indicated that resveratrol reduces the level of the inducible, but not constitutive, COX isoform, thus confirming and expanding the anti-inflammatory activity of resveratrol (Fig. 51.7), as previously suggested [51–53]. Both 35SS and LoxS fruits, which contained different levels of resveratrol, showed higher antioxidant and anti-inflammatory properties than wild-type fruits [38].

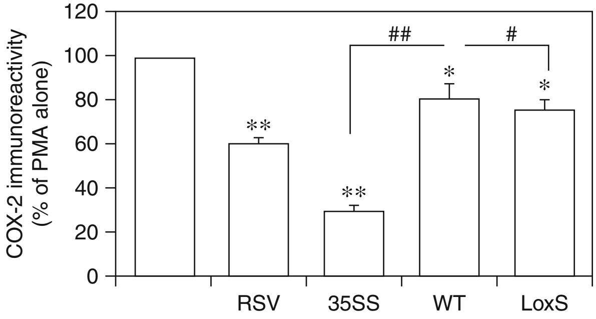


Fig. 51.7 Resveratrol synthesizing tomato fruits inhibited PMA-stimulated COX-2 expression in monocytoid cells. U937 cells were pre-treated with vehicle (ethanol), resveratrol synthesizing tomato fruits (35SS, LoxS) or wild-type fruit, and then stimulated with PMA. Cells extracts, at equal amount of proteins, were immunoblotted with monoclonal antibodies against COX-1 or COX-2. These results are obtained from three independent experiments with similar results. * $p < 0.05$ and ** $p < 0.01$, compared with PMA treated cells; # $p < 0.05$ and ## $p < 0.01$ compared with wild-type fruit treated cells

Remarkably, the extracts of transgenic resveratrol containing tomato fruits displayed an anti-inflammatory effect greater than that of chemically synthesized resveratrol. In conclusion, these results indicate that the presence of a new biosynthetic route responsible for resveratrol biosynthesis improves the health-giving biological activities of tomatoes.

5 Effects of Stilbene Synthase Expression on Reproductive Development of Tomato

The novel STS activity and the significant changes in the levels and/or redox state of soluble primary antioxidants do not have any apparently adverse effect on the normal vegetative growth and development of the transgenic tomato lines. As far as reproductive development is concerned, 35S transformed plants produced seedless fruits.

The development of tomato fruit in the absence of pollination and/or fertilization (parthenocarpy) was achieved using different approaches [54]. STS-induced male sterility has been demonstrated to be a successful approach to genetically engineer male sterility in a model species (tobacco). The resveratrol synthesis in transgenic tomato plants may provide a new method to obtain parthenocarpic fruits. Indeed, pollen development in 35S STS flowers was hampered, resulting in a strongly reduced seed set and all strong yielded parthenocarpic fruits (Fig. 51.2), prompting the authors to hypothesize that specific polyphenols might be efficiently down-regulated by STS gene expression in tomato flowers.

Flavonoids belonging to the class of flavonols have especially been shown to have strong stimulatory effects on pollen development, germination, pollen tube growth, and seed set [55]. When wild-type pollen was applied on transgenic

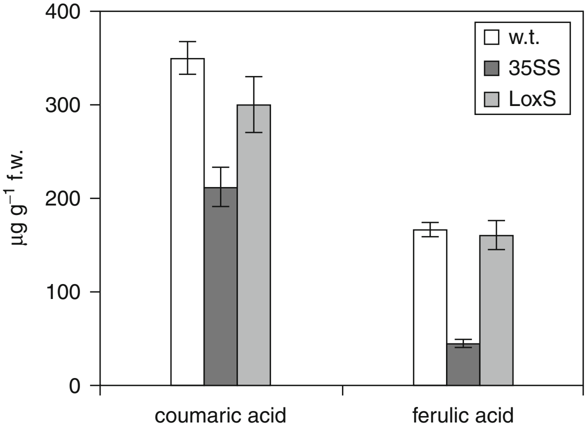

Fig. 51.8 Comparison of coumaric acid and ferulic acid accumulation in wild-type 35SS and LoxS tomato transgenic open flowers

35S STS stigmas, pollen tube growth and seed set were fully rescued thus indicating that fertilization was abolished due to the lack of metabolites in the male reproductive organ [56].

Parthenocarpic tomatoes with suppressed chalcone synthase obtained by using RNA interference [55] showed abolished production of flavonoids. Several studies [55, 57] have clearly demonstrated the importance of flavonols for normal pollen tube development and male fertility. Flavonols have been detected in the pollen of all plant species tested so far and clearly play an important role in pollen tube development. In tomato plants overexpressing STS, the analysis of flavonols showed that pollen ablation was independent of the production of detectable amounts of flavonols in flowers [38].

The authors have introduced an alternative hypothesis for STS -induced male sterility, which, if correct, would significantly contribute to the conclusions drawn by other authors [58]. When expressed in tobacco anthers, STS depletes the substrate for CHS which are key molecules in several other pathways, including those linked to sporopollenin or lignin biosynthesis. Therefore, these pathways may be affected as a result of the decreased availability of precursors. Pollen grains are surrounded by a complex cell wall comprising three layers with an outer exine, a multilayered structure primarily made of sporopollenin; an inner intine, made primarily of cellulose; and a lipid- and protein-rich pollen coat. Several studies have indicated that sporopollenin is a complex polymer composed of fatty acids and phenolic compounds [59]. The analyses of coumaric and ferulic acids, precursors of sporopollenin and lignin, levels suggested impairment in their synthesis in STS sterile male tomato flower tissues (Fig. 51.8). Therefore conclude that when constitutively expressed in tomato, STS competes with CHS for common substrates, in particular in flower tissues where leaded to reduced synthesis of naringenin. Similarly, these compounds are key molecules for other important pathways such as the synthesis of exine layer constituents and lignin.

6 Concluding Remarks

Metabolic engineering is generally defined as the redirection of one or more enzymatic reactions to improve the production of existing compounds, produce new compounds, or mediate the degradation of undesirable compounds. It involves the redirection of cellular activities by modifying the enzymes, endocellular localization, and regulatory functions within cell. Even more sophisticated metabolomic tools and analysis systems will offer the possibility to study both the primary and secondary metabolic pathways in an integrated fashion. Some interesting and important developments may be expected from plant transformation with STS gene.

Therefore, further progress in better understanding of the metabolic pathways and our ability to manipulate gene expression, in genetically modified plants, can be envisaged. Success of this approach depends upon the possibility to change the host metabolism and will depend primarily on a far more sophisticated knowledge of plant metabolism, especially the nuances of interconnected cellular networks.

Identifying rate-limiting steps in the synthesis of specific metabolites could provide targets for genetically engineering biochemical pathways to produce increased amounts of compounds as well as new compounds. Together with traditional plant breeding, genetic engineering provides great opportunities to develop plants with the desired levels and/or composition of specific polyphenols. New insights into stilbene synthase expression restricted to flower tissues may provide a novel hybrid seed system for the development of a nutritionally fortified tomato. Moreover, the consequences of the unintended spread of genetic material through pollen and the risk of cross-pollination with non-transformed plants would be avoided using genetically modified sterile male plants.

Metabolite profiling is an essential tool to analyze the effects of intervention on flavonoid composition itself but also on other related or unrelated metabolic pathways. The availability of phenolic precursors toward specific pathways of the phenylpropanoid network is also controlled by biochemical, genetic, environmental, and developmental parameters [60]. The beneficial effect of *trans*-resveratrol on human health has directed research toward the production of this metabolite in staple plants [61]. The presence of a novel biosynthetic route responsible for resveratrol biosynthesis improved the biological activities of transformed tomatoes [62]. Comparison of the effects of diets containing tomatoes enriched in different polyphenol classes upon onset and progression of diseases in cell assays or animal disease models will allow a quantitative assessment of the efficacy of stilbenes within a common food matrix. The nutritional context could influence the effects of polyphenols, by affecting their bioavailability, or be the result of various dietary phytonutrients acting synergistically, once absorbed [63, 64].

Abstract

Seeds of Theobroma cacao are worldwide in use for production of cocoa butter and confectionary products. The production of raw cocoa from fresh seeds is based on a complex fermentation process, which leads to the aroma precursors. This process enhances the amount of peptides and free amino acids in the seeds, but it also reduces the amount of phenolic compounds, especially the proanthocyanidins. These antioxidative compounds are mostly composed of catechin and epicatechin monomers and oligomers up to decamers. The fermentation has to take into account that both factors, production of aroma precursors as well as

maintenance of health-supporting phenolic factors, are guaranteed. The worldwide rising consumption of high-quality cocoa leads to strong international efforts to develop elite clones of trees with high field performance in resilience, quality, and yield.

Keywords

Antioxidative compounds • breeding aims • fermentation • health claims • phenolics • selection for quality markers

1 Introduction

Theobroma cacao is the unique plant source for production of chocolate. It is a traditional plant product which is in use since more than 3,000 years. Its use is accompanied by myths, and also its scientific name is a reference to the valuable and important seeds, “food of the gods.” In modern science, it is proven that the seeds are delivering health-supporting antioxidative compounds in very high concentrations. Besides these valuable compounds, the cocoa seeds deliver about 50 % of dry weight of fat, cocoa butter, which is in use in cosmetics, confectionary, and pharmacy. Furthermore, cocoa trees are ideal components of small-scale agriculture and are of high importance for about 50 million families that depend economically on this plant for their sustainable lifestyle on the global tropical belt.

Cocoa development organizations are underway to select new, modern cocoa genotypes with good disease resistance, high tolerance to ecological factors like drought and climatic changes, and special flavors and other quality factors. This chapter will present these aspects in detail.

2 Cocoa: Cultivation and Genetic Diversity

Theobroma cacao is a tree native to the eastern Andean slopes in the tropical range of the Northern Amazon basin and is now found on the whole tropical belt [1]. The first wave of selection by man dates back for more than 2,000 years [1, 2], when migrating Indians introduced cocoa trees from the primary center of origin to Central America and Mexico. Their selections formed the basis for the cacao populations in the Circum-Caribbean region and in Central America which are considered to be “the region of secondary distribution of cacao” [1]. Plant material deriving from these populations was used for cultivation and breeding later on by the Mayas in Central America [3]. No exchange with the cacao populations (the gene pool) in the primary center of origin took place. Therefore, the cacao populations in the Circum-Caribbean region and in Central America developed considerable morphological and physiological differences compared to the entire South American cacao populations. These morphological and physiological differences led Cuatrecasas [4] to the formulation of two subspecies, *T. cacao* ssp. *cacao* or “Criollo” (Central America) and *T. cacao* ssp. *sphaerocarpum* or “Forastero”

(South America), which developed independently, separated by the Panama Isthmus [3, 5]. According to the distribution in the Amazonian basin, "Forastero" is further grouped into Upper and Lower Amazon "Forastero." Nowadays, "Criollo" is considered to be a traditional cultivar which has developed in pre-Columbian times due to breeding by the Indians [2]. Besides "Criollo," further traditional cultivars are known, the "Nacional" cacao of Ecuador, a result of intensive selection and translocation from the primary center of origin to the Ecuadorian highlands; the "Trinitario," a group of "Criollo" x "Forastero" hybrids [6]; as well as "Amelonado," a Lower Amazon "Forastero" often planted in West Africa. These cultivars are younger than "Criollo," with "Nacional" being ca 600 years old, "Trinitario" ca 450 years old, and "Amelonado" ca 300 years in use [7, 8].

Under international trading aspects the "Criollo," the "Nacional," and the "Trinitario" are the sources of fine cocoa characterized by special aroma notes (e.g., fruity, floral) [9]. They are grouped as fine or flavor cocoa, whereas Upper and Lower Amazon "Forastero," having, after standard fermentation, a general, but not a specific, chocolate aroma, is classified as bulk cocoa. The latter produces about 95 % of the annual world cacao harvest. Fine or flavor cocoas are generally lower in yield per area than "Forastero" is. Moreover, they are lower in resistance against fungal pathogens and have less growth vigor. Yet, fine or flavor cocoa contains specific aroma components and delivers the material for special high-priced chocolate products.

There are intensive studies on factors that are responsible for fine cocoa aroma development. The main results so far collected revealed that several genetic components are involved [10]. However, fine aroma seems to be achieved only when also an adapted postharvest treatment (e.g., fermentation) of the cocoa seeds is applied [5, 9]. Other research approaches are underway [11], which are aimed at the identification of the key substances for fine aroma. They reveal that some of them may be located in the fruit pulp.

With the molecular methods for differentiation of the genetic constitution of cocoa genotypes, the old nomenclature is under revision, and the most rigorous new approach separates the species T. *cacao* into 10 genetic clusters [12]. This classification together with the recently published genome sequences of a "Forastero" [13] and a "Criollo" [14] genotype allows formulating a completely new era of directed breeding strategies and selections, regarding for instance yield, resistance, and fine aroma. Reevaluation of the cacao germplasm is starting with precise and concise information and thus on an enlarged broad basis of knowledge [5].

2.1 Cultivation Aspects

Cacao is a perennial tree crop revealing special features like a juvenile nonproductive status and a productive mature status. It originates from the understory of the ombrophilic humid tropical rain forest and is naturally adapted to high relative humidity and to low light intensity. Light saturation is given at a light intensity of 400 μM photons m^{-2} s^{-1} [15] and under irrigated conditions up to 600 μM photons m^{-2} s^{-1} [16]. These aspects of high tolerance to environmental conditions led to alternative environmental growth concepts and many plantations are run as full-sun plantation systems with high water input and high fertilizer input with trees pruned in such a way to form a sun crown over a productive shade crown.

Zuidema et al. [17] presented a physiological production model for cacao in which the yield-determining parameters were identified as fruit morphology, photosynthesis and maintenance respiration, the influence of shade was estimated to reduce yield when 60 % or more shade were applied.

3 Directed Breeding Approaches

The development of new characters by breeding is oriented to various fields, especially in high productivity, high resistance against the most important diseases, and on high quality. High productivity comprises a series of factors, starting with optimal photosynthetic parameters, good water use efficiency, drought resistance, tolerance to windbreaks, tree architecture, and suitability for pruning.

Breeding for yield is a complex task, because the final measure is the dry seed, the raw cacao after complex postharvest treatment. Before harvesting ripe pods, there are many steps which depend on the interaction of the plant with environmental factors. This field is still under intensive evaluation, especially under management aspects for the decision if a cacao plantation shall be run under shade trees or in direct sun. Directly combined with these decisions is the shorter lifetime of plantations in direct sun, the high investment costs for high fertilizer input, and the potential need for irrigation [5, 17].

Factors like number of fruits per plant and number of seeds per fruit and per plant, and weight of fresh seeds and dry seeds per tree have been used for evaluation, but there are doubts in their suitability, as cultivars can differ in seed moisture [1]. A comprehensive discussion of the evaluation parameters and their complexity is given by Dias and Resende [7].

Resistance breeding is a wide field, as the diseases which reduce the cocoa production vary with the cultivation area. On global scale, the epidemiologically important diseases are witches broom caused by the basidiomycete *Moniliophthora perniciosa* [18] and frosty pod disease caused by *Moniliophthora roreri* in South and Central America [19]; in West Africa it is dominated by *Phytophthora species* (pod rot) [20] and swollen shoot virus [21]; in Asia it is vascular streak disease (VSD), caused by *Oncobasidium theobromae* [22]. In addition, some pests are severely reducing the production, especially the pod borer in Southeast Asia [23]. Some additional diseases are of local importance like cacao wilt (*Ceratocystis fimbriata*), Verticillium wilt (*Verticillium dahliae*), and pink disease (*Corticium salmonicolor*), though restricted in distribution, these diseases may be of considerable economic importance [24].

The breeding approaches now are directed to combine various resistance factors against pests and diseases in one plant (e.g., Dias [7]). Using the molecular indicators, it is hoped to develop genotypes with accumulated resistance patterns against more than only one disease. This concept of pyramidizing resistance genes is based on intercrossing of resistant genotypes, followed by recurrent selection cycles, but new concepts look forward to use biotechnological approaches and in vitro gen transfer. The basic data for somatic embryogenesis in cacao are under worldwide development [25, 26].

Concerning phenolics as general factors of plant resistance to diseases, especially in control of *Phytophthora*, the amount and composition of preformed phenolic compounds is under study [27]. The ripe cocoa seeds contain high amount of polyphenols and a very active polyphenol oxidase. The feeding deterring action of these substances is well described [28]. In addition, the anthocyanins and anthocyanidins are antifeeding compounds due to their astringency. Pure alkaloids, especially theobromine and coffein, reveal a drastic bitter taste and prevent the seeds from being consumed by herbivores. Cinnamic acid amides and high concentrations of monomers and oligomers of procyanidins act also as repellents and biochemical control agents [29].

The phenolic compounds are protective compounds with respect to herbivores and diseases; they are also highly important as quality factors for consumers due to their health support actions in the vascular systems of chocolate consumers based on the antioxidant properties of these compounds. In directed breeding, these compounds are considered to be very important quality factors. In fact reveals cocoa with 12–18 % polyphenols per whole seed dry weight [30], the highest amount of phenolic substances reported for plant tissue. Also the kinetics of accumulation, the location in the storage tissue, and the free enzymes for oxidative degradation must be regarded as regulatory factors in breeding strategies.

Cocoa butter or Theobroma oil is an edible vegetable fat obtained by hydraulic pressing of whole cocoa seeds or broken nibs [31]. This fat is widely used in cosmetics, pharmaceutical products, and in chocolate products. The melting point is near to 37 °C. The fat market is still demanding for this fat, and the fat content, which may exceed 50 % of dry bean weight, is an important breeding aim [32].

4 Cocoa Bioactive Molecules with Special Focus on Polyphenolics

Under the aspects of their biological function, fresh cocoa seeds are highly effective physiological storage tissues. They contain more than 50 % of fat, the cocoa butter, about 10 % protein, and 8 % starch per dry weight [33], but they also are characterized by a high amount of polyphenols, methylxanthines, minerals, organic acids, and small amounts of amines, terpenoids, and other organic compounds. Many of these compounds are known to act as bioactive ingredients with an expressed impact on human metabolism.

The compounds found in fermented and dried raw cacao, the basis for chocolate production, differ considerably from the compounds present in fresh-harvested cocoa seeds. The transition of fresh seeds to raw cocoa takes place in the fermentation. In order to illustrate the biochemical changes which take place in the course of seed transformation to raw cocoa, the fresh seed conditions will be compared to the fermented and dried raw cocoa sample.

4.1 Fresh Cocoa Seeds

About 12–18 % of defatted dry matter of cocoa seeds is phenolic compounds [30]. These compounds are concentrated in polyphenol cells of the cotyledon storage tissue. About 10–20 % of the storage tissues are special idioblasts which contain the polyphenolics [33–35]. The idioblasts are filled by a vacuole which contains about 14 % of purine alkaloids and over 66 % of phenolic compounds [36].

Figueira et al. [37, 38, 39] assume that the composition of the phenolic compounds of the fresh seeds varies with the genotype and has an influence on the cocoa flavor. In general, there is no significant difference in total phenols in the major groups of cacao, but there are seed-to-seed variations in the amounts of phenolics [40].

The early studies of phenolic compounds have been carried out in 1965 [41] and in 1978 [42]. They reported on phloroglucin, protocatechuic acid, 4-hydroxybenzoic acid, syringic acid, vanillic acid, phenylacetic acid, 4-hydroxyphenylacetic acid, and 2-hydroxyphenylacetic acid.

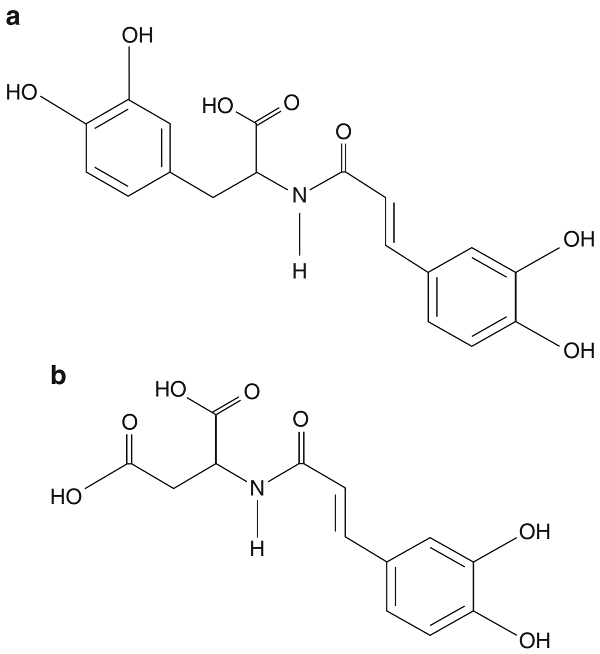
The free hydroxyl cinnamic acids in raw cocoa seeds were p-coumaric acid [41, 42], caffeic acid [43, 44], ferulic acid [41], chlorogenic acid, and neochlorogenic acid [43, 45] in raw cocoa extracts. The existence of chlorogenic acid was also stated by Wollgast [46]. Aesculetin was found 1965 [41].

Hydroxycinnamic acid amides (Fig. 52.1), proanthocyanidins, and flavonol-glycosides are the largest groups of phenolic compounds in cocoa seeds.

Clovamid (N-*trans*-caffeoyl-L-DOPA) and Dideoxyclovamid (N-*trans*-p-cumaryol-L-tyrosin) were described in 1998 [47]. Monodeoxyclovamid (N-*trans*-caffeoyl-L-tyrosine) was found in cell cultures, fresh seeds, and callus cultures of *T. cacao* [26]. N-*trans*-coumaroyl-DOPA was identified by Wollgast [46].

In roasted cocoa powders, 13 Cinnamic acid amides [48–50] have been quantified, which are also found in fresh seeds, but unfortunately there are no quantitative data for these amides in unprocessed fresh cacao seeds:
Caffeoyl-L-DOPA (= clovamid) (58.6 mg kg^{-1} in processed raw cocoa)
Caffeoyl-L-tyrosin (19.07 mg kg $^{-1}$)
p-coumaroyl-L-DOPA (9.04 mg kg^{-1})
p-coumaroyl-L-tyrosin (=Dideoxyclovamid (55.34 mg kg^{-1}))
p-coumaroyl-L-tyrosin (1.1 mg kg^{-1})
(+)-N-(E) caffeoyl-L-aspartate (428.4 mg kg^{-1})
(+)-N-(E)-coumaroyl-L-aspartate (120.4 mg kg^{-1})
(+)-N-(E)-feruloyl-L-aspartate (18.8 mg kg^{-1})
(+)-N-(E)-cinnamoyl-L-aspartate (2.26 mg kg^{-1})
(−)-N-(E)-caffeoyl-L-glutamate (5.55 mg kg^{-1})
(−)-N-(E)-coumaroyl-L-glutamate (3.28 mg kg^{-1})
(+)-N-(E)-caffeoyl-L-tryptophan (0.45 mg kg^{-1})
(+)-N-(E)-coumaroyl-L-tryptophan (0.39 mg kg^{-1})

Fig. 52.1 Cinnamic acid amides: (**a**) Caffeoyl-L-DOPA = clovamid, (**b**) Caffeoyl-L-aspartate



Caffeic acid aspartate with about 430 mg kg^{-1} and coumaric acid aspartate (120 mg kg^{-1}) are of quantitative importance in raw cocoa.

The biological importance of these substances is not really elucidated. They are discussed to reveal antimicrobial or antiviral activity [51], and some of them are astringent and slightly bitter [50]. They may act as feed repellents, but they act also as antioxidants.

The procyanidins are a mixture of oligomers and polymers of the monomers (+)-catechin and (−)-epicatechin (Figs. 52.2 and 52.3). Most of them are linked by position 4 and 8. With normal-phase HPLC, polycyanidins up to decamers can be separated [52, 53], as cited in Gu et al. [54]. Molecules consisting of two to six flavan-3-ol units are generally water soluble; longer chains are either soluble (about 6–12 units) in methanol or are really insoluble.

Kim and Keeny [55] detected between 43,270 and 21,890-mg kg^{-1} epicatechin in eight different cacao genotypes; Tomas-Barberán et al. [56] quantified 25,650-mg kg^{-1} fat-free dry matter; Gotti et al. [57] reported on 15,300–5,700 mg kg^{-1}. It is still unclear whether environmental or genotypic factors dominate the variation. The diastereoisomer (+) catechin is lower in mature cocoa seeds: 646 mg kg^{-1} [56], 450–140 mg kg^{-1} [57].

The occurrence of (+) gallocatechin and (−) epigallo catechin is not really proved for cocoa seed tissue [58].

Fig. 52.3 Stereoisomers of Flavan-3-ol monomers (**a**) (+) catechin, (**b**) (−) epicatechin, (**c**) (−) catechin, (**d**) (+) epicatechin

Proanthocyanidins or condensed tannins [59] are oligomers of flavan-3-ol units. Many dimers are formed (Fig. 52.4).
Procyanidin B-1: Epicatechin [4β → 8] catechin
Procyanidin B-2: Epicatechin [4β → 8] epicatechin
Procyanidin B-3: Catechin [4β → 8] catechin
Procyanidin B-4: Catechin [4β → 8] epicatechin.

Many steps of proanthocyanidin biosynthesis have recently been reviewed [59]. The genes encoding the key enzymes of biosynthesis of flavonols, the transport

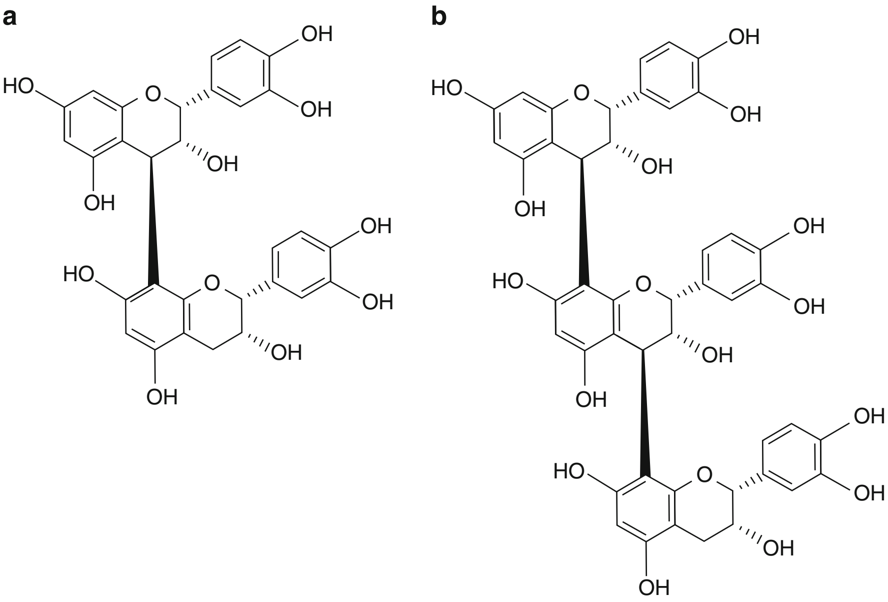

Fig. 52.4 Proanthocyanidins. (**a**) Dimer Procyanidin B-2 Epicatechin [4ß-8] epicatechin. (**b**) Procyanidin *n* = 3 (condensed tannin) trimer

factors, and the factors for transcriptional regulations are presented [60], but some steps remain still unclear [59].

Raw cocoa seeds contain approximately 6.9–18 % proanthocyanidins of defatted dry weight [61, 62]. Porter et al. [63] described (2R,3S)-(+)-catechin, (2R, 3R)-(−)-epicatechin, and the dimers epicatechin-(4β → 8)-catechin (procyanidin B1, see above) procyanidin B, epicatechin-(4β → 6)-epicatechin, and epicatechin-(4β → 8)-epicatechin (procyanidin C1) as the dominating compounds in cacao seeds [63]. Two glycosides 3-0-β-D galactopyranosyl-ent-epicatechin-(2α → 7, 4 α → 8) epicatechin and 3-0-L-arabinopyranosyl ent-epicatechin-(2α → 7, 4α → 8)-epicatechin were found in addition to epicatechin-(2β → 5, 4β → 6)-epicatechin [63, 64].

Griffiths [65] reported about anthocyanidins and anthocyanidin glycosides, which give rise to violet to light red coloring of cocoa seeds, depending on the genetic clusters they belong to. Anthocyanins occur as 4 % [36, 66] or 4.5 % [67] of the polyphenols of cocoa seeds. The highest amounts are cyanidin-3-β-D galactoside and cyanidin-3-α-L-arabinoside with lower amounts of a rutinoside and a pentoside [68]. An exception for extraordinarily high amounts of anthocyanins is the genotypes of the Cameroon group of German cacao, a regional “Trinitario” hybrid population [69]. The seeds of this traditional group contain very high activity of polyphenol oxidases compared to other cocoa seeds and very high amounts of anthocyanidin glycosides, three to five times more than reported for other cocoa seeds [70]. This group of cacao seeds delivers especially red-colored raw cocoa powder.

Quercetin, a flavonol, and corresponding quercetin-3-0-glucoside, quercetin-3-0-galactoside, quercetin-3-0-arabinoside, quercetin-3-0-glucuronide, and free quercetin are found in amounts of some milligrams to more than 300 mg kg^{-1} (e.g., [56]).

Using high sensitive detection LC/ESI/MS, the flavones apigenin, vitexin, isovitexin and luteolin as well as luteolin-7-0-glucoside, isoorientin, and orientin have been detected [71]. They also found flavanone naringenin and its 7-0-glucoside as minor components. Stark et al. [50] also reported on naringenin-7-0-glucoside, luteolin-7-0-glucoside, apigenin-8-c-glucoside, and apigenin-6-C-glucoside. Isovitexin, vitexin, apigenin-7-0-glucoside, luteolin-7-0-glucoside, and chrysoeriol-7-0 glucoside had also been found in cocoa tree leaf extracts [44].

Due to the well-described positive physiological action of phenolic cocoa ingredients on human health, intensive studies on the impact of processing of ripe, fresh cocoa seeds to the fermented and dried raw cocoa as a traded good are underway.

The biological function of the phenolic compounds in the seeds seems to be a repellent function of astringent-tasting flavan-3-ols, of proanthocyanidins, and of the bitter-tasting cinnamic acid amides against herbivores. In addition to the tanning properties of the proanthocyanidins and the rapid enzymatic oxidation of *o*-dihydroxyphenolic compounds by a very high plant polyphenoloxidase [72], these compounds act as repellent, but they also reduce the nutritive value of cocoa seeds by reactions of *o*-diquinones (as oxidation products) with proteins of the seeds and by the inactivation of salivary proteins and proteolytic enzymes. Mono- and oligomeric Flavan-3-ols are described to be bitter (monomeric fraction) and astringent (oligomeric fraction) [50, 73]. Cocoa seeds are consumed by monkeys, rodents, and parrots. These distributors of seeds consume the sweet–sour pulp surrounding the seeds and spit out the bitter seeds.

The antimicrobial property of tannins is assumed to be an important control factor against fungal attack to the germinating seeds [74].

4.2 Biotechnology, Postharvesting Processes: Fermentation and Drying

Cocoa pods are hard-shelled berries which contain 30–50 seeds in five adjacent rows. The seeds consist of two large storage cotyledons and a small embryo axis, surrounded by a flexible, elastic multilayered testa [75]. On the outer testa layer, slimy elongated cells of the endocarp form the pulp. This pulp has to be degraded during postharvest processing (e.g., fermentation) in order to produce the raw cocoa, which can be stored and shipped. Moreover, the characteristic chocolate flavor is only generated during roasting of well-fermented cocoa seeds, whereas no chocolate flavor is formed from roasting of unfermented seeds [76, 77]. Thus, the essential precursors of chocolate aroma are developed in the course of fermentation. Flavor development also is influenced by the genetic constitution of seed and pulp.

During fermentation, the carbohydrates and organic acids of the pulp are degraded to ethanol and further transformed to acetic acid and to lactic acid [78, 79].

The acidification of the seed tissue together with a significant rise in temperature caused by the exergonic process of acetic acid formation leads to the cocoa-specific aroma precursor formation. There are various factors influencing the biochemical outcome of the fermentation process and thus the quality of the raw cocoa. Important factors are, for instance, fruit ripeness, overall amount of seeds used, degree of acetic and lactic acid formation, and rise as well as homogeneity in temperature and oxygen.

The components produced during fermentation are distributed all over the tissue of the storage cotyledons. During drying after end of fermentation, these substances are mixed, and by migration with the water leaving the seeds, they undergo changes which result in various ways, especially in browning of the cocoa seeds. Most of these browning processes are based on oxidation of phenolic compounds and follow reactions of the oxidation products.

4.2.1 Standard Fermentation, Drying, Storage

The fermentation process is characterized by a sequence of biotechnological steps and is carried out in different traditional ways. Standard fermentation time for “Forastero” cacao is about 6–7 days. The time for fine and flavor cacao is 3–5 days [80]. Widely used fermentation methods are heap and box fermentation:

Freshly harvested cocoa pods are opened mechanically to extract the seeds with the pulp. This fresh material is heaped and covered with banana leaves, or transferred into wooden boxes. Because of its high content in free sugars and organic acids, the pulp is an ideal substrate for yeasts. Their high metabolic activity and the insufficient penetration of air into the fermentation mass result in anaerobic conditions consequently leading to ethanol formation. The secretion of pectinases by the yeast causes pulp liquidation and drainage. Subsequently, air enters the fermentation mass, and ethanol is oxidized to acetic acid by acetic acid bacteria. Temperature rises to more than 50 °C, and the combined action of tissue acidification and high temperature kills the embryo (see 79 for details). The entry of acetic acid into the seeds occurs after seed swelling and opening of the micropyle [75]. In the same time also, a transport of matter out of the seeds takes place. In this phase, the first losses of phenolics, purine alkaloids, and further organic compounds occur. Induced by tissue acidification, the preformed proteases in the protein storage vacuoles [81] are activated and deliver peptides and amino acids, which serve as important aroma precursors during later roasting [81–83]. As long as the pH of the seed tissue is around pH 4–5, the reaction of the phenolic compounds is very low, but with the onset of buffer action caused by peptides and free amino acids, the pH rises and first enzymatic oxidations start. The seeds begin to turn from violet to brown. This process explains the losses of procyanidins [84]. After the fermentation, the seeds are spread to thin layers on wood or concrete for drying. The drying phase includes loss of water and water-soluble compounds from the seeds. It enhances the enzymatic oxidation, especially by cell wall immobilized, stable phenolases and leads to further losses of proanthocyanidins (e.g., [85]). The physical cut test [86] is a good indicator for the fermentation and drying-related oxidation of phenolic compounds. After processing the seeds are cut in half, and the color of the seed tissue is evaluated. Slaty seeds are non-fermented, violet seeds are acidified, and red- to violet-colored anthocyanins and glycosides are distributed in the tissue. Most of these substances are tightly bound to the tissue and cannot be extracted anymore by aqueous or organic solutes. In this stage most of the astringent components are not anymore disturbing aroma formation. Other components like cinnamic acid amides may still interfere as quality-reducing factors. The drying process of cocoa seeds will be stopped at about 7 % water content [86, 87]. Aroma-relevant components also are produced in the course of drying like pyrazines, and methylpyrazines from the reactions of amino acids and reducing sugars [88].

The reaction of phenolic compounds during fermentation and drying differs between "Criollo" genetic cluster and other genotype groups [61]. The reduction of the phenolic monomer (−)-epicatechin during fermentation and drying is over 92 % of the content of unprocessed seed. The decrease of (+)-catechin is even more expressed, but in contrast, the diminution of caffeic acid aspartate is far lower. The "Criollo" seeds and the "Forastero" seeds differ in this aspect [61]. This may be due to the fact that the fermentation time reported for "Criollo" is shorter (3–4 days) than for "Trinitario" or "Forastero."

For chocolate production, the raw cocoa is stored, shipped, and processed. The processing steps are roasting and liquor production. The heat treatment induces Maillard reactions, caramelization of sugars, protein degradation, and formation of volatile aroma components [85, 89]. An often applied step to cocoa is the "dutching," the alkali treatment of cocoa powder in order to modify the color, and other physiochemical properties. The pH values of cocoa powders are adjusted from ph 5.3–5.8 in natural powders to higher than 7.6 in heavily dutched materials. The total flavanol contents are reduced from more than 34 to 3.9 g kg^{-1}. In the same way, the antioxidative properties of the powders are diminished [90].

5 Medicinal Importance: Health Support by Phenolics

Cocoa products are rich in phenolics, especially in flavanoids. These substances provide a strong protection against cardiovascular diseases; they are effective antioxidative compounds and scavengers of free radicals. The flavanols reveal beneficial effects on low-density lipoproteins oxidation [91] platelet aggregation [92], endothelial function [93], and blood pressure [94]. Consumption of flavanol-rich diet also reverses dysfunction in diabetes [95].

The mechanisms which are causing the biological effects of flavanols include the modulation of cell signaling pathways [95] and the regulation of nitric oxide (NO) homeostasis, which in turn influences the flow-mediated dilation in capillaries. The antioxidative potential of the flavanols leads to scavenging free radicals and inhibits lipid peroxidation [96].

5.1 Bioavailability and Metabolism

The health benefits of flavanol-rich foods have widely been described. The dominating flavanol in cocoa product is epicatechin and its oligomers from dimer to decamers [54]. The in vitro action of these compounds on the health-supporting reaction like alteration of cellular redox environment, modulation of cellular signaling pathways, and radical scavenging has been analyzed in many experiments, but for the in vivo action, the substances have to be taken up in the blood serum. After administration of flavanol-containing diets to humans within 2 h, specific flavanol metabolites are found. Various *O*-methylated, *O*-glucuronidated, and *O*-sulfated flavanol derivatives occur in the blood serum [97]. These flavanol derivatives form a bioactive circulating flavanol pool, and it remains to be elucidated which of the metabolites contributes to which activity in vivo. The stability of epicatechin and catechin and the related dimeric procyanidins under gastric condition allows to calculate the bioavailability and the uptake kinetics of cacao active ingredients [98].

The uptake of oligomeric proanthocyanidins from a complex diet is influenced by various interacting components and is still under study.

6 Conclusion

The international research on *Theobroma cacao* L. starts into a highly effective selection phase. The elucidation of the complete cocoa genome allows new and rational strategies for directed breeding and gives also rise to develop regional gene pool collections for international plant exchange and for the development of new agricultural qualities of new genotypes. In addition, the analysis of aroma precursors, of fine flavor components, and of health-supporting ingredients supports the use of cacao in many new fields of application. New food qualities, based on antioxidative properties, will be developed for dietary use. The step into a new molecular era of cocoa breeding and cultivation is on its way, and opens a wide activity in quality management for a perennial tropical crop.

Abstract

Flavonoids are structurally diverse plant pigments that comprise the largest group of natural products and are ubiquitously present in the plant kingdom. They exhibit a broad range of functions in plants. Interestingly, these polyphenolic compounds have also shown beneficial health effects in humans by inhibiting or delaying the onset of diseases. Though the biosynthetic pathway of flavonoids in plants is well known, many studies have explored the significance of the flavonoids. In the last 10 years, flavonoids have been produced in

Saccharomyces cerevisiae, *Escherichia coli*, and *Streptomyces* species by heterologously expressing partial or entire plant flavonoids biosynthetic gene clusters and rewiring the native host metabolic networks. Currently, a few natural and novel flavonoids have been produced in significant amounts in microbial systems. However, the development of a microbial factory for the efficient biosynthesis of diverse flavonoids remains incomplete. The integrated use of modern metabolic engineering, proteomics, and synthetic biology tools could aid the design of robust microbial cells for the production and biotransformation of flavonoids in the near future. In this chapter, we will discuss recent progress in the production and biotransformation of flavonoids from engineered microbial cells, transgenic plants, and whole cells of plants and *Streptomyces*.

1 Introduction

Flavonoids are the largest group of naturally occurring polyphenolic compounds with low molecular weight. These compounds are ubiquitous, found in almost all plants in the kingdom. Flavonoids are also known as plant pigments or copigments that are responsible for various colors and combination of colors exhibited by different parts of the plants such as fruits, vegetables, grains, bark, roots, stems, and flowers, as well as in tea, wine, etc. Structurally, these plant secondary metabolites bear C6-C3-C6 skeletons derived from a phenylpropanoid (C6-C3) and three molecules of C3 elongation units of malonyl-CoA. Flavonoids are characterized by two aromatic cycles (A and B rings) linked with a heterocycle (C-ring) (**2, 3, 4**). This C15 phenylpropanoid core is extensively modified by rearrangement, methylation, methoxylation, alkylation, oxidation, glycosylation, and hydroxylation [1, 2] resulting over 9,000 structural variants [3–6].

Based on the position of the aromatic group attached to the chromano (benzopyrano) moiety(**1**), flavonoids are classified into three classes [7, 8].

1. Flavonoids (2-phenylbenzopyrans) (**2**)
2. Isoflavonoids (3-phenylbenzopyrans) (**3**)
3. Neoflavonoids (4-phenylbenzopyrans) (**4**)

All these groups share a chalcone precursor.

The degree of oxidation and saturation in the heterocyclic C-ring further divides the flavonoids into different subgroups. The subgroups and selected examples are presented in Table 53.1 with the general structures of each group [2, 3, 7] (**5–10**).

The second class of flavonoids, isoflavonoids, possesses a 3-phenylchroman (**3**) skeleton that is biogenetically derived by 1, 2-aryl migration in a 2-phenylchroman

Table 53.1 Examples of flavonoid subgroups and related compounds

Flavonoid subgroups	Selected examples
Flavan	Tupichinol, kazinol Q, acutifolin A
Flavan-3-ol	Elephantorrhizol, guibourtinidol, epirobinetinidol
Flavanone	Liquiritigenin, (2S)-naringenin, (2S)-eriodictyol, (2S)-pinocembrin
Dihydroflavonol	Diosalol, plumbaginol, floranol
Flavone	Chrysin, baicalein, luteolin, velutin
Flavonol	Kaempferol, fisetin, morin, rhamnetin, isorhamnetin, myrecetin

precursor. These compounds are also divided into different subgroups (**11–20**), and the isoflavones are one of the largest subgroups because of the varieties of modifications. These compounds are widely found in leguminous plants. However, some rare nonleguminous plants also biosynthesize isoflavonoids.

The third class of flavonoids, neoflavonoids, is closely structurally related to flavonoids and isoflavonoids. They have a 4-phenylchroman (**4**) skeleton. 4-Arylcoumarin (**21**), 3,4-dihydro-4-arylcoumarin (**22**), and neoflavene (**23**) fall into this group.

Chalcones and aurones also contain a flavonoid backbone frame (C_6-C_3-C_6) and were considered as minor flavonoids. Importantly, chalcones are the immediate precursors of all other classes of flavonoids. 2′-OH-chalcone, 2′-OH-dihydrochalcone, 2′-OH-*retro*-chalcone, isoliquiritigenin, hamilcone, and tepanone belong to the chalcones (**24**); aureusidin, bracteatin, broussoaurone A, and auronols are aurones (**25**). Resveratrol and related compounds belong to the stilbene (**26**) family, a nonflavonoid group with a (C_6-C_2-C_6) structure. A number compounds belonging to these groups is significantly increasing day by day. Therefore, the biosynthesis and production of minor flavonoids and stilbenes are also mentioned briefly in this chapter along with flavonoids. Anthocyanidins (**27**), a separate group of flavonoids, are polyhydroxy and polymethoxy derivatives of 2-phenylbenzopyrylium or flavylium salts. Complex types of anthocyanidins, like riccionidin (**28**) and rosacyanin (**29**), are also found in plants [8]. The variety of colors in the different parts of plants is mainly due to anthocyanidins. The number of hydroxyl groups, the nature and number of sugar moieties attached to the aglycone molecule, and the position of the attachment render this group among the largest water-soluble flavonoids. Pelargonidin, cyanidin, delphinidin, peonidin, malvidin, and petunidin are the major subgroups of anthocyanidins. The glycosylated forms of anthocyanidins are called anthocyanins [4, 7–9].

Different conjugated forms of flavonoids are also found in plants. However, the complex flavonoids are not ubiquitously present in all plant species. Biflavonoids (anacarduflavanone, licoagrone, cordigone, leucaediflavone, delicaflavone, licoagrodin, and bicaryone A, B, C, and D are unusual biflavonoids), triflavonoids (aulacomniumtriluteolin), tetraflavonoids (lophiroflavan A, taiwanhomoflavone C), pentaflavonoids (ochnachalcone), and hexaflavonoids (azobechalcone) [7] have been reported from different plant extracts.

Flavonoids play different roles in plant physiology and plant interactions with the environment. They provide flower coloring to attract pollinators and seed dispersers, influence the transport of the plant hormones, offer UV protection, and balance the levels of reactive oxygen species. Moreover, flavonoids also have key roles in signaling between plants and microbes and in male fertility of some species. Flavonoids play crucial roles in legumes-bacterium symbiosis and root-nodule organogenesis. In addition to these properties, flavonoids have antioxidant, antiproliferative, antitumor, anti-inflammatory, antiallergic, antiviral, and anticarcinogenic properties that have been proven by in vitro and in vivo studies. Flavonoid consumption through plant-derived foods and from medicinal plants has beneficial health effects in humans. Flavonoids prevent neurodegenerative diseases associated with oxidative stress such as Alzheimer's and Parkinson's diseases [9–11] by modifying protein kinase-mediated signal transmission, thereby inducing antioxidant and anti-inflammatory genes expression [12] and immune-modulating properties without the potential toxic and adverse side effects [13, 14]. Since both the flavonoid aglycones and the glycol-conjugates can pass the blood–brain barrier, several flavones can bind to the benzodiazepine site on the γ-amino butyric acid-A (GABA-A)-receptor in central nervous system resulting in sedation, anxiolytic, or anticonvulsive effects [15, 16]. Recently, many flavonoids were found to act on biological targets involved in type 2 diabetes mellitus, such as α-glycosidase, glucose cotransporter, or aldose reductase. Therefore, flavonoids are promising lead compounds in type 2 diabetes mellitus [17] drug design and development.

Although a diet rich in polyphenols seems to offer hope in delaying the onset of different disorders, it is still too early to define their exact clinical benefits for treating diseases [18]. However, flavonoids are incorporated as dietary components by different food industries. In this chapter, we will discuss in detail the recent developments in flavonoid biosynthesis and modifications in different prokaryotic and eukaryotic systems for flavonoid production using genetic engineering approaches.

2 Biosynthesis of Flavonoids in Plants

Since Mendel's classical genetic analysis of flower color inheritance patterns in the 1850s and the experimental studies using radiolabeled precursors at the end of 1950s, recently invented sophisticated chemical analyses, enzymology, and gene technology have led to a vast number of studies and detailed information about the genetics of flavonoid biosynthesis in several plant species. The first experimental model plants in this system, maize, snapdragon (*Antirrhinum majus*), and petunia, were established and work on these species led to the isolation of many flavonoid structural and regulatory genes [19]. The development of *Arabidopsis* later as a model plant helped to explore the regulation and subcellular organization of the flavonoid pathway [20]. The flavonoid pathway is well characterized in *Arabidopsis* and is probably the best characterized of all the secondary metabolic pathways. Mutants of *Arabidopsis* lacking genes encoding each enzymatic step or within regulatory genes encoding transcription factors that affect flavonoid biosynthesis are currently available.

Recently, much effort has been directed at elucidating the flavonoid biosynthetic pathway from a molecular genetics point of view by identifying and analyzing genes or cDNAs for flavonoid biosynthetic enzymes and regulatory factors. Moreover, analysis of enzyme structures and functions involved in flavonoid biosynthesis, generation of transgenic plants, development of protein engineering tools, and heterologous production of flavonoids in microbial systems has allowed tremendous progress in the characterization of the flavonoid biosynthesis pathway. This pathway produces a large number of secondary metabolites, such as lignins, stilbenes, phenolic acids, and other polyphenols [7, 8].

Chalcones are the major intermediates of flavonoid biosynthetic pathways; they are produced by the condensation of three molecules of malonyl-CoA and a single molecule of 4-coumaryl-CoA. The major precursor malonyl-CoA is derived from citrate, an intermediate product of the TCA cycle. Acetyl-CoA is produced in mitochondria, plastids, peroxisomes, and cytosol via various routes. The cytosolic acetyl-CoA, produced by the multiple subunit enzyme ATP-citrate lyase, is used by acetyl-CoA carboxylase (ACC) to form malonyl-CoA for flavonoid biosynthesis. Another precursor, 4-coumaryl-CoA, is available via the polypropanoid pathway, in which phenylalanine generated via the shikimate and aerogenate pathway is converted to 4-coumaryl-CoA in three sequential enzyme-catalyzed reactions. In a few species, caffeoyl-CoA and feruloyl-CoA may also be used as substrates for chalcone formation. Phenylalanine ammonia lyase (PAL) catalyzes the conversion of amino acid L-phenylalanine to *trans*-cinnamate by the *trans*-elimination of ammonia and the pro-*3S* proton; *trans*-cinnamate is hydroxylated by cinnamic-4-hydroxylases (C4H) and is finally activated by the 4-coumarate/cinnamate coenzyme, 4-coumaryl-CoA-ligase (4CL), for condensation with malonyl-CoA. The condensation of 4-coumaroyl-CoA and malonyl-CoA is carried out by chalcone synthase (CHS) to form either tetrahydroxychalcone or trihydroxychalcone. The formation of trihydroxychalcone requires one extra enzymatic step catalyzed by chalcone reductase (CHR). Chalcones are converted to the (*2S*)-flavanone naringenin by chalcone isomerases (CHI) in a ring-closing step that forms the heterocyclic C-ring. From these central intermediates, the pathway diverges into several side branches for the synthesis of a variety of other classes of flavonoid molecules that are produced through the combined actions of functionalizing enzymes that hydroxylate, reduce, alkylate, oxidize, and glycosylate the phenylpropanoid core structure [20–23] as shown in Fig. 53.1. Unlike otherflavonoids, stilbenes are produced directly by stilbene synthase (STS) enzyme using 4-coumaryl-CoA and malonyl-CoA without chalcone intermediates.

Flavanone 3-hydroxylase (F3H) catalyzes the stereospecific 3-hydroxylation of (*2S*)-flavanones to dihydroflavonols. For the biosynthesis of anthocyanins, dihydroflavonol reductase (DFR) catalyzes the stereospecific conversion of dihydroflavonols to the respective flavan-3,4-diols (leucoanthocyanins) through NADPH-dependent reduction at the 4-carbonyl. The leucoanthocyanins are further converted to anthocyanidins by leucoanthocyanidin dioxygenase (LDOX) or anthocyanidin synthase (ANS). Flavan-3,4-diols are converted to flavan-3-ols by leucoanthocyanidin reductase (LCR) and finally form proanthocyanidins or condensed tannins in different steps. DFR also catalyzes the conversion of flavanones to flavan-4-ols, which form phlobaphenes in different sequential steps. Moreover, dihydroflavonols are converted to flavonols and their glycosides by the corresponding flavonol synthase (FLS) and glycosyltransferases (GTs). The intermediate flavanones are further diverted to another class of flavonoid, flavones, by flavone synthase I and II (FS I and II) enzymes and to isoflavones by isoflavone synthase (IFS) enzyme. These flavones and isoflavones are further modified by various hydroxylases, methyltransferases, reductases, and glycosyltransferases to form diverse flavonoids and isoflavonoids.

The flavonoid end products are transported to various subcellular or extracellular locations, while those flavonoids involved in pigmentation are generally transported into the vacuole.

Fig. 53.1 Biosynthetic pathway network of different types of flavonoids and related compounds in plants

War I and II, the second phase of traditional microbial biotechnology began with the development of acetone, butanol, and glycerol fermentations, followed by processes yielding citric acid, vitamins, and antibiotics. Industrial microbiology later merged with different interrelated areas of biology, chemistry, and engineering to lead to the development of more than 40 biopharmaceutical products during the early 1970s. Today, microbiology is a major participant in global industry, especially in the pharmaceutical, food, and chemical industries [24], to produce value-added compounds with numerous applications.

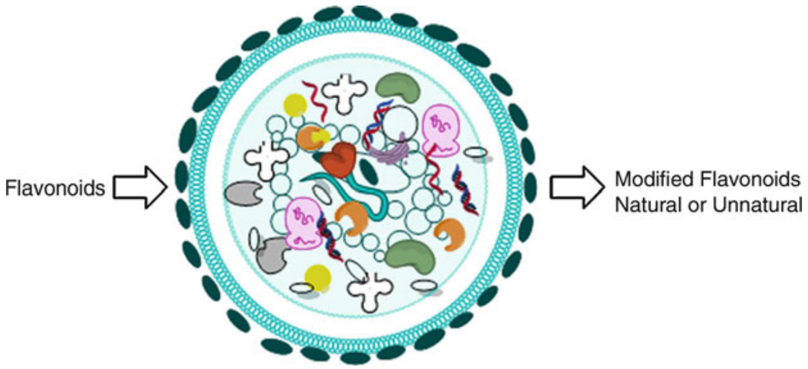

Fig. 53.2 Whole cell biotransformation of flavonoids by wild-type cells of *Streptomyces*, fungi, and plant cells

In general, three different strategies are applied for the production of natural products by microbial systems.

1. Use of wild-type whole cells for biotransformation
2. Use of purified natural or engineered enzymes
3. Use of genetically engineered microbial cells as a microbial cell factory for combinatorial biosynthesis

The first approach is normally applied with *Streptomyces*, fungal mycelia, and plant cells. All these cells contain a wide range of natural product-modifying native enzymes within their cytoplasm. Such enzymes could be constitutively expressed inside the cell. The supplementation of purified natural products, such as flavonoids, in these growing cells at a specific incubation temperature could lead to spontaneous modification of the compound by the cells' own available cofactor(s) or donor molecule(s) (Fig. 53.2). Since this strategy of modification of natural compounds is the simplest, the cheapest, and the easiest, the approach could be scaled up to industrial level upon optimization of the biotransformation conditions for high-level production of target compounds. Importantly, the production of desired products should be significantly high for industrialization. But, the demerit of this method lies with the production of a wide range of unexpected by-products.

The second approach uses purified enzymes and in vitro reactions for target modification of compounds (Fig. 53.3). Such practice is routinely done in the laboratory, although rarely at the industrial level, for the functional characterization of biosynthetic and modifying enzymes from different sources. Moreover, such study could help to determine the exact reaction mechanisms of enzymes, the interaction between different cofactors, ligands, and other molecules with enzymes, and finally the structure of the target modifying proteins. Since this method of natural product modification requires expensive cofactors and donors, efficient enzyme activity, and optimized reaction conditions, application at the industrial

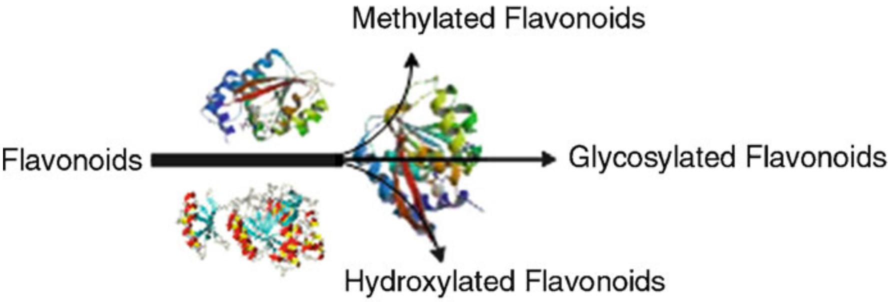

Fig. 53.3 In vitro conversion of flavonoids by recombinant proteins

level is comparatively costly and difficult. However, by this technique, the regiospecifically modified product can be obtained with few or even without by-products.

The last approach is relatively applicable for the biotransformation of flavonoids and other natural products. In this method, the microbial cell factory is constructed by using metabolic engineering, protein engineering, and synthetic biology tools (Fig. 53.4). The genetically well-known microbial cell is modified according to a particular purpose with high cell growth rate and efficient bioconversion of target compounds without a metabolic burden in the cell. The model microbial cells, like *E. coli*, *Streptomyces*, or *Saccharomyces cerevisiae*, are modified by introducing a partial or entire biosynthetic pathway gene cluster for the target compound. The genes of the pathway might be entirely of heterologous origin or partially native to the host. In certain cases, the host can be modified by deleting or blocking some essential genes for enhanced carbon flux through the pathway of interest. The heterologous genes will be functionally expressed and, finally, the biosynthetic pathway and growth conditions can be optimized for high titer product formation or biotransformation. In rare cases, by-products might be produced in very low amount in this method. This strategy of biosynthesis of natural products could be applicable for high-level production of different compounds in industry because of the low cost and the use of a simple fermentation technique.

The development of metabolic engineering, protein engineering, and synthetic biology approaches has revolutionized the use of efficient microbial systems for biosynthesis of value-added products, leaving synthetic chemistry methodologies far behind. Environmentally friendly routes of production, formation of lesser quantities of by-products due to high enzyme specificity, cost efficiency, improved yield and productivity of the target compounds, and easy development of novel derivatives are advantages of microbial biosynthesis over chemical synthesis of different natural products [25]. Obtaining compounds from their native host requires extensive optimization of the growth conditions and metabolic pathways within the native host, which is very difficult because of the adverse growth conditions and lack of ability to grow in laboratories. Therefore, well-characterized microbial cells like

Escherichia coli, *Saccharomyces cerevisiae*, *Streptomyces* species, and *Bacillus subtilis* as universal platform organisms are highly desired due to their well-known physiology and genetics, high growth rates, and availability of abundant genetic tools [25]. Recently, numbers of natural products, their derivatives, and even unnatural compounds have been produced by using such established microbial hosts. Alkaloids, terpenoids, flavonoids, polyketides, and nonribosomal peptides, lantibiotics, antibiotics, organic acids, amino acids, and vitamins are some examples of microbially produced compounds from combinatorial biosynthetic approaches. In this chapter, we will discuss the recent developments in the production of flavonoids from different microbial systems and different approaches in detail.

3.1 Production of Flavonoids from Yeast

Like *E. coli* and other model microbial systems, the yeast *Saccharomyces cerevisiae* was developed as a model microbial factory for the production of different valuable products. Not only flavonoids, but also other terpenoid groups of compounds like artemisinic acid, a precursor of antimalarial drug artemisinin [26], alkaloids like magnoflorine and (*S*)-scoulerine, and taxol, were produced by coculturing a recombinant system of *E. coli* and *S. cerevisiae* [27]; berberine and morphine were produced from *S. cerevisiae* [28]. Metabolites from yeast cells, as well as whole yeast cells, have been used for animal feeding and in the baking industry for a long time. However, rapid developments in the biological sciences in the late 1980s and 1990s led scientists to use microbial hosts for high-level production and generation of new derivatives of pharmaceutical compounds. Recently, by using *E. coli*, Ajikumar and his group [29] produced more than 1 g l^{-1} of taxadiene, a precursor of taxol, by a metabolic engineering approach. Though the production is significantly higher, the drug supply is still insufficient to meet the demand of the world market. Previously, different approaches were applied in *E. coli* and *S. cerevisiae* for the production of taxadiene; unfortunately, titers have been limited to less than 10 mg l^{-1}. Taxol and its derivatives are the most potent and commercially successful anticancer drugs. However, the production of taxol still depends on plant sources.

The rate of development of antibiotic resistance is reaching a crisis point around the globe. Thus, there is an urgent need for replacement with new types of anti-infective or antimicrobial agents. However, developing new adjuncts to lower or reduce the resistance against a particular drug or to inhibit cellular components essential for cell viability is also an effective strategy. Recently, plant-derived natural compounds with antibacterial properties are attracting attention in the development of new drugs. Traditionally, flavonoid-rich medicinal plants are used for treatment and prevention of various infectious diseases, like sores, wound infections, acne, respiratory infections, and gastrointestinal diseases [30]. In vivo and in vitro studies have proven the broad spectrum of biological activities of flavonoids. Therefore, the health-protecting effects of flavonoids have stimulated significant research toward the elucidation of their biosynthetic networks, as well as the development of production platforms using well-characterized hosts, such as *E. coli* and *S. cerevisiae*.

Expression of plant genes involved in flavonoid biosynthesis is not easy in *E. coli*, but the ability of yeast *S. cerevisiae* to express such genes makes it an attractive production platform. However, the functional expression of many plant genes has recently been reported for the heterologous production of value-added products from *E. coli*.

First, Ro and Douglas constructed the initial steps of the plant phenylpropanoid pathway by connecting two enzymes, PAL and C4H, with a cytochrome P450 reductase (CPR) from a plant source in *S. cerevisiae* [31]. This heterologous transfer of plant phenylpropanoid pathway genes into yeast became the platform for the biosynthesis of various flavonoids and related compounds in microbial systems. Within a decade from the beginning of biosynthesis of flavonoids in microbes, a wide variety of derivatives of this group had been produced from yeast *S. cerevisiae* (Fig. 53.5). Monohydroxylated naringenin and unhydroxylated pinocembrin were produced by introducing phenylpropanoid pathway genes of different plant origins, that is, PAL from *Rhodosporidium toruloides*, 4CL from *Arabidopsis thaliana*, and CHS from *Hypericum androsaemum*, into *Saccharomyces cerevisiae*. The yeast produced approximately 7 mg l^{-1} of naringenin (**30**) and 0.8 mg l^{-1} of pinocembrin (**31**) without expression of C4H. This shows that PAL enzyme has tyrosine ammonia lyase (TAL) activity. Several by-products, such as 2′,4′, 6′-trihydroxydihydrochalcone and phloretin, were also identified in the culture broth in trace amounts [32].

In a similar study, different phenylpropanoid acids, such as cinnamic acid (**32**), *p*-coumaric acid (**33**), caffeic acid (**34**), and ferulic acid (**35**), were fed to recombinant yeast containing four different initial flavanone biosynthetic plant genes, C4H, 4CL, CHS, and CHI, at different time intervals to produce flavanones. In cinnamic acid-supplemented culture, 16.3 mg l^{-1} of pinocembrin (**31**) and 0.2 mg l^{-1} of naringenin (**30**) were produced. Naringenin (28.3 mg l^{-1}) and (2*S*)-eriodictyol (6.5 mg l^{-1}) were detected in *p*-coumaric acid- and caffeic acid-supplemented cultures, respectively. No flavanones were produced with ferulic acid precursor substrate [33]. The production of pinocembrin and naringenin in *S. cerevisiae* was 22- and 62-fold higher compared to that of respective flavanones in *E. coli* [34].

5-hydroxyflavanone and 5-deoxyflavanone were also produced from recombinant strains of *E.coli* and *S. cerevisiae* by a similar approach [35]. The same yeast strain producing flavanones was reconstructed by expression of FSI and II, resulting in the production of the flavones, chrysin (**36**), apigenin (**37**), and luteolin (**38**), as major products, along with the intermediate flavanones, pinocembrin, naringenin, and eriodictyol (**39**). Overexpression of yeast CPR1 and the use of acetate as the sole carbon source, rather than glucose or raffinose, led to overall increases in flavone-specific production in the FSII-expressing recombinant strain [36].

Stilbene, a defense compound, is only produced by specific plants, such as *Vitis vinifera*, during fungal infection, wounding, or UV irradiation. Resveratrol (**40**), a stilbene, was produced by using 4CL and STS genes from different plant sources in *S. cerevisiae* with maximum titer of 6 mg l^{-1} from polypropanoid acids as precursors [37, 38]. A transitional fusion protein, joining 4CL and STS, enhanced the production of resveratrol by 15-fold compared to that in the cotransformed yeast cells. This experiment emphasizes the importance of the physical localization of 4CL and STS for facilitated production of resveratrol. Resveratol was also successfully produced in human HEK293 cells by introducing the entire resveratrol pathway [39].

Isoflavonoid production was also achieved in *S. cerevisiae* by using different types of isoflavonoid biosynthetic genes from plants [40]. The supplementation of the intermediate product naringenin (**29**) in growing culture of recombinant *S. cerevisiae* with IFS and CPR genes produced 20.8 mg l^{-1} of genistein (**41**) [41], which was around threefold higher than the production from the *S. cerevisiae*

Fig. 53.5 Biosynthetic pathways engineered in *S. cerevisiae* for the production of varieties of flavonoids, isoflavonoids, and stilbenes

YPH499 strain GEN23 carrying PAL, C4H, CPR, 4CL, CHS, CHI, and IFS genes from different plants [42]. Insignificant production of genistein was reported from coculture of *E. coli* and *S. cerevisiae* recombinants with tyrosine precursor [43]. *S. cerevisiae* YPH499 strain RESV11 (PAL, C4H, CPR, 4CL, and STS) produced resveratrol (**40**), strain NAR12 (PAL, C4H, CPR, 4CL, CHS and CHI) produced naringenin (**29**), strain KAE34 (PAL, C4H, CPR, 4CL, CHS, CHI, F3H, and FLS) produced kaempferol (**42**), and strain QUE44 (PAL, C4H, CPR, 4CL, CHS, CHI, F3H, F3′H, and FLS) produced quercetin (**43**) [42].

The whole cell biotransformation assay with recombinant yeast carrying a single gene revealed a significant bioconversion rate. For example, yeast carrying flavonoid 3′ hydroxylase (F3′H) from Gerbera hybrid produced 200 mg l^{-1} of eriodictyol from naringenin [44]. However, the conversion of aglycone to glycoside is dose dependent, increasing as the initial substrate concentrations increase up to a certain limit. Variation of the glucose concentration in the medium during bioconversion reaction controls the selectivity to produce the desired glycoside. For example, the major product will be either naringenin-7-*O*-glucoside or naringenin-4′-*O*-glucoside depending upon the glucose concentration in the medium when naringenin is fed to yeast carrying flavonoid glucosyltransferase from *Dianthus caryophyllus*. Orotic acid in the medium enhanced the yield and shifted the selectivity toward naringenin-7-*O*-glucoside in the same experiment [45, 46].

3.2 Production of Flavonoids from *E. coli*

The functional expression of plant cytochrome P450 monooxygenases, such as flavonoid 3-hydroxylase, flavonoid 3, 5-hydroxylase, and other genes of flavonoid biosynthetic pathways from plant origin, is difficult in prokaryotic cells [47]. This ultimately results in low titer production of the desired compound. However, the application of recently developed molecular biology, metabolic and protein engineering, and synthetic biology tools significantly increased the production of different natural products in *E. coli*. The high-level production of such value-added products from simple hosts like *E. coli* using renewable substrates has garnered the attention of the entire world. Therefore, the techniques of constructing efficient microbial factories for the production of natural compounds could be applied to generate novel compounds with unique structures and functions by introducing highly catalytic enzymes. Recent data analysis shows that a number of modified natural compounds have been produced from *E. coli*. In this section, the recent approaches used for flavonoid production from *E. coli* will be discussed in detail.

Almost a decade ago, the heterologous expression of anthocyanin biosynthetic genes with individual promoters and ribosome binding sites (RBS) [34] from different plant sources, i.e., *flavanone 3β-hydroxylase*(FHT) from *Malus domestica*, DFR from *Anthurium andraeanum*, ANS from *M. domestica*, and UDP-glucose: flavonoid 3-*O*-glucosyltransferase (UGT) from *Petunia hybrid*, was achieved successfully in *E. coli* (Fig. 53.6). Such recombinant *E. coli* can

convert the colorless flavanones, naringenin (**29**) or eriodictyol (**39**) to the corresponding colorful glycosylated anthocyanins, pelargonidin 3-*O*-glucoside (**44**) or cyanidin 3-*O*-glucoside (**45**) [34, 48]. Similarly, a strain expressing plant 4CL, CHS, CHI, ANS, and 3-*O*-glycosyltransferase produced flavanones up to 700 mg l^{-1} and anthocyanins up to 113 mg l^{-1} [1].

The coexpression of flavonol biosynthetic structural genes 4CL, CHS, CHI, flavanone 3β-hydroxylase (FHT), and FLS, along with plant P450 flavonoid 3′,5′hydroxylase (F3′5′H) as a fusion protein with a P450 reductase, produced three different flavonols: kaempferol (**42**), quercetin (**43**), and myricetin (**46**) [49]. Later, chimeric cytochrome P450 enzymes were developed and used for the bioconversion of naringenin to genistein (**41**), and liquiritigenin to daidzein. The expression of the chimera in bacteria catalyzed fivefold higher production of isoflavones than in yeast expressing wild-type enzymes. The artificial enzyme design could potentially be used to increase the availability of natural pharmaceuticals and for the synthesis of other plant chemicals by industrial microbes [50]. Currently, mutant enzymes are generated to enhance the bioconversion as well as for broad modifications of the compounds by the same enzyme. For example, engineered 7-*O*-methyltransferase from *Populus deltoids* converted quercetin to rhamnetin with an increased conversion rate [51].

Different approaches have been applied to produce a number of natural and unnatural flavonoids in *E. coli*. For example, 4CL-1, ACC, CHS, and CHI genes from plants and bacterial sources were used to develop recombinant *E. coli* as an enzyme bag that converted exogenous fed natural carboxylic acids (cinnamic acid, *p*-coumaric acid, *m*-coumaric acid, *o*-coumaric acid, caffeic acid) and unnatural carboxylic acids (fluorocinnamic acids, furyl, and thienyl and naphthylacrylic acids) to the corresponding natural and unnatural flavanones (Fig. 53.7). When FSI was introduced into the same *E. coli*, 13 flavones were synthesized from the corresponding flavanones, including four unnatural ones. Further introduction of F3H and FLS to the flavanone-producing *E. coli* generated eight different types of flavonols with two unnatural ones. The yields of the natural flavanones were roughly 70–90 mg l^{-1} and those of the unnatural flavanones reached 50–100 mg l^{-1}, whereas the production of natural and unnatural flavones was 30–50 mg/l. Only trace amounts of flavonols were detected. Reconstruction of the same *E. coli* cell with 4CL, ACC, and STS resulted in the production of 15 stilbenes, including five unnatural, upon supplementation with different carboxylic acids. The overall production of unnatural stilbenes was 55–130 mg l^{-1}, while that of stilbenes derived from natural carboxylic acids was 130–170 mg l^{-1}. Overall, 87 polyketides, including 36 unnatural flavonoids and stilbenes, were produced by exogenously feeding different carboxylic acids to this recombinant *E. coli*. This system could be promising for construction of a larger library if it employed other modification enzymes [52].

In many cases, the biosynthetic efficacy is greatly limited by the precursor and cofactor availability in the host. The initial precursors of the phenylpropanoid and flavonoid biosynthetic pathways, L-tyrosine, L-phenylalanine, and malonyl-CoA, are derived from native metabolism in both *E. coli* and *S. cerevisiae*. When the flavonoid biosynthetic pathway is heterologously introduced and expressed in such hosts, the precursor molecules become limited within the cell [53]. This results in relatively low production of the target compound and cell growth rate because of the metabolic burden within the cell [33], which remains a bottleneck for large-scale applications and low-cost production of different flavonoids. Therefore, introduction of alternative carbon assimilation pathways, such as the malonate utilization pathway, and inhibition or deletion of competitive reactions, including fatty acid synthesis and UDP-glucose consumption pathways, could improve the availability of malonyl-CoA and UDP-glucose. The overall modification carried out in yeast, *E. coli* or *Streptomyces* for enhanced carbon flux through malonyl-CoA is presented in Fig. 53.8.

This limitation was partially addressed by rational modification of the acetate-acetyl-CoA–malonyl-CoA metabolic node in order to improve malonyl-CoA

Fig. 53.7 Biosynthesis of natural and unnatural flavonoids and stilbenes in *E. coli*. Supplementation of unnatural synthesized carboxylic acids and natural carboxylic acids in *E. coli* recombinants produced unnatural and natural respective chalcones, flavanones, flavones, flavonols, and stilbenes. The *red circle* shown in the figure is one of the structure/groups shown in the *inset*

precursor availability in flavanone-producer recombinant *E. coli* strains by increasing carbon flux toward malonyl-CoA, which was achieved after overexpression of multisubunit complex of acetyl-CoA carboxylase (ACC)-biotin ligase (BirA) and enzymes of acetate assimilation pathways. Auxiliary expression of ACC with a chimeric biotin ligase (BirA) consisting of the N-terminus from *E. coli* and C-terminus from *Photorhabdus luminescens* increased the production of pinocembrin, naringenin, and eriodictyol up to 1,379 %, 183 %, and 373 % compared to production in strains expressing only the flavonoid pathway; these corresponded to 429, 119, and 52 mg l^{-1}, respectively [54]. Previously, Miyahisa and coworkers [53] reported that the expression of the two-subunit ACC from the gram-positive bacterium *C. glutamicum* resulted in pinocembrin and naringenin synthesis of approximately 1 and 0.7 mg l^{-1}, respectively, from a flavanone-producing *E. coli*.

Fig. 53.8 Diagrammatic representation of engineering of microbial cells for increased carbon flux through malonyl-CoA for enhanced supplementation of flavonoid biosynthetic intermediates. *Dashed arrow* represents multiple steps, *crossed arrow* represents deletion of gene (e.g., *sdhA*, *cite*, *ackA*, *pta*, *adhEbrnQ*), and other genes are overexpressed (e.g., *matB*, *matC*, *acs*, *acc*, *birA*). Extracellular components are supplied to the cell culture growth medium (e.g., Glucose, malonate, phenylpropanoic acids). A detailed explanation of the cell modification for carbon flux through malonyl-CoA and the effect in flavonoid production is given in the text

In another similar study, Cipher of Evolutionary Design (CiED) model was used to generate improved *E. coli* genotypes that more effectively channeled carbon flux toward malonyl-CoA and other cofactors. The deletion of *sdhA*, *adhE*, *brnQ*, and *citE* genes and overexpression of the enzymes acetyl-CoA synthase (ACS), ACC, biotin ligase (BPL), and pantothenate kinase (PNK) along with plant-derived flavanone biosynthetic genes increased the naringenin titer to 270 mg l^{-1} and to 150 mg l^{-1} of eriodictyol in the engineered construct [55].

Recently, naringenin-producing *E. coli* [54] was reconstructed with F3H, a FeII-dependent dioxygenase enzyme from *Arabidopsis thaliana*, and 7-*O*-methyltransferase from *Streptomyces avermitilis* to produce 7-*O*-methyl aromadendrin (**47**) Fig. 53.6. The maximum titer of 7-*O*-methyl aromadendrin (2.7 mg l^{-1}) was achieved by increasing the availability of malonyl-CoA precursor in the pathway by overexpressing ACC α and β subunits (*nfa9890* and *nfa9940*), biotin ligase (*nfa9950*), and acetyl-CoA synthetase (*nfa3550*) genes from *Nocardia farcinica* upon supplementation with *p*-coumaric acid. But when naringenin was supplemented in the growing recombinant culture producing 7-*O*-methyl aromadendrin, the product was enhanced by 12-fold. Dihydrokaempferol (**48**) and sakuranetin were also detected as intermediate products from the same strain [56]. A similar strategy of higher carbon flux through malonyl-CoA has been applied to overcome the shortage of native precursors and cofactors of flavonoids in the cell without retarding cell growth. The deletion of competing pathway enzymes (ackA, pta, adhE) using acetyl-CoA for the production of acetate and ethanol, and overexpression of acetate assimilation enzyme genes (*acs*, *acc*, and *fabD*) led to the creation of an *E. coli* strain with 15-fold higher cellular malonyl-CoA level [57]. Such recombinants would be useful for the high-level production of flavonoids and other natural products that use malonyl-CoA as a precursor or intermediate.

A different approach has been used to produce glycosylated flavonoids from *E. coli* by enhancing the pool of different activated sugars. For example, UDP-glucose dehydrogenase (CalS8) and UDP-glucuronic acid decarboxylase (CalS9) from *Micromonospora echinospora* spp. *Calichensis* were expressed together with an integrated copy of *E. coli* K12 UDP-glucose pyrophosphorylase (GalU) in the background strain *E. coli* BL21 (DE3) with the glucose phosphate isomerase (*pgi*) gene-deleted mutant for excess availability of UDP-xylose along with 7-*O*-glycosyltransferase (ArGt-4) from *Arabidopsis thaliana*. This newly engineered strain was fed naringenin to produce naringenin 7-*O*-xyloside [58]. Similarly, the pools of TDP-L-rhamnose and TDP-D-allose sugars were developed separately by expressing the respective sugar biosynthetic pathway genes from different bacterial sources in the same *pgi*-deleted *E. coli* BL21 (DE3) along with *Arabidopsis thaliana* glycosyltransferase (ArGt-3). When these recombinants were fed quercetin and kaempferol, the respective sugar-producing strains produced 3-*O*-rhamosyl quercetin, 3-*O*-rhamnosyl kaempferol, and only 3-*O*-allosyl quercetin [59]. In another similar recent report, *E. coli* BL21 (DE3) carrying three genes, *ugd* (UDP-glucose dehydrogenase), *arnA* (UDP-L-Ara4N formyltransferase//UDP-GlcA C-4″-decarboxylase), and *arnB* (UDP-L-Ara4O C-4″ transaminase), along with glycosyltransferase AtUGT78D3 from *Arabidopsis thaliana*, produced quercetin-3-*O*-Ara4FN when fed quercetin [60]. This approach of producing flavonoid glycosides might be helpful to generate medically important novel/unnatural flavonoids in *E. coli*. The general scheme of this approach is shown in Fig. 53.9.

During the last decade, metabolic engineering approaches have been used to produce various flavonoid compounds in microbial systems by heterologously expressing plant structural genes. Though strain titers and yields have recently been improved significantly, this strategy of fermentation faces problems like the requirement for supplementation of expensive phenylpropanoic precursors into the media. To overcome this problem, a four-step heterologous pathway consisting of the enzymes TAL, 4CL, CHS, and CHI was assembled within an engineered L-tyrosine *E. coli* overproducer [61] in order to enable the production of the main flavonoid precursor naringenin directly from glucose. Extensive optimization of the enzyme sources and relative gene expression levels achieved high *p*-coumaric acid and naringenin production. Moreover, addition of cerulenin, a fatty acid enzyme inhibitor, increased the 29 mg l^{-1} naringenin production from glucose to 84 mg l^{-1} in minimal medium without additional precursor supplementation [21].

Fig. 53.9 General scheme of production of flavonoid glycosides by using sugar pathway engineered *E. coli*. dTDP-D-allose, dTDP-L-rhamnose, and UDP-xylose sugar biosynthetic pathways genes are overexpressed in *E. coli* BL21(DE3)/(Δ*pgi*) mutant and UDP-*β*-L-Ara4FN sugar biosynthetic pathways genes are overexpressed in nonmutant *E. coli*. The overexpressed genes are mentioned in the pathways

Besides flavonoids and other natural products, other unnatural compounds with significant titer are alternatively synthesized from glucose in *E. coli* through de novo design and development of novel metabolic pathway petrochemicals [62]. Thus, metabolic engineering and use of *E. coli* as a microbial factory has extensively attracted interest in the development of a novel system for modification and efficient production of highly useful compounds.

3.3 Production of Flavonoids from *Streptomyces* and Fungi

Streptomyces and fungi are potential sources of different antibiotics and other natural compounds. Many antibacterial, antiviral, anticancer, and other potential pharmaceutically applicable secondary metabolites have been isolated from these species. Only a few species can grow in defined medium in the laboratory. However, some of them have been developed as potential industrial organisms. For example, *Streptomyces avermitilis*, *S. ceolicolor*, *S. venezualae*, and *S. lividans* are widely used in industry for different purposes. Recently, the genome sequence of different *Streptomyces* became available, which led to the easy development of such microbial cells for industrial purposes. Unlike *E. coli* and other bacteria, *Streptomyces* and fungi are complex in their physiology and metabolism. They grow relatively slowly and require complex culture medium. However, the recent development of *Streptomyces* as a microbial factory has revolutionized the heterologous production of different antibiotics and natural compounds. Plenty of flavonoids and other natural product modification enzymes have been found in the genome of *Streptomyces*. Thus, these microbial cells convert compounds by different modifications by native enzymes, such as hydroxylation, methylation, glycosylation, alkylation, etc. Moreover, different modifying genes have been introduced for specific modification of the target compounds in *Streptomyces*. For example, *S. lividans* TK21 carrying the *bphA1* (*2072*) *A2A3A4* gene cluster, which codes for a shuffled biphenyl dioxygenase holoenzyme with broad substrate specificity, was used for the bioconversion of flavanone and flavone. Flavone was converted into two products, 2′, 3′-dihydroxyflavone (a major product) and 3′-hydroxyflavone (a minor product), whereas flavanone was converted into three products 2′, 3′-dihydroxyflavanone (a major product), 2′-hydroxyflavanone, and 3′-hydroxyflavanone (minor products). Similarly, 6-hydroxyflavone and 6-hydroxyflavanone were converted into 2′, 6-dihydroxyflavone and 3′,6-dihydroxyflavanone, respectively [63]. Few studies have reported the modification of flavonoids by whole cell biotransformation without any modification in the host *Streptomyces* species. For example, *S. avermitilis* MA-4680 showed high *ortho*-dihydroxylation activity to produce 3′,4′,7-trihydroxyisoflavone and 3′,4′,5,7-tetrahydroxyisoflavone from daidzein and genistein, respectively [64, 65]. Similarly, baicalein and hydroxylated phloretin were produced from exogenously fed chrysin and phloretin, respectively, in *S. avermitilis* and *S. ceolicolor*. Use of the cytochrome P450 inhibitor erythromycin in *S. ceolicolor* completely blocked the bioconversion of chrysin [66]. Besides whole cell biotransformation, in vitro bioconversion of flavonoids has been carried out using different modifying enzymes from *Streptomyces* and other sources [67].

In another separate study, native pikromycin polyketide synthase gene-deleted strain *S. venezuelae* DHS2001 was used for expression of flavanone and stilbene biosynthetic genes of different origin for the production of the respective compounds. 4-Coumarate/cinnamate: Coenzyme A ligase from *S. coelicolor* (ScCCL) and CHS from *Arabidopsis thaliana* (atCHS) introduced into a recombinant *Streptomyces* strain produced racemic naringenin and pinocembrin from 4-coumaric acid and cinnamic acid, respectively. When both genes were placed under the *ermE* promoter, production of both flavanones was increased significantly. Resveratrol and pinosylvin stilbenes were produced by overexpression of ScCCL and codon-optimized STS gene from *Arachis hypogaea* [68]. The same strain carrying the codon-optimized flavone synthase I (FS I) gene from *Petroselium crispum* produced flavones apigenin and chrysin from exogenous naringenin and pinocembrin, respectively, while expression of the codon-optimized F3H and FLS gene from *Citrus siensis* and *Citrus unshius*, respectively, produced flavonols, kaempferol, and galangin from flavanones [69]. The overexpression of malonate assimilation operon matB and matC encoding malonyl-CoA synthetase and the putative dicarboxylate carrier protein from *S. coelicolor* enhanced the production of flavanones and flavones, respectively, up to 40 and 30 mg l^{-1}in both biosynthetic gene-overexpressing strains [70].

Fungi, a separate group of microorganisms, are used in biotechnology industries for the production of valuable primary and secondary metabolites. Most fungi have pathogenic properties in plants and animals because of the production of fatal toxins and other secondary metabolites. Therefore, fungi are not widely explored for the biotransformation of natural products in contrast to yeast, *Streptomyces*, *E. coli*, and other bacteria. However, a few reports are available regarding the whole cell biotransformation of flavonoids using fungi. For example, among 138 screened soil fungi, only strain *Trichoderma harzianum*NJ01 was able to grow in media containing puerarin. Under optimized conditions, the mycelium of the fungus converted 41 % of supplemented puerarin into 3′-hydroxypuerarin [71]. Similarly, *Penicillium griseoroseum* isolated from *Coffeea arabica* seeds is grown in 5,7, 3′,4′,5′-pentamethoxyflavanone containing Czapeck's medium. Interestingly, the fungus incorporated a dimethylated tetraketide clavatol, atypical fungal secondary metabolite, into the flavanone structure at C-6, resulting in a novel benzylated flavonoid (**48**) [72].

Besides whole cell fungal biotransformation of flavonoids, aromatic peroxygenases from fungus *Agrocybeaegerita* (*Aae*APO) regioselectively catalyzes the H_2O_2-dependent monohydroxylation of diverse flavonoids [73].

3.4 Production of Flavonoids from Transgenic Plants and Plant Tissue Cultures

Plants are the natural sources of diverse kinds of flavonoids. Isoflavonoids are predominantly found in leguminous plants but rarely in other plants. Therefore, Liu et al. engineered nonleguminous transgenic tobacco, lettuce, and petunia with genes encoding key enzymes of the flavonoid/isoflavonoid pathway to produce isoflavonoids in nonleguminous plants. Upon introduction of soybean IFS into these plants, which do not naturally produce isoflavonoids, genistein was detected in petals and leaves. Likewise, suppression of F3H in tobacco by its antisense gene and overexpression of soybean IFS at the same time increased genistein yield. In addition, overexpression of PAL also led to enhanced genistein production in tobacco petals and lettuce leaves in the presence of IFS compared to that in plants that overexpressed only IFS [74].

Similarly, Sugiyama and coworkers recently used broad substrate-specific prenyltransferases, NphB, SCO7190, and NovQ, from *Streptomyces* and two plant genes, N8DT and G6DT, from *Sophora flavescens* to generate 624 transgenic

Lotus japonicus plants for the production of wide varieties of prenylated flavonoids. In fact, no prenylated products were detected from those transgenic plants. However, when leaves were incubated with naringenin and genistein, prenylated flavonoids 7-*O*-geranylgenistein, 6-dimethylallylnaringenin, 6-dimethylallylgenistein, 8-dimethylallynaringenin, and 6-dimethylallyl genistein were produced in the transgenic plants [75]. This study demonstrated the potential for the production of novel prenylated polyphenols in transgenic plants. A different concept of flavonoid diversification can be applied in plant tissue culture. Different natural product-modifying enzymes are naturally present in the plant cell. The use of such cell cultures may produce diverse types of target compounds in the laboratory. Shimoda et al. investigated the biotransformation of naringin and naringenin by using cultured cells of *Eucalyptus perriniana*. Altogether, ten different types of glycosylated compounds were detected in very small amounts from the culture extract treated with naringin and naringenin. Naringin was converted into diverse glycosides, such as naringenin 7-*O*-β-ᴅ-glucopyranoside, naringenin, naringenin 5,7-*O*-β-ᴅ-diglucopyranoside, naringenin 4′,7-*O*-β-ᴅ-diglucopyranoside, naringenin 7-*O*-[6-*O*-(β-ᴅ-glucopyranosyl)]-β-ᴅ-glucopyranoside, naringenin 7-*O*-[6-*O*-(α-ʟ-rhamnopyranosyl)]-β-ᴅ-glucopyranoside, and 7-*O*-β-ᴅ-gentiobiosyl-4′-*O*-β-ᴅ-glucopyranosylnaringenin. On the other hand, naringenin 7-O-β-ᴅ-glucopyranoside, naringenin 5,7-*O*-β-ᴅ-diglucopyranoside, naringenin 4′,7-*O*-β-ᴅ-diglucopyranoside, naringenin 7-*O*-[6-*O*-(β-ᴅ-glucopyranosyl)]-β-ᴅ-glucopyranoside, naringenin 7-*O*-[6-*O*-(α-ʟ-rhamnopyranosyl)]-β-ᴅ-glucopyranoside, naringenin 4′-*O*-β-ᴅ-glucopyranoside, naringenin 5-*O*-β-ᴅ-glucopyranoside, and naringenin 4′,5-*O*-β-ᴅ-diglucopyranoside were isolated from cultured *E. perriniana* cells that had been treated with naringenin. Among them, two products, 7-*O*-β-ᴅ-gentiobiosyl-4′-*O*-β-ᴅ-glucopyranosyl naringenin and naringenin 4′,5-*O*-β-ᴅ-diglucopyranoside, were novel compounds [76]. Although the compounds were converted into diverse glycosides, the production level was very low.

4 Conclusion

Flavonoids are ubiquitously found in plants and diverse in structure. The significance of flavonoids in human health and their functions in plant physiology and growth have attracted a variety of research into these molecules. Currently, flavonoids are being developed as molecules of choice for drug development. In plant science, the flavonoid biosynthetic pathways have been intensively studied to define the role and mechanism of each gene involved. The recent development of modern molecular tools has expanded the possibility of production of such compounds beyond the native producers, the plants. The incorporation of natural and hybrid biosynthetic pathways into microorganisms has created the potential for not only defined biosynthesis of a multitude of natural products, but also the opportunity to generate unnatural derivatives with potentially novel or refined pharmaceutical activities [77, 78]. Microbial cells like *E. coli*, *Saccharomyces cerevisiae*, and *Streptomyces* are emerging as enzyme bags through genetic engineering modifications. Such microbial factories have produced wide varieties of natural as well as unnatural flavonoids and are apparently expanding the market size for flavonoids along with other biotech-derived small molecules [79]. However, significantly higher production titer has not been achieved yet. Thus, the production of almost all flavonoids still depends on the plant sources. But, once the flavonoid backbones are produced in microbes, they can easily be modified through combinatorial biosynthesis by introducing different modifying genes to generate ranges of derivatives.

In the last decade, *E. coli* and *S. cerevisiae*, as well as some *Streptomyces* species, have been engineered as factories for the production and biotransformation of natural products. The development of microbial factories as a small molecule production platform requires identification of bottlenecks in the biosynthetic pathway and rewiring of native pathways via enhanced carbon flux toward precursors and intermediates to lead to higher production of target compounds. However, exploration of new microbial hosts and novel enzymes is still essential to expand the product range and to create a powerful system [25]. The recent achievement in synthesis of entire bacterial genome sequence has opened the doors for the development of bacterial cells of interest [80]. The combined application of different modern approaches could give birth to new useful microbes that are programmable, controlled, and highly robust for natural product production by a simple fermentation technique, which would also allow us to biosynthesize several other value-added flavonoid molecules in the near future.

Abstract

Isoflavonoids are a class of plant natural products gaining attention due to their pharmaceutical properties. These natural compounds constitute a subclass of flavonoids, which belong to a broader class of plant products known as phenylpropanoids.

Flavonoids have been associated with medicinal properties, while isoflavonoids have shown anticancer, antioxidant, and cardioprotective properties due to their role as inhibitors of estrogen receptors. Isoflavonoids are naturally produced by legumes and, more specifically, organisms belonging to the pea family. Harvesting of these natural products through traditional extraction processes is limited due to the low levels of these phytochemicals in plants, so alternative production platforms are required to reduce cost of production and increase availability. Over the last decade, researchers have engineered artificial flavonoid biosynthesis pathways into *Escherichia coli* and *Saccharomyces cerevisiae* to convert simple, renewable sugars like glucose into flavonoids at high production levels. This chapter outlines the metabolic engineering research that has enabled microbial production of plant flavonoids and further details the ongoing work aimed at producing both natural and non-natural isoflavonoids in microorganisms.

Keywords

Metabolic engineering • mutasynthesis • non-natural isoflavonoids • protein engineering • strain improvement

Abbreviations

3GT	3-*O*-glucosyltransferase
4CL	4-Coumarate-CoA ligase
ACC	Acetyl-CoA carboxylase
Ala	Alanine
ANR	Anthocyanidin reductase
ANS	Anthocyanidin synthase
API	Active pharmaceutical ingredient
Arg	Arginine
BDO	Biphenyl dioxygenase
BMC	Bacterial microcompartment
C4H	Cinnamate 4-hydroxylase
CHI	Chalcone isomerase
CHS	Chalcone synthase
CPR	Cytochrome P450 reductase
CUS	Curcuminoid synthase
DFR	Dihydroflavonol reductase
DH	*Salmonella typhimurium* LT2 TDP-glucose 4,6-dehydratase
EPI	*Streptomyces antibioticus* Tu99 TDP-4-keto-6-deoxyglucose 3,5-epimerase
ER	Endoplasmic reticulum
F7GAT	Flavonoid 7-*O*-glucuronosyltransferase
FHT	Flavanone 3β-hydroxylase
FLS	Flavonol synthase

FSI	Soluble flavone synthase
FSII	Membrane-bound flavone synthase
G1P	Glucose-1-phosphate
G6P	Glucose-6-phosphate
GALU	Glucose-1-phosphate uridylyltransferase
GERF	*Streptomyces* sp. KCTC 0041BP TDP-hexose 3-epimerase
GERK	*Streptomyces* sp. KCTC 0041BP TDP-4-keto-6-deoxyglucose reductase
Glu	Glutamic acid
Gly	Glycine
HEK	Human embryonic kidney cells
hER	Human estrogen receptor
HI4′OMT	2,7,4′-Trihydroxyisoflavanone 4′-*O*-methyltransferase
HID	2-Hydroxyisoflavanone dehydratase
HIDH	2-Hydroxyisoflavanone dehydratase hydroxy type
HIDM	2-Hydroxyisoflavanone dehydratase methoxy type
IFR	Isoflavone reductase
IFS	Isoflavone synthase
Ile	Isoleucine
k_{cat}	Turnover number
K_m	Michaelis constant
KR	*Streptomyces antibioticus* Tu99 TDP-glucose 4-ketoreductase
LAR	Leucoanthocyanidin reductase
LB	Luria-Bertani medium
LDOX	Leucoanthocyanidin dioxygenase
NADPH	Nicotinamide adenine dinucleotide phosphate
NDK	Nucleoside diphosphate kinase
NDO	Naphthalene dioxygenase
PAL	Phenylalanine ammonia-lyase
PGI	Glucose-6-phosphate isomerase
PGM	Phosphoglucomutase
Phe	Phenylalanine
RCIFS	Red clover isoflavone synthase
RCPR	Rice cytochrome P450 reductase
SaOMT-2	*Streptomyces avermitilis* MA-4680 7-*O*-methyltransferase
ScCCL	*Streptomyces coelicolor* A3 cinnamate/coumarate:CoA ligase
Ser	Serine
SERM	Selective estrogen receptor modulator
STS	Stilbene synthase
TAL	Tyrosine ammonia-lyase
TB	Terrific broth
TDP	Thymidyldiphosphate

TGS	*Thermus caldophilus* GK24 thymidyldiphosphoglucose synthase
Thr	Threonine
Trp	Tryptophan
Tyr	Tyrosine
UDG	Uridine diphosphoglucose dehydrogenase
UDP	Uridine diphosphate
UGT	Uridine diphosphate glycosyltransferase
UTP	Uridine triphosphate
UXS1	Uridine diphosphate glucuronic acid decarboxylase
Val	Valine
V_{max}	Maximum reaction rate

1 Metabolic Engineering

1.1 Background

Metabolic engineering involves the genetic manipulation of metabolism for a specific goal, often high-level production of a secondary metabolite. Secondary metabolites are those not critical to the survival of an organism in its normal environment, and they are thus typically found in far lower quantities than primary metabolites involved in energy maintenance and growth [1, 2]. As secondary metabolites have evolved to serve in important ecological roles – usually through interaction with other organisms – they possess unique properties and are thus the target of many metabolic engineering projects [3–5]. Although metabolic engineering has been a distinct discipline for over two decades, advancing technologies in areas such as DNA sequencing and synthesis, computational modeling and optimization, synthetic biology, and protein engineering are enabling metabolic engineers to create economically viable microbial production platforms for specialty chemicals like pharmaceuticals and biofuels [6].

Throughout the past decade, much work has focused on both plant and microbial metabolic engineering for production of pharmaceutically and nutraceutically important plant isoflavonoids [7–11]. This class of phytochemicals has been shown to possess a diverse array of pharmacological activities and demonstrates potential for treatment of certain cancers, cardiovascular diseases, and other conditions [12–17]. In particular, isoflavonoids have high affinity toward human estrogen receptors (hERs) and are therefore being investigated as estrogen receptor agonists and antagonists to modulate estrogen metabolism [18–20]. The relatively low abundance of these valuable compounds in plants makes microbial metabolic engineering an excellent alternative candidate for large-scale isoflavonoid production.

1.2 Metabolic Engineering Products

The majority of work in the field of metabolic engineering has focused on the production of commodity chemicals and biofuels from renewable, simple carbon sources such as glucose and glycerol, or the production of pharmaceutical chemicals and proteins [21–24]. In general, metabolic engineering can be viewed as the process by which scientists combine genes from different sources to construct a biosynthetic pathway in a host organism to convert an inexpensive feedstock into a valuable product. Classic metabolic engineering projects range from the microbial production of biofuels like ethanol and butanol to the production of commodity chemicals like xylitol. Although these efforts are important for ensuring long-term stability of commodity supply from renewable resources, microbial metabolic engineering of valuable plant natural products and other active pharmaceutical ingredients (APIs) with high overhead has the potential to make a much greater impact on society by lowering cost and ensuring availability and widespread access to medically important compounds [6].

1.3 Microorganisms as a Production Platform for Plant Natural Products

1.3.1 Advantages of Microbial Hosts

Microorganisms serve as excellent hosts for production of phytochemicals. The relatively lower genetic complexity of microbes compared to multicellular eukaryotes allows for more accurate prediction of the effects of genetic manipulations in microbes than in plants. Modulation of gene copy or expression level typically leads to an imbalance in reaction fluxes and, subsequently, the accumulation of pathway intermediates. If a genetic pathway is not decoupled from its native environment, accumulation of intermediates can become toxic or elicit unintended regulatory effects like feedback inhibition. Such uncharacterized genetic interactions in multicellular eukaryotic hosts are currently difficult to predict and can be largely avoided by transplanting genes from evolutionarily distinct organisms into an artificial pathway in a microbial host [25].

Perhaps the strongest argument for utilizing microorganisms for metabolic engineering of plant natural products is the high degree of genetic tractability that currently exists for microbial workhorses like *Escherichia coli*, *Saccharomyces cerevisiae*, and *Bacillus subtilis*. Thanks to decades of research, these hosts have innumerable data sets and molecular biology tools available for facile genetic manipulation, characterization, modeling, and scale-up. This genetic tractability reduces experimental unknowns and allows for faster, more predictable experimentation and data collection. Additionally, the high growth rates and simple media requirements associated with microorganisms enable culturing with limited resources [25, 26].

1.3.2 Alternative Production Platforms

Plant natural products have traditionally been harvested through extraction methods, as evidenced by the preparation of traditional medicines and the steeping of tea leaves and coffee beans for millenia. Since plant natural products are generally found at low levels in plant biomass, extraction is usually not a sustainable mass production avenue. Although extraction is still utilized to harvest APIs like the antimalarial drug artemisinin (from *Artemisia annua*, known as Sweet Wormwood) and the chemotherapeutic paclitaxel (from *Taxus brevifolia*, the Pacific yew tree) when chemical synthesis is difficult or expensive, there is a trend and growing necessity to shift toward alternative production platforms to lower cost and increase availability [27, 28].

Alternative production platforms include organic synthesis, plant cell culture, plant tissue culture, and even mammalian cell culture. The field of organic synthesis of complex plant natural products has advanced significantly but is limited as an industrial-scale flavonoid production platform by frequent use of toxic chemicals and extreme reaction conditions, a high number of required steps, exorbitant costs, relatively low overall yields, and nonspecific catalysts leading to by-products and often difficult-to-separate racemic mixtures of target compounds [29–35]. Semisynthesis, which combines organic synthesis steps with biosynthetic steps, is also limited by similar challenges. It is then reasonable to consider plant cell and tissue culture as a closely related alternative production platform since the metabolites of interest are endogenously produced in undifferentiated plant cells [36].

A well-known example of industrial-scale production in plant cell lines is the induction of paclitaxel production through methyl jasmonate elicitation, yielding 0.5 % of dry weight compared to 0.01 % of dry weight by extraction from the Pacific yew [37, 38]. By contrast, chemical synthesis of paclitaxel requires 35–51 steps, with a yield of only 0.4 % [39]. Plant tissue culture is another option, as many secondary metabolic biosynthetic pathways are only active in specific stages of development or in certain tissues [40, 41]. Thus, elicitation of differentiated plant cell tissues by small molecules or light can also be utilized to produce secondary metabolites. Despite progress in plant cell and tissue culture, the elucidation and characterization of all enzymes involved in plant secondary metabolite biosynthetic pathways are still challenging tasks; moreover, the difficulty in unequivocally discerning all sensitive, multilevel regulatory effects instigated by minimal variations in metabolite concentrations often makes the outcome of metabolic engineering in plant cell and tissue cultures unpredictable.

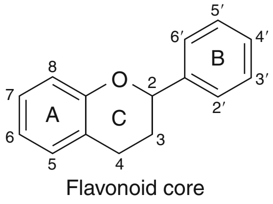
With advances in metabolic engineering of mammalian cells, it is foreseeable that plant natural products might one day be produced and derivatized using mammalian cell culture to take advantage of mammal-specific biotransformations and glycosylation patterns leading to improved pharmaceutical properties and applications. Therapeutic phytochemical production pathways might even be engineered into specific tissues to enable in situ biosynthesis for disease treatment or prophylaxis. To date this alternative remains relatively unexplored; however, engineering of a resveratrol artificial biosynthetic pathway into human embryonic kidney cells (HEK293) circumvented purported difficulties associated with yeast expression of tyrosine ammonia-lyase (TAL) and highlighted the opportunity to move plant pathways into mammalian cells for in situ production of phytochemical therapeutics in human tissue [42]. Just as predictable metabolic engineering of plant cell and tissue cultures is currently limited by cellular complexity, metabolic engineering of mammalian cells can be encumbered with the same difficulties.

2 Plant Phenylpropanoid Biosynthesis

2.1 Background

Isoflavonoids belong to a broad class of compounds known as phenolics. Any chemical containing one or more phenol group can be classified as a phenolic compound, although the plant phenolics with the most biotechnological relevance are flavonoids and other phenylpropanoids. Phenylpropanoids are secondary plant metabolites that are considered to be beneficial for human health [43]. In particular, a subclass of phenylpropanoids known as flavonoids is typified by bioactive compounds with antioxidant, antiviral and antibacterial, anticancer, antiobesity, and estrogenic properties [9]. The microbial production of flavonoids has attracted much attention due to the prospect of utilizing flavonoids for personal health applications [44]. Flavonoids are currently used as dietary supplements and are the subject of intense investigation as pharmaceutical precursors to treat chronic human pathological conditions like cancer and diabetes [45–51]. Anthocyanins **17**, another class of flavonoids, possess brilliant natural colors and are potential replacements for artificial dyes that have adverse health effects. The antioxidant properties of these glycosylated flavonoids may have a positive health influence and make anthocyanins **17** well suited as natural colorants for the food and beverage industry [52–54]. Anthocyanins **17** are good targets for metabolic engineering since glycosylations remain a challenge from a chemical synthesis perspective. Furthermore, plant extraction of phenolics seldom yields greater than 1 % of the dry weight. Metabolic engineering of flavonoid biosynthesis has already gained traction due to the long-standing interest in phenolic compounds and the corresponding detailed characterization of related genetic pathways and enzymes [43].

As a general classification, phenolics do not contain nitrogen and may contain multiple hydroxyl groups as well as heteroatom substituent groups. Phenolics with greater than 12 phenolic groups are generally considered as polyphenols, lignins, or tannins. Flavonoids are the most well characterized and largest class of natural phenolics, and they are biosynthesized from the aromatic amino acid phenylalanine **2** through the common precursor, chalcone **11**. Further classification draws a distinction between five types of flavonoids that are derived from the common flavanone **12** precursor: flavones **14**, flavonols **15**, isoflavones **13**, flavanols, and anthocyanins **17** [55]. Flavonoids are composed of a C_6-C_3-C_6 skeleton that serves as a 15-carbon phenylpropanoid core **1** for downstream decorations such as methylations, hydroxylations, reductions, oxidations, glycosylations, acylations, methoxylations, alkylations, and various rearrangements [44, 56–58]. The flavonoid core **1** consists of 3 rings, labeled A, B, and C.



1

Other phenylpropanoids, so named due to their common phenylalanine **2** precursor, include hydroxycinnamic acids, cinnamic aldehydes and monolignols, coumarins, and stilbenoids **8**.

2.2 Plant Phenylpropanoid Biosynthetic Pathway

Phenylpropanoid biosynthesis is initiated by the conversion of phenylalanine **2** to cinnamic acid **5** as catalyzed by phenylalanine ammonia-lyase (PAL). Cinnamic acid **5** is then converted to flavanone **12** through a series of subsequent enzymatic reactions involving the following steps: the hydroxylation of cinnamic acid **5** to *p*-coumaric acid **6** through cinnamate 4-hydroxylase (C4H); the ligation of *p*-coumaric acid **6** to a CoA group using 4-coumarate-CoA ligase (4CL); the sequential decarboxylative condensation of three acetate units from malonyl-CoA **10** to 4-coumaroyl-CoA **19** by chalcone synthase (CHS), a type III polyketide synthase, to form chalcone **11** in a ring closing step; and the stereospecific isomerization of chalcone **11** to flavanone **12** catalyzed by chalcone isomerase (CHI). Downstream enzymes then catalyze the conversion of flavanones **12** into compounds belonging to the various flavonoid subclasses.

Type III polyketide synthases are particularly relevant to this chapter because they catalyze the formation of phenolic compounds. This group of polyketide synthases consists of CHSs, stilbene synthase (STS), and curcuminoid synthase (CUS), which perform decarboxylative condensations between a starter unit, either *p*-coumaroyl-CoA **19** or cinnamoyl-CoA **18**, and an extender unit, malonyl-CoA **10**. CHS, STS, and CUS convert the substrate molecules into flavonoids (C_6-C_3-C_6), stilbenoids **8** (C_6-C_2-C_6), and curcuminoids **9** (C_6-C_7-C_6), respectively [59]. Stilbenoids **8** and curcuminoids **9** are out of the scope of this chapter but possess medicinal properties as well; resveratrol is a well-known stilbenoid **8** associated with longevity, and curcumin is a common curcuminoid **9** that is responsible for the yellow color in turmeric and can be utilized as a natural pigment possessing antioxidant and anti-inflammatory properties [60–63]. For an in-depth treatment of plant polyketide production in microbes, the reader is directed to a recent comprehensive review by Boghigian et al. [64].

2.3 Plant Flavonoid Pathways

Plant flavanones **12** are enzymatically converted to five major subclasses of flavonoids. Flavanones **12** are oxidized to flavones **14** by the action of either a soluble flavone synthase (FSI) or, as in most cases, a membrane-bound cytochrome P450 monooxygenase flavone synthase (FSII) [65]. Flavone synthases belong to the oxidoreductase family of enzymes and effectively remove the stereocenter from flavanones **12** by oxidation of C3 and introduction of a double bond between C2 and C3. Apigenin, luteolin, and chrysin are common flavones **14** that contribute to human diet as glycosides and are found in large quantities in parsley and celery [66–68].

Alternatively, isoflavone synthase (IFS) catalyzes the 1,2-aryl ring B migration from C2 to C3 on ring C of the phenylpropanoid core **1** and the hydroxylation of C2, converting flavanones **12** to 2-hydroxyisoflavanones [69, 70]. Dehydration of 2-hydroxyisoflavanones into isoflavones **13** occurs spontaneously through the 1,2-elimination of water, but accelerated dehydration is catalyzed by one of two hydro-lyases known as 2-hydroxyisoflavanone dehydratases (HID hydroxy type, HIDH; HID methoxy type, HIDM), depending upon the occurrence of an intermediate 4′-*O*-methylation catalyzed by 2,7,4′-trihydroxyisoflavanone 4′-*O*-methyltransferase (HI4′OMT) [71]. Isoflavonoids are characterized by a 3-phenylchroman skeleton, in contrast to the 2-phenylchroman core **1** possessed by flavonoids, and are incredibly diverse in structure despite being limited to natural existence primarily in leguminous plants [72]. Soy beans and soy bean food products contain high concentrations of isoflavone **13** glycosides such as genistin **31** and daidzin **30** and relatively lower quantities of their respective aglycones, daidzein **27** and genistein **26** [74]. Isoflavones **13** are classified as phytoestrogens because of the structural similarity shared with estrogens, and they are among the most highly studied polyphenols due to their affinities for steroid receptors and demonstrated pharmacological properties [18–20, 74]. These characteristics make isoflavones **13** important metabolic engineering targets.

Flavanones **12** also serve as the substrate for flavanone 3*β*-hydroxylase (FHT), which catalyzes the hydroxylation of C3 on the flavanone core **1** into dihydroflavonol **16**, the common precursor to both flavonols **15** and anthocyanins **17**. Dihydroflavonols **16** are subsequently converted to flavonols **15** by reduction of C2 by the oxidoreductase enzyme flavonol synthase (FLS), again removing the stereocenter and introducing a double bond between C2 and C3 [75]. Flavonols **15** such as kaempferol and quercetin exist primarily as glycosides at appreciable levels in onions and kale [67, 68].

Initiating another branch of the flavonoid pathway, C4 of dihydroflavonol **16** can be reduced from a carbonyl group to a hydroxyl group by the oxidoreductase enzyme dihydroflavonol reductase (DFR), producing leucoanthocyanidins, or the colorless precursors to anthocyanins **17**. Leucoanthocyanidins are unstable and are quickly converted to anthocyanidins by anthocyanidin

Fig. 54.1 Plant phenylpropanoid and flavonoid biosynthetic pathways; representative compounds from each subclass are named

synthase (ANS), synonymously leucoanthocyanidin dioxygenase (LDOX), working jointly with DFR [76]. Anthocyanidins and leucoanthocyanidins can alternatively be reduced to their corresponding flavan-3-ols (proanthocyanidins, or condensed tannins) by anthocyanidin reductase (ANR) and leucoanthocyanidin reductase (LAR), respectively. A flavonoid glycosyltransferase then adds a sugar to the anthocyanidin, enabling pigment storage in the form of stable anthocyanins **17** [77]. Many brilliant red, blue, and purple plant hues arise from anthocyanin-mediated coloration. Figure 54.1 illustrates the alternative pathways for biosynthesis of various plant phenylpropanoid and flavonoid subclasses.

3 Plant Isoflavonoid Production in Microbes

3.1 Construction of an Artificial Biosynthetic Pathway for Flavonoid Production in Microbes

The first construction of an artificial plant flavonoid biosynthetic pathway in microbes involved the transformation of *E. coli* with four heterologous genes. These genes are required for the synthesis of flavanones **12** from phenylalanine **2** and tyrosine **3** (through a promiscuous PAL having the ability to accept both phenylalanine **2** and tyrosine **3** as substrates) [78–80]. This exercise provided a platform for the microbial biosynthesis of a plethora of natural and non-natural flavanone **12** derivatives. It should also be noted here that bacterial TAL catalyzes the conversion of tyrosine **3** to *p*-coumaric acid **6** in one step and can replace the two-step conversion of phenylalanine **2** to *p*-coumaric acid **6** by PAL and C4H in an artificial biosynthetic pathway if so desired [81]. Also, depending upon choice of aromatic amino acid precursor, two parallel biosynthetic paths exist for phenylalanine-based flavonoids in contrast to tyrosine-based flavonoids; other common natural and non-natural aromatic acrylic acids like caffeic acid **4** serve as substrates for 4CL in plants and microbes [82, 83]. The substrate flexibility of all enzymes involved allows for perpetuation of extra hydroxyl side groups throughout the entire pathway, affording flavanones **12** or other flavonoids with divergent hydroxylations. Another key distinction to note while reading this section is whether the project being described utilizes an entirely fermentative process to produce complex compounds from primary microbial metabolites or whether the project takes advantage of intermediate chemical supplementation. Although neither approach is absolutely superior to the other, distinctions can be drawn between them.

For instance, a fermentative approach often suffers from low production due to pathway complexity and increased number of steps, but it allows for production of complex compounds such as phytochemicals from simple, renewable carbon compounds like glucose. Conversely, intermediate supplementation is often utilized to simplify pathway construction and is associated with higher product yields. Although supplementing a microbial culture with an expensive precursor might be feasible for a small-scale experiment, it severely hinders industrial applicability. However, if an inexpensive, readily available intermediate can be utilized as a precursor, an entirely fermentative process with lower titers might not be justifiable. A metabolic engineer must then weigh the impact of generating a complex product entirely from primary metabolites versus the value associated with significantly higher production levels. As will be seen throughout this chapter, research efforts are often initiated with intermediate supplementation in order to limit confounding variables, and full fermentative pathways are constructed after significant breakthroughs are achieved and once distinct metabolic pathways can be connected in vivo.

The experiment described in the beginning of this section involved the incorporation of four heterologous genes: *S. cerevisiae* PAL, *Streptomyces coelicolor* A3 cinnamate/coumarate:CoA ligase (ScCCL) with substrate specificity toward both cinnamic acid **5** and *p*-coumaric acid **6**, licorice plant (*Glycyrrhiza echinata*) CHS,

and *Pueraria lobata* CHI. Transformation of *E. coli* with a plasmid harboring these four heterologous genes coupled with overexpression of the *Corynebacterium glutamicum* gene encoding two acetyl-CoA carboxylase subunits, accBC and dtsR1, produced ~60 mg L^{-1} of the flavanones **12** (2*S*)-naringenin **23** and (2*S*)-pinocembrin **22**. The artificial biosynthetic pathway constructed for plant flavanone **12** biosynthesis in microbes is shown in Fig. 54.2. Acetyl-CoA carboxylase (ACC) was selected for overexpression to increase the intracellular pool of malonyl-CoA **10**, which is required for synthesis of flavanones **12** from either 4-coumaroyl-CoA **19** or cinnamoyl-CoA **18**. Further introduction of FSI from *Petroselinum crispum*, FHT from *Citrus sinensis*, and FLS from *Citrus unshiu* produced the flavones **14** apigenin and chrysin, as well as the flavonols **15** kaempferol and galangin in low concentrations [80, 84]. This seminal work has enabled the production in *E. coli* and *S. cerevisiae* of many valuable phenylpropanoid compounds, including natural and non-natural flavones **14**, flavonols **15**, anthocyanins **17**, stilbenoids **8**, and curcuminoids **9** [42, 60, 65, 82, 84–107]. As this chapter focuses on isoflavonoids, however, the reader is directed to a detailed review of microbial biosynthesis of other valuable plant phenylpropanoids by Limem et al. [43].

3.2 Engineering the Plant Isoflavonoid Pathway in Microbes

3.2.1 Production of Isoflavonoid Aglycones in Microbes

The successful construction of an artificial plant flavonoid biosynthetic pathway in microbes, combined with the first report of functional activity of IFS in yeast microsomes by Akashi and coworkers in 1999, paved the way for high-level isoflavonoid production [69]. However, a significant barrier to prokaryotic expression of IFS hampered progress and precluded taking advantage of the high growth rate of *E. coli* and the abundance of molecular biology tools available for the microbe. IFS is a membrane-bound cytochrome P450 that requires an electron transfer system that is not present in bacterial cells; thus, coexpression of functional IFS with the flavanone **12** pathway in recombinant *E. coli* required creative engineering solutions. Eukaryotic microbes like *S. cerevisiae* and other unicellular fungi possess the requisite machinery for cytochrome P450 enzyme expression; specifically, they constitutively express an endogenous cytochrome P450 reductase (CPR) that is an integral redox partner for IFS and other cytochrome P450s, and they possess an endoplasmic reticulum (ER) on which the N-terminal signal-anchor peptide sequences of cytochrome P450 enzymes can bind [108, 109].

Katsuyama et al. overcame this impediment by coculturing a flavanone-producing *E. coli* strain with recombinant *S. cerevisiae* transformed with a T7-inducible plasmid harboring IFS from *G. echinata*. To demonstrate the production of the isoflavone **13** genistein **26** and the feasibility of coincubation, the yeast strain was first transformed with a pESC vector containing the genes CHS from *G. echinata*, CHI from *P. lobata*, and IFS from *G. echinata*, all under the control of galactose-inducible *GAL* promoters. Growth under supplementation with the precursor, *N*-acetylcysteamine-attached *p*-coumarate (*p*-coumaroyl-NAC), yielded ~342 μg L^{-1} genistein **26**. To examine the possibility of production without precursor feeding, a naringenin-producing *E. coli* strain (57 mg L^{-1} of (2*S*)-naringenin **23**) was constructed as described in the previous section and cocultured with a recombinant yeast strain transformed with a vector containing *G. echinata* IFS under control of a galactose-inducible *GAL* promoter [80]. Simultaneous incubation of equal weights of engineered *E. coli* and *S. cerevisiae*, in addition to supplementation of the coculture media with 3 mM tyrosine **3** as a substrate for *E. coli*, yielded ~6 mg L^{-1} of genistein **26** [110]. This "one-pot synthesis" scheme for production of genistein **26** from tyrosine **3** represented the most valuable microbial isoflavonoid production platform at the time of its publication. Optimization of coculture conditions subsequently improved genistein **26** production up to 100 mg L^{-1} [111].

In order to produce isoflavonoids in a model plant, a native flavonoid pathway must be hijacked by diverting a common precursor away from its natural product and toward the desired isoflavonoid product. Tian and colleagues accomplished production of genistein **26** in the nonleguminous, model plant tobacco through protein engineering of a fusion between IFS and CHI [112]. The spatial proximity between CHI and IFS was engineered to increase the local concentration of the IFS substrate, naringenin **23**, such that the production of nonnative genistein **26** was favored over the dominant, endogenous pink anthocyanin **17** accumulation pathway. Localization of the protein chimera at the ER was maintained by constructing the fusion with IFS at the N-terminus so its innate, hydrophobic N-terminal membrane anchor was free to target the ER as usual [87, 113]. A flexible linker peptide composed of glycine-serine-glycine (Gly-Ser-Gly) residues connected the C-terminus of IFS with the N-terminus of CHI to ensure proper folding of the two independent catalytic domains. Expression of this engineered protein fusion in transgenic tobacco successfully shifted flavonoid accumulation toward isoflavonoids and enabled production of isoflavonoids in nonleguminous plants. Yeast expression of the protein fusion under precursor supplementation conditions also produced isoflavonoids and highlighted the possibility to utilize protein engineering to improve plant natural product titers in microbes [112].

Although *E. coli* and *S. cerevisiae* have both been utilized as model organisms for plant flavonoid production, it is often beneficial to express entire biosynthetic pathways in a single organism to avoid bidirectional metabolite transport limitations through the cell walls of two organisms simultaneously and to obviate media optimization for two different species at once. Functional expression of IFS in *E. coli* would eliminate the necessity for coculture with yeast. As such, Leonard and colleagues designed and expressed a set of artificial P450 enzymes that enabled robust biosynthesis of the isoflavones **13** genistein **26** and daidzein **27** from the flavanones **12** naringenin **23** and liquiritigenin in *E. coli* for the first time [114]. Two challenges to functional prokaryotic expression of eukaryotic cytochrome P450 enzymes were overcome in this research: the translational fusion of *Catharanthus roseus* CPR to *Glycine max* IFS spatially organized the redox partners for efficient electron shuttling from nicotinamide adenine dinucleotide phosphate (NADPH) to substrate, and rational design of several IFS N-terminal membrane signal sequences modulated activity of the protein fusion, enabling selection of a high-level isoflavone **13** producing chimera [114].

The protein engineering effort began with deletion of 71N-terminal amino acids from CPR to minimize membrane association without hindering catalytic activity. A glycine-serine-threonine (Gly-Ser-Thr) linker sequence was then designed to connect the CPR N-terminus with the IFS C-terminus while thwarting any secondary structure formation that could lead to incorrect folding of the two domains. The protein fusion was then truncated by a varying number of residues from the N-terminus of IFS, and two peptide leader sequences (one mammalian and one endogenous) were independently appended to these constructs in a semicombinatorial manner. Each chimera was separately expressed in *E. coli* and evaluated for production of isoflavone **13** from supplemented precursor. The most prominent fusion produced 10 and 18 mg g^{-1} (dry cell weight) of genistein **26** and daidzein **27**, respectively, and consisted of the deletion of 6 membrane-anchor residues and the addition of an 8 residue mammalian leader sequence to the N-terminus of IFS. To determine a baseline production level, plant IFS and CPR were coexpressed in *E. coli* and found to yield negligible isoflavonoid concentrations compared to the engineered strain. *S. cerevisiae* coexpressing plant IFS and CPR produced isoflavones **13** at low concentrations approaching those of the poorly performing protein fusion constructs expressed in *E. coli*. After accounting for the significantly higher biomass of yeast versus *E. coli* in minimal media, the specific production level of isoflavones **13** in *E. coli* represented approximately 20-fold increase over yeast [114]. The methodology implemented in this work provides an approach for soluble expression of other eukaryotic membrane-bound cytochrome P450s in prokaryotes. Although not performed in this set of experiments, this research facilitated the impending construction of a complete artificial biosynthetic pathway from aromatic amino acids to isoflavonoids in a single microorganism.

A later report of functional expression of IFS in prokaryotes involved construction of a protein fusion between red clover IFS (RCIFS) and rice CPR (RCPR) in *E. coli* [115]. This work built upon previous results demonstrating that coexpression in yeast of IFS with CPR from rice can convert 100 μM naringenin **23** to 77 μM genistein **26**, research predicated on the hypothesis that a plant CPR, as opposed to a constitutively expressed yeast CPR, would interact more efficiently with a plant IFS [103]. In this project RCIFS was truncated by deletion of the codons for the first 21 amino acids on the N-terminus, a sequence predicted to code for a helical region as indicated by computational secondary structure analysis. Changing the first remaining codon to a start codon (encoded by the nucleotide sequence ATG) enabled functional expression of RCIFS in *E. coli*, while removal of the IFS stop codon and addition of a Gly-Ser-Thr linker sequence followed by the RCPR coding sequence (also with the N-terminal membrane binding domain deleted) enabled expression and proper folding of the two fused domains. It should be noted here that this protein fusion design differs from that constructed previously by Leonard primarily because, in this case, the hydrophobic N-terminal membrane-associated domains were entirely removed from both enzyme constituents in the fusion to enhance solubility of the final construct. The functional expression and spatial proximity afforded by the soluble RCIFS-RCPR protein fusion enabled conversion of 80 μM naringenin **23** into 56 μM genistein **26** in *E. coli*. Difference in conversion between yeast and *E. coli* was not investigated but could be due to disparate expression and growth levels in the two distinct species. Again, it is likely that higher-efficiency electron transfer from NADPH to substrate occurred in *E. coli* due to the conjoined RCPR and RCIFS domains [115].

Coexpression in *S. cerevisiae* of all seven genes in the artificial isoflavone **13** pathway (PAL and CPR from a hybrid poplar, *Populus trichocarpa* × *Populus deltoides* and C4H, 4CL, CHS, CHI, and IFS from soybean, *G. max*), with phenylalanine **2** supplementation, was ultimately achieved by Trantas et al. and marked the first reported reconstitution of an entire isoflavonoid biosynthetic pathway in microbes. Although yeast contains a chromosomal copy of CPR, coexpression of a heterologous CPR from a the hybrid poplar increased *p*-coumaric acid **6** production fourfold, once again demonstrating the advantage of selecting a plant CPR to improve activity of the other enzymes in the cytochrome P450 metabolon [101, 116]. Only 0.1 mg L^{-1} genistein **26** was produced when the cultures were fed with phenylalanine **2** versus 7.7 mg L^{-1} when fed with naringenin **23**, suggesting the presence of at least one limiting enzyme or that cellular metabolism was burdened by the genes upstream of naringenin **23**. On average, the yeast strains in this work consumed 3.4 mmol L^{-1} phenylalanine **2**, while the wild-type strain consumed 2.8 mmol L^{-1}, a difference in phenylalanine **2** uptake of 0.8 mmol L^{-1} that can be attributed to flux through the heterologous flavonoid pathway. Stoichiometrically, this should lead to 0.8 mmol L^{-1} genistein **26**, but production of only 0.4 μmol L^{-1} indicated approximately 0.05 % efficiency of conversion of phenylalanine **2** to genistein **26** through the artificial biosynthetic pathway. Measurement of some upstream intermediates showed 83 % flux efficiency through PAL and C4H, efficient conversion through 4CL as deduced from the rapid depletion of *p*-coumaric acid **6**, and approximately 8 % efficiency to naringenin **23**, which suggests that CHS or CHI are rate limiting but could not be confirmed due to the inability to quantify concentrations of the intermediate compounds 4-coumaroyl-CoA **19** and naringenin chalcone **21** [101]. As described by Akashi, coexpression of an HIDH in this engineered *S. cerevisiae* strain could potentially accelerate the spontaneous conversion of naringenin **23** to genistein **26** but was not attempted in this work [71].

The first attempt to coexpress HIDH with IFS and CPR confirmed this speculation. Chemler and coworkers coexpressed IFS, CPR, and HIDH from five various plant sources in yeast in a combinatorial fashion to determine the impact of gene source on individual enzyme activity and coupled enzyme activities [117]. IFS-encoding genes from *G. max*, *Trifolium pratense*, *G. echinata*, *Pisum sativa*, and *Medicago truncatula* were individually cloned into a pYES2.1 vector under control of the *GAL1* promoter and transformed into *S. cerevisiae* strain INVSc1. After growth on minimal medium, the cultures were induced with galactose and supplemented with naringenin **23**. Genistein **26** production was monitored, and *T. pratense* IFS was selected as the best enzyme because it showed significantly higher in vivo activity than the IFS enzymes from other sources. Since it had previously been shown that plant IFS activity in yeast is improved upon coexpression of plant CPR, the researchers coexpressed CPR from *C. roseus* and *G. max* with IFS from either *G. max* or *T. pratense* to determine the enzyme pair with highest coupled activity. Upon comparing genistein **26** production in these engineered strains to yeast expressing IFS with endogenous CPR, the strain coexpressing *T. pratense* IFS with *G. max* CPR was found to be the highest producer at 15 mg L^{-1} day^{-1}. This illustrates the value in combining different gene sources to determine optimal protein pairing, particularly in the case of enzyme-mediated redox reactions. To assess whether expression of plant HIDH could increase genistein **26** production over its spontaneous generation from its 2-hydroxyisoflavanone precursor in yeast, coexpression of *G. max* or *G. echinata* HIDH was evaluated in the engineered strains. The best triple-enzyme combination was found to include *T. pratense* IFS, *G. max* CPR, and *G. max* HIDH, followed closely by the cognate combination of *G. max* IFS, CPR, and HIDH. Interestingly, *T. pratense* IFS holds some advantage over *G. max* IFS when coexpressed with *G. max* CPR and HIDH, despite presumption that the *G. max* enzymes evolved to work optimally together. Ultimately the three-enzyme combination showed greater than tenfold improvement in production rate over expression of IFS alone, but total production in all strains maximized at around 35 mg L^{-1} genistein **26**. After further experimentation, it was shown that isoflavones **13** like genistein **26** and biochanin A **29** strongly inhibit conversion of naringenin **23** by IFS in yeast. It was speculated that isoflavone **13** glycosylations, methylations, and other enzymatic biotransformations might ameliorate product inhibition and increase overall isoflavonoid production [117]. The basic artificial biosynthetic pathway for plant isoflavone **13** production from flavanones **12** in microbes is illustrated in Fig. 54.3.

3.2.2 Production of Isoflavonoid Glycosides in Microbes

Many flavonoids and other secondary metabolites exist as glycosides in plants, and examples of engineered microbial glycosylation of various flavonoids like quercetin and anthocyanidins have been reported over the last decade [85, 96, 118, 119]. Glycosylation of flavonoid aglycones is important because it often increases mammalian bioavailability, solubility, and stability [68, 120–129]. In the first example of microbial isoflavonoid glycosylation, expression of UGT71G1, a uridine diphosphate glycosyltransferase (UGT) from the model legume *M. truncatula*, in heterologous *E. coli* with supplementation of genistein **26** and biochanin A **29** yielded mg quantities at greater than 70 % conversion to genistein **26** and biochanin A **29** 7-*O*-glucosides (genistin **31** and sissotrin **33**, respectively) after 24-h incubation (Fig. 54.4). Terrific broth (TB) culture medium supported higher growth than Luria-Bertani (LB) culture medium and thus provided 3.5-fold higher yield of 7-*O*-glucoside. Scale-up to 500 mL culture achieved conversion rates of 30–60 %, about 80 % efficient compared to small scale, yielding up to 20 mg L^{-1} of isoflavanone glycosides [98]. Of note, 90 % of the glycosylated products were secreted from the cell, enabling facile collection and suggesting that increased solubility or sugar moiety-related signaling affects efflux from the cell. As such, this work suggests that coexpression of *M. truncatula* UGT71G1 in Chemler's engineered yeast strain (*T. pratense* IFS, *G. max* CPR, *G. max* HIDH) could convert naringenin **23** to genistin **31**, the genistein **26** 7-*O*-glucoside, at much higher rates than previously reported because feedback inhibition would be minimized by the glycosylation and subsequent export from the cell. Whereas extraction of plant flavonoid glycosides is inefficient, and regioselective glycosylation of flavonoids through chemical synthesis methods requires intermittent blocking and deblocking of hydroxyl groups and yields only about 50 % conversion due to the occurrence of nonspecific glycosylations, glycosylation through biotransformation offers a highly efficient and cheap alternative [130–133]. A major barrier to high-level microbial production of any flavonoid glycoside, however, is intracellular supply of uridine diphosphate (UDP) glucose.

As seen in Fig. 54.4, nucleotide-activated sugars are required as donors for glycosylation. In previous work, Yan and colleagues engineered a four-step metabolic pathway for plant anthocyanin **17** biosynthesis in *E. coli*, which involved expression of four heterologous genes including *Malus domestica* FHT and ANS, *Anthurium andraeanum* DFR, and *Petunia hybrida* UDP-glucose:flavonoid 3-*O*-glucosyltransferase (3GT). Anthocyanidins were converted by 3GT to the first stable glycosidic anthocyanins **17** in the flavonoid biosynthetic pathway, pelargonidin 3-*O*-glucoside and cyanidin 3-*O*-glucoside [85]. The researchers identified UDP-glucose as the rate-limiting step in anthocyanin **17** biosynthesis in *E. coli* and thereafter optimized UDP-glucose production by supplementing with orotic acid, a cheap uridine triphosphate (UTP) precursor, and performing a gene deletion and a set of gene overexpressions. As synthesis of UDP-glucose interfaces nucleotide biosynthesis, the pentose phosphate pathway, glycolysis, and energy production pathways, engineering its overproduction is a nontrivial task. Episomal overexpression of endogenous phosphoglucomutase (PGM) and glucose-1-phosphate uridylyltransferase (GALU), which convert glucose-6-phosphate (G6P) to glucose-1-phosphate (G1P) and produce UDP-glucose from G1P and UTP, respectively, shunted carbon flux from the pentose phosphate pathway toward UDP-glucose through the G6P branching point [57, 134]. These genetic modifications combined with the overexpression of endogenous nucleoside diphosphate kinase (NDK), the limiting step in the linear UTP synthesis pathway by orotic acid assimilation, and deletion of a gene encoding UDP-glucose dehydrogenase (UDG), which consumes UDP-glucose to form UDP-glucuronic acid, to yield increased UDP-glucose accumulation of 104 mg L^{-1} [96, 135, 136]. Due to the natural production of UDP-glucose in *E. coli* for cell wall synthesis and the ability to achieve increased production of UDP-glucose, microbial glycosylation of isoflavonoid aglycones with heterologous glycosyltransferases is an economically viable option. To the best of our knowledge, Table 54.1 summarizes the most representative studies of microbial production of plant natural isoflavonoids to date.

4 Mutasynthesis and Protein Engineering for Non-natural Isoflavonoid Production in Microbes

Mutasynthesis is a common semisynthetic tool that hijacks natural product biosynthesis through the feeding of non-natural substrate analogs to produce non-natural analogs to natural products. This methodology takes advantage of the natural allowable range of

[a]Protein fusion

enzyme-substrate specificity and favors highly promiscuous enzymes that can convert non-natural analogs of the natural substrate to novel products. Since many plant natural products possess valuable medicinal properties, it is of significant interest to explore the space of non-natural product analogs that has not yet been evolutionarily surveyed because of the lack of non-natural substrates in the environment. Presumably some of these non-natural analogs could have enhanced or even unique pharmaceutical properties. Production of flavonoids using mutasynthesis or substrate feeding has been accomplished by several groups as reported elsewhere [60, 82, 97, 100].

Structural studies often utilize protein engineering tools such as site-directed mutagenesis to evaluate the roles of various amino acid residues in catalytic mechanisms. While this can furnish indispensable insight on enzyme-substrate interaction, it is of significant interest to metabolic engineers because it also enables construction of tailor-made enzyme mutants with improved kinetic properties, with the ability to accept structurally related substrates, with reaction reversibility for substrate-product interconversion, and with altered substrate and product regiospecificity. Protein engineering tools such as site-directed mutagenesis and directed evolution have been applied to improve production of both natural and non-natural flavonoid, isoflavonoid, and other plant natural product derivatives [87, 138–147]. Plant natural products can also be microbially catalyzed by enzymes native to the microbe to form compounds not known to exist in plants [82, 100, 119, 148–153]. These phytochemical derivatives have the potential to be utilized as human therapeutics, as the microbes catalyzing these novel reactions have been isolated from the human gut and are purported to have beneficial health impacts on their human hosts [152–157].

4.1 Mutasynthesis for Non-natural Isoflavonoid Production

Mutasynthesis involves the chemical synthesis of non-natural substrates that are similar in structure to natural substrates. After a library of non-natural analogs are chemically synthesized, enzymatic conversion of the non-natural analogs is performed to isolate novel non-natural compounds, and the results can then be assessed to elucidate mechanisms of enzymatic catalysis and to determine substrate specificity requirements. This so-called semisynthetic approach, or the combination of chemical synthesis and biosynthesis, has also been utilized for production of non-natural isoflavonoids.

In a multiplex experiment, Chemler and colleagues evaluated the substrate specificity of IFS enzymes from five different plant species (*G. max, T. pratense, G. echinata, P. sativa, and M. truncatula*) [117]. Each enzyme was cloned into yeast and was supplemented with compounds from a library of natural and non-natural flavanones **12**. Non-natural flavanones **12** were synthesized to mimic natural flavanones **12** and isoflavones **13**; specifically, many library constituents were 7-monohydroxylated or 5,7-dihydroxylated. The library also consisted of flavanones **12** with B-ring substituents, such as single or multiple hydroxy, methoxy, ethoxy, and halide side groups. Ultimately 19 non-natural flavanones **12** and 7 natural flavanones **12** were utilized to assess IFS substrate flexibility, resulting in the biosynthesis of 4 natural isoflavones **13** and 14 non-natural isoflavone **13** analogs which are tabulated in Table 54.2. IFS substrate requirements were deduced from the rate of conversion of different flavanones **12**, including the necessity for hydroxylation at C7, the expendability of C5 hydroxylation, the incompatibility of C2′ or C6′ substitutions, the toleration of small side-group substitutions at C3′ or C5′, and the absolute requirement of C4′ hydroxylation for production of 2-hydroxyisoflavones. Due to the high affinity of genistein **26** for human estrogen receptors *α* (hER*α*) and *β* (hER*β*), isoflavones **13** are selective estrogen receptor modulator (SERM) drug candidates [158–161]. SERMs can be used to inhibit or stimulate estrogen receptors, thereby enabling their use as hormone replacements and decreasing the risk of diseases such as osteoporosis and breast cancer [17, 50, 53, 160]. In an effort to determine the therapeutic potential of the semisynthetic isoflavones **13** in the previously described library, the interaction of each compound with hER*α* and hER*β* was assessed using an in vitro competitive binding assay. As expected, the different isoflavones **13** were found to show variable activity against the human estrogen receptors. Of particular interest, both 3′-bromo-4′,5,7-trihydroxyflavone and the natural isoflavone **13** orobol displayed binding capabilities equal to genistein **26**. Structure-activity relationships between isoflavones **13** and hERs were then deduced to yield insight for future design of isoflavone **13** SERMs. Of note, the authors suggest that novel isoflavones **13** with small substituents at the C3′ position should elicit improved interactions with estrogen receptors [117].

4.2 Protein Engineering for Non-natural Isoflavonoid Production

Protein engineering has been utilized to study the mechanism by which isoflavonoid aglycones are converted to isoflavonoid glycosides by uridine diphosphate glycosyltransferases, a large protein class catalyzing the transfer of activated

Table 54.2 Mutasynthesis for natural and non-natural isoflavonoid production

	Side-group decoration				
Flavanone precursor	R^5	R$^{3'}$	R$^{4'}$	R$^{5'}$	Primary biotransformation product
Naringenin 23	OH	H	OH	H	Genistein 26

3′-Bromo-4′,7-dihydroxyflavanone	OH	Br	OH	H	3′-Bromo-4′,7-dihydroxyisoflavone

sugars to various substrates. These studies yield insight into the interactions between specific amino acid residues and substrate, enabling rational design of enzyme mutants for specific purposes. Structure-guided enzyme engineering is often directed at or around the active site or binding pocket region to alter substrate specificity, enzymatic activity, and product regioselectivity. In the case of UGT71G1 from *M. truncatula*, a point mutation in residue 202 from tyrosine (Tyr) **3** to alanine (Ala), Y202A, enables the conversion of genistein **26** to both 7-*O*-glucoside and 5-*O*-glucoside, whereas the native enzyme only enables conversion of genistein **26** to the 7-*O*-glucoside product. Residue 202 is located at one end of the acceptor (isoflavonoid aglycone) binding pocket, so this mutation from an amino acid with a large aromatic side group to one with a small side group presumably increases the volume of the pocket, providing the acceptor with an increased number of possible docking configurations [140].

Another protein engineering effort for isoflavonoid production focused on *M. truncatula* UGT85H2. A point mutation in residue 305 from isoleucine (Ile) to threonine (Thr), I305T, showed a 19-fold increase in enzyme activity with a 25-fold decrease in the Michaelis constant (K_m) for conversion of biochanin A **29** into sissotrin **33**. Additionally the mutation of residue 200 from valine (Val) to glutamic acid (Glu), V200E, imparted deglycosylation activity in the presence of UDP in the reaction mixture, enabling the removal of the glucose residue from sissotrin **33**, the biochanin A **29** 7-*O*-glucoside, to form biochanin A **29** aglycone. The mutation also decreased K_m by sevenfold, increased maximum velocity (V_{max}) and turnover number (k_{cat}) by sevenfold, and increased catalytic efficiency by 54-fold. Amino acid 200 resides on one end of the acceptor binding pocket, and docking studies indicate that the negatively charged glutamic acid side group might interact with the 7-OH of biochanin A **29**. This novel method utilizing mutagenesis to impart reversibility could be applied to deglycosylation of other flavonoids [141].

The aforementioned UGT mutagenesis studies involved variations in activity and regioselectivity. However, glycosylation of flavonoids with sugars other than glucose occurs in nature and should be possible to engineer in microbes. In addition to UDP-glucose, for instance, UDP-glucuronic acid, UDP-galactose, UDP-xylose, and UDP-rhamnose are all known to act as nucleotide-activated sugar donors in various plant species [162]. In *Bellis perennis* (red daisy) BpUGT94B1, the positively charged guanidinium side group of a single arginine (Arg) residue at position 25 is critical for UDP-glucuronic acid donor activity due to its interaction with the negatively charged carboxylate group on glucuronic acid [139]. Similarly, a family of UGTs known as flavonoid 7-*O*-glucuronosyltransferases (F7GATs) found in plants from the Lamiales order share a conserved arginine residue in the sugar donor binding pocket that is responsible for the specificity toward UDP-glucuronic acid. Site-directed mutagenesis of *Perilla frutescens* UGT88D7 residue 350 containing arginine (which corresponds to tryptophan (Trp) 360 in UGT71G1) to Trp abolished UDP-glucuronic acid specificity and instead invoked UDP-glucose sugar donor specificity. Once again the cationic guanidinium moiety on arginine is crucial for recognition and interaction with the anionic carboxylate group on UDP-glucuronic acid.

4.3 Other Isoflavonoid Biotransformations

In a series of recent reports, a G6P isomerase (PGI, catalyzing the isomerization of G6P to fructose-6-phosphate) knockout strain of *E. coli* was engineered to produce flavonoid glycosides from flavonoid aglycones. Specifically, the strain produced 7-*O*-xylosyl naringenin and 7-*O*-glucuronyl quercetin by overexpressing an *Arabidopsis thaliana* UGT and an artificial UDP-sugar biosynthetic gene cluster (containing *E. coli* K-12 GALU and *Micromonospora echinospora* spp. *calichensis* UDG and UDP-glucuronic acid decarboxylase, known as UXS1) in combination with naringenin **23** and quercetin feeding [163, 164]. Continuing their efforts, Simkhada and coworkers recently engineered *E. coli* for production of 3-*O*-rhamnosyl quercetin, 3-*O*-rhamnosyl kaempferol, and 3-*O*-allosyl quercetin by assembling artificial thymidyldiphosphate (TDP)-sugar biosynthetic pathways for TDP-L-rhamnose and TDP-6-deoxy-β-D-allose and feeding the strain with quercetin and kaempferol aglycones.

TDP-sugar production was enabled by the deletion of PGI to shunt flux toward G1P and overexpression of TDP-glucose synthase (TGS) from *Thermus caldophilus* GK24 to form the activated nucleotide sugar [165]. TDP-L-rhamnose was produced by overexpression of *Salmonella typhimurium* LT2 TDP-glucose 4,6-dehydratase (DH) and *Streptomyces antibioticus* Tu99 TDP-4-keto-6-deoxyglucose 3,5-epimerase (EPI) and TDP-glucose 4-ketoreductase (KR); TDP-6-deoxy-β-D-allose was produced by overexpression of *T. caldophilus* GK24 DH and *Streptomyces* sp. KCTC 0041BP TDP-hexose 3-epimerase (GERF) and TDP-4-keto-6-deoxyglucose reductase (GERK). Overexpression of a 3GT from *A. thaliana* completed the 3-*O*-glycosylation of the flavonoid aglycone precursors with the TDP-sugars [166]. These engineering efforts demonstrate the potential for regiospecific glycosylation of isoflavonoids with tailored sugar moieties that could one day enable design of therapeutics with altered activities and varying degrees of bioavailability; from a microbial production perspective, customizable glycosylations might also mitigate cellular toxicity while improving isoflavonoid solubility, stability, and transport from the cell, ultimately leading to higher product yields [126, 167].

Other flavonoid biotransformations catalyzed by microbial enzymes will also allow for production of novel, nonplant flavonoids from amino acid precursors. Two bacterial nonheme dioxygenases, biphenyl dioxygenase (BDO) and naphthalene dioxygenase (NDO), have recently been shown to regioselectively and stereoselectively convert flavonoids, including isoflavones **13** and isoflavanols **34**, to epoxides and dihydrodiols [151, 168–172]. BDO from *Pseudomonas pseudoalcaligenes* KF707 and NDO from *Pseudomonas* sp. strain NCIB9816-4 are able to accept various flavonoids as substrates due to the presence of biphenyl and naphthalene moieties within the flavonoid core structure **1** [168]. Additionally, expression of *Streptomyces avermitilis* MA-4680 7-*O*-methyltransferase (SaOMT-2) in *E. coli* shows substrate promiscuity and transfers a methyl group to flavones **14** and isoflavones **13** [173]. This is the first example of a methyltransferase known to act upon both flavones **14** and isoflavones **13**, opening up a route for biosynthesis of non-natural methylated isoflavones **13** by feeding of non-natural precursors. Another example of microbial isoflavonoid biotransformation is the reduction of daidzein **27** to equol. Although several microorganisms isolated from mammalian digestive tracts have been shown to catalyze the nonstereospecific transformation, a recently isolated gram-negative anaerobic species, MRG-1, shares high homology with *Coprobacillus* species and was shown to exhibit stereospecific reductase activity for conversion of several isoflavones **13** to the corresponding isoflavanones. Stereoselective reduction from the highly active MRG-1 isoflavone reductase (IFR) opens new biotechnological routes for production of enantiopure flavanones **12** [153].

5 Conclusions

Metabolic engineering of microbes for isoflavonoid biosynthesis showcases state-of-the-art methodologies for high-level production of pharmaceutically and nutraceutically relevant compounds. Decoupling production of plant secondary metabolites from their native, convoluted regulatory backgrounds enables predictable control and design, while transplanting biosynthetic pathways into fast-growing, well-characterized microorganisms allows utilization of advanced genetic and computational tools and an abundance of biological data. Genetically tractable microbes such as *E. coli* and *S. cerevisiae* provide an unmatched platform for combinatorial biosynthesis of complex plant natural products and their non-natural derivatives by transformation with heterologous genes from different organisms.

Though microbial production of plant natural products is a promising alternative to traditional methods, further research will continue to improve titers and assist in the discovery of novel isoflavonoid biotransformations. A significant challenge that has not yet been accomplished is the expression of the entire isoflavonoid metabolic pathway in *E. coli*, from aromatic amino acid precursors without supplementation of intermediates. Given the propensity for feedback inhibition and host toxicity of many flavonoid and isoflavonoid intermediates, protein engineering efforts will likely be required to enable high-level isoflavonoid production [174–176]. Furthermore, in vivo characterization of all enzymes in the isoflavonoid pathway will help determine rate-limiting steps that require higher relative promotion or expression level. Stoichiometric-based modeling and computational algorithms can also be utilized to predict genetic manipulations for maintaining high growth coupled with high specific production. Several thorough reviews have addressed the relative merits of various algorithms [177–182].

Feedback inhibition can be limited by optimizing both upstream and downstream enzyme expression such that the inhibitor does not significantly accumulate. In instances where a metabolite inhibits an enzyme in the isoflavonoid pathway, enzyme mutagenesis can alter the structural interaction between the enzyme and its inhibitor to block the inhibition mechanism. Recently, allosteric feedback inhibition of a tomato peel 4CL by naringenin **23**, a product several steps downstream, was significantly reduced through directed evolution in *E. coli* [181].

Cellular toxicity can also be ameliorated by various engineering strategies. Toxicity caused by intracellular accumulation of an intermediate can be limited by pathway optimization to ensure that the metabolite is utilized soon after it is produced. Pathway optimization can be achieved by accurate in vivo characterization of all enzymes in the pathway. Additionally, spatial localization of the enzymes catalyzing subsequent steps in a pathway serves as a "pipeline" to channel intermediate substrates to their respective catalyzing enzymes [184, 185]. This spatial proximity effectively leads to increased local substrate concentration and can be engineered by creating a protein fusion between adjacent enzymes, by docking multiple enzymes to a protein or RNA scaffold at minimal distance from each other, or by compartmentalizing all of the enzymes in a biosynthetic pathway in an isolated enclosure, such as a bacterial microcompartment (BMC) or an artificial organelle [186–191]. Such methodologies have enabled significant improvement in production levels of other microbial products and are outlined in great detail in a recent review by Agapakis and colleagues [185]. If the final product is toxic to the cell, one conceivable method for reducing the toxicity would be to engineer BMCs or artificial organelles for sequestration of the responsible metabolites. An alternative method is to engineer product transport. Overexpression of a library of efflux pumps and extracellular transporters can pinpoint proteins capable of selective export of a target product, while product glycosylation or deglycosylation could also improve export from the cell [192–194]. It is also important to consider if the product is natively transported into the cell from the extracellular environment; blocking transport of the toxic compound back into the cell can be accomplished by knocking out genes involved in product uptake.

Further work aimed at bioprospecting, culturing hard-to-culture microbes, searching for "unknown" and "orphan" enzymes that have not yet been characterized, and designing promiscuous enzymes capable of decorating and transforming flavonoids and their unnatural analogs will increase the range of isoflavonoid derivatives produced in microbes [195]. The search for enzymes capable of such manipulations should not be limited to plants, however, as many microbes endemic to mammalian guts have evolved to metabolize the plant phenylpropanoids ingested by their hosts. Current research efforts in these areas will lead to economically viable microbial platforms for production of isoflavonoids and products of high medicinal value.

Abstract

The use of grapevine cell cultures to increase *trans*-resveratrol and stilbene-related production under controlled conditions is viewed as a promising biotechnological alternative to their extraction from the whole plant or their chemical synthesis. At present, in vitro plant cultures are rarely used as a commercial method for the production of bioactive compounds. The major problems hindering the development of the large-scale culture of plant cells include low productivity, cell line instability, and the difficulties involved in scaling up. This chapter describes how the composition of the medium, culture conditions, elicitors, bioreactor design, and other critical parameters influence the behavior of grapevine cell cultures and how optimization of these factors could allow improvements in *trans*-resveratrol and stilbene-related production. For these reasons, this chapter describes how high-producing *Vitis* cell lines, nutrient and precursor feeding, elicitation with stress factors, and signaling molecules, as well as metabolic engineering can be used to increase the production of these secondary metabolites.

UV	Ultraviolet
Vsts	*Vitis* stilbene synthase

1 Introduction

Plants elaborate a vast array of natural products, which, as they evolve, confer selective advantages against environmental stresses. Among such products are the phenylpropanoids, a large family of secondary metabolites that are involved in plant responses to biotic and abiotic stresses. Many phenylpropanoids are antimicrobial compounds synthesized in response to pathogen or herbivore attack and classified as phytoalexins. However, other roles have been described for stress-induced phenylpropanoids, including the signaling of defense responses and protection against ultraviolet (UV) light damage [1].

Stilbenes are a small group of phenylpropanoids characterized by a 1,2-diphenylethylene backbone. Most plant stilbenes have phytoalexin activity and are mainly derivatives of the monomeric unit *trans*-resveratrol (*trans*-R, 3,4′,5-trihydroxystilbene) although other stilbene structures are found in plants.

Vitis is a genus of about 60 species of dicot angiosperm plants. The fruit, which is a berry normally ovoid in shape and juicy, is grown commercially in the case of several *Vitis* species for consumption as fresh grapes and for fermentation into wine. Worldwide, *Vitis vinifera* (Fig. 55.1) is one of the most important species since it is used for the production of table grapes, raisins, and wine. The berries and the products derived from them are one of the most important sources of stilbenes available in nature [2].

The formation of stilbenes is considered to be a part of the general defense mechanism since they display strong antifungal and antimicrobial activities [3, 4]. In fact, *trans*-R is found in both grapevine tissue and berries and in cell cultures as the result of both abiotic and biotic stress [5]. Since *trans*-R is postulated to be involved in the health benefits associated with a moderate consumption of red wine, it is one of the most extensively studied natural products.

Indeed, hundreds of studies have reported the beneficial effects of *trans*-R on neurological [6] and cardiovascular systems [7]. One of the most striking biological activities of *trans*-R is its anticancer activity, preventing carcinogenesis in the three stages of tumor development [8]. Further data provide interesting insights into the effect of this compound on the life span of different organisms, suggesting that *trans*-R might be regarded as a potential antiaging agent in treating age-related human diseases [9]. In addition, the effects described in mice subjected to a high-calorie diet [10] open up new approaches for treating not only age-related diseases but also obesity-related disorders [11].

trans-R was first detected in 1939 as a root constituent of the medicinal plant white hellebore lily (*Veratrum grandiflorum*). Years later, the presence of *trans*-R was described in a species native to Western Australia, *Eucalyptus wandoo*, by Hathway and Seakins [12] although the richest source of this compound is the roots of the weed *Polygonum cuspidatum* [13], an Asian medicinal plant whose root extracts are used in traditional Chinese and Japanese medicine (Ko-jo-kon) for their

Fig. 55.1 *V. vinifera* plant

high content of *trans*-R and derivatives. Therefore, the strategy commonly used to produce stilbenes and specifically *trans*-R involves their direct extraction from plants. However, in some cases, the production of stilbenes from plants is not always satisfactory since their presence is often restricted to a given species or genus and might be activated only during a particular development stage or under specific seasonal, stress, or nutrient availability conditions [14]. For this reason, the chemical synthesis is often considered to obtain these compounds, although the stereospecificity, the strict conditions of the reactions, and the high costs involved represent a disadvantage of this approach. As a consequence, much effort has been put into the use of in vitro cultures as one attractive biotechnological strategy for producing this natural compound of commercial interest. In fact, plant cell cultures offer a good alternative to whole plants because they allow *trans*-R and stilbene-related production in controlled and reproducible conditions. Likewise, several strategies including precursor feeding, in situ product removal, elicitation, and metabolic engineering have been described as useful for increasing the production of these secondary metabolites.

In this chapter, we describe these strategies and recent advances in our understanding of the *trans*-R biosynthetic pathway, its regulation, and how to gain further knowledge using biotechnological, genomic, and metabolic approaches to improve the production of these high value compounds.

2 Distribution and Localization of Stilbenes and *trans*-Resveratrol in Plants and Specifically in *Vitis* Species

Stilbenes and particularly *trans*-R are found in a large number of plant families. Indeed, these low molecular weight phenolics are found in gymnosperm plants belonging to the Pinaceae and Gnetaceae families; in monocot angiosperm

plants belonging to the Poaceae, Cyperaceae, and Liliaceae families; and in dicot angiosperm plants from the family of Myrtaceae, Fabaceae, Moraceae, Fagaceae, Palmaceae, Polygonaceae, and Vitaceae (Fig. 55.2) [15].

Stilbenes and *trans*-R are synthesized by several species belonging to the genus *Vitis*. Most *Vitis* species are found in temperate regions of the Northern Hemisphere, where they occur in widely different geographical areas and show a great diversity of forms. The exact number of species is uncertain, with an estimates ranging from 40 to more than 60. Some of the more notable are *V. vinifera*, the European grapevine, native to the Mediterranean area and Central Asia; *V. labrusca* and *V. riparia*, native to the eastern part of the United States and Canada; *V. rotundifolia* and *V. aestivalis*, native to the southeastern part of the United States; *V. amurensis*, native to Asia, including parts of Siberia and China; and *V. coignetiae*, a species from East Asia. *V. vinifera* is a species distributed in the Mediterranean region, central Europe, and southwestern Asia, from Morocco and the north of Portugal to southern Germany and in northeastern Iran. There are many different grapevine cultivars (cv) and hybrids, such as the primary crosses between *V. vinifera* and one or more of the *V. labrusca*, *V. riparia*, and *V. aestivalis* [16].

Stilbenes and *trans*-R are induced (as phytoalexins) in nonwoody plant organ/tissues [17], whereas they are constitutively synthesized in woody and hard plants [18]. Most of them are present in berries and wines produced from them. The production of stilbenes depends on the grapevine cv, and their levels can also vary from year to year. The level of these compounds can also be modified by nutritional conditions and stress factors associated with the vineyard such as weather, UV light, and fungal or bacterial infections. In grape berries, most *trans*-R is located in the skin, while the type of wine fermentation determines the final *trans*-R content in wines [17]. For example, the content of *trans*-R in Spanish white wines (0.05–1.80 mg L^{-1}) is lower than in Spanish red ones (1.92–12.59 mg L^{-1}) and red musts (1.14–8.69 mg L^{-1}), probably due to the very high concentration of *trans*-R found in the skin of red grapes (about 1.50–7.80 mg *trans*-R g^{-1} fresh weight (FW)). The ability of grape berries to synthesize stilbenes and *trans*-R varies during grape development, since the content of *trans*-R decreases during ripening, whereas the level of flavonoids increases.

3 The Biosynthetic Pathway of *trans*-Resveratrol: Key Enzymes and its Regulation

Flavonoids and stilbenes have a common origin as both derive from the phenylpropanoid metabolism. However, flavonoids are ubiquitous in plants, whereas stilbenes are specific to certain plant families. Phenylalanine (Phe), an end product of the shikimate pathway, is a key intermediate linking the primary metabolism with phenylpropanoid, flavonoid, and stilbenoid secondary metabolic pathways. Thus, the first step in the stilbene pathway consists in the transformation of Phe into cinnamic acid in a reaction catalyzed by phenylalanine ammonia-lyase (PAL). The consecutive action of cinnamate 4-hydroxylase (C4H) and 4-coumarate-CoA ligase (4CL) transforms cinnamic acid into p-coumaroyl-CoA, which is the common precursor of most of the phenolic compounds found in plants: lignins, flavonoids, and stilbenoids (Scheme 55.1). Then, one molecule of p-coumaroyl-CoA is condensed with three C2 units from malonyl-CoA to produce *trans*-R, through the action of stilbene synthase (STS), or to produce naringenin chalcone by the action of chalcone synthase (CHS) [19]. However, *trans*-R is synthesized via cleavage of four carbon dioxide molecules, while naringenin chalcone is formed via cleavage of three carbon dioxide molecules. Thus, both STS and CHS catalyze three condensation reactions with malonyl-CoA molecules, giving the same long-chain polyketide intermediate, but STS also catalyzes the loss of the terminal carboxyl group, which leads to the production of the C14 molecule instead of the CHS-catalyzed C15 product [19] (Scheme 55.1).

Structure–function analysis suggests that STS uses an aldol-switch mechanism to carry out a region-specific C2–C7 cyclization, rather than the C1–C6 cyclization of CHS. CHS is responsible for the formation of chalcone in many higher plants, but STS, which shares 75–90 % amino acid sequence identity with CHS, is only found in species that accumulate stilbenes. Tropf et al. [20] showed evidence indicating that STS has evolved in a limited number of phylogenetically related plants by gene duplication and subsequent mechanistic divergence from CHS.

The STS protein was purified first from elicited cell cultures of peanut (*Arachis hypogaea*). The cloning of two peanut *sts* genes revealed extensive homology with

the peanut *chs* gene throughout the coding region, and the position of the single intron was conserved in both genes. Subsequently, the first gene coding a *Vitis* stilbene synthase (*Vsts*) was cloned by Melchior and Kindl [21]. Later, *sts* genes were also cloned from Scots pine (*Pinus sylvestris*) and other species. *sts* genes exist as a family of related genes in many plant species ([1] and references therein). STS proteins are classified into p-coumaroyl-CoA-specific types, such as resveratrol synthase, or cinnamoyl-CoA-specific types, such as pinosylvin synthase, depending on their preferred starter molecule. The former type occurs mostly in angiosperms such as peanut, grapevine, and sorghum, whereas the latter type is typical in gymnosperms and has been reported in several pine species such as *P. sylvestris*, *P. strobus*, and *P. densiflora*. Analysis of the grapevine genome sequence confirmed the large size of this multigene family, with an estimated number of around 20–40 *sts* genes. At least 20 different *sts* genes are expressed in grapevine following infection with *Plasmopara viticola*, which is consistent with this estimation ([1] and references therein).

On the other hand, stilbene biosynthesis is induced in response to a wide range of biotic and abiotic elicitors, resulting in increased gene expression of the stilbene biosynthetic pathway and accumulation of the corresponding enzymes. Regulation of stilbene biosynthesis by stress is particularly well documented in grapevine, where the expression of *sts* genes and the production of stilbenes are induced upon elicitation with different fungal pathogens, including powdery mildew (*Erysiphe necator*), downy mildew (*P. viticola*), and gray mold (*Botrytis cinerea*). Stilbene biosynthesis is also triggered by abiotic stimuli such as aluminum ions, methyl jasmonate (MeJa), ethylene, and UV light irradiation [22]. Cloning of different *sts* genes in various plant species revealed the differential regulation of some members of this gene family. In grapevine, expression patterns of two *sts* genes exhibited striking differences in elicited grapevine cell cultures, indicating they may be responsible for different responses to one inducer treatment [23]. Similarly, three *sts* genes of peanut were transcribed in response to various inducers, indicating that different members of this gene family respond differentially to these different types of stress [1]. However, Lijavetzky et al. [24] found the expression of two *sts* genes, strongly coordinated with the expression of *pal*, *c4h*, and *4cl* genes, increased when grapevine cell cultures were simultaneously treated with two different elicitors. Furthermore, the synergistic interaction of both elicitors on *trans*-R production was the result of the synergistic effect observed on gene expression of the biosynthetic pathway.

In recent years, a growing number of transcription factors involved in the regulation of flavonol, lignin, and anthocyanin metabolism have been characterized [1]. However, to date, no transcription factors responsible for regulating the stilbene biosynthetic pathway have been characterized.

Grapevine *sts* genes retain their inducibility to stress when they are used to transform other plant species that do not normally synthesize stilbenes. Thus, tobacco was transformed with a grapevine genomic DNA fragment containing the *Vsts1* and *Vsts2* genes, under the control of their own promoters. *sts* gene expression was sensitive to elicitor treatments in these transgenic tobacco lines, indicating that *sts* genes are regulated by stress response pathways, which are not specific to plants that naturally synthesize stilbenes [19].

As regards the localization of STS protein in grape berry, STS is found in berry exocarp tissues in all stages of fruit development, but the levels of this protein decrease gradually from exocarp to mesocarp, where the protein is only detected occasionally. STS localization is the same before and after berry veraison. Nevertheless, the amount of this protein decreased significantly in ripe berries, in agreement with the lower *trans*-R content measured in the same tissues.

At the subcellular level, STS is predominantly found within vesicles, along the plasma membrane and in the cell walls, suggesting a protein secretion pathway toward the apoplast compartment. Also, STS localization in exocarp cell walls is consistent with its role in synthesizing defense compounds and suggests that a differential localization of phenylpropanoid biosynthetic machinery regulates the deposition of specific secondary products at different action sites within the cells ([19] and references therein).

4 Biotechnological Approaches to Improve *trans*-Resveratrol and Stilbene-Related Production Using *Vitis* Cell Cultures Without Genetic Transformation

Much effort has been dedicated to the use of plant in vitro cultures as a biotechnological strategy to produce secondary metabolites of commercial interest. The advantages of these systems for the industrial production of these compounds include uniform product quality, independence from climate and seasonal changes, supply stability, and a closer relationship between supply and demand. In some cases, the production of secondary metabolites using large-scale in vitro cultures is technically feasible since the generation and maintenance of cell biomass are accompanied by a high yield of these metabolites.

In this sense, *Vitis* cell cultures could become an important system as cell factories for the production of stilbenes. The analysis of *trans*-R production in untreated plant cell cultures revealed low levels of *trans*-R accumulation, less than 0.1 mg g^{-1} dry weight (DW) or 2–3 mg L^{-1} [22]. Different approaches have been used to increase the production of *trans*-R, elicitation being the most important strategy in this respect, in some cases, combined with the use of highly productive *Vitis* cell lines, optimized culture conditions, and sugar and/or nutrient feeding. Also, genetic modification and metabolic engineering are promising biotechnological approaches that could improve the production of both stilbenes and *trans*-R.

Screening and selection for high-producing *Vitis* cell lines starts with the selection of the plant from which cell and tissue cultures will be initiated. Then, cell and tissue cultures have to retain the capacity to biosynthesize the secondary metabolite and maintain production stability during subsequent subcultures. Considering *trans*-R and stilbene-related biosynthesis as a result of the defense response (constitutive or inducible) and the variability of this response in *Vitis* genotypes, it is important to choose genotypes that have the ability to produce high *trans*-R levels. In addition, elicitors, which stimulate defense responses, have been used as a tool to select high-yielding cell lines. Likewise, the levels of *trans*-R and stilbene-related production that can be obtained in response to elicitors fluctuate widely according to the plant species and cultivars, the elicitors used, and culture conditions [25].

Zamboni et al. [26] studied the differential response of *Vitis* cell cultures for the production of *trans*-R, finding that elicited cell cultures of *V. amurensis* and those resulting from the crossing between *V. riparia* and *V. berlandieri* were able to produce more *trans*-R than cell cultures of *V. vinifera* cv Pinot Noir or Merzling.

Also, modification of the culture medium and physical factors is important for increasing the metabolite accumulation. The expression of many secondary metabolite pathways is easily altered by factors such as nutrients, light, and growth regulators. Many of the constituents of plant cell culture media are important determinants of growth and the accumulation of secondary metabolites. In the case of *Vitis* cell cultures, the medium and culture conditions are critical parameters that influence the improvement of *trans*-R and stilbene-related production. Waffo-Teguo et al. [27] observed that *trans*-R and stilbene glycosides accumulated when *V. vinifera* cv Gamay Fréaux was grown in a polyphenol-inducing medium in which $(NH_4)_2SO_4$, NaH_2PO_4, $MgSO_4$, and sucrose concentrations were changed. Indeed, the amount of the sugar is one of the key culture conditions since sugars represent the carbon source of the culture medium. In plants, sugars are not only energy sources and structural components but are also physiological signals regulating the expression of a variety of genes involved in both primary and secondary metabolism. The effect of sugars on plant cell cultures seems to be mainly associated with the coupling of two mechanisms: osmotic stress and a disturbed cellular metabolism [28]. In addition, sugars act as specific regulatory signals through an intracellular sugar-sensing pathway.

Since grapevine cell cultures are grown in heterotrophic conditions, usually adding sucrose as carbon source, the level of sucrose added to the culture medium has been seen to regulate the production of polyphenols in *V. vinifera* cv Gamay Fréaux cell cultures. In fact, the production of anthocyanins markedly increased in *V. vinifera* cells after adding 0.15 M (51.30 g L^{-1}) sucrose to the culture medium, while the content of piceids (glucosylated forms of both *cis*- and *trans*-R) was only slightly affected [29]. Also, the addition of 0.08 M sucrose (27.36 g L^{-1}) to the same *V. vinifera* cell cultures provoked a slight extracellular accumulation of *trans*-R which peaked after 18 h of treatment (52 nmol g^{-1} FW; i.e., 11.87 μg *trans*-R g^{-1} FW), whereas this sucrose concentration did not induce any accumulation of piceids in these cells [30]. In fact, the addition of sucrose to these cells did not affect the expression of *pal* or *sts* genes.

On the other hand, precursor feeding has been proved to increase the levels of *trans*-R in grapevine cell cultures. In particular, feeding with Phe has been extensively studied [31–33]. Kiselev et al. [31] demonstrated that feeding *V. amurensis* callus cultures with 0.1 mM Phe resulted in a slight increase of *trans*-R (0.50 mg g^{-1} DW) compared with control cells (0.43 mg g^{-1} DW), while the addition of higher concentrations of Phe did not cause any further increase of this compound. Therefore, the possibility that a low pool of *trans*-R precursors might be the cause of low *trans*-R production is unlikely since the addition of Phe to the culture medium was not very effective [31].

Saigne-Soulard et al. [32] analyzed the influence of Phe on stilbene biosynthesis in *V. vinifera* cv Gamay Fréaux cell cultures, observing that the treatment of the cells with 1 mM Phe resulted in an enrichment in stilbenes (62 mg L^{-1}), the maximal stilbene levels being reached when Phe was completely metabolized by the cells. Aumont et al. [33] also studied the effect of the administration of 3 mM Phe to *V. vinifera* cv Gamay Fréaux cell cultures. Their results pointed out an increase in the production of stilbenes (360 mg L^{-1}) after 14 days when *V. vinifera* cell cultures were fed with Phe using a high cell density (300 g FW L^{-1}) in a 2-L stirred-tank bioreactor.

In contrast to these results, Yue et al. [34] analyzed the effect of different Phe concentrations on the production of *trans*-R in *V. vinifera* cv Gamay Fréaux cell cultures showing that the addition of Phe (1–3 mM) did not result in a significant increase in the production of *trans*-R.

On the other hand, Chen et al. [35] analyzed the effect of adding alanine to *V. labrusca* cell cultures on *trans*-R production and gene expression involved in its biosynthetic pathway. They found that alanine feeding (50 mg L^{-1}) significantly increased the production of *trans*-R both in the culture medium (0.27 mg L^{-1}) and in the cells (0.09 mg L^{-1}). Moreover, the addition of this amino acid also induced *pal*, *c4h*, and *sts* gene expression.

4.1 Elicitation Strategies to Improve *trans*-Resveratrol and Stilbene-Related Production

The term *elicitor* refers to chemicals from various sources, biotic or abiotic, as well as physical factors, that can trigger a response in living organisms resulting in a high accumulation of secondary metabolites. Therefore, elicitors are useful tools for improving the production of plant valuable compounds ([36] and references therein). The effectiveness of elicitation as a tool to enhance the production of secondary metabolites depends on a complex interaction between the elicitor and the plant cell. There is evidence that the same elicitor can stimulate secondary metabolism in different cell cultures and that certain plant cultures are responsive to diverse elicitors. Treatment of a particular plant cell culture with different elicitors will result in the accumulation of a particular class of compounds, since these are specific of each plant culture. Although the class of metabolite depends on the plant species, the kinetics of induction or accumulation levels can vary with different elicitors.

As has been described previously, *V. vinifera* cell cultures have been used to the production of *trans*-R [22, 25]. The main advantage of these cultures is that genetic modification of cells is not necessary because grapevine cells produce *trans*-R constitutively, or in response to stress, so grapevine cell cultures can be directly exploited. Therefore, the use of biotic or abiotic elicitors could be considered one of the most effective strategies to increase the productivity of this compound.

4.1.1 The Use of Biotic Elicitors Enhances *trans*-Resveratrol and Stilbene-Related Production

When grapevine is under biotic stress, *trans*-R and derivatives are synthesized acting as phytoalexins (namely, viniferins in *Vitis*). Gray mold (*B. cinerea*), downy mildew (*P. viticola*), powdery mildew (*E. necator*), berry rot (*Rhizopus stolonifer*), and some *Aspergilli* sp. are some of the main fungi that attack grapevine and lead to *trans*-R and stilbene-related production in both grape berries and leaves [37]. Therefore, extracts from these fungi can be used as elicitors. In fact, elicitors resulting from the activity of fungal-degrading enzymes on host cell walls may induce *trans*-R and stilbene-related production by cells, as in the case of grapevine cells treated with cell fragments of *B. cinerea* [38] or with a cellulase extracted from the fungus *Trichoderma viride*, which also acts as a biofungicide to control other pathogenic fungi [39]. Commun et al. [40] studied *trans*-R and stilbene-related production in *Vitis* sp. protoplasts during their isolation and culture. Even using low concentrations of hydrolytic enzymes for cell wall removal, *trans*-R could be detected as early as the fourth hour of incubation, and it gradually accumulated during cell wall digestion. In addition, *trans*-R production during cell wall digestion was not specific to one *Vitis* genotype since this compound was detected in leaf protoplasts of different *Vitis* genotypes tested, and its production was due to the de novo activation of the *Vsts1* gene. Also, leaf protoplasts in culture, regardless of the genotype, continued to produce *trans*-R during the first week of the culture. For example, when *trans*-R produced from Chardonnay leaf protoplasts was quantified during the first 2 weeks of culture, maximal *trans*-R accumulation was observed between days 2 and 7 (over 15 μg *trans*-R 10^{-6} protoplasts, which were obtained from 0.03 g fresh leaves). These results suggest that cell wall enzymatic digestion with different fungal cellulases induces the expression of *Vsts1* gene, thus leading to the accumulation of *trans*-R.

Similarly, chitosan, a linear D-(1,4) glucosamine polymer produced by the deacetylation of chitin, which is an important structural component of the cell wall of several fungi, can also mimic a fungal pathogen attack, and thereby promote *trans*-R and stilbene-related production [41, 42]. In particular, the endogenous content of *trans*-R in *V. vinifera* cv Barbera cell cultures treated with 50 μg mL^{-1} chitosan was maximal 4 days after treatment (over 34.23 μg *trans*-R g^{-1} DW). However, chitosan decreased *trans*-R release into the culture medium by 62% (around 45.65 μg *trans*-R g^{-1} DW, at day 2, [43]). Proteomic analysis of chitosan-treated cells at day 4 demonstrated the specific effect of chitosan in increasing the amount of six different STS protein spots compared with to those observed in controls [43]. However, the response to one elicitor could be cultivar-dependent since the *trans*-R content in *V. vinifera* cv Italia cells elicited with 50 μg mL^{-1} chitosan was 141 μg *trans*-R g^{-1} DW, a very similar value to that found in control cells (98 μg *trans*-R g^{-1} DW, [42]). Also, this treatment led to a release of a very low amount of *trans*-R (0.12 mg L^{-1}) to the culture medium.

Grapevine cells also respond to the presence of polysaccharides. For example, when laminarin, which is a β-1,3 glucan derived from the brown algae *Laminaria digitata*, was used as elicitor in *V. vinifera* cv Gamay cells, 65 μg *trans*-R g^{-1} FW was accumulated in the culture medium after 8 h of treatment [44]. ε-viniferin was present predominantly inside the cells, where it peaked (130 μg g^{-1} FW) after 20 h, although a significant amount of ε-viniferin (62 μg g^{-1} FW) was also detected after 12 h in the extracellular medium [44].

Oligogalacturonides have also been used to produce *trans*-R in grapevine cells cv Gamay [45]. In fact, 2 mg oligogalacturonides g^{-1} FW induced an extracellular accumulation of 20 μg *trans*-R g^{-1} FW after 12 h of treatment, and similar *trans*-R levels were found when these Gamay cells were elicited with a purified glycoprotein from *B. cinerea* (namely, endopolygalacturonase 1). In cells treated with this glycoprotein, ε-viniferin was detected inside the cells reaching its highest levels between 24 and 60 h after treatment in comparison with the low levels of ε-viniferin detected in oligogalacturonide-treated cells [45].

Oligosaccharides appear to be efficient in the production of *trans*-R. In fact, the most significant success in increasing *trans*-R content from *Vitis* cell cultures has been reached using cyclodextrins (CDs). CDs are a family of compounds made up of sugar molecules bound together in a ring (cyclic oligosaccharides). CDs are produced from starch by enzymatic conversion. They are used in the food, pharmaceutical, and chemical industries, as well as in agriculture and environmental engineering, since they are able to solubilize nonpolar compounds in aqueous media. A typical CD contains several glucose monomers ranging from six to eight units in a ring, forming a cone shape. β-CDs, which are seven-sugar ring molecules, have often been used for increasing *trans*-R in *Vitis* cell cultures [4, 5, 46]. In fact, under CD elicitation, grapevine cell cultures produced high levels of *trans*-R, which is secreted and accumulated outside the cells. This effect is due to the fact that CDs chemically resemble the alkyl-derived pectic oligosaccharides released from the cell walls during fungal attack [5] and grapevine cells respond to their presence by synthesizing *trans*-R. Thus, when cell cultures of *V. vinifera* cv Gamay were treated with different types of β-CDs [5], these treatments resulted in high levels of *trans*-R (more than 3,000 mg L^{-1}), which were secreted to the culture medium, facilitating the extraction of this compound. Similarly, *V. vinifera* cv Monastrell cell cultures accumulated high amounts of *trans*-R (up to 4,000 mg L^{-1}) after treatment with different types of CDs [5]. In addition, the high levels of *trans*-R accumulated in the culture medium have no toxic effect on the cell lines, allowing successful subcultures and subsequent re-elicitations using the same cell biomass [47]. Therefore, CDs act not only as inducers of *trans*-R biosynthesis but also as promoters of complexes that remove *trans*-R from the medium, reducing both feedback inhibition and *trans*-R degradation, and allowing its accumulation in high concentrations [48].

4.1.2 The Addition of Signaling Molecules Induces *trans*-Resveratrol and Stilbene-Related Production

When plants are attacked by pathogens, they defend themselves against such invasion with an arsenal of defense mechanisms. Studies on early signal transduction pathways with elicitors revealed the mobilization or generation of diverse signaling molecules which regulate many processes, including the production of phytoalexins and pathogenesis-related proteins through transcriptional and metabolic changes [49]. In this sense, a sequential event in elicitor-induced defense responses involves the production of ethylene (ET), salicylic acid (SA), and jasmonate. These compounds coordinate the activation of a large set of defense responses, and when applied exogenously, they are able to induce resistance in both plants and cell cultures.

Studies with different plant–pathogen systems have shown that plants can activate different defense pathways which depend on the type of infection [50]. The ET- and jasmonic acid (Ja)-dependent defense responses seem to be activated by necrotrophic pathogens [51], whereas the SA-dependent response is triggered by biotrophic pathogens [52]. Some studies indicate that ET or Ja and SA responses inhibit each other, suggesting that cross talk exists between the pathways, enabling the plant to adapt the response depending on the type of pathogen [53].

These signaling molecules can be used in *Vitis* cell cultures to enhance *trans*-R production, the most commonly used being a Ja-active derivative, MeJa [30, 31, 54, 55], and SA [31, 43].

As described above, Ja and MeJa act as key compounds of the signal transduction pathway involved in the induction of the secondary metabolite biosynthesis which takes part in plant defense reactions [56, 57]. Thus, the production of secondary metabolites increases when plant cell cultures are elicited with jasmonates [36, 49, 58]. In *Vitis*, *trans*-R and stilbene-related production is increased by adding Ja or MeJa [30, 54]. In this respect, Tassoni et al. [54] showed that the addition of 10 μM MeJa was more effective in stimulating endogenous *trans*-R accumulation (24 μg g^{-1} DW) than 10 μM Ja (around 4.5 μg g^{-1} DW), although both elicitors promoted its release into the extracellular medium in *V. vinifera* cv Barbera cell cultures (around 8 μg *trans*-R g^{-1} DW after 2 days of elicitation). In the same way, Santamaria et al. [42] also investigated the ability of Ja (20 μM) and MeJa (20 μM) to increase the production of *trans*-R in *V. vinifera* cv Italia cell cultures. They detected a peak of *trans*-R inside cells (55 and 84 μg g^{-1} DW using Ja and MeJa, respectively) after 20 days of culture. In this case, Ja was most effective in inducing the release of *trans*-R into the medium (1.55 mg L^{-1}) than MeJa (0.27 mg L^{-1}). Belhadj et al. [30] working with *V. vinifera* cv Gamay Fréaux cell cultures elicited with 20 μM MeJa detected an extracellular accumulation of 11.87 μg *trans*-R g^{-1} FW after 18 h of treatment. Belchi-Navarro et al. [59] observed that the addition of 25 μM MeJa provoked an enhancement of *trans*-R in the culture medium of 1.02 mg g^{-1} DW (i.e., 51 μg g^{-1} FW) in *V. vinifera* cv Monastrell cell cultures. Moreover, these authors showed that in the presence of 50 or 100 μM MeJa, the *trans*-R levels increased to reach values of 3.74 mg g^{-1} DW (i.e., 187 μg g^{-1} FW).

Krisa et al. [60] showed that the amount of total stilbenes secreted to the culture medium when 25 μM MeJa was added to three *V. vinifera* cultivars (one of Gamay Fréaux and two strains of Cabernet-Sauvignon, CS4 and CS6) was negligible, although the accumulation of piceids inside cells of Cabernet-Sauvignon, strain CS4 was notably induced (6.30 mg piceids g^{-1} DW). In contrast to these results, when *V. vinifera* cell cultures cv Gamay Fréaux were elicited with 10 μM Ja, the total production of *trans*-piceid decreased compared with the control cells, and *trans*-R was not detected [34].

These results suggest that the production of *trans*-R is dependent on both MeJa dosage and grapevine cell line elicited, so that the use of both an optimal MeJa dose and highly productive cell lines is strongly advisable.

On the other hand, SA has long been known to play a central role in plant defense reactions. SA levels increase in plant tissue following pathogen infection, and exogenous application of SA enhances the resistance to a broad range of pathogens [61]. In fact, SA is involved in some signal transduction pathways in which enzymes catalyzing biosynthetic reactions are induced to form defense compounds of a phenolic nature [62]. In fact, the addition of 50 μM SA to *V. amurensis* callus cultures increased both *pal* and *sts* gene expressions while *trans*-R levels reached were 0.45 mg g^{-1} DW [63]. However, the addition of 100 μM SA or 1 mM ET to *V. vinifera* cv Monastrell cell cultures did not increase *trans*-R production [64]. Similarly, Yue et al. [34] observed that the content of *trans*-R was negligible when *V. vinifera* cv Gamay Fréaux cell cultures were treated with 500 μM SA for 10 days. Therefore, the levels of *trans*-R in *Vitis* cell cultures after treatment with MeJa or SA [31, 54, 59, 60] did not exceed 3.74 mg g^{-1} DW.

4.1.3 The Use of Abiotic Elicitors Enhances *trans*-Resveratrol and Stilbene-Related Production

It has also been shown that UV light acts as an abiotic factor which stimulates the biosynthesis of secondary metabolites [65]. The effect of UV light irradiation on the stilbene content of grapevine cell cultures is little known, and most of the research related with UV light has been directed at enhancing the stilbene content of grape berries [66, 67], leaves [68], and callus tissue [69, 70]. For example, Keller et al. [71] found that only actively growing calli of grapevine cv Cabernet-Sauvignon irradiated with UV-C light were capable of producing stilbenes, whereas old calli had lost this ability. Similar results were described by Keskin and Kunter [69] working with Cabernet-Sauvignon callus cultures irradiated with UV-C light. They found that the effect of UV-C light on *trans*-R production was dependent on callus age since the highest *trans*-R production was found in 12-day-old calli (62.66 μg g^{-1} FW), which was greater than those values obtained in 15-day-old calli (18.12 μg g^{-1} FW) for the same irradiation time (10 min). These authors also studied the effects of UV-C light on *trans*-R production in callus cultures of *V. vinifera* cv Öküzgözü. In this cultivar, the highest *trans*-R accumulation (62.23 μg g^{-1} FW) was determined after 48 h of treatment in callus irradiated for 15 min [70]. Similarly, the effect of UV-C irradiation for 10, 20, or 30 min on *trans*-R production in grapevine callus was studied by Liu et al. [72]. They observed an increase of *trans*-R accumulation to 19.60, 22.50, and 23.30 μg g^{-1} FW after 10, 20, and 30 min of treatment, respectively. In addition, they observed that the accumulation of *trans*-R peaked at about 32.50 μg g^{-1} FW at 48 h after 20 min UV-C irradiation. These authors also studied the effect of genotypic variation and the origin of tissue type on *trans*-R accumulation in callus at 48 h after 20 min UV-C irradiation [72]. The results showed significant differences in the levels of *trans*-R among the different grape genotypes and tissue types. The highest levels of *trans*-R were found in calli from "Zhi 168" and "Beta" (38.60 and 32.50 μg g^{-1} FW, respectively), whereas "Jingxu" and "Merlot" were the genotypes that accumulated the lowest levels of *trans*-R (16.0 and 12.0 μg g^{-1} FW, respectively). Likewise, they observed maximal values of *trans*-R in callus obtained from leaves 32.50 μg g^{-1} FW and exocarp 29.70 μg g^{-1} FW, whereas callus obtained from seed produced the lowest levels of *trans*-R (11.70 μg g^{-1} FW).

Recently, Almagro et al. [48] studied the effect of short or long exposures to UV-C or A light on *trans*-R production in *V. vinifera* cv Monastrell cell cultures, finding that the irradiation with UV light produced a negligible extracellular amount of *trans*-R.

On the other hand, phenolic compounds are recognized as being strongly affected targets of highly phytotoxic ozone [73]. Sgarbi et al. [74] analyzed two differentially ozone-sensitive cell cultures obtained from *V. vinifera* cv Lambrusco leaf explants, one rich in polyphenols and brown pigmented (Ph+) and other, phenol-poorer and pale (Ph-). An accumulation of *trans*-R (over 342.37 μg g^{-1} FW) was observed in Ph- callus 24 h after ozone treatment. In addition, they also observed a strong induction of STS activity in Ph- callus between 12 and 24 h after ozone treatment. These results suggest that the *trans*-R could be directly involved in the effective detoxifying response of Ph- grapevine callus to ozone, acting as an antioxidant compound.

On the other hand, Cai et al. [75] examined the effect of hydrostatic pressure on the extracellular production of stilbenes using *V. vinifera* cv Gamay Fréaux cell cultures. They observed that the pressure treatment of 40 MPa for 10 min provoked an increase in *cis*-resveratrol 3-*O*-β-glucoside (identified as *cis*-piceid by Waffo-Teguo et al. [27]) of 2.20 μg g^{-1} FW on the second day of the treatment.

4.1.4 The Combined Use of Elicitors Enhances *trans*-Resveratrol and Stilbene-Related Production

Biotic and abiotic elicitors are associated to different mechanisms of elicitation and, when used in combination, could enhance metabolite production in plant cell cultures. Indeed, the combined effect of elicitors is a widely used strategy to increase *trans*-R and stilbene-related production [48].

V. vinifera cv Gamay cell cultures responded to the combination of 20 μM MeJa and 0.08 M sucrose by increasing extracellular *trans*-R levels (27.39 μg g^{-1} FW, [30]) over those obtained with MeJa or sucrose alone (described above).

Similarly, Belchi-Navarro et al. [59] studied the effect of different sucrose concentrations (10, 20 or 30 g L^{-1}) in *V. vinifera* cv Monastrell cell cultures elicited with a fixed concentration of 50 mM CDs and different MeJa concentrations. Their results showed that when grapevine cell cultures were elicited in a culture medium with 10 g L^{-1} sucrose, maximal *trans*-R production (11.48 mg *trans*-R g^{-1} FW; i.e., 229.61 mg *trans*-R g^{-1} DW or 2,290 mg L^{-1}) was reached using the lowest MeJa dose (25 μM), whereas the highest degree of *trans*-R production was obtained using 30 g L^{-1} sucrose and 50 μM MeJa (13.80 mg *trans*-R g^{-1} FW; i.e., 276.18 mg *trans*-R g^{-1} DW or 2761.80 mg L^{-1}). In addition, the maximal levels of *trans*-R were observed using 20 g L^{-1} sucrose and 100 μM MeJa (over 304.7 mg g^{-1} DW; i.e., 3047.60 mg L^{-1}). In contrast, when the cell cultures were elicited only with CDs, the *trans*-R production values were lowest (over 73.7 mg g^{-1} DW; i.e., 737.0 mg L^{-1}), and no significant differences in *trans*-R production were seen at the different sucrose concentrations tested.

Yue et al. [34] found that the combination of Ja with adsorbents like HP2MGL (a non-aromatic resin, 200 g L^{-1}) added to *V. vinifera* cv Gamay Fréaux cell cultures provided a much higher *trans*-R yield (around 2,300 mg L^{-1}) than when used separately (0 and 1,800 mg L^{-1} using Ja and HP2MGL, respectively) so that the effect on *trans*-R production was synergistic. These authors also reported that the combination of SA and HP2MGL did not induce any increase in the levels of *trans*-R. Moreover, when SA, Ja, and HP2MGL were jointly added, the total production of *trans*-R was improved, reaching 2666.7 mg L^{-1}. Also, when these grapevine cells were fed with 1 mM L-Phe and elicited in the presence of 10 μM Ja and 500 μM SA, the production of *trans*-R increased gradually from day 5 (746.20 mg L^{-1}) to day 10 (1144.10 mg L^{-1}) of treatment.

Cai et al. [75] examined the joint effect of hydrostatic pressure and elicitors on the extracellular production of stilbenes using *V. vinifera* cv Gamay Fréaux cell cultures. They observed that the highest production of *cis*-piceid (0.56 mg L^{-1}) was observed when 28 mg L^{-1} ethephon and a hydrostatic pressure of 40 MPa were jointly used as elicitors, showing that hydrostatic pressure is an effective stimulant for the production of *cis*-piceid, and ethephon may enhance this production. However, *trans*-R was not detected in any of the conditions tested.

Saigne-Soulard et al. [32] analyzed the effect of the joint action of various inductive factors: 25 μM MeJa, 50 mg L^{-1} of hydrolyzed fungal cell wall isolated from the inner bark of *Taxus chinensis*, or 0.15 M (51.30 g L^{-1}) sucrose combined with 1 mM L-Phe on stilbene production in *V. vinifera* cv Gamay Fréaux cell cultures. They observed that the treatments of the cells with sucrose and L-Phe were not significantly different from the effect obtained with L-Phe alone (described above). However, the addition of fungal elicitor or MeJa in the presence of L-Phe induced an increase in the production of stilbenes.

The most significant success in increasing the *trans*-R content in *Vitis* cell cultures was reached using 50 mM CDs in combination with 100 μM MeJa [59, 76]. In fact, when grapevine cell cultures were simultaneously elicited with CDs and MeJa, the accumulation of *trans*-R increased (304.7 mg g^{-1} DW; i.e., 3047.60 mg L^{-1}) exponentially reaching a concentration plateau after 168 h. These same authors also used CDs separately or in combination with MeJa, plus SA and/or ET to elicit *V. vinifera* cv Monastrell cell cultures during 96 h [64]. The results showed that *trans*-R levels in cells elicited with CDs and ET (68 mg g^{-1} DW; i.e., 680 mg L^{-1}) were higher than those observed in the presence of CDs and SA (26 mg g^{-1} DW; i.e., 260 mg L^{-1}). Likewise, they observed that the presence of CDs, MeJa, and ET induced a greater increase in *trans*-R levels (154 mg g^{-1} DW, 1,540 mg L^{-1}) than when they used CDs, MeJa, and SA (104 mg g^{-1} DW, 1,040 mg L^{-1}). In addition, when cell cultures were elicited with CDs, MeJa, SA, and ET, the production of *trans*-R was 136 mg g^{-1} DW. These findings indicate that the presence of SA provokes a decrease in the production of *trans*-R [64].

Almagro et al. [48] carried out experiments with *V. vinifera* cv Monastrell cell cultures using 50 mM CDs and 100 μM MeJa, followed by short or long exposures to UV-C light. They provided lower *trans*-R levels (5 min and 30 min UV-exposed cells, 22.8 and 4 mg g^{-1} DW, respectively) than UV-unexposed cells (134.4 mg g^{-1} DW), so that UV-C light exposure was clearly detrimental to produce *trans*-R. In fact, prolonged exposure to UV-C light caused a drastic reduction in *trans*-R accumulation, although no cell browning was observed. However, when *V. vinifera* cv Monastrell cell cultures were jointly elicited with CDs and MeJa and exposed to UV-A light, the maximal level of *trans*-R was found after long exposures (30 min, 165.2 mg g^{-1} DW). The results suggested that the effect of UV light on *trans*-R production was dependent not only on exposition time (short or long) and UV light type (C or A) but also on the presence of other elicitors (CDs and MeJa).

4.2 Large-Scale *trans*-Resveratrol and Stilbene-Related Production

Taking the biotechnological production of a natural product by plant cell cultures from laboratory's scale in shaken flasks to a commercial scale relies on the cultivation of the cell cultures in bioreactors as an essential step of the process. Initially, the production is optimized in laboratory scale bioreactors, typically of 2-L capacity, and then the bioreactor geometry is kept while the capacity is increased steadily from some tens to several thousand times in a bioreactor cascade system. The world's largest plant cell culture facility, located in Ahrensburg, Germany, has a cascade of five stirred-tank bioreactors ranging from 75 to 75,000 L. The transfer from shake flasks to bioreactors raises several issues that in many cases are species- or even cell-line-dependent; thus, upscaling is not always straightforward and has to be resolved in a case-by-case manner. The major issues to tackle are linked to the bioreactor design, the operation mode, the culture environmental conditions in the bioreactor and biomass, and the target compound productivity in the bioreactor as compared to shaken flasks. In addition, when biomass and target compounds production are not coupled, a two-stage production system, for example, first biomass and then metabolite, has to be implemented in bioreactors.

The scale-up of natural compound bioproduction by grapevine cells in bioreactors has been attempted by different laboratories. In some cases, the major issue was the intracellular polyphenolics accumulation linked to biomass production [33, 77–79] in a one-stage culture system. Others addressed the advantageous extracellular accumulation of resveratrol mediated by the use of elicitors that either promotes the secretion of the metabolite [80] or the simultaneous overproduction and extracellular accumulation in a one-stage [55] or two-stage [81, 82] culture system. A further refinement of the bioproduction process involves the reuse of the producing cells for several cycles in a fed-batch production system [82].

In spite of the initial perception of the difficulty in culturing plant cell in suspension due to their high shear sensitivity, a wide variety of bioreactor designs have been successfully used for cultivating plant cell cultures. These designs include classical configurations such as stirred tank, airlift, and bubble column bioreactors but also new types of bioreactor specially designed for highly

Table 55.1 Grapevine cell biomass production in bioreactors

shear-sensitive plant cultures such as the centrifugal impeller bioreactor [83] and disposable concept bioreactors made of plastic bags [84] which can be gently agitated by a rocking platform that creates a wave motion of the culture [85]. For a comprehensive review on bioreactor designs suitable for plant cell and tissue cultures, see [78]. Most of the efforts carried out to grow up grapevine cell suspensions in bioreactors have used stirred-tank commercial designs [33, 55, 77, 80, 81] but also designs of low shear stress such as wave motion [78], and bubble column bioreactors [81, 82] have proved to be suitable for this purpose. Table 55.1 summarizes the grapevine biomass concentration and productivity achieved in the different works carried out in bioreactors. Productivity in terms of g FW L^{-1} day^{-1} or g DW L^{-1} day^{-1} is very much dependent on the initial concentrations of carbon source and biomass inoculums, and these vary among the different studies. Likewise, the operation mode in batch or fed batch greatly influences the final biomass yield. Unfortunately, growth in terms of growth rate constant (μ day^{-1}) in the exponential phase is not always provided. A comparison between two bioreactor designs, stirred tank and bubble column V-shaped, using the same cell line shows that μ may not vary significantly with the sucrose concentration, only slightly among the bioreactors, while the maximum biomass production and the productivity greatly depended on the initial sucrose concentration [81]. The highest reported productivity of 40 g FW L^{-1} day^{-1} has been achieved in a 1-L wave bioreactor [79], but also in a stirred-tank bioreactor biomass, productivities as high as 32 g FW L^{-1} day^{-1} have been reported [33]. In general, the different trials to grow up grapevine cells in bioreactors have been successful although there are differences that are in part due to the differential shear sensitivity of the cell lines. *V. vinifera* cv Gamay Fréaux cell cultures appear to be quite tolerant to shear stress [77] displaying a good biomass

Table 55.2 Stilbene and resveratrol (both *cis*- and *trans*-isomers) production by grapevine cell cultures grown in bioreactors

Bioreactor design	Process mode	Working volume (L)	Grapevine cv/sucrose (g L^{-1})	Elicitor	Stilbene and resveratrol yield (mg g^{-1} FW) and location	References

yield in different bioreactors and under high regimes of aeration even at moderate agitation speeds. However, rootstock 41B (*V. vinifera* cv Chasselas x *V. berlandieri*) cell cultures tolerated only very low aeration flows and agitation speeds [55], and *V. vinifera* cv Barbera cell cultures underwent a decrease of cell biomass ranging from 20% to 60% during the first 4 days of cultivation [80] probably due to cell lysis. Table 55.2 summarizes the results achieved in relation to stilbene and *trans*-R production in bioreactors using grapevine cell cultures. In one application, grapevine cells were used to produce ^{13}C bio-labeled polyphenols, including *trans*-R, by feeding the culture with [1-^{13}C] L-Phe, but *trans*-R was accumulated intracellularly only as the glycosylated derivative, piceid [33], as occurred in a previous work where labeled precursors were not added [77]. The rest of studies utilized elicitors, in particular chitosan, MeJa, and CDs, with the aim of enhancing *trans*-R production and promoting its extracellular accumulation. *trans*-R production is often reported as g L^{-1}, but the biomass concentration has a strong influence on overall production; thus, a more appropriate variable to compare across different studies is the specific production expressed in mg g^{-1} and referred to either FW or DW. Elicitation with chitosan or MeJa led to a similar yield slightly above 1 mg g^{-1} FW. However, while the addition of chitosan in *V. vinifera* cv Barbera cell cultures led to a mixture (*cis*-, *trans*- and free and glycosylated) of intra- and extracellular resveratrol monomers, the addition of MeJa in the rootstock 41B cell cultures led mainly to extracellular *trans*-R, and also the dimer ε-viniferin. In addition, the significantly higher biomass yield of the rootstock 41B cell cultures as compared to the *V. vinifera* cv Barbera cell cultures involves a much higher overall *trans*-R production.

In shaken flasks, *V. vinifera* cv Monastrell cell cultures elicited with CDs has proven to be the most efficient way to promote the accumulation of large amounts of *trans*-R in the extracellular medium [5], and the combination with MeJa leads to a synergistic effect that multiplies the accumulation for at least threefold [24]. Thus, the *trans*-R yield becomes higher than 3 mg g^{-1} FW for elicitation with CDs alone, and higher than 10 mg g^{-1} FW when combined with MeJa. As seen in Table 55.2, such yields are reached in all the bioreactors tested either in one-stage batch or in two-stage fed-batch modes. Thus, the scale-up of CDs and MeJa-mediated *trans*-R production in bioreactors is demonstrated as feasible.

5 Biotechnological Approaches to Improve *trans*-Resveratrol and Stilbene-Related Production Using Genetic Engineering in Different Biological Systems

5.1 Increasing *trans*-Resveratrol Content by Genetic Manipulations in Plants and Grapevine Cell Cultures

Metabolic engineering offers new perspectives for improving the production of compounds of interest. Metabolic engineering is generally defined as the redirection of one or more enzymatic reactions to produce new compounds in an organism, to improve the production of existing compounds, or to mediate the degradation of compounds. Although progress in pathway gene discovery and the ability to manipulate gene expression in transgenic plants has been impressive during recent decades, attempts to use these tools to engineer plant metabolism have met with limited success. Though there are notable exceptions, most attempts at metabolic engineering have focused on modifying (positively or negatively) the expression of single genes affecting pathways. This approach can be used for improved metabolite production in a plant or plant cell cultures, or even in other plant species or organisms.

Engineering of *trans*-R in plants and microbial organisms is such an approach, and one that has become feasible in the last two decades. In fact, many authors have carried out the overexpression of *sts* genes as a valuable strategy to increase *trans*-R production in plants ([22] and references therein). Unfortunately, there is abundant information about the *trans*-R content of transgenic plants; the same is not true for transformed cell cultures. However, the comparison of *trans*-R levels in different transgenic plant overexpressing *sts* genes is interesting. For example, the transformation of various plants including *Vitis* with the *Vsts* gene resulted in increased *trans*-R levels. In fact, the highest *trans*-R levels (around 350 μg g^{-1} DW) were obtained after transforming the genome of 41B rootstock with a chimeric gene which combines an alfalfa PR10 promoter, which is a DNA fragment of a pathogenesis-related class 10 proteins, and *Vsts1* [86]. In the same way, the transformation of *Nicotiana tabacum* with *Vsts1* and *Vsts2* under control of the Vsts1 promoter provoked an increase of *trans*-R levels (400 μg g^{-1} FW) [87]. In both cases, these transgenic plants showed increased resistance to *B. cinerea* [86, 87]. However, the transformation of other plants did not result in high *trans*-R levels. Thus, the transformation of *Solanum lycopersicum* with *Vsts* gene under control of CaMV 35 S promoter triggered only a small amount of *trans*-R (4 μg g^{-1} FW) [88]. In addition, using the same promoter but incorporating the *Vsts* gene in *Lactuca sativa*, the values of *trans*-R were 56.40 μg g^{-1} FW [89]. Therefore, it is possible that the enzymes encoded by these *Vsts* genes do not actively participate in *trans*-R biosynthesis or have a low specific activity [90].

On the other hand, it has been reported that *rol* genes located in R_i-plasmids of *Agrobacterium rhizogenes* may enhance the biosynthesis of certain groups of secondary metabolites in transformed plant in vitro cultures [91]. In fact, the introduction of *rolB* gene, which is essential for plant cell growth and development, in *N. tabacum* root cultures and *Rubia cordifolia* cell cultures has been shown to strongly induce the production of alkaloids and anthraquinones, respectively [92, 93]. Recently, Kiselev et al. [31] have shown that the *rolB* gene also stimulates *trans*-R biosynthesis in *V. amurensis* callus cultures. These authors established two *rolB* transgenic callus lines of *V. amurensis* with different levels of *rolB* expression [31] and found that the higher expression of *rolB*, the greater the production of *trans*-R (31.50 mg g DW^{-1}). They also observed that *trans*-R production in the transformed callus cultures was dependent on the presence of both 6-benzylaminopurine and 1-naphthaleneacetic acid. However, an increase in the concentration of indole-3-acetic acid and 2,4-dichlorophenoxyacetic acid had a negative effect on *trans*-R biosynthesis. These same authors also demonstrated that *trans*-R production is enhanced by increasing gene expression levels of *pal* and *sts* in *V. amurensis* callus cultures transformed with the *rolB* gene.

Kiselev et al. [63] also showed that the addition of 50 μM SA enhanced both gene expression of *pal* and *sts* and the production of *trans*-R (0.4 mg g^{-1} DW) in *rolB* transgenic callus lines of *V. amurensis*. In same way, Dubrovina et al. [94] observed an increase in the production of *trans*-R (1.40 mg g^{-1} DW) as well as specific *pal* and *sts* gene expression in *rolC* transgenic callus lines of *V. amurensis*. Their results suggested that transformation of *V. amurensis* calli with the *rol*C gene induced *trans*-R production via selective enhancement of expression of certain *pal* and *sts* genes.

5.2 Incorporating Genes from the *trans*-Resveratrol Biosynthetic Pathway in Microbial Organisms

Microorganisms are widely used biological systems for the production of numerous valuable molecules. Engineering bacteria or yeasts for *trans*-R production might thus represent a valuable means for its large-scale production. The *trans*-R pathway needs to be tailored because they do not possess the genes encoding enzymes responsible of this pathway. One strategy consists in introducing specific genes from the phenylpropanoid and stilbene pathways, such as *pal*, *c4h, 4cl*, and *sts* genes, using p-coumaric acid as a starting block [25]. In this sense, Trantas et al. [95] were capable of transforming yeast (*Saccharomyces cerevisiae*) with *pal*, *c4h, 4cl*, and *sts* genes isolated from *Populus trichocarpa x P. deltoides, Glycine max, V. vinifera*, and *P. trichocarpa x P. deltoides*, respectively. This strain secreted *trans*-R into the culture medium when it was fed with 164 mg L^{-1} p-coumaric acid, reaching values of 0.31 mg L^{-1}. Similarly, Becker et al. [96] reported that the co-expression of *4cl* and *sts* genes (obtained from *P. trichocarpa x P. deltoides* and from *V. vinifera*, respectively) in yeast cells (*S. cerevisiae*) produced 1.50 mg L^{-1} of *trans*-R in the presence of 10 mg L^{-1} p-coumaric acid. In the same way, Zhang et al. [97] demonstrated that when *4cl* and *sts*, cloned from *A. thaliana* and *V. vinifera*, respectively, were incorporated to *S. cerevisiae* genome, the strain exhibited a slight increase of *trans*-R production (5.25 mg L^{-1}) in presence of 12 mg L^{-1} p-coumaric acid. These results suggest high p-coumaric acid concentrations did not result in an improvement of *trans*-R production. Moreover, it was reported that p-coumaric acid inhibited the growth of yeast cells at high concentrations (above 20 mg L^{-1}, [98]).

Wang et al. [98] working with yeasts (*S. cerevisiae*) were capable of overexpressing a resynthesized tyrosine ammonia-lyase gene (namely, *tal-made*), which is able to catalyze the formation of 4-coumaric acid from tyrosine directly, improving the availability of p-coumaric acid in the culture medium. Thus, yeast cultures that co-expressed *4cl* and *sts* together with *tal-made* were able to produce 1.06 mg *trans*-R L^{-1}. Moreover, the production of *trans*-R increased (1.90 mg L^{-1}) when yeast cells fed with tyrosine. Likewise, Wang et al. [98] also demonstrated that the low-affinity, high-capacity bacterial *araE* transporter enhanced the accumulation of *trans*-R when yeast cells were transformed with *araE* and *sts*, reaching the *trans*-R content of 3.1 mg L^{-1}. This result suggests that the arabinose-H^+ transport protein participates in transporting *trans*-R even though this transporter shows no affinity toward *trans*-R.

On the other hand, the production of *trans*-R in bacterial cells can be higher than when yeast cells are used. Beekwilder et al. [99] compared the production of *trans*-R in *S. cerevisiae* cells with those obtained from *Escherichia coli* cells. In both systems, *4cl* from *N. tabacum* and *sts* from *V. vinifera* were expressed. These authors observed that the addition of *p*-coumaric acid increased the production of *trans*-R, reaching levels of 16 mg L^{-1} in *E. coli* and 6 mg L^{-1} in yeast cells. Similarly, Watts et al. [100] used *E. coli* transformed with *4cl* from *A. thaliana* and *sts* cloned from *A. hypogea* to analyze the production of *trans*-R. The expression of these enzymes in *E. coli* fed with 4-coumaric acid provoked an increase of *trans*-R levels (over 100 mg L^{-1}). Moreover, the introduction of *4cl* gene from *Lithospermum erythrorhizon* and *sts* gene from *A. hypogaea* in *E. coli* and the subsequent feeding of this recombinant strain with p-coumaric acid produced very high levels of *trans*-R (171 mg L^{-1}) [101].

6 Conclusions

The use of grapevine cell cultures to increase *trans*-R and stilbene-related production under controlled conditions is viewed as a promising biotechnological alternative to their extraction from the whole plant or their chemical synthesis. At present, only few plant in vitro cultures are undertaken commercially for the production of bioactive compounds. The major problems hindering the development of the large-scale culture of plant cells include low productivity, cell line instability, and difficulties involved in scaling up. Medium composition, culture conditions, elicitors, bioreactor design, and other critical parameters influence the behavior of grapevine cell cultures. However, the optimization of medium composition and culture conditions does not improve substantially the production of these compounds.

Grapevine cell cultures enhance the levels of *trans*-R and stilbene-related production in response to biotic and abiotic elicitors so that elicitation of cells using different elicitors in combination might represent a powerful strategy for increasing *trans*-R and stilbene-related production. Moreover, when an adsorbent is added to elicited grapevine cell cultures, as *trans*-R is produced, this is removed from the culture medium, reducing both feedback inhibition and *trans*-R degradation, and allowing its accumulation in high concentrations. Thus, the combined addition of Ja and HP2MGL to *V. vinifera* cv Gamay Fréaux cell cultures provided a high *trans*-R yield (around 2,300 mg L^{-1}), which increased even more when SA, Ja, and HP2MGL were jointly added (2666.7 mg L^{-1}). However, other authors observed that the presence of CDs, MeJa, and ET induced a greater increase in *trans*-R levels (1,540 mg L^{-1}) than when they used CDs, MeJa, and SA (1,040 mg L^{-1}) to elicit *V. vinifera* cv Monastrell cell cultures for 96 h. These findings indicate that different high-producing *V. vinifera* cell lines respond differentially to the presence of signaling molecules.

One of the most significant successes in increasing the *trans*-R content in *Vitis* cell cultures was reached using CDs in combination with MeJa. In these conditions and using shaken flasks, the accumulation of *trans*-R increased exponentially reaching a concentration plateau (3047.60 mg L^{-1}) after 168 h. Indeed, the *trans*-R yield was 15.24 mg g^{-1} FW, and such yields can also be reached in all the bioreactors tested either in one-stage batch or in two-stage fed-batch modes. Thus, the scale-up of CDs- and MeJa-mediated *trans*-R production in bioreactors is clearly feasible.

Many efforts have been made to synthesize high levels of *trans*-R using metabolic engineering in plants and microbes. There is abundant information about the *trans*-R content of transgenic plants, although *trans*-R levels were seen to be not very high (around 350 μg g^{-1} DW). Only experiments with *rolB* transgenic callus lines of *V. amurensis* showed an enhanced production of *trans*-R (31.50 mg g DW^{-1}).

Efforts to increase the production of *trans*-R for commercial applications have focused on heterologous expression of the phenylpropanoid and stilbene pathways in *S. cerevisiae* and *E. coli*, although as the stilbene pathway does not exist in yeast or bacteria, the entire functional pathway needs to be introduced. Thus, when in both systems, *4cl* from *N. tabacum* and *sts* from *V. vinifera* were expressed, 16 and 6 mg L^{-1} *trans*-R were produced in *E. coli* and yeast cells, respectively. However, the highest levels of *trans*-R (171 mg L^{-1}) were reached using a *4cl* gene from *L. erythrorhizon* and a *sts* gene from *A. hypogaea* in recombinant *E. coli*.

Abstract

Phytonutrients in fruits and vegetables or their individual components (nutraceuticals) positively contribute to human health. Mostly, these nutrients

have antioxidative property that impacts redox imbalance and can lead to prevention of cancer, cardiovascular diseases, diabetes, osteoporosis, and age-related disorders such as dementia. Over 7,000 flavonoids (and phenolic compounds) and 600 naturally occurring carotenoids seemingly with health benefits have been documented in plants. Fruits and vegetables are dietary sources of pro-health nutrients (nutraceuticals); however, the level of an individual antioxidant is low in the currently used germplasm, thus limiting them in meeting the recommended daily allowance (RDA). Nonetheless, the awareness about their health benefits has increased the global demand for and consumption of fruits and vegetables. Advanced molecular breeding and genetic engineering approaches are providing novel tools to greatly increase the levels of many desirable nutraceuticals, which is being made easier because their metabolic pathways are now known. The biotechnological interventions have already allowed severalfold increases in the content of flavonoids and carotenoids in fruit crops and essential fatty acids in oil crops. This chapter gives an overview of three classes of phytonutrients – flavonoids, carotenoids, and essential fatty acids, their dietary sources, metabolic pathways, and important genes/enzymes involved in their production. Several examples of the biotechnological intervention to boost endogenous levels of phytonutrients in various crop plants are highlighted.

Keywords

Biotechnology • genetic engineering • functional food • GM crops • nutrition • transgenic plants

Abbreviations

ABA	Abscisic acid
ACP	Acyl carrier protein
CVD	Cardiovascular disease
DHA	Docosahexaenoic acid (C22:6n-3)
DW	Dry weight
EPA	Eicosapentaenoic acid (C20:5n-3)
FW	Fresh weight
GLA	ω-6 γ-linolenic acid
LDL	Low-density lipoprotein
PA	Proanthocyanidin
PUFA	Polyunsaturated fatty acids
RDA	Recommended daily allowance
SDA	Stearidonic acid (C18:4n-3)
UV-B	Ultraviolet-B radiation

1 Introduction

Functional foods is a designated term for foods that can provide health benefits in addition to basic nutrition. Functional foods include edible produce in which the concentration of one or more bioactive compounds (phytonutrients) – vitamins, antioxidants, micronutrients – has been increased through breeding, environmental manipulations or precision-based genetic engineering, and processed foods fortified with health-promoting additives. Fruits and vegetables are main sources of dietary phytonutrients especially antioxidants. Functional components, sources, and benefits of various phytonutrients are listed in Table 56.1. Numerous epidemiological studies and clinical trials have suggested that diets rich in fruits and vegetables can reduce the risk of chronic disease [1]. Thus, regular intake of phytonutrients could potentially prevent cancer, cardiovascular diseases, diabetes, osteoporosis, and age-related disorders such as dementia [2–4]. Likewise, carotenoids including lycopene, flavonoids, vitamins C and E, and isothiocyanates/glucosinolates have the potential to prevent chronic diseases, including epithelial cancers, cardiovascular diseases, digestive disorders, and immune deficiency [2, 3, 5]. In this regard, carotenoids have attracted significant attention, particularly because β-carotene as a provitamin A is important for retinal health: preserving eyesight, preventing night blindness, and protection against cataract [6] as also lutein in preventing age-related macular degeneration of eye [7]. Carotenoids have also been implicated in reducing low-density lipoprotein (LDL) improving immune system and preventing neurodegenerative diseases such as Alzheimer’s, Parkinson’s, and vascular dementia [4]. Flavonoids also have antioxidant properties that reduce the risks of age-related diseases, heart ailments, and cancers [8]. The potential of phytonutrients in protecting against or delaying the incidence of fatal diseases is believed largely to occur via their antioxidative and free radical-scavenging properties, by protecting cellular macromolecules from oxidative damage induced by prooxidants, especially during aging [9].

Fruits and vegetables contain thousands of biologically active phytochemicals some of which likely interact in a number of ways to prevent disease and promote health [9, 10]. The nature of such multiple interactions among nutrients that promote health and prevent disease is unclear [11, 12]. Evidence that very high doses of isolated individual micronutrients or phytochemicals, grouped as nutraceuticals, can be as effective as eating fruits and vegetables is inconsistent and relatively weak. The awareness of their health-promoting properties has increased the worldwide consumption of fruits and vegetables and globally increased their demand. Enhancement of nutritional quality of staple foods in developing and underdeveloped countries is of paramount importance in reducing several diseases and disorders due to nutrition-deficient foods. However, the available level of a specific phytonutrient in the currently used germplasm is not sufficient to meet the recommended daily allowance within a reasonable daily intake of edible portions. Thus, a significant focus of scientists in recent years

Table 56.1 Functional components, sources, and health benefits of phytonutrients[a]

Functional component(s)	Source	Potential benefits
Phenolics		
Anthocyanidins	Fruits	Neutralize free radicals; reduce risk of cancer
Catechins	Tea	-do-
Flavanones	Citrus	-do-
Flavones	Fruits/vegetables	-do-
Lignins	Flax, rye, vegetables	Prevention of cancer, renal failure
Tannins (proanthocyanidins)	Cranberries, cranberry products, cocoa, chocolate	Improve urinary tract health. Reduce risk of cardiovascular disease
Carotenoids		
α-Carotene/β-carotene	Carrots, fruits, vegetables	Neutralize damaging free radicals
Lutein	Green vegetables	Reduces the risk of macular degeneration
Lycopene	Tomato products (ketchup, sauces)	Reduces the risk of prostate cancer
Fatty Acids		
Long-chain ω-3 fatty acids – DHA/EPA	Salmon and other fish oils	Reduce risk of cardiovascular disease; improve mental and visual functions
Conjugated linoleic acid (CLA)	Cheese, meat products	Improves body composition; decreases risk of certain cancers

[a] Adapted from http://lpi.oregonstate.edu/infocenter/phytochemicals/flavonoids/index.html#intro

has been to elevate cellular levels of known health-promoting nutrients in fruits and vegetables using novel approaches.

Genetic engineering has been increasingly applied to secure nutritional enhancement of the crops once the need of nutritional food security became apparent as a major health risk in the world [9]. Many desirable crop traits are multigenic in nature, the final outcome being a function of a group of genes. However, most metabolic pathways leading to the formation of important nutrients have a rate-limiting step(s), which calls for innovation in selecting the right kind of genes and using specific promoters to drive their expression. Three basic strategies have been used to accomplish the objective of enhancing a multigenic trait. These include the co-expression of multiple genes and engineering transcription factors that control a number of downstream genes. Simultaneous introduction of several genes helped develop high-β-carotene rice, now commercially known as Golden Rice [13]. The latter study also demonstrated that the source of gene(s) plays a significant role in increasing a preferred molecule/nutrient. Noticeably, the use of carotene desaturase from *Erwinia uredovora* resulted in a 23-fold increase in total carotenoids in rice [13]. Other phytonutrients whose content has been enhanced by genetic engineering include α-tocopherol [14–19], vitamin C corn [20–22], and folate [23–25].

Molecular breeding based on genetic analysis has provided another tool that has made “candidate” gene approach a reality to test phenotypic role of a particular gene by altering its expression during plant growth and development [26]. A major lesson learned from such studies is that a clear understanding of the complex gene expression, selection of the promoter, and regulation of the production of a desired metabolite are critical in enabling targeted expression of a transgene at a desired stage of development of a specific tissue. The gain of function by using ectopic overexpression or loss of function by antisense RNA repression or RNAi approach has made it possible to characterize the phenotypes associated with a single gene and its potential to regulate desirable phenotype in crop plants. This chapter focuses on and summarizes examples in the literature on the genetic engineering of fruits and vegetables, in particular the studies on enhancing the content of flavonoids, carotenoids, and essential fatty acids.

2 Flavonoids/Phenolics

2.1 Diet Source/Distribution/Occurrence

Flavonoids are aromatic, low-molecular-weight secondary metabolites [27]. Their hydrophilic properties [28] complement the hydrophobic nature of carotenoids. This group of antioxidants includes secondary metabolites constituting more than 7,000 chemical structures [29–31]. Flavonoids are classified, based on degree of unsaturation and oxidation of a three-carbon bridge in flavone skeleton between phenyl groups of flavonoids, and divided into subclasses (Table 56.2) such as flavanols (catechin, epicatechin, proanthocyanidins), flavanones (hesperetin, naringenin, eriodictyol), flavonols (quercetin, kaempferol, myricetin, isorhamnetin), flavones (apigenin, luteolin), and anthocyanidins (cyanidin, delphinidin, malvidin). Flavonoids are present at different levels in fruits, vegetables, legumes, tea, and red wine. Flavonoid content of some flavonoid-rich foods (Table 56.3) are, in fact, approximate values considering that a number of factors affect their levels, including agricultural practices used, environmental factors, ripening process, processing, storage, and cooking. Green and black tea, apple, and apricot are rich in flavanols; parsley, thyme, and green celery in flavones; the veggies – onions, kale, leek, broccoli, green chili pepper, and celery in flavonols; and fresh orange and grapefruit in flavanone. Fruit juices containing high levels of flavanones are a major source of flavonoids in human diet. The total fruit juice consumption may account for 20–30 % of dietary intake of flavonoids [27]. The berries (blackberry, blueberry) and red grapes are considered super sources of flavonoids including anthocyanins and proanthocyanidins (PAs) and have high order of antioxidative capacity (Table 56.3) [32–34]. A multitude of phenolic compounds (proanthocyanidins, anthocyanin, flavonol, and phenols) have been detected in the berries and leaves of sea buckthorn; their contents are variable depending upon the species and cultivar type, cultivation site, and the ecological and environmental conditions [35–37]. There is only minimal information on the temporal and spatial accumulation patterns of these compounds during fruit development.

Table 56.2 Subclasses of common dietary flavonoids[a]

Flavonoid subclass	Dietary flavonoids	Some common food sources
Flavanols	Monomers (catechins): Catechin, epicatechin, epigallocatechin, epicatechin gallate, epigallocatechin gallate Dimers and polymers: Theaflavins, thearubigins, proanthocyanidins	Catechins: teas (particularly green and white), chocolate, grapes, berries, apples. Theaflavins, thearubigins: teas (particularly black and oolong). Proanthocyanidins: chocolate, apples, berries, red grapes, red wine
Flavanones	Hesperetin, naringenin, eriodictyol	Citrus fruits and juices, e.g., oranges, grapefruits, lemons
Flavonols	Quercetin, kaempferol, myricetin, isorhamnetin	Widely distributed: yellow onions, scallions, kale, broccoli, apples, berries, teas
Flavones	Apigenin, luteolin	Parsley, thyme, celery, hot peppers
Isoflavones	Daidzein, genistein, glycitein	Soybeans, soy foods, legumes
Anthocyanidins	Cyanidin, delphinidin, malvidin, pelargonidin, peonidin, petunidin	Red, blue, and purple berries; red and purple grapes; red wine

[a] Adapted from http://lpi.oregonstate.edu/infocenter/phytochemicals/flavonoids/index.html#intro

Polyphenolic compounds are derived via the shikimate-phenylpropanoids-flavonoids pathways. They have been shown to protect plants against UV-B light and microbes [38, 39]. The antimicrobial property is important for fruits to maintain their resistance against fungi during storage. Though these flavonoids play significant role in the interaction of plants to the environment functions, for example, as pigments, signaling molecules, UV-B protectants, phytoalexins, and auxin transport regulators [40–43], the specific relationship between structure and function of flavonoids is not fully understood. Flavonoids also contribute toward various fruit quality attributes including color (red, violet, blue), flavor, and texture. The undesirable brown pigmentation (bruises) on fruit surface has been attributed to oxidation of phenols to quinones, which then polymerize into brown pigments, for example, flavan-3-ols in apples [27, 44, 45]. The flavonols are perceived to protect fruit skin against UV-B light [46]. They also accumulate in the seed coat [47]. The proanthocyanidins (PAs) are condensed tannins, oligomers, and polymers of flavan-3-ols. They are mostly common in woody plants but are also present in herbaceous species, as factors that contribute to defense and stress resistance. In seeds, PAs are often present in the seed coat [48]. The red and blue pigments of ripe fruits are anthocyanins that attract frugivores, fruit-eating birds that assist in pollination and seed dispersal [49]. However, in the developing fruits, the astringency and bitterness of PAs provide a defense mechanism against frugivores [50]. Interestingly, while the anthocyanins and PAs share a common biosynthetic pathway, their biological functions are typically opposite, one attracting and the other repelling herbivores, respectively.

2.1.1 Biosynthetic Pathway, Genes, and Enzymes Involved

Basic flavonoid structures and their development from the standpoint of molecular biological and natural products chemistry aspects have been well characterized. Thirty-five flavonoid biosynthetic genes, including genes encoding 12 transcription factors, 10 structural enzymes, and 10 modification enzymes, have been characterized in the model plant *Arabidopsis* [47, 51–56]. Flavonoids are mainly synthesized from phenylalanine via the phenylpropanoid pathway. Following cinnamate hydroxylation by cinnamate 4-hydroxylase and 4-coumarate-CoA ligase step, flavonoid biosynthesis pathway branches out into phenolics (chlorogenic acid) and favonols (naringenin, quercetin, and their derivatives) [57, 58]. Condensation of p-coumaroyl-CoA (C6-C3) with three malonyl-CoA (C3) molecules results in naringenin chalcone with a diphenylpropane (C6-C3-C6) unit, which is converted to naringenin with the flavone (2-phenylchromen-4-one) backbone by conjugate ring closure. These and further modifications yield a variety of structural forms including chalcones, flavanones, dihyroflavonols, flavans, anthocyanins, flavones and flavonols, and isoflavonoids.

Flavonoid biosynthesis was originally discovered and characterized in Arabidopsis (*Arabidopsis thaliana*), maize (*Zea mays*), and petunia (*Petunia hybrida*) [47]. Entry into the flavonoid pathway from general phenylpropanoid metabolism is controlled by chalcone synthase (CHS), which condenses p-coumaroyl-CoA and three malonyl-CoAs into a chalcone, followed by isomerization by chalcone isomerase (CHI) to form a flavanone (Fig. 56.1). This intermediate is subsequently hydroxylated by flavanone-3 β-hydroxylase (FHT) to dihydroflavonol. It is further converted to a flavonol via flavonol synthase or reduced by dihydroflavonol reductase (DFR) to leucoanthocyanidin, a key intermediate for PAs and anthocyanins. Hydroxylation at the C-3′ and C-5′ positions of the β-ring occurs in some species via the activity of cytochrome P450-dependent flavonoid hydroxylases (F3′H and F3′5′H). The anthocyanidin flavylium ion is produced by anthocyanidin synthase (ANS) and then glycosylated by UDP-Glc-flavonoid-3-O-glycosyltransferases (UFGT). Methylation of the 3′ and 5′ hydroxyl groups of anthocyanins gives rise to peonidin, malvidin, and petunidin (Fig. 56.1). Anthocyanidins can be diverted into PA synthesis via anthocyanidin reductase (ANR), which produces epicatechin-type flavan-3-ols (Fig. 56.1). Catechin-type flavan-3-ols are thought to be produced from leucocyanidins by leucoanthocyanidin

Fig. 56.1 A schematic presentation of the flavonoid biosynthetic pathway in plants. Enzymes (with abbreviations) indicated are phenylalanine ammonia-lyase (*PAL*), cinnamate 4-hydroxylase (*C4H*), 4-coumarate CoA ligase (*4CL*), chalcone synthase (*CHS*), chalcone isomerase (*CHI*), flavanone 3 beta-hydroxylase (*F3H*), flavonoid 3′-hydroxylase (*F3′H*), flavonoid 3′ 5′-hydroxylase (*F3′5′H*), flavonol synthase (*FLS*), dihydroflavonol 4-reductase (*DFR*), leucoanthocyanidin dioxygenase (*LDOX*), UDP glucose-flavonoid 3-o-glucosyl transferase (*UFGT*), O-methyltransferase (*OMT*), leucoanthocyanidin reductase (*LAR*), and anthocyanidin reductase (*ANR*) (Source http://pmn.plantcyc.org. MetaCyc (MetaCyc.org) database was used to draw the pathway [59])

reductase (LAR) [60]. It was recently demonstrated that PA precursors are actively moved into the vacuole by multidrug and toxin extrusion transport proteins, where they are polymerized.

Various regulatory and biosynthetic genes involved in the flavonol and anthocyanidin pathways have been isolated and characterized from various plants [30, 61]. However, sequential glycosylation, acylation, and methylation modification in the flavonoid pathways are still comparatively less understood. In earlier investigations, the flavonoid biosynthesis pathway was studied by genetic analyses of inheritance pattern of flower colors, to which radiolabeling and improved analytical methods were later added. In recent years, the candidate gene approach using genetic engineering technology has played a major role in expanding our knowledge about biosynthetic enzymes, substrates and their diversity among various plant species (Table 56.4), and added to our understanding of flavonoids and their biosynthesis pathways. Mutants and transgenic plants have provided direct evidence on the function of various genes involved in flavonoid biosynthesis pathway [83].

Table 56.4 Important food crops transformed with biosynthetic and regulatory genes for flavonoid metabolism

Transgenzic crop	Gene origin/ GE	Promoter/gene	Enzyme	Metabolic product	Metabolite (higher/lower)	References
Tomato	Tomato/RNAi	CaMVd35S/ *CHS*	Chalcone synthase	Chalcones	Lower total flavonoid and parthenocarpic fruit	[62]
Tomato	(Petunia) (alfalfa)/ overexpression	CaMV35S/ *CHS1* + *CHR*	Chalcone synthase + chalcone reductase	Chalcones + deoxychalcones	Higher butein, isoliquiritigenin, naringenin, chalcone, and rutin	[63]
Strawberry	Strawberry/ antisense	CaMV35S/*CHS*	Chalcone synthase	Chalcones	Higher phenylpropanoids (100 versus 1 % control), cinnamoyl glucose caffeoyl glucose, feruloyl glucose, p-coumaryl alcohol and p-coumaryl-1-acetate	[64]
Flax	Petunia hybrid/ overexpression	CaMV35S/CHS + CHI + DFR	Chalcone synthase, chalcone isomerase, and dihydroflavonol 4-reductase	Chalcones, flavanones, chlorogenic acid	Higher in flavonoids (kaempferol), phenolic acids (coumaric, ferulic, synaptic acids) in seedcake extracts	[65]
Tomato	Grape/ overexpression	TomLoxB/ *StSy*	Stilbene synthase	Resveratrol	Higher resveratrol, *trans*-resveratrol and piceid	[66]
Tomato	Grape/ overexpression	CaMV35S/ *StSy*	Stilbene synthase	Resveratrol	High trans-resveratrol (48.48 mg kg^{-1} FW) and trans-piceid (126.58 mg kg^{-1} FW)/ decrease in rutin (2-fold) and naringenin (2.4-fold) Seedless fruit	[67]
Tomato	Grape/ overexpression	CaMVd35S/ *STS*	Stilbene synthase	Resveratrol	High stilbenes (resveratrol and piceid), naringenin chalcone, rutin	[63]

Apple	Grape/ overexpression	Vst1/ *Vst1*	Stilbene synthase	Flavanol/*trans*-piceid	Higher flavanol (20–80 μg g^{-1} fw) and piceid	[68]
Strawberry	Frost grape/ overexpression	CaMV 35S and fil1/Vst3	Stilbene synthase	Resveratrol	Higher cinnamate, coumarate, and ferulate derivatives/ lower flavonols	[69]
Tomato	Soybean/ overexpression	CaMV35S/ *IFS2*	Isoflavone synthase	Genistein	Higher genistin in leaves but marginal increase in fruit peel, higher naringenin chalcone in fruit peel	[70]
Tomato	Petunia/ overexpression	CaMVd35S/ *chi-a*	Chalcone isomerase	Flavanones	Higher flavonols mainly rutin in peel (78-fold)	[71]
Tomato	Petunia gerbera/ overexpression	CaMV35S/ *CHI* + *FNS-II*	Chalcone isomerase + Flavone synthase	Flavanones + flavones	Higher rutin (16-fold), luteolin-7-glucoside, luteolin aglycon, quercetin glycosides, naringenin chalcone	[63]
Potato	Petunia hybrida/ overexpression	CaMV 35S/ *DFR*	Dihydroflavonol 4-reductase	Chlorogenic acid	Higher phenolic acid and anthocyanin; chlorogenic acid (2.5 vs.1.5 mg g^{-1}dw; pelargonidin:0.4 vs. 0.1 mg g^{-1}dw; petunidin: 3.0 vs. 0.5 mg g^{-1}dw)	[72]
Apple	Maize/ overexpression	Lc	Lc	Leaf color regulatory	Higher levels of anthocyanin idaein (12-fold), flavan 3-ol epicatechin (14-fold), isomeric catechin (41-fold), and dimeric proanthocyanidins (7–134-fold) in leaves	[73]

(*continued*)

Table 56.4 (continued)

Transgenzic crop	Gene origin/ GE	Promoter/gene	Enzyme	Metabolic product	Metabolite (higher/lower)	References
Rice	Rice/ overexpression	*CaMV35S*/(Rc-MYB1, Rc-MYB2 and Rc-bHLH)	*bHLH, DFR*	MYC-type regulatory proteins	Higher proanthocyanidins/red-colored rice	[74]
Tomato	Sesame/ overexpression	CaMV35S/ *Myc-rp*	RP	Myc-like TFs regulate anthocyanin biosynthesis	Higher anthocyanin in vegetative tissues and flowers	[75]
Tomato	Antirrhinum/ overexpression	CaMV35S/*Del*	Delila	Myc TFs that activate biosynthesis of anthocyanin	Higher anthocyanins in mature leaves (23-fold), corolla (40-fold), and stamen (50-fold) but no change in fruit	[76]
Tomato	Snap dragon/ overexpression	E8/ *Ros1* + *Del*	Rosea1 + Delila	TFs that activate biosynthesis of anthocyanin	Higher anthocyanin in pericarp comparable to blackberries and blueberries	[77]
Tomato	Arabidopsis/ overexpression	CaMV35S/ *MYB12*	MYB12	R2R3-MYB TF mediates the accumulation of flavonoids in tomato peel	Higher chlorogenic acid (27-fold), dicaffeoylquinic acid (26-fold), tricaffeoylquinic acid (42-fold), quercetin rutinoside (67-fold), kaempferol rutinoside (593-fold)	[54]
Tomato	Tomato/RNAi	CaMV35S/ *MYB12*	MYB12	R2R3-MYB TF mediates the accumulation of flavonoids in tomato peel	Lower flavonoid pigment naringenin chalcone Exhibited a *y*-like phenotype	[78]
Tomato	Maize/ overexpression	E8 or CaMVd35S/*LC* + *C1*	C1 + LC	MYB-type C1 and MYC-type LC are TFs required for production of anthocyanin in plants	Induced flavonoid synthesis in fruit flesh Higher total flavonoids (10-fold) and total flavonol (20-fold) mainly kaempferol	[79]

Tomato	Tomato/ overexpression	CaMV35S/ *MYB12*	MYB12	R2R3-MYB TF mediates the accumulation of flavonoids in tomato peel	Rescued colorless-peel "y" tomato mutant phenotype	[78]
Tomato	Tomato/ overexpression	CVM/ *ANT1*	ANTHOCYANIN 1	Flavonoid-related R2R3-MYB TF	Higher anthocyanin (500-fold)	[80]
Tomato	Tomato (*Solanum chilense*)/ overexpression	CaMV35S/*ANT1*	ANTHOCYANIN 1	Flavonoid-related R2R3-MYB TF	Higher anthocyanidins (petunidin, malvidin, delphinidin) in fruit	[77]
Tomato	Tomato/ overexpression	E8/ *TAGL1* (*TAGL1-SRDX*)	TOMATO AGAMOUS-LIKE 1	MADS-box TF	Lower lycopene and isoprenoids	[81]
Tomato	Tomato/ overexpression	CaMV35S/ *TAGL1*	TOMATO AGAMOUS-LIKE 1	MADS-box TF	Higher lycopene and naringenin chalcone	[81]
Tomato	Tomato/RNAi	CaMV35S/ *CUL4*	Cullin 4	DDB1a and DET1 form a complex with CUL4, a ubiquitin-conjugating E3 ligase, and target proteins for proteolysis	Pleiotropic phenotype higher anthocyanins and carotenoids and also higher lycopene (2-fold)	[82]
Tomato	Tomato/RNAi	E8/ *DDB1*	UV-DAMAGED DNA BINDING PROTEIN 1	TF negatively regulates photomorphogenic responses	Higher pigment accumulation due to increase in plastid compartment space	[82]

2.1.2 Biotechnological Interventions

Crops successfully enhanced for higher accumulation of flavonoids using genetic engineering are summarized in Table 56.4. Genetic transformation of flax (*Linum usitatissimum* L.), in which a group of genes of the pathway – chalcone synthase (CHS), chalcone isomerase (CHI), and dihydroflavonol reductase (DFR) – were simultaneously expressed, resulted in a significant increase of antioxidant capacity of the transgenics [65]. A strong correlation was found in the phenolic acid content and antioxidant capacity. Field tests of these plants revealed that seedcake extracts of transgenic flax were significantly higher in flavonoids (kaempferol), phenolic acids (coumaric, ferulic, synaptic acids), and lignan content compared to non-transformed control plants. Fibers, another product of flax plant, were enriched in catechine and acetylvanillone but were decreased in phenolic acids [84]. Another feature of transformed flax plants was their higher yield and resistance to *Fusarium culmorum* and *F. oxysporum* as compared to the control plants [65].

In tomato fruit peels, the main flavonoids that accumulate are naringenin chalcone, flavonol rutin, and kaempferol 3-*O*-rutinoside [71, 79, 85]. The ectopic expression of petunia chalcone isomerase (*CHI*) in tomato resulted in a substantial, 78-fold increase in peel flavonols, which was mainly due to accumulation of a quercetin glycoside, rutin. Even after fruits from this line were processed, the remaining paste still contained 65 % of the total flavonols found in fresh fruit, supporting the potential of transgenic plants for food-based industry [79]. Tomato fruit flesh is richer in carotenoids than flavonoids. Therefore, genetic engineering was used to increase flavonoid content in fruit flesh, including the production of new flavonoids by introducing stilbene synthase, chalcone synthase, chalcone reductase, chalcone isomerase, and flavone synthase genes [63]. This strategy caused a threefold higher content of novel flavones and flavonols in tomato fruit that also resulted in higher total antioxidant capacity.

Tomato fruit does not normally produce resveratrol, a stilbenoid flavonoid, because it lacks stilbene synthase (*StSy*) activity. Nonetheless, expression of a grape *StSy* not only induced the production of resveratrol in transgenic tomato fruits but also led to accumulation of *trans*-resveratrol and *trans*-resveratrol-glucopyranosides (piceid), further elevating the antioxidant capacity of the tomato fruit [66, 67]. The combined expression of Petunia chalcone synthase and alfalfa chalcone reductase was found to induce higher levels of butein and isoliquiritigenin (deoxychalcones). Constitutive expression of hydroxycinnamoyl transferase *HQT* gene [86] and that of cryptochrome *cry-2* gene [87] caused severalfold accumulation of chlorogenic acid and other flavonoids. The combined expression of Petunia chalcone isomerase and Gerbera flavone synthase elevated production of luteolin-7-glucoside, luteolin aglycon (flavones), and quercetin glycosides (flavonols) in transformed tomato. The constitutive overexpression of *StSy* that led to a tenfold higher resveratrol content resulted in male sterility mainly due to deficiency of coumaric and ferulic acid [88]. However, it is noted here that seedless parthenocarpic fruit phenotype associated with male sterility is desired by both the consumer and food industry [89–91]. Isoflavones are legume-specific flavonoids. Tomato plants engineered to constitutively overexpress soybean isoflavone synthase (*35S:GmIFS2*) showed only a marginal increase of isoflavones in fruit peel but increased naringenin chalcone, indicating that naringenin is a rate-limiting substrate for isoflavone biosynthesis in tomato peel [70]. In another study where β-carotene content was increased using RNAi suppression of the *DET1* gene, the authors also found severalfold increase in flavonoid content [92]. Another co-stimulation of carotenoids with flavonoids was reported in tomato by upregulating *TOMATO AGAMOUS-LIKE 1* (*TAGL1*), a MADS-box transcription factor, which resulted in higher accumulation of lycopene and naringenin chalcone [81].

Various transcription factors from different plant sources have also been employed to enhance flavonoid content. Expression in tomato of maize transcription factors implicated in anthocyanin production, MYB-typeC1 and MYC-type LC, led to higher flavonoid content in fruit flesh [79]. Main increase seen in the ripe tomato fruit was that of kaempferol [79, 93]. Employing other anthocyanin-related transcription factors, *Roseal* and *Delila*, fused to ripening-specific E8 promoter enhanced anthocyanin content in fruit pericarp whose concentrations were comparable to normally anthocyanin-rich blackberries and blueberries [77]. Similarly, anthocyanidins including petunidin, malvidin, and delphinidin were enhanced in transgenic tomatoes constitutively transformed with flavonoid-related R2R3-MYB transcription factor, *ANTHOCYANIN1* (*ANT1*) [94].

In strawberry, antisensing chalcone synthase (*CHS*) caused the substrates to be utilized by the pathway making other phenolics such as cinnamoyl glucose, caffeoyl glucose, feruloyl glucose, *p*-coumaryl alcohol, and *p*-coumaryl-1-acetate at levels ranging from 363 % to 1,092 % of the control plants. These phenolics occur otherwise only in trace amounts in the control fruit [64]. These results highlighted the step of CHS as a key point of substrate flow between the flavonoid and the phenylpropanoid pathways. An increase in such phenolics at the cost of flavonoids may compromise resistance of strawberry (and other fruits) against disease [69].

In apple (*Malus domestica* Borkh.), flavonoid biosynthetic pathway was engineered by introducing maize leaf color (Lc) regulatory gene [73]. Leaf tissue of Lc-transgenic lines had higher levels of anthocyanin idaein (12-fold), flavan 3-ol epicatechin (14-fold), isomeric catechin (41-fold), and dimeric proanthocyanidins (7- to 134-fold).

Rice pericarp colors are varied and attempts to modify them have also been successful. The dihydroflavonol-4-reductase (DFR) gene is associated with red-color (*Rd*) locus. Its introduction into a brown-colored rice mutant (*Rcrd*) resulted in red-colored rice [74].

3 Carotenoids

3.1 Diet Source/Distribution/Occurrence

Carotenoids are an important class of over 600 naturally occurring molecules synthesized by plants, algae, and photosynthetic bacteria. Dependent upon which

Table 56.5 Food rich in carotenoids[a]

Alpha-carotene	Beta-carotene	Beta-cryptoxanthin	Lycopene	Lutein + zeaxanthin
Carrots	Carrots	Papayas	Watermelon	Kale
Plantains	Cantaloupe	Sweet red peppers	Tomatoes	Spinach
Tomatoes	Spinach	Tangerines	Pink grapefruit	Collard Greens
Tangerines	Lettuce	Watermelon	Peppers, sweet, red	Turnip, greens
Avocados	Apricots	Oranges	Cabbage, red	Squash

of them is preponderant can impart yellow, orange, or red pigmentation to an organism [95]. They are also highly antioxidative. Fruits and vegetables are the source of dietary carotenoids: α-carotene, β-carotene, β-cryptoxanthin, lutein, lycopene, and zeaxanthin [96]. Broadly, carotenoids fall into two classes: carotenes (α-carotene, β-carotene, and lycopene) and xanthophylls (β-cryptoxanthin, lutein, and zeaxanthin). α-Carotene, β-carotene, and β-cryptoxanthin are provitamin A carotenoids, converted by the body to retinol. Lutein, lycopene, and zeaxanthin are not converted to retinol. The foods rich in various carotenoids per serving are listed in Table 56.5. Fruits – raw tangerines, cantaloupe, watermelon, oranges, and nectarines – serve as good sources of carotenoids. Tomato and tomato products (paste, puree, soup, and juice) are concentrated in lycopene as also vegetable juice cocktail, raw watermelon, and pink grapefruit (Table 56.5). Vegetables (spinach, kale, turnip, collards, and green dandelion) contain lutein, zeaxanthin, α-carotene, β-carotene, and β-cryptoxanthin. Carotenoids in foods are mainly in the all-*trans* form. Carotenoids form complexes with proteins and therefore to make them bioavailable plants need to be chopped, homogenized, and cooked [97, 98]. Lycopene becomes more bioavailable from tomatoes by boiling or heating them in oil [99, 100].

3.1.1 Biosynthetic Pathway, Genes, and Enzymes Involved

Carotenoids are essential for diverse processes in plant biology, ranging from photosynthesis, photomorphogenesis, free radical detoxification, lipid peroxidation, to synthesis of plant hormone abscisic acid [4]. The carotenoid biosynthetic pathway (Fig. 56.2) is well known, enzymes involved have been identified, and genes encoding the enzymes have been cloned. Nevertheless, the processes that regulate their biosynthesis and accumulation are complex and poorly understood [102]. The first dedicated step in carotenoid biosynthesis is the ubiquitous C20 isoprenoid precursor geranylgeranyl pyrophosphate (GGPP) [103]. Phytoene synthase (PSY) condenses two GGPP molecules in a head to tail manner to form phytoene (C40). Phytoene contains three conjugated double bonds as a 15-cis geometric isomer. Desaturation reactions extend the series of conjugated double bonds. Phytoene desaturase (PDS) introduces a double bond at the 9′ of the phytoene molecule to create 15, 9′-di cis-phytofluene, and another double bond at the 9 position forms 9, 15, 9′-tricis-ζ-carotene. double bonds give this molecule a characteristic yellow/green color. Lycopene with eleven conjugated double bonds forms the chromophore that imparts red color to ripe tomato fruit. Lycopene is then stepwise cyclized to β-carotene and α-carotene by β-cyclase (LCY-B, CYC-B) and ε-cyclase (LCY-E) enzymes, respectively.

Cyclization of lycopene proceeds only after an all-*trans* lycopene is formed by the action of carotene isomerase (CRTISO) in nongreen tissue. In the photosynthetic tissues, this conversion is catalyzed by light and chlorophyll (acting as a sensitizer). Oxygenation of the cyclic carotenoids yields xanthophylls. Introduction of hydroxyl groups at positions 3 and 3′ in β-carotene produces zeaxanthin. Zeaxanthin epoxidase (ZEP) and violaxanthin de-epoxidase (VDE) act in tandem to regulate the formation of violaxanthin. Violaxanthin is next converted to 9-cis-neoxanthin, ABA precursor, by neoxanthin synthase. Lutein is mainly present in photosynthetic tissues, biosynthesized from α-carotene via catalysis by β- and ε-hydroxylases.

Carotenoid accumulation in fruits is coordinated with fruit ripening and cellular changes that transform chloroplast to chromoplast. The chloroplast-chromoplast differentiation involves quantitative and qualitative change in the carotenoid profiles [104].

3.1.2 Biotechnological Interventions

Carotenoids have attracted attention because of their potent antioxidant property and their potential in preventing malnutrition and disease. Fruits and vegetables (to name some, tomato and carrots) are good sources of carotenoids. However, the levels present are below the RDA [105, 106]. Molecular approaches used to enhance the carotenoid levels in edible produce to levels that are in sync with the RDA have achieved reasonable success. Some of these advances include the production of β-carotene in rice endosperm [13] and maize [22] and lycopene in tomatoes [92, 107]. A major regulatory step in carotenoid biosynthesis is *Psy* gene, which encodes phytoene synthase. The *Psy* cDNA from different sources was used along with the bacterial phytoene desaturase (*Crt1*) gene under the endosperm-specific promoter to transform rice. Using maize *psy*, the total carotenoid level of 37 μg/g achieved in Golden Rice 2 [13] was 23-fold higher than previous reports [108, 109]. In addition to β-carotene, lutein and zeaxanthin also accumulated in the transgenic rice. Four cDNAs encoding enzymes in β-carotene, ascorbate, and folate pathways were used to develop transgenic maize [22]. This study showed that maize endosperm of the transformed plants accumulated β-carotene (59.32 μg/gDW), lycopene (22.78 μg/gDW), vitamin C (ascorbate) (106.94 μg/gDW), and zeaxanthin (35.76 μg/gDW). Using a different strategy, yeast SAM decarboxylase (*ySAMdc*) gene was expressed in a fruit ripening-specific manner (using E8 promoter) in tomato, which led to the accumulation of biogenic amines (polyamines), spermidine, and spermine, at the cost of their precursor diamine putrescine [107]. Fruits of these transgenic tomato lines accumulate 120–175 μg/gFW lycopene as well as the micronutrient choline in addition to other attributes including higher processing quality [107, 110].

A number of other studies have focused on increasing the levels of β-carotene in tomato (Table 56.6). Ectopic expression of a bacterial phytoene synthase (crtB) in a fruit-specific manner increased phytoene (2.4-fold), lycopene (1.8-fold), β-carotene (2.2-fold), and lutein levels in tomato fruit [113]. Suppression RNAi was used to downregulate *DE-ETIOLATED1* (*DET1*), photomorphogenesis

Table 56.6 Important food crops transformed with biosynthetic and regulatory genes for carotenoid metabolism

Transgenic crop	Gene origin/GE	Promoter/ gene	Metabolite (higher/lower)	References
Tomato	Arabidopsis/ overexpression	*CaMV35S/ HMGR-1*	Higher phytosterol (2.4-fold). No change in lycopene or β-carotene	[111]
Tomato	Bacteria/ overexpression	Fibrillin or CaMV35S/ *DXS*	Higher carotenoids (1.6-fold), phytoene (2.4-fold), and β-carotene (2.2-fold)	[111]
Potato	*E. coli*/ overexpression	*Patatin/DXS*	Higher 3.0 versus 0.4 μg g^{-1}fw in control	[112]
Tomato	Bacteria/ overexpression	*PG/crtB*	Higher phytoene (2.4-fold), lycopene (1.8-fold), and β-carotene (2.2-fold)	[113]
Tomato	Tomato/ overexpression	CaMV35S/ *Psy-1*	Higher total carotenoids (1.2-fold), β-carotene (1.3- fold), phytoene (2.3-fold), and phytofluene (1.8-fold)	[53]
Tomato	Bacteria/ overexpression	CaMV35S/ *crtI*	Higher β-carotene (3-fold)/lower lycopene and phytoene/no effect on total carotenoids on plant growth and development	[114]
Rice	Daffodil/ overexpression	CaMV35 and Gt1 PSY	Higher phytoene with both promoters; 0.74 μg g^{-1}dw (with pGt1); 0.32 μg g^{-1}dw(with CaMV35S)	[115]
Rice	Daffodil and bacteria/ overexpression	Gt1 and CaMV35S/ *Psy* and *Crt1*	Higher accumulation of β-carotene and lutein and zeaxanthin	[108]
Rice	Daffodil and bacteria/ overexpression	Gt1 and CaMV35S/ *Psy* + *Crt1* and *Lcy*	Higher accumulation of β-carotene (1.6 μg/g) in heterozygous lines and variable total carotenoids	[108]
Rice	Maize and daffodil/ overexpression	Glu1/psy + crtI	Higher total carotenoid (37 μg g^{-1}dw) and β-carotene, 84 μg g^{-1}dw	[13]
Potato	Bacteria/ overexpression	Patatin/*CrtB*	35 versus 5.6 μg g^{-1}fw	[116]
Potato	Potato/antisense	Pat1/*CrtI*, *CrtB*, and *CrtY*	Higher total carotenoid, 114 versus 5.8 μg g^{-1}dw; β-carotene, 47 vs. 0.013 μg g^{-1}dw;	[117]
Maize	Bacteria/ overexpression	LMW glutelin/ *Psy1and crt1*	β-carotene, 4.79 versus 0.09 μg g^{-1} dw; lycopene, 22.78 versus 0 μg g^{-1}dw	[22]
Maize	Bacteria/ overexpression	γ-Zein/*crtB* + *crt1*	Provitamin A, 7 versus 0.39 μg g^{-1}dw; total carotenoids, 33 versus 1.01 μg g^{-1}dw	[118]

(*continued*)

Table 56.6 (continued)

Transgenic crop	Gene origin/GE	Promoter/ gene	Metabolite (higher/lower)	References
Potato	*Cyanobacterium*/ co-transformation	CaMV 35S/ *crtO*	Accumulation of ketocarotenoids; up to ∼ 10–12 % of total carotenoids	[119]
Brassica	*B. napus* (RNAi)	P35S /ε-CYC	Total carotenoid: versus 5.34 µg g^{-1}fw; β-carotene, 90.76 versus 0.49 µg g^{-1}fw; lutein, 76.22 vs.3.30 µg g^{-1}fw	[120]
Flaxseeds	Bacteria/ overexpression	CaMV35S FAE1/*crtB*	Higher carotenoid (7.8- to18.6-fold, 156.3 versus 8.4 µg g^{-1}dw	[121]
Canola	Bacteria/ overexpression	Napin/*crtB*	Higher (50-fold, 1,000–1,500 µg/ gFW) total carotenoid/orange-colored seed	[122]
Canola	Bacteria/ overexpression	*crtI* + *crtb*	Higher carotenoid 857 versus 5 µg g^{-1}fw	[123]
Canola	Bacteria/ overexpression	*crtI* + *crtb*	44 versus 33 µg g^{-1}fw	[123]
Canola	Bacteria/ overexpression	*crtI* + *crtb*	44 versus 33 µg g^{-1}fw	[123]
Canola	RNAi	CaMV35S/ *DET1*	7 µg versus 0.5 µg g^{-1}fw	[124]
Carrot	Algae (Haematococcus pluvialis)/ overexpression	Ubi, CaMV35S and RolD/ *CrtO*	Higher amounts of total β-carotene (70 %) converted to ketocarotenoids (2.400 µg g^{-1}dw)	[125]
Tomato	Tomato/antisense	CaMV35S/*B*	Higher lycopene but not significant/lower levels of β-carotene (>6- folds)	[126]
Tomato	Tomato/ overexpression	CaMV35S/ *Lycb-1*	Higher β-carotene (31.7-fold)/ lower lycopene/normal plants	[127]
Tomato	Tomato/antisense	Tomato Pds/ *β-Lcy*	Higher lycopene (1.3-fold), lutein (1.7-fold), and lower β-Lcy expression (1.7-fold)	[128]
Tomato	Citrus/ overexpression	CaMV35S/ *Lycb-1*	Higher total carotenoids (30 %) and β-carotene (4.1-fold)	[129]
Tomato	Arabidopsis/ overexpression	Tomato Pds/ *β-Lcy*	Higher β-carotene (6-fold) but no effect on lycopene	[128]
Tomato	Bacteria/ overexpression	atpI/*crtY*	Higher β-carotene (4-fold)/lower total carotenoids and lycopene	[130]
Tomato	Arabidopsis and pepper/ overexpression	Pds/*b-Lcy and b-Chy*	Higher total xanthophyll (10-fold) and β-carotene (12-fold)	[131]
Potato	Potato/antisense	Patatin B33/ *LCY-e/*	Higher total carotenoid, 12,272 versus 4,672 ng g^{-1}dw; β-carotene, 43 versus 3 ng g^{-1}dw; zeaxanthin, 990 versus 262 ng g^{-1}dw	[118]

(*continued*)

Table 56.6 (continued)

Transgenic crop	Gene origin/GE	Promoter/ gene	Metabolite (higher/lower)	References
Tomato	Tomato/ RNAi	E8/*NCED3*	Higher β-carotene and lycopene/ lower ABA (20–50 %)	[132]
Potato	Cauliflower/ overexpression	GBSS/*Or*	Higher total carotenoid (6-fold, 31 versus 5.5 μg gdw^{-1})	[133, 134]
Tomato	Tomato/RNAi	P119 2A11 TFM7/*DET1*	Higher lycopene (2-fold), β-carotene (4-fold), flavonoids (3.5-fold)	[92]
Tomato	Tomato/ overexpression	CaMV35S/ *CRY2*	Higher lutein (1.5-fold), carotenoids (1.7-fold) and flavonoids (2.9-fold)	[87]
Tomato	Tomato/RNAi	CaMV35S/ *HY5*	Lowered carotenoid level	[10]
Tomato	Tomato/RNAi	CaMV35S/ *COP1-like*	Higher carotenoids (2-fold)↑	[10]
Tomato	Yeast/ overexpression		Higher lycopene (40 %)	[135]
Tomato	Apple/ overexpression	CaMV35S/ *SPDS1*	↑ *PSY* and *PDS* and ↓ *CRTL-B* and *CRTL-E* transcripts 1.3- to 2.2-fold ↑ lycopene	[136]
Tomato	Yeast/ overexpression	E8/*SPE2*	Higher lycopene (2- to 3-fold)	[107]
Wheat	*Oat*	Ubi-1/*ADC*	Higher polyamines in seeds putrescine (7-fold), spermidine (2.5-fold), and spermine (1.8-fold)	[137]

regulatory protein gene that negatively regulates light-mediated responses [92]. The transformed tomato accumulated high carotenoid levels. Fruit-specific [128, 131] or constitutive [127] expression of lycopene β-cyclase, and constitutive expression of phytoene desaturase [114], all led to high levels of β-carotene in tomato fruit.

Among other studies, canola was transformed with *E. uredovora* phytoene synthase (*crtB*) gene driven by seed-specific napin promoter [122]. Orange-colored canola seeds were thus obtained which accumulated a 50-fold higher (1.0–1.5 mg/gFW) total carotenoid level than the wild type (0.033 mg/gFW). Later, canola that coexpressed *crtI* and *crtB* genes accumulated lycopene (29 μg/gFW) and β-carotene (857 μg/gFW) [123]. Expression of bacterial *crtB* gene in a seed-specific manner in flaxseeds led to 7.8- to18.6-fold increase in the carotenoid levels [138]. Transgenic potatoes expressing the *crtB* gene in a tuber-specific manner accumulated violaxanthin, lutein, and β-carotene in the tuber [116]. The constitutive expression of citrus lycopene β-cyclase (*CRTL-B*) in tomato increased β-carotene 4.1-fold with a 30 % increase in total carotenoids while suppressing fluxes downstream into β-carotene pathway and concomitant increase in α-carotene [129]. However, phytoene, lycopene, and lutein decreased by about 26 %, 10 %, and 44 %, respectively, in the transgenic lines [129].

Constitutive RNAi suppression of a component of Cul4-based E3 ligases, CUL4, also resulted in increased carotenoid accumulation in tomato [82]. Tuber-specific expression of the cauliflower *Or* gene, which causes β-carotene accumulation in cauliflower, led to a sixfold higher level of total carotenoids in transgenic potato versus the controls [133, 134].

Other strong antioxidants in plants comprise ketocarotenoids. They are used as dietary supplements and pigments in aquaculture and nutraceutical industries. Constitutive expression of algal *Haematococcus pluvialis* β-carotene ketolase gene in transgenic carrot converted β-carotene to ketocarotenoid that reached a level of 2.4 mg/g root dry weight [125]. Such transgenic carrots are well suited for biopharming ketocarotenoids as functional food and in nutraceutical and aquaculture industries. A mutation in zeaxanthin epoxidase (*zep1*) creates abscisic acid (ABA) deficiency in tomato plants with concomitant accumulation of 30 % more carotenoids in mature red tomato fruit [139]. Similarly, suppression of ABA synthesis led to accumulation of upstream carotenoids, β-carotene and lycopene, in transgenic tomato fruits in which 9-cis-epoxycarotenoid dioxygenase 3 (*NCED3*), an enzyme that catalyzes first step of ABA biosynthesis, was silenced in a fruit-specific manner using RNAi [132]. Likewise, expression of cryptochrome 2 (35S:CRY2) resulted in 1.7-fold increase in carotenoids and 2.9-fold increase in flavonoids [87]. Repression of *ELONGATED HYPOCOTYL 5* (*HY5*) by RNAi reduced carotenoid accumulation, while suppression of *CONSTITUTIVELY PHOTOMORPHOGENIC 1* (*COP1*)-like gene elevated carotenoid levels in tomato fruit, suggesting involvement of light signaling factors in carotenoid biosynthesis [10].

4 Essential Fatty Acids

4.1 Diet Source/Distribution/Occurrence

The “omega” fatty acids are polyunsaturated fatty acids (PUFA), considered as essential nutrients since mammals including humans are unable to synthesize unsaturated fatty acids with a double bond at the n-6 (ω6) or the n-3 (ω3) position in the *cis* orientation [140]. The substrate for ω-6 series is linoleic acid (18:2n-6), while α-linolenic acid serves as the substrate for 18:3n-3 series. The “fatty” diet of humans in the Western world has changed from 1:1 ratio of ω-6 to ω-3 fatty acids [97] to close to a 10:1 (ω 6/ω 3) ratio because of the increased use of oils rich in LA [141].

Linoleic acid is found in soybean, safflower and corn oil, nuts, seeds, and some vegetables. α-Linolenic acid is found in flaxseeds, walnuts, and their oils; canola oil is also a good source of α-linolenic acid. Edible oils rich in monounsaturated fatty acids are stable, flavorful, and nutritious for humans and animals. Oleic acid-rich soybean oil is more resistant to degradation by heat and oxidation and requires little or no postrefining processing (hydrogenation). In addition, α-linolenic acid is a substrate for the synthesis of longer chain ω-3 fatty acids found in fish, eicosapentaenoic acid (EPA; C20:5n-3) and docosahexaenoic acid (DHA; C22:6n-3). Stearidonic acid (SDA; C18:4n-3), EPA, and DHA possess anticancer properties and have been implicated in the regulation of inflammatory immune reactions and blood pressure, brain development, and the development of cognitive function [142–144]. Research indicates that the ratio of n-3 to n-6 fatty acids may be as important to health and nutrition as the absolute amounts present in the diet or in the body tissues. EPA and DHA in the diet are generally provided by fish, a source that is not a possibility for vegetarians and also appears unable to cope up with the increasing global demand [145].

4.1.1 Biosynthetic Pathway, Genes, and Enzymes Involved

Fatty acid synthase (FAS) constitutes a multisubunit complex in the plastid where it catalyzes ordered synthesis of fatty acids, initiated from acetyl CoA and malonyl CoA [146, 147]. Stepwise FAS activity generates the products 16:0-acyl carrier protein (ACP) and 18:0-ACP. Most of the 18:0-ACP is desaturated by a soluble stearoyl-ACP desaturase, yielding 18:1 D9-ACP [148]. Acyl-ACP thioesterases release ACP from 16:0-ACP and 18:0-ACP; the deacylated fatty acids exit the plastid and are then esterified with coenzyme A (CoA) to form respective acyl-CoAs [148]. These acyl moieties are then esterified to phosphatidylcholine (PC) and then undergo desaturation by D12- and D15-desaturases to yield the essential fatty acids, linoleic acid, and α-linolenic acid [148–150]. All higher plants have the enzymes for synthesizing the C18 PUFAs linoleic acid and α-linolenic acid. The primary genes involved in PUFA biosynthesis have been reviewed [151].

4.1.2 Biotechnological Interventions

Traditional breeding, induced selection, and modern biotechnology have eased modifying the fatty acid composition of oilseeds to enhance their nutritional value and food oil applications. Because of the nature of its use on a daily basis, modifying fatty acid composition in vegetables, and thereby in vegetable oil, is a convenient means of delivering a healthier product to consumers, requiring no significant change in the daily diet. Marketed modified oils include low- and zero-saturated fat soybean and canola oils; medium-chain fatty acid canola oil; high-stearic acid canola oil (for trans-fatty acid-free products); high-oleic acid (monounsaturated) soybean oil; and canola oil containing the PUFA γ-linolenic acid (18:3 n-6) and stearidonic acid (18:4 n-3), long chain fatty acids [152], and ω-3 fatty acids [153] (Fig. 56.3; Table 56.7).

Oleate desaturase expression by antisense RNA in soybean led to an oil containing over 80 % oleic acid as compared to a normal 23 %, with significant decrease in polyunsaturated fatty acids [155]. Canola does not normally accumulate capric and caprylic acids. But the introduction of the *Cuphea hookeriana* acyl-ACP thioesterase cDNA in canola resulted in the accumulation of these two medium-chain fatty acids in the seeds [156]. In plants, ω-6 desaturase-catalyzed pathway in the microsomes is a major source of polyunsaturated lipids. Introduction of the

fungal (Mortierella) Δ^6- desaturase gene in canola produced ω-3 fatty acids [157]. ω-6 and γ-linolenic acid (GLA) content was engineered in safflower oil to amounts as high as 40 %, which is four times higher than levels found in evening primrose (*Oenothera biennis*) and borage (*Borago officinalis*) [158]. Transformation of safflower by introducing *Saprolegnia diclina* Δ^6-desaturase produced GLA to levels higher than 70 % (v/v) [159]. Ruiz-Lopez et al. [151] consider the production of a plant equivalent of marine oil as a major challenge and that transgenic technology is critical for enhancing the levels of PUFAs for food and nutritional security.

5 Conclusions

Functional foods with the bioactive natural phytonutrients are emerging as the next frontier for the biologists and nutritionists alike. The revised US dietary guidelines have laid the emphasis on plant-based fiber and five to nine daily servings of fruits and vegetables with significant reduction in animal fat consumption. Increased understanding of how diet(s) influences whole body health, lesser susceptibility to diseases, high quality of life, and individual's (personal) genetic potential for longevity is highly desired and needed. Such an understanding will be directly linked to efforts for developing crop plants that have the capacity to accumulate

Table 56.7 Sources of omega-6 and omega-3 fatty acids[a]

Linoleic acid (18:2n-6)	Alpha-linolenic acid (18:3n-3)
Safflower oil	Flaxseed oil
Sunflower seeds, oil roasted	Walnuts, English
Pine nuts	Flaxseeds, ground
Sunflower oil	Walnut oil
Corn oil	Canola oil
Soybean oil	Soybean oil
Pecans, oil roasted	Mustard oil
Brazil nuts	Tofu, firm
Sesame oil	Walnuts, black

enhanced levels of beneficial bioactive nutrients. Enhancement of bioactive phytonutrient content in crop plants requires that a clear understanding be in place also of metabolic pathways and regulatory genes that control fluxes of primary and secondary metabolites. Fortuitously, a multitude of technologies are emerging that should help in accomplishing these charges. Thus, deep sequencing, proteomics, and metabolomics are collectively helping unravel “systems biology” of crops by elucidating networks between genes, protein (enzymes) and metabolites, and processes that regulate them. Based on such information, novel strategies of gene engineering are being coupled with transformation of important crops to develop designer crops, functional foods, with the desired enhancement(s) in the levels of bioactive compound(s). Significant progress has already been made in developing such genetically modified plants as is evident from the literature included in this chapter. Undoubtedly, rapid progress is assured in this field in the coming decades. One goal of these developments is to enable dietary intervention in human health to combat monogenic or polygenic diseases.

The recognition of phytonutrients as important determinants of human health has catalyzed investigations into broader aspects of plant-based nutraceuticals. These include elucidating biochemical pathways and identifying the rate-limiting steps; engineering metabolic pathways to direct the intermediary metabolism flux toward a particular nutrient (nutraceutical); testing efficacy of either an isolated nutraceutical or a crop engineered with an enhanced nutrient level in animal and human models; testing crops silenced for a health-detrimental factor including allergins; and comparing bioavailability of an individual nutrient (nutraceutical) fed either as a food supplement or in the form of a fortified food. However, the “functional foods” will have a limited success in advancing public health until their benefits are widely confirmed and effectively communicated to the consumer. In this regard, proactive efforts have been made by the Harvard School of Public Health (Boston, MA, USA) and the International Food Information Council

Table 56.8 Important food crops transformed with biosynthetic and regulatory genes for EFA metabolism

Transgenic	Gene origin/ GE	Promoter/ gene	Enzyme	Metabolic product	Metabolic effect	References
Canola	Bacteria	Napin/ *CrtB*	Phytoene synthase	Fatty acyl composition	Higher 18:1 (oleic acid) component	[122]

Abstract

Flavanols are a wide group of polyphenols that include flavan-3-ols (e.g., catechin and proanthocyanidins), flavan-4-ols, and flavan-3,4-diols. They arise from plant secondary metabolism through condensation of phenylalanine derived from the shikimate pathway with malonyl-CoA obtained from citrate that is produced by the tricarboxylic acid cycle, leading to the formation of the key precursor in the flavonoids biosynthesis: the naringenin chalcone. The exact nature of the molecular species that undergo polymerization and the mechanism of assembly in proanthocyanidins are still unknown. From a structural point of view, flavanols

comprise a C15 (C6-C3-C6) general structure composed by a benzopyran moiety (A and C rings) with an additional aromatic ring (B ring) linked to carbon C-2 of C ring. Flavanols are present in nature in monomeric, oligomeric, and polymeric forms and differ from each other essentially in the configuration of carbon C-2, the hydroxylation/methoxylation pattern of the rings, the type of linkage between each unit, and the degree of galloylation. Flavanols in foods are described to present several beneficial effects such as antioxidant and anticarcinogenic properties and also contribute to the sensory properties of some food products, such as astringency and color. Some of these aspects are discussed herein.

1 Introduction

Flavanol monomers and proanthocyanidins (*syn.* condensed tannins) are polyphenolic compounds derived from plant secondary metabolism being present in a wide variety of plants and plant-derived foods such as fruits, cereals, seeds, wines, ciders, teas, beers, and cocoa [1–7].

Flavanols are involved in the protection against the abiotic (e.g., sunlight) and the biotic stress (e.g., predation, pathogen attack) of plants [8, 9]. Proanthocyanidins (PAs) have the capacity to interact and precipitate alkaloids and proteins [10, 11]. Their ability to precipitate salivary proteins in the oral cavity is described to be at the origin of the astringency character that is generally associated to tannin-rich foods [11–13]. Flavanols can also contribute to the color of some food products such as red wines, in one hand through their association with anthocyanins (copigmentation phenomenon) enhancing the color of red wines [14–19] and on the other hand by their chemical reaction with anthocyanins leading to the formation of new colored compounds with different spectroscopic features [20–26]. Furthermore, flavanols may form stable complexes with metal ions [27–30] influencing the bioavailability of several minerals [31, 32]. Like other polyphenols, flavanols are good reducing agents showing important antioxidant and radical-scavenging properties [33–36]. Based on these properties, numerous studies have been published evidencing PAs health benefits over the last years. Proanthocyanidins have been shown to prevent low-density lipoproteins [37–40] and lipid peroxidation [41–44] and also to inhibit platelet aggregation [45, 46], which are two major mechanisms described to be at the origin of arteriosclerosis and cardiovascular diseases [47, 48]. Several in vitro studies have also suggested a protective role of PAs against several types of cancers [49–51]. More recently, PAs have been shown to present some antinutritional effects as they were found to inhibit the three main classes of digestive enzymes: lipases [52], glycosidases [53], and proteases [54, 55].

2 Structural Features

2.1 Flavanol Monomers

Flavan-3-ols, flavan-4-ols, and flavan-3,4-diols are different classes of flavonoid compounds comprising a C15 (C6-C3-C6) general structure of a benzopyran moiety (A and C rings) that presents an aromatic ring (B ring) linked to carbon C-2 of

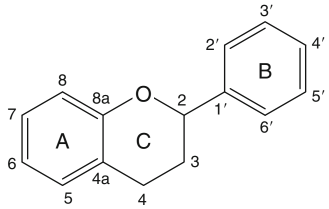

Fig. 57.1 General structure of the flavanic core

pyranic ring C (Fig. 57.1). The difference between each of these classes is in the hydroxylation pattern of the pyran ring. On the other hand, in the case of flavan-3-ols, flavan-4-ols, and flavan-3,4-diols, there is a hydroxyl group present at carbon C-3, C-4 or C-3, and C-4, respectively. In the case of flavans, there is no hydroxyl group in the pyranic ring.

However, these latter are more rarely found in nature [56–58]. Flavan-4-ols and flavan-3,4-diols are also unlikely to be detected in nature due to their high reactivity as electrophiles in weakly acidic conditions [59, 60].

On the other hand, flavan-3-ols are very abundant in nature (Table 57.1), and their structures differ from each other in the stereochemistry of the asymmetric carbons (C-2 and C-3) of the pyranic ring C and in the hydroxylation pattern of rings A and B. The most common flavan-3-ols in plant kingdom are hydroxylated at carbons C-5 and C-7 in ring A, differing only in the hydroxylation pattern of ring B and in the stereochemistry of carbon C-3 from ring C [62, 63] (Fig. 57.2). Carbon C-2 in the naturally occurring flavan-3-ols is almost exclusively present in the 2*R* configuration. The less common flavan-3-ols presenting a carbon C-2 with a 2*S* configuration are named with the prefix *ent*, as in *ent*-catechin ((−)-catechin) that has a 2*S*,3*R* absolute configuration [63, 64]. The carbon C-3 can be found in the 3*S* or 3*R* configuration. For example, in flavan-3-ols with an *ortho*-dihydroxylated ring B (C-3′,C-4′), two situations may be observed: carbons C-2 and C-3 present a 2*R*,3*S* absolute configuration (*trans* conformation) like in (+)-catechin or present a 2*R*,3*R* configuration (*cis* conformation) as in (−)-epicatechin (Fig. 57.2). Flavan-3-ols with a 3*R* absolute configuration in carbon C-3 present the prefix epi. Furthermore, ring B monohydroxylated and trihydroxylated give rise to (+)-afzelechin or (−)-epiafzelechin, (+)-gallocatechin or (−)-epigallocatechin, respectively (Fig. 57.2).

Flavan-3-ols can also be esterified with gallic acid or glucosylated in the hydroxyl group of carbon C-3 of the pyranic ring C [65, 66], although the glucosylated forms are scarce in the plant kingdom [63, 67, 68] (Fig. 57.3).

2.2 Proanthocyanidins

Proanthocyanidins are oligomeric or polymeric chains of flavan-3-ols that are present in nature in a great diversity of structures. This is due to structural features of the monomeric units and also to the type of interflavanic bond, the degree of polymerization, and esterification with gallic acid [69, 70].

PAs can be divided in two main groups according to their ring A type: phloroglucinol or resorcinol derivatives (Fig. 57.4) [71, 72]. A-type phloroglucinol ring proanthocyanidins are much more abundant in nature. Among these, procyanidins (PCs) and prodelphinidins (PDs) represent the most common classes of proanthocyanidins with 3′,4′-dihydroxylated (catechins) and 3′,4′,5′-trihydroxylated (gallocatechins) ring B, respectively (Fig. 57.5) [10]. The names procyanidin and prodelphinidin result from the fact that these compounds are decomposed by heat in a strong mineral acidic medium, leading to the formation of cyanidin and delphinidin, respectively, according to the mechanism proposed by Bate-Smith [13].

Dimeric and trimeric PAs are divided in different groups according to the kind of interflavanic bond that is present between each monomeric unit. Each group is identified with a letter A, B, C, or D and a number that identifies the different isomers between each group with same type of interflavanic bond [73, 74].

B-type dimeric PAs (Fig. 57.6) result from the condensation of two flavan-3-ol molecules where the upper unit is linked through carbon C-4 to the carbon C-8 or C6 of the lower unit [74]. In PCs and PDs, the C-4 → C-8 interflavanic bond is *trans* regarding to the hydroxyl group at carbon C3 [75].

In A-type dimeric PAs, in addition to the C-4 → C-8 or C-4 → C-6 linkage, there is an additional ether linkage between the carbon C2 of the upper unit and the hydroxyl group in carbon C-5 or C-7 of the lower unit (Fig. 57.7).

Trimeric PAs can also be divided in two groups: C-type PAs that present two B-type linkages and D-type PAs that present one B-type and one A-type linkage. Higher polymerized structures may have a very high number of isomeric forms due to the variety of the bond linkage types and also to the stereochemistry of the monomeric units. Oligomeric PAs have up to six monomeric units, and polymeric ones have more than six condensed units (Fig. 57.8) [71].

A nomenclature may also be adopted where the location of the interflavanic bond is represented within parentheses, and its orientation at C-4 is represented as α or β as in the IUPAC rules. For example, procyanidin B1 can also be represented as (−)-epicatechin-(4β → 8)-(+)-catechin (Fig. 57.5).

3 Biosynthesis

The two key flavonoid biosynthetic precursors are phenylalanine derived from the shikimate pathway and malonyl-CoA obtained from citrate that is produced by the tricarboxylic acid cycle (Fig. 57.9). Phenylalanine is converted into 4-coumaroyl-CoA through the action of several enzymes such as PAL (phenylalanine ammonia lyase) [76], C4H (cinnamate 4-hydroxylase) [77], and 4CL (4-coumarate:CoA ligase) [78]. Then, the first precursor in the PAs biosynthesis and in all flavonoids biosynthesis – naringenin chalcone – is formed from the condensation and subsequent intramolecular cyclization of three malonyl-CoA molecules with one hydroxycinnamic acid-CoA (HCA-CoA) ester, usually 4-coumaroyl-CoA catalyzed by the enzyme CHS (chalcone synthase) [79]. Then, naringenin chalcone is isomerized to naringenin flavone. Although this isomerization can occur spontaneously, it was demonstrated that the presence of CHI (chalcone isomerase) stereospecifically directs and accelerates the intramolecular cyclization of the chalcone to form the (2*S*)-flavanone naringenin through an acid catalysis mechanism [80, 81]. F3′H (flavonoid 3′-hydroxylase) and F3′,5′H (flavonoid 3′,5′-hydroxylase) catalyze the formation of the 3′-hydroxyl (eriodictyol) and 3′,5′-hydroxyl (pentahydroxyflavanone) groups in ring B of naringenin, respectively [82, 83]. By this way, these enzymes determine the B-ring hydroxylation pattern of flavan-3-ols and consequently of PA molecules. Additionally, (2*S*)-flavanones are stereospecifically converted to (2*R*,3*R*)-dihydroflavonols (dihydrokaempferol, dihydroquercetin, and dihydromyricetin) by the enzyme flavanone 3β-hydroxylase (F3H) [84, 85]. The dihydrokaempferol (dihydroflavonol) can also be substrate for the enzymes F3′H and F3′,5′H, leading to the formation of dihydroquercetin and dihydromyricetin, respectively [82, 83]. After this, (2*R*,3*R*)-dihydroflavonols are stereospecifically reduced by DFR (dihydroflavonol 4-reductase), giving rise to the respective leucoanthocyanidins ((2*R*,3*S*,4*S*)-flavan-2,3-*trans*-3,4-*cis*-diols) or flavan-3,4-diols (leucopelargonidin, leucocyanidin, and leucodelphinidin) [85, 86]. Anthocyanin synthase (ANS), also known as leucoanthocyanidin dioxygenase (LDOX), plays an important role not only in the anthocyanins biosynthesis but also in that of PAs [87]. Its function is to catalyze the oxidation of leucoanthocyanidins to anthocyanidins (pelargonidin, cyanidin, and delphinidin) [88]. The final step in the formation of the 2*R*,3*R*-*cis*-flavan-3-ols ((−)-epiafzelechin, (−)-epicatechin, and (−)-epigallocatechin) involves the reduction of anthocyanidins (or the pseudobase form) catalyzed by ANR (anthocyanidin reductase) enzyme [89]. Through another pathway, leucoanthocyanidins can also be substrate for the enzyme LAR (leucoanthocyanidin reductase) that removes the 4-hydroxyl group from leucoanthocyanidins to produce the respective 2*R*,3*S*-*trans*-flavan-3-ols such as (+)-afzelechin, (+)-catechin, and (+)-gallocatechin [90, 91].

The shikimate pathway is also important in the formation of other molecules such as gallic acid [92] that is essential for the synthesis of galloylated PAs, which are the major PAs found in numerous plants, for instance, in tea (*Camellia sinensis*) and grapes (*Vitis vinifera*) [93, 94]. Nevertheless, the galloylation mechanism in PAs remains unknown.

Flavanol biosynthesis occurs in the cytoplasm where all the enzymatic machinery is mostly present [95]. Although PAs are mainly found in the cell vacuoles [96–100], they can also be found bound to proteins of the internal face of the tonoplast or bound to cell wall polysaccharides [100–103]. So, it is important to understand the

Fig. 57.9 General flavonoid biosynthetic pathway leading to the formation of flavan-3-ols and proanthocyanindins

flavan-3-ol polymerization that seems to occur also in the vacuole and the transport of the PA precursors from the cytoplasm to the vacuole [104–106].

Pang et al. [107] demonstrated that in the early stages of seed development in *M. truncatula*, it is possible to detect the presence of epicatechin-3-*O*-glucoside (E3G) that is thought to be the vacuolar transport of epicatechin. However, its fate inside the vacuole is still not known. The levels of E3G decrease to zero with the increase of the PA content, which suggests that hydrolysis occurs and that epicatechin is incorporated in the PA polymer. The exact nature of the molecular species that undergo polymerization and the mechanism of assembly in PAs is still unknown [94]. However, there are a few hypotheses trying to explain how this may occur, but all the models stated until now seem to fail at some point.

Most studies point to a nonenzymatic pathway for the polymerization of PAs involving the condensation of the molecules through the electrophilic attack of the carbon C-4 from the pyranic ring C of an extension unit (leucoanthocyanidin) to a nucleophilic carbon C-8 or C-6 of a terminal unit (flavan-3-ol) [76, 90, 91, 108, 109]. Polymerization continues with the electrophilic attack of carbon C-4 of a flavan-3,4-diol to the carbon C-8 or C-6 from the dimer previously formed. However, this hypothesis fails in the fact that the majority of extension units in PAs found in *planta* are 2,3-*cis* and leucoanthocyanidins are 2,3-*trans* [86]. Thus, it was proposed that a leucoanthocyanidin derivative must be involved in the polymerization mechanism, such as quinone methides and carbocation products. Another proposal comprises the conversion of the 2*R*,3*S*,4*S*-leucoanthocyanidins into 2*R*,3*S*-quinone methides that can be directly used as extension units. These compounds can also be converted in 2*R*,3*R*-quinone methides via flavan-3-en-3-ol that can be further used as extension units [110]. In another pathway, the 2*R*,3*S* and 2*R*,3*R*-quinone methides can be transformed in the respective carbocations and attack (+)-catechin or (−)-epicatechin, leading to the formation of the diverse PA molecules (Fig. 57.10).

An enzymatic approach for the polymerization of PAs includes the conversion of flavan-3-ols ((+)-catechin and (−)-epicatechin) to the corresponding quinone methide catalyzed by the enzyme PPO (polyphenol oxidase). These quinone methide could be converted in the corresponding carbocations with flavan-3-en-3-ol as intermediate or reduced to the carbocation through coupled nonenzymatic oxidation. These carbocation products might be used as direct extension units. Since PPO is mainly present in chloroplasts and PAs synthesis occur in the vacuoles [111], another form of PPO has to exist with an alternative localization [112] in order to the enzymatic pathway for the polymerization of PAs be possible. Nevertheless, polymerization of flavan-3-ols mediated by PPO did not give rise to PAs with a natural structure but oligomers composed by oxidized flavan-3-ols with specific configurations [113].

4 Occurrence

Flavanols are present in nature in a great diversity of plants. However, the data available in the literature about their concentrations in plants and foodstuffs regard

mainly flavanols in general and not specially to the PAs as these are difficult to extract and hence hard to quantify. PA oligomers and polymers are present in food extracts as complex mixtures, which makes their separation very difficult. By using reverse phase HPLC, the presence of many isomers yields in overlapping retention times of different PAs, being the separation of higher oligomers (DP > 4) and polymers not possible [114, 115]. The acid-catalyzed depolymerization of PAs in the presence of a nucleophilic agent such as phloroglucinol or benzyl mercaptan converts the flavan-3-ol extension units into the respective phloroglucinol adducts or thioesters, respectively, and the flavan-3-ol terminal units are released [116]. This allows the determination of the proportion of the constitutive units of the PAs present and also the estimation of the mean degree of polymerization (mDP). However, this method does not allow the determination of the proportion of individual PAs. Using normal-phase HPLC, it is possible to separate PA oligomers according to their degree of polymerization up to 10 [117, 118]. It is also possible to obtain a single group of PAs with DP $>$ 10 using a sharp gradient elution at the end of the HPLC run [117]. The extraction of PAs in their native form is most of the times very difficult as they have the tendency to form strong complexes with the insoluble polymeric plant material such as cell wall polysaccharides [115, 119–121]. Hence, the total PA content is most of the times underestimated if only the extractable PAs are quantified. There are a few studies combining normal phase and reverse phase HPLC to determine the extractable and unextractable PAs, respectively [122, 123]. Table 57.1 shows the content of PAs of several food products according to the degree of polymerization [61]. According to this data, in almost all food products, the main fraction of PAs refers to the most polymerized one (DP $>$ 10).

During fruit ripening, the amount of flavan-3-ols and proanthocyanidins of some fruits was described to decrease sharply from the early stages of development where they are present at the highest concentration until the harvest period where they stay constant. This drop in flavanol concentration affects more flavan-3-ol monomers than the proanthocyanidin dimers [124–130]. On the other hand, it appears that the mean degree of polymerization changes during fruit ripening, but the increase or decrease depends on the type of fruit [124, 127, 131–134]. For example, in grape seeds, the mDP seems to decrease and in grape skins to increase during ripening [131].

Tables 57.2 and 57.3 show the contents in flavan-3-ol monomers, as well as dimeric and trimeric PAs of several different sources of plants and foodstuffs determined by chromatographic techniques. There is a great divergence between the values obtained for a given product by the different authors, and this may be due to the method used in the extraction and quantification or may be owned to the intrinsic variability of the sample that includes the variety, stage of ripeness, and processing into foodstuff. From Table 57.2, it is possible to observe that (+)-catechin and (−)-epicatechin are the flavan-3-ol monomeric units more abundant in all the food products and that the 3-*O*-galloylated forms such as (+)-catechin-3-*O*-gallate, (+)-gallocatechin-3-*O*-gallate, (−)-epicatechin-3-*O*-gallate, and (−)-epigallocatechin-3-*O*-gallate are mainly present in green, oolong, and black teas. With respect to dimeric PAs (Table 57.3), it seems that B1, B2, B3, and B4 are the most abundant dimers in all the food products analyzed.

5 Proanthocyanidin-Protein Interaction

The term “tannins” also attributed to proanthocyanidins (condensed tannins) was defined by Bate-Smith and Swain in 1962 as “water soluble phenolic compounds having molecular weights between 500 and 3,000 Da and, besides giving the usual phenolic reactions, they have special properties such as the ability to precipitate alkaloids, gelatine and other proteins.” Tannins have been widely employed in the tanning process converting hide collagen in leather [292].

The interaction between tannins and proteins has been described by many authors as a result from the cross-linking between the tannins and the proteins involving different kinds of bonds that include (1) hydrogen bonds between the hydroxyl groups of the tannin and the carbonyl group and amine groups of the protein [11, 134, 218–221], (2) Van der Waals interactions between the hydrophobic benzene ring of the phenolic compounds and the apolar amino acid side chains [222–227], (3) ionic bonds between the phenolate anions and cationic sites of proteins [218, 228], and (4) covalent bonds resulting from the reaction of the nucleophilic groups of proteins such as $-NH_2$ and $-SH$ and quinone groups resulting from phenolic oxidation [218, 229, 230] or carbocations resulting from acid-catalyzed condensed tannins depolymerization [231].

In a food context, the astringency sensation is one of the main characteristics associated to tannin-rich foods and is thought to result from the interaction between tannins and salivary proteins leading to the formation of protein-tannin aggregates in the mouth [232–234]. This feature leads to the diminution of the oral lubrication that is usually described as dryness, puckering, and rough mouthfeel [13]. In the case of astringency, only mechanisms (1) and (2) described above are thought to be involved in the tannin-protein interactions at slightly acid or neutral pH (Fig. 57.11).

All the referred interactions between the phenolic compounds and proteins are strongly influenced by the phenolic structural features including the degree of hydroxylation, size, and conformation. Generally, the affinity of tannins for proteins increases with the molecular weight (MW) and degree of galloylation due to the increase of the number of sites of interaction. It was demonstrated that grape seed PCs with high MW (mDP $\sim$ 6) interacted and precipitated human salivary proteins more readily than smaller PCs [235]. Similar studies with BSA (bovine serum albumin) and α-amylase showed that the binding affinity increases with the size of PCs up to MW $\sim$ 2,000 Da (mDP $\sim$ 6) [236]. However, the affinity to different model proteins of higher MW PCs (>3,400 Da) from grape seeds has shown to decrease, probably due to their lack of flexibility [237]. It has also been demonstrated that small differences in the PCs structure such as the configuration of the carbon C-3 or the hydroxylation pattern of the ring B could also result in different affinities with proteins. Epicatechin has shown a lower tannin specific activity for human proline-rich proteins (PRPs) than catechin [238]. Also, flavan-3-ols with at least one 1,2,3-trihydroxylated ring ((+)-gallocatechin, (−)-catechin-3-*O*-gallate, (−)-gallocatechin-3-*O*-gallate, and (−)-epigallocatechin-3-*O*-gallate) revealed a higher affinity for proteins when compared with (+)-catechin and B2 dimer [239]. Studies performed in model solutions with C-4 → C-8 dimers B3 and B4 have shown that they present a greater affinity to human PRPs when compared with their C-4 → C-6 dimers (B6 and B8) counterparts, which can be due to conformational constraints presented by the C-4 → C-6 interflavonoid linkage [240]. Different results were obtained by Ricardo da Silva and colleagues when measuring the PC dimers concentrations in wine model solutions of grape seed procyanidins after fining

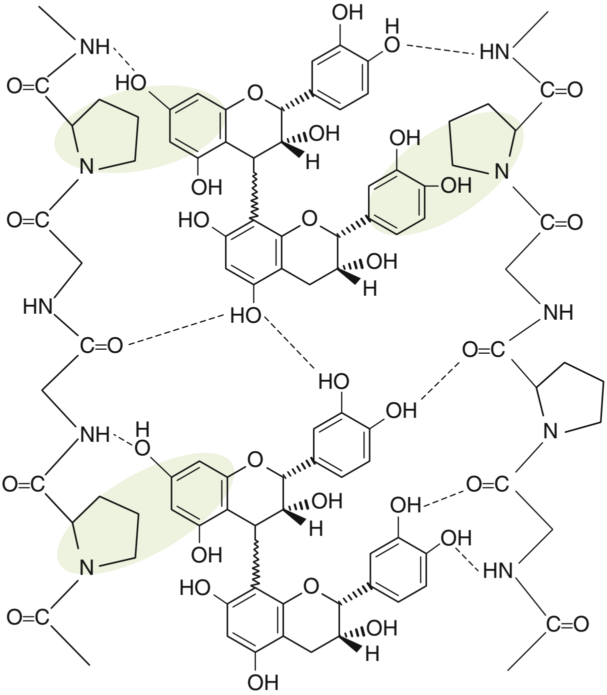

Fig. 57.11 Proanthocyanidin-protein interaction showing the hydrogen bonds and Van der Waals hydrophobic interaction between the benzene ring of the phenolic compounds and the apolar amino acid side chains

treatment with different proteins. In that study, the C-4 → C-6 dimers were found to bind more efficiently with proteins than the C-4 → C-8 dimers [241].

6 Copigmentation

Copigmentation is a phenomenon that occurs in solution when colored compounds (anthocyanins) form molecular associations or complexes with noncolored compounds, such as catechins and proanthocyanidins, phenolic acids, flavonols among others. These kinds of associations usually lead to the increase of the solution absorbance intensity (hyperchromism) and a positive displacement in the visible wavelength (λ_{max}) of the pigment (bathochromism). Intermolecular copigmentation generally occurs in berries and berry-derived products. Copigmentation occurs due to the formation of a vertical hydrophobic stacking between the aromatic core of the anthocyanin and the phenolic copigment strengthened by hydrogen bonds [242, 243] (Fig. 57.12). In aqueous solution, this complex prevent the nucleophilic attack of water to the colored flavylium structure of anthocyanin and therefore reduce the

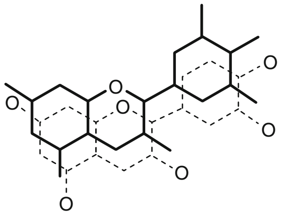

Fig. 57.12 Schematic representation of the intermolecular copigmentation between anthocyanins and flavonoids. (—), anthocyanin; (--), flavonoids [170]

color fade [71]. The extent of the copigmentation is directly related to the anthocyanidin and copigment structures.

Hydrophobic effects are thought to position the anthocyanin chromophore and the copigment to form a π-π complex [244], and by this way, the most efficient overlap would occur with planar flavonols when compared with hydroxycinnamoyl, galloyl esters, or with the nonplanar flavan-3-ols [245]. Usually, it is thought that the flavylium ion is the major colored species that contributes to the copigmentation phenomenon [244, 246]. However, some authors have suggested that the neutral quinoidal base is the main species involved [247, 248].

Although copigmentation is very important in nature, being responsible for the extraordinary colors observed in many flowers [71, 247, 249–251], the role of proanthocyanidins as copigments is almost exclusive of red wines [14, 15, 18, 252, 253].

7 Chemical Transformations

During food processing and conservation, flavanols can undergo several chemical reactions. These chemical transformations have been deeply studied in wine and tea [254–258].

According to the procedure of the manufacture of teas, it is possible to obtain three different kinds of teas: green tea that is unfermented, oolong tea that is partially fermented, and black tea that is fully fermented. Young green leaves of the tea plant (*Camellia sinensis* var. *sinensis*, *Camellia sinensis* var. *assamica*) contain high concentrations of flavanol monomers such as (−)-epicatechin, (−)-epigallocatechin, (−)-epicatechin gallate, and (−)-epigallocatechin gallate [259]. Throughout the fermentation process, browning reactions occur induced by oxidative enzymes. Through oxidative transformation by polyphenol oxidase (PPO), flavanols originally present in green tea give rise mainly to dimeric theaflavins that present an orange-red color and red-brown oligo/polymeric thearubigins that are found in black tea [254, 255, 257, 258] (Fig. 57.13). Minor compounds such as the dimeric theasinensins were also found to occur [260, 261] (Fig. 57.13). Although thearubigins account for about 60% of the solids in a black tea infusion, their chemical structure is the least well understood as well as their formation mechanism. Figure 57.13 shows a hypothetic structure for thearubigins [254].

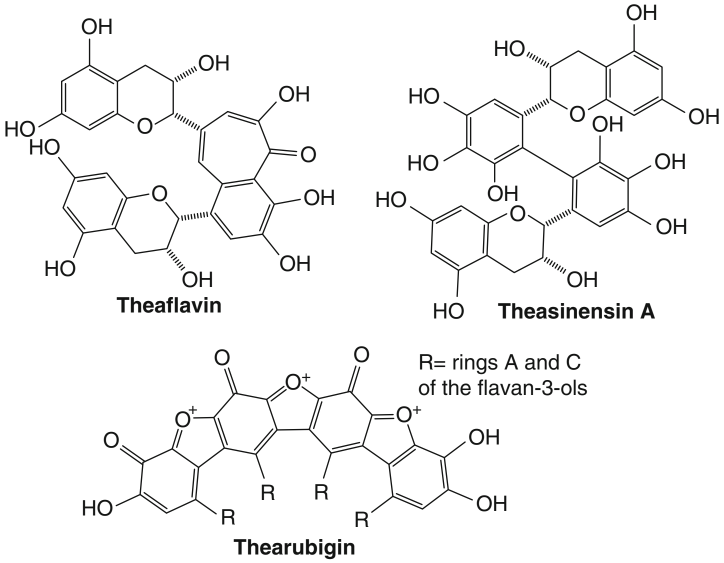

Fig. 57.13 Structures of the main tannin-like compounds found in black tea. The structure of thearubigin is hypothetic [180]

In wine, flavanols may also be transformed by oxidation through two different mechanisms: the enzymatic and the nonenzymatic browning [256]. The enzymatic browning occurs almost entirely in grape must. On the other hand, nonenzymatic browning happens both in must and wine. Phenolic compounds are considered the major substances at the origin of wine browning [262, 263], and the oxidation of phenols is dependent on the phenolic composition and their levels, being the *o*-diphenols the most oxidizable ones [264, 265].

In enzymatic browning, flavanols (*o*-diphenols) are firstly oxidized by PPO in the presence of oxygen to *o*-quinones. Then, a rapid coupled oxidation of the quinones with other phenolic molecules occur, leading to the formation of dimers or the regeneration of the original phenols that are catalyzed by acid. The quinones produced can also be polymerized with many other compounds (phenolic and non-phenolic molecules) forming brown pigments [113, 266] (Fig. 57.14). Like in enzymatic browning, in the nonenzymatic browning, also called chemical oxidation, *o*-diphenols such as caffeic acid, catechin, epicatechin, or cyanidin are considered the most susceptible compounds toward oxidation. Moreover, the levels of flavanols have been well correlated with the browning degree of white wines [267, 268]. In the chemical oxidation, the presence of iron and copper can catalyze the oxidation of phenols, leading to the formation of quinones that are further polymerized in a similar way to what happens in the enzymatic browning [269, 270].

Other routes for the polymerization of flavan-3-ols involve the presence of acetaldehyde and glyoxylic acid [25, 271–275]. Acetaldehyde and glyoxylic acid are present in wine due to the oxidation catalyzed by metals of ethanol and tartaric

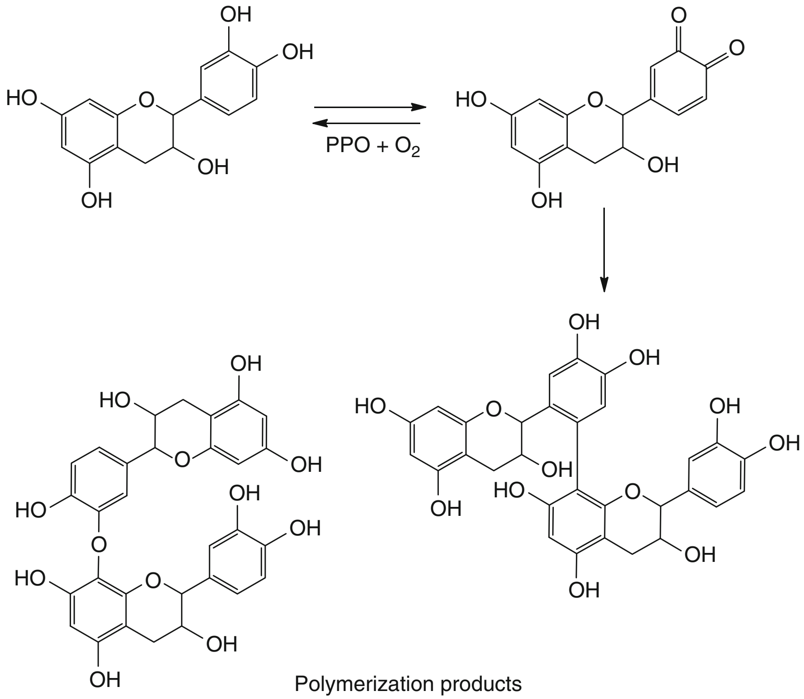

Fig. 57.14 Enzymatic browning products obtained in the oxidation of flavan-3-ols by PPO [113]

acid, respectively. Acetaldehyde can also be derived from the metabolism of yeast during fermentation. Flavanols in acidic medium can undergo electrophilic substitution by acetaldehyde on the electronegative positions C-6 or C-8 of ring A, leading to the formation of dimers and trimers (Fig. 57.15) according to the mechanism first proposed by Timberlake and Bridle [25] and later confirmed by other authors [272, 276].

It was demonstrated by Fulcrand et al. [277] that the glyoxylic acid formed in wine through the oxidation of tartaric acid could react with flavanols in a similar mechanism than that described for acetaldehyde, forming a colorless catechin-8,8-carboxymethine-catechin compound. Further transformation gives rise to the formation of a yellow xanthylium cation (Fig. 57.16) [259]. Also, a lactone structure was proposed from the cyclization of the carboxymethine group with the hydroxyl group of the phloroglucinol ring of the upper flavanol unit (Fig. 57.12) [278]. Similar xanthylium compounds were also identified from the reaction of flavanols with furfural and hydroxymethylfurfural (HMF) [279, 280].

Flavanols were also shown to react with cinnamic aldehydes like coniferaldehyde or sinapaldehyde, leading to the formation of colored (orange color) compounds with a catechinpyrylium structure (Fig. 57.17) [281, 282]. These compounds were named oaklins since they were found in wines aged in oak from which cinnamic aldehydes were extracted.

In red wines, flavanols may also react directly with anthocyanins, leading to the formation of anthocyanin-flavanol and flavanol-anthocyanin adducts [283–285]. The condensation may also occur mediated by aldehydes, such as acetaldehyde, furfural, HMF, benzaldehyde, and others, leading to the formation of alkyl-methine bridged adducts. These latter display the same λ_{max} in the visible region at around 540 nm, which is bathochromically shifted when compared with the original anthocyanin ($\lambda_{max} \sim 525$ nm) [279, 280, 286–289], thereby contributing to the color change in red wine.

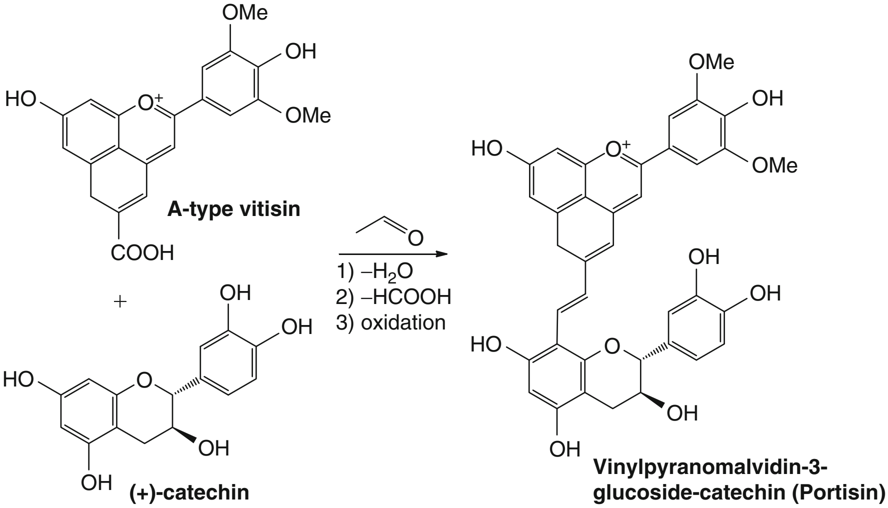

Fig. 57.18 Formation of vinylpyranomalvidin-3-glucoside-catechin (portisin) from the reaction of carboxypyranomalvidin-3-glucoside (A-type vitisin) and (+)-catechin in the presence of acetaldehyde

More recently, a new family of anthocyanin-derived compounds (named portisins) has been detected in Port wine and found to display unusual spectroscopic features, presenting a bluish color at acidic conditions [290] (Fig. 57.18). Studies performed in wine model solution revealed that these pigments are formed from the reaction of carboxypyranoanthocyanins with flavanols mediated by acetaldehyde [290, 291].

8 Conclusion

In the literature, there are a large number of different flavanols found in many different plants worldwide. Their structures differ from each other in the stereochemistry of the asymmetric carbons, the hydroxylation pattern of the aromatic rings, type and number of ester-linked substituents (e.g., methyl, glucosyl derivatives) or ester-linked substituents (e.g., phenolic acid derivatives), degree of polymerization, etc.

These natural compounds are of particular relevance due to their biological activities that contribute to the therapeutic properties attributed to some plants, especially those highlighted since many years ago by the traditional Chinese medicine. These features make flavanols a particular target of the pharmaceutical industry. Besides this, flavanols are also responsible for some antioxidant and sensorial properties presented in fruits and fruit-derived products. The astringency sensation is one of those properties resulting from the interaction between flavanols and salivary proteins in the oral cavity. On the other hand, flavanols can also contribute to the color of anthocyanin-rich foodstuffs, through their association with anthocyanins (copigmentation phenomenon) enhancing the overall color and by their chemical reaction with anthocyanins leading to the formation of new colored compounds with different spectroscopic features. Although there are already several works demonstrating the importance of flavanols in different fields, more research involving their structural characterization and food sensorial and bioactivity properties is expected in the forthcoming years.

Abstract

Anthocyanins are a group of plant phenolics characterized by their blue-orange-red color. They have a double interest as plant constituents, one technological, since they can not only be used as natural colorants in the food industry but also can interact with other plant components influencing the final characteristics of the processed product, and the other is related to their implications on human health as they can be considered functional ingredients and have shown themselves as potential targets for the pharmacological industry.

This chapter summarizes the existing literature in this area: from anthocyanin occurrence and phytochemistry to their biosynthesis, biological activities, and an overview of the biotechnological approaches that are in use at present.

Keywords

Anthocyanins • occurrence • biological activity

Abbreviations

AATs	Anthocyanin acyltransferases
ACE	Angiotensin-converting enzyme
CHS	Chalcone synthase
DFR	Dihydroflavonol 4-reductase
F3′H	Flavonoid 3′-hydroxylase
FLS	Flavonol synthase
MCP-1	Monocyte chemoattractant protein 1
ROS	Reactive oxygen species
TNF-α	Tumor necrosis factor-α
TRAP	Thrombin receptor-activating peptide
VEGF	Vascular endothelial growth factor

1 Introduction

The term anthocyanin is derived from the Greek words *anthos*, meaning flower, and *kyanos*, meaning blue. Anthocyanins, the largest group of water-soluble natural pigments, are widely distributed among plants. They are responsible for the attractive colors of flowers, fruits (particularly berries), and vegetables and thereby add to the aesthetic quality of products derived from many plant sources. These polyphenolic substances are glycosides of polyhydroxy and polymethoxy derivatives of 2-phenylbenzopyrylium or flavylium salts. Glycosylation and acylation of the aglycone moieties (mainly six anthocyanidins: pelargonidin, cyanidin, peonidin, delphinidin, petunidin, and malvidin) by different sugars and acids, at different positions, account for the broad structural diversity of these pigments (Fig. 58.1). The sugars most commonly bonded to anthocyanins are glucose, galactose, rhamnose, and arabidose. Di- and

OCH_3	OCH_3	Malvidin

Fig. 58.1 General structure of anthocyanidins and substitution of the most commonly found in foods

trisaccharides, formed by combination of these four monosaccharides can also glycosylate anthocyanins. The most common acids, bonded to the sugar residue, are *p*-coumaric, caffeic, ferulic, synaptic, *p*-hydroxybenzoic, malonic, oxalic, malic, succinic, and citric acid [1].

In plants, anthocyanins play a role in attracting animals in pollination and seed dispersal; they may also enhance plant resistance to insect attack [2], act as endogenous plant antioxidants and as photoprotectors [3]. Available evidence also suggests that this group of phytochemicals, besides being nontoxic and nonmutagenic, could exhibit multiple biological effects, such as antioxidant-antiradical activity, anti-inflammatory action, inhibition of blood platelet aggregation, and antimicrobial activity, and could be used in the treatment of diabetic retinopathy and prevention of cholesterol-induced atherosclerosis [1, 4–6].

Anthocyanins are rather unstable compounds, and this has to be considered when trying to isolate or use them as part of more complex formulations. A number of factors influence anthocyanin stability, including pH, heat-humidity, light, oxygen, enzymes as well as the presence of ascorbic acid, sugars, sulfur dioxide or sulfite salts, metal ions, and copigments [7, 8]. A major impediment to the use of anthocyanins as food colorants is their inherent instability, whether in cellular juice or in aqueous model solutions and especially in complex systems such as foods. In actual food products, anthocyanins show greater stability under acidic conditions, but are generally unstable under normal processing and storage conditions, and easily degrade to form first colorless derivatives and subsequently insoluble brown pigments.

It is known that hydroxylation of the basic nucleus at position 5 or 7 tends to stabilize the molecule, whereas hydroxylation at position 3 renders it more labile. Similarly, hydroxy substitution in the B ring leads to low stability but this is overcome if the groups are methoxyl rather than hydroxyl. The substitution of hydroxyl groups by sugars or acyl groups also increases stability. Timberlake and Bridle [9] found that substitution of the anthocyanin at position 4 (not normally substituted) with methyl or phenyl groups conferred stability to the molecule.

Copigmentation is a phenomenon widely seen in plant tissues and their extracts, which influences the color and functional properties of this group of phenolics.

Molecules acting as copigments, such as flavonoids, alkaloids, and organic acids, usually have no color by themselves, but when added to an anthocyanin solution, they greatly enhance the color of the solution [10]. Results obtained by Maccarone et al. [11, 12] and Teh and Francis [13], working with model systems and fruit juices, supported the hypothesis that the phenomena of copigmentation and self-association can influence color, intensity, and stability of anthocyanins. Several studies which have dealt with encapsulated anthocyanins [14, 15] led to the conclusion that encapsulation significantly reduces the degradation rate of the core material and thereby improves the shelf life of the colorant at different humidity environments.

2 Occurrence

Anthocyanins are present in different plant organs, such as fruits, flowers, stems, leaves, and roots [16]. These pigments are normally found dissolved uniformly in the vacuolar solution of epidermal cells. However, in certain species, the anthocyanins are localized in discrete regions of the cell vacuole, called anthocyanoplasts [17]. The main sources of anthocyanin (Table 58.1) are red fruits, mainly berries and red grapes; cereals, principally purple maize and red-purple; and vegetables such as eggplant [6, 18].

In general, cyanidin and its glycosides are the anthocyanins most frequently found in fruits. This is the case of cherry, apple, figs, or peach. Grapes, for example, are characterized by the presence of, in some varieties, derivatives of the six most frequent anthocyanins. However, in most winemaking varieties, malvidin-3-glucoside is the most abundant one. On the other hand, delphinidin is characteristic of pomegranate or eggplant.

Anthocyanin content may vary from fruit to fruit of the same type due to different external and internal factors, such as genetic and agronomic factors, intensity and type of light, temperature, processing, and storage. For example, anthocyanin concentrations in red grapes are specially variable, being able to reach values of up to 250 mg/100g, while in red wines, the concentrations vary in accordance with the varieties of grapes employed as well as with the type of vinification and, specially, with aging. However, a medium value could be established of around 500 mg/L anthocyanins in young wines. Moreover, it is

Table 58.1 Classification of plant products based on their anthocyanin contents

High anthocyanin content products (>100 mg in 100 g)	Bilberry, black currant, black olives, black rice, blackberry, blueberry, cherry, chokeberry, elderberry, red grapes, pomegranate, purple corn, raspberry, red cabbage
Medium anthocyanin content products (>10 mg <100 mg)	Apple (red varieties), black bean, cranberry, eggplant, gooseberry, plum, red currant, red onion, red radish, rhubarb, strawberry
Low anthocyanin content products (<10 mg)	Grapefruit, lettuce, nectarine, peach, pear, strawberry

important to note that anthocyanins are used as food additives in beverages, fruit fillings, snacks, and dairy products.

The glycosides of the three non-methylated anthocyanidins (delphinidin, cyanidin, and pelargonidin) are the most abundant in nature, which represent 80% of leaf pigments, 69% in fruits, and 50% in flowers. The distribution of the six most common anthocyanidins in the edible parts of plants is cyanidin (50%), pelargonidin (12%), peonidin (12%), delphinidin (12%), petunidin (7%), and malvidin (7%). The most widespread anthocyanin in most fruit is cyanidin-3-glucoside [19]. However, malvidin glycosides are the most characteristic anthocyanins in red grape and derived products (wine, juice, etc.) [1].

3 Phytochemistry

The basic structure of anthocyanins can be differentially substituted to produce a variety of structures with different colors and properties. Differences between individual anthocyanins are the number of hydroxyl groups in the molecule, the degree of methylation of the hydroxyl groups, the nature and number of sugars attached to the molecule and the position of the attachment, and the nature and number of aliphatic or aromatic acids attached to the sugars in the molecule.

As mentioned before, the most common anthocyanins are pelargonidin, cyanidin, peonidin, delphinidin, petunidin, and malvidin (Fig. 58.1). In nature, they are found mostly in their glycosylated forms, even if they have been also found in low amounts as their aglycons. One of the possible ways of classifying anthocyanins is based on the number of sugars linked to the basic anthocyanidin. In this way, we can talk of monosides, biosides, triosides, etc.

Since each anthocyanidin (aglycone) may be glycosylated and acylated by different sugars and acids, at different positions, the number of anthocyanins is 15–20 times greater than the number of anthocyanidins. The sugars most commonly bonded to the aglycones are glucose, galactose, rhamnose, and arabinose. The following four classes of anthocyanidin glycosides are the most common: 3-monosides, 3-biosides, 3,5-diglycosides, and 3,7-diglycosides. However, glycosylation of the 3′-, 4′-, and 5′-OH group has also been demonstrated. In many cases, the sugar residues are acylated by *p*-coumaric, caffeic, ferulic, synaptic, *p*-hydroxybenzoic, malonic, oxalic, malic, succinic or acetic acid. Methoxyl substituents are found at the 3′ and 5′ position and less frequently at positions 7 and 5.

However, all these changes are not sufficient to account for the large color variations attributed to anthocyanins in plants. These are in fact due to two types of mechanisms, namely, (1) conversion of the flavylium ions to secondary anthocyanins forms in aqueous media and (2) molecular interactions.

In aqueous media, most of the natural anthocyanins behave like pH indicators, being red at low pH, bluish at intermediate pH and colorless at high pH. It has been demonstrated that in acidic or neutral media, four anthocyanin structures exist in equilibrium: the flavylium cation (AH+), the quinoidal base, the carbinol pseudo base and the chalcone. In general, anthocyanins are present in the flavylium form at pH below 2, being the major form of anthocyanins the hemiacetal in equilibrium with the chalcone in the pH range 2–7, while the quinoidal base appears to be very unstable. But we can see the red color due to the presence of low amounts of this form at that pH.

At the plants' pH values (3–7), anthocyanins are mostly present as colorless structures. But a stabilizing mechanism takes place. Such effects are provided by complexation of the color form with other species present in the solution, which can be either an identical anthocyanin molecule (self-association), one of its aromatic acyl groups substituents (intramolecular copigmentation) or another molecule (intermolecular copigmentation).

Color of anthocyanins-containing media depends on the structure and concentration, of the pigment, pH, temperature, presence of ascorbic acid, copigments, metallic ions, enzymes, oxygen, sugars and their degradation products, sulfur dioxide, and other factors.

Anthocyanins are considered to be poor substrates for the enzymes responsible of other flavonoids degradation, such as polyphenol oxidase, peroxidases, glycolases, and esterases. Nevertheless, some papers in the literature confirm their direct degradation by some of them. But we cannot forget that even if the enzymes do not react directly with the anthocyanin, they can react with the quinones formed during anthocyanin degradation in a food process, and this could give a change in color.

Antioxidants, such as ascorbic acid or sulfites, often added to prevent enzymatic degradation, have been shown to decolorize anthocyanins.

Reactions of anthocyanins have been especially investigated in red wines and related model systems. In fact, the progressive change from the red-purple to tawny as the wine ages is believed to be due to conversion of grape anthocyanins to more stable polymeric forms, where a reaction with, for example, acetaldehyde is the first step leading the reaction.

Nevertheless, it has also been demonstrated that the anthocyanins with a methyl or phenyl group in C4 are much more stable, even more than some synthetic colorants.

However, some anthocyanin extracts (such as elderberry extract) are frequently used by the industry for coloring jams, juices, ice lollies, or candies.

Anthocyanin analysis generally involves extraction with weakly acidified alcoholic solvent, followed by concentration under vacuum and purification and separation of the pigments, while the whole extract is used for coloring foodstuffs.

4 Biosynthesis

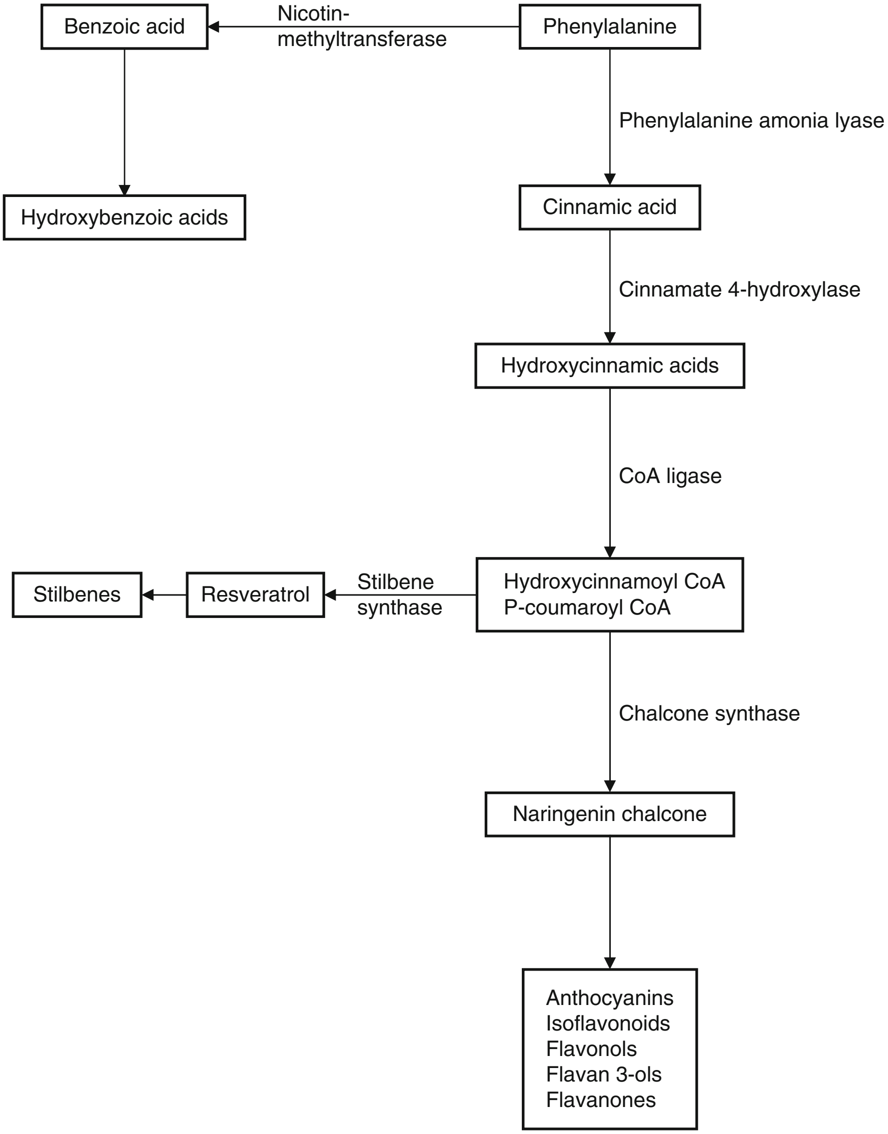
The amino acid phenylalanine is derived from gallic acid, being this compound biosynthesized in the shikimic acid metabolic route. Most of the phenolic compounds from higher plants are also derived from this amino acid, formed in the phenylpropanoid metabolic route, in the cell cytoplasm, being various enzymes involved in this metabolism. Phenylalanine ammonia lyase interacts with phenylalanine forming cinnamic acid, that is, hydrolyzed by cinnamate-4-hydroxylase, rendering *p*-coumaric acid. Different hydroxylations and/or methoxylations, of this acid, would end in hydroxycinnamic acids or *p*-coumaroyl CoA, if the third key enzyme of this route, CoA ligase, is involved. This is a very complex biosynthetic route, in which very similar compounds are synthesized in different types of cells and in different development stages, implying very complex regulation mechanisms. Nevertheless, this route key regulation control point is located in those steps where the enzymes phenylalanine ammonia-lyase, cinnamate-4-hydroxylase, and CoA ligase interact. These three enzymes are well characterized due to their importance in the secondary metabolism, and their biosynthesis seems to be regulated by a multigenic form [20]. Stilbenes, hydroxycinnamic acids, and flavonoids, including anthocyanins, derive from *p*-coumaroyl CoA. By the action of chalcone synthase (CHS), three acetate units from malonyl-CoA and one *p*-coumaroyl-CoA molecule can condense to produce naringenin chalcone. Chalcone isomerase (CHI) then catalyzes the stereospecific isomerization of the yellow-colored naringenin chalcone to the colorless naringenin which is converted to dihydrokaempferol by flavanone 3-hydroxylase (F3H). Dihydrokaempferol is also the potential substrate for flavonoid 3′-hydroxylase (F3′H) and flavonoid 3′,5′-hydroxylase (F3′5′H) to produce the corresponding colorless dihydroflavonols, dihydroquercetin, and dihydromyricetin, respectively. F3′,5′H can also convert dihydroquercetin to dihydromyricetin. Thereafter, dihydroflavonol 4-reductase (DFR) can reduce these dihydroflavonols to their corresponding leucoanthocyanidins. Anthocyanidin synthase (ANS), a 2-oxoglutarate iron-dependent oxygenase, catalyzes, with the help of ferrous iron, the oxidation of the colorless leucoanthocyanidins to their corresponding colored anthocyanidins (Fig. 58.2).

Anthocyanin modification typically involves *O*-glycosylation, *O*-acylation, and *O*-methylation. *O*-Glycosylation is the first modification to occur, and it is catalyzed by family 1 glycosyltransferases (UGTs) [21]. Glycosylation is an important modification for increasing the hydrophilicity and stability of anthocyanins and is also essential for their color stability. *O*-methylation occurs late in anthocyanin biosynthesis pathways to follow *O*-glycosylation of anthocyanidins. *O*-Acylation is an important modification because it plays an important role in the formation of pigment-stabilizing tertiary structures. Anthocyanin acyltransferases (AATs) catalyze transfer of either aromatic or aliphatic acyl groups from a CoA-donor molecule to hydroxyl residues of anthocyanin sugar moieties.

The phenylpropanoid biosynthetic route is induced by stress. In this way, the enzymes of phenylalanine ammonia-lyase and cinnamate-4-hydroxylase are induced at transcriptional level as a defense mechanism against different damages [22]. Specifically, anthocyanins are induced as a response to high levels of UV light [23]. Nutrient deficiencies, especially of phosphorus (P) and nitrogen (N), may also induce the accumulation of anthocyanin in many plant species [24].

5 Biological Activities

Many beneficial activities have been attributed to anthocyanins. Most of the first studies carried out in this sense in past were related to the antioxidant characteristics



Benzoic acid
Nicotin-methyltransferase
Phenylalanine
Phenylalanine amonia lyase
Hydroxybenzoic acids
Cinnamic acid
Cinnamate 4-hydroxylase
Hydroxycinnamic acids
CoA ligase
Stilbenes
Resveratrol
Stilbene synthase
Hydroxycinnamoyl CoA
P-coumaroyl CoA
Chalcone synthase
Naringenin chalcone
Anthocyanins
Isoflavonoids
Flavonols
Flavan 3-ols
Flavanones

Fig. 58.2 Anthocyanin biosynthesis pathway

of anthocyanin-rich diets and the enhancement of cardiovascular health. However, most of them were in vitro studies, and a few of them were carried out in vivo in general by measuring total antioxidant capacity in plasma after consumption of a source rich in anthocyanins.

Anthocyanins are able to prevent oxidative damage to DNA, proteins, lipids, and other macromolecules caused by reactive oxygen species (ROS). Anthocyanins have a systemic action, since they are absorbed and circulate in the blood, and it is in this circulating form that they act upon different target tissues in the human body. Anthocyanins may also act locally, in the gut, if they are not absorbed by intestinal mucosa. Finally, they may also act as topical agents, for example, by protecting the skin from UV radiation.

In the case of the gut, it is not yet clear if these local effects are caused by the original anthocyanin or by the metabolites formed by the colonic microflora. The formation of these degradation products may be involved in the protective action of anthocyanins against colon and rectum cancer. This is an area of research that is growing very recently due to the potential of this kind of the interaction bacteria-anthocyanin as an explanation for the final health effect encountered for this group of polyphenols.

So far, anthocyanins have been found in biological samples, either urine, feces, plasma, or different animal tissues, in different forms. They may be found in their original form, either as glycosides or as acylated compounds, but also as their corresponding glucuronides, sulfate derivatives, or methylated in different positions. They can also be found as their breakdown products such as gallic acid, protocatechuic acid, or other phenolic acids. This complicated scenario makes it difficult to discern between the effects encountered for anthocyanins and those derived from the ingestion of other groups of flavonoids or polyphenols since they may have common metabolites and thus common biological actions.

The biological activity of isolated anthocyanins and anthocyanidins or of anthocyanin-rich foods can be manifested at different levels.

5.1 Prevention of Cardiovascular Disease

This is possibly the most studied effect and the one for which a great quantity of epidemiological evidence exists. Anthocyanins are capable of acting on different cells involved in the development of atherosclerosis, one of the leading causes to cardiovascular dysfunction. The chemokine monocyte chemotactic protein-1 (MCP-1) is known to mediate in the recruitment of macrophages to sites of infection or inflammation, and direct involvement of MCP-1 on atherogenesis has been established. Anthocyanins have been shown to have a protective effect against TNF-α-induced MCP-1 secretion in primary human endothelial cells [25]. Vascular endothelial growth factor (VEGF) is a major pro-angiogenic and pro-atherosclerotic factor, but anthocyanins have been shown to prevent the expression of VEGF in vascular smooth muscle cells [26]. In macrophages, blackberry anthocyanins inhibit LPS-induced nitric oxide biosynthesis [27]. Anthocyanins also inhibit TRAP-induced platelet aggregation but do not influence platelet reactivity when faced with strong agonists such as collagen and ADP [28]. Anthocyanin extracts from chokeberry, bilberry, and elderberry have shown endothelium-dependent relaxation capacity in porcine coronary arteries [29]. Moreover, anthocyanins have an effect on cholesterol distribution, protecting endothelial cells from CD40-induced proinflammatory signaling [30].

A key factor in cardiovascular disease prevention is vasodilation. It has been shown that anthocyanins act at this level by inhibiting angiotensin-converting enzyme (ACE) activity [31]. Anthocyanins may also induce endothelium-dependent vasorelaxation by activating endothelial nitric oxide synthase and increasing the production of the vasorelaxant agent nitric oxide, and by decreasing endothelin-1 production [32]. Finally, a possible implication of estrogenic receptor agonist/antagonist effect of anthocyanins has been described as a possible mechanism for their antiatherogenic activity [31].

5.2 Anticancer, Antitumor, and Antimutagenic Activity

It has been suggested that anthocyanins possess anti-inflammatory as well as chemopreventive properties. Distinct cell growth- and cell cycle-related pathways have already been identified as targets for anthocyanins in in vitro and laboratory animal studies. It has been shown that the anthocyanin-containing fraction of red wines is capable of suppressing proliferation of HCT-15 human colon cancer cells and gastric adenocarcinoma (AGS) cells [33, 34]. Administering purple corn, with a high anthocyanin content, to rats decreases the incidence and multiplicity of colorectal adenomas and carcinomas induced by 1,2-dimethylhydrazine (DMH) and 2-amino-1-methyl-6-phenylimidazo(4,5-β)pyridine (PhIP) [35]. Liu et al. [36] have shown that the proliferation of human hepatocellular liver carcinoma cells (HepG2) is inhibited by raspberry extracts, containing among other flavonoids anthocyanins. Marko et al. [37] have reported an inhibitory effect of the anthocyanidins, delphinidin, cyanidin, petunidin, pelargonidin, peonidin, and malvidin on cell proliferation in human vulva carcinoma cells (A431) and human colon carcinoma cells (HT29). Moreover, the authors showed that depending on the substitution pattern of their B ring, anthocyanidins may interfere with different signaling cascades involved in the regulation of cell growth. It has been shown that cyanidin-3-glucoside as well as different anthocyanin-rich extracts induce apoptosis in different human leukemia cell lines [38].

Angiogenesis plays a critical role in the development of cancer. Liu et al. [39] have found that anthocyanins from black raspberry can reduce tumor development by inhibiting angiogenesis.

Mutagenicity is closely related to carcinogenicity. Juices from anthocyanin-rich fruits such as strawberry, blueberry, and raspberry significantly inhibited mutagenesis caused by the direct-acting mutagen methyl methanesulfonate and the metabolically activated carcinogen benzo(a)pyrene [40].

Another possible via for the protection against cancer is the inhibition of DNA damage. Sarma and Sharma [41] have observed that copigmentation between cyanidin derivatives and DNA has a protective effect on both molecules against the action of hydroxyl radicals generated by the Fenton reaction.

5.3 Beneficial Effects in Diabetes

Basically, anthocyanins may have a beneficial effect on diabetes at different levels. On one hand, they can interfere with glucose absorption and insulin secretion; on the other hand, they may have a protective effect on pancreatic cells. It has been shown that the simultaneous and daily administration to rats of anthocyanins from red wine together with streptozotocin, a diabetogenic compound with beta-cytotoxic effects, decreases glucose concentration in urine and serum. Additionally, anthocyanins from red wine prevent the generation of free oxygen radicals and decrease lipid peroxidation [19]. Jayaprakasam et al. [42] have shown that anthocyanins are also able to stimulate insulin secretion from rodent pancreatic beta-cells. It has been shown that cyanidin-3-glucoside and protocatechuic acid exert insulin-like activities by activation of peroxisome proliferator-activated receptor-γ (PPAR-γ), reveling a causal relationship between this transcription factor and adiponectin and GLUT4 upregulation [43]. Cyanidin-3-rutinoside has shown to retard the absorption of carbohydrates by inhibition of α-glucosidase [44].

5.4 Ocular Effects

Consumption of black currant-based extracts or concentrates of anthocyanins has a positive effect on night vision, i.e., dark adaptation, though the positive effect on human vision of *Vaccinium myrtillus* (bilberry) extracts is controversial and still needs to be clarified [45]. However, recent studies in animal models suggest that long-term supplementation with bilberry extracts is effective in the prevention of macular degeneration and cataract [46].

In subjects with myopia, it has been shown that the administration of anthocyanins for 4 weeks improved subjective symptoms and objective contrast sensitivity [47]. So far, several authors agree in the protective effect of anthocyanins against retinal damage via different mechanisms and using different experimental models. For instance, Liu et al. [48] have shown that the suppression of retinal damage by anthocyanins is mediated by protecting rod photoreceptor cells and improving the blood circulation of the retina under strong light conditions.

5.5 Antimicrobial and Antiviral Activity

Even though many studies have shown that isolated anthocyanins or plant extracts rich in this group of flavonoids have an effect on microbial growth, results are not yet conclusive. Puupponen-Pimia et al. [49] showed that extracts from different berries had an inhibitory effect on gram-negative bacterial growth, but had no effect on gram-negative bacteria. Moreover, they showed that black currant extracts stimulated the growth of different strains of *Lactobacillus rhamnosus* and *Lactobacillus paracasei* but inhibited those of *Escherichia coli*. Recent studies have demonstrated that black currant concentrates inhibit the growth of different strains of *Staphylococcus aureus*, *Escherichia coli*, and *Enterococcus faecium* but stimulate the growth of *Saccharomyces cerevisiae*.

The effect of anthocyanins on microbial pathogens has not been studied in depth up to now. Some few studies exist, however, on the effect of berry extracts on pathogens. Among the berries and bacteria assayed by Puupponen-Pimia et al. [49], cloudberry and raspberry were the best inhibitors, and *Staphylococcus* and *Salmonella* the most sensitive bacteria. In another study by Nohynek et al. [50], they showed that of all the pathogens assayed, the most sensitive bacteria to berry phenolics were *Helicobacter pylori* and *Bacillus cereus*.

Different cyanidin glycosides present in extracts of *Ribes nigrum* L. have shown antiviral properties toward influenza A and B viruses and herpes-1 virus [51, 52].

5.6 Effects on Neurodegenerative Processes

Joseph et al. have shown that anthocyanin-rich fruits may be beneficial in reversing the course of neuronal and behavioral aging. Moreover, by using transgenic mice as a model for Alzheimer's disease, Joseph et al. [53] have reported on the beneficial effect of blueberry extracts on the outcome of this neurodegenerative illness. It has been shown that cyanidin-3-glucoside may ameliorate ethanol-induced neuronal death in the developing brain reducing the ethanol-meditated caspase-3 activation, neurodegeneration, and microglial activation in the cerebral cortex [54].

6 Biotechnological Approaches

Biotechnological approaches, by introduction of genes encoding novel anthocyanin enzyme activities and transcription factors or inactivation of endogenous genes, have been used to modify flower color and plant coloration as well as to analyze the potential of the anthocyanin pathway in plant defense response. Several important structural genes and regulatory elements required for anthocyanin biosynthesis have been cloned and characterized in a variety of plant species over the past few years, including some with direct practical applications. With the generation of transgenic petunia plants using a DFR gene from maize, a novel flower color was created by genetic engineering for the first time [55]. DFR enables the production of pelargonidin in petunia and leads to a change in flower color from pale pink to brick red. Similar results have been observed in petunia by overexpressing heterologous DFR genes from rose [56]. An approach involving the co-suppression of the CHS gene has been used to prevent the formation of flower pigments in different plant species. By contrast, overexpression of the CHS gene has been used to reduce flower pigments in petunia and chrysanthemum. White and blue-white transgenic varieties of Torenia hybrida taken from the blue variety cv. Summer wave were obtained by co-suppressing the expression of both the CHS and DFR genes [57].

F3′H and F3′5′H, members of the cytochrome P450 family, play a key role in determining the pattern of anthocyanin; while F3′H is necessary for the synthesis of

3′-hydroxylated anthocyanins (e.g., cyanidin), F3′5′H participates in the synthesis of 3′5′-hydroxylated anthocyanins (e.g., delphinidin). Overexpression of F3′5′H produced purple to violet transgenic flower colors due to the induction of the synthesis of delphinidin derivatives [56], and a dramatic change of flower color from pink to magenta with a high content of 3,5′-hydroxylated anthocyanins was observed in petunia. However, transgenic torenia expressing F3′H cDNA exhibited redder flower color due to the increase in 3′-hydroxylated anthocyanins [58].

Another useful strategy for introducing or increasing anthocyanin production in target ornamental species is the alteration of the balance between flavonoid enzyme activities by genetic modification. The dihydroflavonols are the direct substrates for colorless flavonol and colored anthocyanin biosynthesis. Thus, the introduction of a DFR sense transgene in white-flowered lines of petunia, which accumulates flavonol, resulted in a pink-flowered phenotype. Furthermore, inhibition of flavonol biosynthesis by co-suppression of the flavonol synthase (FLS) also led to anthocyanin production and a pink-flowered phenotype [59]. In torenia, the inactivation of the DFR gene by genetic transformation caused the accumulation of flavones, possible copigments, resulting in a copigmentation likely to make the torenia flowers bluer [60].

Advances are also being made in understanding the action mechanisms of regulators in anthocyanin biosynthesis. A general role for the basic helix-loop-helix (bHLH) MYB- and WD40-repeat proteins as regulators of the anthocyanin pathway has been conserved in a wide variety of species [61]. The overexpression of the R gene, encoding a bHLH, from maize enhanced the expression of anthocyanins in *Arabidopsis*, petunia, tobacco, and *Caladium* bicolor [62]. Overexpression of bHLH from *Antirrhinum* and *Perilla frutescens* also increased pigmentation in the whole tomato plant and in the tobacco flower [63]. A recent study shows that mutation of PH4, which encodes a MYB domain protein, results in a bluer petunia flower color, increased pH in petal extracts, and, in certain genetic backgrounds, the disappearance of anthocyanins and fading of the flower color [64].

Transgenic approaches uncovered a strong relationship between structural and/or regulatory anthocyanin gene expression and plant defense response levels. It has been suggested that anthocyanin functions as photoprotective pigments and that its accumulation can reportedly be induced in many plants by biotic and abiotic stresses, such as UV-B radiation, pathogen infection, or low temperature [65]. Anthocyanin accumulation appears to be a general response to cold stress. However, evidence suggests that anthocyanin itself is not essential for freezing tolerance, although some responses essential to freezing tolerance may be governed by a regulatory pathway or biochemical level that is also involved in the anthocyanin response [66].

The ectopic expression of anthocyanin 5-*O*-glucosyltransferase (5-UGT) cDNA in potato increased anthocyanin diglucoside levels and improved the resistance of transgenic lines to Erwinia carotovora subsp. Carotovora. Likewise, simultaneous expression of genes encoding CHS, CHI, and DFR in potato resulted in a significant increase in trisaccharide derivatives of pelargonidin and petunidin. However, transgenic lines showed a decrease in starch levels, accompanied by an increase in sucrose levels [67], suggesting that the limitation of flavonoid synthesis might depend on the availability of carbohydrates for phenolic compound synthesis.

Tomato fruits (*Lycopersicum esculentum*) are not usually reported to contain anthocyanin. However, tomato accession LA1996 with the anthocyanin fruit (Aft) gene has elevated anthocyanin levels in the skin and outer pericarp tissues of the fruit produced by the glycosylated anthocyanidins of petunidin, malvidin, and delphinidin [68]. These authors proposed that the introduction of the Anthocyanin fruit characteristic into carotenoid-rich tomatoes would provide the opportunity for developing new cultivars rich in water- and lipid-soluble antioxidants.

7 Conclusion/Prospects

Anthocyanins are excellent targets for biotechnological and health-related research lines. There is a great interest on increasing their directed biosynthesis, by increasing not only their total concentration in vegetable raw materials, but also the concentration of specific compounds with enhanced properties, either for their use as food colorants or for their health-related properties. Further studies are needed in the study of the biochemical pathways implicated in their glycosylation and acylation. The selective activation of those metabolic pathways conducting the synthesis of more stable or bioactive final products will open a promising perspective for the design of functional foods or new foods with health-related claims.

Regarding their biological activity, a lot is yet missed. Mechanistic studies that help to understand their implications in the prevention of cardiovascular disease, cancer, ocular health, and aging are still needed. Studies on absorption and distribution are still needed, especially those targeted to study the effect of intestinal microflora on anthocyanin structure and to identify gut flora metabolites. The effect of long-term exposure to anthocyanins is still largely unknown. The existing literature on biological activities gives enough evidences to think that anthocyanin-rich products, such as berries or red wine, may have a protective effect on human health, especially by preventing cardiovascular diseases and some types of cancer. However, more studies, preferably in vivo, are needed in order to establish the real implications of anthocyanins in these health-promoting properties.

Abstract

Flavonoids are natural products widely distributed in the plant kingdom and currently consumed in large amounts in the daily diet. These are categorized according to their molecular structures into flavonols, flavones, flavanones, catechins, anthocyanidins, dihydroflavonols, isoflavones and chalcones. Among them, flavones and flavonols define the largest subgroups. The diverse functions of flavones and flavonols in plants as well as their various roles in the interaction with other organisms offer many potential applications, not only in plant breeding but also in ecology, agriculture, and human nutrition and

1 Introduction

Within the secondary metabolite class of flavonoids which consist of more than 9,000 known structures [1], flavones and flavonols define the largest subgroups. Their natural distribution is demonstrated for almost all plant tissues. The basic structural features of flavones and flavonols are 2-phenyl-chromones and 2-phenyl-3-hydroxy-chromones, respectively (**1**–**2**) [2]. It is already well established that flavones and flavonols have a significant impact on various aspects of plant biology. They exhibit a wide range of functions in physiology, biochemistry, and ecology, for example, in UV protection, flower coloration, interspecies interaction, and plant defense. Moreover, flavones and flavonols have been utilized in the chemotaxonomy of some plants as useful markers. Other highly remarkable properties of certain flavones and flavonols are their nutritional values and medicinal benefits to humans, represented among others by antioxidant or putative anticancer activities [3]. In this chapter, we first describe the distribution and biosynthesis of flavones and flavonols in plants. Moreover, the various roles of flavones and flavonols in the plants' physiology and ecology and also their meaning for human health will be presented. At last, metabolic engineering strategies of flavone and flavonol pathways will be discussed.

2 Occurrence

Commonly, flavones are present in vacuoles of cells as *O*- and/or *C*-glycosides, but some compounds, especially simple and polymethylated flavones, occur in heartwood of *Prunus* species; farinose exudates of *Primula* spp. and ferns;

Table 59.1 The sorts and distribution of naturally occurring flavones

Sorts	Distribution
Flavone aglycones: more than 400 kinds	*Prunus* (Rosaceae) (heartwoods), *Alnus*, *Betula, Ostrya* (Betulaceae) (bud wax), *Primula* (Primulaceae) (farinose exudates), *Pityrogramma*, *Cheilanthes*, *Notholaena* (pteridophytes) (farinose exudates), etc.
Flavone *O*-glycosides: about 500 kinds (as commonly 7-, 3′-, 4′-glycosides and their various combinations), 5-*O*-glycosides (rare)	Widespread from bryophytes to higher plants
Flavone *C*-glycosides: about 300 kinds (as 6-, 8- or 6, 8-glycosides)	Widespread from Chlorophyta (*Nitella*) to bryophytes and higher plants

Pityrogramma, *Cheilanthes*, and *Notholaena* species; bud wax of *Alnus*, *Betula*, and *Ostrya* species (Betulaceae); and so on as aglycones [4, 5]. Up to now, more than 400 kinds of flavone aglycones have been identified and about 500 kinds of *O*-glycosides have widely been reported in plants as 7-, 3-, 4′-glycosides and in various combinations in most cases, but 5-*O*-glycoside is rare, since the 5-hydroxyl group forms hydrogen bonding with the adjacent 4-carbonyl group. Flavone *C*-glycosides (ca. 300 kinds) are also distributed from green algae to higher plants. The flavonoid compounds, which have been found in the most primitive plants, green algae, *Nitella hookeri*, liverworts, *Takakia lepidozioides*, and *T. ceratophylla*, are *C*-glycosyl flavones [6, 7] (Table 59.1).

The majority of flavonols are present as *O*-glycosides and very rarely as *C*-glycosides. There are about 900 flavonol *O*-glycosides identified as commonly 3-, 7-, 3-, 4′-glycosides and their various combinations. 5-*O*-Glycosides are rare as in the cases of the flavone glycosides. The glycosidic sugars are generally glucose, frequently galactose and rhamnose, and sometimes xylose, arabinose, and glucuronic acid. Very rare allose was found in *Glaucidium palmatum* Sieb. et Zucc. (Glaucidiaceae) as kaempferol, quercetin, and rhamnocitrin (kaempferol 7-methyl ether) 3-*O*-allosides [8]. Apiose, mannose, and galacturonic acid are also rare as glycosidic sugars. Flavonol glycosides are widely distributed in higher plants from Bryophytes. In a liverwort, *Takakia lepidozioides*, two flavonol glycosides, kaempferol 3-*O*-glucoside-7-*O*-xyloside and quercetin 3-*O*-glucoside, occur with some flavone *C*- and *O*-glycosides [7]. As the cases of flavones, free flavonols, particularly simple and polymethylated flavonols, also occur as farinose, bud, and leaf exudates of ferns, *Betula* (Betulaceae), *Cheilanthes* and *Notholaena*, *Artemisia* (Compositae), etc. [9, 10]. More exceptionally, two flavonols, 5, 2-dihydroxy-3, 7, 8- trimethoxyflavone and chlorflavononin (3′-chloro-5, 2′-dihydroxy- 3, 7, 8-trimethoxyflavone), were isolated from a fungus, *Aspergillus candidus* [11]. About 450 kinds of aglycones have been reported as naturally occurring substances (Table 59.2).

Table 59.2 The sorts and distribution of naturally occurring flavonols

Sorts	Distribution
Flavonol aglycones: about 450 kinds	*Artemisia* (Compositae) (leaf exudates), *Betula* (Betulaceae) (bud exudates), *Cheilanthes* (pteridophytes), etc.
Flavonol glycosides: about 900 kinds (as 3-, 7-, 3′-, 4′-glycosides and their various combinations), 6-*O*-glycosides (rare)	Widespread to higher plants from bryophytes

3 Biosynthesis

3.1 Biosynthesis of Flavone and Flavonol Aglycones

Almost all green plant cells are capable of synthesizing flavonoids. The biosynthesis invariably begins with the ubiquitous amino acid phenylalanine [12]. In the early steps of flavonoid biosynthesis, phenylalanine is converted into trans-cinnamate by phenylalanine ammonia-lyase (PAL) through the trans-elimination of ammonia and the pro-3S proton [13]. Then, cinnamate 4-hydroxylase (C4H) catalyzes the hydroxylation of trans-cinnamate to trans-4-coumarate in the initial oxygenation step of phenylpropanoid biosynthesis, which introduces the 4′-hydroxyl that is common to most flavonoids [14]. 4-Coumarate, the product of C4H, is key for flavonoid biosynthesis. It is activated by 4-coumarate: CoA ligase (4CL) for entry into the later branches of phenylpropanoid biosynthesis through formation of the corresponding CoA thiol esters.

Using 4-courmaroyl-CoA (in most species) and three molecules of malonyl-CoA, chalcone synthase (CHS) carries out a series of sequential decarboxylation and condensation reactions, to produce a polyketide intermediate that then undergoes cyclization and aromatization reactions that form the A-ring and the resultant chalcone structure. The chalcone formed from 4-courmaroyl-CoA is naringenin chalcone. In a few species, caffeoyl-CoA and feruloyl-CoA may also be used as substrates for chalcone formation. Malonyl-CoA is formed from acetyl-CoA by acetyl-CoA carboxylase (ACC). Acetyl-CoA may be produced in mitochondria, plastids, peroxisomes, and the cytosol by a variety of routes. It is the cytosolic acetyl-CoA that is used for flavonoid biosynthesis, and it is produced by the multiple subunit enzyme ATP-citrate lyase that converts citrate, ATP, and CoA to acetyl-CoA, oxaloacetate, ADP, and inorganic phosphate [15].

In a reaction that establishes the flavonoid heterocyclic C-ring, chalcone isomerase (CHI) catalyzes the stereospecific isomerization of chalcones to their corresponding (2*S*)-flavanones via an acid–base catalysis mechanism [16]. (2*S*)-Flavanones are converted stereospecifically to the respective (2*R*, 3*R*)-dihydroflavonols (DHFs) by flavanone 3β-hydroxylase (F3H). In the formation of both flavones and flavonols, a desaturation reaction forming a double bond between C-2 and C-3 of the C-ring is involved, and the respective substrates involved, (2*S*)-flavanones and (2*R*, 3*R*)-DHFs, differ only in the presence or absence of the 3-hydroxyl. Two distinct flavone synthases (FNS), FNS I and FNS II, have been characterized that convert flavanones to flavones. In most plants, FNS is a P450 enzyme (FNS II), but species in the Apiaceae have been found to contain the 2-oxoglutarate-dependent dioxygenases (2OGD) FNS I. Flavonols are formed from DHFs by the FLS. A similar reaction mechanism has been proposed for F3H, FLS, and FNS I, involving *cis*-hydroxylation at C-3 followed by dehydration, with (2*R*, 3*S*)-*cis*-DHFs as possible intermediates [17, 18]. Akashi et al. have suggested that the FNS II reaction likewise involves a C-2 hydroxylation step followed by dehydration [19]. However, the studies of Martens et al. [20, 21] suggest direct 2, 3-desaturation of flavanones by FNS I and FNS II, as previously proposed from biochemical studies of FNS I [22] (Scheme 59.1).

3.2 Flavone and Flavonol Modifications

The tremendous structural and functional diversity of flavonoids found in nature results from the modification by many enzymes that perform the substitution reactions. This is driven in part by opportunities for metabolic engineering of flavonoid biosynthesis for agronomic and nutritional improvement of plants. Glycosyltransferase, methylases, and sulfotransferases confer many of the ultimate chemical and bioactive properties of flavones and flavonols, for example, modulating flower color or enhancing the activity of these compounds for use in defense against herbivores and pathogens. These modifications also may play an important part in controlling the distribution of flux across branch pathways by altering intermediates to favor utilization by one or more competing enzymes at critical branch points. It is noteworthy that many of the substitution reactions are quite species-specific and most are still poorly understood both in terms of enzymology and their biochemical or physiological significance.

3.2.1 Glycosylation of Flavones and Flavonols

The addition of sugar groups has been well documented to enhance the solubility of flavonoids, as well as many other metabolites, and is likely to be critical for the transport and storage of these compounds at the final destinations in the vacuole or cell wall. Most flavonoid end products exhibit complex glycosylation patterns involving the addition of one or more glucose, rhamnose, or other sugars. Recent progress in understanding how this occurs includes elucidation of the terminal steps in the biosynthesis of maysin, a flavone produced in maize that provides resistance against the corn earworm, *Helicoverpa zea*. Quantitative trait locus and metabolite analysis of the maize *salmon silk* (sm) phenotype by McMullen and colleagues has shown that the *sm1* and *sm2* genes encode or control a glucose modification enzyme and a rhamnosyltransferase activity, respectively, in the maysin pathway [23]. possible the ordering of the final intermediates in the pathway from the flavone, luteolin, to isoorientin, to rhamnosylisoorientin, and then to the bioactive product, maysin.

Progress also has been made in the identification of genes encoding UDP-rhamnose: flavonol-3-*O*-rhamnosyltransferase and UDP-glucose: flavonol-3-*O*-glycoside-7-*O*-glucosyltransferase in *Arabidopsis* based on homology to other known flavonoid glycosyltransferases and combined genetic and biochemical analyses. The UGT78D1 gene encodes a specific UDP-rhamnose: flavonol-3-*O*-rhamnosyltransferase with activity only on kaempferol and quercetin, out of various flavonoids tested [24]. The recombinant protein from the UGT73C6 gene transfers glucose to the 7-hydroxyl of a range of flavonols and flavones, as well as the 6-hydroxyl of the unnatural 6-hydroxyflavone substrate. However, its in vivo activity is likely as a UDP-glucose: flavonol-3-*O*-glycoside-7-*O*-glucosyltransferase. The recombinant *Allium cepa* (onion) UGT73G1 protein also showed wide regiospecificity, adding glucose to the 3-, 7-, and 4′-hydroxyls of a wide range of flavonoids, including chalcones, flavanones, flavones, flavonols, and isoflavones, producing both mono- and diglucosides [25]. In contrast to these activities, recombinant protein from *A. cepa* UGT73J1 showed both high regiospecificity and tight substrate specificity, adding glucose at the 7-hydroxyl of only quercetin 3-*O*-glucoside and genistein out of many flavonoid substrates tested. A cDNA from *Vigna mungo* (black gram) seedlings encodes a protein with UDP-galactose: flavonoid 3-*O*-galactosyltransferase activity [26]. A 20-fold preference for UDP-galactose over UDP-glucose was found with kaempferol as a substrate.

P. hybrida pollen accumulates kaempferol and quercetin 3-*O*-(2″-*O*-glucopyranosyl)-galactopyranosides, which are not prevalent elsewhere in the plant, by the action of flavonol 3-*O*-galactosyltransferase (PhF3GalT) and flavonol 3-*O*-galactoside-2″-*O*-glucosyltransferase. Miller et al. [27] isolated a cDNA for a pollen-specific gene from *P. hybrida* whose recombinant protein showed the same activity profile as the previously characterized PhF3GalT. Unlike most of the GTs discussed previously, the PhF3GalT showed strong preference and high catalytic efficiency to kaempferol and quercetin, with other lower activities being limited to a range of flavonol aglycones. Notably, the PhF3GalT also catalyzed the reverse reaction, a deglycosylation. The enzyme, therefore, could be involved in modulating the abundance of a biologically active aglycone.

3.2.2 Methylation of Flavones and Flavonols

A variety of *O*-methylated flavones and flavonols have been described, involving substitutions at the 3, 5, 6, 7, 8, 2′, 3′, 4′, and 5′ positions. Many native *O*-methyl transferase (OMT) and their recombinant proteins are responsible for the formation of these compounds. A recombinant protein from semiaquatic freshwater plant *Chrysosplenium americanum* had an activity that methylated the 3′ hydroxyls of luteolin and quercetin [28]. Another recombinant protein from AtOMT1 (an *A. thaliana* cDNA) showed flavonol 3′-OMT activity, using quercetin and myricetin (flavonol aglycones) efficiently; however, it had much lower activity with luteolin [29]. A flavonoid 3′, 5′-OMT that has been identified from *C. roseus* could sequentially methylate the 3′- and 5′-hydroxyls of both myricetin and dihydromyricetin and showed weaker activity against the 3′-hydroxyl of dihydroquercetin [30]. A wide range of flavonols, including 6-hydroxykaempferol, quercetin, 6-hydroxyquercetin (quercetagetin), 8-hydroxyquercetin (gossypetin), myricetin, and quercetin 3-*O*-glucoside, were accepted as substrates by the recombinant protein from PFOMT (a *Mesembryanthemum crystallinum* cDNA), as were some flavones, flavanones, and HCA-CoA esters and glucosides. The reaction product for quercetin was shown to be isorhamnetin (3′-methoxyquercetin), while with quercetagetin five different products with 5-*O*-, 6-*O*-, 3′-*O*-, 5, 3′-*O*-, or 6, 3′-*O*-methylation were generated. This range of substrate choice and products with the recombinant protein is wider than for the purified native enzyme, the major products of which are only the 6-*O*- and 6, 3′-*O*-methyl ethers. This difference has been shown to be due to the N-terminal region of the protein, as a recombinant protein with the first 11N-terminal amino acids removed shows the same enzyme characteristics as the native enzyme [31]. The dual methylation reaction suggests a large and flexible active site, which is rare for the OMTs characterized to date.

3.2.3 Sulfurization of Flavones and Flavonols

Flavonoids esterified with sulfate groups have been reported to occur in many plant species, in particular mono- to tetrasulfate esters of flavonols and flavones and their methylated or glycosylated derivatives. These are likely generated by soluble sulfotransferases (STs), which transfer a sulfonate group from 3′-phosphoadenosine 5′-phosphosulfate (PAPS). Two subgroups of STs have been reported. The first contains enzymes with generally wide substrate acceptance that are typically involved in detoxification of small metabolites. Enzymes of the second subgroup, which includes the flavonoid STs, show high specificity, and in animals are involved in processes such as steroid transport and inactivation. The first plant STs characterized at the molecular level were the flavonol 3-*O*- and 4′-*O*-STs (F3ST and F4′ST) from *Flaveria chloraefolia* [32], followed by a second F3ST, BFST3, from *Flaveria bidentis* [33]. These enzymes form part of a group of flavonol STs that act sequentially to generate the range of flavonol polysulfates found in this genus. Strict specificities are shown to the 3-hydroxyl of flavonol aglycones (F3ST), or the 3′-, 4′- (F4′ST), or 7-hydroxyls of flavonol 3, 3′ or 3, 4′-disulfates [34]. Analysis of the recombinant proteins found the *F. chloraefolia* F3ST used only flavonol aglycones as substrates (both kaempferol and quercetin, and the methylated rhamnetin and isorhamnetin), and the F4′ST used only the flavonol 3-*O*-sulfates. BFST3 recombinant protein showed similar activity to the *F. chloraefolia* F3ST, except that kaempferol was not accepted as a substrate. A range of ST cDNAs has been identified from functional genomics studies of *A. thaliana*, including one (AtST3) that has been shown to encode a flavonoid 7-ST. Unlike BFST3, AtST3 recombinant protein accepts a number of flavonol and flavone aglycones, as well as their 3-*O*-monosulfated derivatives. However, strict specificity to the 7-hydroxyl was found. The plant soluble STs have around 25–30% amino acid identity with mammalian soluble STs, and are of a similar size [32]. Comparisons between *F. chloraefolia* F3ST and F4′ST, combined with mutational analysis and data from the crystal structure of mouse estrogen ST, have defined amino acid residues important for PAPS binding, substrate binding and catalysis, and the mechanism of sulfonate transfer [35, 36].

4 Biological Activity

4.1 Role of Flavones and Flavonols in Plants

The flavonoids are essential constituents of the cells of all higher plants. As two members of flavonoid family, flavones and flavonols have roles in many facets of plant physiology. One of their most important roles is to influence the transport of the phytohormone auxin, or indole-3-acetic acid (IAA) [37]. Flavonoids, particularly the flavone kaempferol and the flavonol quercetin could compete with naphthylphthalamic acid (NPA) to perturb auxin transport [38]. They are present in the root cap and columella of *Arabidopsis* seedlings [39, 40]. As kaempferol inhibits mammalian monoamine oxidases that are similar to characterized IAA oxidases [41] and flavonoid-deficient *Arabidopsis* mutants exhibit increased leakage of radiolabeled IAA or oxidized IAA from the root tip [39, 40], kaempferol may function in limiting the oxidation of auxin destined for basipetal redirection at the root tip. Quercetin accumulation in response to increased IAA levels may serve to scavenge reactive oxygen species that accumulate during IAA catabolism [42–44].

An obvious function of flavones and flavonols is as a filter for UV radiation [45]. UV-B radiation (280–315 nm) induces oxidative damage to DNA and proteins and degradation of the photosystem II reaction center [46]. These compounds filter UV-B radiation, thereby protecting plants by acting as a “sunscreen.” UV-B radiation also induces the synthesis of flavonols with higher hydroxylation levels. Because hydroxylation does not affect the UV-absorbing properties of these compounds but does affect their antioxidant capacity, it was suggested that flavonols may play as yet uncharacterized roles in the UV stress response.

Another important feature of flavones and flavonols that could have driven evolution is their allelochemical character. They are involved in various interactions with other organisms, microbes, as well as insects or other plants. For the host plant, these interactions can be both beneficial or harmful. Arbuscular mycorrhizae form mutualistic or symbiotic associations with plants. Quercetin, acacetin, and rhamnetin accumulated in roots of clover inoculated with mycorrhizae but not in noninoculated plants [47], suggesting that flavonols may mediate colonization. In addition, the root and shoot flavonoid composition was altered between colonized and noncolonized plants, which may be a direct or indirect effect of colonization [47]. Under low phosphate conditions, melons synthesized a *C*-glycosylflavone, isovotexin 2″-*O*-β-glucoside, which increased mycorrhizal colonization [48], thereby enhancing phosphate uptake. Apigenin, coumestrol, and daidzein increased mycorrhizal root colonization in soybean [49]. Although the signal that initiates colonization is unknown, flavonoids modulate the development of the association. Siqueira et al. [50] showed that among other flavonoids the flavone, chrysin can increase both mycorrhiza root colonization and root growth of *Trifolium repens*. Certain flavones have also been demonstrated to promote *Glomus* hyphal growth and spore germination [51].

A defined role for flavones as signaling molecules has been realized in the symbiosis between legumes and nitrogen-fixing rhizobia. Among other flavonoids, flavones from the host roots are exuded and selectively recognized by the respective bacterial symbiont. Subsequently, the synthesis of bacterial nod factor signals is initiated, which in turn are recognized by the plant host [52]. The first flavone identified to participate in such a communication was luteolin (5, 7, 3′, 4′-tetrahydroxyflavone) [53], but much more are described up to now [54]. Recent evidence has shown that flavones and flavonols are not only required to signal symbiotic bacteria in the legume-bacterium symbiosis but also play important direct roles in root nodule organogenesis [55, 56]. Flavonoids also accumulate in the progenitor cells for different legume organs [57, 58] and influence the development of in vitro root formation [59].

These elegant in vivo studies first confirmed that specific flavones, such as 7, 4′-dihydroxyflavone, were required to stimulate the production of nod factor synthesis in Sinorhizobia in the rhizosphere and in planta. Second, these findings suggested that certain flavonols such as kaempferol play direct roles in orchestrating plant organogenesis. This most likely occurs via the ability for kaempferol to induce localized inhibition of auxin transport, thus establishing more favorable hormonal gradients to enable root nodule formation from differentiated root cells [56].

In plant–insect interactions, flavones can be employed as copigments of delphinidin derivatives in blue-flowered plants, the preferred flower color of bees, thus contributing to the attraction of pollinators [60]. Again, in combination with a second compound that must be present, flavones (e.g., luteolin 7-*O*-(6″-*O*-malonyl)-β-D-glucoside together with *trans*-chlorogenic acid) are described to stimulate oviposition of certain insects on host plants [61]. Another aspect of flavones in plant–insect interaction is their impact on feeding of herbivores. As reviewed by Simmonds [62], flavones can affect insects in various ways, for instance they inhibit larvae feeding or act as feeding deterrent. Other flavones, such as 4″-hydroxy-maysin (5, 7, 3′, 4′-tetrahydroxyflavone 2″-*O*-α-L-rhamnosyl-6-*C*-[6-deoxy-*xylo*-hexos- 4-ulosyl]) can repress the development of corn earworm moth, *Heliothis zea*. An inheritance study with groundnut showed good evidence that the flavonols quercetin and its glycoside rutin are related to larval mortality of the tobacco armyworm *Spodoptera liture* [63]. The species *Arachis hypogaea* is a nonresistant host, whereas the wild species A. kempffmercadoi is resistant due to its flavonols. Feeding experiments with interspecific hybrids revealed a positive correlation between the flavonol content of the plants and larval mortality.

Besides their effectiveness against insects, certain flavones also exhibit activities against a variety of different organisms, for example, other plants [64, 65], nematodes [66], molluscs [67], fungi [68–70], oomycetes [69, 70], and bacteria [71]. These activities are often but not always and necessarily directed against attacking or phytopathogenic organisms. In such cases, the flavones are frequently inducible and have to be classified as phytoalexins. Mostly, these compounds are constitutively present in the particular plants. Unfortunately, no evident structure-function relationship has been identified that suggests why one flavone is involved in symbiotic communication, while others act as deterrents to herbivores or can be active as phytoalexins. However, a study by Picman et al. [72] on the inhibition of mycelial growth of the fungus *Verticillium albo-atrum* as indicator of biological activities showed that totally unsubstituted flavone was more effective (in the range of

1–5 ppm) than substituted derivatives, suggesting that at least the toxic effects might be due to hydrophobicity and their ability to interact with membrane structures.

4.2 Biological Activities of Flavones and Flavonols in Animals

Apart from being important components in plants, many biological activities of flavones and flavonols are known in animal systems, such as antioxidative activity. Flavones and flavonols are the powerful antioxidants for protecting the body against reactive oxygen species (ROS). ROS collectively denotes oxygen-centered radicals such as superoxide ($O_2^{\bullet -}$) and hydroxyl ($^{\bullet}OH$) as well as nonradical species derived from oxygen, such as hydrogen peroxide, singlet oxygen ($^1O_2$), and hypochlorous acid (HOCl). Data obtained from many studies showed that flavones and flavonols, such as quercetin, kaempferol, morin, myricetin and rutin, by acting as antioxidants, exhibited beneficial effects such as anti-inflammatory, antiallergic, antiviral, as well as anticancer activity. They have also been suggested to play a protective role in liver diseases, cataracts, and cardiovascular diseases [73, 74]. The radical-scavenging activity of flavones and flavonols depends on the structure and the substituents of the heterocyclic and B rings, as suggested by Bors et al. [75]. The presence of a 3-hydroxyl group in the heterocyclic ring also increases the radical-scavenging activity, while additional hydroxyl or methoxyl groups at positions 3, 5, and 7 of rings A and C seem to be less important. These structural features contribute to increase the stability of the aroxyl radical, that is, the antioxidant capacity of the parent flavonoid. Thus, flavonols and flavones containing a catechol group in ring B are highly active, with flavonols more potent than the corresponding flavones because of the presence of the 3-hydroxyl group. Glycosylation of this group, as in rutin, reduces greatly the radical-scavenging capacity. An additional hydroxyl group in ring B (pyrogallol group) enhances further the antioxidant capacity, as exemplified by myricetin.

Because of their antioxidative properties, flavones and flavonols are likely to have a major influence on the vascular system. Oxygen radicals can oxidize LDL, which injures the endothelial wall and thereby promotes atherosclerotic changes. Flavones and flavonols may directly scavenge some radical species by acting as a chain-braking antioxidant [76]. The ability of quercetin and the quercetin glycosides to protect LDL against oxidative modification has shown a significant protective effect. Furthermore, flavonols are particularly antithrombotic because they directly scavenge free radicals, thereby maintaining proper concentration of endothelial prostacyclin and nitric oxide [77].

Numerous enzymes are inhibited by flavones and flavonols. They include hydrolases, oxidoreductases, DNA synthetases, RNA polymerases, phosphatases, protein phosphokinases, oxygenase, and amino acid oxidases. In some cases, the type of inhibition is competitive, but more often it is allosteric. The stunning variety of the types of enzymes, the activities of which are influenced by flavonoids, spans across almost all enzyme classes. The enzymes summarized in Table 59.3 are not exhaustive and aims to familiarize the reader with the extent of enzyme modulatory activities recorded.

Table 59.3 Effects of flavones and flavonols on activity of enzymes

Enzymes	Flavones or flavonols	References
Protein kinase C (PKC)	Fisetin, quercetin, and luteolin	[78, 79]
Mitogen-activated protein (MAP) kinase	Quercetin	[80]
Myosin light chain kinase (MLCK)	Kaempferol	[81]
Protein tyrosine kinases (PTK)	Quercetin, fisetin, robinetin, myricetin, and apigenin	[82–84]
Phospholipase A_2 (PLA2)	Quercetin, quercetagetin, kaempferol-3-O-galactoside, and scutellarein	[85, 86]
ATPases	Quercetin	[87–89]
Lipoxygenases	Baicalein, cirsiliol, quercetin	[90–95]
Cyclooxygenases	Luteolin, morin, galangin,	[96]
	Flavone, chrysin, apigenin, and phloretin	[97]
	Silymarin	[98]
	Oroxinidin, quercetagetin-7-glucoside, and tambuletin	[93]
Phospholipase C	Quercetin	[99]
Adenylate cyclase	Chrysin and apigenin	[97]
Reverse transcriptase	Amentoflavone, scutellarein, and quercetin	[100]
	Baicalein	[101]
	Quercetagetin, and myricetin	[102]
	Fisetin	[103]
HIV-1 proteinase	Myricetin, morin, quercetin, and fisetin	[104]
HIV-1 integrase	Quercetin	[105]
Ornithine decarboxylase (ODC)	Quercetin	[106]
	Apigenin	[107]
Topoisomerase	Fisetin and quercetin	[108]
	Baicalein, quercetin, quercetagetin, and myricetin	[109]
Glutathione *S*-transferase (GST)	Quercetin	[110]
Epoxide hydrolase	Flavone and 7,8-benzoflavone	[111]
Glyoxalase	Quercetin, fisetin, and myricetin	[112]
Xanthine oxidase	Quercetin	[113, 114]
	Baicalein	[115]
Aromatase	Quercetin, chrysin, apigenin, and kaempferol	[116]
		[117]
Aldose reductase	3′,4′-dihydroxyflavones	[118]
	3′,4′-dihydroxy-5,6,7,8-tetramethoxyflavone	[119]
Carbonyl reductase	Quercitrin	[120]
Hyaluronidases	Kaempferol and silybin	[121]
Malate dehydrogenase	Quercetin	[122]
Lactate dehydrogenase	Quercetin	[123]
Pyruvate kinase	Quercetin	[123]
Amylase	Quercetin	[124]

(*continued*)

Table 59.3 (continued)

Enzymes	Flavones or flavonols	References
RNA and DNA polymerases	Quercetin, kaempferol, and fisetin	[125]
	Quercetagetin, myricetin, and baicalein	[102]
Sialidase	5,7,4′-trihydroxy-8-methoxyflavone	[126, 127]
Nitric-oxide synthase	Quercetin, morin, apigenin, taxifolin, and fisetin	[128]
Monoamine oxidase	Coumarins	[129]

Flavones and flavonols can exert the anti-inflammatory activity in many animal models and are useful in allograft rejection and rheumatic diseases as an immunosuppressive agent. A number of reports have been published which demonstrate that flavones and flavonols, such as quercetin, myricetin, and fisetin, can modulate arachidonic acid metabolism via the inhibition of cyclooxygenase and lipoxygenase activity [130, 131]. Quercetin prevents immune cells and inhibits both the production and release of histamine and is useful in allergic conditions like asthma, hay fever, etc. [132].

Flavones and flavonols, especially quercetin, have been reported to possess antidiabetic activity. A cohort study that predicted the effects of flavonoids on chronic diseases showed that a trend toward a reduction in risk of type 2 diabetes was associated with higher quercetin and myricetin intakes. Vessal et al. reported that quercetin brings about the regeneration of pancreatic islets and increases insulin release in streptozotocin-induced diabetic rats [133]. Also in another study, Hif and Howell reported that quercetin stimulates insulin release and enhances Ca^{2+} uptake from isolated islet cells which suggest a place for flavonoids in non-insulin-dependent diabetes [134, 135].

It has become evident that flavones and flavonols are able to exert neuroprotective actions even at low concentration via their interactions with critical neuronal intracellular signaling pathways pivotal in controlling neuronal survival and differentiation, long-term potentiation, and memory. Early indications regarding the ability of flavonoids to impact upon brain function were reported in the 1950s, with flavones reported to act as novel brain-stem stimulants [136]. Jung et al. showed that quercetin at a dose of 10, 20, 40 mg/kg p.o. impairs cognitive function by suppressing pAkt and pCaMKII thus decreasing pCREB expression in hippocampus [137]. Maher et al. reported fisetin to facilitate memory by activating ERK and inducing cAMP response element-binding protein phosphorylation [138].

Some flavone derivatives were found to be ligands for the GABAA (γ-aminobutyric acid type A) receptors in the central nervous system, and thus, they bind to the benzodiazepine binding site with resulting depressant actions in mice [139]. These were also found to possess sedative action. Considering the sedative, the spontaneous locomotor activity and thiopental induce sleeping time effects obtained with the flavonoid glycosides. Position of the sugar on the flavonoid nucleus seems relevant as well, and position-7 is the most effective, but the presence of a double bond between carbons 2 and 3, resulting in flavone derivatives with planar configuration (i.e., linarin), does not appear to be critical for activity.

Flavonoid glycosides form the newest group within the growing family of flavonoids with activity on the central nervous system [139].

Flavones and flavonols have also been found to possess hepatoprotective activity. In a study carried out to investigate the flavonoid derivatives silymarin, apigenin, and quercetin, as putative therapeutic agents against microcrystin LR-induced hepatotoxicity, silymarin was found to be the most effective one [140]. Gulati et al. studied hepatoprotective studies on *Phyllanthus emblica* and quercetin and found that if the extract is producing hepatoprotection at a dose of 100 mg/100 g p.o., then quercetin is producing hepatoprotection at a dose of 15 mg/100 g p.o., thus concluding that quercetin is a potent hepatoprotective agent [141]. Oh et al. reported that among various flavonoids, that is, apigenin, luteolin, kaempherol-3-*O*-glucoside, and quercetin-3-*O*-glucoside isolated from *Equisetum arvense*, onitin and luteolin exhibited hepatoprotective activity against tacrine-induced cytotoxicity in human liver-derived Hep G2 cells [142].

Flavonoids have been used extensively since centuries for the treatment of various diseases. Galangin is a flavonol commonly found in propolis. Propolis has been used referred even in the Old Testament for its healing properties. The antimicrobial activity of propolis has been attributed to its high flavonoid content. It has been reported to possess inhibitory actions against *Aspergillus tamarii*, *Aspergillus flavus*, *Cladosporium sphaerospermum*, *Penicillium digitatum*, *Penicillium italicum* [143]. Rattanachaikunsopon et al. isolated morin-3-*O*-lyxoside, morin-3-*O*-arabinoside, quercetin, and quercetin-3-*O*-arabinoside from *Psidium guajava* leaves and reported that these four possess bacteriostatic action against all food-borne pathogenic bacteria including *Bacillus stearothermophilus*, *Brochothrix thermosphacta*, *Escherichia coli*, *Listeria monocytogenes*, *Pseudomonas fluorescens*, *Salmonella enteric*, *Staphylococcus aureus*, *Vibrio cholerae* [144] (Table 59.4).

There has been mounting concern about the anticancer activity of flavones and flavonols. The weight of the epidemiological evidence for a protective effect of flavones and flavonols against cancer is impressive. A growing number of epidemiological studies suggest that high flavonoid intake may be correlated with a decreased risk of cancer [145]. In a cohort study of 25-year follow-up on 9,959 Finnish men and women aged 15–99 years and initially cancer-free, dietary intake of flavones and flavonols was inversely associated with the incidence of cancer at all sites combined [146]. Knekt and coworkers [147] also estimated flavonoid intakes of 10,054 men and women mainly on the basis of the flavonoid concentrations in Finnish foods with a dietary history method. They found that men with higher quercetin intakes had a lower lung cancer incidence, and men with higher myricetin intakes had a lower prostate cancer risk. A population-based case–control study in Hawaii further investigated the association between intake of flavone- and flavonol-powerful dietary and lung cancer risk. This study involved 582 patients with incident lung cancer and 582 age-, sex-, and ethnicity-matched control subjects [148]. These results agree well with a former case–control study involving 541 cases of lung cancer and 540 hospitalized controls in Uruguay [149]. Another case–control study in Spain, including 354 cases of gastric cancer and 354 hospitalized

Table 59.4 Antimicrobial activities of flavones and flavonols

Activity	Organism	Flavones or flavonols
Antibacterial activity	*Staphylococcus aureus*	Quercetin, Baicalin, Fisetin
	Staphylococcus albus	Fisetin
	Streptococcus pyogenes	Apigenin
	Streptococcus viridians	Apigenin
	Streptococcus jaccalis	Chrysin
	Streptococcus baris	Chrysin
	Streptococcus pneumonia	Chrysin
	Pseudomonas aeruginosa	Rutin, Baicalin, Hydroxyethylrutoside
	Escherichia coli	Quercetin
	Bacillus subtilis	Quercetin
	Bacillus anthracis	Rutin
	Proteus vulgaris	Datisetin
	Clostridium perferingens	Hydroxyethylrutoside
Antiviral activity	*Rabies virus*	Quercetin, Rutin
	Herpes virus	Quercetin
	Para influenza virus	Quercetin, Rutin
	Herpes simplex virus	Galangin, Quercetin, Kaempferol, Apigenin
	Respiratory syncytial virus	Quercetin
	Immunodeficiency virus	Apigenin
	Auzesky virus	Quercetin, Morin, Apigenin
	Polio virus	Quercetin
	Mengo virus	Quercetin
	Pseudorabies virus	Quercetin
Antifungal activity	*Candida tropicalis*	Quercetin
	Fusarium solani	Chrysoeriol
	Botrytis cinerea	Chrysoeriol
	Verticillum dahliae	Chrysoeriol
	Azotobacter vinelandii	Quercetin, Rutin
	Alternacia tennisima	Apigenin

controls, suggests that flavonoids such as quercetin and kaempferol may have protective effects against gastric cancer while specific carotenoids (alpha-carotene, beta-carotene, lutein, and lycopene) may not [150].

Many researchers have conducted *in vitro* studies on the potential anticancer activity of flavones and flavonols in diverse cell systems. An array of 55 flavones having a variety of substituents was evaluated by Cushman and Nagarathnam for cytotoxicity in five cancer cell cultures, A-549 lung carcinoma, MCF-7 breast carcinoma, HT-29 colon adenocarcinoma, SKMEL-5 melanoma, and MLM melanoma [151]. Other reports also revealed that flavones and flavonols exhibited cytotoxicity in vitro to many human cell lines, including esophageal cancer cells [152, 153], colon cancer cells [154, 155], hepatoma cells [156, 157], prostate carcinoma cells [158, 159], and cervical carcinoma cells [160, 161].

Animal studies and investigations using different cellular models suggested that certain flavones and flavonols could inhibit tumor initiation as well as tumor progression [162–164]. Quercetin inhibited DMBA-induced carcinogenesis in hamster buccal pouch [165] and in rat mammary gland [166]. When given during the initiation stage, quercetin also inhibited DEN-induced lung tumorigenesis in mice [167]. In a medium-term multiorgan carcinogenesis model in rats, quercetin (1 % in the diet) inhibited tumor promotion in the small intestine [168]. Feeding rats with quercetin (0.05 % in the diet), during initiation or promotion stage, inhibited 4-NQO-induced carcinoma formation in the tongue.

The plethora of effects of flavones and flavonols on the metabolism of cancer cells is difficult to rationalize to a few basic, specific mechanisms. These compounds interfere with a large number of regulatory pathways, for example, those of growth, energy metabolism, apoptosis, cell division, transcription, gene repair, neuronal transmission, inflammation, and stress response [169–176]. They can act as antioxidants, free-radical scavengers, enzyme inhibitors, hormones (including neurotransmitters), antihormones, or inducers of gene expression.

These effects can be divided into two classes, the electronic and the steric. The high mobility of the electrons in the benzenoid nucleus of flavones and flavonols accounts for both their antioxidant and free-radical-scavenging properties, whereas the structural resemblance between the flavone and flavonol aglycone and many substances inherent to the biochemistry of normal biological cells, for example, nucleic acid bases, coenzymes, steroid hormones, and neurotransmitters, explains their inhibition of enzymes, cytoplasmic/nuclear hormone receptors, and neurotransmitters, as well as gene induction. The high affinity of flavones and flavonols for heavy metal ions provides additional opportunities for interference with the action of enzymes and Zn^{2+} fingers in DNA-binding proteins. The biochemical pathways, which are influenced by flavones and flavonols, can roughly be classified according to their sensitivities. Generally, the actions mediated by the family of cytoplasmic/nuclear hormone receptors are highly sensitive to flavonoids, whereas enzyme inhibition and similar processes, for example, at synaptic membranes, require higher concentrations of flavonoids [177].

5 Genetic Engineering

Flavones and flavonols become more and more commercially important for the floricultural, agricultural, food, and pharmaceutical industry, respectively. Consequently, genetic engineering can provide a valuable tool to expand the plant gene pool and thus promoting the generation of new commercial plant varieties or plant-derived products (e.g., food supplements, functional foods, herbal drugs). Generally, flavones and also flavonols contribute as common copigments to the color appearance of cyanic pigments in plant tissues. Therefore, by metabolic engineering of this step the copigment level can be modified. However, as flavones and anthocyanins share common precursors, the levels of copigments and anthocyanin are generally negatively correlated. Practically, that means that a reduction on flavone level, for example, by antisense suppression, will likely cause in increase of anthocyanin level due to precursor flow in only one direction. However, downregulation of the FNS II gene in blue torenia *(Torenia hybrida)* using antisense technique decreased the level of flavones as expected. Those of its precursor, the flavanones, are increased. Unexpectedly, the levels of anthocyanins were reduced and the resultant flower color was pale blue [178]. The strong copigment effect of flavones was documented in transgenic carnation *(Dianthus caryophyllus)*. FLORIGENE Moonshadow^{TM}, the first blue carnation, was analyzed regarding the flavonoid pattern. Besides delphinidin derivatives, the transgenic petals also contained an apigenin derivative that is proposed to have a strong copigment effect on the anthocyanin [179].

Flavonol formation requires the expression of CHS, CHI, F3H, and FLS, this last gene encoding flavonol synthase, which converts dihydrokaempferol or dihydroquercetin to the corresponding flavonols, kaempferol, and quercetin, respectively. Little continues to be known about how this branch of the flavonoid pathway is regulated. The regulators of anthocyanin biosynthesis can induce the accumulation of flavonols, as recently shown by the comprehensive analysis of the metabolic changes associated with the expression of the R2R3-MYB transcription factor PAP1 gene in Arabidopsis [180]. Interestingly, however, while the overexpression of PAP1 resulted in a significant increase in the expression of many flavonoid biosynthetic genes, FLS was not among the upregulated genes, suggesting that the increase in flavonol accumulation is likely a consequence of the presence of a constitutively expressed FLS, together with an increased flux through the flavonoid pathway.

In tomato, which produces naturally only low amounts of kaempferol and quercetin in the fruit peel, the introduction and overexpression of the regulatory genes *Lc* and *C1* of maize led to an increase in kaempferol formation of up to 60 %, mainly in the flesh of the fruits. Moreover, introducing the *CHI* gene of *Petunia* resulted in an increase of up to 70 % in quercetin formation in the peels. Expressing *Lc* and *C1* in potatoes also caused a marked accumulation of kaempferol in the tubers [181]. In the future, the availability of the *FLS* gene from several sources may allow a more directed engineering of flavonol synthesis. Moreover, the recent cloning of the gene encoding FNS II [19, 182] provides the means for manipulating flavone formation for agronomic and nutritional purposes.

AtMYB12, encoding a R2R3-MYB transcription factor with high identity to the maize P1 regulator of the phlobaphene pigments [183], recently has been identified as a regulator of flavonol biosynthesis in Arabidopsis [184]. AtMYB12 regulates the expression of CHS, CHI, F3H, and FLS but not of the anthocyanin biosynthetic genes. A mutation in AtMYB12 results in a significant decrease in flavonol accumulation, suggesting that other regulators may contribute to the control of this branch of the pathway. These studies also showed that P1 can control the expression of the flavonol biosynthetic genes in Arabidopsis, suggesting that P1 may regulate flavonol biosynthesis in maize. However, in maize, P1 is unable to activate F3H, and no flavonols were detected among the several flavonoids induced by P1 expression [185]. Similar to P1, AtMYB12 functions independently of the known bHLH coactivators. The studies on AtMYB12 make this gene the only bona fide regulator of the flavonol pathway that so far has been described.

6 Conclusion

The diversity, ubiquity, and bioactivity of flavones and flavonols make these compounds of interest to a wide variety of research. It is still unknown exactly how these compounds exert their influence on growth, auxin transport, and other biologically relevant interactions in the plant kingdom. It is obvious that considerably more research is required to dissect out the complexities involved with flavone and flavonol functions in the animal kingdoms. There is a need to improve research on mechanisms of bioactivity in animals and plants. The advances in genomics, proteomics, and metabolomics provide new approaches to define the role of flavones and flavonols in plant development and to explore their potential application in agriculture and medicine.

Abstract

Isoflavonoids are subclass of flavonoids and have been isolated from a wide variety of leguminous and non-leguminous plants. Isoflavones are characterized by having the B-ring attached at C_3 rather than C_2 position and undergo various modifications; these modifications lead to formation of simple isoflavonoids such as isoflavanones, isoflavans, and isoflavanols, as well as more complex structures including rotenoids, pterocarpans, and coumestans. Isoflavones are present in berries, wine, grains, nuts, soybeans, and other legumes including kudzu root (*Pueraria lobata*), peanuts (*Apios americana*), and chickpeas (*Cicer arietinum*). Isoflavonoids are derived from the phenylpropanoid pathway which is established both enzymatically and genetically. There are many biological

activities associated with the isoflavones, including reduction in osteoporosis, cardiovascular disease, and prevention of cancer and for the treatment of menopause symptoms. Recent data indicate that the protective effect of isoflavonoids may extend beyond their antioxidant activity on molecular and cellular levels and modulating activity of many other enzymes. Biotechnological approaches have been used to produce isoflavonoids through cell cultures of different species grown in shake flasks and bioreactor using normal and transformed cells. Currently, isoflavonoids are an area of active and advancing research with huge potential for the benefit of human health.

1 Introduction

In recent years, the role of phenolic compounds and flavonoids as protective dietary constituents has become an increasingly important area of human nutrition research. Flavonoids are polyphenolic compounds comprising of 15 carbons with two aromatic rings connected by a three-carbon bridge. Isoflavonoids form a distinct class among flavonoids and have a characteristic structure with very limited distribution in nature (Fig. 60.1). Isoflavonoids are derived from the phenylpropanoid pathway and are synthesized predominantly in leguminous plants [1]. Simple isoflavonoids are dietary phytoestrogens and their glycosides, although coumestrol (a more complex isoflavonoid derivative) is also a phytoestrogen. The number of known isoflavone glycosides [e.g., genistin (genistein7-*O*-β-D-glucopyranoside)] is small when compared with the vast range of known flavonoid glycosides, and in this *O*-glycosides are in majority [2]. Up to now, the isoflavanoid compounds have been studied intensively and about 1,600 isoflavonoids have been identified. Much of this molecular diversity is generated through the biosynthetic modification of core isoflavonoid chemical scaffolds. In general, isoflavonoid

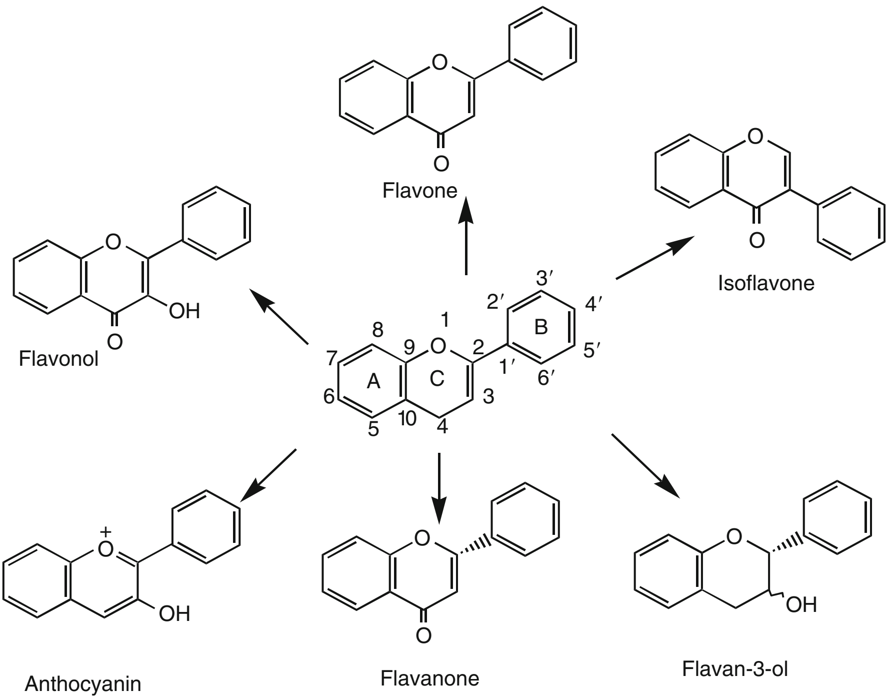

Fig. 60.1 Generic structures of the major flavonoids

compounds primarily occur in legumes, but have also been found in a considerable number of non-legumes. To date, at least 225 isoflavonoids have been isolated from about 59 non-leguminous families [1].

Isoflavone molecules do not exist at high levels in their biologically active form in natural food products, but rather are at high abundance in precursor form. For example, daidzin, the precursor of daidzein, is the glycosidic form that contains a carbohydrate moiety (portion) of the molecule. Daidzin is metabolized in the gastrointestinal tract by intestinal bacteria, which hydrolyzes the carbohydrate moiety, to the biologically active isoflavone, daidzein. Daidzein is then further metabolized in the intestine to equal at relatively low or high levels dependent upon several biological, dietary, and, presumably, environmental factors [3]. Isoflavones are inactive molecules when in the glycosidic form (genistin, daidzin), but as aglycones (without sugar moiety; genistein, daidzein) intestinal absorption is possible. Intestinal absorption varies greatly between individuals, which may be related to the content of dietary fiber and the state of intestinal microflora. After absorption, isoflavones are reconjugated to glucuronides and excreted unchanged in the urine [4]. Soy is recognized as the major dietary source of phytoestrogens, and soy-based products have been shown to contain significant quantities of total isoflavones. Isoflavones are known for their estrogenic activity due to their ability to bind to estrogen receptor and have received much attention due to their putative role as potential treatments for many disorders including cardiovascular disease, osteoporosis, age-related diseases, and hormone-dependent cancers [3].

Historically, legumes have played an important role in the diets of most cultural groups, and in many Asian countries, the most commonly consumed legume is the soybean (Table 60.1). Human consumption of isoflavones has the largest impact due to its availability and variety in food products. As expected, high levels of genistein and daidzein, as well as substantial amounts of coumestrol (Fig. 60.2), were found in traditional soy-based foods, as well as soy protein isolate, soy concentrate, or soy flour added to foods. Pulse grains contain a large number of bioactive compounds which have a metabolic benefit when consumed on a regular basis. The world production of soybean in 2009 is presented in Fig. 60.3. Demand for pulses has increased in recent years for human consumption either to extract a functional compound (e.g., starch, protein, or fiber), to incorporate this into cereal-based products, or to extract bioactive compounds which can be used as nutraceutical products [5].

2 Occurrence

Isoflavones are present in berries, wine, grains, and nuts, but are most abundant in soybeans and other legumes including kudzu root (*Pueraria lobata*), peanuts (*Apios americana*), and chickpeas (*Cicer arietinum*) [7]. Different isoflavone contents have also been reported in soybeans and soy-derived foods (soy milk, tofu, and tempeh), and other legumes such as adzuki beans, fenugreek, tepary beans, fava beans, soybeans, alfalfa, red clover, cowpeas, black gram, lentils, chickpeas, and licorice (Table 60.2). Daidzein and genistein are the two most well-characterized isoflavones [8]. Isoflavones are closely related to the antioxidant flavonoids found in other plants, vegetables, and flowers. Isoflavones, such as genistein and daidzein, are found in only some plant families, because most plants do not have the enzyme, CHI, which converts a flavone precursor into an isoflavone. *Pueraria lobata* (kudzu) and other species of *Pueraria* are also major source of isoflavonoids. Various parts of *Pueraria* plant like root, stem, and flowers accumulate isoflavonoids [9]. Isoflavonoid, puerarin (7-hydroxy-3-(4-hydroxyphenyl)-1-benzopyran-4-one 8-(β-D-glucopyranoside), is the major isoflavonoid present in root tubers of *Pueraria* species.

Some of isoflavone molecules have also been identified in 23 other angiosperm families [10]. Several leguminous and non-leguminous plant species contain different isoflavonoids with estrogenic activity (Table 60.3). Major active compounds in several nutraceuticals are the soy phytoestrogens, the isoflavonoid puerarin from Kudzu vine (*Pueraria lobata*), and formononetin from clovers and fenugreek. Another example is the root of licorice (*Glycyrrhiza echinata*), which contains an estrogenic isoflavan (glabridin) and isoflavene (glabrene) [2]. Seven isoflavones were also isolated from sprouted chickpea seeds, namely, biochanin A, calycosin, formononetin, genistein, trifolirhizin, ononin, and sissotrin [11].

Table 60.1 World production and consumption of isoflavones containing major legume crops (Modified from [6])

Edible legumes Latin name	Common name	World crop production (metric tons)	Main region of consumption
Pulses		3,819	
Dry beans (*Phaseolus* spp.)		1,162	Worldwide Americas, Africa

Genista sagittalis	16,33,600	3,100
Maackia amurensis	Traces	1,920
Pueraria tuberosa	6,042	8,682

3 Phytochemistry

Flavonoids are polyphenolic compounds containing 15 carbons with two aromatic rings connected by a three-carbon bridge, hence C_6-C_3-C_6 arrangements [12]. Flavonoids (about 5,000 structures known) are grouped into eight different subclasses, according to the oxidative status of the C-ring. These subclasses are flavanol, flavandiol, flavanone, dihydroflavanol, flavones, flavonol, isoflavone (about 1,000 structures known), and anthocyanidin. Isoflavonoids are a large subclass of flavonoids, consist of a phenyl ring fused with the six-membered heterocyclic C-ring and another phenyl ring (the B-ring) at the C_3 position, whereas for flavonoids, the B-ring is substituted to the C_2 position [13]. At the beginning of plant chemistry, isoflavonoids

were studied by phytochemists only and considered useful chemosystematic markers (chemical markers used for identification/classification of the species). Subsequently, they became known for their antifungal and insecticidal properties and were considered as phytoalexins by phytophysiologists [10]. The chemical structure of isoflavones is very similar to that of animal hormone estrogen (estradiol as female and testosterone as male hormone) (Fig. 60.2).

In plants, isoflavones occur predominantly as β−glucosides (genistin, daidzin, glycitin), or as acetyl-β-glucosides and malonyl-β−glucosides, and are, therefore, polar, water-soluble compounds. The biological and biochemical properties of isoflavonoids vary considerably with only minor modifications in structure (Table 60.4). Dietary isoflavones can be divided into four categories: (1) Aglycones (without attached glucose): daidzein, genistein, glycitein, formononetin, and biochanin A (Fig. 60.4); (2) Glucosides or glucones: daidzin, genistin, glycitin, ononin, and sissotrin; (3) Acetylglucosides or acetylglucones: 6″- acetyldaidzin, 6″-acetylgenistin, and 6″-acetylglycitin; (4) Malonylglucosides or malonylglucones: 6″- malonyldaidzin, 6″- malonylgenistin, and 6″-malonylglycitin. The low aqueous solubility of the isoflavone aglucones is due to the acidic nature of the phenolic groups and is pH-dependent. One of the most important chemical properties of isoflavones is the ability to participate in redox processes. Isoflavones act as free radical scavengers (chain-breaking antioxidants) when the phenoxilic head group encounters a free radical [14].

Table 60.4 Derivates formed due to isoflavone substitutions

Isoflavone substitution	Trivial name
7,4′-(OH)2	Daidzein
5,7,4′-(OH)3	Genistein
7,4′-(OH)2, 6-OCH3	Glycitein
5,4′-(OH)2, 7-OGlc	Genistin
4′-OH, 7-OGlc	Daidzin
4′-OH, 7-OGlc, 6-OCH3	Glycitin
7-OH, 4′-OCH3	Formononetin
5,7-(OH)2, 4′-OCH3	Biochanin A
7-OGlc, 4′-OCH3	Ononin
5-OH, 7-OGlc, 4′-OCH3	Sissotrin
7,3′-(OH)2, 4′-OCH3	Calycosin
5,4′-(OH)2, 7-OCH3	Prunetin
5,7,3′-(OH)3, 4′-(OCH3)	Pratensein
7-OH, 3′-O-CH2-O-4′	Pseudobaptigenin
5,7,3′,4′-(OH)4	Orobol
6,7-(OH)2, 4′-OCH3	Texasin
7-OH, 6,4′-(OCH3)2	Afrormosin
4′-OH, 7-OCH3	Isoformononetin

4 Biosynthetic Pathway

Isoflavones are synthesized as one group of end-products (iso-flavones) in the phenylpropanoid biosynthetic pathway (Fig. 60.5). They occur in highest levels in the roots, developing seedlings, and seeds of leguminous plants, but are found in lower amounts in leaves, stems, roots, and flowers of older plants. In seeds, they are

stored primarily as glucosyl conjugates (e.g., daidzin and genistin). As seeds of legumes germinate, the stored isoflavone conjugates get hydrolyzed by β-glucosidases to aglycones such as genistein and daidzein; this is accompanied by renewed synthesis of these compounds [15].

The precursors of flavonoid biosynthesis include shikimic acid, phenylalanine, cinnamic acid, and *p*-coumaric acid. Shikimic acid acts as an intermediate in the biosynthesis of aromatic acid. The basic pathways to the core isoflavonoid skeletons have been established both enzymatically and genetically [16]. The synthesis of isoflavones can be broadly divided into three main synthetic pathways: the formylation of deoxybenzoins, the oxidative rearrangement of chalcones and flavanones, and the arylation of a preformed chromanone ring. In leguminous plants, the major isoflavonoids are produced via two branches of the isoflavonoid biosynthetic pathway, and the different branches share a majority of common reactions [1]. Unlike the common flavonoid compounds, which have a 2-phenyl-benzopyrone core structure, isoflavones, such as daidzein and genistein, are 3-phenyl-benzopyrone compounds. Biochemically, the synthesis of isoflavones is an offshoot of the flavonoids biosynthesis pathway. Several attempts have aimed to increase

Table 60.5 Effects of isoflavonoid compounds on human and animal health

Compound	Effect	Model system/Species
Daidzein	Hepatoprotective, Anticancer	Rat
	Metabolizing phenotypes in relation to mammographic breast density	Women

	Osteoporosis,	White rabbits
	Alcohol abuse	Bone marrow cells
Biochanin A	Inhibition of stomach tumor growth	Human cell lines

isoflavone levels in soybean and introduce isoflavone biosynthesis in non-legumes [17]. Various key enzymes involved in the biosynthesis of isoflavonoid are chalcone synthase (CHS), chalcone isomerase (CHI), isoflavone synthase (IFS), 2-Hydroxyisoflavanone dehydratase (HID), *o*-methyltransferases (OMTs), UDP-glycosyltransferases (UGTs), and *o*-malonyltransferases (OMT). Chalcone reductase (CHR) is an enzyme that facilitates the biosynthesis of the 6′-deoxychalcone precursors of both 5-deoxyflavonoids and 5-deoxyisoflavonoids [18]. Genistein is biosynthetically the simplest isoflavonoid. It is a central intermediate in the formation of more complex isoflavonoids with roles in establishing or inhibiting interactions between plants and microbes. Daidzein differs from genistein by lack of a hydroxyl group at the 5-position. This hydroxyl group arises naturally from the head-to-tail condensations of malonyl CoA residues during the formation of naringenin chalcone by chalcone synthase [2].

5 Biological Activities

Dietary consumption of foods and food additives containing isoflavone phytoestrogens has been associated with several beneficial properties to human health (Table 60.5), such as prevention of coronary heart disease and osteoporosis, reduction of menopausal symptoms, and prevention of distinct cancer forms (e.g., breast, prostate, and colon cancer) [19, 20]. The potential health benefits of isoflavones for humans have been the subject of several reviews that have analyzed clinical, animal, and in vitro evidence for biological activity [5]. Several studies have reported that isoflavone consumption by postmenopausal women correlated with lower body mass index (BMI), and higher HDL levels (good cholesterol), while a number of studies have also reported absence of beneficial effects of soy on classical metabolic parameters such as bodyweight, serum lipid profiles, fat mass, blood glucose, and insulin profiles [21].

According to the USDA survey on isoflavone content, lentils do not contain significant amounts of these isoflavonoids [22]. Chickpeas contain daidzein, genistein, and formononetin (0.04, 0.06 and 0.14 mg 100 g^{-1} respectively) and approximately 1.7 mg 100 g biochanin A. Soybeans have significantly higher levels of daidzein and genistein (47 and 74 mg 100 g^{-1}, respectively) but contain less amount of formononetin and biochanin (Fig. 60.4) compared to chickpeas, 0.03 and 0.07 mg, 100 g^{-1} respectively [6]. The fact that isoflavones have been shown to exert estrogenic effects raises the possibility that this class of phytochemicals may affect glucose and lipid metabolism. In soybean, isoflavones are tightly associated with proteins. The substantial variability of phytoestrogen content found in soy products are 0.1–5 mg isoflavones/g of soy protein in mature and roasted soybeans, 0.3 mg/g soy protein in green soybeans and tempeh, and 0.1–2 mg/g soy protein in tofu and some soy milk preparations [21].

5.1 Cancer Prevention

The isoflavonoids possess many biological properties offering new strategies for cancer chemotherapy. Several papers have reviewed the potential roles of soy or its isoflavones in decreasing the risk of cancer [20]. Epidemiological data suggest that a diet rich in isoflavones provides protection against several forms of cancer, particularly those that are hormone-dependent, such as breast, prostate, and lung cancer [23]. These have shown a significant difference in cancer incidence among different ethnic groups, which is believed to be partly attributed to dietary habits. The incidences of breast and prostate cancers are much higher in the United States and European countries compared with Asian countries such as Japan and China. Genistein, the predominant isoflavones found in soy, has been shown to inhibit the carcinogenesis in animal models. There are growing body of experimental evidence that show the inhibition of human cancer cells by genistein through the modulation of genes that are related to the control of cell cycle and apoptosis. Moreover, it has been shown that genistein inhibits the activation of NF-kappa B and Akt (protein kinase also known as PKB) signaling pathways, both of which are known to maintain a homeostatic balance between cell survival and apoptosis [24]. Genistein causes inhibition of cell growth in breast [25] and prostate cancers in vivo and in vitro. Both genistein and genistin induce cell cycle arrest [26] and are able to induce significant apoptosis. Some other isoflavonoids, like puerarin was isolated from *Pueraria radix* and the study showed that puerarin also possessed anticancer properties. Methyl thiazolyl tetrazolium (MTT) assay revealed a dose-dependent reduction of HT-29 cellular growth in response to puerarin treatment. These findings indicate that puerarin may act as a chemopreventive and/or chemotherapeutic agent in colon cancer cells by reducing cell viability and inducing apoptosis [27]. Molecular mechanism of suppression of MDR1 (multidrug resistant) tumor cells by puerarin from *Pueraria lobata* via NF-κB pathway and cAMP-responsive element transcriptional activity-dependent up-regulation of AMP-activated protein kinase in breast cancer MCF-7/adr cells [28] was also reported.

5.2 Cardiovascular Diseases

Soy protein-containing foods are a rich source of isoflavone phytoestrogens, such as genistein and daidzein. There is great interest in these substances, as lower rates of chronic diseases, including coronary heart disease, have been associated with high dietary intake of soy-containing foods [29]. Genistein and daidzein were found to protect against cytotoxic effects of oxidized LDL as assessed by cellular morphologic features as well as lactate dehydrogenase released by cultured endothelial cells.

Isoflavones prevent atherosclerosis; the most cited example in this case is the inhibition of LDL oxidation, formation of which is central in atherogenesis [7]. Many investigations have demonstrated that soy protein inhibits cardiovascular diseases and reduces atherosclerosis risk in animals and humans, for example, genistein upregulates the expression of human endothelial nitric oxide synthase and lowers blood pressure in spontaneously hypertensive rats [30].

5.3 Antioxidant Activity

Soybean isoflavones may exhibit their cancer preventive function through their antioxidant properties. Genistein, the major component of soybean isoflavones, has been demonstrated to inhibit ultraviolet-B (UVB)-induced skin tumorigenesis in hairless mice. The antioxidant properties of genistein may explain the mechanisms of its anti-photocarcinogenic action either by direct quenching of reactive oxygen species or indirect anti-inflammatory effects. Genistein was found to substantially inhibit a series of oxidative events elicited by UVB irradiation, including hydrogen peroxide (H_2O_2) production, lipid peroxidation, and 8-hydroxy-2′-deoxyguanosine (8-OHdG) formation [31]. Genistein potently scavenges both H_2O_2 and superoxide anions, which suggests genistein has potential anticarcinogenic function in photocarcinogenesis through its antioxidant property [32]. Genistein has also been shown to inhibit hydrogen peroxide production and increase the activity of antioxidant enzymes, such as catalase, superoxide dismutase, glutathione peroxidase, and glutathione reductase. Furthermore, genistein and daidzein can inhibit superoxide anion generation by xanthine/xanthine oxidase [4]. The root extract of *Pueraria lobata* (a rich source of these isoflavonoids) showed in vivo antioxidant activity in diabetic rat model [33]. Therefore, antioxidant activity of pure isoflavonoids or plant extracts has been established.

5.4 Estrogenic Activity

Because of the similarity in structure, isoflavonoids can interfere with the action of estrogen in human being. Depending on the type of estrogen receptor on the cells, isoflavones may reduce or activate the activity of estrogen. Isoflavones can compete with estrogen for the same receptor sites thereby decreasing the health risks of excess estrogen. They can also increase the estrogen activity. Estrogenic activity is dependent on the affinity of binding to the estrogen receptors, which is determined by the presence of the aromatic ring as well as hydroxyl groups at specific sites. Compared with estradiol, genistein and daidzein bind estrogen receptors with 100 and 1,000 times less affinity, respectively [4]. Isoflavonoids studies showed that developmental exposure to genistein causes deleterious effects on the reproductive system of mice. Oral exposure to genistin (25 mg/kg) increases uterine weight at 5 days of age similar to subcutaneous injection of genistein (20 mg/kg) suggesting that subcutaneous injection of genistein is a suitable model for oral exposure to genistin [34]. The root extract of *Pueraria mirifica* showed an estrogenic effect on human mammary adenocarcinoma (MCF-7) cells [35]. Root extract of *Pueraria tuberosa* also showed antifertility effect in male rate [36]. The isoflavonoid daidzein adversely affected erectile function in rats in a dose- and time-related manner that was attributable to androgen deficiency [37].

6 Biotechnological Approaches

A biotechnological approach, specifically plant tissue culture plays a vital role in search for alternatives to produce desirable medicinal compounds from plants. Plants and plant cell cultures have served as resources for flavors, aromas and fragrances, enzymes, preservatives, cosmetics, natural pigments, and bioactive compounds. These are secondary metabolites also present in unorganized callus or suspension cultures of the species. To meet the growing demand by pharmaceutical industries these compounds have been isolated from sources other than the original plants and different strategies have been adapted to improve their yield in cell cultures. These include screening and selection of high-producing cell lines, optimization of nutrient media for growth and production, organ culture, culture of immobilized cells, etc. [38, 39].

Many of plants in vitro cultures have been reported for the production of useful isoflavonoids (Table 60.6). Employment of cell and tissue culture in liquid medium (Fig. 60.6) predominantly provides uniform conditions for growth and metabolite synthesis, rapid biomass gain, better amenability for precursor feeding, elicitation, higher feasibility for bioreactor scaling up and easy extraction. Isoflavonoid production in cell cultures of *Pueraria tuberosa* as influenced by several nutrient factors, elicitors, plant growth regulators, and angiospermic parasite (*Cuscuta reflexa*) was studied in our laboratory. The optimized elicitation conditions were used in vessels of varying capacity where maximum yield of ~91 mg l^{-1} of

Table 60.6 Isoflavonoids production from in vitro cultures of different plant species

Plant species	Type of culture	Isoflavonoids produced	References

Genista tinctoria	Callus culture	genistein, daidzein Formononetin	[53]
Trifolium pratense	Cell culture	Formononetin, biochanin A	[54]

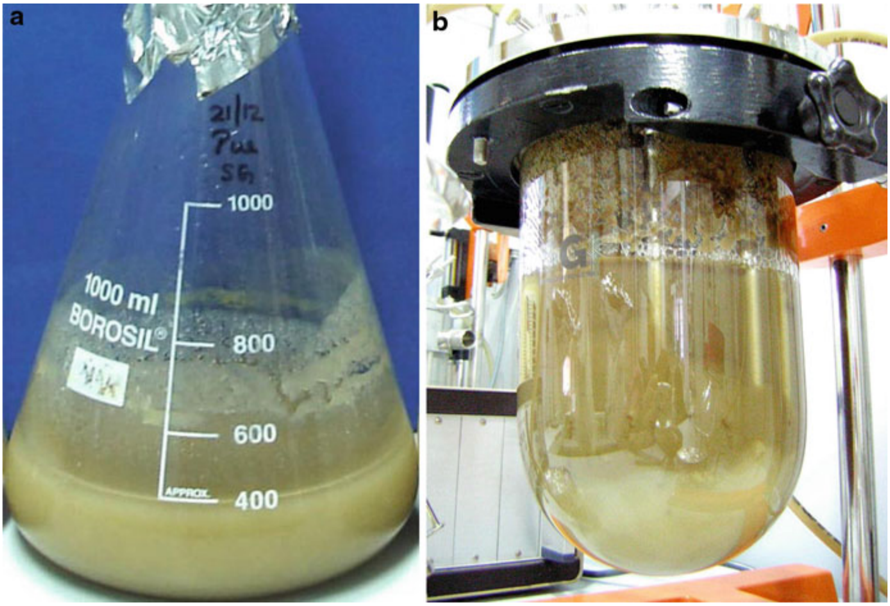

Fig. 60.6 Cell cultures of *Pueraria tuberosa* grown in shake flasks on a rotary shaker and in 2 L stirred tank bioreactor for the production of isoflavonoids

isoflavonoid was recorded in 2 l bioreactor which was about 19 % higher than the values achieved earlier [40–43]. Improved isoflavonoid production in *Pueraria candollei* hairy root cultures was achieved on day 3 of elicitation [44]. Biotechnology approaches are not limited to tissue culture but also extend up to genetic transformation and molecular biology for the production of high-level bioactive molecules. The cell cultures of *Cicer arietinum*, *Pueraria lobata*, and *P. thomsonii* have been studied for elicitor-induced manipulation of isoflavonoid production [45, 46]. The organ cultures are stable in the production of secondary metabolites than undifferentiated callus and cell cultures [47, 48]. These recent works suggest a great promise for exploitation of isoflavones production by cell cultures technology.

7 Conclusion

Pulses are traditionally consumed in Asian and east Asian countries. Health benefits of continuous consumption of soybean and pulses are now known scientifically and established. Therefore, efforts are required to improve these legumes not only for their primary nutrient contents but also for the bioactive molecules. The beneficial effects of these isoflavonoids have been established and hence these products can be either used directly or as extracts for fortification of nutraceuticals. Genetic engineering and plant cell culture technologies hold great promise for the improvement of the legume plants and production of bioactive molecules. The legume plants as well as cell cultures can be explored further for the identification of minor bioactive molecules in these materials not known so far. This will have great consequences in food and medical industries.

Abstract

Chalcones, flavanones, dihydrochalcones, and aurones are categorized into minor flavonoids. However, these compounds take the significant roles in plant kingdom. These minor flavonoids are unique to plants and are an essential part of their success in adapting to life as sedentary organisms in diverse and inconstant surrounding. Furthermore, these compounds are subclasses of the interesting naturally occurring flavonoids in view of their structural pattern as well as biochemical and pharmacological relevance. It seems that they are important not only for plants but also for animals including human beings. This chapter deals with these minor flavonoids.

Keywords

Aurone • chalcone • dihydrochalcone • flavanone

Abbreviations

AmAS1	Aureusidin synthase
CHI	Chalcone isomerase
CHS	Chalcone synthase
CoA	Coenzyme A
COX	Cyclooxygenase
LPS	Lipopolysaccharide
NADPH	Reduced nicotinamide adenine dinucleotide phosphate
NF	Nuclear factor
NO	Nitric oxide
ROS	Reactive oxygen species
TNF	Tumor necrosis factor

1 Chalcone

1.1 Introduction

Chalcones, 1,3-diaryl-2-propen-1-ones, belong to the plant flavonoid family. The name “chalcone” comes from a Greek word *chalcos* (bronze). Chemically, they consist of open-chain flavonoids in which the two aromatic rings (A and B) are joined by a three-carbon α,β-unsaturated carbonyl system. Chalcones possess the conjugated double bond and a completely delocalized π-electron system on both aromatic rings. Although chalcone skeleton is the initial intermediate structure used in biosynthesis of all flavonoids, chalcones are one of the minor subclasses of flavonoids.

1.2 Occurrence of Chalcones

Chalcones were originally discovered in plants as the yellow flower pigments of *Coreopsis* and other yellow-rayed Compositae. After that, they have subsequently been found in other plant families including Solanaceae, Anacardiaceae, Caesalpiniaceae, Piperaceae, and Apiaceae. 6′-Deoxychalcones were known to be chemical constituents of leguminous plants, but it is scarcely reported that they were found in other plant species. A lot of chalcones were isolated from either Compositae (Asteraceae) or Leguminosae (Fabaceae), two families well known to accumulate these. Besides, various prenylchalcones can be found in hop plants (Cannabaceae).

1.3 Phytochemistry of Chalcones

Chalcone numbering is shown in Fig. 61.1. A vast number of naturally occurring chalcones are polyhydroxylated in the aromatic rings. Usually, chalcones have hydroxyl group at C2′-, C4′-, and/or C6′-positions in A-ring because the A-ring is biosynthesized via the acetate-malonate pathway. Prenylchalcones have prenyl group(s) between the hydroxyl groups. Cyclization of the prenyl group and the adjoining hydroxyl group produces pyrano ring on the aromatic ring. Chalcones, which do not have an oxygen function at the 2′-position, are called retrochalcones. The B-ring generally has a hydroxyl group at C4-position. They are both intermediates and end products in flavonoid biosynthesis, act as defensive compounds, participate in plant-insect interactions, and contribute to the medicinal value of herbs.

1.4 Biosynthesis of Chalcones

Chalcones are biosynthesized through the combination pathway of acetate-malonate and shikimate pathways [1–3]. Malonyl-CoA is synthesized from acetyl-CoA, whereas *p*-coumaroyl-CoA originates from phenylalanine, which is produced via the shikimate pathway. Chalcone synthase (CHS) catalyzes the significant step of chalcone biosynthesis. It first condenses a phenylpropanoid-CoA (e.g., *p*-coumaroyl-CoA) with three units of malonyl-CoA and cyclizes the resulting tetraketide intermediate to afford a chalcone (e.g., naringenin-chalcone). 6′-Deoxychalcones (e.g., isoliquiritigenin) having a resorcinol-type A-ring are biosynthesized by coactions of NADPH-dependent chalcone reductase and CHS (Scheme 61.1).

1.5 Biological Activities of Chalcones

Considerable attention has been devoted to research of chalcones [4–6], which are distributed in fruits, spices, tea, and soy-based foodstuff, because of their interesting and potential pharmacological activities. Naringenin-chalcone is found in Compositae, Lamiaceae, and Solanaceae [7]. Naringenin-chalcone is one of the predominant flavonoids found in tomatoes (*Solanum lycopersicum*) and accumulates almost exclusively in the tomato peel [8]. This compound inhibited histamine release with an IC_{50} value of 68 μg/ml and was found to be the most promising antiallergic polyphenol of this extract [9]. The effect on the production of naringenin-chalcone proinflammatory mediators in lipopolysaccharide (LPS)-stimulated macrophages has been examined. This compound inhibited the production of tumor necrosis factor (TNF)-α, monocyte chemoattractant protein (MCP)-1, and nitric oxide (NO) by LPS-stimulated RAW 264.7 macrophages in a dose-dependent manner [10]. Naringenin-chalcone exhibited anti-inflammatory properties by inhibiting the production of proinflammatory cytokines in the interaction between adipocytes and macrophages. In addition, the oral administration of naringenin-chalcone was shown to suppress Th2 cytokine production from CD4 T cells in the spleen and to attenuate allergic airway inflammation and airway hyperreactivity [11]. The eating naringenin-chalcone could contribute to the prevention and improvement of insulin resistance and related metabolic syndrome [12]. Isosalipurposide, the glucoside derivative of naringenin-chalcone isolated from *Nymphaea caerulea* or *Helichrysum maracandicum*, exhibited the inhibition of ROS (reactive oxygen species) generation in HL60 cells [13] and strong antiproliferative activity against cultured cells of SENCAR mouse in vitro [14]. Isoliquiritigenin is found in *Glycyrrhiza* species (Leguminosae) such as *G. uralensis*, *G. glabra*, *G. inflata*, Lardizabalaceae, and Amaryllidaceae [15–19]. Isoliquiritigenin is known as a natural aldose reductase inhibitor [20]. It was reported to possess antioxidative and super oxide scavenging activities [16], antiplatelet aggregation effect [21], estrogenic property [22], and inhibitory on xanthine oxidase activity in vitro [23]. And it demonstrates its anti-inflammatory effect by inhibiting LPS-induced iNOS and COX-2 expression via the attenuation of NF-κB in RAW 264.7 macrophages [24]. Interestingly, isoliquiritigenin was also found to inhibit cocaine-induced dopamine release by modulating $GABA_B$ receptor [25]. Besides, it was found that isoliquiritigenin had good effects on inhibition proliferation, including apoptosis and locking cell cycle progression in the G1 phase against human lung cancer A549 cells [26]. It induced cell cycle arrest and p21 expression in these cells [27], apoptosis and p53-expression in human liver carcinoma Hep G2 cells [28], and also induces apoptosis by depolarizing mitochondrial membranes in human prostate cancer DU145 cells [29]. Moreover, isoliquiritigenin induced monocytic differentiation of human leukemia HL60 cells [30]. It was reported that isoliquiritigenin has the ability to protect cells from AA (arachidonic acid) and iron-induced ROS production and mitochondrial dysfunction; the cytoprotective effect mediated via AMPK (AMP-activated protein kinase)-dependent GSK3β (glycogen synthase kinase-3β) inactivation.

Fig. 61.2 Structures of bioactive chalcones

Isoliquiritigenin is useful to protect mitochondria from an iron catalyzed burst of oxidative stress [31]. 2′-*O*-Methyl isoliquiritigenin isolated from the root of *Dalbergia odorifera T. Chen* had the obvious antioxidative effect and the inhibitory effect of decrease of glutathione (GSH) level of rat lens induced by UV irradiation [32] (Fig. 61.2).

Butein (2′,3,4,4′-tetrahydroxychalcone) can be isolated from stembark of cashews and *Rhus verniciflua* Stokes. Past investigations suggested that butein exhibits anticarcinogenic effects. The organic extract purified from *R. verniciflua* Stokes inhibited the growth of transformed hepatic cells but not the untransformed parent cells [33], whereas butein alone could induce G(2)/M phase arrest in Hep G2 cells [34]. Its antiproliferative or pro-apoptotic effects can be brought about through downregulating STAT3-related gene expressions [35] and inhibiting telomerase activity [36]. This compound can also resensitize the TRAIL-resistant leukemia cells undergoing apoptosis upon TRAIL treatment [37] and reduce clonogenic growth of human breast cancer UACC-812 cells [38]. In addition, butein can suppress the proliferation of many human cancers including colon carcinoma, osteosarcoma, and hepatic stellate cells in vitro [39–43]. Sappanchalcone isolated from sappan lignum (the dried heartwood of *Caesalpinia sappan*) showed rapid vasorelaxant activity on the mesenteric artery [44]. This chalcone exhibited the anti-inflammatory effect in LPS-induced human periodontal ligament HPDL cells by protecting from H_2O_2 [45]. Sappanchalcone suppressed human oral cancer cell

(HN4 and HN12) growth and induces apoptosis through the activation of p53-dependent mitochondrial, p38, ERK, JNK, and NF-κB signaling [46]. Additionally, other biological effects of this compound involve the inhibition of β-hexosaminidase release [47] and anti-influenza virus activity [48]. Flavokawin A and B were isolated from kava (*Piper methysticum*) with anti-inflammatory activity. They inhibited TNF-α-induced degradation and translocation of p50 and p65 NF-κB subunits from the cytoplasm to the nucleus [49]. Flavokawin B produced pronounced antinociception effect against both chemical and thermal models of pain in mice that exhibited both peripheral and central analgesic activity [50]. Cardamonin isolated from *Alpinia rafflesiana*, *Artemisia absinthium*, or *Syzygium samarangense* inhibited NO and prostaglandin E_2 (PGE_2) production from LPS- and IFN-γ-activated RAW 264.7 macrophages by the inhibition of p65NF-κB nuclear translocation due to prevention of I-κBα phosphorylation, which subsequently caused the accumulation of I-κBα [51, 52]. This chalcone also inhibited the generation of the stable thromboxan metabolite, thromboxan B2 (TxB_2), via both COX-1 and COX-2 pathways; generation of intracellular ROS; and secretion of TNF-α from RAW 264.7. Cardamonin demonstrated its cytotoxic activity against human colon cancer SW-480 cells [53].

Xanthohumol, desmethylxanthohumol, 4′-methylxanthohumol, and 2′-*O*-methyl-3′-prenylchalconaringenin can be found in hop plants (*Humulus lupulus*). Xanthohumol is the most abundant prenylchalcone present in hops (concentrations up to 1 %, w/w). It is accompanied by its homologue, desmethylxanthohumol, albeit in lower concentrations [54]. Xanthohumol, desmethylxanthohumol, and 4′-methylxanthohumol were reported to exhibit strong antioxidative effects in ORAC assay [55]. Xanthohumol has been suggested to have potential cancer chemopreventive activities by inhibiting human breast MCF-7, colon HT-29, ovarian cancer A-2780 [56], and B-chronic lymphocytic leukemia cell proliferation in vitro [57]. This also showed antiangiogenic properties in vitro and in vivo where it inhibited proliferation of endothelial and Kaposi's sarcoma-derived tumor cells in vitro, prevented angiogenesis in the Matrigel sponge model, and reduced Kaposi's sarcoma xenograft growth in vivo. The antiangiogenic effects of xanthohumol correlated with a block of NF-κB activation and decreased phosphorylation of Akt [58, 59]. Isobavachalcone, which is a prenylchalcone found in *Angelica keiskei*, *Dorstenia barteri*, or *Psoralea corylifolia*, has been demonstrated to exhibit cancer antipromotive and antiproliferative activity [60]. Previous studies have shown that isobavachalcone exerts inhibitory effect against skin tumor promotion in vivo mouse skin carcinogenesis [61], and the ability of this chalcone to induce apoptosis in neuroblastoma IMR-32 and NB-39 cells has been reported [62]. Isobavachalcone significantly reduced pro-caspase-3 and pro-caspase-9 and subsequently increased the level of cleaved caspase-3 and cleaved caspase-9 in both cell lines. In addition, isobavachalcone demonstrated strong antifungal activity against various fungi, *Candida albicans*, *C. glabrata*, *Microsporum audorium*, and *Trichophyton rubrum* [63]. Crotaorixin isolated from the aerial parts of *Crotalaria orixensis* and medicagenin, which is a diprenylchalcone, isolated from the roots of *Crotalaria medicagenia* exhibited

the high antimalarial activity. They showed 100 % inhibition of maturation of *Plasmodium falciparum* parasites from ring stage to schizont stage at low concentrations [64] (Fig. 61.3).

Licochalcones such as licochalcone A, B, and C isolated from licorice (the root and rhizome of *Glycyrrhiza* spp. *G. uralensis*, *G. glabra*, and *G. inflate*) are classified into the retrochalcones (chalcones which do not have an oxygen function at the 2′-position). The content of licochalcone A in licorice was found to be very high [65]. Previous studies showed that licochalcone A possessed radical scavenging [65], antileishmanial [66], and antispasmodic effects [67]. This chalcone has been used to treat various abdominal spasmodic symptoms in Japan [68]. Licochalcone A is well known to be a natural antiparasitic agent. Licochalcone A is a potent membrane-active compound that transforms normal erythrocytes into echinocytes in parallel with the inhibition of growth of *P. falciparum* cultures. The erythrocyte membrane-modifying effect was also transiently observed in vivo in mice after intravenous administration [69]. This compound exhibited the antimicrobial activity by inhibiting the growth of *Staphylococcus aureus*, *Bacillus subtilis*, and the activity of *Helicobacter pylori* [70, 71]. Furthermore, licochalcone A significantly inhibited LPS-induced NF-κB activation. This chalcone specifically inhibited the phosphorylation of p65 NF-κB at serine 276, leading to the inhibition of NF-κB transactivation [72]. Licochalcone A also has

anticancer effects, induced apoptosis in MCF-7, HL60, and human prostate cancer LNCaP cells, and arrested G2 and late-G1 in human prostate cancer PC-3 cells [73–75]. Licochalcone B showed the high antioxidative effect stronger than that of licochalcone A on the 5-lipoxygenase-dependent peroxidation in arachidonate metabolism [76]. Licochalcone C also exhibited the anti-inflammatory activity by inhibiting NF-κB signaling [77]. Recently, chalcone glycosides, which do not have an oxygen function at the 2′-position, were isolated from the aerial parts of *Brassica rapa* L. "hidabeni" [78]. These 4′-*O*-β-D-glucopyranosyl-4-hydroxy-3′-methoxychalcone and 4′-*O*-β-D-glucopyranosyl-3′,4-dimethoxychalcone markedly inhibited antigen-stimulated degranulation in rat basophilic leukemia RBL-2H3 cells. The inhibitory effects were mainly due to suppression of intracellular Ca^{2+} elevation by suppression of intracellular ROS production through NOX inactivation [79]. Moreover, 4′-*O*-β-D-glucopyranosyl-3′,4-dimethoxychalcone inhibited LPS-induced iNOS expression and NO production in rat immortalized microglia HAPI cells. The inhibitory effect is due to the prevention of phosphorylation of signal transduction and activator of translocation 1 (STAT1) [80] (Fig. 61.4).

Lonchocarpin, which is a pyranochalcone, isolated from *Lonchocarpus sericeus* showed significant antiplatelet effect. The effect was suggested to be mediated by phosphodiesterase activity by inhibition or elevation of intracellular levels of adenosine 3′:5′-cyclic monophosphate and guanosine 3′:5′-cyclic monophosphate [81]. Crotaramosmin isolated from *Crotalaria ramosissima* showed weak antimalarial activity and strong antileishmanial effect [64].

Carthamin, which is a bichalcone, occurs in the tubular flowers at a late phase of the flowering stage in safflower *Carthamus tinctorius* [82]. This compound is known to be

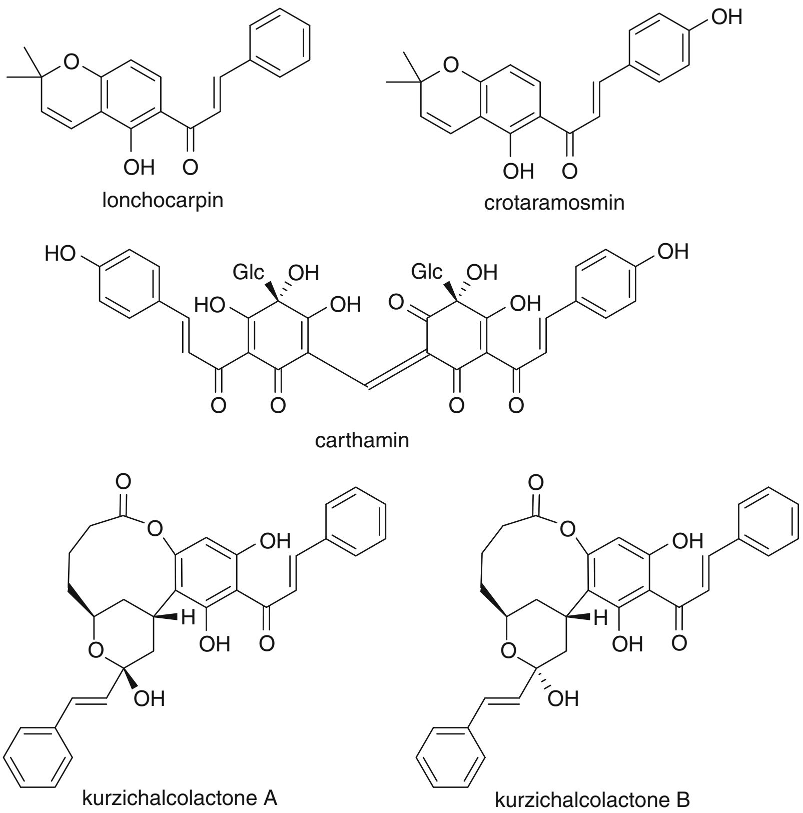

Fig. 61.5 Structures of rare chalcones

called Natural Red 26. Carthamin has been extensively used as a natural food color additive and created to cosmetics for geisha and kabuki artists for a long time in Japan. Carthamin administration could improve the blood fluidity by decreasing whole blood viscosity [83]. Kurzichalcolactones A and B, which have an unprecedented carbon side chain on the chalcone A-ring, were isolated from *Cryptocarya kurzii* with cytotoxic activity against human epidermoid carcinoma KB cells [84] (Fig. 61.5).

2 Flavanone

2.1 Introduction

Within the plant secondary metabolites of flavonoids, flavanones define one of the minor subclasses. They may be called dihydroflavones. The basic chemical structure of flavanones involves two benzene rings (A and B), which are linked by a heterocyclic ring (C). The most characteristic point of flavanone structures is that the C-ring is saturated. Flavanones have an asymmetric carbon at C2-position.

They are also interesting compounds because they are the obligate intermediates in flavonoid biosynthesis. Although flavanones are minor chemical constituents of plants, they have attracted a lot of attention in chemistry and biological sciences.

2.2 Occurrence of Flavanones

Flavanones occur in several plant families including Libiatae, Annonaceae, Acanthaceae, Compositae, Leguminosae, and also Rutaceae [85]. Flavanones having a hydroxyl group at 5-position in A-ring constitute the majority of flavonoids in Rutaceae fruits such as sweet (*Citrus sinensis*), sour oranges (*C. aurantium*), and their relatives. All orange-type citrus fruits contain the flavanone aglycones naringenin and hesperetin, but they rarely occur as free aglycones in the fruit itself. The dominant flavanone glycosides in sweet oranges (*C. sinensis*) are hesperidin and narirutin, whereas in sour oranges (*C. aurantium*), the two predominant flavanone glycosides are neohesperidin and naringin. The major difference between the flavanone glycosides of sweet and sour oranges is in their sugar moieties, which influence taste. The sugar rutinose (6-*O*-α-ʟ-rhamnosyl-β-ᴅ-glucose) causes the flavanones hesperidin and narirutin to have a neutral taste and is relatively high in sweet oranges, tangerines, and tangors. The sugar neohesperidose (2-*O*-α-ʟ-rhamnosyl-β-ᴅ-glucose) is high in tangelos and sour oranges and imparts a tangy or bitter taste to the glycosides neohesperidin and naringin [86]. The representative citrus flavanones and their glycosides are shown in Fig. 61.6. On the other hand, various flavanones, which do not have a hydroxyl group at 5-position, can be found in Leguminosae (Fabaceae) family.

2.3 Phytochemistry of Flavanones

Flavanone numbering is shown in Fig. 61.7. As a rule, flavanones have hydroxyl groups at 5- and 7-positions in A-ring and 4′-position in B-ring. And flavanones exist as glycosides in nature. Naturally occurring flavanones usually have the 2*S*-configuration, but racemization can occur during extraction. Flavanones can be easily converted to isomeric chalcones in alkaline media (or vice versa in acidic media) provided that there is a hydroxyl substituent at 2′- or 6′-position of the chalcone. In general, the physical properties of flavanones are greatly different from that of flavones. The content of flavanones may control the sweetness or bitterness of fruits. The flavanones are less soluble than the chalcones, tend to separate first in fractional crystallization, and are easily precipitated at low pH, especially if solutions are chilled or frozen.

2.4 Biosynthesis of Flavanones

The enzyme chalcone isomerase (CHI) is the second key enzyme of flavonoid biosynthesis in higher plants and catalyzes the conversion of chalcones to their

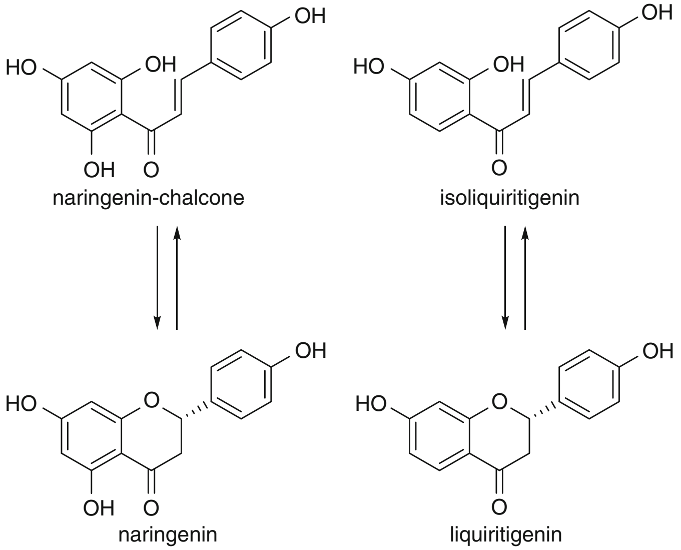
corresponding flavanones. Chalcones having a hydroxyl group at C2′-position, especially those further possessing a 6′-hydroxy substitution, are spontaneously converted into a racemic mixture of the respective 2 *S*- and 2*R*-flavanones. However, they are stereospecifically isomerized into 2*S*-flavanones more rapidly by CHI



Scheme 61.2 Biosynthesis of flavanones

than spontaneous conversion in plants (Scheme 61.2). Flavanones have a chiral center at C-2 position so that naturally occurring members are often optically active.

2.5 Biological Activities of Flavanones

Naringenin, which is abundant in grapefruits (*Citrus* × *Paradisi*) and other citrus fruits, has been shown to inhibit microsomal lipid peroxidation [87], nonenzymatic lipid peroxidation [88], and ascorbic acid-induced malondialdehyde (MDA) formation. Hesperetin showed a similar level of inhibition. Naringenin, however, had no effect on ferrous sulfate-induced MDA production [88]. This flavanone was found to inhibit TxB_2 production in platelets stimulated with either thrombin or AA (arachidonic acid), whereas the glycoside form naringin was inactive [89]. Naringenin also inhibited the formation of oxygenated metabolites in platelets stimulated with thrombin and inhibited AA-induced platelet aggregation. Although eriodictyol offered protection against TNF-α-induced cytotoxicity in murine fibroblast L-929 cells, naringenin was not protective [90]. Naringenin and hesperetin have beneficial effects on cardiovascular diseases involving vasodilation. They displayed a concentration-dependent inhibition of the agonist-induced contractile responses [91]. It was known that naringenin was able to traverse the blood-brain barrier [92] and exert a diverse array of neuronal effects through their ability to interact with the protein kinase C (PKC) signaling pathways [93]. Naringenin can bind to both estrogen receptors, ER-α and ER- β [94]. Importantly, naringenin competed more effectively with 17-β-estradiol for binding to ER-β than for ER-α.

Interaction of naringenin with ER-β may be relevant for cardiovascular effects as this receptor is present in significant amount in arterial tissue [95]. Furthermore, results of anticarcinogenesis experiments indicated that naringenin, but not naringin, inhibited aflatoxin B1-induced carcinogenesis [96] and that naringenin caused cytotoxicity and apoptosis via a transient induction of caspase-3 activity in HL60 cells [97]. Additionally, it exhibited strong antiproliferative activity in various cancer cells, and its treatment dose showed no toxic effect on normal cells [98–101]. Narirutin, which is found in immature oranges, was reported to inhibit airway inflammation in the allergic mouse model [102]. The anti-inflammatory effect is likely to be associated with the reduction in the ovalbumin (OVA)-induced increases of interleukin (IL)-4 and immunoglobulin E (IgE). Naringin, which is found in the peels of citrus fruits such as grapefruit, *C. hassaku*, and others, is hydrolyzed to a major metabolite, naringenin which readily crosses the blood-brain barrier. It has been reported to possess antiviral, antihypertensive, and neuroprotective effects [103–105]. Naringin has potent antioxidative activity which has been observed in various in vitro and in vivo animal models [106, 107]. This compound also has metal chelating, free radical scavenging properties and offers some protection against mutagenesis and lipid peroxidation [108]. The antioxidative effects have been shown to be similar to GSH (glutathione). Naringin plays the important role in regulating antioxidative capacity by increasing superoxide dismutase (SOD) and catalase (CAT) activities and by upregulating the gene expression of SOD, CAT, and glutathione peroxidase (GPx) [109]. In cholesterol metabolism, naringin is known to act as an inhibitor for a hydromethylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in the mevalonate pathway [110]. In addition, naringin enhanced the proliferation of cells including rat osteosarcoma UMR106, mouse osteoblastic MC3T3-E1, and mouse leukemia P388 cells [99, 111, 112]. Hesperetin is reported to be a powerful radical scavenger and a promoter of cellular antioxidant defense-related enzyme activities [113]. This compound exhibited anti-inflammatory activity by inhibiting of LPS-induced expression of the COX-2 gene in RAW 264.7 macrophages [114]. Hesperetin is a potent chemopreventive agent; its supplementation during the initiation, post-initiation, and entire period stages of colon carcinogenesis in the male rat model in vivo significantly reversed these activities [115]. Administration of hesperetin to 1,2-dimethylhydrazine (DMH)-treated rats decreased the tumor incidence and the number of aberrant crypt foci with simultaneous enhancement of tissue lipid peroxidation, glutathione S-transferase (GST), GPx, SOD, and CAT activities [116]. Hesperetin induced Notch homolog 1 (NOTCH1) expression in human gastrointestinal carcinoid (BON) cells, subsequently suppressing tumor cell proliferation and bioactive hormone production [117]. Therapeutically useful properties of hesperidin, which is found in the peels of citrus fruits (*C. aurantium* var. *daidai*, *C. natsudaidai*, and *C. unshiu*), have also been described. Hesperidin can prevent microvascular leakage by virtue of its vasoprotective action through the inhibition of the enzyme hyaluronidase which is reported to regulate the permeability of capillary walls and supporting tissues [118]. Additionally, it has been demonstrated that hesperidin can decrease blood cell and platelet aggregation, believed to be beneficial in cases of capillary permeability and fragility [119]. Besides, their effect on vascular permeability and ocular blood flow, both hesperidin and hesperetin, demonstrate strong antioxidative properties [120]. The antioxidative activity is through their ability to quench oxidative radical chain reactions and can thus help preserve neuronal health. Hesperidin also exhibited significant anti-inflammatory activity by modulating the prostaglandin synthesis and COX-2 gene expression pathways [114]. Hesperidin has been reported to possess analgesic, hypolipidemic, antihypertensive, and diuretic activity [121–123]. Another potential therapeutic application of hesperidin is its anticancer activity mediated through the suppression of cell proliferation [124, 125]. Neohesperidin also showed antiproliferative activity in Hep G2 cells [126] and the antiallergic effect on dermatitis in mice [127]. Eriodictyol, which is abundant in lemon, was found to reduce NO production from LPS-stimulated RAW 264.7 macrophages [128]. The inhibitory effect was found to be caused by blockage of NF-κB activation and phosphorylation of p38 mitogen-activated protein kinase (MAPK), extracellular signal-regulated kinases 1 and 2 (ERK1/2), and c-Jun N-terminal kinase (JNK). It has been reported that eriocitrin, which is a lemon (*C. limon*) flavanone, is effective in the prevention of oxidative damages caused by acute exercise-induced oxidative stress in the rat liver [129]. Neoeriocitrin showed free radical scavenging activity, the inhibition of superoxide formation [130], and the better effect than naringin on proliferation and osteogenic differentiation in mouse preosteoblast MC3T3-E1 cells [131]. Isosakuranetin, which is found in blood oranges (*C. sinensis*), grapefruits, and others, exhibited the neuroprotective effect. This compound increased cell viability and catalase activity (CA) and decreased membrane damage, ROS generation, intracellular calcium level ($[Ca2^+]_i$), and caspase-3 activity in H_2O_2-treated PC12 cells [132]. Interestingly, isosakuranetin is known to be an allelopathic molecule and acts by affecting K^+ uptake and K^+-dependent acid extrusion [133].

Liquiritigenin is extracted from *Glycyrrhizae radix*, a herbal that is frequently used to treat injury or swelling or for detoxification in traditional medicine. Liquiritigenin is also one of the major active compounds of menopausal formula 101 (MF101), a herbal extract used in clinical trials for the treatment of hot flushes and night sweats in postmenopausal women [134]. Liquiritigenin is shown to be a selective agonist of ER-β [135] and that targeting this receptor may be associated with anti-inflammatory effects. Liquiritigenin inhibited NO and TNF-α production induced by LPS in RAW 264.7 macrophages [136]. Studies have already proven that liquiritigenin exerts cytoprotective effects against heavy metal-induced toxicity in cultured hepatocytes [137] and has protective effects against liver injuries induced by acetaminophen and buthione sulfoximine (BSO) in rats [138]. Besides, liquiritigenin has been reported to have the choleretic effect and the ability to induce hepatic transporters and phase II enzymes [139] and inhibit amyloid β-peptide-induced neurotoxicity, not only in hippocampal neurons [140], but also in rats [141]. In addition, liquiritigenin inhibited the growth of human gastric carcinoma SGC-7901, human hepatocellular carcinoma SMMC-7721, and human colorectal cancer Lovo cells [142]. Liquiritin, an active component of *Glycyrrhiza uralensis*, might be a good candidate for treating various neurodegenerative diseases including Alzheimer's disease or Parkinson's disease [143]. This compound showed neuroprotection and neurotrophism on primary cultured hippocampal cells

[144]. Liquiritin provided obviously neuroprotective effect on middle cerebral artery occlusion (MCAO)-induced focal cerebral ischemia/reperfusion (I/R), the effect attributable to its antioxidative and antiapoptosis activities [145]. It has been reported that liquiritin produced significant antidepressant effects in the forced swimming test and tail-suspension test in mice [146]. Prunin showed the inhibitory effect on caffeine N3-demethylation, a marker activity of CYP1A2, in human liver microsomes [147]. Additionally, prunin was tested against Gram-positive and Gram-negative bacteria, yeasts, and molds. Prunin showed no inhibitory effect against the microorganisms assayed but stimulated growth of *Pseudomonas aeruginosa* and different *Bacillus* sp. [148] (Fig. 61.8).

Isobavachin, which is a prenylated flavanone, isolated from *Psoralea corylifolia* showed cytotoxicity against rat hepatoma H4IIE and rat glioma C6 cells [149], promoting effect on neurogenesis of mouse embryonic stem cells by prenylation of protein [150]. Lavandulylated flavanones such as kurarinol and kurarinone were isolated from the root of *Sophora flavescens*. Kurarinol is known to be a natural tyrosinase inhibitor; this compound markedly inhibited melanin synthesis [151, 152]. And kurarinol is a potent inhibitor of sortase A, an enzyme that plays a key role in cell wall protein anchoring and virulence in *Staphylococcus aureus* [153]. Kurarinol and kurarinone were reported to exhibit hypolipidemin effects in cholesterol-fed rats [154]. In addition, these flavanones also showed significant inhibitory activities against intracellular ROS levels as well as NF-κB activation [155] (Fig. 61.9).

3 Dihydrochalcone

3.1 Introduction

Dihydrochalcones, 1,3-diphenylpropan-1-ones, are natural phenolics related to chalcones. They consist of the C_6–C_3–C_6 skeleton structure, two aromatic rings connected by a C_3 chain. The difference with chalcones is that dihydrochalcones lack a double bond at C_2–C_3 position.

3.2 Occurrence of Dihydrochalcones

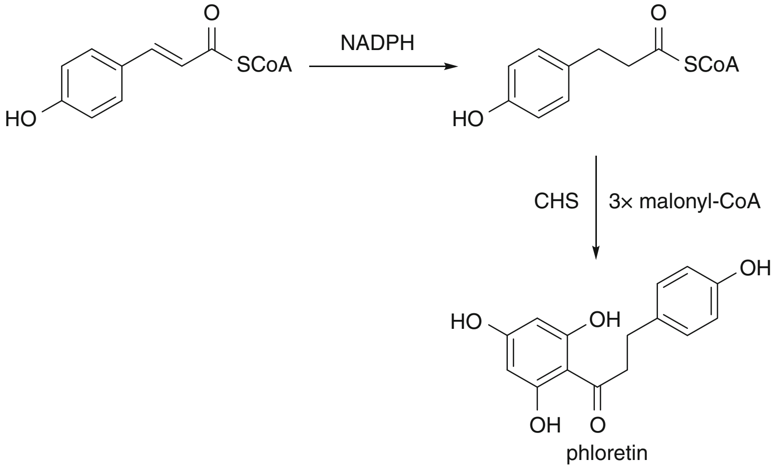
In contrast to the ubiquitously present flavonoids, occurrence of dihydrochalcones is limited. In apple trees, the major subclass of flavonoids is represented by dihydrochalcones, which are found in large amounts (up to 5% of dry weight) in leaves and immature fruits. Although they were thought for a long time to be exclusive of *Malus* sp., dihydrochalcones have been reported in several other genera like *Balanophora*, *Fragaria*, and *Symplocos*. Nowadays, dihydrochalcones seem to be restricted to approximately 30 plant families, especially Rosaceae, Rutaceae, Lauraceae, and Leguminosae.

3.3 Phytochemistry of Dihydrochalcones

Dihydrochalcone numbering is the same as the chalcone ones. The substituted pattern of hydroxyl group of dihydrochalcones resembles that of chalcones, too. Their function *in planta* remains unresolved. They have been hypothesized to act as UV filters in leaves, and a role in resistance to pathogens has been suggested.

3.4 Biosynthesis of Dihydrochalcones

Whereas *p*-coumaroyl-CoA is the precursor for the naringenin-chalcone and further flavonoid formation, *p*-dihydrocoumaroyl-CoA is required for the biosynthesis of



Scheme 61.3 Biosynthesis of dihydrochalcones

dihydrochalcones such as phloretin. It is assumed that *p*-dihydrocoumaroyl-CoA is formed from *p*-coumaroyl-CoA by a NADPH-dependent dehydrogenase. Dihydrochalcones are produced by the common CHS with equal chalcone biosynthesis [156, 157] (Scheme 61.3). However, in past radiolabeled biosynthetic experiments, *p*-dihydrocoumaric acid was not detected as the intermediate.

3.5 Biological Activities of Dihydrochalcones

Phloretin and its glycoside phloridzin are abundantly present in apples (*Malus* × *domestica*), especially in the peel, and strawberries. Phloretin has been reported to display antioxidative properties [158] and to prevent cytokine-induced expression of endothelial adhesion molecules and to reduce activation of human platelet activation [159]. In addition, phloretin may be beneficial for reducing insulin resistance through its potency to regulate adipocyte differentiation and function [160, 161]. Phloretin is a penetration enhancer in the delivery of lidocaine, which is a common local anesthetic and antiarrhythmic drug, through skin [162, 163]. Phloretin has been reported to inhibit the growth of human acute lymphoblastic leukemia MOLT4 cells in vitro [164] and Fisher bladder carcinoma and rat mammary adenocarcinoma cells in vivo [165]. And phloretin induced apoptosis B16 melanoma 4A5 cells by inhibition of glucose transmembrane transport [166]. Phloridzin, which is mainly distributed in plants of *Malus*, is known to be an antidiabetic agent. This compound inhibited intestinal glucose uptake via the sodium D-glucose cotransporter and similarly inhibited renal glucose reabsorption

[167, 168]. Correction of hyperglycemia with phloridzin has been shown to normalize the effects of insulin on glucose metabolism in the liver and other peripheral tissues such as muscle and adipose tissue in diabetic rat models [169]. In addition, phloridzin improved hyperglycemia but not hepatic insulin resistance in a transgenic mouse model of type 2 diabetes [170]. Other biological functions of phloridzin involve estrogenic and antiaging activity and the inhibitory effect against the three human concentrative nucleoside transporters hCNT1, hCNT2, and hCNT3 [171–173]. Sieboldin and trilobatin, which can be found in apple leaves, were reported to contribute to the antioxidative activity and blocking effects of bacterial spread of apples [174]. Trilobatin inhibited against α-glucosidase and α-amylase linked to type 2 diabetes [175] (Fig. 61.10).

Neohesperidin dihydrochalcone, which is a non-nutritive sweetening agent of oranges, inhibited DPPH radical, lipid peroxidation, inflammation-related ROS, and xanthine oxidase activity [176–178]. Aspalathin, a dihydrochalcone *C*-glycoside, is the most abundant flavonoid in rooibos (*Aspalathus linearis*), which is well known as a herbal tea in many countries. Unfermented rooibos plant material contains between 4% and 12% aspalathin. Aspalathin also has beneficial effects on glucose homeostasis in type 2 diabetes through stimulating glucose uptake in muscle tissues and insulin secretion from pancreatic β-cells [179]. Aspalathin appeared to have in vitro antioxidative and antimutagenic effects [180–182]. Nothofagin, which is found in *Aspalathus linearis*, has been reported to exhibit the antioxidative and antimutagenic effects as same as aspalathin [182, 183] (Fig. 61.11).

Crotaramin and crotin, which are pyranodihydrochalcones isolated from *Crotalaria ramosissima*, exhibited weak inhibition of maturation of *Plasmodium falciparum* (NF-54) parasites [64]. Dimeric dihydrochalcones verbenachalcone and littorachalcone were isolated from the aerial parts of *Verbena littoralis*. These compounds were reported to act as enhancers of nerve growth factor (NGF)-mediated neurite outgrowth and axonal branching in rat pheochromocytoma PC12D cells [184, 185] (Fig. 61.12).

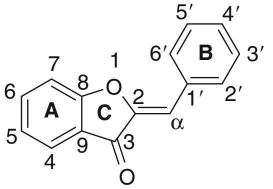
Fig. 61.13 Basic skeleton of aurone



4 Aurone

4.1 Introduction

Aurones, 2-benzylidene-coumaran-3-ones, belong to the subclass of plant flavonoids that provides the bright yellow color of some important ornamental flowers. The name "aurone" comes from a Latin word *aurum* (= gold) because of the golden yellow color of the pigments. They consist the three-ring C_6—C_3—C_6 system, and the heterocyclic C-ring is the five-membered ring [186]. Aurones are structurally the isomeric of flavones.

4.2 Occurrence of Aurones

Aurones are found in a number of flowers of some Scrophulariaceae (e.g., snapdragon [*Antirrhinum majus*]) and Compositae (e.g., *Coreopsis*, *Cosmos*, and *Dahlia*). The yellow snapdragon flower is probably one of the best sources of aurones in the vacuoles of the epidermal cells of the flowers. In some other plant species, however, aurones are also found in the bark, wood, leaves, seedlings, and nectar. In 2001, the occurrence of aurone (4′-chloroaurone) in marine organisms has been reported [187]. However, its structure was revised to 3-(4′-chloroisocoumarin) later [188].

4.3 Phytochemistry of Aurones

Aurone numbering is shown in Fig. 61.13. Naturally occurring aurones are polyhydroxylated in the aromatic rings. On the whole, aurones have hydroxyl groups at 4- and 6-positions in A-ring and 4′-position in B-ring. Aurones have been described as phytoalexins, used by the plant as defense agents against various infections.

4.4 Biosynthesis of Aurones

Biosynthesis of aurones from chalcones involves dual chemical transformation of chalcones such as hydroxylation of the B-ring moiety and oxidative cyclization (2′,α-dehydrogenation) to give the aurone structure [2]. Several lines of evidence

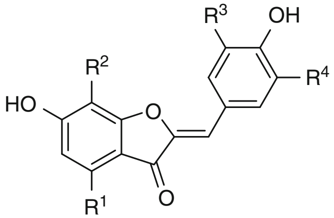
Scheme 61.4 Biosynthesis of aurones

Fig. 61.14 Structures of bioactive aurones



R^1 = OH, R^2 = H, R^3 = OH, R^4 = H : aureusidin
R^1 = OH, R^2 = H, R^3 = OH, R^4 = OH : bracteatin
R^1 = H, R^2 = OH, R^3 = OH, R^4 = H : maritimetin
R^1 = OH, R^2 = H, R^3 = H, R^4 = H : 4,4′,6-trihydroxyaurone
R^1 = H, R^2 = H, R^3 = H, R^4 = H : hispidol
R^1 = H, R^2 = H, R^3 = OH, R^4 = H : sulfuretin

suggest that a single enzyme, which is called aureusidin synthase (AmAS1), catalyzes both these transformations. Aureusidin can be produced from either naringenin-chalcone or isoliquiritigenin, whereas bracteatin arises solely from isoliquiritigenin. The mechanistic investigations showed that AmAS1 acts as an oxygenase. It was established that AmAS1 is responsible for the transformation of a variety of chalcones to aurones [189]. According to the screening of a panel of hydroxylated and glycosylated chalcones, it is found that only chalcones, which are hydroxylated at C2′ and C4′ positions, are transformed to aurones (Scheme 61.4). Furthermore, the AmAS1 is definitely specific to chalcones because flavanones are inert for the enzyme action.

4.5 Biological Activities of Aurones

Aureusidin which is found in snapdragon, maritimetin which is an anthochlor pigment of *Coreopsis tinctoria* and *Baeria chrysostoma*, and bracteatin which is isolated from *Helichrysum bracteatum* have been studied with regards to their radical scavenging potential using density functional theory (DFT) [190–192]. 4,4′,6-Trihydroxyaurone isolated from *Pterocarpus santalinus* and *Smilax bracteata* and hispidol which can be found in *Trichilia hispida* were able to induce significant tyrosinase inhibition. In particular, 4,4′,6-trihydroxyaurone was highly active when compared to kojic acid [193]. Sulfuretin isolated from the heartwood of *Rhus verniciflua* is an active antirheumatoid arthritis agent. This compound showed significant inhibitory effects on hind paw edema and trypsin inhibitor activity induced by Freund’s complete adjuvant reagent (FCS reagent) and on vascular permeability caused by acetic acid [194]. In addition, sulfuretin exhibited the anti-inflammatory effect by the suppression of NF-κB transcription activity via the inhibitory regulation of IκB kinase β-phosphorylation in LPS-induced RAW 264.7 macrophages [195]. Also, sulfuretin demonstrated the antidiabetogenic effect by the suppression of NF-κB activation [196] (Fig. 61.14).

5 Conclusions

The minor flavonoids are important subclasses of plant polyphenols. Especially, chalcones and flavanones are the obligate intermediates in flavonoid biosynthesis. These naturally occurring compounds also play significant roles as pigments, phytoalexins, and signaling molecules in pathogenesis and symbiosis. Additionally, considerable attention has been devoted to these compounds because of their potential pharmaceutical applications in recent years. For this reason, they are an object of continuously growing interest among the scientists. The attention is mainly drawn to the common skeleton and possibilities for its modifications guided by mechanistic and structure-activity relationship studies.

Abstract

Stilbenoids are a class of plant phenolics containing C6–C2–C6 unit in their structures and classified into five groups, covering stilbenes, oligostilbenes, bibenzyls, bisbibenzyls, and phenanthrenes. They have been a hot research topic for their intricate structures and diverse biological activities. Resveratrol and combretastatin A-4 are the star compounds due to their potent cardioprotective, chemopreventive, and antitumor properties and have the potential to be developed as new drugs. The stilbenoids do not enjoy a wide distribution and are only found in special genus. Although the constituent unit is simple, the structures of stilbenoids highlight the chemical diversity by different substitutes and various oligomeric styles. In a biogenesis viewpoint, they are formed by a branch of the flavonoid biosynthetic pathway. This chapter provides a summary of the occurrence, phytochemisty, biosynthesis, and biological aspects of the stilbenoids.

Keywords

Bibenzyls • bioactivities • biosynthesis • bisbibenzyls • occurrence • oligostilbenes • phenanthrenes • phytochemistry • stilbenes • stilbenoids

1 Introduction

The term “stilbenoids” was proposed by Gorham in 1980 [1, 2], which refers to a class of plant phenolics with 1,2-diphenylethylene or 1,2-diphenylethane nucleus in their structures. Stilbenoids are regarded as plant phytoalexins and have been a hot research topic for their intricate structures and diverse biological activities. The phytochemical research concerning the stilbenoids developed quickly in recent years. More than 1,000 compounds belonging to this group have been discovered, compared with just over 100 listed in 1980 and about 300 in 1995 [2]. Recent advances in analytical and spectroscopic techniques, especially the NMR methods, speed up the discovery and elucidation of the intricate structures of stilbenoids. The intricate structures and stereochemistry of oligostilbenes and bisbibenzyls were established based on the modern techniques. Furthermore, these compounds demonstrated diverse biological activities, including antitumor, antimicrobial, antioxidant effects, antiplatelet aggregation, phytotoxicity, etc. These bioactive compounds and their derivatives are of great interest for drug research and development as a result of their potential in therapeutic or preventive applications, exemplified by resveratrol and combretastatin A-4. In this chapter, we will give an overview of structural features, occurrence, phytochemical aspects, biosynthesis, and biological activities of the stilbenoids.

2 Phytochemical Aspects

According to their structural characteristics, stilbenoids are mainly divided into five categories, stilbenes, oligostilbenes, bibenzyls, bisbibenzyls, and phenanthrenes.

In the section of phytochemical aspects, the structural characteristic, distribution, typical representatives, and their structures of each group are introduced.

2.1 Stilbenes

Stilbenes possess a skeleton with two aromatic rings joined by a methylene bridge. The simple stilbene nucleus is generally substituted by different groups of hydroxyl, methyl, methoxy, prenyl, geranyl, etc., and combined with sugars to form glycosides. The double bonds in naturally occurring stilbenes are usually *E*-configuration, but stilbenes with *Z*-configuration are also observed. The compounds of this group highlight the chemical structural diversity through the modification of above styles on the nucleus. About 125 new stilbenes have been discovered between the year of 1995 and 2008 [3]. They mainly occur in the families of Aceraceae, Anchinoidae, Asteraceae, Bombycidae, Burseraceae, Combretaceae, Cyperaceae, Dipterocarpaceae, Euphorbiaceae, Gnetaceae, Hepaticae, Iridaceae, Leguminosae, Lejeuneaceae, Liliaceae, Meliaceae, Moraceae, Ophioglossaceae, Orchidaceae, Polygonaceae, Rosaceae, Stemonaceae, Vitaceae, and Zingiberaceae.

Resveratrol **1** is the most famous representative of this group and occurs in *Polygonum cuspidatum* root and *Vitis* species. It is a phytotoxin produced by several plants in response to infection or other stresses and attracted attention for its cardioprotective effect in red wine. In addition, it is the most important unit for the construction of oligomeric stilbenes.

Combretastatins, a series of bioactive stilbenes (combretastatin A series), bibenzyls (B series), phenanthrenes (C series), and macrocyclic lactone (D series), were obtained from the African willow tree *Combretum caffrum* (Combretaceae). Among them, the A series of combretastatins belonging to stilbenes, including combretastatins A-1 to A-6 **2–7**, are found to be tubulin polymerization inhibitors.

Typical stilbenes substituted with hydroxyls, methyl, methoxy, menthane groups, and their origin were listed as follows. *Trans*-4-[2-(3,5-dimethoxyphenyl) ethenyl]-1,2-benzenediol **8** was isolated from *Sphaerophysa salsula* (Leguminosae) [4]. Thunalbene **9** was obtained from *Thunia alba* (Orchidaceae), and the structure was designated as 3,3′-dihydroxy-5-methoxystilbene [5]. The *Phragmipedium* species produced three new stilbenes including 2,3′-dihydroxy-5′-methoxystilbene **10**, 2,3-dihydroxy-3′,5′-dimethoxystilbene **11**, and 2,3′-dihydroxy-5,5′-dimethoxystilbene **12** [6]. Phoyunbenes A-D **13–16** were found in *Pholidota yunnanensis* (Orchidaceae) [7]. 5,4′-Dihydroxy-3-methoxystilbene **17**, 3,5-dihydroxy-4′-methoxystilbene **18**, and (*E*)-3,3′-dimethoxy-4,4′-dihydroxystilbene **19** were isolated from *Rumex bucephalophorus* and *Leuzea carthamoides* [8, 9], respectively. Two *Z*-type stilbenes named (*Z*)-3-methoxy-5-hydroxystilbene **20** and (*Z*)-3,5-dihydroxystilbene **21**, together with a menthane-substituted stilbene (*E*)-1-(1-terpinen-4-olyl)-3-methoxystilbene **22**, were obtained from aerial parts of *Alpinia katsumadai* (Zingiberaceae) [10, 11].

There are two stilbene representatives isolated from special origins. Bryophytes are characterized by the production of bisbibenzyls, and no stilbene has been obtained before the isolation of 3,4-dihydroxy-3′-methoxystilbene **23** from *Marchesina bongardiana* (Lejeuneaceae) [12]. *Kirkpatrickia variolosa*, a kind of Antarctic red sponge of Anchinoidae family, yielded a triacetate derivative 3,4,5-triacetoxystilbene **24** which was the only marine natural stilbene [13].

Two stilbene glycosides, named (*E*)-3,4′-dimethoxyl-5-rutinosyl stilbene **25** and 3,5-dimethoxy-4′-*O*-(β-rhamnopyranosyl-(1→6)-β-glucopyranoside)stilbene **26**, were isolated from *Guibourtia tessmanii* (Leguminosae) [14, 15]. *Acer mono* (Aceraceae), a Korean folk medicine for hemostasis, produced two new stilbene glycosides 5-*O*-methyl-(*E*)-resveratrol 3-*O*-β-D-glucopyranoside **27** and 5-*O*-methyl-(*E*)-resveratrol 3-*O*-β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside **28** [16].

Prenyl substitution is a conventional derivatization style in stilbenes, exemplified by artoindonesianin N **29** from *Artocarpus gomezianus* [17]. The prenyl groups in stilbenes cyclize to form new derivatives. 4-Hydroxy-5′-methoxy-6″,6″-dimethylpyran[2″,3″:3′,4′]stilbene **30**, 3,5′-dimethoxy-4-hydroxy-6″,6″-dimethylpyran[2″,3″:3′,4′]stilbene **31**, and 3,4,5-trimethoxy-6″,6″-dimethylpyran [2″,3″:3′,4′]stilbene **32**, with dimethylchromene ring in their structures, have been obtained from *Lonchocarpus utilis* (Leguminosae) [18]. Furthermore, schweinfurthins A-C **33–35** from the leaves of *Macaranga schweinfurthii* (Euphorbiaceae) are typical samples of the prenylated stilbenes [19].

Arylbenzofuran derivatives are a group of special stilbenes formed by C_7–O–C_7 linkage, for instance, gnetofurans B **36** and C **37** from *Gnetum klossii* [20]. In addition, schoenoside **38**, a phenylbenzofuran glucoside discovered from *Schoenocaulon officinale* (Liliaceae), as well as stemofurans A-C **39–41** from *Stemona collinsae* belongs to this group [21, 22].

2.2 Oligostilbenes

The structures of oligostilbenes are produced by coupling between homogeneous or heterogeneous monomeric stilbenes, leading to the construction of dimer, trimer, and even the octamer. They do not enjoy a wide distribution in plant kingdom and have been found in the family of Agavaceae, Apiaceae, Arecaceae, Celastraceae, Cyperaceae, Dipterocarpaceae, Gnetaceae, Haemodoraceae, Iridaceae, Leguminosae, Moraceae, Musaceae, Orchidaceae, Pinaceae, Polygonaceae, Ranunculaceae, Vitaceae, and Welwitschiaceae. Thereinto, Vitaceae, Leguminosae, Gnetaceae, and Dipterocarpaceae are particular rich resource of this group.

Oligostilbenes are constructed by C–C or C–O–C linkage of various stilbene units with diverse coupling patterns and producing structures with diverse skeletons, complex configurations, and different degrees of oligomerization. The most common monomeric stilbene units which comprised the oligostilbenes are resveratrol, isorhapontigenin, piceatannol, oxyresveratrol, etc. (Fig. 62.1). Therefore, oligostilbenes are classified into six groups which are resveratrol oligomers, isorhapontigenin oligomers, piceatannol oligomers, oxyresveratrol oligomers, resveratrol and oxyresveratrol oligomers, and finally miscellaneous oligomers [3].

2.2.1 Resveratrol Oligomers

The group of resveratrol oligomers comprises the largest number of oligostilbenes and is characterized by the polymerization of two to eight resveratrols. About 180 constituents of this group covering dimer to octamers have been reported, which is produced by diverse polymeric styles.

Vitisinol A **42** isolated from *Vitis thunbergii* is a dimer linked by four C–C or C–O–C bonds [23]. Two dimeric stilbene glycosides **43** and **44** were reported from *Polygonum cuspidatum* (Polygonaceae) [24]. Thereinto, **44** is a symmetrical molecule and possesses a novel four-membered ring which is very rare in natural products. Isoampelopsin F **45** linked by three C–C bonds and heimiol A **46** with seven-member ring were isolated from *Parthenocissus tricuspidata* and *Neobalanocarpus heimii* [25]. A novel resveratrol dimer with a five-membered lactone ring, namely, shorealactone **47**, was obtained from *Shorea hemsleyana* [26]. Schneide reported the isolation of anigopreissin A **48** from the *Anigozanthos*

preissii (Haemodoraceae) and *Musa cavendish* (Musaceae), which is the first dimer containing unsaturated benzofuan moiety [27]. Moreover, an aldehyde-substituted derivative, (−)-viniferal **49**, was isolated from *Vitis vinifera* [28].

Two trimers containing rare tribenzobicyclo[3.3.2]decatriene system were isolated from *Vatica rassak* and *V. pauciflora*, named vaticanol G **50** and vaticaside D **51** [29, 30]. Caragaphenol A **52**, with a nine-membered ring in the molecules, was found in *Caragana stenophylla* [31]. Three isomers which have bicyclo[5.3.0]decane ring system were obtained including amurensin G **53** from *Vitis amurensis* [32] and suffruticosols A **54** and B **55** from *Paeonia suffruticosa* (Ranunculaceae) [33].

Two new resveratrol pentamers, named amurensins E **56** and F **57**, have been isolated from *Vitis amurensis* [34]. The isolation and structural elucidation of a hexamer vaticanol D **58** and a heptamer vaticanol J **59** from *Vatica rassak* have been reported [29]. An octamer vateriaphenol A **60** from *Vateria indica* was reported by Ito and coworkers, and it is the largest molecules of stilbenoids [35].

2.2.2 Isorhapontigenin Oligomers

Oligostilbenes of this group mainly occur in the genus of *Gnetum*. The representatives comprise gnetuhainins P **61** and I **62** from *G. hainanense* [36, 37], dimeric stilbene epimers gnetifolins M **63** and N **64** from *G. montanum* [38], gnemonol M **65** from *G. gnemon* [39], gneafricanin F **66** found in *G. africanum* [40], as well as bisisorhaphontigenin B **67** obtained from *G. africanum* [41]. With the exception of *Gnetum* species, *Salacia lehmbachii* produced three isorhapontigenin dimers, named lehmbachols A-C **68–70** [42]. The only two isorhapontigenin trimers, gnetuhainins N **71** and O **72**, which are stereoisomers have been found in *Gnetum hainanense* [43]. A tetramer named gnetuhainin R **73** was obtained from the same species (*G. hainanense*) [44].

2.2.3 Piceatannol Oligomers

Only piceatannol dimers have been discovered from the plant species. Longusol C **74** and gneafricanin C **75** were isolated from *Cyperus longus* and *Gnetum africanum* [40, 45]. Tibeticanol **76** was obtained from *Caragana tibetica* [46]. Two piceatannol dimer glycosides named piceasides A–B **77–78** were isolated from Norway spruce *Picea abies* as a mixture in a ration of 1:1 [47].

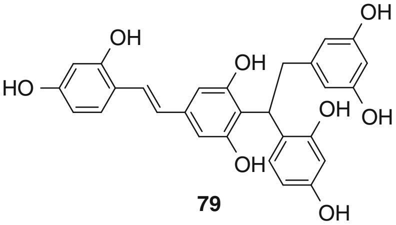
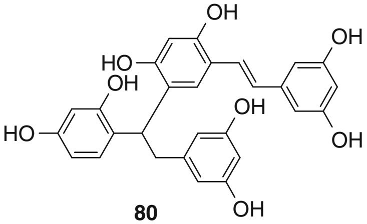
2.2.4 Oxyresveratrol Oligomers

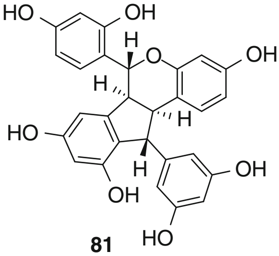
Andalasin A **79** and artogomezianol **80** were isolated from *Artocarpus gomezianus* (Moraceae) [48]. Structures **79** and **80** are possible intermediates in the biogenesis of oxyresveratrol dimers. Parvifolol C **81** and gnetumontanin A **82** were discovered in two *Gnetum* species *G. parvifolium* and *G. montanum* [49, 50].



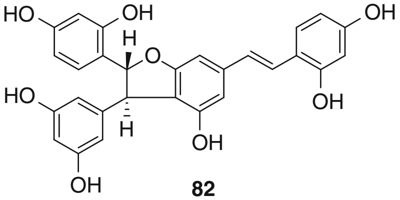
79



80



81



82

2.2.5 Resveratrol and Oxyresveratrol Oligomers

The resveratrol and oxyresveratrol oligomers are only obtained from the genus *Gnetum* (Gnetaceae) and polymerize by oxidative coupling between resveratrol and oxyresveratrol. About 24 compounds of this group have been elucidated. A dimer containing a benzofuran and a dihydrobenzofuran moiety, named gnemonol G **83**, was isolated from *G. gnemon* [51]. Four stilbene dimers, gnetuhainins A **84**, B **85**, D **86** and E **87**, were obtained from *G. hainanense* [52]. Gnemonoside J **88**, a diglucoside of **84**, was isolated from *G. africanum* [53]. Three stereoisomers including parvifolols A **89** and B **90** and gnetuhainin S **91** have been founded from *G. parvifolium* and *G. hainanense* [44, 49, 54]. Gnemonol A **92** and its stereoisomers and gnemonol I **93** composed of two resveratrol units and one oxyresveratrol unit were discovered in *G. gnemon* [51, 55]. Gnemonol J **94** from *G. gnemon* possesses the same skeleton of **92** and **93**; however, it is coupled by one resveratrol unit and two oxyresveratrol units [51]. Gnemonol C **95** from *G. gnemonoides* is a stilbene tetramer constructed by three resveratrol and one oxyresveratrol units [55].

2.2.6 Miscellaneous Oligomers

Oligostilbenes polymerize from different stilbene units with the exception of resveratrol and oxyresveratrol oligomers, and containing miscellaneous structural skeleton will be classified into this group. Longusol B **96** from *Cyperus longus* [45] is a stilbene dimer composed of resveratrol and piceatannol units. Gnetuhainin Q **97**, an isorhapontigenin and resveratrol dimer, was found in *Gnetum hainanense* [36]. The first isorhapontigenin and oxyresveratrol dimer named gnetuhainin J **98** was isolated from *G. hainanense* [37]. An isorhapontigenin and piceatannol dimer, gneafricanin B **99** was discovered in *Gnetum africanum* [41]. Two isorhapontigenin and 2-hydroxyisorhapontigenin dimers were obtained from *G hainanense* and named gnetuhainin G **100**. An isorhapontigenin and gnetol dimer gnetuhainin K **101** was isolated from *G*. *hainanense* [36].

2.3 Bibenzyls

The bibenzyls are characterized by the presence of one 1,2-diphenylethane structure in their molecules. Similar with the stilbene structures, there are hydroxyls, methyl, methoxy, prenyl, geranyl, etc., located in the structures of bibenzyls. Bibenzyls have been mainly isolated from bryophytes. In addition, a few compounds of this group were reported from the genera of *Stemona*, *Dendrobium*, and *Polygonum*.

According to the suggestion given by Gorm et al. [56], bibenzyl compounds are classified into four groups. However, a few groups of bibenzyls are new addition to the growing list of naturally occurring bibenzyls, such as tyrolobibenzyls. In addition, bibenzyls containing isoprene units, regardless of branched or heterocyclic ring-forming isoprene units, are regarded as the same group. Therefore, the bibenzyls are reclassified into five groups according to their substitute patterns on both the benzene nucleus and ethylidene bridge.

2.3.1 Group A: Simple Bibenzyls

Bibenzyls having halogenated, hydroxylated, methyled, methoxylated, carboxylate, benzoyl, and/or methylenedioxy substitutes constitute the group of simple bibenzyls. The representatives are 2′,6′-bis(*p*-hydroxybenzyl)-3,3′-dihydroxy-5-methoxybibenzyl **102** from *Bletilla formosana* [57], bulbophyllum **103** from *Bulbophyllum protractum* [58], 2-carboxy-4-hydroxy-3,4′-dimethoxybibenzyl **104** from *Plagiochila* species [59], 2-chloro-3-hydroxybibenzyl **105** from *Riccardia marginata* [60], 1-(3′,5′-dihydroxyphenyl)-2-(4′-hydroxyphenyl)-ethane-1,2-diol **106** from *Polygonum cuspidatum* [61], methyl 4-hydroxy-4′-*O*-methyllunularate **107** from *Plagiochila spinulosa* [62], tragopogonic acid **108** from *Tragopogon porrifolius* [63], and 2,4,6-trichloro-3-hydroxybibenzyl **109** from *Riccardia marginata* [60].

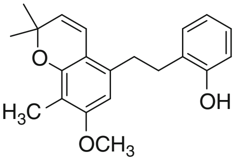
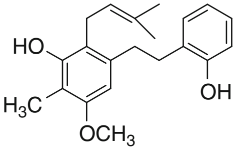
2.3.2 Group B: Isoprene Unit–Substituted Bibenzyls

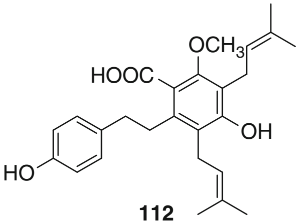
Bibenzyls of this group are characterized by the presence of prenyl, geranyl, and/or farnesyl substitutes. Isoprene units in the structures may be branched and/or form five- to seven-member rings. The typical compounds of this group are bauhinols A **110** and B **111** from *Bauhinia saccocalyx* [64], 2-carboxy-3-methoxy-4,6-di-(3-methyl-2-butenyl)-5,4′-dihydroxy-bibenzyl **112** from *Lethocolea glossophylla* [65], 2-isopropenyl-6-hydro-4-(2-phenylethyl) dihydrobenzoluran **113** from *Radula perrottetii* [66], and 3,5,4′-trihydroxy-4-(3,7,11-trimethyl-2,6,10-dodecatrienyl)bibenzyl **114** from *Radula* species [67].



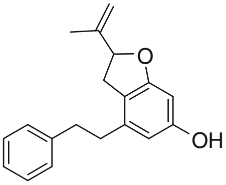
110



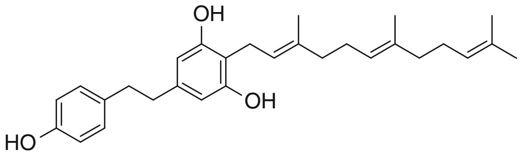
111



112



113



114

2.3.3 Group C: Glycosylated Bibenzyls

Bibenzyls conjugated with glycosyl substitutes on the aromatic rings or benzylic methylenes (excluding tyrolobibenzyls) belong to this group. The representatives of this group include 2′-carboxy-4,3′-dihydroxybibenzyl-3-*O*-β-D-glucopyranoside **115** from *Ricciocarpus natans* [68], 2-carboxyl-3,4′-dihydroxy-5-β-D-xylopyranosyloxybibenzyl **116** and 5,4′-dihydroxy-3-α-L-rhamnopyranosyl-(1→3)-β-D-xylopyranosyloxybibenzyl **117** from *Tragopogon porrifolius* [63], and combretastatin B-1,2′-β-D-glucoside **118** from *Combretum erythrophyllum* [69].

118

2.3.4 Group D: Tyrolobibenzyls

Tyrolobibenzyls are a new class of naturally occurring bibenzyl derivatives possessing a unique phenylethyl-benzofuran skeleton. Tyrolobibenzyls A **119**, B **120**, D **121**, and F **122** from *Scorzonera humilis* L. (Asteraceae) are the typical constituents of this group [70–72].

2.4 Bisbibenzyls

Bisbibenzyls are dimeric bibenzyls and chemically constructed by two lunularin moieties with diarylether and/or biphenyl linkages, and producing cyclic and acyclic four aromatic rings system. They are usually distributed in liverworts and

Table 62.1 Cyclic and acyclic bis(bibenzyl) types and their distribution

rarely found in other plant species. The first bisbibenzyl not obtained from liverworts is perrottetin H **149**, which was isolated from a pteridophyte *Hymenophyllum barbatum* [2]. It is also believed that the distribution of bisbibenzyls in both pteridophytes and liverwort is an important marker of determining the evolutionary ladder of terrestrial spore-forming plants.

Bisbibenzyls are classified into ten types of cyclic bisbibenzyls and six types of acyclic bisbibenzyls on the basis of basic bisbibenzyls skeletons (see Table 62.1). Over 100 cyclic and acyclic bisbibenzyls have been obtained from plant kingdom to date.

2.4.1 Macrocyclic Bisbibenzyls

According to the constitution of the macrocyclic ring, these bisbibenzyls can be divided into three main groups, those with two diarylether bonds (marchantins, isomarchantins, neomarchantins, and riccardins II), those with two biphenyl bonds (isoplagiochin II), or those with one diarylether bond and one biphenyl bond (riccardin I, isoriccardin C, plagiochins, isoplagiochin I, and planusin A) (see Table 62.1). The range of macrocyclic structures is extended ultimately and derived from additional functions (e.g., carbonyl, hydroxyl, and methoxyl) on both the benzene nucleus and ethylidene bridge and the ways in which aromatic rings are linked.

Asakawa and his coworkers reported the isolation of a marchantin-type macrocyclic bisbibenzyl marchantin P **129** from the liverwort *Marchantia chenopoda* collected in Venezuela [76]. Three isomarchantin-type macrocyclic bisbibenzyls were isolated from the liverwort *Ptychantus striatus*, belonging to the Lejeuneaceae, and designated them as ptychantols A-C **130–132** [77]. Neomarchantins A and B **133–134** were obtained from *Schistochila glaucescens* [78].

Two riccardin I-type compounds, riccardins F **135** and H **136**, were isolated from *Blasia pusilla* [79] and *Marchantia polymorpha* [80], respectively. Riccardin B **137** from *Preissia quadrata* belongs to the riccardin II-type bisbibenzyls. Isoriccardin C **138**, a compound of isoriccardin group, was obtained from *Plagiochila sciophila* [81].

Plagiochins A-B **139** and **140** were plagiochin-type constituents from *Plagiochila fruticosa* [81]. Isoplagiochins E-F **141–142**, belonging to the isoplagiochin I-type bisbibenzyls, have been isolated from several *Plagiochila* species. Isoplagiochins C **143** and D **144** with two biphenyl linkages, which are different from isolagiochin I-type bisbibenzyls, represent isolagiochin II-type of macrocyclic bisbibenzyls. Planusin A **145** with a *cis*-stilbene moiety was discovered from cultured cells of the liverwort *Heteroscyphus planus* and classified into planusin-type bisbibenzyls [82].

2.4.2 Acyclic Bisbibenzyls

Compared with cyclic bisbibenzyls, acyclic bisbibenzyls receive less attention due to their small number and poor structural diversity. Some novel acyclic bisbibenzyls, however, have been obtained in the past few years. These bisbibenzyls can be divided into two main groups, those with one diarylether bond (perrottetins and paleatins) or those with one biphenyl bond (isoperrottetin A, plagilins, isoplagilin, plagiolin, artogomezianol, and andalasin). The linkages occurred between two aromatic rings or between one benzene nucleus and ethylidene bridge (see Table 62.1).

Perrottetins and isoperrottetins represent the most frequently encountered skeletal types of acyclic bisbibenzyls. They are of much interest for the investigation of biogenesis of macrocyclic bisbibenzyls, for example, the derivatives of riccardin, plagiochin, ptychantol, and isoplagiochin types. Examples of the perrottetin-type compounds are perrottetins E-H **146–149**. They have been found in different liverwort species and a fern *Hymenophyllum barbatum* [83]. Isoperrottetin A **150** and its chlorinated derivative **151** belong to isoperrottetin-type compounds [66, 84], which contain one biphenyl bond between aromatic rings instead of one diarylether bond for perrottetins.

Plagilin **152**, isoplagilin **153**, and plagiolin **154** were obtained from a neotropical *Plagiochila* species [85]. Another plagilin-type bisbibenzyl, vittarin-E **155**, has been isolated from the whole plant of *Vittaria anguste-elongata* [74]. This is one more evidence for the occurrence of acyclic bisbibenzyls in the pteridophytes.

Paleatins A **156** and B **157** were isolated from the methanol extract of *Marchantia paleacea* var. *diptera* [86]. These phenolic compounds are of interest because they are the linear analogues of the macrocyclic bisbibenzyl ethers and possible biogenetic precursors of the plagiochins and riccardins.

2.5 Phenanthrenes

The phenanthrenes are a rather uncommon group of aromatic constituents formed by oxidative coupling of the aromatic rings of stilbene precursors and existed in the form of monomers, dimers, and even trimers [87]. A large number of phenanthrenes have been isolated from higher plants (mainly in the Orchidaceae family) and covering 49 species. The genera *Dendrobium*, *Bulbophyllum*, *Eria*, *Maxillaria*, *Bletilla*, *Coelogyna*, *Cymbidium*, *Ephemerantha*, and *Epidendrum* were particularly rich resources of phenanthrenes. In addition, a few phenanthrenes have been discovered in the family of Dioscoreaceae, Combretaceae and Betulaceae, and the Hepaticae class. The greatest number of phenanthrenes has been obtained from the *Juncus* species.

2.5.1 Monomeric Phenanthrenes

Most of the phenanthrenes are present in the form of monomers, containing about 210 compounds. Hydroxyl and methyloxyl are the most common substitutes located in the phenanthrene skeletons and occupy about 50% of all monomers. For instance, coeloginanthrin **158** from *Coelogyne cristata* [88], 4-methoxyphenanthrene-2,3,7-triol **159** and 4-methoxyphenanthrene-2,3,6,7-tetrol **160** from *Bulbophyllum vaginatum* [89], as well as 2-methoxy-3,4,7-trihydroxy-phenanthrene **161** from *B. inconsipicum* [90] are hydroxyl- and/or methyloxyl-substituted ones.

With the exception of hydroxy and methyloxy groups, methyl-, hydroxymethyl-, carboxy-, formyl-, prenyl-, and vinyl-substituted compounds are observed, with stemanthrenes A-D **162–165**, **166**, **167**, dehydroeffusal **168**, and gancaonin U **169** as the representatives [91–94]. Furthermore, glycosides were isolated from the plants of *Juncus effusus*, *Epimedium koreanum*, *Dendrobium chrysanthum*, and *Bulbophyllum striata*, for example, effuside I **170**, epimedoicarisoside A **171**, and denchryside A **172** [95–97].

Phenanthraquinones are special phenanthrenes with quinone group in the structures. Ephemeranthoquionone **173** from *Dendrobium plicatile*, cymbinodin A **174** from *C. aloifolium*, and moniliformin **175** from *D. moniliforme* were typical constituents of this group [98–100].

2.5.2 Dimeric Phenanthrenes

The dimeric phenanthrenes are commonly constructed by 1-1′ linkage of monomers, and the dimers with 1-3′, 1-8′, and 3-3′ link patterns also existed. Nearly 40 dimeric phenanthrenes have been found in the plants [87]. The representatives are cirrhopetalanthrin **176** from *Cremastra maculosum* [101], blestrianol A **177** from *Bletilla striata* [102], blestriarene B **178** from *Bletilla formosana* [57], and spiranthesol **179** from *Spiranthes sinensis* [103].

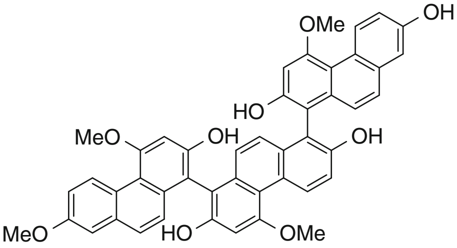
Hitherto, only one triphenanthrene **180** has been reported from the tubers of an orchidaceous plant *Cremastra appendiculata* [104].



180

3 Biosynthesis

3.1 Biosynthesis of Stilbenes

The biosynthesis of simple stilbenes has been found out, and it shared a similar biosynthetic pathway with the flavonoids. Taking resveratrol for example, it starts from a cinnamoyl-CoA unit and extended the chain with three malonyl-CoA molecules (Scheme 62.1) [105]. Then, the resveratrol structure is produced by aldol reaction with the presence of stilbene synthase. Nevertheless, the flavonoids are formed depending on chalcone synthase and Claisen reaction.

3.2 Biosynthesis of Oligostilbenes

Sotheeswaran has mentioned that the oligostilbenes with dihydrobenzofuran moiety are biosynthesized through an important intermediate *trans*-ε-viniferin [106]. Combined with the reported work of oligostilbenes, the biosynthesis of oligostilbenes is summarized. For instance, the dimers named (+)-ampelopsin B, (−)-ampelopsin D, and (+)-ampelopsin F are produced by isomerization and/or rearrangement of *trans*-ε-viniferin (Scheme 62.2). The differences in their structures are caused by the different protonation position at the initial stage of reaction. Furthermore, *trans*-ε-viniferin is able to transform to the isomers (Scheme 62.3) and then forming the tetramers, (+)-vitisin A, (−)-vitisin B, (+)-hopeaphenol, and (+)-viniferol A, etc., by oxidative coupling (Scheme 62.4) [2, 107].

3.3 Biosynthesis of Bibenzyls and Bisbibenzyls

The biosynthesis of marchantins A and C has been certified by a C-labeled precursor feeding experiment. It shows that rings A and C of the marchantin molecules are derived from the benzene ring of L-phenylalanine. The bibenzyl

lunularic acid is biosynthesized through dihydro-*p*-coumaric acid coupling with three malonyl-CoA units and then coupled in typical ways to form bisbibenzyls marchantins A and C (Scheme 62.5) [108].

Evidences have confirmed that bisbibenzyls can be produced by the coupling of two phenolic systems by means of free-radical reactions. These reactions can be mediated by oxidase enzymes. C–C bonds involving positions *ortho* or *para* to the original phenols, or ether linkages, may be formed in coupling of two of these bibenzyl structures [105]. A previous hypothesis for the biogenesis of

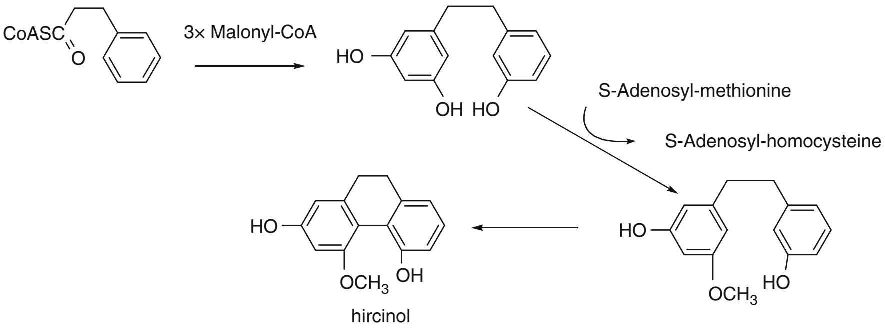
marchantins, riccardins, and plagiochins considers cyclization of open-ring precursors, such as perrottetin E **146**, through intramolecular phenol oxidation, accompanied by C–O or C–C linkage of the terminal *m*-hydroxyphenyl units [109]. Likewise, isoplagiochins A-D might be biosynthesized from isoperrottetin A **150** (Scheme 62.6) [110].

3.4 Biosynthesis of Phenanthrenes

Bibenzyls are regarded as the bicyclic intermediates of 9,10-dihydrophenanthrenes, and the biosynthetic pathway of 9,10-dihydrophenanthrenes was proposed as showed in Scheme 62.7. Oxidative coupling of the bibenzyl intermediate leads to the formation of phenanthrene [2].



Scheme 62.7

4 Biological Activities

4.1 Antitumor Activity

4.1.1 Stilbenes and Oligostilbenes

Resveratrol, as a representative compound of stilbene, possesses diverse pharmacological activities. The antitumor property has taken the spotlight for its cancer preventive effect on skin cancer in a mice model. Subsequently, plenty of in vivo experiments targeting different tumor model were carried out to evaluate its therapeutic effects on tumors [111]. The results definitely show that resveratrol is able to inhibit or possess chemopreventive functions on different tumors, including breast cancer, liver cancer, gastric cancer, colorectal cancer, prostate cancer, leukemia, lung cancer, neuroblastoma, etc. In these experiments, the incidences, tumor volume, and metastasis are improved. Clinical trials of investigating resveratrol's effects on colon cancer and melanoma (skin cancer) are intending to launch.

Combretastatins attract a lot of interests for their potent antitumor properties by inhibiting tubulin polymerization and disrupting the formation of tumoral vasculature. Combretastatin A-4 **5** was proved to be the most potent candidate of combretastatins with GI_{50} of 3.20 nM in an antitumor screening project against the NCI-60 human tumor cell lines, followed by combretastatins A-1 **2** and A-2 **3** [112]. Further studies focused on the antitumor mechanism of combretastatins, and the results suggested that compounds **2**, **3**, and **5** possessed potent antimitotic effect through binding to the tubulin at colchicine site [113]. Combretastatin A-4, its prodrug combretastatin A-4 phosphate (CA-4-P), and other analogues are currently being investigated in the clinical trials. CA-4-P, being developed as vascular targeting agents, in combination with carboplatin has entered into phase III clinical trial for the treatment of anaplastic thyroid cancer.

The seeds of *Iris halophila* (Iridaceae) produced halophilol A, which possesses moderate cytotoxicity against KB cells and human mammary epithelial cells

(HMECs) with IC_{50} values of 17.28 and 22.47 μM [114], respectively. The prenyl stilbenes **30–32** with dimethylchromene ring exhibit cytotoxic activity against Hepa-1clc7 cells with IC_{50} values of 8.5, 13.0, and 7.0 μM [18], respectively. Tested in the NCI-60 cell line human cancer screen, schweinfurthins A **33** and B **34** show significant cytotoxic activity with mean panel GI_{50} of 0.36 and 0.81 μM. Schweinfurthins E-H were isolated from *M. alnifolia* [115] and display potent antiproliferative effect against A2780 human ovarian cancer cell line with IC_{50} values ranging from 0.26 to 5.0 μM, respectively. Lakoochins A and B also possess cytotoxic activity against breast cancer cell line (6.1 and 3.1 μg/mL) and nasopharyngeal carcinoma cell line (20 and 6.1 μg/mL) [116].

4.1.2 Oligostilbenes

Three trimers nepalensinols A, C, and D and three tetramers nepalensinols B, G, and F were obtained from *Kobresia nepalensis* (Cyperaceae) [117, 118]. The inhibitory effect of the above six oligomers against the decatenation activity of topoisomerase II on kinetoplast DNA is evaluated with IC_{50} values ranging from 0.02 to 10.8 μg mL^{-1}. Among them, nepalensinol B exhibits the strongest activity with an IC_{50} of 0.02 μg mL^{-1}, much better than the clinical antitumor drugs daunorubicin (IC_{50} 4.8 μg mL^{-1}) and etoposide (IC_{50} 70.0 μg mL^{-1}). Vaticanol C is a resveratrol tetramer with dibenzobicyclo[3.2.1]octadiene moiety, is widely distributed in Dipterocarpaceae species, and shows potent growth suppressive activity with IC_{50} values of 5.9 μM against HL60 cells. Upunaphenol A is a hexamer obtained from *Upuna borneensis* and was found to suppress cell growth in HL60 cells through induction of apoptosis with IC_{50} at 9.2 μM [119].

4.1.3 Bibenzyls and Bisbibenzyls

Erianin (also named dihydrocombretastatin A-4), a dihydro derivative of combretastatin A-4 which has been initiated phase II clinical trial as antitumor agent, possessed potent cytotoxicity toward diverse cancer cell lines. It was evaluated against A-549 lung carcinoma, MCF-7 breast carcinoma, HT-29 colon adenocarcinoma, SKMEL-5 melanoma, and MLM melanoma cell lines with ED_{50} ranging from 0.002 to 0.33 μM, respectively [120]. It also showed potent inhibitory activity on the proliferation of HL-60 cells (IC_{50} 38 nM) and was able to alter expression of *bcl*-2 and *bax* genes in HL-60 cells [121].

Bauhinols A **110** and B **111** exhibit significant cytotoxicity against NCI-H187 (small-cell lung cancer) and BC (breast cancer) cell lines with IC_{50} values ranging from 1.1 to 9.7 μg/mL. In addition, bauhinol A **110** is active toward KB cells (IC_{50} 4.5 μg/mL) [64]. 3,5-Dihydroxy-4-methylbibenzyl shows cytotoxic activity, which is able to inhibit the growth rate of P-388 leukemia and hepatoma cell lines by 99.7% and 83.6% at 10 μg/mL, respectively [122].

The bisbibenzyls neomarchantins A **133** and B **134**, marchantin C, and Glaucescens Bis Bibenzyl A and B possess moderate cytotoxicity against P-388 leukemia cells with IC_{50} ranging from 8 to 18 μg/mL [123]. Riccardin C and pusilatins B-C display moderate cytotoxicity against KB cells with ED_{50} of 7.1 to 16.4 μg/mL [79].

Table 62.2 In vitro cytotoxic activity of **181** and **182** with human cancer cell lines (ED_{50} μg/mL)

	Human cancer cell lines											
	A-431	BC1	Col2	HT	KB	KB-V (+VLB)	KB-V (−VLB)	Mel2	LNCaP	Lu1	U373	ZR-75-1
181	11.3	6.9	13.1	5.5	15.0	0.8	3.0	10.0	19.0	6.1	>20	11.2
182	9.4	13.4	>20	3.1	6.4	3.6	5.9	9.2	10.3	19.9	3.2	10.5

A-431, human epidermoid carcinoma; BC1, human breast cancer; Co12, human colon cancer; HT, human fibrosarcoma; KB, human oral epidermoid; KB-V(+VLB), drug-resistant KB + vinblastine (1 lag/mL); KB-V(−VLB), drug-resistant KB (no vinblastine); LNCaP, human prostate cancer; Lul, human lung cancer; Mel2, human melanoma; U373, human glioma; ZR-75-1, hormone-dependent human breast cancer

4.1.4 Phenanthrenes

The cytotoxic activities both in vitro and in vivo of lusianthridin and denbinobin isolated from *Dendrobium nobile* are evaluated. Both of them exhibit potent antitumor effects against A549 human lung carcinoma, SK-OV-3 human ovary adenocarcinoma, and HL-60 human promyelocytic leukemia with EC_{50} values ranging from 0.11 to 9.8 μg/mL [124].

Dimeric phenanthrenes denthyrsinol, denthyrsinone, and monomer denthirsinin demonstrate potent cytotoxicity against cervix adenocarcinoma HeLa, K-562, and MCF-7 cells with IC_{50} values from 1.6 to 9.9 μM [125]. A series of phenanthrenes, including 7-hydroxy-2,3,4,8-tetramethoxyphenanthrene, 3-hydroxy-2,4,-dimethoxy-7,8-methylenedioxyphenanthrene, 2-hydroxy-3,5,7-trimethoxyphenanthrene, 2-hydroxy-3,5,7-trimethoxy-9,10-dihydrophenanthrene, and confusarin are evaluated on their antitumor properties against HeLa cell line with IC_{50} values of 0.97–14.21 μM. [126, 127].

3,6-Dihydroxy-l,7-dimethyl-9-methoxyphenanthrene **181** and 3,6-dihydroxy-L-hydroxymethyl-9-methoxy-7-methylphenanthrene **182** are found to demonstrate significant cytotoxic responses against several tumor cell lines (Table 62.2). Compound **181** is more active against drug-resistant KB cells, while **182** is active against HT (fibrosarcoma) and U373 (glioma) cell lines [128].

4.2 Antioxidant Activity

4.2.1 Stilbenes and Oligostilbenes

Lespedezavirgatol was obtained from *Lespedeza virgata* and shows potent antioxidant property. Its oxygen radical absorbance capacity (ORAC) value for Trolox equivalents is 762.96 at 1.5 μM, much better than 164.56 of vitamin C. Inhibitory effects of lespedezavirgatol against lipid peroxidation toward malondialdehyde levels in rat kidney homogenate and plasma are also evaluated with IC_{50} values of 0.16 and 0.18 mM, better than the control vitamin C, with IC_{50} values of 5.54 and 3.05 mM. The above results suggest that lespedezavirgatol is a potent candidate for antioxidants [129]. Tibeticanol **76** was obtained

Table 62.3 Effect of compounds from *V. thunbergii* on ABTS$^+$ scavenging

Compounds	Free-radical scavenging activity (EC_{50} μM)
Vitisinol B	3.6 ± 0.1
Vitisinol C	4.5 ± 0.1
Vitisinol D	4.1 ± 0.1
(+)-ε-Viniferin	2.8 ± 0.1
(−)-Viniferal	4.4 ± 0.1
Ampelopsin C	5.4 ± 1.2
Miyabenol A	6.6 ± 1.2
(+)-Vitisin A	13.8 ± 2.7
(+)-Vitisin C	4.8 ± 0.1
Trolox (positive control)	28.4 ± 5.2

from *Caragana tibetica* and exhibits strong superoxide anion scavenging activity with an IC_{50} of 1.33 μM [46].

A series of oligostilbenes isolated from *Vitis thunbergii* are evaluated on their antioxidant properties based on the radical scavenging effect of the stable ABTS$^{\bullet+}$ free radical. The results are shown in Table 62.3. All of the tested compounds are more active than the positive control Trolox and display free-radical scavenging activity with EC_{50} values from 2.8 to 13.8 μM. Among them, (+)-ε-viniferin shows the most potent radical scavenging potency with EC_{50} of 2.8 μM [23].

4.2.2 Bibenzyls and Bisbibenzyls

Marchantin H is able to inhibit nonenzymatic iron-induced lipid peroxidation in rat brain homogenates and NADPH-dependent microsomal lipid peroxidation with an IC_{50} of 0.51 and 0.32 μM [130]. It also possesses inhibitory effects of copper-catalyzed oxidation of human low-density lipoprotein. Marchantinquinone exhibits inhibitory effects of Fe^{2+}-induced lipid peroxidation in rat brain homogenates (IC_{50} 15.3 μM) and displays radical scavenging activity [131]. Schwartner et al. reported the antioxidative potential of three macrocyclic bisbibenzyls [marchantins A, B, and D], one acyclic bisbibenzyl (paleatin B) and a prenylated bibenzyl (perrottetin D) by pulse-radiolytic and EPR-spectroscopic techniques. The results confirm that these compounds are effective antioxidants [132]. Isoamoenylin and 5,4′-dihydroxy-3-α-L-rhamnopyranosyl-(1→3)-β-D- xylopyranosyloxybibenzyl showed radical scavenging activity, comparable with the control vitamin C and ascorbic acid [63, 133]. Five prenylated dihydrostilbenes, α,α-dihydro-3,5,3,4-tetrahydroxy-4,5-diisopentenylstilbene, α,α-dihydro-3,5,3,4-tetrahydroxy-5-isopentenylstilbene **183**, α,α-dihydro-3,5,4-trihydroxy-4,5-diisopentenylstilbene, α,α-dihydro-3,5,4-trihydroxy-5-isopentenyl stilbene, and α,α-dihydro-3,5,3-trihydroxy-4-methoxy-5-isopentenylstilbene **184**, from *Glycyrrhiza glabra* were tested for antioxidant effects by measuring the absolute inhibition rate constant (k_{inh}) of the oxidation process. Compounds **183** and **184** display potent antioxidant properties with k_{inh} values of 1.1×10^4 and $0.9 \times 10^4\ M^{-1}s^{-1}$ [134].

Table 62.4 Effect of compounds isolated from *V. thunbergii* on the platelet aggregation induced by AA and U46619

	IC_{50} (μM)	
Compounds	AA	U46619
Vitisinol B	>100	7.8 ± 2.2
Vitisinol C	13.4 ± 2.2	10.5 ± 3.4
Vitisinol D	15.0 ± 4.8	5.7 ± 1.4
(−)-Viniferal	7.0 ± 2.9	3.1 ± 2.5
Ampelopsin C	8.1 ± 1.1	5.9 ± 0.9
Miyabenol A	9.0 ± 1.6	7.5 ± 2.0
(+)-Vitisin A	10.3 ± 1.2	13.3 ± 2.1
(+)-Vitisin C	5.7 ± 1.3	3.9 ± 0.7
Aspirin (positive control)	32.7 ± 6.4	Not detected

4.3 Antiplatelet Activity

Resveratrol prevents platelet aggregation and thrombus formation in vitro. In a hypercholesterolaemic diet-induced rabbit model, administration of resveratrol inhibited the platelet aggregation. This effect was also verified by reducing the atherosclerotic area and the size of the thrombus generated by laser-induced damage to the endothelium in mice.

Vitis thunbergii (Vitaceae), a folk medicine in Taiwan, produced several resveratrol oligomers, including vitisinol C with a tropilene structure in molecule, vitisinols B and D, and some known compounds (−)-viniferal, (+)-ε-viniferin, and (+)-vitisin C, etc. The isolated compounds were evaluated for antiplatelet aggregation activities induced by arachidonic acid (AA) and 9,11-dideoxy-11α,9α-epoxy-methanoprostaglandin F2α (U46619). Most of the tested oligomers demonstrate potent antiplatelet aggregation property with $IC_{50} < 10$ μM, more positive than aspirin (EC_{50} 32.7 μM). In the above bioassay, (−)-viniferal and (+)-vitisin C are most effective against aggregation induced by AA and U46619, with IC_{50} values of 5.7 and 3.1 μM, respectively [23]. The results are summarized in Table 62.4.

Marchantinquinone displays potent inhibitory activity on the aggregation of washed rabbit platelets induced by thrombin, arachidonic acid (AA), collagen, U46619, and platelet-activating factor (PAF) [135, 136]. It inhibits thromboxane B_2 (TxB_2) formation induced by thrombin, PAF, and collagen. In addition, marchantinquinone is able to inhibit the rising intracellular Ca^{2+} concentration stimulated by five inducers mentioned above [136]. Gigantol exhibits antiplatelet aggregation activity on SD-rat platelet aggregation [137]. 3-Methylgigantol possesses significant inhibitory effects against aggregation induced by AA, collagen, and PAF [138]. Among them, 3-methylgigantol is most potent effective against AA-induced aggregation (IC_{50} 30 μM). Moscatilin is able to inhibit AA- and collagen-induced platelet aggregations [139]. Perrottetin E **146** shows inhibitory activity of thrombin (IC_{50} 18 μM) [140].

The phenanthrenes, erianthridin, and denbinobin display potent antiplatelet activity on washed rabbit platelets against aggregation induced by either thrombin, arachidonic acid (AA), collagen, or PAF at a dose of 100 μg/mL. Erianthridin is proved to be the most potent compound with an IC_{50} of 9 μM against AA-induced aggregation [138].

4.4 Antidiabetic Activity

5,4′-Dihydroxystilbene-3-*O*-α-arabinopyranoside, named rumexoid, was found in *Rumex bucephalophorus* (Polygonaceae). This compound and resveratrol display potent α-glucosidase inhibitory activity even better than the commercial antidiabetic agent acarbose [141]. 2′-*O*-Demethylbidwillol B and addisofurans A-B were prenyl-substituted arylbenzofurans isolated from *Erythrina addisoniae*. Those compounds are inhibitors of type II diabetes target protein tyrosine phosphatase 1B with IC_{50} values of 13.6–15.7 μM. The linear prenyl chain was responsible for its inhibitory activity, and the cyclization of prenyl group decreased this effect [142]. In a bioassay-guided fractionation against α-glucosidase, 13-hydroxykompasinol A and scirpusin C were obtained from the seeds of *Syagrus romanzoffiana* and possess potent inhibitory activity against α-glucosidase type IV from *Bacillus stearothermophilus* with the IC_{50} value of 6.5 and 4.9 μM [143].

4.5 Antimicrobial Activity

4.5.1 Stilbenes and Oligostilbenes

Machaeriol B, a compound with hexahydro-6*H*-benzo[c]chromene system, was obtained from *Machaerium multiflorum* (Leguminosae), and it demonstrates potent antimalarial activity (IC_{50} 0.12 μg/mL) against *Plasmodium falciparum* [144]. Preracemosols A and B exhibit moderate antimalarial activity with EC_{50} of 18.0 and 3.0 mg/mL, respectively [145]. *Trans*-4-isopentenyl-3,5,2′,4′-tetrahydroxystilbene was discovered in *Artocarpus integer* (Moraceae) and possesses antimalarial activity against *Plasmodium falciparum* ($EC_{50}=1.7$ μg mL^{-1}) [146]. This is the first report of antimalarial activity of stilbenes.

A series of arylbenzofuran-type stilbenes, guided by bioautographic assay for antifungal activity against *Cladosporium herbarum*, have been isolated from the root of *Stemona collinsae* (Stemonaceae) and tested in microwells against another four microfungi *Alternaria citri*, *Fusarium avenaceum*, *Pyricularia grisea*, and *Botrytis cinerea* [22]. Among them, stemofuran B shows the highest antifungal potency against above four parasitic fungi with EC_{50} values of 1.4 μg/mL. Stemofuran E exhibited antifungal property against *C. herbarum* with EC_{50} of 0.09 μg/mL.

Stilbene derivatives were obtained from *Calligonum leucocladum*, and the structures were determined as (*E*)-resveratrol 3-(6-galloyl)-*O*-β-d-glucopyranoside.

Although ineffective when tested alone, it is able to restore oxacillin's effectiveness against oxacillin/methicillin-resistant *Staphylococcus aureus* when used in combination. The galloyl group may play a role in this synergistic activity [147].

Hopeanolin was obtained from the stem bark of *Hopea exalata* and exhibits potent antifungal properties against six types of pathogenic fungi *Alternaria attenata*, *Alternaria solani*, *Colletotrichum lagenarium*, *Fusarium oxysporum f.* sp. *vasinfectum*, *Pyricularia oryzae*, and *Valsa mali* with MIC values ranging from 0.10 to 22.5 μg mL^{-1} [148].

4.5.2 Bibenzyls and Bisbibenzyls

Bryophytes normally grow in humid habitats; however, they are seldom damaged by fungi. It indicates that bryophytes are able to elaborate constitutive and inducible antifungal natural products against adverse effects. A large amount of bibenzyls and bisbibenzyls with antifungal activity have been found in plants, primarily in bryophytes (Table 62.5), which provided important sources for research and development of antifungal agents. The antifungal effects of bibenzyls and bisbibenzyls were summarized in Table 62.5.

The bibenzyls 4-hydroxy-3′-methoxybibenzyl, 2,4,6-trichloro-3-hydroxybibenzyl, 2, 4-dichloro-3-hydroxylbibenzyl, 2-chloro-3-hydroxybibenzyl, together with bisbibenzyls neomarchantins A **133** and B **134**, and marchantin C show antimicrobial activity against the gram-positive bacterium *Bacillus subtilis* [60, 123, 150]. In addition, 4-hydroxy-3′-methoxybibenzyl is active toward *Escherichia coli* [150].

4.6 Anti-inflammatory Activity

Anti-inflammatory properties of resveratrol have been confirmed, which is an effective inhibitor of cyclooxygenase (COX) in vitro. It is also found that resveratrol significantly reduces acute and chronic chemically induced edema, lipopolysaccharide-induced airway inflammation, and osteoarthritis. Resveratrol could also present as an alternative, instead of aspirin, for treatments of chronic inflammation because of the latter's side effect on the stomach. Resveratrol derivatives displayed similar anti-inflammatory effects. For instance, resveratrol (*E*)-dehydrodimer 11-*O*-β-D-glucopyranoside and resveratrol (*E*)-dehydrodimer from *Vitis vinifera* show significant inhibitory activity against cyclooxygenase-1 (COX-1) with IC_{50} of 5.2 and 4.3 μM and against cyclooxygenase-2 (COX-2) with IC_{50} of 7.5 and 3.7 μM. From the above results, these two compounds seem to be the worthy candidates for further research to find application in anti-inflammatory treatment [151].

(+)-Vitisifuran A and heyneanol A were found in *Vitis* genus and display potent inhibition on biosynthesis of LTB_4 with inhibitory rate of 72% and 76% at a concentration of 10 μM [152]. A tetramer named gnetuhainin R **73** was obtained from the same species (*G. hainanense*) and shows potent histamine receptor antagonism (IC_{50} 0.1 μM) [44]. Aiphanol exhibited significant inhibitory activities against COX-1 (IC_{50} 1.9 μM) and COX-2 (9.9 μM) [153].

Table 62.5 Antifungal bibenzyls and bisbibenzyls

Compound	Fungi	Dose	References	Compound	Fungi	Dose	References
Bauhinol B	*Candida albicans*	28.9^{a}	[64]	2,4-Dichloro-3-hydroxy bibenzyl	*Candida albicans*	2^{f}	[60]

[e] MIC (μg/mL)
[f] Width of the zone of inhibition (mm) at 30 μg/disk

Stemofurans B, D, G, and J and stilbostemin G were reported possessing anti-inflammatory effects with IC_{50} values ranging from 3.7 to 26.3 μM by inhibiting leukotriene formation [154]. The inhibition of lipopolysaccharide-induced nitric oxide synthase (NOS) by 19 bisbibenzyls in RAW 264.7 macrophages has been reported, and marchantin A is most effective with IC_{50} values of 1.44 μM. The structure-activity relationship (SAR) is discussed, and the phenolic hydroxyl groups and diarylether bonds play important roles in its inhibitory effect [155]. Pusilatins B-C exhibit selective DNA polymerase-β inhibitory activity with IC_{50} of 13.0 and 5.16 μM [79]. Bauhinol B **111** and 3,5-dihydroxy-2-(3-methyl-2-butenyl)bibenzyl are potent inhibitors of COX-1 and COX-2 with IC_{50} ranging from 1.3 to 9.0 μg/mL [134].

Phenanthrenes obtained from the *Stemona* species were evaluated on their leukotriene biosynthesis inhibition property using human neutrophile granulocytes in vivo. Stemanthrenes A **162** and D **165** display inhibitory activity in a dose-dependent manner, with IC_{50} values of 8.5 and 4.8 μM. Stemanthrenes B **163** and C **164** possess 100% inhibition against leukotriene biosynthesis at 25 μM. The phenanthrenes might be responsible for the anti-inflammatory and antiasthmatic principles of the *Stemona* species [154]. Denbinobin, a phenanthraquinone from *Dendrobium moniliforme*, shows in vitro anti-inflammatory activity. It inhibits the formation of tumor necrosis factor and prostaglandin E2 induced by lipopolysaccharide in RAW 264.7 and N9 cells at a dose of 1 μM [100].

4.7 Neuroprotective Activity

In vivo pharmacological studies have indicated that resveratrol has a neuroprotective effect, including reduced lipid, peroxidation and neurological cell destruction, attenuation of induced lesion areas, induced tolerance to brain injury, reduced frequency of seizures, impairment of motor coordination, and enhancement of learning [111].

Stilbostemin B 3′-β-D-glucopyranoside, stilbostemin H 3′-β-D-glucopyranoside, and stilbostemin I 2″-β-D-glucopyranoside possess significant neuroprotective activity against 6-hydroxydopamine-induced neurotoxicity in human neuroblastoma SH-SY5Y cells [156]. Hopeahainol A from *Hopea hainanensis* contains an unprecedented carbon skeleton and shows potent acetylcholinesterase inhibitory effect with an IC_{50} value of 4.33 μM, comparable even to that of huperzine A (IC_{50} 1.6 μM) [157]. The tetramer neohopeaphenol A from the same species also displays significant inhibitory action against AChE with an IC_{50} value of 7.66 μM [158].

4.8 Hepatoprotective Activity

Acer mono (Aceraceae), a Korean folk medicine for hemostasis, produces two potent hepatoprotective stilbene glycosides, 5-*O*-methyl-(*E*)-resveratrol 3-*O*-β-D-glucopyranoside and 5-*O*-methyl-(*E*)-resveratrol 3-*O*-β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside [16]. Those two compounds significantly prevent the depletion of glutathione (GSH) in H_2O_2-injured primary cultured rat hepatocytes and potently restore the level of GSH depleted by buthionine sulfoximine or diethylmaleate in the presence or absence of H_2O_2. In addition, they preserve the effects of antioxidant enzymes such as superoxide dismutase, glutathione reductase, and glutathione peroxidase reduced by H_2O_2 insults. Therefore, it is concluded that both compounds exerted significant hepatoprotective effects against H_2O_2-induced hepatotoxicity by maintaining the antioxidant defense system [159].

4.9 Cardioprotective Activity

It is well known that drinking wine and grape juices will reduce cardiovascular, cerebrovascular, and peripheral vascular risks due to the presence of resveratrol. As a natural antioxidant, resveratrol is able to prevent LDL oxidation, scavenge intracellular reactive oxygen species, lower the oxidative stress, and induce NO synthesis. Resveratrol modulates various aspects of cardiovascular diseases and is effective against atherosclerosis, hypertension, ischemia reperfusion injury and heart failure, and many other cardiac dysfunctions [111].

4.10 Phytotoxicity

The phenanthrenes, ephemeranthol-A and fimbriol A from *Epidendrum rigidum*, together with erianthridin from *M. densa* demonstrated phytotoxicity against *Amaranthus hypochondriacus* with IC_{50} values of 0.12, 5.9, and 58.2 μM [160]. The phenanthrenes from the *Juncus* genus show growth inhibitory effects against the green alga *Selenastrum capricornutum* with IC_{50} values ranging from 11.1 to 19.9 μM [161].

Bibenzyls are elaborated to confer the producing plants' selective advantage against the competition from the other plants and microbial attack. Gigantol, batatasin III, 2,3-dimethoxy-9,10-dihydrophenathrene-4,7-diol, and 3,4,9-trimethoxyphenanthrene-2,5-diol from the orchid *Epidendrum rigidum* inhibit radicle growth of *Amaranthus hypochondriacus* with IC_{50} of 0.65, 0.1, 0.12, and 5.9 μM [160].

5 Conclusion

Stilbenoids represent a group of important natural products in the plant kingdom. The developments of modern analytical methods accelerate the discovery of these compounds, and to this day more than 1,000 stilbenoids have been isolated. For the stilbenes, bibenzyls, and phenanthrenes, these three groups shared the feature of their nucleus with hydroxyls, methyl, methoxy, prenyl, geranyl, glycosyl, etc., substituents. The oligostilbenes and bisbibenzyls are formed by polymerization of stilbene and bibenzyl units, and the diverse polymerized patterns produced their diverse structures. They display diverse biological activities and have the potential to be developed as new drugs, especially in the field of antitumor, anti-inflammation, and cardioprotective drug research. The representative compounds resveratrol and combretastatin A-4 phosphate are currently being evaluated as drugs for the treatment of Alzheimer's disease and tumors in clinical trials and have shown satisfactory therapeutic effects. Furthermore, resveratrol displays developing prospects as a cardioprotective drug.

There are problems that need to be noted. Concerning the oligostilbenes, they commonly possess large molecules, intricate structures, and complex stereochemistry, and these characteristics cause troubles in structure identification and chemical total synthesis, therefore, limiting the probability to be developed to new drug. The bisbibenzyls are mainly distributed in the bryophytes, which are very small terrestrial spore-forming green plants, and different for collections. Therefore, getting enough plant materials for phytochemical investigation and new drug research is really a Gordian knot and resorts to the chemical synthesis for resolving the resource problems.

Abstract

Phenolic acids are plant metabolites widely spread throughout the plant kingdom. Recent interest in phenolic acids stems from the potential protection they offer against oxidative damage diseases (e.g., coronary heart disease, stroke, and cancers) when consumed in fruits and vegetables. This chapter discusses the function of plant phenolic acids associated with diverse roles, including nutrient uptake, protein synthesis, photosynthesis, and allelopathy. It also provides an update of the

health-promoting benefits of their important biological and pharmacological properties, especially anti-inflammatory, antioxidant, and antimutagenic and anticarcinogenic activities. The main methodologies currently being used for the extraction and quantification of these important phenolic compounds are also discussed.

1 Introduction

Secondary metabolites are products of plant interaction with the environment and have a restricted occurrence. Many have economical importance, for example, as drugs, antioxidants, flavors, fragrances, dyes, insecticides, and pheromones [1]. Secondary metabolites can be classified according to their biosynthetic building blocks or their carbon skeleton. Approximately 8,000 naturally occurring compounds belong to the category of “phenolics,” all of which share a common structural feature: an aromatic ring bearing at least one hydroxyl substituent, that is, a phenol [2]. The hydroxyl group(s) can be free or engaged in another function as ethers, esters, or glycosides [3].

A straightforward classification attempts to divide the broad category of phenolics into simple phenols and polyphenols, based exclusively on the number of phenol subunits present, but many plant phenolic compounds are polymerized into larger molecules. Thus, the term “plant phenolics” encompasses simple phenols, phenolic acids, coumarins, flavonoids, stilbenes, hydrolyzable and condensed tannins, lignans, and lignins [4].

Widely distributed in plants, phenolic compounds are synthesized either as soluble or cell wall–bound compounds during plant growth and especially in response to conditions such as infection, wounding, UV radiation, etc. [5].

Phenolics have generated considerable interest due to their important biological and pharmacological properties, especially their anti-inflammatory, antioxidant, and antimutagenic and anticarcinogenic activities [6–8].

Phenolic acids are a subclass of the larger phenolics category (Fig. 63.1), occurring in food plants as esters or glycosides conjugated with other natural compounds such as flavonoids, alcohols, hydroxyfatty acids, sterols, and glucosides. Although much knowledge is still needed on the role of phenolic acids in plants, they have been associated with diverse functions, including nutrient uptake, protein synthesis, enzyme activity, photosynthesis, structural components, and allelopathy [9].

Phenolic acids (phenolcarboxylic acids) are phenols that include substances containing a phenolic ring and at least one organic carboxylic acid function. Depending on the carbon units of the lateral chain attached to the phenolic ring, the phenolic acids can be divided into C6-C3, C6-C2, and C6-C1 compounds, the most important being C6-C3 (derived from the hydroxycinnamic acid) and C6-C1 (compounds with a hydroxybenzoic structure) (Fig. 63.1). Although the basic skeleton remains the same, phenolic acids differ in the number and position of the hydroxyl groups on the aromatic ring.

The majority of phenolic acids are linked through ester, ether, or acetal bonds either to structural components of the plant (cellulose, proteins, lignin) or to larger polyphenols (flavonoids), or smaller organic molecules (e.g., glucose, quinic, maleic, or tartaric acids) or other natural products (e.g., terpenes) [10–14]. Many phenolic acids like cinnamic and benzoic acid derivatives exist in all plant and plant-derived foods (e.g., fruits, vegetables, and grains) [15]. However, only a minor fraction exists in the free acid form. Due to their ubiquitous presence in plant-based foods, humans consume phenolic acids on a daily basis. The estimated range of consumption is 25 mg to 1 g a day depending on diet (fruit, vegetables, grains, teas, coffees, spices, etc.).

Phenolic acids have been the subject of a great number of chemical, biological, agricultural, and medical studies [1].

1.1 Hydroxybenzoic Acids

Hydroxybenzoic acids have a general structure of C6-C1 derived directly from (BA), for example, p-hydroxybenzoic acid (p-HBA); salicylic acid (SA);

2,3-dihydroxybenzoic acid (2,3-DHBA); 2,5-dihydroxybenzoic acid (2,5-DHBA); 3,4-dihydroxybenzoic acid (3,4-DHBA); 3,5-dihydroxybenzoic acid (3,5-DHBA); gallic acid (GA); and vanillic acid (Fig. 63.2).

Variations in the structures of individual hydroxybenzoic acids lie in the hydroxylations and methylations of the aromatic ring [16]. Four acids commonly occur: p-hydroxybenzoic, vanillic, syringic, and protocatechuic acid. They may be present in soluble form conjugated with sugars or organic acids as well as bound to cell wall fractions, for example, lignin [8].

1.2 Hydroxycinnamic Acids

The hydroxycinnamic acids (HCAs) include PA, CA, FA, SIA, and their esterified/etherified conjugates such as chlorogenic acids. Chemical structures of these compounds are depicted in Figs. 63.1 and 63.2. The most commonly found naturally occurring HCAs is chlorogenic acid (5-*O*-caffeoylquinic acid), which is caffeic acid

esterified with quinic acid. Hydroxycinnamates are found in food as monomers, dimers, and bound forms esterified with hydroxy acids, mono/disaccharides, and polymers. They also occur as amides (with amino acids and amines), particularly in coffee and cocoa [4]. The conjugated forms are esters of hydroxy acids such as quinic, shikimic, and tartaric acid, as well as their sugar derivatives [15] (Table 63.1).

1.3 Biosynthesis of Hydroxycinnamic Acids

The formation of hydroxycinnamic acids (caffeic, ferulic, 5-hydroxyferulic, and sinapic acids) from p-coumaric acid requires two types of reactions: hydroxylation and methylation. The phenylalanine/hydroxycinnamate pathway is defined as general phenylpropanoid metabolism. It includes reactions leading from L phenylalanine to the hydroxycinnamates and their activated forms [15]. The enzymes catalyzing the individual steps in general phenylpropanoid metabolism are (PAL), (CA4H), and (C4L). The introduction of a second hydroxyl group into p-coumaric acid to give caffeic acid is catalyzed by monophenol mono-oxygenases, a well-known group of plant enzymes [8, 16] (Fig. 63.3).

Table 63.1 Phenolic acids: hydroxybenzoic and hydroxycinnamic acids

	Syringic acid	H	OCH_3	OH	OCH_3
	Gentisic acid	OH	H	H	OH
	Veratric acid	H	OCH_3	OCH_3	H
	Salicylic acid	OH	H	H	H
Hydroxycinnamic acids					
	Cinnamic acid	H	H	H	H
	o-Coumaric acid	OH	H	H	H
	m-Coumaric acid	H	OH	H	H
	p-Coumaric acid	H	H	OH	H
	Ferulic acid	H	OCH_3	OH	H
	Sinapic acid	H	OCH_3	OH	OCH_3
	Caffeic acid	H	OH	OH	H

Methylation of caffeic acid leads to the formation of ferulic acid, which, together with p-coumaric acid, are the precursors of lignins. The methylation is catalyzed by an *O*-methyltransferase. Caffeic acid is the substrate for the rare 5-hydroxyferulic acid, which yields sinapic acid as a result of *O*-methylation. The formation of hydroxycinnamic acid derivatives requires the formation of hydroxycinnamate-CoAs (e.g., p-coumaroyl-CoA) catalyzed by hydroxycinnamoyl-CoA ligases or by the action of *O*-glycosyl transferases.

Moreover, hydroxycinnamate-CoAs can conjugate with organic acids. In the biosynthesis of sugar derivatives of hydroxycinnamic acids, the transfer of glucose from uridine diphosphoglucose to hydroxycinnamic acid is catalyzed by glucosyl transferase [8, 16].

1.4 Biosynthesis of Hydroxybenzoic Acids

Benzoic acids are structurally simple natural products, so it is quite surprising that many different pathways may be employed for their biosynthesis. Pathways may differ according to the organism, and sometimes more than one pathway may exist in a single

organism. Some of the simple hydroxybenzoic acids (C6-C1 compounds), such as GA and 4-hydroxybenzoic acid, can be formed directly from intermediates early in the shikimate pathway, especially from dehydroshikimic acid; this reaction is the main route to gallic acid [3]. However, they can also be produced by the degradation of hydroxycinnamic acids, in a similar manner to the b-oxidation of fatty acids; the main intermediates are cinnamoyl-CoA esters (Fig. 63.3). Hydroxybenzoates are also produced occasionally by the degradation of flavonoids. Moreover, hydroxylations and methylations of hydroxybenzoic acids are known to occur in an analogous way to the phenylalanine/hydroxycinnamate pathway. Knowledge of the mechanisms and above all the enzymes involved in the biosynthesis of hydroxybenzoic acids and their derivatives is rather limited, especially regarding fruits, although gallic acid and its derivatives play an important role in the formation of hydrolyzable tannins [8, 16].

2 Functions in Plants

Although a great deal is still unknown regarding the roles of phenolic acids in plants, they have been connected with diverse functions, including nutrient uptake, protein synthesis, enzyme activity, photosynthesis, structural components, and allelopathy [17].

A variety of evidence suggests that phenolic compounds influence the pools and fluxes of inorganic and organic soil nutrients. Phenolic compounds can directly affect the composition and activity of decomposer communities, thus influencing the rates of decomposition and nutrient cycling. To determine how individual phenolic acids in a mixture might affect phosphorus (P) uptake, cucumber seedlings grown in solution culture were treated with ferulic, vanillic, p-coumaric, or equimolar mixtures of these phenolic acids. The dose required for 50% inhibition of P uptake was approximately two to three times higher for vanillic acid (6.73 mM) than for ferulic (2.27 mM) and p-coumaric acids (3.00 mM) when the dose was based on the initial treatment concentrations [18], even though the concentrations of individual compounds are well below their inhibitory levels. Different types of soluble phenolics, such as ferulic acid and gallic acid, have been found to inhibit either seed germination or root growth. The allelopathic effects of these phenolic acids seem not to be species specific, but they act like a broad-spectrum preemergence herbicide that affects seedling establishment while not affecting established turfgrass. The allelopathic effects of phenolic acids may be at least partly responsible for preventing the establishment of new plants in the sward [19].

Either biotic or abiotic stress, or a combination of both, increases the production of phenolic compounds. Different kinds of stress may affect different parts of the Systemic Acquired Resistance (SAR) pathways and may determine whether (SA), (JA), ethylene or more than one signaling compound is employed in different plant species [20]. Simple phenolic acids are signaling molecules involved in plant-microbe interactions. Methyl salicylate is synthesized in the site of primary infection and protects the plant from the spread of infection and future attack [21].

2.1 Biotechnological Production of Phenolic Acids

Tissue and cell cultures are a potential model to elucidate the biosynthetic pathways of many secondary compounds and understand their regulation, as well as to improve the production of secondary metabolites of chemical-pharmaceutical interest [1, 2]. Compared with the traditional approach of whole plant cultivation in the natural environment or on agricultural farms, plant tissue culture in shake-flasks or bioreactors has the advantages of offering better controlled and more sustainable culture systems without the limitations of natural factors, such as geographical location and seasonal variation [21–25]. It has been regarded as a promising way for the mass production of valuable secondary metabolites, such as food additives, pharmaceuticals and nutraceuticals, and antimicrobials and pesticides, particularly from rare and slow-growing plant species [26–30].

2.2 Phenolic Acids in Foods

Phenolic acids account for almost one third of the dietary phenols and are associated with organoleptic, nutritional, and antioxidant properties of foods [4, 31]. Phenolic acids are abundant in a balanced diet that includes adequate amounts of fruits, vegetables, and whole grains. Sources include mangoes, berries, apples, citrus fruits, plums, cherries, kiwis, onions, tea, coffee, red wine, and wheat, rice, corn, and oat flours. Since they are widespread in plant-based foods, humans consume phenolic acids on a daily basis. They are easily absorbed due to their simplicity. The estimated range of consumption is 25 mg to 1 g a day, depending on diet [15, 32]. Among fruits, the highest contents are in rowanberry (28 mg/100 g). Coffee (97 mg/100 g) as well as green and black teas (30–36 mg/100 g) are the best sources among beverages. Additionally, the food industry has investigated the content and profile of phenolic acids, their effect on fruit maturation and prevention of enzymatic browning, and their roles as food preservatives [15].

Plant antioxidant activity is due to phenolic acid content, especially caffeic and p-coumaric. The greater antioxidant activity of caffeic acid than p-coumaric acid stems from the 3,4-position of dihydroxylation on the phenolic ring [33].

Phenolics behave as antioxidants due to the reactivity of the phenol moiety (hydroxyl substituent) on the aromatic ring [34]. Caffeic acid is expected to have higher antioxidant activity because of additional conjugation in the propanoic side chain, which might facilitate the electron delocalization, by resonance, between the aromatic ring and proanoic group [35].

Although the exact nature of the antioxidant or protective effects in vivo is not well established, some preliminary investigations have been carried out. Caffeic, ferulic, chlorogenic, and sinapic acid have shown antioxidant or protective effects in vivo by several mechanisms. The predominant mode is believed to be radical scavenging via hydrogen atom donation or established antioxidant, radical quenching mechanisms via electron donation, and singlet oxygen quenching [36, 37].

2.3 Phenolic Acids in Human Health

Phenolic acids have been reported to have important biological and pharmacological properties and may have benefits for human health. These compounds are important components of the human diet, due to their potential antioxidant activity, their capacity to diminish oxidative stress-induced tissue damage resulting from chronic diseases, and their potentially important anticancer activities [38, 39].

The literature provides information that correlates a diet rich in phenolic acids with the maintenance of health and disease prevention. The high antioxidant contents in fruits and vegetables inhibit oxidative damage diseases such as coronary heart disease, stroke, and cancers [40–42]. Certain foods are even classified as functional foods, owing to their established protective effects on human health.

Caffeic acid, one of the most prominent naturally occurring cinnamic acids, is known to selectively block the biosynthesis of leukotrienes, components involved in immunoregulation diseases, asthma, and allergic reactions [35].

Phenolic acids have been reported to exert an antibacterial effect. Ferulic, isovanillic, p-hydroxycinnamic, p-hydroxybenzoic, syringic, caffeic, gentisic, protocatechuic, p-coumaric, vanillic, and p-hydroxybenzoic acids, isolated from different plant sources, have exhibited potent antibacterial activities. The mechanism of action of phenolic compounds is described as being nonspecific and resulting in alterations of the cytoplasmic membrane [32]. Caffeic acid and some of its esters might possess antitumor activity against colon carcinogenesis [43]. This compound also inhibits aflatoxin production of *Aspergillus flavus* without inhibiting the fungal growth and shows bactericidal activity toward *Pseudomonas aeruginosa* and *Staphylococcus aureus* [32].

Gallic acid can reduce allergic symptoms by acting as an antihistamine. Recent investigations by Maggi-Capeyron et al. [100] have linked a series of phenolic acids with the inhibition of AP-1 transcriptional activity. AP-1 is an activator protein implicated in the processes that control inflammation, cell differentiation, and proliferation, so gallic acid is a potent anti-inflammatory agent.

The human immunodeficiency virus (a virus that is often abbreviated to HIV and causes acquired immunodeficiency syndrome (AIDS) which ultimately destroys the immune system) is extremely difficult to treat because it hosts itself inside the body's cells and constantly mutates into new strains. Caffeic acid derivatives (e.g., dicaffeoylquinic and dicaffeoyltartaric acids) have been shown to be potent and selective inhibitors of human immunodeficiency virus type 1 (HIV-1) integrase. This enzyme catalyzes the integration of viral DNA into the host chromatin. Therefore, these hydroxycinnamate derivatives are currently being investigated for their potential antiviral therapy [44]. Cancer develops when the deoxyribonucleic acid (DNA) in cells becomes damaged, resulting in rapid, uncontrollable cell growth, ultimately leading to the formation of a tumor. It is known that some phenolic acids exert a direct antiproliferative action [44]. Furthermore, their direct interaction with the aryl hydrocarbon receptor, nitric oxide synthase inhibition, and their pro-apoptotic effect provide some insights into the phenolic acid biological mode of action [45, 46].

Consumption of products rich in phenolic acids, such as wine and the "Mediterranean diet," correlates with a reduced risk of cardiovascular disease. Since phenolic acids may exhibit antioxidant properties, a role in protecting low-density lipoprotein (LDL) from oxidative modification has been proposed [47, 99].

2.4 Presence and Therapeutic Properties of the Main Phenolic Acids

The phenolic acids found in natural sources are present in variable quantities and those with therapeutic properties have a higher added value in the market. An overview of the general therapeutic and chemical properties of phenolic acids has already been given, and the most important compounds are now described in more detail, including their present applications.

2.4.1 Ferulic Acid

FA (Fig. 63.1) is a ubiquitous plant constituent that arises from the metabolism of phenylalanine and tyrosine. It occurs primarily in seeds and leaves both in its free form and covalently linked to lignin and other biopolymers. Due to its phenolic nucleus and an extended side chain conjugation, it readily forms a resonance stabilized phenoxy radical, which accounts for its potent antioxidant potential.

FA is mainly conjugated with mono- and oligosaccharides, polyamines, lipids, and polysaccharides and seldom occurs in a free state in plants. It is a phenolic acid of low toxicity and can be absorbed and easily metabolized in the human body. FA has been reported to have many physiological functions, including antioxidant, antimicrobial, anti-inflammatory, anti-thrombosis, and anticancer activities [48, 49]. It also protects against coronary disease, lowers cholesterol, and increases sperm viability. In addition to this, provisional evidence suggests that FA may have further health benefits in the human body, although further studies are required for confirmation. These potential health benefits include possibly preventing bone degeneration, cancer, hot flushing symptoms in menopausal women, protecting the skin from ultraviolet (UV) damage, reducing blood levels of LDL cholesterol (a type of cholesterol which can cause blockages in the arteries and increase risk of heart disease), and treating diabetes by reducing blood glucose levels [50].

Due to its properties and low toxicity, FA is now widely used in the food and cosmetic industries. It serves as the raw material for the production of vanillin and preservatives, as a cross-linking agent for the preparation of food gels and edible films, and as an ingredient in sports foods and skin protection agents.

2.4.2 Salicylic Acid

SA (Fig. 63.3), also called 2-hydroxybenzoic acid, is used chiefly in the preparation of aspirin and other pharmaceutical products. Salicylic acid occurs in such diverse plants as *Salix* spp., *Sauromatum guttatum*, *Grindelia* spp., and *Mespilus germanica* and is also produced by the bacterium *Pseudomonas cepacia* [51].

SA has keratolytic, anti-inflammatory, antipyretic, analgesic, antiseptic, and antifungal properties for several skin conditions such as dandruff and seborrhoeic dermatitis, ichthyosis, psoriasis, acne, etc. [52]. It functions as a hormonal mediator of plant resistance responses to environmental stress and pathogen attacks. The free acid occurs naturally in small amounts in many plants.

Plants have developed an array of structural, chemical, and protein-based defenses designed to detect invading organisms and stop them before they are able to cause extensive damage. Disease can be caused by living (biotic) agents, including fungi and bacteria, or by environmental (abiotic) factors such as nutrient deficiency, drought, lack of oxygen, excessive temperature, ultraviolet radiation, or pollution. In order to protect themselves from damage, plants have developed a wide variety of constitutive and inducible defenses. This phenomenon is called systemic acquired resistance (SAR) and involves the mobilization of plant resources in case of further attack. Plants respond with a salicylic-dependent signaling cascade that leads to the systemic expression of a broad spectrum and long-lasting disease resistance that is efficient against fungi, bacteria, and viruses [53].

SA in plants is thought to be derived from the phenylalanine pathway by the cinnamic acid chain oxidative pathway [54].

2.4.3 Cinnamic Acids

The antioxidant activity of CA (Fig. 63.1) and four homologous derivatives has been shown to differ according to the kind of aromatic substitution (p-hydroxy, p-hydroxymethoxy, p-hydroxydimethoxy, dihydroxy). The antioxidant activity was studied using a competition kinetic test that measured the relative capacity to quench peroxyl radicals and the in vitro oxidative modification of human low-density lipoprotein. In both models, cinnamic acids were more efficient than their benzoic counterparts [55].

2.4.4 3-Hydroxybenzoic Acid

3-Hydroxybenzoic acid is found in common plants such as *Citrus paradisi*, *Olea europaea*, and *Mespilus germanica*. p-Hydroxybenzoic acid (4-hydroxybenzoic acid) has been isolated from many sources, including *Daucus carota*, *Elaeis guineensis*, *Vitis vinifera*, and numerous other species including East African *Fagara macrophylla*, *Xanthophyllum rubescens*, *Paratecoma peroba*, *Tabebuia impetiginosa*, *Pterocarpus santalinus*, *Catalpa bignonioides*, *Vitex negundo*, *Areca catechu*, *Roystonea regia*, and *Mespilus germanica* [56]. It shows antifungal, antimutagenic, antisickling, and estrogenic activities [57, 58].

2.4.5 Gentisic Acid

G (2,5-dihydroxybenzoic acid) is an analgesic, anti-inflammatory, antirheumatic, antiarthritic, and cytostatic agent, and inhibits low-density lipoprotein oxidation in human plasma [59].

G is thought to be responsible for the anti-carcinogenic activity of China-rose hibiscus (*Hibiscus rosa-sinensis*) extract, and a recent study has shown that gentisic acid is a Fibroblast Growth Factor (FGF) inhibitor [60, 61].

2.4.6 Gallic Acid

GA (3,4,5-trihydroxybenzoic acid) (Fig. 63.1) is a widespread phytochemical that occurs in *Allanblackia floribunda*, *Garcinia densivenia*, *Bridelia micrantha*, *Caesalpinia sappan*, *Dillenia indica, Diospyros cinnabarina*, *Paratecoma peroba*, *Psidium guajava*, *Syzygium cordatum*, *Rhus typhina*, *Tamarix nilotica*, *Vitis vinifera*, *Hamamelis virginiana*, and *Toona sinensis* [62].

GA exhibits a ROS-mediated anticancer activity in human prostate cancer cells [63] and possesses antimelanogenic properties. A phenolic fraction from evening primrose (*Oenothera biennis*) containing 55% of GA showed antitumor activity [64]. It has been proposed as a candidate for treatment of brain tumors as it suppresses cell viability, proliferation, invasion, and angiogenesis in human glioma cells. GA induces the death of HeLa cervical cancer cells via apoptosis and/or necrosis [17].

GA has shown promising results as an anti-HSV-2 (Herpes simplex virus) agent [65]. It is also used in the pharmaceutical industry as an astringent and styptic agent.

2.4.7 Vanillic Acid

Vanillic acid (4-hydroxy-3-methoxybenzoic acid) (Fig. 63.1) occurs in many plants such as *Fagara spp*., *Alnus japonica*, *Elaeagnus pungens*, *Erica australis*, *Gossypium mexicanum*, *Melia azedarac*h, *Panax ginseng*, *Paratecoma koraiensis*, *Pterocarpus santalinus*, *Rosa canina*, *Picrorhiza kurroa*, *Trachelospermum asiaticum*, *Amburana cearensis*, and *Lentinula edodes*. Besides antisickling and anthelmintic activities, vanillic acid could suppress hepatic fibrosis in chronic liver injury [66]. It is also found to be an inhibitor of snake venom 5′-nucleotidase [67].

2.4.8 Sinapic Acid

SIA (4-Hydroxy-3,5-Dimethoxy-Cinnamic Acid) (Fig. 63.2) is a phenylpropanoid compound found in various herbal materials and high-bran cereals. It has been reported that sinapic acid has antioxidant efficacy as a metal chelator due to the orientation of functional groups. Administration of sinapic acid exhibited significant reversal of arsenic-induced toxicity in hepatic tissue [68].

Diabetes is a major public health problem and the development of new therapies that are able to improve glycemia management and even to cure diabetes is of great interest. In a study designed to evaluate the effect of sinapic acid on physiological and biochemical parameters in streptozotocin-induced diabetic rats, oral administration of sinapic acid for a period of 35 days restored all these biochemical parameters to near normal [69].

2.4.9 Digallic Acid

Digallic acid ([3,4-dihydroxy-5-(3,4,5-trihydroxybenzoyl)- oxy]benzoic acid) is isolated from *Acacia farnesiana*, *Acacia arabica*, *Metasequoia glyptostroboides*, *Castanopsis spp*., *Quercus aliena*, *Mangifera indica*, *Rhus chinensis*, *Adenia cissampeloides*, *Terminalia chebula*, and *Pistacia lentiscus*. It is an HIV reverse transcriptase inhibitor and has cytotoxic/antiapoptotic activity and also shows antigenotoxic and antioxidant activities [70].

2.4.10 Diferulic Acids

They have been found in the cell walls of most plants, but are present at higher levels in the grasses and also sugar beet. The 8-*O*-4′-DiFA tends to predominate in grasses, but also predominate in barley bran. In sugar beet, the predominant diferulic acids are 8-*O*-4′-DiFA and 8,5′-DiFA, respectively [71]. Ferulates are thought to play an important role in modifying the mechanical properties of cell walls as well as in limiting polysaccharide degradation by exogenous enzymes by acting as a cross-link between polysaccharides and between polysaccharides and lignin [72]. Dimerization of ferulates is a mechanism for cross-linking cell wall polysaccharides. Ferulates have been extracted attached to a few sugar molecules at both ends, but so far no definitive proof of them linking separate polysaccharide chains has been found. In suspension-cultured maize cells, dimerization of ferulic acid and their esterification to polysaccharides occurs mostly in the protoplasm, but may occur in the cell walls when peroxide levels increase due to pathogenesis. In suspension-cultured wheat cells, only the 8,5′-diferulic acid is formed intraprotoplasmically with the other dimers being formed in the cell wall [73, 74].

2.4.11 Rosmarinic Acid

RA (α-*O*-caffeoyl-3,4-dihydroxyphenyllactic acid, RA) is a phenolic acid:(R)-alpha-[3-(3,4-Dihydroxyphenyl)-1-oxo-2E-propenyl]oxydihydroxybenzenepropanoic acid is found in many medicinal species belonging to *Lamiaceae* and *Boraginaceae*, including basil, sage, rosemary, mint, and *Perilla frutescens* [75].

RA has been shown to exert antioxidant effects in vitro against superoxide radicals and hydroxyl radicals [76].

RA exhibits various pharmacological activities including antiviral, antithrombotic, and antiplatelet suppression of cytokine-induced proliferation of murine-cultured mesangial cells, prevention of oxidation of low-density lipoprotein, inhibition of murine cell proliferative activity, and of cyclooxygenase, and anti-allergic action [77, 78, 101]. RA is used to treat peptic ulcers, arthritis, cataract, cancer, rheumatoid arthritis, and bronchial asthma. RA and its derivatives possess promising biological activities, such as improvement of cognitive performance, prevention of the development of Alzheimer's disease, cardioprotective effects, reduction of the severity of kidney diseases and cancer chemoprevention.

RA has been used topically as an anti-inflammatory drug. In order to alleviate inflammation, it seems to be able to suppress 5-lipoxygenase and 5-HETE synthesis (a pro-inflammatory compound in the omega-6 metabolic chain) [79]. During this process of inflammation several pathological changes occur: cyclooxygenase-2 (COX-2), a key enzyme in the inflammatory response, is thought to affect carcinogenesis indirectly via its modulatory effect on the inflammatory response and the immune system. RA is capable of reducing or eliminating leukotriene production and modulating the complement system without adverse reactions.

In vivo, RA has been reported to inhibit cobra venom factor (CVF)-induced paw edema, immune complex-mediated passive cutaneous anaphylaxis, and complement-dependent stimulation of prostacyclin synthesis.

Sanbongi et al. (2004) have shown that the oral administration of RA has an effective intervention for allergic asthma. Oral supplementation with this compound has been shown to suppress allergic reactions in mice and, more recently, in humans. RA relieves allergy symptoms by kill allergy-activated T cells and neutrophils during allergic prevention by activation of immune responder cells and by inducing apoptosis.

RA furnished notable antibacterial activity against *Bacillus subtilis*, *Micrococcus luteus*, and *Escherichia coli* [80].

The biosynthesis production of RA have been extensively studied using cell and organ culture systems because. RA biosynthesis represents an interesting model system in which two parallel biosynthetic pathways must be regulated in a coordinated manner, caffeic acid moiety and the 3,4-dihydroxyphenyllactic acid moiety are derived from phenylalanine and tyrosine, respectively (Fig. 63.4). RA synthase catalyzed the condensation of 4-hydroxyphenyllactic acid, derived from tyrosine, with 4-coumaroyl-CoA formed through the phenylpropanoid pathway, to yield α-*O*-4-coumaroyl-4′-hydroxyphenyllactic acid (CHPL). CHPL is then converted to RA through two consecutive hydroxylation reactions as shown in Fig. 63.4.

Biotechnology offers an opportunity to sustainably exploit plant cells, tissues, organs, and the entire plant organism, using in vitro cultures and genetic manipulation, for the production of plant secondary metabolites, including rosmarinic acid, that are beneficial for human health.

Rosmarinic acid (RA) is one of the first secondary metabolites produced in plant cell cultures in extremely high yields, up to 19 % of the cell dry weight. More complex derivatives of RA, such as rabdosiin and lithospermic acid B, were also later obtained in cell cultures at high yields (Table 63.2).

Table 63.2 Phenolic acid in plant cell cultures

Plant species	Compounds	References

2.5 Extraction and Determination of Phenolic Acids

The most common solvents used for the extraction of phenolic acids from plant matrices are ethyl acetate, diethyl ether, methanol or aqueous methanol [24]. Enzymatic hydrolysis with b-glucosidase or hydrocinnamoyl-quinate esterase has been applied for the analysis of phenolic acids. However, acid and alkaline hydrolysis are more commonly used for the determination of phenolic acids in plants [81].

2.5.1 Chromatographic Techniques

HPLC, particularly RP-HPLC, is the method of choice in the chromatographic analysis of phenolic acids. The solvent systems used in the analytical HPLC usually include binary gradient elutions using solvents of aqueous acetic, formic, or phosphoric acids with methanol or acetonitrile as an organic modifier. The pH and ionic strength of the mobile phase are known to influence the retention of phenolics in the column depending on protonation, dissociation, or a partial dissociation [82]. A change in pH that increases the ionization of a sample could reduce the retention in a reversed-phase separation. Thus, small amounts of acetic (2–5 %), formic, phosphoric, or trifluoroacetic acid (0.1 %) are included in the solvent system to suppress ionization of phenolic and carboxylic groups and hence to improve resolution and reproducibility of chromatographic runs.

2.5.2 Detection and Identification of Phenolic Acids

Phenolic compounds absorb in the UV region and the most commonly used detector for HPLC is a variable-wavelength UV or UV-vis detector [23].

Most benzoic acid derivatives display their maxima at 246–262 nm, except for gallic acid and syringic acid, which have absorption maxima at 271 and 275 nm, respectively. Hydroxycinnamic acids absorb in two UV regions, one maximum being in the range of 225–235 nm and the other in the range of 290–330 nm. At 320 nm, cinnamic acid derivatives can be detected without any interference from benzoic acid derivatives, which have a higher absorptivity at 254 nm. However, detection at 280 nm is the best alternative for the determination of both classes of phenolic compounds. The extensive use of photodiode array detection (PDAD) in the analysis of phenolic acids can be attributed to the ability to collect online spectra without using stopped-flow techniques [23, 83, 84]. This has led to a considerable improvement in the HPLC analysis for identification purposes and has demonstrated the usefulness of qualitative information in phenolic analysis that is based on the absorption spectrum [32].

HPLC-MS is a fast and reliable method for structural analyses of nonvolatile phenolic compounds, since better techniques (interfacing systems) have been developed for the removal of the liquid mobile phase before ionization.

3 Conclusion

Phenolic compounds constitute a very large and complex group of secondary products found in plants. Among these phenolic compounds the phenolic acids are a large family of natural compounds widely distributed in plants, with very important and useful properties both for the producer plants and for the human health. In this review, the nature of the various phenolic acids present in food sources and the influence on physiological process in the plants and in human health are reviewed. The phenolic acids have a very high antioxidant effect and different studies in human health are discussed. According to modern theory of free radical biology and medicine, reactive oxygen species are involved in several disorders. The harmful action of the free radicals can, however, be blocked by antioxidant substances which scavenge the free radicals and detoxify the organism. Current research into free radicals has confirmed that foods rich in antioxidants play an essential role in the prevention of cardiovascular diseases and cancers and neurodegenerative diseases. Therefore, plant-derived antioxidants are now receiving special attention. A large number of phenolic compounds, including most part of the phenolic acids present in vegetable foods, such as fruits and nuts, have been reported to possess these good antioxidant properties.

The biosynthetic pathways of phenolic acids in plants are quite well known; special emphasis was given to the hydrocinnamic, benzoic acids and rosmarinic acid biosynthetic pathways. The biotechnological production of secondary compounds of interest for the chemical-pharmaceutical industry is one of the main aims of the plant biotechnology. For these reasons, the in vitro culture of phenolic acid producer plants, mainly those endangered, is one aspect of the biotechnology that can offer an important response to the high world demand of these compounds. In this chapter, the major studies about the production of phenolic acids in plant cell cultures are included.

Several reviews have been published on the analysis of phenolic acids in plants and the optimization of the extraction methods, as well as to their chromatographic separation and identification techniques. The processing methods on extraction and purification presented in this review are the most employed in phenolic acids analysis.

Abstract

The structural diversity displayed by these gallic acid metabolites is comparable to that of other classes of plant secondary metabolites such as alkaloids and terpenoids. The first aim of this chapter is to provide a condensate the state-of-the art on ellagitannin natural products and their significance as plant secondary metabolites, as well as interesting leads in the continuous search of new pharmaceutical drugs with original structural features. The following sections of this chapter will address research performed on *C*-glucosidic ellagitannins subclass over the last decade and will, in particular focus on their implication in wine chemistry as well as their putative role as active principles in traditional herbal remedies to their potential applications in more conventional medicinal approaches.

1 Classification of Hydrolyzable Tannins

1.1 Gallotannins and Ellagitannins

The chemical structures of the hydrolyzable tannins are basically composed of a central sugar core, typically a glucose unit, to which gallic acid (**1**) and gallic acid-derived moieties are esterified. β-Glucogallin (**2**), the simplest glucosyl gallate and first precursor of this class of phenolic natural products was isolated in 1903 from Chinese rhubarb (*Rheum officinale*) [1]. The variety of hydrolyzable tannin structures thus resulting from glucose and gallic acid is so large that subdividing it into distinct categories in a logically ordered manner was far from being a trivial task [2]. Hydrolyzable tannins are first grossly divided into two subclasses: (1) the gallotannins, which are characterized by the presence of depsidically-linked galloyl units, and (2) the ellagitannins, which are characterized by the presence of biarylic dehydrodigalloyl so-called hexahydroxydiphenoyl (HHDP) units [3]. Haslam and co-workers subdivided the ellagitannins into two differents groups and proposed a three-group classification: (A) (B) (C) [4, 5]. Group A corresponding to the gallotannins featuring a core of β-penta-*O*-galloyl-ᴅ-glucopyranose (**3**) to which several other galloyl ester groups are linked in depside fashion (Fig. 64.1) [6]. The presence of two C–C-coupled galloyl ester groups at the 2,3- and/or 4,6-positions of a $^{4}C_{1}$-glucopyranose core was used to define ellagitannins, such as tellimagrandins I (**5**) and II (**6**), as belonging to group B of the hydrolyzable tannins [7]. This 6,6′-dicarbonyl-2,2′,3,3′,4,4′-hexahydroxybiphenyl bisester group, commonly referred to as the hexahydroxydiphenoyl (HHDP) unit, is the structural characteristic that defines hydrolyzable tannins as ellagitannins. Hydrolytic release of HHDP units from ellagitannins gives rise to their facile and unavoidable conversion into

the bislactone ellagic acid for which these natural products are named. Haslam's group C gathers ellagitannins in which HHDP units are connected to the 1,6-, 2,4- and/or 3,6-positions of the D-glucopyranose ring in its least thermodynamically favored $^1C_4$-conformation, as exemplified by the structure of geraniin (**7**) [8]. However, this classification was soon found too simple to accommodate many of the newly identified structures. More recently, Okuda proposed four main types of

hydrolyzable tannins on the basis of the oxidation level of their galloyl ester groups [2, 9, 10]. This revised classification, which is modeled on a plausible progressive biogenetic elaboration of hydrolyzable tannins, first hypothesized by Schmidt and Mayer [11], defines gallotannins as type-I hydrolyzable tannins. Type II gathers the HHDP-bearing ellagitannins such as the monomeric tellimagrandins II (**5**) and I (**6**) [12, 13], and type III those featuring the dehydrohexahydroxydiphenoyl (DHHDP) unit (i.e., dehydroellagitannins), as exemplified by geraniin (**7**, Fig. 64.1). Ellagitannins in which the DHHDP unit has suffered additional transformations, such as chebulagic acid (**8**) and ascorgeraniin (**9**), belong to the type-IV group (Fig. 64.2). The chebuloyl and elaeocarpusoyl ester groups are only two examples out of a large series of ester units derived from the parent DHHDP unit [14]. Several other DHHDP-derived units have been identified such as *inter alia* in phyllanthusiins A-C (**10**–**12**), repandusinic acid (**13**) [15, 16], and putranjivain A (**14**) [17], whose 2,4-DHHDP-derived unit results from decarboxylation of the elaeocarpusoyl unit of ascorgeranin (**9**) [14]. All of these ellagitannins also belong to Okuda's type-IV hydrolyzable tannin group (Fig. 64.3).

19: mallotusinic acid

20: camelliatannin F

Fig. 64.3 Examples of Okuda's type II+ and type III+ ellagitannins

However, this classification still left out many monomeric ellagitannins, the structures of many of which resulting from chemical transformations other than those strictly mediated by oxidative processes. In this vein, some important structural modifications have to do with the opening of the D-glucopyranose core, the formation of *C*-arylglucosidic bonds and condensation reactions taking place at the glucose C-1 locus. Since these ellagitannins still mostly display the characteristic structural features of compounds belonging to primary types II–IV, Okuda refined his classification system and accordingly added four subtypes [9]. Type II+ principally gathers HHDP-bearing *C*-glucosidic ellagitannins, such as 5-*O*-desgalloylstachyurin (**15**) and casuariin (**16**), and their flavanoid hybrids (sometimes referred to as complex tannins), such as camelliatannins A/B (**17/18**), which result from condensation reactions with the flavan-3-ols catechin or epicatechin at the C-1 center of their open-chain glucose core (Fig. 64.3). Dehydroellagitannins that feature moieties resulting from a diaryl ether linkage with another phenolic or polyphenolic unit belong to the type-III+ group. An example of this type is mallotusinic acid (**19**, Fig. 64.3), having a valoneoyl group (*vide infra*) linked to the 3,6-positions of a 2,4-DHHDP-bearing $^{1}C_4$-glucopyranose core [18, 19]. Transformed dehydroellagitannins that feature moieties resulting from a C–C linkage with another phenolic or polyphenolic unit belong to the type-IV+ group. The *C*-glucosidic epicatechin-containing complex tannin camelliatannin F (**20**, Fig. 64.3) is an example of a structure of this type that is derived from the oxidative metabolism of a structure of type II+ (i.e., camelliatannin A (**17**, Fig. 64.3).

This classification work does not stop there and becomes further complicated by the fact that ellagitannins of essentially types II and II+ oligomerize via various modes based on oxidative coupling reactions between free and C–C-coupled galloyl groups (i.e., HHDP units) on different glucopyranosic ellagitannins, as well as on condensation reactions at the C-1 center of *C*-glucosidic ellagitannins. Once again, Okuda brought order into this seemingly chaotic ensemble of oligomeric structures. After a first proposal based on the structures of the constituting monomers [20], they instead classified oligomers into five types according to the nature of the interunit linkage between monomers [21]: (i) GOG (and GOGOG), (ii) DOG, (iii) GOD, (iv) $D(OG)_2$ and (v) *C*-glucosidic type, for which G = galloyl, O = oxygen and D = HHDP. In GOG- and GOGOG-type oligomers, the interunit linkages are composed of two (or three, not shown) G units linked together via a diaryl ether bond such as in agrimonin (**21**, Fig. 64.4) [12], having a *meta*-GOG type linking unit (i.e., one of the oxygen atoms *meta*-positioned to the carboxyl group-bearing carbon of one G unit is C-linked to one of the unsubstituted *ortho*-positions of the other G unit). This type of unit is also referred to as the dehydrodigalloyl (DHDG) unit. Although less frequently encountered, isodehydrodigalloyl units (i.e., *para*-GOG type) are observed in some oligomers isolated from plant species of the family Tamaricaceae such as *Reaumuria hirtella*, which produces a dimer named hirtellin C (**22**, Fig. 64.4) that results from a double oxidative coupling of two molecules of tellimagrandin II (**5**) [22]. This double coupling mutually occurs between the *O*-1-galloyl group of one monomer and the *O*-2-galloyl group of the other monomer and *vice versa*, but one C–O coupling gives rise to the *m*-GOG type unit, whereas the other one led to the more sterically encumbered *p*-GOG type unit [22]. Interestingly, the same plant species in Tamaricaceae are also capable of combining the same monomeric ellagitannin tellimagrandin II (**5**) in different ways via oxidative C–O coupling of galloyl groups. The structure of hirtellin B (**23**) illustrates one of these alternative oligomerization processes [23]. The two *O*-2-galloyl groups are linked together by a *m*-GOG type unit, the oxygen-donating *O*-2-galloyl group being similarly linked to the *O*-1-galloyl group of the same monomeric unit. The resulting *m*-GO-*m*-GOG type unit is also referred to as the hellinoyl group (Fig. 64.4).

The DOG-type units are also subdivided into their *meta* and *para* variants. In these units, a HHDP unit is O–C-linked to a G unit. The *m*-DOG type unit that is also referred to as the valoneoyl unit is found in numerous oligomeric ellagitannins [21], as well as in some monomeric ellagitannins such as the aforementioned type-III+ mallotusinic acid (**19**). The dimer oenothein B (**24**) [24], isolated in significant quantities from *Oenothera* and *Epilobium* species in Onagraceae and from *Lythrum*

anceps in Lythraceae, and its α-monogalloylated variant woodfordin C (**25**) [25, 26], isolated together with **24** from *Woodfordia fruticosa* in Lythraceae, constitute structurally fascinating examples of macrocyclic ellagitannin structures featuring two valoneoyl groups as macroring-forming interunit linkages (Fig. 64.5).

The *m*-DOG-type valoneoyl unit is probably the most often encountered interunit linkage in ellagitannin oligomerization via oxidative coupling processes. The construction of the highest oligomers fully characterized to date such as the tetramer trapanin B (**26**) [27], isolated from *Trapa japonica* (Trapaceae) and the pentamers melastoflorins A (**27**)-D [28], isolated from *Monochaetum multiflorum* (Melastomataceae), relies on multiple occurrence of this unit type (Fig. 64.5). The valoneoyl group also occurs in some biogenetically intriguing dimers composed of a glucopyranosic monomer *m*-DOG-linked to an open-chain *C*-glucosidic monomer. Reginins A (**28**) and B (**29**, Fig. 64.5) are examples of this type of dimers in which the 4,6-HHDP of a pedunculagin (**58**) monomer is linked to the 5-*O*-galloyl group of either stachyurin (**37**) or casuarinin (**38**) [29].

In the GOD type unit, which appears to exist only in its *meta* version, a HHDP unit of one monomer is C–O-linked to a G unit of another monomer. This type of interunit linkage is also referred to as the sanguisorboyl unit and is found in a small number of oligomers, here exemplified by the dimer sanguiin H-6 (**30**, Fig. 64.6), isolated from *Sanguisorba officinalis* (Rosaceae) [30].

The D(OG)$_2$ type unit is composed of a HHDP unit that has engaged two of its hydroxyl groups in oxidative O–C coupling with two G units. Two isomeric versions exist in which the diaryl ether bonds involve either the two oxygen atoms *meta* to the HHDP carboxyl group-bearing carbons and *para* to the biaryl axis (i.e., *m*,*m*′-D(OG)$_2$), or one of these two oxygen atoms and its adjacent oxygen atom *para* to the carboxyl group-bearing carbon of the same HHDP galloyl-derived moiety (i.e., *m*,*p*-D(OG)$_2$, also referred to as the euphorbinoyl unit). These two units are also found in a small number of oligomers, here exemplified by the trimer oenothein A (**31**), which is commonly isolated from Onagraceae and Lythraceae plant species [31], and euphorbin C (**32**, Fig. 64.6), a type of dimer that is characteristic of Euphorbiaceae plant species and composed of the type-II monomer tellimagrandin II (**1**) and the type-III dehydroellagitannin geraniin (**7**) [26].

To these four types of interunit linkages in oligomeric ellagitannins derived from phenolic C–O oxidative coupling processes should be added a fifth one derived from intermolecular (and atroposelective) C–C coupling between HHDP (D) and G groups. This "DG" type unit is known as the flavogallonyl unit and is found in a handful of dimeric structures known as the rhoipteleanins A (**33**)-F isolated from *Rhoiptelea chiliantha* (the sole species of the Rhoipteleaceae in the Juglandales order of the *Hamamelidae* subclass) (Fig. 64.6) [32, 33].

The fifth and last type of oligomeric ellagitannins proposed by Okuda and associates corresponds to oligomers of open-chain *C*-glucosidic ellagitannins, which, by virtue of the special reactivity expressed at their benzylic C-1 locus lead to three major subtypes of structures in this category [21]. Thus, the CD-type oligomers result from a C–C connection between the C-1 center of one *C*-glucosidic (C) unit and the 4,6-HHDP (D) of another such as in the dimer roburin D (**46**) [34], and so on up to the pentamer castaneanin D (**34**) [35], the highest known member of this class of oligomers commonly isolated from *Quercus* and *Castanea* species (Fagaceae) (Fig. 64.7). Casuglaunin A (**35**) [36], isolated from *Casuarina glauca* (Casuarinaceae), is an example of a CG type dimer in which the C-1 center of one

C-glucosidic (C) unit is linked to a galloyl (G) group of another; in this case, the 5-*O*-galloyl group of casuarinin (**38**) (Fig. 64.7). Finally, the CFC type dimers correspond to complex tannin structures in which a flavanoid unit serves as a linker between two *C*-glucosidic units such as in anogeissinin (**36**), isolated from *Anogeissus acuminata* (Combretaceae) [37].

This rather extensive but outstandingly comprehensive classification should enable natural products chemists to rapidly determine the type of structure displayed by any ellagitannin compounds. Furthermore, phytochemists and botanists should find use for this classification as a guiding tool to delineate plant systematics. Indeed, Okuda and associates made some interesting and valuable observations that led them to correlate the apparent progressive metabolism of the simplest monomeric ellagitannins into more complex species and oligomers, mainly through oxidative processes, to plant taxonomy and hierarchic ranking in Cronquist's system of plant

evolution [9, 28, 38]. Thus, for example, only types II and II+ ellagitannins are produced in the *Magnoliidae*, the earliest subclass in the *Dicotyledoneae*, whereas oxidized ellagitannins of types III, III+ and IV are additionally and frequently found in the *Rosidae*, a highly developed subclass. The occurrence of certain types of ellagitannins and their oligomers can be restricted to some plant families within an order of a given subclass, and sometimes even to a few genera of a particular family [9, 21]. Some ellagitannins can hence be used as chemotaxonomic markers because of their specific occurrence, and this becomes even more relevant that their structures get more and more complex. Thus, late-stage biosynthesized oligomeric structures can be more specifically correlated than their constituting monomers with plant systematics, as evidenced *inter alia* for GOG- and DOG-type oligomers in the Rosaceae and in the Melastomataceae [10, 28].

1.2 The *C*-Glycosidic Ellagitannins: A Special Subclass of Ellagitannins

Numerous ellagitannins of the *C*-glucosidic type, including monomers, oligomers and complex tannins (*vide infra*), have been isolated over the years from various plant species belonging to the Hamamelidaceae, Fagaceae, Betulaceae, Casuarinaceae, Juglandaceae and Rhoipteleaceae families in the *Hamamelidae* subclass, to the Rosaceae, Combretaceae, Lythraceae, Melastomataceae, Myrtaceae, Punicaceae, Trapaceae and Elaeagnaceae families in the *Rosidae* subclass, and to the Theaceae and Stachyuraceae families in the *Dilleniidae* subclass [9, 21, 38]. The *C*-glucosidic ellagitannins are a subclass of hydrolyzable ellagitannins that present the structural particularity of having a highly characteristic C–C linkage between the carbon C-1 of the open chain of glucose core and the carbon C-2 of the 2-*O*-galloyl unit. Their C-1-linked galloyl-derived unit is either part of a HHDP ester group bridging the 2- and 3-positions of the glucose core, as exemplified in the structures of stachyurin (**37**) and casuarinin (**38**), or part of a terarylic nonahydroxyterphenoyl (NHTP) variant (also known as the flavogalloyl group) that is attached *via* three ester bonds to the 2-, 3- and 5-positions of the glucose core, as exemplified in the structures of vescalagin (**39**) and castalagin (**40**) (Fig. 64.8). In contrast with the plant distribution of other *C*-glucosidic ellagitannins, the NHTP-bearing *C*-glucosidic ellagitannins appear to be limited to the family Fagaceae, Combretaceae, Lythraceae, Melastomataceae, Myrtaceae [10].

Vescalagin (**39**) and its C-1 epimer castalagin (**40**) are the first members of this sub-class that have been isolated from *Castanea* (chestnut) and *Quercus* (oak) species in 1971 [39–42]. Their content in the heartwood of oak species, such as *Q. petraea* and *Q. robur* together with the grandinin (**41**), roburins A (**43**), B (**44**), C (**45**), D (**46**), and E (**42**) [34, 43, 44] can vary from *ca.* 3 to 24 mg/g of dry wood, depending on the species, age and sampling height of the sampled tree [45]; chestnut heartwood can even contain up to 63 mg/g of dry wood [46] (Fig. 64.8). Since the characterization of **39** and **40**, a large variety of *C*-glucosidic ellagitannin oligomers has been isolated. To date, the largest known *C*-glucosidic ellagitannin oligomer is the vescalagin-based pentamer castanaenin D (**34**), which was isolated from heartwood of the Japanese chestnut tree (*Castanea crenata*) [35] (Fig. 64.9).

Like in the previously described ellagitannin groups, the *C*-glucosidic ellagitannin subclass also displays a large diversity of structures, as illustrated for example by the structures of the punicacorteins C (**47**) and D (**48**) isolated from the bark of *Punica granatum* (Punicaceae), which have the particularity of featuring a tetraphenyl ellagic acid-derived bislactone bisester group, known as the gallagyl unit, linked to the 4- and 6-positions of the glucose core [8] (Fig. 64.9). Another example of this structural diversity is paeonianin E (**49**) isolated from *Paeonia lactiflora* (Paeoniaceae), which is an unusual *C*-glucosidic ellagitannin featuring a gallic acid methyl ester group C–C-linked to the C-1 position of the open-chain glucose core. Also isolated from the same plant species, the paeonianins A-D are composed of a 5-*O*-desgalloylstachyurin (**15**) unit C_1–C-linked, respectively, to the 2- (**50**), 3-, 4- or 6-galloyl group of a β-PGG unit [48]. Many additional *C*-glucosidic ellagitannins, including monomers and oligomers, have been identified over the years from species belonging to the selection of plant families mentioned above [2, 10, 49].

The *C*-glucosidic ellagitannin subclass also includes complex tannins known as flavano-ellagitannins, which are hydrolysable tannin hybrids with a *C*-glucosidic ellagitannin moiety such as stachyurin (**37**) or vescalagin (**39**) and a flavan-3-ol

moiety such as catechin or epicatechin. In these complex tannins, both moieties are connected via a C–C linkage between the C-1 locus of the *C*-glucosidic ellagitannin moiety and the C-8 or C-6 centers of the A-ring of the flavan-3-ol unit. Variations of the nature of each moiety lead to complex tannins that display a large diversity of structures such as the catechin-based stenophyllanins A (**51**) and B (**52**) [50] and acutissimins A (**53**) and B (**54**) [51] or the epicatechin-based camelliatannins A (**17**), B (**18**), and F (**20**) (Fig. 64.10). Dehydrogenerative oxidation of these complex tannins leads to additional derivatives such as mongolicains A (**55**) and B (**56**) [52], which contain a hydroxyphenylcyclopentenone (HPCP) motif. Like for the simpler *C*-glucosidic ellagitannins, complex tannins are only found in plant species belonging to a very few number of families such as the Fagaceae, Combretaceae, Myrtaceae, Theaceae and Melastomataceae [53].

2 Biosynthesis

β-Glucogallin (**2**) is the simplest glucosyl gallate known and it notably serves as a galloyl unit donor in the biosynthesis of the fully galloylated β-D-glucopyranose (**3**, β-PGG), which is itself considered as the branching point leading to either gallotannins or ellagitannins [54–57] (Fig. 64.1). Gallotannins are the result of further galloylations of β-PGG and are characterized by the presence of one or more depsidically-linked galloyl moieties, as exemplified with the hexagalloylglucose 2-*O*-digalloyl-1,3,4,6-tetra-*O*-galloyl-β-D-glucopyranose (**4**). Alternatively, β-PGG (**3**) can evolve through intra- and intermolecular oxidative phenolic coupling processes leading to the formation of covalent bonds such as C–C biaryl and C–O diaryl ether bonds between galloyl groups. The intramolecular coupling leads to the formation of biarylic hexahydroxydiphenoyl (HHDP) unit, which is the characteristic structural motif of ellagitannins. Acidic hydrolysis of such tannins releases the bislactonic ellagic acid (Fig. 64.1). Okuda's type-II ellagitannins are characterized by the presence of this HHDP unit [2, 10]. The atropoisomerism of these axially chiral biaryl motifs, such as the (*S*)-HHDP unit of the tellimagrandins or the

Fig. 64.10 Example of (+)-catechin-containing flavano-ellagitannins (complex tannins)

(*R*)-HHDP unit of geraniin (**7**) is determined by the positioning of the galloyl groups on their glucopyranosic precursors in either its $^4C_1$- or its $^1C_4$-conformation. Furthermore, the HHDP motif can go through an additional oxidative transformation leading to the so-called dehydrohexahydroxydiphenoyl (DHHDP) unit that is the structural characteristic of Okuda's type-III ellagitannins or dehydroellagitannins, such as geraniin (**7**) [58–61]. The DHHDP unit can undergo further transformations notably leading to the formation of the chebuloyl or elaeocarpusoyl groups, which characterized Okuda's type-IV ellagitannins (Fig. 64.2) [2, 10].

A β-pentagalloylglucopyranose oxidizing enzyme has recently been shown to mediate the formation of the 4,6-HHDP-containing tellimagrandin II (**5**) [62]. A different laccase-type phenol oxidase has also been shown to promote the conversion of tellimagrandin II (**5**) into the diaryl ether-linked dimer cornussiin E [63]. This is all we know today about enzymatic implications in the ellagitannins biosynthetic pathway. One has to admit that the task is enormous, due to the large structural diversity expressed by ellagitannins simply derived for the most part from glucose and gallic acid (**1**). More dedicated investigations are in demand to identify the enzymes involved in the biosynthetic pathway leading to glucopyranosic ellagitannins, as well as their *C*-glucosidic anabolites. As stated above, the occurrence of ellagitannins harboring *C*-glucosidic bonds appears to be limited to species of specific plant families.

A proposal for the biosynthetic pathway leading to *C*-glucosidic ellagitannins would start from β-PGG (**3**), the presumed pergalloylated glucopyranosic parent of all ellagitannins [56, 62, 63]. Two successive and diastereoselective oxidative galloyl coupling reactions would then result in the formation of two (*S*)-HHDP units at the 4,6- and 2,3-positions of the glucopyranose core. A 1-*O*-desgalloylation would then afford pedunculagin (**58**) (Fig. 64.11) [64]. The first key step leading from such a glucopyranosic ellagitannin to the *C*-glucosidic ellagitannins is the opening of the glucose core from its anomeric hemiacetal position. The thus-released hydroxyl group at the *O*-5 position of the resulting aldehydic open-chain glucose would be galloylated to form liquidambin (**59**), which has notably been isolated from the leaves of *Liquidambar formosana* [65]. The ellagitannin content of the leaves of this Hamamelidaceae plant has been thoroughly investigated, since members of both the glucopyranosic ellagitannin and the open-chain *C*-glucosidic ellagitannin classes co-exist [13, 66]. Interestingly, the ratio between these two classes of ellagitannins change over the leaves growing season. In early spring, the leaves of *Liquidambar formosana* contain high amounts of tellimagrandin II (**5**), whereas in summer, the amount of tellimagrandin II (**5**) becomes negligible and two other ellagitannins, pedunculagin (**58**) and the *C*-glucosidic casuarinin (**57**) become predominant throughout summer until autumn. This seasonal variation of the ellagitannin content in *Liquidambar formosana* was proposed to reflect the following biogenetic filiation (Fig. 64.11): from tellimagrandin II (**5**) to casuarinin (**38**) via pedunculagin (**58**) and liquidambin (**59**) [66]. Liquidambin (**59**) thus constitutes the molecular keystone between the glucopyranosic ellagitannins and the open-chain *C*-glucosidic ellagitannins. The second key step leading to the *C*-glucosidic ellagitannins is the intramolecular aldol-type nucleophilic addition of the 2,3-HHDP unit to the aldehyde function of **59**, which establishes the characteristic *C*-glucosidic bond, first featured in stachyurin (**37**) and its C-1 epimer casuarinin (**38**) [12, 13, 67–69]. An additional oxidative coupling between the glucose C–C-linked 2,3-HHDP unit and the free 5-*O*-galloyl group of **37** and **38** would then leads to the characteristic nonahydroxyterphenoyl (NHTP) unit of, respectively vescalagin (**39**) and castalagin (**40**) [43].

Once monomeric *C*-glucosidic ellagitannins such as the epimeric couples vescalagin (**39**)/castalagin (**40**) and stachyurin (**37**)/casuarinin (**38**) are formed, they can serve as precursors of numerous other *C*-glucosidic ellagitannins, as well as several so-called complex tannins (Fig. 64.12), such as the NHTP-bearing

Fig. 64.12 Putative pathway from monomeric *C*-glycosidic ellagitannins to oligomeric and glycosilated *C*-glycosidic ellagitannins as well as to flavano-ellagitannins. Acid-catalyzed condensation reactions of *C*-glycosidic ellagitannins via benzylic-type carbocation intermediates

C-glucosidic grandinin (**41**), roburins A (**43**), B (**44**), C (**45**), D (**46**), and E (**42**) [34, 43] and the flavano-ellagitannins acutissimins A (**53**) and B (**54**). The acid-catalyzed deshydroxylation of the benzylic alcohol at the C-1 position of the glucose core of monomers **37** or **39** results in the formation of benzylic cation intermediates **60** or **61**. Various nucleophilic species, including **37–40**, as well as lyxose, xylose, flavan-3-ols and many more, can trap these cationic intermediates, hence building up the structural diversity expressed by the *C*-glucosidic ellagitannins. This S_N1-type nucleophilic substitution process proceeds under a strict stereochemical control that results in a β-orientation of the newly formed bond at the C-1 position. This stereochemical preference is observed in all known vescalagin (**39**)/castalagin (**40**) and stachyurin (**37**)/casuarinin (**38**) derived *C*-glucosidic ellagitannins, including all of the flavano-ellagitannins. The stereoelectronic nature of the benzylic cation intermediate **61** has been characterized through molecular modeling and offered a sound rationale for this remarkable diastereoselective S_N1-type nucleophilic substitution reaction (*vide infra*) [2, 43, 70–72].

3 Involvement of *C*-Glucosidic Ellagitannins in Wine Chemistry

The presence of *C*-glucosidic ellagitannins in beverages such as wines and spirits is the result of their presence in high amounts in fagaceous wood species such as *Quercus petraea*, *robur* and *alba*, for the heartwood of these oak species is used to manufacture barrels in which those beverages are stored or aged. The main *C*-glucosidic ellagitannins extracted by wines during their aging in oak barrels are the two monomers vescalagin (**39**) and castalagin (**40**), as well as the glycosilated monomers **41** and **42** and dimers **43–46** [73]. Once in the wine solution, the *C*-glucosidic ellagitannins are slowly but continuously transformed through condensation, hydrolysis, and oxidation reactions. Taken together the fact that the hydro-alcoholic wine solution aged in barrels extracts *C*-glucosidic ellagitannins from the oak wood, the fact that wine (especially red wine) contains a large amount of flavan-3-ols such as catechin and epicatechin with concentrations of about 115–190 mg/L and 80 mg/L, respectively [74, 75], and the fact that wine is a slightly acidic solution (pH ~ 3–4 in the case of red wine), the presence of the flavano-ellagitannins acutissimins **53** and **54** in red wine has been verified and confirmed.

3.1 Occurrence of Flavano-ellagitannins in Red Wine

Flavano-ellagitannin hybrids such as acutissimins A (**53**) and B (**54**) present a characteristic structure with a *C*-glucosidic ellagitannin moiety derived from vescalagin (**39**) or castalagin (**40**) connected, respectively, to the carbon C-8 and C-6 of the flavan-3-ol catechin (**62**) moiety. Acutissimins A (**53**) and B (**54**) were first isolated from the bark of *Quercus acutissima* [51], and were later found to express interesting biological activities, notably as inhibitors of human DNA topoisomerase II [43, 70, 71].

The hemisynthesis of **53** and **54** has been achieved in a high yield of about 87 % by simply reacting vescalagin (**39**) with catechin (**62**) in an acidic medium (1.5 vol% of TFA in THF) at 60 °C over a period of 7 h [70, 71]. Interestingly, the mixture of **53** and **54** thus obtained by hemisynthesis exhibit a ratio similar to that observed from the isolation of these two regioisomers from *Quercus acutissima*, i.e., 75:25 and 81:19, respectively [51]. The formation of acutissimin A (**53**) as the main regioisomer in both cases results from the more accessible and higher nucleophilic character of the carbon C-8 of the catechin (**62**) [70, 71]. The hemisynthesis of the not yet isolated epiacutissimin A (**64**) and B (**65**) has also been achieved by reacting vescalagin (**39**) with epicatechin (**63**) using the same procedure. Both epiacutissimin regioisomers were obtained in similar yield (~78 %) as for the reaction leading to the acutissimins, but with a regioisomeric ratio slightly different (67:33) [70, 71].

The mechanistic description of those hemisyntheses corresponds, as stated above, to a classical acid-catalyzed S_N1-type nucleophilic substitution that starts

Fig. 64.13 Hemisynthesis of acutissimins **53**, **54** and epiacutissimins **64**, **65** from vescalagin (**39**) and either (+)-catechin (**62**) or (−)-epicatechin (**63**) respectively, in acidic media

with the protonation of the OH-1 group of vescalagin and the departure of H_2O from this locus to first afford the benzylic cation **61** (Fig. 64.13) [1]. This stable cationic intermediate **61** is then predominantly attacked by the carbon C-8 of the flavan-3-ol units and, to a lesser extent, by the carbon C-6, which is more encumbered and less nucleophilic than its C-8 counterpart [76, 77]. These C–C bond-forming nucleophilic substitution reactions proceed with full diastereofacial differentiation, resulting in retention of configuration at C-1 relatively to that of the starting vescalagin (i.e., β-orientation of the flavan-3-ol units linked at C-1).

Interestingly, attempts to generate the acutissimins **53** and **54** by using castalagin (**40**) instead of vescalagin (**39**) under the same mild conditions as those described above was totally unsuccessful. The inefficiency of **40** to form flavano-ellagitannins in a mildly acidic medium has been rationalized by molecular modeling calculations [2, 70–72]. This marked difference in reactivity between the two epimers castalagin (**40**) and vescalagin (**39**) is quite remarkable when considering their structural similarity, the only difference being the orientation of their OH-1 group. The deshydroxylation of the benzylic alcohol group of castalagin (**40**) appears to be very difficult and requires very drastic conditions, whereas that of vescalagin (**39**) easily occurs under mildly acidic conditions and leads to an expeditive formation of the benzylic cation **61**. Those opposite features have been rationalized by separate computational examination of each epimers [70–72].

The hemisynthesis of the flavano-ellagitannins **53**, **54**, **64** and **65**, which was initially performed in organic media, was also achieved in a wine model solution,

consisting of a 12 vol% hydro-alcoholic (ethanol) solution with 5 g/L of tartaric acid at pH 3.2, in order to confirm their possible formation in wine. After several days at room temperature, the reaction mixture between **39** and **62** or **63** resulted in the formation of the corresponding flavano-ellagitannins, together with that of the β-1-*O*-ethylvescalagin (**66**) (Fig. 64.14a). The formation of **66** in such a wine model solution is the result of the nucleophilic attack of ethanol on the intermediate benzylic cation **61**. With this evidence that flavano-ellagitannins **53**, **54**, **64** and **65** can be formed in wine, an HPLC/ESI/MS-based identification and quantification procedure has been used to confirm their presence, as well as that of β-1-*O*-ethylvescalagin (**66**), in a sample of red wine aged during 18 months in oak barrels. Their concentrations were determined to range from 0.30 to 0.40 mg/L [78].

After this first detection and quantification in red wine, the kinetic evolution of the concentrations of the native oak-derived *C*-glucosidic ellagitannins and their wine hybrids was comparatively monitored during red wine aging in either oak barrels or in stainless steel tanks in which oak chips were added. Although the use of oak chips during red wine aging can lead to red wines with a woody aromatic profile (vanilla, smoky, coconut) close to that of a red wine traditionally aged in oak barrels, the global *C*-glucosidic ellagitannin concentration in those red wines appeared to be four times lower than that in the wine aged in oak barrels. Moreover, under the wine aging conditions used, the concentration in *C*-glucosidic ellagitannins increased regularly to reach its maximum after 3–4 months and then slowly decreased during the rest of the aging in barrels [73]. For the red wine aged in stainless steel tanks with oak chips, the *C*-glucosidic ellagitannin maximum concentration was obtained after only 1.5–2 months. These differences in reaching maximum concentration levels could have an impact on the wine gustative properties such as astringency, bitterness, amplitude and roundness of the wine. The rates of formation of the flavano-ellagitannins **53**, **54**, **64** and **65** and of the β-1-*O*-ethylvescalagin **66**, as well as the evolution of their concentrations was thus monitored for the first time in a red wine aged in either oak barrels or in stainless steel tanks with oak chips [73]. Interestingly, the total amount of these vescalagin derivatives **53**, **54**, **64–66** appeared to be lower for the red wine aged in stainless steel tanks with oak chips than for the red wine aged in oak barrels. However, despite these overall concentration differences, the relative composition between these five vescalagin derivatives **53**, **54**, **64–66** was similar under both red wine aging conditions.

Even if these quantitative analyses indicated relatively low concentrations of these vescalagin derivatives **53**, **54**, **64–66** (i.e., around 2 mg/L in red wine aged in new oak barrels), their occurrence constitutes compelling evidences that oak-derived *C*-glucosidic ellagitannins do react, via condensation at their C-1 position, with various nucleophilic species in wine. Moreover, red wine is a slow but continuously evolving mildly acidic and aerobic medium in which the newly formed flavano-ellagitannins **53**, **54**, **64** and **65** certainly go through further phenolic oxidation processes and can, for example, generate products such as mongolicain A (**55**), an oxidation product derived from acutissimin A (**53**). However, as long as grape-derived flavan-3-ols and oak-derived vescalagin (**39**) are present in wine, **53**, **54**, **64** and **65** will be continuously formed. Furthermore, one must not forget that red wine contains an even much broader panel of nucleophilic species, such as other flavonoids (anthocyanins, proanthocyanidins) and, more generally, different kinds of nucleophilic phenols, alcohols, amines, carboxylic acids, enolizable carbonyl compounds, and thiols that may all also compete in the trapping event of the benzylic cation intermediate **61** [2, 71].

3.2 Reactions of *C*-Glucosidic Ellagitannins with Non-phenolic Wine Nucleophiles

The formation of any adduct between vescalagin (**39**) and the cysteine-containing tripeptide glutathione (**67**) has also been investigated. This study originates from empiric observations made by oenologists showing that the level of glutathione (**67**) considerably diminishes during the aging of white wines in new oak barrels [79]. Glutathione (**67**) plays an important antioxidant role in preserving some organoleptic properties of white wines, because of its protective action against oxidative degradation of volatile thiols, such as 4-mercapto-4-methylpentan-2-one and 3-mercaptohexanol, which contribute to the fruity aroma of white wines. It has been previously observed that the thiol function of the cysteine residue featured in **67** can engage in nucleophilic addition reactions with electrophilic *ortho*-quinones derived from the oxidation of caftaric acid in white must [80, 81]. However, before our investigations highlighted below, no covalent interaction between oak *C*-glucosidic ellagitannins and glutathione (**67**), which is present in white must at concentrations ranging from 3 to 24 mg/L [77, 78], had been proposed and evidenced as a chemical event conceivably affecting the amount of glutathione (**67**) in wines.

The hemisynthesis of β-1-*S*-glutathionyl vescalagin (**68**) has been achieved using conditions similar to those used for the hemisynthesis of the flavano-ellagitannins **53**, **54**, **64** and **65** [71] (Fig. 64.14b). The hemisynthesis of **68** has also been confirmed in a wine model solution, in which the sulfoxide variant of **68** and β-1-*O*-ethylvescalagin (**66**) were also formed. The contribution of *C*-glucosidic ellagitannins on the decrease of the concentration of glutathione (**67**) in wine was then definitely evidenced by the detection of β-1-*S*-glutathionyl vescalagin (**68**) in a white wine aged during 12 months in oak barrels [82].

3.3 Impact of the *C*-glucosidic Ellagitannins on Red Wine Color Modulation

Together with astringency and bitterness, color is another main organoleptic criterium for red wine quality. The maceration and alcoholic fermentation step of the wine-making process allow the extraction of anthocyanins from red grape skins and result in the intense color of young red wines. However, these native grape pigments progressively disappear during wine maturation, especially during the aging in oak barrels and are replaced by more stable wine-specific pigments through various chemical reactions [83, 84]. A considerable amount of investigations have been conducted in order to understand, characterize and eventually control the physicochemical mechanisms causing the red wine color modulation. Most of these studies reveal that several chemical reactions between the anthocyanins and nucleophilic or electrophilic components in wine, such as flavan-3-ols, ethanal, and pyruvic acid, occur and generate new pigments displaying different coloring properties (i.e., either bluer or more orange tints) [85–89]. Moreover, physical co-pigmentation phenomena that result from stacking of the colored anthocyanin flavylium cations with other wine phenolic species [84, 90, 91], as well as complexation with metallic cations [92, 93], have also been shown to contribute to this color modulation. Surprisingly, covalent interactions between grape anthocyanins and oak *C*-glucosidic ellagitannins have not been considered as a possible means

Fig. 64.15 Hemisynthesis of the two first anthocyano-ellagitannin **69** and **70** from vescalagin (**39**) and either malvidin (**71**) or oenin (**72**) respectively, in acidic media as well as their visible spectra in aqueous 1 M HCl solutions (pH 1)

underpinning the color modulation of red wine aged in oak barrels. The remarkably efficient hemisynthesis of the flavano-ellagitannins **53**, **54**, **64** and **65** from the oak *C*-glucosidic ellagitannin vescalagin (**39**) in an acidic organic solution and in a wine model solution supports the assumption that similar condensation reactions should occur between **39** and a grape-derived anthocyanin pigment.

The first hemisynthesis of two first anthocyano-ellagitannins, **69** and **70**, was thus performed under conditions similar to those used for the formation of the flavano-ellagitannins **53**, **54**, **64** and **65** [71, 94] (Fig. 64.15). Both anthocyano-ellagitannins **69** and **70** also result from an acid-catalyzed nucleophilic substitution at the C-1 center of vescalagin (**39**) by either oenin (**72**) or its aglycone malvidin (**71**), respectively. The oenin (**72**) was selected as a model substrate for the anthocyanins present in red wine obtained from *Vitis vinifera* grape, since **72** is the main anthocyanin with concentrations ranging from 24 to 240 mg/L [74, 95].

From an oenological perspective, the fascinating aspect of the formation of these anthocyano-ellagitannins is their color compared to that of their respective anthocyan(id)ins precursors, as observed during their hemisynthesis, the initial bright red color progressively becoming deep purple. The visible absorption spectra of both anthocyano-ellagitannins **69** and **70** have been recorded in water at pH 1 and

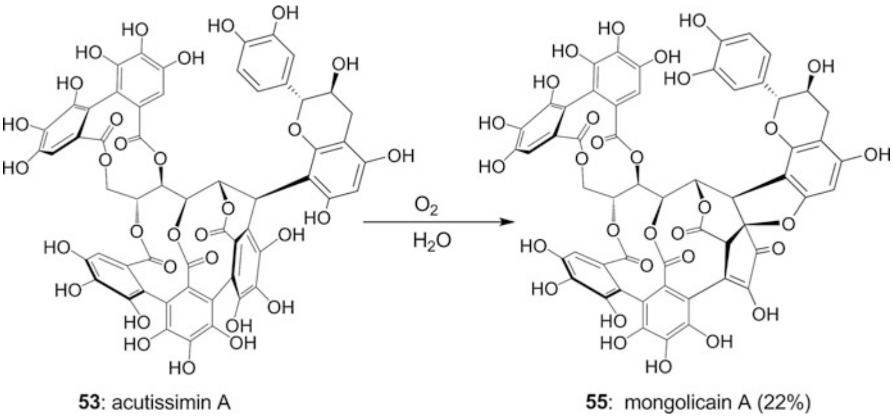

Fig. 64.16 Oxidative hemisynthesis of the mongolicain A (**55**) form the acutissimin A (**53**) in aqueous solution

revealed an important bathochromic shift of about 20 nm (Fig. 64.15). This bathochromic shift was initially recorded from aqueous solutions at pH 1 to ensure that the anthocyanidins moieties of **69** and **70** were entirely in their cationic flavylium forms, but the same shift was also observed in solutions at wine pH (i.e., 3.2). Such a bathochromic shift is generally observed when anthocyan(id)ins are covalently linked by their C-8 position to colorless phenolic compounds [96, 98]. This color modulation involving a chemical reaction with a *C*-glucosidic ellagitannin such as vescalagin (**39**), as well as the pH-dependent equilibrium of the resulting anthocyano-ellagitannins **69** and **70**, have been investigated in details and rationalized [94].

3.4 Effect of Oxidation on the Flavano-ellagitannin Profile

Red wine is a slow but continuously evolving mildly acidic and aerobic media in which the main polyphenolic constituents such as tannins and anthocyanins go through various oxidative transformations that generate a large variety of oxidized derivatives. Once dissolved in wine, oxygen is thus progressively and rather rapidly consumed by various substrates, such as phenolic acids (e.g., gallic acid, caftaric acid), anthocyanins, flavanols and proanthocyanidic oligomers [92, 99–101]. However, very few studies have addressed what happens to oak ellagitannins in this context at the molecular level, and the information available from the literature is rather contradictory [102, 103].

The formation of oxidation products derived from the acutissimin A (**53**), as well as their occurrence in red wine, have been investigated [82] (Fig. 64.16). The formation of mongolicain A (**55**) as the main product of the oxidation of acutissimin A (**53**) (22 % isolated yield) has been achieved in a de-ionized aqueous solution, as well as in a wine model solution, under atmospheric air pressure. The presence of

55 in a red wine aged in oak barrels, together with that of its precursor acutissimin A (**53**), were confirmed by mass spectrometry [82]. The mongolicain A (**55**) presents a connection between the catechin (**62**) moiety and the vescalagin (**39**) unit similar to that of its precursor **53**, as expected [52]. The oxidative formation of mongolicain A (**55**) in aqueous media implies a participation of both the vescalagin (**39**) and the catechin (**62**) moieties of acutissimin **53** to forge the characteristic *o,m*-hydroxyphenylcyclopentenon (HPCP) motif of mongolicain A (**55**). This characteristic motif is the result of a multi-step oxidative process that starts with the deshydrogenation of the NHTP-galloyl ring-I of the vescalagin moiety, leading to the formation of an α-hydroxy-*ortho*-quinone intermediate, which is followed by an intramolecular nucleophilic attack of the OH-7 of the catechin moiety of **53**. This nucleophilic addition is then followed by prototropic rearrangement, decarboxylation, and a second oxidative deshydrogenation finally leading to the formation of the HPCP motif of **55** [2, 72].

4 Biological and Pharmacological Activities

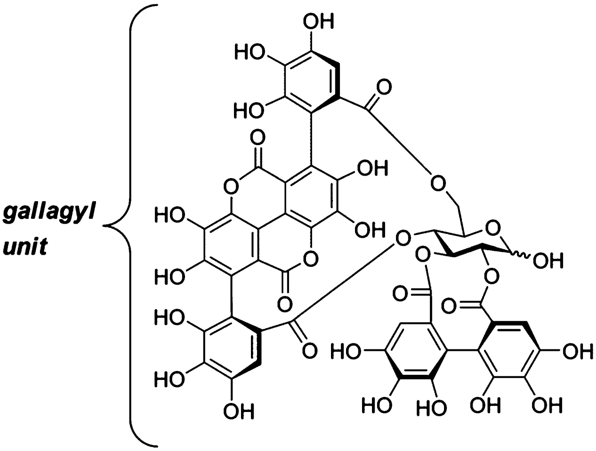
Hydrolysable tannins share with other polyphenols two fundamental physicochemical properties that are often cited as the origin of their health beneficial actions in traditional herbal remedies. The first one is their capability to scavenge reactive oxygen species. This antioxidant activity is commonly thought to enable *inter alia* the prevention of age-related health deteriorations such as carcinogenesis, neurodegenerative and cardiovascular diseases, including atherosclerosis. Their second property is their ability to participate in complexation processes with macromolecules, like proteins and polysaccharides. These associations of polyphenols with such biomolecules have been proposed to underlie beneficial health effects of herbal remedies against internal inflammations, hemorrhages, stomach disorders and other digestive problems [104, 105].

Besides these general activities based on chemical reactivity and structural features that are inherent in any polyphenolic substance (i.e., antioxidation and complexation) [1], ellagitannins are also capable of expressing remarkable biological activities such as potent antibacterial and antiviral activities, inhibition of mutagenicity of carcinogens and tumor promotion, as well as remarkable host-mediated antitumor effects [28, 106–108].

4.1 Hydrolysable Tannins in Folk Medicine

Most of the plants species used in folk medicine, especially in Asia, contain ellagitannins and gallotannins [108]. For example, one of the most popular medical plants in Japan (i.e., *Geranium thumbergii*) contains in its aerial parts an important amount of geraniin (**7**), which is used wildly as an antidiarrheic agent, as well as as a preventing agent against constipation. Both of these antagonist effects results from the action of geraniin (**7**), which expresses a protective action on the intestinal

Fig. 64.17 Punicalagin, a glucopyranosic monomeric ellagitannins found in *Punica granatum*



73: punicalagin

mucous membrane. The potent antioxidant and related activities of geraniin (**7**) may also participate in these effects [10]. Similarly, the leaves of *Mallotus japonica* that also yield geraniin (**7**), and mallotusinic acid (**19**), are also used for their stomach protective effects [27, 109, 110], like the fruits of *Trapa japonica*, which contain trapanin B (**26**) [27].

The *Agrimonia pilosa* herb, which contains agrimoniin (**21**), the first isolated dimeric ellagitannin, is used as an anti-cancer agent in Chinese medicine [10]. It is also used as an antidiarrheic and as a hemostatic agent in Japan. Agrimoniin (**21**) has also been subjected to detailed investigations related to its host-mediated antitumor activities [111, 112].

The root and fruit peels of *Punica granatum* (Punicaceae) have also been used in central and western Asia for their medicinal purposes (i.e., as a gargling liquid for throat diseases) [10]. Pomegranate fruits are consumed fresh and in processed form as juice, wines, flavors, and extracts. Commercial pomegranate juice has one of the highest antioxidant activities compared to other fruit juices, red wine, and green tea [113]. This can be attributed to its high content of polyphenols and in particular to its ellagitannins, the major ones being punicalagin (**73**, Fig. 64.17) [113, 114].

Plant extracts from *Quercus* and *Castanea* species containing acutissimins A (**53**) and B (**54**) are used to treat diseases such as gastritis and gastric ulcer, diarrhea, various inflammations (e.g., oral, genital and anal mucosa, skin) [115], and are also used as tonic and antitussive medicines [10, 51].

This short list of plants used in Asian folk medicines and furnishing ellagitannin-rich decoction and extracts are thus used to treat a large variety of diseases. To date, most of the investigations on ellagitannin-containing herbal medicines focus on the search of compounds capable of exhibiting antiviral or antitumor activity. The remarkable stability of most ellagitannins, despite the presence of several phenolic groups on their chemical structure, allows evaluation of their biological and pharmacological activities.

4.2 Antiviral Activities

Some monomeric and dimeric ellagitannins, as well as some gallotannins, also act as potent inhibitors of herpes simplex HSV-1 (i.e., labial herpes) and HSV-2 (i.e., genital herpes) infection [116]. In this study it has been observed that, among all of the studied compounds, tannins having galloyl groups or hexahydroxydiphenoyl groups (i.e., ellagitannins) express the most potent anti-HSV activity. Their 50 % effective doses (0.03–0.1 μg/mL) were by two to three orders of magnitude lower than their 50 % cytotoxic doses (>10 μg/mL). More recently, the monomeric *C*-glucosidic ellagitannins casuarinin (**38**) was also found to express antiviral activity against herpes simplex virus of type 2 (HSV-2) in plaque reduction assay. Interestingly, this antiherpetic activity of casuarinin (**38**) remained active even when it was added 12 h after infection, thus indicating that it affects some late event(s) of HSV-2 infection [117]. The NHTP-containing *C*-glucosidic ellagitannins extracted from oak wood such as vescalagin (**39**), castalagin (**40**), grandinin (**41**), roburin C (**45**), and roburin D (**46**) were also evaluated against four HSV-1 (labial herpes) and HSV-2 (genital herpes) strains, two of which were resistant to acyclovir (ACV), the reference drug against HSV-mediated diseases [43]. All five compounds effectively inhibited the replication of ACV-resistant mutants in cultured cells with activities at least 10^4 to 10^5 times higher than that of ACV.

Several ellagitannin monomers and dimers, as well as complex tannins show inhibition of HIV-induced cytopathic effects and HIV-specific antigen expression [118]. Interestingly, condensed tannins and simpler polyphenols including flavan-3-ol (e.g., epicatechin) also tested at the same time were found inactive [118]. Similarly, punicacortein C (**47**), a gallagyl-bearing ellagitannin, has been identified as a potent inhibitor of the human immunodeficiency virus (HIV) replication in infected H9 lymphocyte with little cytotoxicity [119].

4.3 Antimicrobial Activities

Gallotannins and ellagitannins also exhibit strong and very interesting antimicrobial activities, especially against some drug-resistant bacteria in the presence of some other antimicrobial agent. For example, *Helicobacter pyroli*, which is related to chronic gastritis, gastric ulcer, duodenal ulcer and also stomach cancer, was potently inhibited by tellimagrandin I (**6**), geraniin (**7**) and casuarictin (**57**). Interestingly, the ellagitannins tested were not toxic to *E. coli*, which is a normal inhabitant of the human intestinal microflora. Therefore, ellagitannins are potential agents that could be used to suppress *H. pylori* without affecting gastric epithelial cells and nonpathogenic intestinal bacteria. Moreover, corilagin and other ellagitannins also exhibit activities against *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella pneumoniae*, *Bacillus subtilis*, *Pseudomonas aeruginosa*, and *Proteus mirabilis* [10, 49, 120].

4.4 Antitumoral Activities

Over the last decades, numerous studies related to inhibitory activities on tumor incidence and propagation have been performed ranging from the evaluation of complex plant or fruit extracts to the specific cytotoxicities activities of purified or hemisynthesized ellagitannins. Studies on in vitro activities on cancer cell lines of ellagitannin-rich berries such as strawberries [121–125], raspberries [122, 125, 126], cloudberries [125], and pomegranate [114, 127, 128] demonstrated inhibition of cell proliferation, induced apoptosis and cell cycle arrest in human colon, liver, lung breast or cervical cancer. Even if most of these studies were performed on crude extracts, it was suggested that the antiproliferative activity was mostly associated with the ellagitannin content of these plant extracts.

Several gallotannins, ellagitannins, and complex tannins have been evaluated for their cytotoxicities against a series of six different human tumor cell lines [129]. In this study, *C*-glucosidic ellagitannins, such as vescalagin (**39**), castalagin (**40**), grandinin (**41**) and acutissimin A (**53**), exhibited moderate but selective cytotoxicity against PRMI-7951 melanoma cells with IC_{50} values ranging from 0.1 to 0.8 μg/mL [130]. Moreover, antitumor promoting activity was also observed for monomeric and dimeric *C*-glucosidic complex ellagitannin such as stenophyllanin A (**51**) [131].

Similarly, several *C*-glucosidic ellagitannins, including complex tannins, were identified as potent in vitro inhibitors of human DNA topoisomerase II (top2), a current target of chemotherapeutic anticancer strategies [132]. Castalagin (**35**), vescalagin (**39**), casuarinin (**38**), punicacortein C (**40**), acutissimin A (**53**) and mongolicain A (**55**) were found to be from 100 to 250 times more potent than etoposide (VP-16), a clinically used drug against top2. More recently, the activity of some NHTP-bearing ellagitannins as potent anti-top2 has been evaluated. In addition to vescalagin (**39**), castalagin (**40**) and acutissimin A (**53**) previously investigated [132], three novel compounds, the epiacutissimins A/B (**64/65**), and ethylvescalagin (**66**) were tested using a standard kDNA decatenation assay. All of these *C*-glucosidic ellagitannins inhibited top2-mediated decatenation of kDNA at concentrations as low as 1 μM and showed a much higher activity than VP-16. Moreover, at 10 μM concentrations, an almost complete inhibition of top2-mediated decatenation was observed for the acutissimin A/B (**53/54**) and epiacutissimin A/B (**64/65**) (i.e., 85–97.5 % of inhibition) [2, 70, 71].

Abstract

Phenols are an important group of phytochemicals with significant health beneficial effects. Extraction of phenols from the biological sources is a growing field of interest and is an integrated part of analytical methods. Some of the common methods of extraction of phenolic compounds are solvent extraction, accelerated solvent extraction, supercritical fluid extraction, ultrasonic extraction, and microwave extraction. Separation is the next important step of analytical methods, which is done to separate the required phenolic components from the unwanted part of the extract. In case of phenols, methods such as

liquid-liquid separation and chromatographic separation are applied; however, solid-phase extraction has been found to be one of the most popular methods of separation of phenolic compounds. All the above-mentioned different extraction and separation methods, along with some other analytical methods applied for phenols, have been discussed in detail in this chapter.

1 Introduction

Phenols are an important group of naturally occurring compounds which have many particular and interesting properties. They have a potential to be a major contributor in the nutraceutical sector. According to the Bureau of Nutritional Sciences, of the Food Directorate of Health Canada [1], “A nutraceutical is a product isolated or purified from foods that is generally sold in medicinal forms not usually associated with food. A nutraceutical is demonstrated to have a physiological benefit or provide protection against chronic disease,” and phenolic compounds fulfill the criteria mentioned in the definition. Phenolic compounds are mainly popular as potential antioxidants, and their antioxidant effects have been found to generally increase with the amount of phenolic content of a food or sample [2–4]. They have been reported to have anticarcinogenic [5], antidiabetic, antibacterial, positive ocular, and gastric effects [6]. They have been also reported to have protective effects against cardiovascular disorders [5], hepatic damage, and neurodegenerative disorders [6] and help in the prevention of cytotoxic effects of oxidized low-density lipoprotein (LDL) and consequently atherosclerosis [7]. These health beneficial effects not only encourage the consumption of fresh fruits but also promote the utilization of food industry wastes as the source of phenolic compounds extract, which can be further utilized in enrichment of other food products and production of nutraceutical additive concentrates or powders.

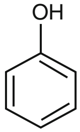

Fig. 65.1 Basic structure of phenol

Bioavailability, that is, the availability of the bioactive compounds at the cellular level to an organism when consumed, is one of the major factors which govern the effectiveness of different bioactive compounds. Bioavailability is affected by various factors which have been discussed in different reviews [8, 9]. It has been observed that sometimes either the pure form of a polyphenol is more helpful or combinations of some particular polyphenols are more effective. Hence, extraction of the bioactive compounds with efficient processes, proper separation with least losses, and encapsulation with appropriate methods are required. For all the studies related to bioactive compounds such as polyphenols, including characterization, quantification, or biomedical in vivo or in vitro studies, extraction is the fundamental method which can be divided into the various steps, mainly preparation, extraction, separation, and purification [10]. This chapter concentrates on the phenols and properties of phenol which affect the extraction efficiency. Other factors affecting the extraction efficiency have also been discussed along with the different methods of extraction. Different methods of separation applied for the polyphenols have also been discussed.

2 Phenolic Compounds

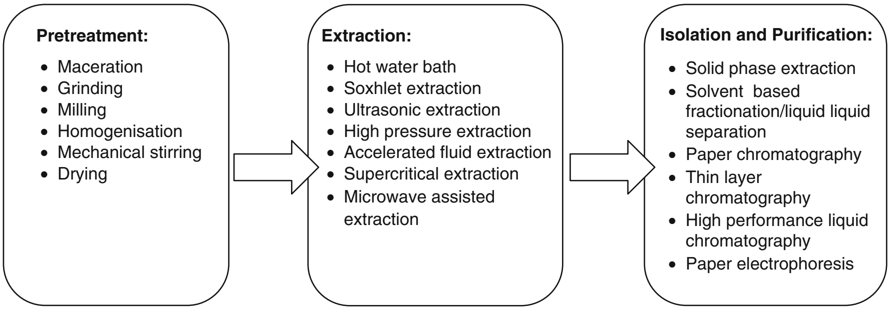
All compounds which have one or more hydroxyl groups attached directly to an aromatic ring are known as phenolic compounds. The entire group is based on the structure of phenol (Fig. 65.1) [11]. These are the widely distributed and important aromatic secondary metabolites present in plants. Fruits have been reported to have higher polyphenolics than vegetables [12]. Parts of the plants other than fruits have also been observed to be rich in polyphenols [13–16]. The industrial wastes obtained after the processing of fruits and vegetables have also been found to be a good source of polyphenols [17, 18].

There are several ways in which phenols have been categorized. Harborne and Simmonds categorized polyphenols based on the number of carbon atoms, which includes simple phenols (C_6); phenolic acids and related compounds (C_6—C_1); acetophenones and phenyl acetic acids (C_6—C_2); cinnamic acids, cinamyl aldehydes, and alcohols (C_6—C_3); coumarins, isocoumarins, and chromones (C_6—C_3); flavonoids (C_{15}); biflavonyls (C_{30}); stilbenes (C_6—C_2—C_6); benzophenones and xanthones (C_6—C_2—C_6); quinones (C_6, C_{10}, C_{14}); betacyanins (C_{18}); and lignans, lignins, tannins, and phlobaphenes (which are dimmers, oligomers, or polymers) [19]. Polyphenols have also been categorized by some researchers based on their distribution such as “common and less common” [11, 20] and “widely distributed, less widely distributed and polymers” [11, 21]. The detailed description regarding the classification of polyphenols and their properties have been discussed in other books such as “Plant Phenolics” edited by J.B. Harborne [22] and “Phenolic Compound Biochemistry” by Vermerris and Nicholson [11] and also in chapters of Part I of this book.

The structural differences between the different groups of polyphenols decide the chemical and physical properties of polyphenols. Some of these properties also affect the extraction efficiency of the phenols. Because of the presence of aromatic ring which is a common feature of polyphenols, the hydrogen of phenolic hydroxyl is labile, making phenols weak acids [11]. The level of acidity of phenols affects their properties related to extraction. As stated by Vermerris and Nicholson, pK_a is important and plays an important role in “the way certain polyphenolics are extracted” [11]. They have mentioned that, in case of a mixture of phenols, which include strong acids and weak acids, the addition of sodium carbonate (Na_2CO_3) or sodium bicarbonate ($NaHCO_3$) to the mixture allows separation of these phenols. “The weak base picks up the H^+ from the strong acids or the more acidic phenols” [11], which results in formation of phenolate salts (derived from the more acidic phenols after losing the H^+) of the phenols, soluble in water. “The less acidic phenols are not neutralized or do not lose a H^+ and tend to remain as free phenols and are not as soluble in water. These compounds can then be extracted with organic solvents” [11]. Hence, some of the common solvents used in the extraction of polyphenols include ethanol, methanol, and in some cases butanol as well.

Hydrogen bond formation can be considered as another important factor affecting the various aspects of extraction and separation of phenolic compounds. The intramolecular hydrogen bonding has been reported to reduce the reactivity of phenolic hydroxyl group, thus reducing the solubility in alcohol (which may affect the extraction efficiency, as methanol and ethanol are two of the most used solvents). It has also been mentioned by some authors that intermolecular hydrogen bonding makes it “difficult to purify phenolic compounds from mixtures, because of the interactions between different molecules including the solvent” [11].

Structural differences between different polyphenols decide their chemical properties and thus affect their extractability. Antioxidant effect, which is one of the most commonly studied effects of polyphenols, has been found to generally increase with the amount of polyphenols in the extracts [23–25]. However, the factors such as solvents and the reactivity and solubility of different polyphenols in different solvents also affect the extraction efficiency and antioxidant activity of the different polyphenols. Hence, the extraction processes and the solvents to be chosen are very much dependent on the type of polyphenols to be extracted, and the processes are chosen to obtain the highest amount of polyphenols possible. Study of the mechanisms of different extraction methods, their basic principles, and factors affecting the extraction processes can be helpful in deciding the best method for the extraction of different polyphenols from different sources.



Pretreatment:
Maceration
Grinding
Milling
Homogenisation
Mechanical stirring
Drying
Extraction:
Hot water bath
Soxhlet extraction
Ultrasonic extraction
High pressure extraction
Accelerated fluid extraction
Supercritical extraction
Microwave assisted extraction
Isolation and Purification:
Solid phase extraction
Solvent based fractionation/liquid liquid separation
Paper chromatography
Thin layer chromatography
High performance liquid chromatography
Paper electrophoresis

Fig. 65.2 Different processing steps in the extraction of phenolics

3 Methods of Extraction

Extraction methods are selected mainly depending on the nature of the compounds, the importance of the facilities, and the end use of the manufactured substance. Several pretreatment steps have been also applied in different studies including drying, maceration, homogenization, grinding, and/or milling [10]. These processes increase the interaction between the solvent and the analyte (the polyphenols) during the step of extraction. Drying generally reduces the mass of the raw material required to be used for extraction. Pretreatment methods such as maceration and grinding lead to breakdown of cellular structure to increase the surface area of the biomaterial exposed for extraction and increase the amount of polyphenols extracted. The most common method of extraction is solvent extraction, and many of the above-mentioned treatments are combined with solvent extraction to optimize the final yield. The different pretreatment/preparation, extraction, and separation methods have been summarized in Fig. 65.2.

There are several other advanced methods of extraction for polyphenols which have been found to be more efficient methods than standard solvent extraction. These advanced methods of extraction are also based on solvent extraction, that is, they use the most suitable solvents with advanced processes to drive the extraction. With concerns regarding energy conservation, lower solvent consumption, and prevention of pollution, methods such as microwave extraction and ultrasonic extraction have been recently highly encouraged. Other efficient methods include accelerated solvent extraction (ASE), supercritical extraction, and pressurized fluid extraction. All these methods along with the operating factors affecting the extraction of polyphenols are discussed in the following subsections.

3.1 Solvent Extraction

Solvent extraction is the most common method of extraction. Solvent-based extraction method such as Soxhlet extraction and hot-water-bath extraction has been used

Table 65.1 Solvents used for phenolic compound extraction

I. Most common solvents used for polyphenolic extraction	
Methanol	
Ethanol	
Ethyl acetate	
Aqueous solutions of methanol and ethanol	
II. Other solvents used for some specific phenolic groups	
Phenolic groups	*Solvents*
Lipophilic flavonoids	Chloroform [22]
	Dichloromethane [22]
	Acetone [22]
Phenolic acids and their glycosides	Alcohol and water mixtures rather than pure alcohols [22]
Anthocyanins	Methanol and ethanol with different acids [30]
	Acetone with chloroform [10]
	Acetonitrile [10]
Tannins	0.5% vanillin solution in methanol containing 4% HCl (v/v) [31]
Stilbenes	Polar to mildly polar solvents (acetone to ethyl acetate) [22]
Flavones and flavonol glycosides	Ether, hexane, or dichloromethane [22]

Note: The numbers in the square brackets “[]” represent the respective references

quite often to extract different polyphenolic compounds. Soxhlet extraction has been used for extraction of polyphenolic compounds from solid samples and is a quite inexpensive method which needs little specialized training [26, 27]. It has been modified according to the modern requirements and has been combined with many other modern technologies to increase the efficiency of extraction. In the case of hot-water-bath extraction, the water bath is the medium of maintenance of the temperature required for extraction of the phytochemical from the matrix into the surrounding solvent in which it is dispersed. There are several factors affecting the efficiency of solvent-based extraction methods, which include nature and type of solvent, time of extraction, and temperature maintained during the extraction. Other methods such as vortexing followed by centrifugation [28] and mechanical stirring can also be used along with the solvent extraction to further increase the extraction efficiency by increasing the contact surface area, which is a controlling factor as well [29]. Another important factor affecting the extraction is the source of the compound, that is, the type of tissue from which it is extracted. For example, extraction of biflavonoids from plant tissues such as powdered heartwood is done using a long extraction process by Soxhlet reflux or using hot solvent for up to 40 h [22]. However, in other cases, the time taken can be shorter or longer than this.

Most common solvents for extraction of polyphenols from plant sources include methanol, ethanol, ethyl acetate, and their aqueous solvents. However, the choice of solvent depends on the type of polyphenol to be extracted (Table 65.1). Because of the high boiling point and economic availability, aqueous methanol has been reported as a popular choice [12]. Ethanol and aqueous ethanol solutions are chosen as solvents in most of the cases where the extracted phytochemical is to be used as a nutraceutical or as a clinical standard. However, methanol and ethanol are not appropriate solvents for the phenolics bound to insoluble carbohydrates and proteins [22]. Choice of extraction method depends on the type of phenolic compound to be extracted, and some solvents have been used more frequently for certain phenolic compounds. Lipophilic flavonoids are solvent extracted using chloroform, dichloromethane, and acetone [22]. In order to avoid contamination with lipid material or to avoid partial esterification, phenolic acids and their glycosides are preferably extracted with alcohol and water mixtures rather than pure alcohols. Also when the plant sample is devoid of lipophilic phenols, it is suggested to be pretreated with petroleum or hexane to remove chlorophyll, carotenoids, and sterols. “Test extractions with labelled compounds should always be performed in order to check the validity of the proposed procedure and, if required, correction factors should be employed” [22]. In case of anthocyanins, combinations of solvents such as methanol and ethanol with different acids [30], acetone with chloroform, and acetonitrile are used for extraction [10]. Hydrochloric acid is comparatively the most common acid used for anthocyanin extraction; however, to prevent the hydrolysis and change in the native form of the anthocyanins, weaker organic acids such as formic, citric, or tartaric acid, or small amount of highly volatile acids such as trifluoroacetic acid, or lower concentrations of hydrochloric acid are preferred [12]. For other phenolic compounds such as tannin, several other variations of solvents have been used for successful extraction, which include 0.5% vanillin solution in methanol containing 4% HCl (v/v) [31]; for stilbenes, polar to mildly polar solvents are used for extraction ranging from acetone to ethyl acetate. Flavones and flavonol glycosides need comparatively less polar solvents for extraction which can be ether, hexane, or dichloromethane, and soaking the biomaterial in the solvent for a short period of time has been found sufficient for the extraction of these compounds. Biflavonoids have been found to be soluble in all solvents except aliphatic hydrocarbons such as hexane [22].

Other than the type and nature of solvents, temperature is another important factor and is controlled depending on the nature of biomaterial from which the compound is to be extracted and also depending on the stability of the compound itself. For instance in a study, it was observed that temperatures higher than 100 °C lead to a decrease in the recoveries of catechin and epicatechin whereas caffeic acid was not affected [32]. High temperature increases solubility of compounds in general because of the increased intermolecular interactions within the solvent and the molecules of biomaterial, giving rise to relatively higher molecular motion with decreased viscosity of the solvent with increased temperature. Temperature may also aid in the breaking of analyte-matrix bond, thus increasing the extraction efficiency further. Also cell rupture occurs because of the increased pressure induced by high temperature inside the cellular structure leading to opening of cell matrix and increased interaction of the solvent with compounds present in the cell matrix [29]. However, it has been observed that the polyphenolic content increase in the extract is limited to a certain temperature during extraction, and beyond that, the concentration of several polyphenolic compounds decreases because of oxidation and degradation at higher temperature [32]. It has been reported that polyphenolic compounds with higher number of hydroxyl-type substituents are more prone to destruction at higher temperatures [33].

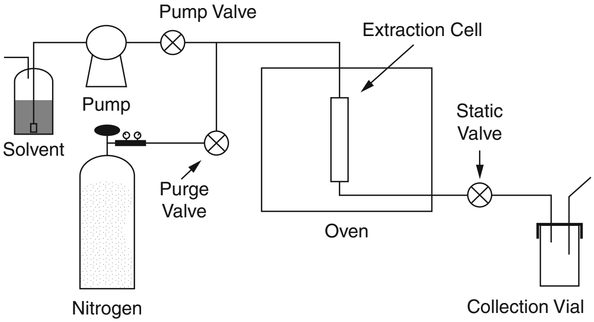
However, the destructive effect of temperature can be controlled by controlling the time of application of high temperature and pressure. With an increase in time up to an optimum time, the yield of extraction has been found to increase. However, after that optimum time, the extraction yield decreases if the extraction process still continues. There are certain cases of solvent extraction where high hydrostatic pressure is also applied, in high-pressure extraction. These are generally batch processes and are fast extraction processes, where low temperature can be maintained for extraction [34, 35]. Hence, the optimum time of extraction differs with the pressure level, the temperature of extraction, and the additional processes if applied, such as mechanical stirring, ultrasound, microwave, or vortexing. Another important factor is the mass of the sample used for extraction which will affect the volume of solvent and time of extraction. Solvent volume is an important factor. In extraction methods oriented toward the quantification of polyphenolic compounds, several iterations of the extraction process are applied to fully extract the compounds from the biological matrix. The iterations are conducted with fresh solvents to prevent solvent saturation with the compounds and maintain the extraction kinetics [29]. All the extraction parameters are interdependent; hence, all bioproduct extraction parameters have to be optimized for every extraction method.

The solvent extraction can be enhanced by utilizing carbohydrate-hydrolyzing enzymes, for instance pectinase, cellulase, hemicellulase, and many other enzymes, which can be used to disintegrate the plant cell-wall matrix leading to more efficient release of phenolic compounds [36]. Enzymatic-assisted extraction has been applied for superior extraction of polyphenolic compounds from different biomaterials, such as black currant juice press residues [37, 38], pigeon pea leaves [39], and grape pomace [40].

Light and oxygen are some of the normally present environmental factors during standard solvent extraction, and exposure of the polyphenolic extract to light and oxygen can lead to polyphenol oxidation [11]. "Formation of cross-linked structures as a result of exposure to light and oxygen" is known as autoxidation [11]. As mentioned by Vermerris and Nicholson, "under the influence of light, oxygen can abstract a proton," thus leading to the formation of radical [11]. The radical generated through oxidation can subsequently react with other radicals to form dimer. "Since the radical electron is delocalized, several structures can be formed depending on the precise location of the radical electrons at the time of the reaction" [11]. This is an important point to be considered carefully in case of extraction, separation, and extract storage methods. Oxidation can lead to formation of some unwanted complex compounds in the extract; hence, technological modifications in the solvent extraction have to be applied to prevent these degradation processes as well.

Considering all the factors (factors supporting and opposing the extraction) mentioned above, many new advanced processes of solvent extraction have been devised, which utilizes many modern technologies with specific advantages.

Fig. 65.3 Schematic of accelerated solvent extraction (Source: Richter et al. 1996 [45])



3.2 Accelerated Solvent Extraction

Accelerated solvent extraction (ASE^{TM}, which is a Dionex trademark) is a fast and efficient extraction method mainly operated with the control of two major factors affecting solvent extraction: temperature and pressure. Generally, high temperature and high pressure are applied during the process, and extraction is conducted for a very short period of time. However, there are certain exceptions where lower temperature levels are also applied [41], as for thermolabile polyphenolic compounds, lower temperature levels might be preferable [42]. This method of extraction is also known as pressurized liquid extraction, pressurized fluid extraction, or pressurized solvent extraction. The matrices of the samples of extraction are either solid or semisolid. Extraction systems for both single extraction and simultaneous multiple extractions are available, and the Dionex ASE^{TM} has been reported to be used in most of the reported studies [41, 43, 44]. According to the schematic of ASE described by Richter et al. (Fig. 65.3) [45], which is one of the earliest report on ASE, the system consists of a pump (for pumping solvent), extraction chamber, gas cylinder, collection vial, tubing, and three high-pressure valves (purge valve, static valve, and pump valve). As described by Camel [46], the extraction takes place in several steps. The extraction cell is filled with the sample and the liquid solvent, then they are pressurized to the level required, and the mixture is heated (the temperature is achieved in a short time because of the high pressure). Static extraction is carried out for a certain period of time, and in certain cases, a multiple number of extraction cycles are repeated [41]. The pressure is released after the static extraction phase, and the extract gets collected in the collection vials. The extraction cell is rinsed with fresh solvent to avoid losses of extracts. To ensure total extraction and avoid memory effects, the cell is purged with inert gas. The typical volume collected depends on the cell size [46]. To avoid oxidation of the analytes during the operation, the solvents used are degassed beforehand [41]. In certain cases to prevent clogging of the extraction cell with the biological matrix during extraction, layers of diatomaceous earth are added, and cellulose filters are provided at the bottom of the cell to avoid discharge of suspended particles into the collection vial [41, 47].

High pressure and high temperature accelerate the extraction process by ensuring increased contact of the polyphenolic compounds with the solvents [32]. Increased diffusion rate is observed because of the increased temperature leading to increased extraction kinetics with reduced viscosities. The pressure helps in rapid filling of the extraction cell and forcing the liquid solvent into the matrix; however, high-pressure application mainly helps in maintaining the solvent in liquid state even at very high temperatures [42, 46]. Even though high pressure and temperature are applied in this case, the solvents are still below their critical conditions. This process allows extraction of polyphenolics under an inert atmosphere and protection from light, which are some of the major advantages of the process as polyphenolic compounds are both prone to oxidation as well as light deterioration or degradation. The increased rate of extraction also helps in reducing the chance of certain negative reaction which takes place in the extract with increased time of exposure leading to the inactivity of certain compounds due to oxidation or isomerization [32].

Generally organic solvents are used in ASE in their pure form or as mixtures of several organic solvents with water. Several cases of ASE with the specific solvents (emphasizing some of the recent studies and some of the most cited studies), the corresponding temperature and pressure levels, and the different matrices have been summarized in Table 65.2. Water can also be used as an extraction solvent utilizing ASE apparatus for extraction of polyphenolic compounds [48]. This process using pressurized hot water or subcritical water (as mentioned before, the solvents are still under their critical conditions) with ASE apparatus is generally known as pressurized hot-water extraction or subcritical-water extraction [42, 49].

3.3 Supercritical Fluid Extraction

Supercritical fluid extraction (SFE) is obtained at particular temperature and pressure combinations, which are higher than their critical values for a specific solvent where the solvent is said to be in its supercritical state. “The critical point of a pure substance is defined as the highest temperature and pressure at which the substance can exist in a vapour liquid equilibrium” [36]. Supercritical fluids possess certain properties similar to both gases and liquid. The density and dissolving power of these fluids depend on their density which can be adjusted by adjusting the pressure and temperature. At this high temperature and pressure, viscosity of the supercritical fluid is lower than that of the liquids. These solvents also have higher diffusion coefficient leading to higher mass transfer and efficient extraction [42, 46]. A supercritical fluid can be easily recovered as it is highly volatile. CO_2 is the most commonly used solvent (CO_2 is less expensive, nonflammable) in SFE, and it is a nontoxic solvent extraction method which generally does not leave any harmful residue in the extract (environmentally friendly process) [36]. The process uses high-pressure conditions and has the flexibility of changing temperature and pressure conditions to retain the supercritical condition of the solvent fluid. Boiling point increases with increase of pressure, and some solvents have very low boiling

Table 65.2 Examples of application of ASE for the extraction of polyphenolic compounds from biological matrices

Biological matrix	Solvent	Parameters (temperature/pressure)	Phenolic compound	References
Peel and pulp of Basque cider apple	Methanol	40 °C/6.895 MPa	Many polyphenolic compounds	Alonso-Salces et al. 2001 [41]
Different types of samples (dried and fresh) of apricot	Mixture of methanol, water (70:30 v/v) including 0.1 g of tert-butylhydroquinone (*t*BHQ) (best combination)	60 °C/10.342 MPa	17 polyphenols	Erdoğan and Erdemoğlu 2011 [44]
Different propolis samples (from honey-producing locations of Anatolia)	Ethanol:water: HCl; (70:25:5, v/v/v) containing 0.1% *t*BHQ	40 °C/10.342 MPa	Gallocatechin (GCT), catechin [50], epicatechin gallate (ECTG), caffeic acid (CA), chlorogenic acid (ChA)	Erdogan et al. 2011 [51]
[a]Spinach	Water AND 70% aqueous ethanol	<130 °C AND <150 °C/13.8 MPa	Flavonoids	Howard and Pandjaitan 2008 [52]
Dried ground sunbelt red grape pomace	10–70% Ethanol	40–120 °C/6.8 MPa	Anthocyanins	Monrad et al. 2010 [48]
Almond skin powder	30–90% aqueous methanol in 5% acetic acid	100 °C/10.342 MPa	Flavonoids and phenolic acids	Bolling et al. 2009 [53]
Pomegranate peels	Deionized water	40 °C/10.345 MPa	Different phenolic compounds	Çam and Hışıl 2010 [54]
Oak wood chips	Dichloromethane	150 °C/20 MPa	Lignin dimer derivatives	Vichi et al. 2007 [55]
Epimedium sagittatum	70% aqueous ethanol	120 °C/10.342 MPa	15 Flavonoids	Chen et al. 2007 [56]
Green parts of *Trifolium* L.	Methanol, 75% aqueous methanol, acetone, and acetone-water (75:25, v/v)	75–125 °C/10 MPa	Isoflavones	Grażyna 2009 [57]

[a] Two separate temperature conditions with two different solvents were found suitable; hence, the solvents and temperatures are written in sequence separated by AND

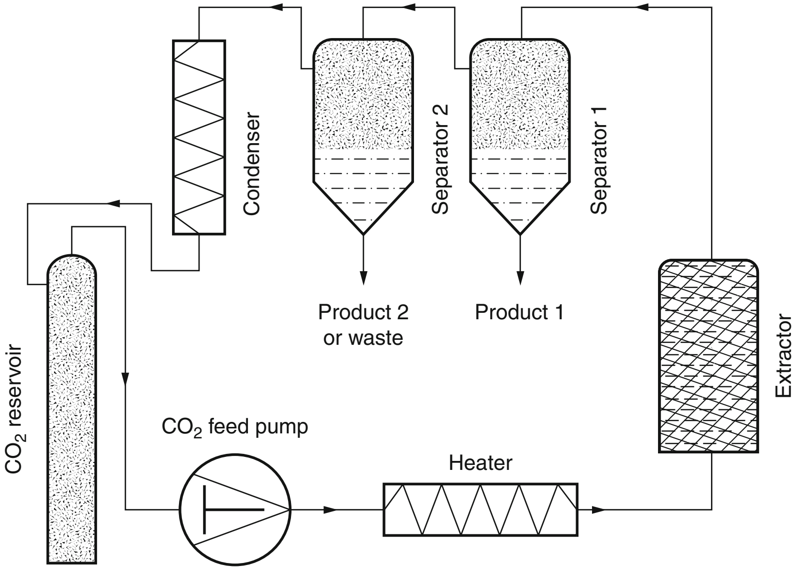


Fig. 65.4 Schematic diagram of a process-scale supercritical fluid extraction system (Source: Wang and Weller 2006 [42])

point temperatures at atmospheric pressure; the hazards caused due to boiling of the liquid can be avoided at elevated pressures. Low temperature level can be used for extraction which is helpful in case of thermolabile compounds, and for thermostable compounds with high boiling points, very high temperature can also be applied for extraction [36, 42, 46]. The dissolved phenolic compounds can be separated from the solvents by decreasing the density of supercritical solvents achieved through decreasing pressure. Hence, SFE can reduce or eliminate the requirement of concentration, which saves a lot of time and also minimizes the deteriorating effect on polyphenols, by reducing exposure of the compounds to high temperature and oxidation [42]. One of the earliest accounts of SFE is the extraction of resorcin derivatives from *Ginkgo biloba* fruits and leaves dated back to 1993 [58]. In the 1990s, most of the application of SFE was in the environmental sector and soil analysis. Since then SFE has been increasingly used in the food, plants, and waste utilization sector to optimize operating factors to obtain the highest yield of extractable polyphenolic content.

A SFE system basically consists of a high-pressure pump to deliver the fluid solvent at high pressure, an extraction cell provided with temperature controllers, and valves at both ends to maintain the high temperature and high pressure. Process scale extraction systems (Fig. 65.4) are provided with separators to separate the extracts and waste present in the solvent (unwanted compounds present in solvent other than extracts) from the solvent fluid which is generally CO_2 and condensers to condense CO_2 and reuse it in subsequent extraction processes. In case of SFE, sometimes the commercially manufactured extraction systems are used [59], and in certain cases, SFE extractor units are assembled in their respective laboratory units [60].

In the preparation of SFE samples, ground, dry materials are preferred for efficient extraction. During SFE, after loading the biological matrix in the extraction cell, it is pressurized with solvent fluid (generally supercritical CO_2) from the pump (modifiers, which are generally organic co-solvents, are added to the biological matrix that increases solubility of polar phenolic compounds, and then CO_2 is pressurized) [42, 46]. Both static extraction (while the mixture is in the extraction cell) and dynamic extraction take place for a relatively short period of time, after which the pressure and temperature levels of the solvent fluid with the extract and impurities are adjusted which leads to selective separation of extract from the solvent and then CO_2 is condensed in the condenser to be reused [42, 59]. Other solvents can be used, for example, in lignin extraction, supercritical fluids such as supercritical alcohols [61] and supercritical acetone have also been used. SFE has been applied successfully for lignin as it has been observed that the high-pressure application does not alter the wood structure [22]. Phenolic acids and their esters have been reported to be soluble in supercritical CO_2 [62]. Hydroxycinnamic acid and coumaric acid derivatives have been found to be partially soluble in supercritical CO_2 without co-solvent [36]. However, in the case of polar polyphenols, since CO_2 is nonpolar, modifiers are used for extraction. Organic co-solvents such as methanol, ethanol, and acetone, which are used as modifiers, increase the solubility of polar phenolic compounds (due to hydrogen bonding and dipole interaction [63]); however, the critical temperature is increased when a polar co-solvent is added, which implies that the process could be disadvantageous for thermolabile compounds [36, 42]. The modifiers can be added to the biological matrix in the extraction chamber through an additional pump [46]. Methanol appears to be the most used co-solvent; however, for nutraceutical purposes, ethanol is more acceptable. A mixture of modifiers can also be applied [42].

Along with factors such as the type of compound to be extracted, the nature of solvents, and the temperature, pressure, and time of extraction, the efficiency of SFE also depends on the nature of modifier applied. The dependence on so many factors increases the selectivity of SFE which is another beneficial characteristic property of SFE other than higher extraction kinetics. Selective extraction and fractionations are also possible because “the solubility of a chemical in a supercritical fluid can be manipulated by changing pressure and/or temperature of the fluid” [42]. However, depending on the quantity and nature of the modifier, its addition can also reduce the extraction selectivity, while more nontarget analytes can get co-extracted [46]. Yet there are many reports of successful extraction of polyphenols using a solvent with modifiers in case of SFE [10]. Some of the successful reports of different polyphenolic compounds extraction have been summarized in Table 65.3. Use of aqueous solution of methanol has been reported to provide higher yield than the case where pure solvents were added as modifiers individually [64]. Water increases the polarity further leading to efficient extraction of polar polyphenols [10]. The extract composition has been found to be varying with time, since less polar and low molecular weight compounds are more readily extracted while the extraction mechanism is generally controlled by internal diffusion [42]. Overall, different combinations of factors lead to the extraction of different compounds varying in terms of their quantities as well (Table 65.3).

Table 65.3 Examples of application of SFE for extraction of polyphenolic compounds from biological matrices

Biomaterial matrix	Solvent/ modifier	Temperature/ pressure	Phenolic compounds extracted	References
Arbutus unedo fruits	CO_2/19.7% ethanol[a]	48 °C/60 bar[a]	Total phenolic	Akay et al. 2011 [65]
Leaves of *Jatropha curcas* Linn.	CO_2/70% methanol	50 °C/20 MPa[a]	Gallic acid	Manpong et al. 2009 [60]
Vitis vinifera seeds	CO_2/20% or 15% ethanol	50 or 30 °C/ 300 bar, 30 °C/ 250 bar	Gallic acid, epigallocatechin, epigallocatechin gallate/catechin, epicatechin/ epicatechin gallate[b]	Yilmaz et al. 2011 [66]
Physalis peruviana L.	CO_2/4 and 5% ethanol	60 °C/400 bar	Flavonoids and phenol	Wu et al. 2006 [59]
Solid waste generated by industrial berry juice	CO_2/ethanol	60 °C/ 80–300 bar	Total phenolic content	Laroze et al. 2010 [67]
Guava seeds	CO_2/ethanol	40, 50, 60 °C/ 10, 20, 30 MPa	Total phenolic content	Castro-Vargas et al. 2010 [68]
Pine barks	CO_2/ethanol	60 °C/200 bar	Flavonoid content	Yesil-Celiktas et al. 2009 [69]
Roasted wheat germs	CO_2	58 °C/336 bar[a]	Total phenolic content	Gelmez et al. 2009 [62]
Phyllanthus niruri Linn.	CO_2/water; 30, 50, and 70% ethanol	60, 100 °C/100, 200 bar	Gallic acid, ellagic acid	Markom et al. 2007 [70]
Theobroma cacao hulls	CO_2	50 °C/100, 150, 200 bar	Phenolic compounds	Arlorio et al. 2005 [71]
Pistachio (*Pistachia vera*) hull	CO_2/methanol	35, 45, 55 °C/ 100, 200, 350 bar	Total phenolics	Goli et al. 2005 [72]
Wine industry by-product extract	CO_2/methanol[c]	45 °C/250, 150 or 100 bar	Polyphenols	Louli et al. 2004 [73]
Mellissa officinalis	CO_2/methanol	60 °C/40 MPa	Phenolic compounds	Ziaková and Brandšteterová 2002 [74]
Grape seeds	CO_2/methanol	313 K/20 MPa and above	Low polymerized proanthocyanidins, catechin, epicatechin, low molecular weight phenolics	Murga et al. 2000 [75]
Olive leaf samples	CO_2/10% methanol	100 °C/334 bar	Phenols	Le Floch et al. 1998 [76]

[a] The conditions were found optimum

[b] The different compounds are separated by "/" to indicate that different extraction combinations have been applied

[c] The co-solvent or modifier was applied only with the combination 250 bar and 45 °C

3.4 Ultrasonic Extraction

Ultrasonic extraction (UE) or sonication-assisted extraction is an inexpensive, simple, and efficient method of extraction. The extraction method involves sound waves with frequencies higher than 20 kHz, which are mechanical vibrations in all the states of matter. The principle behind sonication-assisted extraction involves the expansion and compression cycles in the medium through which these mechanical waves travel. “Expansion pulls molecules apart and compression pushes them together” [42]. The expansion process creates bubbles in the liquid medium and produces negative pressure. These bubbles form, grow, and collapse. “Close to a solid boundary, cavity collapse is asymmetric, which produces high-speed jets of liquid” [42]; these jets lead to a “strong impact on the solid surface” [42]. Ultrasonic baths and closed extractors fitted with ultrasonic horn transducer are used for UE. The ultrasonic machines (in certain cases, ultrasonic cleaner is used as well) are also equipped with pressure, temperature, and time control [77]. There are several ultrasonic horns available which operate at different power levels and frequencies. Application of ultrasonics can be continuous or pulsed as well [78].

The cavitation effect of an ultrasonic process leads to superficial tissue or cell-wall disruption in a short period of time, increase in solvent transfer into the biological matrix, and release of cellular content, consequently leading to higher surface mass transfer [42, 79]. Scanning electron micrographs of the biological cells treated with ultrasound have showed evidences of mechanical stress created by ultrasound leading to cell destruction [42]. These cavitation bubbles present hydrophobic surfaces within the extraction liquid, thus increasing the net hydrophobic character of the extraction medium which makes possible the extraction of polar compounds into less polar extraction media or even hydrophilic extraction media [79]. Along with factors such as nature of the biological compound to be extracted, nature of the biological matrix, solvent properties, particle size, temperature level, and time of extraction, there are several other factors which affect the extraction efficiency, such as frequency, ultrasonic power, distribution of ultrasound in the extraction cavity, and pressure. All the solvents which are used for solvent extraction can be used in the case of ultrasonic extraction as well. Ultrasound wave distribution in the extractor is usually not uniform, and the maximum ultrasound power is observed in the vicinity of the radiating surface of the ultrasonic horn (source). Ultrasonic intensity decreases with increase in distance from radiating surface and also decreases in the presence of solid particles. To avoid standing waves and for a more uniform distribution of the solid particles, shaking or agitation can also be used. Ultrasound also produces heat, so the temperature level should be checked for prevention of excess heating (which might lead to temperatures higher than the range required for extraction and lead to the degradation of temperature-sensitive compounds). Use of ultrasound decreases the time required for extraction, with the same solvent used without ultrasound. Furthermore, the extraction time should be controlled to prevent spoilage of the extract quality. The use of ultrasound also decreases the requirement of a temperature increase for the extraction; hence, it is suitable for thermolabile compounds, and it has been reported to increase product quality [42].

Application of ultrasonics has evolved with time, and one of the first applications of ultrasonics can be dated back to 1980s when lignin was extracted from spruce wood, decreasing the extraction time from 14 days to 14 h [80]. Ultrasonics has been applied for different phenolic compounds such as tannins [81], flavonoids [82–84], anthocyanins [85–87], and many others [78, 88–90]. Also it has been applied to a variety of materials to extract their polyphenolic content, such as medicinal plants like *Selaginella doederleinii* [91] and *Citrus aurantium* [92], food industry wastes such as litchi [93] and longan pericarp [94], pomegranate [78] and orange peel [89], and grape by-products [86].

3.5 Microwave-Assisted Extraction (MAE)

Microwaves are nonionizing electromagnetic waves located between the radio-frequency range at the lower frequency and infrared at the higher frequency in the electromagnetic spectrum, within the frequency band of 0.3–300 GHz. A frequency of 2,450 MHz is generally used in domestic microwave and for microwave-assisted extraction as well. A microwave apparatus consists of "microwave generators, waveguide transmission, resonant cavities, mode stirrers (only for multi-mode cavities), and a power supply" [95]. The microwave generators are special oscillator tubes such as magnetrons and klystrons which generate the microwaves, which are transported to the resonant cavities (ovens) by means of waveguides. Waveguides can be used as applicators of microwave, where "the material to be heated is introduced by wall slots and the waveguide is terminated by a matched load" [29]. The field maxima keep changing with time in this case; hence, this configuration is called a traveling-wave device. The other kind of configuration is the "standing wave device where the microwaves irradiate the slot arrays (that cut the wall currents) or horn antennas (specially formed open ends) of waveguides" [29, 96]. "The mode stirrer ensures homogeneous heating by distributing the microwave radiation between the different resonant modes of the cavity" [95, 96]. There can be two types of microwave ovens: monomode or multimode cavities. Monomode cavity is used in case of focused microwave ovens (Fig. 65.5); it generates a frequency which excites only one mode of resonance. In this case, as the distribution of field is known, sample can be placed at the maximum of the electric field. MAE systems can be closed systems or open systems as well. One of the earliest studies on MAE was by Ganzler et al. in 1986, regarding extraction of organic compounds from biological and soil samples [97]. A method of MAE of natural products was patented by Paré et al. in 1991 [98]. Since then there have been many modifications in the parameters, modeling, and methodology of MAE, which have made possible the use of many different categories of biomaterials and extraction of many different kinds of compounds (Table 65.4).

The distribution of electromagnetic (EM) energy in MAE systems is determined by Maxwell's equations with suitable boundary conditions defined by the makeup

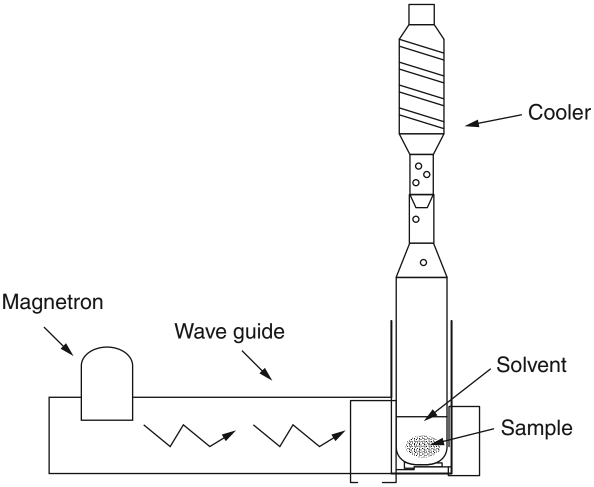

Fig. 65.5 Schematic diagram of an open focused-microwave system for extraction (Source: Kaufmann and Christen 2002 [119])

of the systems and the interfaces amid the treated biomaterial and remaining space. The dielectric properties of the biomaterial samples are the key property parameters of Maxwell's equations and therefore significantly affect the "efficiency of EM energy absorption into the materials, EM field distribution and conversion of EM energy into thermal energy within those biomaterials" [29]. The dielectric properties of a material can be explained in terms of the complex relative permittivity (ε* relative to that of free space) presented in the following equation:

$$\varepsilon^* = \varepsilon' - j\varepsilon'' \text{ where } \mathrm{j} = \sqrt{(-1)}$$

where ε′, the real part of the relationship, is the dielectric constant, reflecting the ability of the material to store electrical energy from an EM field, and ε″, the imaginary part, is the dielectric loss factor, influencing the conversion of the EM energy to thermal energy. The ratio of the real and imaginary parts of permittivity represents tangent of loss angle (δ), which is another important parameter expressed as

$$\tan \delta = \varepsilon''/\varepsilon'$$

which, in conjunction with the dielectric constant, determines the "attenuation of microwave power in a biological matrix" [29]. In the EM field, the amount of EM energy converted to thermal energy in biological material is proportional to the value of the loss factor ε″ (in case of biomaterial with similar dielectric constant) [109]. Hence, the dielectric properties, which depend on the characteristic properties of the biological sample such as composition of the biological matter, moisture content, and other physicochemical characters, determine the effectiveness of the microwave extraction method.

Table 65.4 Examples of application of MAE for extraction of polyphenolic compounds from biological matrices

Biomaterial	Solvent	Temperature/ power level	Time of application of microwave	Extract component	References
[a]Mandarin peels	Deionized water	400 W	3 min	Polyphenols	Ahmad and Langrish 2012 [99]
[a]*Agaricus blazei Murrill*	60% ethanol	500 W	3 extraction cycles (each 5 min)	Gallic acid, protocatechuic acid, catechin, myricetin, quercetin	Zhang et al. 2012 [100]
[a]Sweet potato (*Ipomoea batatas* (L.) Lam)	53% ethanol	302 W	123 s	Total phenolics	Song et al. 2011 [101]
[a]Fruit hulls of tea-oil tree (*Camellia oleifera*)	Water	76 °C	35 min	Total phenolics	Zhang et al. 2011 [102]
Parts of *Hippophae rhamnoides*	Ethanol	150 W	20 min	Phenolic components	Sharma et al. 2007 [103]
[a]*Radix puerariae*	65% ethanol	100 °C	2 min	14 phenolic compounds	Du et al. 2010 [104]
Peanut skin	30% ethanol	285 W	30 s	Total phenolics	Ballard et al. 2010 [105]
Mandarin peels	66% methanol	152 W	49 s	Phenolic acids	Hayat et al. 2009 [106]
[b]*Radix astragali*	90% ethanol	110 °C	25 min	Flavonoids	Xiao et al. 2008 [107]
Grape seed	Methanol or 90% methanol	150–300 W	20–200 s	Total phenolics	Hong et al. 2001 [108]

[a]The conditions are the optimum conditions
[b]The conditions mentioned yield the highest amount of extract component

In case of microwave heating, the energy transfer occurs via two mechanisms, specifically, by dipole rotation and ionic conduction, that is, by means of reversals of dipoles (which lead to molecular friction of the permanent dipoles within the material as they try to reorient themselves with the oscillating electric field of the microwave) and displacement of charged ions present in the solute as well as the solvent [110, 111]. The radiation frequency corresponds to the rotational motion of the molecules; in condensed matter, energy absorption immediately causes energy redistribution between molecules and heating of the surrounding medium [111]. During MAE, the disruption of weak hydrogen bonds initiated by the dipole rotation of the molecules also occurs with associated heat release [112].

Also there is migration of dissolved ions subsequently increasing penetration of the solvent into the biological matrix sample, thus leading to the collection of the target compounds [112]. To extract any biochemical component from a biological matrix, first it has to be removed from the matrix with cellular release into the surrounding solvent [113, 114]. During microwave application, a substantial amount of pressure builds up inside the biological matrix which modifies the physical properties of the matrix, improving the porosity and allowing better penetration of the solvent [115, 116]. Swelling occurs because of the pressure-building effect of the microwave, which generally forces the cells to split. During an image study of extraction of pectin from orange peel using microwave, it was observed that the destructive effect with microwave radiation was much more as compared with the traditional method. The final structure of pectin obtained after microwave treatment was particulate form similar to crystals and not cluster form as obtained in case with no microwave application [117]. Microwave application does not need any contact between the energy source and the target. MAE leads to rapid volumetric heating [110]. In case of uniform solvent composition (for extraction) and biomaterials with higher water content, MAE leads to uniform volumetric heating [110]. Along with lower solvent consumption and faster extraction, another major benefit of microwave-assisted extraction includes better extract quality [118].

"In general, the higher the dielectric constant and dielectric loss, the higher is the capacity of the solvent to absorb microwave energy" [29] and faster is the rate of heating of solvent with respect to the plant material, which eventually leads to a faster extraction rate. However, by combining different solvents, the solvent properties can be modified, and selectivity of the solvent for different compounds can be controlled or modified. A solvent combination with comparatively lower dielectric properties and higher dissolving power for the desirable extract components can be used for extraction of thermolabile compounds and ensuring that the solvent temperature remains low enough to cool down the solutes once they are extracted into the solvent combination. In this case, the microwave interacts more with the plant matrix with higher water content [119] leading to efficient release of the plant compounds in the cooler solvent. The extraction kinetics also depends on the solubility of the analytes in the surrounding solvent. In case of MAE, both polar [120] and nonpolar solvents [121] can be used; however, the rate of heating of polar solvents such as methanol and ethanol is generally higher than nonpolar solvents. Many polyphenolic compounds are soluble in polar solvents, though the solubility in different polar solvents depends on the number of hydroxyl groups and nature of the sugar molecule present [27]. Polyphenols vary in polarity, so solvents varying with level of polarities can also be used in MAE. Water can be used as a potential solvent because of its high polarity. Ionic solvents have also been tried for MAE of polyphenols. It has been observed that anions and cations of ionic liquids influence polyphenol extraction, and ionic liquids with electron-rich aromatic π-system enhance the yield [122]. Similar to the cases of other solvent extraction methods, MAE also depends on the concentration and nature of solvents, nature of the biochemical to be extracted, and temperature and pressure levels (MAE can be conducted at atmospheric pressure or under pressurized conditions), and the effect of various factors is the same as in other extraction methods. The microwave power level is another important factor which affects the extraction yield by affecting the rate of heating and the temperature attained depending on the nature of solvent (polarity) and time of application of microwave. Generally, the higher is the power level, the higher is the rate of heating of the material (solvent and biomaterial), leading to higher extraction yield with the higher rate of heating and subsequent increase of mass transfer and extraction kinetics. However, very high power levels should be avoided as they might lead to very high temperature level and loss of the desirable extract components and their properties. Hence, with the right combination of factors, MAE can be an efficient method of extraction of polyphenols.

All the extraction methods have their advantages and disadvantages when compared to one another. For specific compounds and the same extraction method, the selection of a particular solvent might be more effective than the other, and with a particular solvent in mind, a particular extraction method might be more helpful than the other. For example, it was observed that ASE at 85 °C with water as the solvent produced best results for flavonoid glycosides, whereas SFE using CO_2 and 10% ethanol as the modifier gave higher yields of flavonoid aglycones [123]. There are many other cases where different extraction methods when combined together become more efficient in terms of time and solvent consumption and extract quality. Methods such as high-pressure MAE [124] and vacuum MAE [125] have been successfully applied for extraction of different polyphenolic compounds from different biomaterials. However, some of the major drawbacks of the advanced methods of polyphenol extraction methods include high capital investment required for setting up the equipments (especially for methods such as ASE, SFE, and MAE) and energy costs as well.

4 Methods of Separation

Generally, extraction methods lead to production of crude extracts (non-phenolic components such as chlorophyll, terpenes, waxes, and other undesirable compounds are also extracted during the extraction process) from which the pure forms are further extracted or separated. Solvent extraction produces a mixture of many phenolic components which have to be separated from each other to be quantified or further utilized. Separation methods generally depend on the nature of extract and the end use of the desired separated component. It generally can be accounted as a purification method used to obtain a purer extract. It has typical application to characterize the compounds present in the extract using different analytical methods. It is also used for quantification of different components present in the extract or for the production of concentrated compounds to be marketed as a nutraceutical food. These can also be used as chemical standards or used for analysis of the biological effects during various animal tests or clinical trials. The separation and purification of different phenolic compounds is often required because some phenolic compounds interfere during the analytical procedures, thus affecting the characterization and quantification of different compounds present in an extract.

To separate the plant material from the extract, centrifugation for 15–20 min at 20,000–25,000 *g* is applied [126]. Ultrafiltration can also be used for separation of polyphenols; however, it depends on the particle size of the polyphenolic molecules. Generally, particles with a molecular weight of 3,000–100 kDa and higher can be separated using the regular ultrafiltration membranes [36].

The extraction solvents are then evaporated in the rotary evaporator under vacuum condition to concentrate the extract, to which other solvents can be added for purification and separation. Solubility of compounds in different solvents and pH are important criteria used for the separation and purification of polyphenolic compounds. Separation of phenolic compounds from the mixtures of compounds can be done using solvent separation methods and various chromatographic methods (including solid-phase extraction).

4.1 Liquid-Liquid Phase Separation

Liquid-liquid phase separation or solvent separation basically depends on the difference in solubility of the different compounds in different solvents. In case of crude extracts of flavonoids obtained after extraction using polar solvents such as methanol and water, many other impurities such as chlorophyll and lipids might be present. These can be removed by shaking with a small volume of petroleum ether or can be washed with hexane. The petroleum ether layer containing the green chlorophyll part is discarded, and the process is repeated until there is no green segment in the extract. The free sugars still present in the purified extract can be separated using ether (fraction containing glycosides) and ethyl acetate (fraction containing aglycones). However, if very polar glycosides are present in the aqueous residual part of the extract, they can be further purified using different methods of chromatography [22]. According to another liquid-liquid phase purification method, extraction of phenolic compounds from defatted/depigmented aqueous extract can be done with ethyl acetate to which ammonium sulfate (20%), metaphosphoric acid (2%), and ethanol (20%) are added, which are necessary for quantitative extraction of the phenolic compounds [126]. However, with this method, anthocyanins are not extracted as they are insoluble in ethyl acetate and remain in the aqueous phase. Acid and alkaline hydrolysis is also carried out for purification of polyphenolic compounds. The O-glycosides and esters of phenols and phenolic acids can be hydrolyzed by heating the concentrated aqueous-alcohol extract with reflux under N_2, using 2 M HCl; after cooling, the aglycones can be separated with suitable solvents such as diethyl ether and ethyl acetate. For alkaline hydrolysis, 2 M NaOH can be used under the similar conditions; however, before separation, acidification is applied where addition of borax to alkali prevents the oxidation of cinnamic acid and benzoic acid derivatives. The extract can be partitioned against different solvents of increasing polarity as well, such as petrol, n-hexane, chloroform, diethyl ether, ethyl acetate, and n-butanol, where generally most aglycones remain in the nonpolar fractions and glycosides and sugar esters are dissolved in more polar and aqueous fractions. In case of lignin analysis, different oxidation, reduction, and solvent-based methods have been summarized by Monteis in “Plant Phenolics” [22].

4.2 Chromatographic Separation/Purification Methods

Chromatographic methods are the separation methods where the constituents of a mobile phase (solvent or fluid carrying the extracted compounds) are separated using a stationary phase (a medium used in chromatography through which the solvent or fluid with extracted compounds is passed). There are many chromatographic methods which can be applied for separation of phenolic compounds; however, some are more prevalent than the others because of their convenience of use and efficiency and degree of utility in terms of end result. These methods can be preparative or analytical methods or both, and some methods are quantitative as well. The basic principles of certain methods and their utility in certain cases have been briefly discussed, which include paper chromatography, thin-layer chromatography, solid-phase extraction, high-performance liquid chromatography (HPLC), and gas chromatography (GC). Solid-phase extraction (SPE) is presented separately in the following subsection. It is one of the most widely used preparative separation methods.

Paper chromatography is used for separating and identifying the compounds present in the mobile phase depending on their solubility in the mobile phase and their adsorption capacity on the stationary phase. This technique is mostly used for phenolic compounds soluble in water (mainly flavonoid glycosides) [22]. It has been used for different phenolic compounds like gallic acid, vanillin, and hydroquinone [127]; and flavonoid pigments [128, 129]. Identification can be done using the tabular data on known compounds, by comparing the distance traveled by phenols on the stationary phase in a particular study with the tabular record on phenols summarized on the basis of previously observed interpretations. One of the greatest disadvantages of this method is the low resolving power and longer duration required for characterizing closely similar compounds [22]. Thin-layer chromatography (TLC) is another chromatographic method based on the difference in adsorption rate and movement up the plate due to capillary action of the phenolic components dissolved in different solvents. The plate (stationary phase) is generally glass, plastic, or aluminum coated with thin layers of silica gel or polyamide or microcrystalline cellulose. Less-hydrophilic phenolics have been reported to be successfully separated with TLC using silica gel and polyamide, and cellulose matrices have been found to be helpful for hydrophilic phenolic compounds. TLC has also been reported in many cases [130–132] for its flexibility in the choice of solvents, and TLC separation has been found to be more time efficient than paper chromatography [22]. However, SPE has been found to be a more helpful method than TLC for qualitative and quantitative separation of phenolic compounds and has the advantage of having the ability to be combined with HPLC for further analysis. For the successful characterization and quantification, more precise methods like HPLC have been found to be more helpful.

HPLC is a liquid chromatography method which has been applied for combined separation, quantification, and characterization of phenolic compounds. HPLC has been applied for different kinds of phenolic compounds [28, 133, 134], and one of the major advantages of HPLC is the simultaneous characterization and quantification of a variety of different compounds in a relatively short period of time based on their retention time and retention factor. Gas chromatography is another useful quantitative method used for simultaneous separation, detection, and quantification of many phenolic compounds, mostly restricted to volatile samples and for the phenolic compounds with low boiling point [22]. These methods are discussed in detail in ▶ Chap. 67, "Analytical Methods of Phenolic Compounds."

4.3 Solid-Phase Extraction (SPE)

SPE has been found to be an economical, easy preparative technique for separating the components from a mixture of different compounds. SPE is an efficient method which can be used for purification, concentration, and/or isolation. Polyphenols can be fractionated as neutral and acidic groups using methods based on solid-phase extraction or can be separated into anthocyanin-containing fraction and non-anthocyanin fraction, which makes the fraction easier to be analyzed [12]. Different protocols regarding use of SPE to separate different fractions of phenolic extract have been discussed in the "Handbook of Food Analytical Chemistry-Pigments, Colorants, Flavors, Texture, and Bioactive Food Components" [12]. During SPE, extracts are passed through different columns with different sorbents. Either the unwanted compounds from the extract get adsorbed on the sorbents which are removed by washing with different solvents in which they are soluble, or different desirable compounds are adsorbed which are fractionated by eluting using different solvents in definite sequences [135].

For SPE, different types of sorbents are used in the case of the separation of polyphenolic compounds such as alkylated silica gels principally C8 and C18 and also the combination of different cartridges with different sorbents such as C18 and quaternary amine [36]. The different cartridges have different characteristic features which make them more suitable for separation of certain phenolic compounds than others; however, the efficiency differs with the property of the different compounds as well. The potential of any SPE also depends on the solvents used for elution and the sequence of their application. Alkylated silica gel cartridges are hydrophobic in nature and have been suggested as a good method of separation for flavonoids and phenolic acids. With different C18 solid-phase support, the adsorption properties of the cartridges are modified [136], including physical properties, carbon loading, and pore size [126]. If the average pore size is high, then the retention capacity increases because of the "stronger interactions between the nonpolar surface and analyte" [126]. The capacity factor and carbon loading have been found to have a close linear relationship, which implies that higher carbon loading leads to greater retention of the ionized form of phenolic acids. Sep-Pak C18 cartridges have been used for the purification of phenolic compounds in many cases [12, 137–141]. Sephadex LH-20 is another liquid chromatography medium, which is beaded, cross-linked dextran, and has been hydroxypropylated for the matrix to be both hydrophilic and lipophilic in nature [142]. In this case, the separation is based on the extent of hydrogen bonding between the molecules and the matrix [126, 143], which also depends on the number of phenolic hydrogens per molecule. Sephadex LH-20 is useful for cleanup and had also been used for the separation of compounds such as condensed tannins [144], catechin [143], and fractionation of proanthocyanidin/condensed tannins [126] and also for other phenolic compounds [145]. Sephadex G-25 and G-50 which are generally used in gel filtration chromatography (which is a size-exclusion chromatography, based on size and/or shape of molecules) have also been used for purification of phenolic compounds and fractionation as well (especially proanthocyanidin or condensed tannins) [22, 146–148]. In this case, larger molecules which generally have less access to the pore volume elute before the smaller ones. Many other stationary phases are used for the separation, purification, and fractionation of phenolic compounds such as Amberlite XAD resins [149, 150], Serdolot PAD IV [149], and polyamide (for column chromatography) [151, 152]. In the case of polyamide column chromatography, hydrogen bonding between phenolic hydroxyl groups and amide has also been observed, because of which it has been applied for separating phenolic substances. During a comparative study regarding the applicability of different Amberlite XAD resins in flavonoid analysis, polystyrene resins were detected to be more appropriate for fractionation of flavonoids than polyacrylic resins. For fractionation and recovery of flavonoids from plant sources, Amberlite XAD-2 was reported to be more fitting [153].

Solvents used for elution in various cases are different, and the order of use also makes differences. For fractionation of polymeric proanthocyanidins, the solvent combination used is acetone with water which is applied for both Sephadex G-50 and LH-20 [22, 154]. The elution of solvents depends on the solubility of specific phenolic components in specific solvents. Anthocyanins are not soluble in ethyl acetate; however, many other polyphenolic compounds are soluble in ethyl acetate. Hence, in the protocol mentioned in the book "Handbook of Food Analytical Chemistry-Pigments, Colorants, Flavors, Texture, and Bioactive Food Components" for the separation of anthocyanins from the rest of the components in a polyphenolic extract, ethyl acetate is used for elution of the polyphenolic components other than anthocyanins, while the anthocyanins are eluted with acidic methanol [12]. pH is another important property affecting the separation of polyphenols through SPE. Phenolic acids have been reported to be "completely ionized at pH 7.0 and un-ionized at pH 2.0"; hence, this property is used as the basis for fractionation of neutral polyphenolics at pH 7.0 and acidic polyphenolics at pH 2.0, which helps in prevention of interference in-between polyphenolic compounds during HPLC [12]. In certain cases, combination of various SPE methods is used for the fractionation of the extracts, and then the purified extracts are further processed to be analyzed [140, 141, 150].

There are several analytical steps carried before SPE, and in some cases, SPE is followed by several analytical steps as well. Preconditioning of the matrices for achieving a certain pH level or a certain physical condition, washing of the cartridges with appropriate volumes of the solvent (e.g., 0.01 N aqueous HCl) to remove other unwanted components, and drying of cartridges with N_2 to prevent exposure to O_2 (leading to possible oxidation of polyphenols) are some of the important steps necessary to follow in a particular sequence [12]. After SPE with the proper solvents, the solvent containing the phenolic group of interest for further analysis is sometimes concentrated using rotary evaporator (preferably at temperature set at 40 °C or lower, keeping in mind the degradation temperature of different phenolic compounds). Overall success of SPE methods for the separation of polyphenols depends on the compound to be separated, nature of the other expected components of the extract, nature of solvent and the SPE matrix, and the overall order of the entire process, depending on the ultimate requirements.

5 Conclusion

Extraction of polyphenolic compounds is an important part of many analytical methods and in the production of phenolic concentrates for the nutraceutical industry. Standard solvent extraction method is still the most used extraction method; however, other advanced solvent-based extraction methods, such as ASE, SFE, UE, and MAE, are currently becoming more widely used extraction methods. With advancement of technologies and changing requirements, existing methods are improving, and new methods are being devised. Separation methods are an integrated part of the entire extraction process which contribute significantly in the improvement of the quality of the end product and increase in the rate of repeatability of the results. Because of the complexity of phenolic compounds, many separation methods have been applied, and for specific compounds, some protocols have been found to be more efficient. Solid-phase extraction method has been found to be the most applied separation method in case of phenolics and might retain its popularity for the time being, unless and until some other more efficient method of separation is devised. In future, we hope for the development of much more advanced methods which will contribute potentially in improving the polyphenolic compounds extraction further and increase the use of environmentally helpful processes, simultaneously making the extraction method simpler, less time consuming, and more accurate.

Abstract

Phenolics are an important class of natural products that have received immense interest for their remarkable biological activities. These are widely distributed in the plant kingdom. Nowadays, increasing attention is paid on rapid identification and characterization of phenolic acids from natural sources. This chapter particularly emphasizes on the diverse mass spectrometric application for the detection of phenolic acids, and several aspects related to fragmentation behavior of phenolic acids are discussed.

1 Introduction

Crude plant extracts contain several hundreds of secondary metabolites of varying chemical nature and spectroscopic parameters. Several of these compounds are also present as conjugates within the cell and are difficult to separate from the tissue matrix. Extraction, chromatographic purification, or isolation is thus important for the detection, identification, and quantification of such compounds. Several chromatographic methods such as paper chromatography (PC), thin layer chromatography (TLC), high-performance liquid chromatography (HPLC), and gas chromatography (GC) have been standardized for the purpose of isolation and quantification of secondary metabolites. These instruments when coupled to detectors, the most popular being the UV–vis detector for HPLC may detect a separated compound; however, identification depends on matching the retention time to that of a known standard compounds and pattern of UV–vis scan if a diode array detector is available largely limiting the process to previously known reported compounds. In addition to univariate identification, e.g., retention time in chromatography, and wavelength/frequency in spectrometry, the use of mass spectrometry is an excellent tool to define the chemical identification.

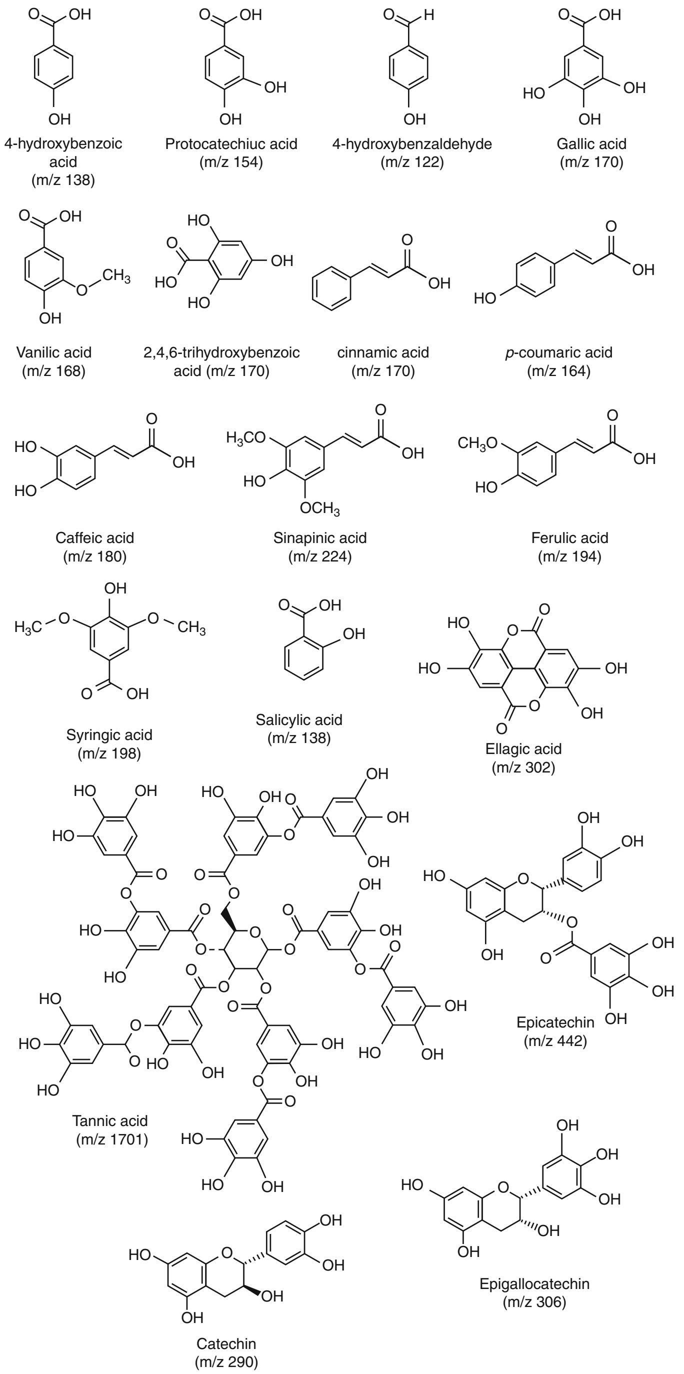
The first application of mass spectrometry to the analysis of biomolecules was reported in 1958 [1]. In 1989, Hans Dehmelt and Wolfgang Paul were awarded half of the Nobel Prize in Physics for the development of the ion trap technique in the 1950s and 1960s. Again, in 2002, the Nobel Prize in Chemistry was awarded to John Bennett Fenn for the development of electrospray ionization (ESI) and Koichi Tanaka for the development of soft laser desorption (SLD) and their application to biological macromolecules, especially proteins [2]. Mass spectrometry (MS) is an excellent analytical tool in modern techniques that measures the mass-to-charge (m/z) ratio of charged particles. Now, it is regularly used for determining masses of biomolecules, elemental composition of a sample or molecule, and elucidating the chemical structures of molecules, such as peptides and other chemical compounds [3].

The function of a mass spectrometry is divided into three major units: ionization source, mass analyzer, and detector. The method of sample introduction to the ionization source depends on the ionization procedure. Many ionization methods have been developed [4], and instruments are named accordingly. Each ionization procedure has its own advantages and disadvantages. The ionization techniques are atmospheric pressure chemical ionization (APCI), electron impact ionization (EI), chemical ionization (CI), thermospray ionization (TSP), field desorption ionization (FDI), fast atom bombardment (FAB), electrospray ionization (ESI), and matrix-assisted laser desorption ionization (MALDI). The ESI and MALDI ionization techniques have been widely used in biomolecules detection. The ionization procedure is involved in the formation of molecular ions; both positively and negatively charged ions are generated depending on the proton affinity of the sample. The ionization source chamber must be conducted in vacuum (atmospheric pressure 760 Torr) because ions are very reactive and short-lived. The pressure under which ions may be handled is roughly 10^{-5}–10^{-8} Torr (less than a billionth of an atmosphere). After ionization, it is separated by accelerating and focusing the ions in a beam, which is then bent by an external magnetic field. The ions are then detected electronically and analyzed in a computer-based algorithm.

The most intense ion is assigned an abundance of 100 and is referred as base peak. Most of the ions formed in a mass spectrometer have a single charge, so the m/z value is equivalent to mass itself. The highest-mass ion in a spectrum is normally considered to be the molecular ion, and lower-mass ions are fragments from the molecular ion. Fragmentation of molecular ion carries the significant message for structure and composition of a molecule. Taken into account, tandem mass spectrometry (MS/MS) is powerful tool than only MS to determine the accurate structural information and identification of biomolecules. In tandem mass spectrometry, the gas-phase ion is fragmented with different stages of mass analysis. There are different types of fragmentation and several methods of fragmentation of the ions have been reported [5]. The data acquisition in tandem mass spectrometry occur through different modes. Among them, product or daughter ion scan is particularly useful for providing structural information concerning phenolic acids. The first analyzer is used to select specified sample ions or molecular ions $[(M + H)^{+}$ or $(M-H)^{-}]$ arising from a particular component. Then, it passes into the collision cell and is bombarded by the gas molecules, resulting in generation of fragment ions. These fragment ions are separated according to their mass-to-charge ratios by the second analyzer. Fragment ions arise directly from the precursor ions and produce a fingerprint pattern specific to the compound.

2 Plant Phenolic Compounds

Phenolic compounds are widely distributed in the plant kingdom with approximately 8,000 characterized structures and represent a class of plant bioactive secondary metabolites having one or more hydroxyl groups attached to an aromatic ring (benzene), phenol being the structure on which the entire group is based (Fig. 66.1). They are weak acids due to the aromatic ring which renders the hydrogen of the phenolic hydroxyl labile. The phenolic compounds are generally found in the bound form as glycosides in the cytosol and lignins as attached to the cell wall.



4-hydroxybenzoic acid (m/z 138)
Protocatechiuc acid (m/z 154)
4-hydroxybenzaldehyde (m/z 122)
Gallic acid (m/z 170)
Vanilic acid (m/z 168)
2,4,6-trihydroxybenzoic acid (m/z 170)
cinnamic acid (m/z 170)
p-coumaric acid (m/z 164)
Caffeic acid (m/z 180)
Sinapinic acid (m/z 224)
Ferulic acid (m/z 194)
Syringic acid (m/z 198)
Salicylic acid (m/z 138)
Ellagic acid (m/z 302)
Tannic acid (m/z 1701)
Epicatechin (m/z 442)
Epigallocatechin (m/z 306)
Catechin (m/z 290)

Fig. 66.1 Structural representation of some simple and compound phenolic acids

As the phenolics incorporate a diverse group of compounds, several classifications are available, namely:

- Swain and Bate-Smith [6] – "common" and "less common" categories.
- Harborne and Simmonds [7] – based on the number of carbon atoms in the molecule (C_6: simple phenolics; $C_6 - C_1$: phenolic acids and related compounds; $C_6 - C_2$ acetophenones and phenylacetic acid; $C_6 – C_3$: cinnamic acids, cinnamic aldehydes, cinnamyl alcohols, coumarins, isocoumarins and chormones; C_{15}: chalcones, aurones, dihydrochalcones; flavans, flavones, flavanonols, anthocyanidins, C_{30}: biflavonyls; $C_6 - C_1 - C_6$, $C_6 - C_2 - C_6$: benzophenones, xanthones, stilbene; $C_6 - C_6$, C_{10}, C_{14}: quinones, C_{18}: betacyanins; lignans, neolignans (dimmers and oligomers); lignin (polymers); tannins (oligomers, polymers).
- Ribereau-Gayon [8] grouped the phenolic compounds in three groups: widely distributed phenols, less widely distributed, polymers.

Three different metabolic pathways are known to be involved in the synthesis of different classes of phenolic compounds, namely, (1) ($C_6 - C_3$) phenylpropanoid derivatives produced by the shikimate/chorismate pathway; (2) side chain elongated phenylpropanoids, flavonoids ($C_6 - C_3 - C_6$), and few quinones synthesized by the acetate/malonate or polyketide pathway; and (3) the aromatic terpenoids synthesized through the acetate/mevalonate pathway.

Phenolic compounds play a major role in the physiology and biochemistry of plants and are involved in plant defense as phytoalexins, antifeedants, pollinator attractants, antioxidants, and protective agents against UV light and plant pigmentation to name a few. Exposure of the subepidermal layers of plant tissue to biotic and abiotic stress often triggers the production and accumulation of characteristic phenolic derivatives [9, 10]. Elicitations by pathogens or pathogenic determinants elevate the amount of phenolic compounds in plant tissues that are involved in defense signaling within plants and the development of systemic acquired resistance [11]. They are important contributors to plant growth and reproduction and determinants of sensory and nutrition quality in fruits and vegetables. Biosynthesis of phenolic compounds in chloroplasts is enhanced in the presence of light [12]. While, photoinhibition and several nutrition stress conditions may also trigger the accumulation of phenylpropanoids in some plants species [13, 14]. Simple phenolic acids are important determinants of nodule formation in plants [15, 16]. The antimicrobial [17, 18] and antioxidant properties of these compounds have been traditionally utilized in disease prevention and cure in humans and are active ingredients of several indigenous drugs. In the industry, polyphenols are utilized as food preservatives, natural colorants, and in the production of paints, paper, cosmetics, and nutraceuticals.

3 Isolation, Detection and Characterization of Phenolic Compounds

Chromatography techniques, most commonly TLC (thin layer chromatography) and HPLC (high-performance liquid chromatography), are the most popular methods for the separation and detection of phenolic compounds. In recent years, HPLC is coupled to DAD (diode array detector) and later mass spectrometers (MS) for better characterization. While DAD distinguishes the compounds based on their characteristic UV–vis spectrum, MS enables access to intact molecular as well as fragment ions enabling the determination of both molecular weight and structural features. However, with the increasing complexity and molecular mass of phenolic compounds and the presence several regio- and stereoisomers, there is a subsequent decrease in the resolution of chromatographic profiles.

4 Mass Spectrometry in Phenolic Acids Characterization

Several analytical tools coupled to mass spectrometers as GC-MS (gas chromatography) and LC-MS (liquid chromatography), including ICP-MS (inductively coupled argon plasma), SCF-MS (supercritical fluid), NMR-MS (nuclear magnetic resonance), and IR-MS (infrared-MS), are routinely used to determine the phenolic acids. With the development of soft ionization techniques, fast atom bombardment (FAB) [19] and plasma desorption (PD) [20], followed by the electrospray ionization (ESI) [21], have been used for phenolic acid analyses.

4.1 GC-MS

Gas chromatography (GC) has been widely utilized in the detection of phenolic compounds from plants. Most of the earlier detectors involved flame ionization, a major concern being the low volatility of phenolics [22–24]. Analysis of phenolic compounds by GC generally requires derivatization of the hydroxyl group (which increases the melting point by H-bond formation) to ethers or esters, although some reports are available on detection of underivatized acids [25]. Phenolic compounds are present in a complex matrix in the plant tissues and are moreover sometimes glycosylated increasing the difficulty of the derivatization process. However, the coupling of GC and MS increases the quantum of information that can be obtained from the analyte facilitating accurate identification [26]. Trialkylsilyl group is the most common derivative generated by covalently linking the alkyl-substituted silicon atom to the hydroxyl oxygen. The process is simple with both functional groups (acid and phenol) derivatized in the same step and is either mostly free of unwanted side products or the by-products are volatile and do not interfere with the analysis. Some derivatives may become unstable on exposure to moisture in air, which can be prevented by keeping them in an organic solvent after removal of solvent from the reaction step. Among the various commercially available silylating reagents are *N*,*O*-bis(trimethylsilyl)acetamide (BSA), *N*,*O*-bis (trimethylsilyl)trifluoroacetamide (BSTFA), and *N*-methyl-*N*-(trimethylsilyl) triflouroacetamide (MSTFA). Fused silica columns are popular for the analysis of phenolic compounds in GC with lengths varying from 25 to 30 m and inner dimensions from 0.25 to 0.5 mm. DB5 is the most common coating material used which contains 5 % phenyl silicon and 95 % methyl silicone. Gradient methods are

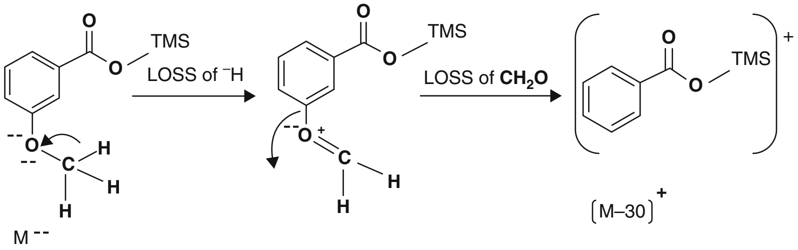


Fig. 66.2 Mechanism for the loss of formaldehyde and formation of ion [M-30]

preferred over isothermal methods with rate increments varying from 2 °C to 40 °C with the initial column temperature ranging from 40 °C to 140 °C.

In comparison to FID, MS performed in the electron ionization mode (EI), where electrons are removed from the analyte by an electron beam, has become the method of choice for GC separated samples. The high reproducibility of the method has made possible the construction of entire MA libraries such as NIST (www.nist.gov). The ionization voltage is normally set at 70 eV and spectra collected from *m*/*z* 39–650 in a continuous scanning mode. The cleavage patterns of several silylated phenolic isomers are dissimilar providing additional criteria of identification of complex compounds. Silylation of the hydroxyl groups generates distinct fragmentation patterns, and generally, the [$M^{+\bullet}$] is a prominent peak in the mass spectrum. Some of the phenolic compounds are exceptions such as gentisic acid which poses a substituent at the 2-position of the benzene ring. For these analytes, generation of the [M-15] fragment, loss of methyl group via alpha-cleavage is observed in both TMS ethers and esters and provides a base peak. In several analytes, like cinnamic acid (*m*/*z* 161), *p*-coumaric acid (*m*/*z* 249), and *p*-benzoic acid (*m*/*z* 223), TMS esters undergo subsequent fragmentation generating the [M-59] fragment. CO_2 is expelled subsequent to the loss of methyl group from the TMS group after rearrangement resulting in [M-59]. For derivatized carboxylic groups, loss of *O*TMS is also a common fragmentary pathway. The cleavage of the methoxy substituent of the phenyl ring yields the predominant [M-30] fragment (Fig. 66.2).

The base peak of sinapic acid and ferulic acid is produced by similar pattern of fragmentation. A [M-117] peak is generated for gallic, caffeic, and protocatechuic acids on fragmentation. Chemical ionization (CI) is also employed in some GC-MS systems where an electron beam is used to ionize a gas (methane or ammonia), which subsequently ionizes the analyte. This method gives more prominence to the molecular ion and results in less ionization.

4.2 LC-MS/MS and LC-ESI-MS

HPLC has been widely used for the separation and characterization of phenolic compounds, and reverse phase (RP) column is the most popular, and there are several reviews on the topic. RP-C_{18} is the preferred column with column diameter

Table 66.1 Identification of molecular ion and fragmented ions from different phenolic acids

Compounds	MW	$[M + H]^+$	MS/MS
4-Hydroxy benzoic acid	138	139	93, 97
3,5-Dihydroxybenzoic acid	154	155	80, 97, 108, 126, 136
4-Hydroxybenzaldehyde	122	123	57, 65, 71, 81, 92, 97, 107, 121

Vanillic acid	168	179	
2,4,6-Trihydroxybenzoic acid	170	171	52, 69, 85, 126
Cinnamic acid	148	149	63, 73, 77, 103, 131, 135, 145
p-Coumaric acid	164	165	145, 119
Caffeic acid	180	181	61, 73, 117, 147
Sinapinic acid	224	225	112
Ferulic acid	194	195	91, 102, 117, 139, 145, 160, 175
Syringic acid	198	199	78, 89, 95, 106, 122
Salicylic acid	138	139	93, 137
Ellagic acid	302	303	78, 151, 190, 228, 246
Catechin	290	291	55, 68, 91, 111, 119, 123, 139, 147, 161
Epigallocatechin	306	307	289
Epicatechin gallate	442	443	289
Epigallocatechin gallate	458	459	289

ranging from 2.1 to 5 mm, particle size 3–5 μm, and column length 100–300 nm, although several smaller sized columns are also used currently. Acidic aqueous solvent systems comprising mainly methanol and acetonitrile with predominately linear gradients are employed. UV–vis with photodiode array (PDA) detection is a common method to detect phenolic acids which have characteristic spectrum at wavelengths from 190 to 380 nm.

Recently, a series of literature has been published on LC-MS/MS analysis of both simple/compound phenolic acids and flavonoids. The major advantage of LC-MS/MS is that simultaneously retention time and MS data could be consider for identification of natural phenolic acids. The common fragment for all simple phenolic acids in MS/MS spectra in negative mode is $[M–H–CO_2]^-$ formed by elimination of a carboxy group from deprotonated molecular ions. Several phenolic acids conjugate with glycosides that also produce some common fragmentation ions during MS/MS analysis. The cleavage of intact sugar and aglycon fragments in MS/MS revealed the nature of glycosides. LC-MS/MS analysis produces fragmented ions that are useful for correct chemical identity of the compounds. Identification is aided by comparisons with standard references or by previous reports. Table 66.1 lists a series of phenolic acids and their MS/MS fragmented patterns where few fragmented ions are specific to compound identity. LC-ESI-MS technique is straightforward than LC-MS/MS where fragmented ions are less in number. We have applied some standard phenolic acids in LC-ESI-MS, and their reference spectra are shown in Fig. 66.3.

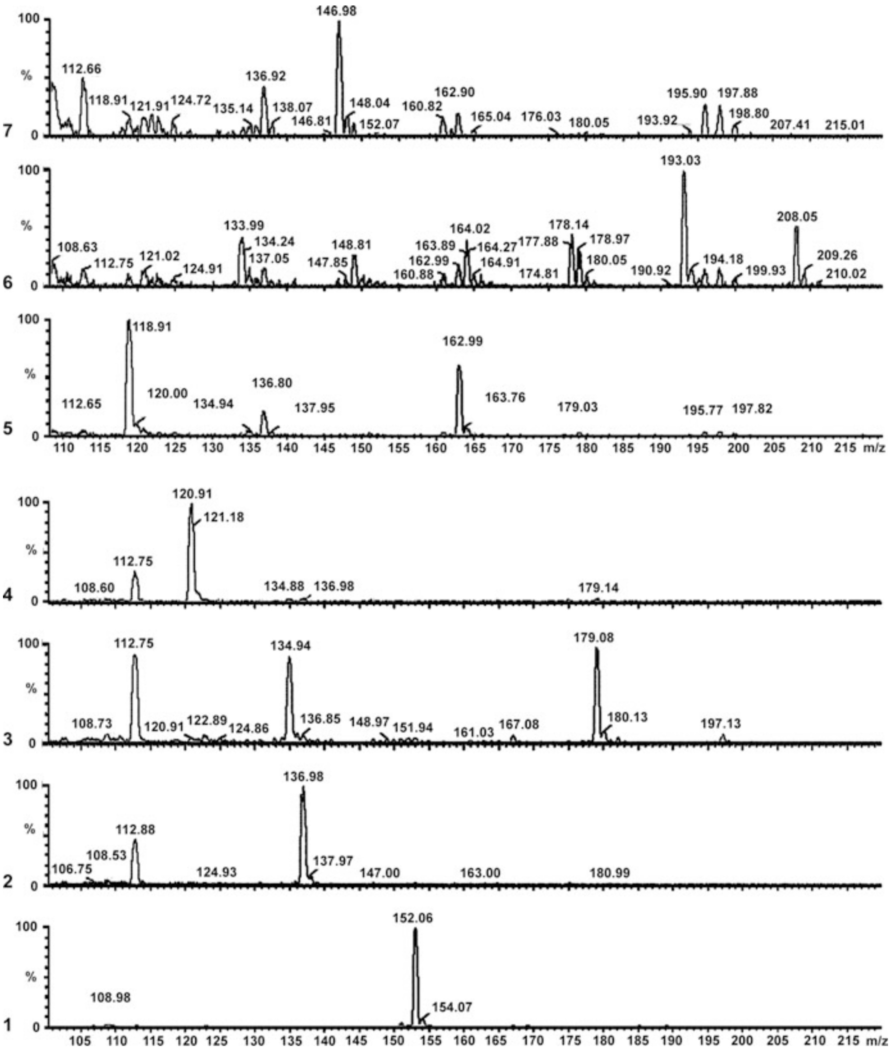

Fig. 66.3 ESI-MS spectrum of individual phenolic acids. Spectra of phenolic acids are marked as number *1* protocatechuic acid, *2* *p*-hydroxybenzoic acid, *3* caffeic acid, *4* *p*-hydroxybenzaldehyde, *5* *p*-coumaric acid, *6* ferulic acid, and *7* cinnamic acid

4.3 MALDI-TOF MS

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is also an efficient tool for large biomolecule analysis [27]. MALDI-TOF MS has several advantages over other methodologies, including speed of analysis, high sensitivity, and wide applicability with a good tolerance toward contaminants, and ability to analyze complex mixtures [28].

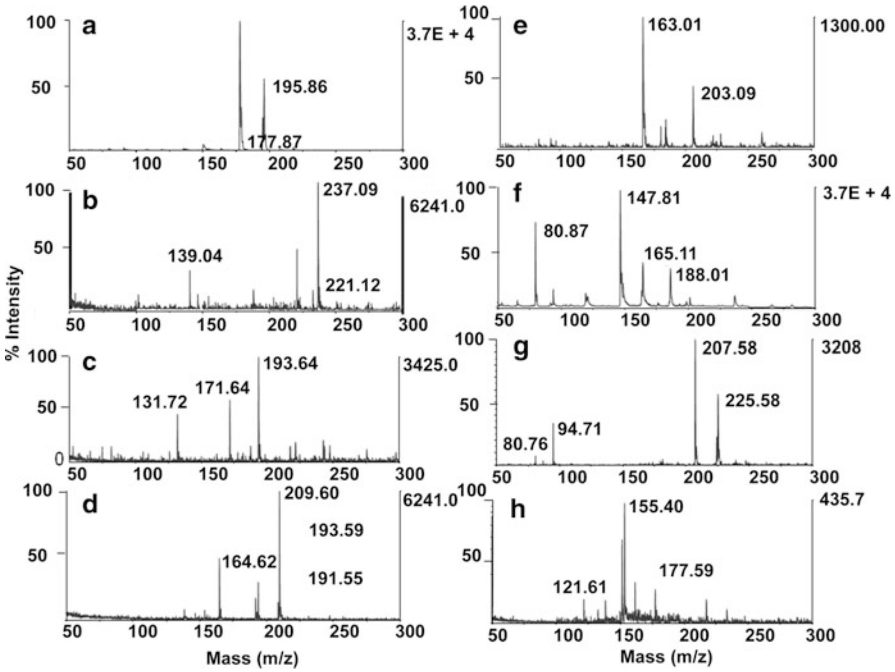

Fig. 66.4 Representative MALDI-TOF MS spectra of phenolic acids. MALDI-TOF MS spectra of phenolic acids are marked as number (**a**) ferulic acid, (**b**) syringic acid, (**c**) cinnamic acid, (**d**) gallic acid, (**e**) caffeic acid, (**f**) *p*-coumaric acid, (**g**) sinapic acid, (**h**) dihydroxybenzoic acid

Recently, the applications of MALDI-TOF MS have been extensively used in food analysis for oligomeric polyphenol and anthocyanin detection [29, 30]. Attempts have been made to characterize a series of phenolic acids using MALDI-TOF MS. Interestingly all the phenolic acids were ionized directly devoid of MALDI matrix. In general, matrices are used in MALDI technique to absorb the laser wavelength which cause codesorption of the analyte upon laser irradiation and promote analyte ionization. Phenolic acids absorb the nitrogen laser wavelength (337 nm) and cocrystallize on MALDI steel plate with solvent acetonitrile or methanol [31].

MALDI-TOF spectra of several standard phenolic acids were obtained in positive ion linear mode under a Voyager DE^{TM} Pro (Fig. 66.4). Spectra acquired from ferulic acid showed major ions at m/z 195 corresponding to the protonated $[M + H]^+$ mass of ferulic acid and with loss of one water molecule $[-H_2O]$ show a fragment ion of m/z 177. Direct MALDI-TOF analysis of syringic acid shows major ions at m/z 237 and m/z 221 which might be speculated in the addition of one potassium ion $[M + K]^+$ and one sodium ion $[M + Na]^+$, respectively. MALDI-TOF MS of polyflavons tend to favor an association with sodium $[M + Na]^+$ and potassium $[M + K]^+$ ions over the formation of a protonated molecular ion $[M + H]^+$ [32]. Another ion was observed at m/z 139 corresponding to the loss of $[CO_2 + CH_3]$ ion, i.e., [M- (CO_2 + CH_3)]$^+$. In case of cinnamic acid analysis, two major ions were observed as m/z 193 [M + 2Na] $^+$ and m/z 171 [M + Na]$^+$ indicating the successive addition of two sodium ions. One fragmented ion from cinnamic acid was observed at m/z 131 represents the loss of [OH] ion, [M-OH]$^+$. For gallic acid, the analysis is straightforward and it has the affinity to combine with both sodium and potassium ions, representing as m/z 193 [M + Na]$^+$ and m/z 209 [M + K]$^+$. Caffeic acid revealed only sodium ion addition as m/z 203 [M + Na]$^+$ and one fragmented ion, m/z 163, comes from the loss of one –OH ion. *Para*-coumaric acid is a naturally abundant simple phenolic acid which showed one major ion with addition to sodium, m/z 188 [M + Na]$^+$, and one molecular ion without addition of any metal ion, m/z 165 [M + H]$^+$. The fragmented ions from p-coumaric acid were m/z 147 and m/z 80 corresponding to the loss of one water molecule [M–H_2O]$^+$ and loss of [M–CO_2–C_3H_5]$^+$, respectively. Similarly, sinapic acid also showed ion, m/z 225 [M + H]$^+$, and fragmented ions were m/z 207 due to the loss of one water molecule. Dihydroxybenzoic acid represents the intact molecular ion m/z 155 [M + H]$^+$ and with addition with one sodium ion, m/z 178 [M + Na]$^+$. So, a general trend was observed for MALDI-TOF MS analysis of phenolic acids that addition of naturally occurring metal ions [Na or K] was universal. Moreover, the analysis is very simple and straightforward due to the absence of excessive fragmented ions.

5 Conclusion

Phenolic compounds are important bioactive constituents derived from plants and are active ingredients in traditional medicine, pharmaceuticals, and nutraceuticals. Extraction process for phenolic acids requires standardization as within plant tissue they can stay either in the soluble fraction or as conjugates with carbohydrates or linked to cell wall components. HPLC is by far the most popular method of separation. Mass spectrometers, especially LC-MS and MALDI-TOF, provide a viable rapid and accurate method of identification and characterization of the simple phenolic acids.

Abstract

Polyphenols are the most important phytochemicals found in a variety of fruits, vegetables, and plant-based foods. Currently there is an increasing interest for the separation, characterization, and valorification of these compounds due to their bioactive properties, health benefits, and potential use as natural antioxidants in foods, pharmaceuticals, and cosmetics.

The samples preparation and extraction of phenolics from source materials is the first step involved in their analysis. While colorimetric methods are used for determination of different classes of phenolics, chromatographic and

1 Introduction

Polyphenols are a widespread group of secondary metabolites found in plants derived from phenylalanine and tyrosine, and they are characterized by the presence of several phenol groups (i.e., aromatic rings with hydroxyls) [1]. Plant phenolics include simple phenols, phenolic acids (benzoic and cinnamic acid derivatives), coumarins, flavonoids, stilbenes, hydrolysable and condensed tannins, lignans, and lignins [2, 3].

Polyphenols have received tremendous attention among nutritionists, food scientists, and consumers due to their biological activities and health-promoting benefits [2].

Phenolic compounds are important antioxidants, because of their high redox potentials. They act as reducing agents, hydrogen donors, singlet oxygen quenchers, and as metal-chelating agents [4].

These valuable properties of polyphenols are attracting a great deal of attention due to increasing evidence suggesting that they may prevent different chronic affections such as cancer, atherosclerosis, and neurological diseases [5].

On the other hand, polyphenols have many industrial applications, being used as natural colorants and preservatives in cosmetic or food industry [6].

Characterization of phenolic compounds requires methods that are comprehensive, rapid, and rich in spectral information.

The methodology used to analyze these compounds in plant-based materials, generally, includes a series of steps ranging from exhaustive solvent extraction, clean-up of extracts, and preconcentration procedures to simple filtration and centrifugation in liquid samples. After the extraction procedures, the phenolic compounds are characterized and quantified [7, 8]. Various complex analytical methods have been used for the determination of these compounds in natural samples and the most important of them are described in detail in this chapter.

2 Sample Pretreatment

Before the extraction and isolation of polyphenols, samples containing these compounds must be collected, preserved, and properly prepared.

According to their nature, the sources of phenolic compounds can be classified in liquid samples (beverages such as juice, tea, coffee, wine, biological fluids, etc.) and solid samples (fruits, vegetables, medicinal plants, by-products resulted from industrial processes, etc.).

The solid samples must be air-dried, frozen, sometimes with liquid nitrogen or freeze-dried [9–12], to remove the moisture that can significantly influence the extraction process. To improve the extraction process, the solid must be grounded and reduced to small particles to increase the contact surface between the raw material and the solvent and to reduce the extraction time because, theoretically, extraction time varies inversely with the square of the characteristic dimension of the solid particles.

Care must be taken to minimize the loss of compounds of interest during transportation, preparation, and preservation of the samples [2].

Heating and exposure to light and oxygen may affect the polyphenolic composition in many cases; therefore, high-temperature drying should be avoided as much as possible [13, 14].

The liquid samples requires less pretreatment than the solid ones, and in this case, they are usually freeze-dried, filtered, centrifuged, or directly submitted to the isolation step or sometimes directly submitted to the analysis [14, 15].

3 Extraction of Polyphenols

3.1 Extraction Conditions

The extraction of phenolic compounds from plant materials is considerably influenced by some factors such as: the nature of the sample, the chemical structure of polyphenols, the extraction method employed, the extraction agent involved, sample particle size, as well as the presence of interfering substances.

The chemical nature of plant phenolics varies from simple molecules (phenolic acids) to complex polyphenols such as flavonoids, anthocyanins, and highly polymerized substances that include varying proportions of phenolic acids, phenyl propanoids, anthocyanins, and tannins, among others [3, 16–18].

Therefore, natural extracts of plant materials are always a mixture of different classes of phenolics that are soluble in the solvent system used. Solubility of phenolic compounds is governed by the type of solvent (polarity) used, degree of polymerization of phenolics, as well as interaction of phenolics with other constituents and formation of insoluble complexes.

Thereby, there is no uniform or completely satisfactory procedure that is suitable for extraction of all phenolics or a specific class of phenolic substances in plant materials.

The chemical nature of polyphenols makes them relatively hydrophilic, thus free polyphenols, including aglycones, glycosides, and oligomers, are extracted using water, polar organic solvents such as methanol, ethanol, acetonitrile and acetone, or their mixtures with water [6, 19–21].

The most common extraction solvents, conditions, and sample pretreatments are reported in Table 67.1.

Also important is the pH of the extraction solvent. For polyphenols, most extractions are carried out under acidic conditions because they are generally

Table 67.1 Extraction conditions and pretreatment for different raw materials

			Sample pretreatment	
Matrix	Sample preparation	Extraction	Fractionation/Purification	References
Waste water olive oil	Stored at −20°C Filtration	Liquid–liquid microextraction with ethyl ether, *n*-hexane, dichloromethane, trichloromethane, and ethyl acetate	Directly submitted to analysis	[10]
Honey	Mixed with water, pH 2 Stirring Filtration	–	Directly submitted to analysis	[72]
Grapes	Grounded	Ethanol	Directly submitted to analysis	
Apples	Dried, grounded	Ethanol	Sephadex LH-20 column elution with aqueous ethanol 30% Solvent extraction: ethyl acetate, light petroleum Preparative HCCC elution with hexane/ethyl acetate/1% aqueous acetic acid	[73]
Propolis	None	Ethanol	Centrifugation	[74]
Cabbage leaves	Cut into small pieces	Accelerated solvent extraction with water/ethanol/formic acid	Filtration through a 0.45 mm Millex HV13 filter	[75]
Commercial juices	Filtered and diluted	–	Directly submitted to analysis	[7]
Mate leaves	None	Hydrochloric acid in 50% aqueous methanol acetone–water 70%	Centrifugation	[12]
Grapes skins	Flash frozen in liquid nitrogen ground	Acidified methanol	Centrifugation Filtration through a 0.45 μm membrane Dilution with 5% formic acid	[11]

			Sample pretreatment	
Matrix	Sample preparation	Extraction	Fractionation/Purification	References
Blood orange	Squeezed in a centrifugal extractor	Macroporous adsorption resin	TSK gel Toyopearl HW-40S column eluted with 2 % formic acid acidified aqueous methanol	[76]
	Centrifugation	Weakly acidic-cation exchange resin		
	Stored at −18°C	Elution with acidic ethanol and ethyl acetate		
Eugenia myrtifolia Sims	Cut in small pieces	0.1% HCl in methanol	Filtration on a Buchner funnel, Concentrated, C-18 Sep-Pak cartridge eluted with ethyl acetate and methanol containing 0.01%HCl	[23]
Grape skins and seeds	Freeze-dried and grounded	Methanol/water/formic acid	Centrifugation, concentration, liquid–liquid extraction with ethyl acetate and diethyl ether	[9]
Hawthorn, common pine and skullcap	Grounded	Acetone	Fractogel Toyopearl HW-40S eluted with methanol	[54]
		Ethyl acetate	Sep-Pak C-18 eluted with acetonitrile and methanol	
		Methanol	Sephadex LH-20 eluted with 40 % isopropanol solution in 1% acetic acid	
Bark pine	Dried and grounded	98% ethanol under stirring	Liquid extraction with ethyl acetate	[13]
Tea	–	Acetone 75%	Polyamide column elution with methanol 2% acetic acid in methanol and *N*,*N*-dimethylformamide	[77]
Red and white grapes	Separation into skins and seeds	Acidic methanol	C18 Sep-Pak cartridges, AccuBond ENVI PS-DVB	[78]
		Stirring		
	Freeze-dried	Flushing with nitrogen	Elution with acidified MeOH (0.1 % Hcl, v/v) and ethyl acetate (pH 3, pH 7)	
	Grounded			

Almond skins	Milled	Acetone/water	Centrifugal UF membrane devices Amicon Ultra® from Millipore	[67]
	Lipid removal with hexane	Vortexed and sonicated		
Leaves of *Myrtus communis L.*	Quenched in liquid nitrogen stored at −80 °C, grounded in a mortar under liquid nitrogen.	70% EtOH for polyphenols	Liquid–solid extraction (LSE) on Extrelut cartridge	[79]
		Hexane for lipophilic compounds	Elution with hexane, ethyl acetate, acidic MeOH	
Mangosteen fruits	Lyophilized and stored in polyethylene bags at −20 °C	Aqueous methanol 80%	Diethyl ether	[27]
	Grounded			
Alcohol free beers	Acidified to pH 1.5	None	C18 Sep-Pak cartridge eluted by hexane, dichloromethane, ethyl acetate, acetonitrile, methanol, and acetone	[59]
Olive leaves	Dried	Acetone, ethanol, and their aqueous forms (10–90%,v/v)	Powdered silk fibroin elution with water and then with aqueous EtOH solutions	[80]
	Grounded			
Teucrium polium L.	Dried and powdered	Petroleum ether, chloroform, methanol, and water, by percolation successively	Silica gel 60 eluted with petroleum ether and petroleum ether: chloroform, chloroform, and chloroform: EtOAc, EtOAc, and EtOAc: MeOH	[81]
			Purified by TLC on silica gel 230–400 mesh and eluted with EtOAc: water: formic acid: glacial acetic acid	

more stable in low pH, and the acidic condition helps polyphenols to stay neutral, thus readily extracted into organic solvents [5, 6, 22, 23]. This is done using weak acid or low concentrations of a strong acid. High acid concentration can cause hydrolysis of glycosides or acylglycosides and thus may give different pictures of native polyphenol profiles [2].

Phenolic compounds may also exist as complexes with carbohydrates, proteins and other plant components, and some high-molecular weight phenolics, and their complexes may be quite insoluble [6].

For example, phenolic acids such as ferulic acid and lignans are often present as insoluble bound complexes, which are coupled to cell wall polymers through ester and glycosidic links and are not extractable by organic solvents. Bound phenolic acids are typically liberated by base hydrolysis, acid hydrolysis, or both [24]. The main step in most procedures involves base hydrolysis with NaOH ranging from 2 to 10 M, using incubation time up to 16 h, sometimes under nitrogen [25–27]. Following base hydrolysis, acid hydrolysis (2–4 M HCl) is sometimes performed to liberate bound phenolics that have not been previously hydrolyzed [19, 27–29].

Sometimes enzymatic hydrolysis-assisted extraction is performed to obtain aglycones using different types of commercial enzymes such as Ultraflo L, Viscozyme L, and α-Amylase or α-glucosidase [30, 31].

The hydrolysis step is also applied when the glycosylation patterns are extremely complex, and when standard reference materials of polyphenol glycosides are unavailable. The hydrolysis can simplify the chromatographic profile during separation, and aid quantification and structural identification of the polyphenols [1, 2, 22].

In conclusion, it must be mentioned that irrespective of the extraction method applied, the solvent selection is an important step based on several properties:

1. Solubility of the specific compounds in the solvent.
2. Recovery, if the solvent will be reused in subsequent extractions. If distillation or evaporation is used, the solvent should not form azeotropes and the latent heat of vaporization should be low.
3. Interfacial tension and viscosity. The solvent should be capable of wetting the solid matrix and penetrate through pores and capillaries. The viscosity should be sufficiently low so that it can flow easily. A low viscosity of the solvent also leads to low pressure drop and good heat and mass transfer.
4. Ideally, the solvent should have a good chemical and thermal stability and should be nontoxic, nonflammable, harmless to the environment, and cheap.
5. The solvent must have a high selectivity for the compounds that have to be extracted and the minimization of further substances recovery is required.

3.2 Extraction Methods

Many different extraction methods are available for different types of samples. For the majority of liquid samples, solvent extractions such as liquid–liquid partitioning and SPE (solid-phase extraction) are most frequently employed in the laboratory. The liquid extracts are sometimes partitioned with solvents such as ethyl acetate, diethyl ether, or chloroform, depending on the solubility of the target polyphenols [32–34].

The recovery of phenolic compounds from solid matrix is a more complex process where different methods can be applied, and it must be mentioned that in this case, the extraction of polyphenols requires special care, because they are easily oxidized and rapidly degraded by light and high temperatures. Antioxidants such as butylated hydroxytoluene (BHT) and ascorbic acid are often added to samples to avoid oxidation of the polyphenols when high temperatures are required [2, 8, 35].

Solid–liquid extraction is a multicomponent, multiphase, un-steady state mass transfer operation. It involves transfer of more than one chemical species – the solute – from a solid to a solvent. The solute is sometimes referred to as the extract, when the chemical species being recovered are ill defined, as occurs in the extraction of phytochemicals from plants [36, 37].

Conventional solvent extraction methods rely on conductive and convective processes to heat the product, and therefore, require longer extraction times. Longer extraction times increases the risk of degradation of thermolabile constituents.

Traditional Soxhlet extraction has been the most regarded among all the conventional extraction methods even though one of the major significant shortcomings of this method is the lengthy extraction time that can be 8, 16, 24 h, or more, which results in consumption of considerable time, solvent, and heat energy [8, 18, 22]. Additionally, the extended extraction times severely decrease sample throughput, which is a tremendous liability in terms of commercial applicability [38, 39].

Recently, different techniques such as ultrasound-assisted extraction, supercritical fluid extraction (SFE) – using either pure or modified CO_2 – and microwave-assisted extraction (MAE) have been applied. These techniques offer a better control over the extraction conditions and allow the extraction to be performed in shorter times and in a more selective way [40].

Thus, alternative novel extraction procedures are also able to reduce the solvent consumption, increase sample throughput, and improve analyte recovery.

Ultrasound-assisted extraction depends on the destructive effects of ultrasonic waves which accelerate the extraction process. The possible advantages of ultrasound in extraction are as follows:

- Intensification in mass transfer
- Cell disruption
- Enhanced penetration
- Capillary effects

Enhancement in mass transfer arises from creation of very high effective temperatures, which increase the solubility and diffusivity, and pressures that favor penetration and transport [41, 42].

During sonication, the cavitation process causes the swelling of cells or the breakdown of cell walls, which allow high diffusion rates across the cell wall in the first case or a simple washing out of the cell contents in the second [43, 44].

The extraction of bioactive compounds under microwaves irradiation is also one of the upcoming extraction techniques due to its inherent advantages (reduction in extraction time and solvent volume) over more traditional extraction techniques.

MAE uses microwave energy to directly heat the molecules within the material often in a matter of seconds. This procedure is suitable for the recovery of labile components such as polyphenols from different complex matrices. Using microwave irradiation, the degradative effects of high temperatures can be avoided. The energy of the microwaves facilitates rapid desorption of compounds from the matrices [45].

Recently, there has been an increasing interest in the use of supercritical fluid extraction (SFE) with carbon dioxide (CO_2) as a solvent. This process uses the properties of gases above their critical points to extract selective soluble components from a raw material. Carbon dioxide is an ideal solvent for the extraction of natural products because it is nontoxic, nonexplosive, readily available, and easy to remove from extracted products [3, 6]. SFE has the ability to use low temperatures, leading to less deterioration of the thermally labile components in the extract. In addition, SFE is typically carried out in the absence of air which also ensures minimal alteration of the active ingredients and preservation of the curative properties [46, 47]. SC CO_2 is generally efficient in the purification and fractionation of hydrophobic compounds, such as flavonoids and cinnamic acid derivatives from plant matrixes [49].

This process shows advantages over conventional ones, such as the possibility of continuous modulation of the solvent power/selectivity, elimination of polluting organic solvents, and the reduction of post-processing costs since there is no longer the need to eliminate solvents from the extracts [3, 6].

The only disadvantage of supercritical carbon dioxide is that it is often difficult to extract polar compounds, but this can be easily solved by using small amounts of organic modifiers [50].

SCFs have relatively low viscosity and high diffusivity, and they can penetrate into porous solid materials more effectively than liquid solvents and may render much faster mass transfer resulting in faster extractions. In SFE, a fresh fluid is continuously forced to flow through the samples; therefore, it can provide quantitative or complete extraction [38, 51]. Moreover, SFE may allow direct coupling with a chromatographic method, which can be a useful to extract and directly quantify the desired compounds.

In conclusion, to perform properly the extraction of polyphenols, the following important aspects must be kept in mind:

1. Sample pretreatment (drying, freeze-drying, grounding, etc.).
2. Solvent selection (selectivity, polarity, pH).
3. The use of an antioxidant if it is required.
4. The method employed must ensure a nearly complete recovery of phenolics, low consumption of time, solvent, and energy.
5. The removal of lipophilic fraction or other compounds that can interfere in the extraction process of the desired products.
6. The necessity to apply hydrolysis for the extraction of bound phenolics.

4 Purification Methods

The extraction methodologies described previously imply the co-extraction of nonphenolic substances such as sugars, organic acids, waxes, fats, terpenes, chlorophylls, and proteins [52, 53].

In this case, additional steps may be required to remove unwanted phenolics and nonphenolic substances.

The analytes isolation from liquid samples or liquid extracts obtained from a solid matrix is usually achieved by liquid–liquid extraction (LLE), SPE (solid-phase extraction), or size exclusion chromatography (SEC).

In the case of LLE, the most common solvents used are ethyl acetate and diethyl ether containing a small amount of an organic acid. LLE is usually directed at the isolation of aglycones. It must be mentioned that anthocyanins that are weakly soluble in ethyl acetate remain in the aqueous phase [6, 9, 10, 22, 54].

LLE can also be applied for the removal of lipophilic compounds using a suitable solvent, usually hexane [55].

Conventional LLE approach for sample pretreatment is tedious and time-consuming and requires great volumes of sample and organic solvents, which implies environmental contamination, risks for human health, and additional costs for residue treatment [14, 18].

Because of the importance of developing clean chemistry procedures, emerging methods for food matrices are based on solvent-free procedures. Newer sample preparation techniques offer automation and are clean, selective, rapid, and efficient.

Solid-phase extraction (SPE) is one of the most widely used technique for purification and preconcentration, mainly because of its ease of use and wide-ranging applicability and because it is a nonharmful environmentally preconcentration technique [56].

The most common stationary phases used for the separation of different classes of phenolics are silica gel, Sep-Pak C18, Toyopearl HW-40, Polyamide gel, Polystyrene resin, Fractogel TSK, Biogel P-2, Polyamide, Amberlite, and Sephadex LH-20 [57–64].

Solid-phase extraction with C18 cartridges has been extensively employed for the selective extraction of phenolics from complex mixtures. There are important differences between C18 solid-phase supports in relation to physical characteristics such as carbon loading and pore size. A higher average pore size increases the retention capacity due to stronger interactions between the nonpolar surface and the analyte. The SPE can be used for the isolation of neutral and acidic polyphenols. The cartridges must be preconditioned by sequentially passing through different solvents usually water/methanol adjusted to pH 7 for neutral phenolics and HCl for acidic phenolics. The samples are loaded onto the cartridge and washed with a suitable solvent in order to extract the desired compounds. The washing step is critical and should not provoke losses of compounds.

Extraction of phenolics can also be achieved using ion exchange cartridges. Phenolic acids, for example, as weakly acidic compounds are extracted most effectively by anion-exchange sorbents (quaternary amine columns) while polyvynil pyrrolidone (PVP) or PVP–silicagel has been employed to separate individual anthocyanins [65, 66].

In all cases, conditioning, washing, and elution of the cartridges or minicolumns have to be performed. Sequential elution with different solvents according to their polarity is useful for fractionation of different classes of phenolics. Solvents maybe slightly acidified to prevent ionization of the compounds.

SPME (Solid-phase microextraction) has recently been developed as a rapid, inexpensive, and solvent-free technique. This technique uses a fine fused silica fiber with a polymeric coating to extract organic compounds from their matrix. The main advantages of SPME are simplicity, high sensitivity, small sample volume, and lower cost per analysis. SPME techniques can be successfully applied for polar and nonpolar compounds in gas, liquid, and solid samples and can be easily coupled with various analytical instruments such as GC, GC–MS, HPLC, and LC–MS [22, 56].

Other significant aspects of SPME techniques are reproducibility, repeatability, fiber stability, and the possibility of quantitative determinations.

Prodanov et al. (2008) developed as an alternative to the above-mentioned purification methodologies, the membrane-based ultrafiltration (UF) technique which has not been much applied for the analytical purification of phenolics. Centrifugal membrane devices, suitable for the treatment of small volumes of samples, have shown good potential for separating high from low or middle size MM compounds in complex mixtures such as plant extracts. They permit fast and easy management of a large number of samples under mild operational conditions (low temperature and restricted exposure to oxygen and light). Complete recovery of both the permeate (filtrate) and the retentate (concentrate) from the centrifugal membranes is also possible [67].

Gel permeation chromatography using Sephadex LH-20 has been extensively used with good results for fractionating proanthocyanidins.

Generally, the GPC separation depends exclusively on the molecular size of the polymers, with no influence from other phenomena such as adsorption, partition, or ion exchange. It is, therefore, a fast, simple, and appropriate method for the study of the molecular weight (MW) distributions of polymeric molecules [68, 69].

On the other hand, the presence of hydroxyl groups in the tannin molecules can promote interactions by adsorption on the gel or intermolecular linkage by hydrogen bonding, which would lead to incorrect estimation of the MW. These phenomena can be minimized by the use of very polar mobile phases, such as dimethylsulfoxide (DMSO), dimethylformamide (DMF), or tetrahydrofuran (THF) [68–70]. Another procedure is to protect the hydroxyl groups as acetyl derivatives, methyl derivatives, or silyl derivatives [71].

The simultaneous use of an eluent such as THF and the acetyl derivatives provides better results for the GPC study of the MW distributions of tannins and other biopolymers, for example, lignins [68].

The methodologies used for the extraction, purification, separation, and analysis of phenolic compounds are briefly mentioned in Fig. 67.1.

5 Spectrophotometric Methods for Quantification of Polyphenols

Spectrophotometric methods especially colorimetric methods are nowadays intensively used for the quantification of different classes of polyphenols (total phenolic content, tannins content, flavonoids, and anthocyanins contents).

While these methods are rapid and simple, they lack the specificity for individual compounds. Interferences from nonpolyphenolic components of the sample can also cause false readings and thus lead to erroneous results. In order to accurately quantify and identify the individual polyphenols, these compounds must be firstly separated [2, 82].

5.1 Determination of Total Phenolic Content

The total phenolic content of plant extracts is usually determined by colorimetric method using Folin Ciocalteu reagent. This method entails oxidation of the phenolate ion coupled to the reduction of the phosphotungstic–phosphomolybdic reagent [6, 83, 84]. The chromophore produced is a blue phosphotungstic–phosphomolybdic complex which has a maximum absorption in the region of 750 nm [22, 85]. The total phenolic content is expressed as the number of equivalents of gallic acid, tannic acid, or caffeic acid used for the calibration curves.

The Prussian blue method is based on the reduction of Fe(III) to Fe(II) and the subsequent detection of Fe(II) by formation of the hexacyanoferrate(II) chelate (Prussian blue).

It is a popular method to quantify total phenolics because it is simple, rapid, and with little interferences by nonphenolic compounds. Critical for the successful use of this assay are temperature, pH, and order in which reagents are added, since this affects the formation of $Fe_4[Fe(CN)_6]_3$ (Prussian blue) [86, 87].

5.2 Determination of Condensed Tannins

Several methods have been described in the literature to quantify proanthocyanidins (condensed tannins); however, the most common are the acid-butanol assay and vanillin assay.

Acid-butanol assay uses an acid-catalyzed oxidative depolymerization of condensed tannins to yield red anthocyanidins. Proanthocyanidins depolymerize when treated in hot mineral acid to produce colored anthocyanidins with an absorbance maximum around 550 nm [88, 89]. The anthocyanidins result from the autoxidation of the carbocations initially formed by cleavage of the interflavonoid bond. Iron sulfate can be added to the reagent to accelerate the autoxidation reaction that increases color intensity and consistency of anthocyanidin yield [90].

Although the method is simple and gives good indication of the presence of condensed tannins, the color intensity can be affected by some factors such as the ratio of acid-butanol in the reaction mixture, chemical characteristics of tannins, and the amount of water in the samples [86, 91].

On the other hand, the choice of standards remains an unresolved issue because of the heterogeneity of condensed tannins and the lack of appropriate standards for their quantification. The use of internal standards obtained from the plant materials under study has been considered to minimize the problems derived from the use of inappropriate standards [87, 92, 93].

Despite the shortcomings outlined above, the acid-butanol assay remains the most commonly used method for determination of proanthocyanidins in foods [94].

The vanillin procedure involves reaction of an aromatic aldehyde, vanillin, with the meta-substituted ring of flavonols to yield a red adduct. Although the vanillin assay is used for the estimation of condensed tannins (proanthocyanidins), the reaction with vanillin is not specific particularly for tannins and any appropriately substituted flavonol reacts in this assay [22, 86, 93].

On the other hand, it must be taking into account that catechin, which is commonly used to standardize the vanillin reaction, also reacts with vanillin at different rates [95, 96]. Therefore, the use of internal standards is advisable.

Another method used for the estimation of total tannins content is based on the adsorption on casein. The total phenolic content of the sample is determined using Folin Ciocalteu reagent, before and after the adsorption process. The difference between absorbances of the initial and the final solution corresponds to the concentration of casein-adsorbed tannins in sample [97].

5.3 Determination of the Total Content of Flavonoids and Anthocyanins

The total content of flavonoids and flavones is usually determined using aluminum chloride as reagent. This method is based on the formation of a complex flavonoid-aluminum having the absorptivity maximum at 510 nm. Rutin or quercetin is used as a reference compound and total flavonoid content calculated from the calibration curve of the standard will be expressed as mg rutin equivalents [85, 98, 99].

The most common method employed for the determination of the anthocyanins content is the pH differential method which is generally accepted in international analytical practice [6, 100].

In an acidic medium, anthocyanins are found in the form of cation flavilia, which causes the bright red color of the solution. When the pH increases, the cation is transformed to carbinol and becomes colorless. It has been shown that the difference in absorption at the wavelengths 510 and 700 nm of solutions with $pH = 1$ and $pH = 4.5$ is proportionate to the anthocyanin content. Taking into consideration the small difference in the values of molar absorption of individual anthocyanins, it is possible to determine the total concentration of all the pigments relative to a single one, for example, cyanidin-3-glucoside.

6 Separation, Identification, and Analysis of Polyphenols

As discussed above, even though polyphenols share the common phenolic feature, due to the structural diversity, these phytochemicals vary significantly in their physicochemical properties [101–103]. Owing to the chemical complexity of polyphenols, the separation and quantification of these compounds remain as challenging as ever, despite the recent advances in new instrumentation. While it is nearly impossible to develop a protocol for all polyphenols, there are some advanced analytical techniques with large applicability in the analysis of phenolic compounds.

6.1 Chromatographic Techniques

6.1.1 Gas Chromatography (GC)

Gas liquid chromatography is a powerful technique designed to separate volatile compounds from a complex mixture. This technique uses the temperature of vaporization specific to each compound to separate them from a solution by passing the sample through a heated column where it is partitioned between an inert gas under pressure and a thin layer of nonvolatile liquid coated on an inert support inside the column [103].

The affinity of a particular molecule for the stationary phase determines the retention time of that constituent in the column. The molecules for each component of the sample will travel through the column at nearly the same rate and exit (elute) from the column within a narrow time band that is specific to that component. Thus, compounds with different retention times in the column are physically separated for presentation to a detector and analyzer. The instrument also includes a heated injection port to vaporize all volatile constituents of the sample and an oven to keep the constituents in gas form as they pass through the column.

Despite the numerous advantages of GC, its use in the separation of phenolic compounds is relatively restrictive because of the lack of volatility of most polyphenols.

For this reason, the vaporization capacity must be improved by replacing the hydroxyl groups by other chemical groups like trimethylsilyl groups before the injection onto GC [104, 105]. Therefore, before the injection onto GC, the ionic fraction obtained after polar extraction is derivatized by silylation in order to ensure a good vaporization of the sample and obtain volatile and thermostable derivatives [106, 107].

Although a very few studies based on gas chromatography (GC) have been proposed for the separation of different classes of phenolics, the use of GC with mass spectrometry (MS) detection provides important advantages because of the combination of the separation capabilities of GC and the power of MS as an identification and confirmation method [56].

6.1.2 High-Performance Liquid Chromatography (HPLC)

High-performance liquid chromatography is the most frequently used technique for the separation and characterization of polyphenols.

HPLC is a versatile and adaptable instrument with various advantages such as high selectivity, sensitivity, resolution, precision, and sample preservation [3, 108, 109].

HPLC is designed to separate compounds from complex mixtures based on polarity, solubility, and size properties of each compound. High-pressure liquid chromatography coupled with a photodiode-array detector (HPLC-DAD) provides extensive information on polyphenol structures [6, 110].

To obtain the identity of a polyphenol, the most common method is to compare the retention time of a particular compound with the standard. The photodiode-array detector DAD can collect UV/visible spectral data as the compounds are separated; thus, when a peak matches the retention time and the UV/Vis spectrum of a standard, it can be tentatively identified [2, 22, 111].

The quantitative determination involves analyzing a series of standards covering the concentration range of interest, and the sample analytes are quantified based on the calibration curves for each standard [112].

However, considering the lack of standards for some classes of polyphenols, especially, flavonoid glycosides and proanthocyanides, the HPLC analysis cannot be successfully applied.

To achieve a good separation, the flavonoid glycosides are usually hydrolyzed and converted to aglycones.

On the other hand, chiral separation of some flavonoids was also carried out by HPLC using a chemically bonded chiral stationary phase or more often by the addition of chiral additives in the mobile phase facilitating separation of enantiomers on conventional stationary phases [8, 22, 86]. For the separation of different polyphenols, chromatographic conditions involve almost exclusively the use of a RP C18 column and a binary solvent system containing acidified water using acetic acid, phosphoric acid, or sulfuric acid and a less polar solvent such as methanol or acetonitrile [113–121].

The separation of phenolic compounds can be achieved in isocratic mode when only one solvent is used or a mixture of solvents with constant composition or in gradient mode using two solvents whose composition varies throughout the analysis. According to the target polyphenols, different wavelengths' detection is required.

Several examples of HPLC conditions for polyphenols analysis are summarized in Table 67.2.

Although HPLC is one of the most used techniques, it presents some limitations in detection and quantification limit. Also in complex matrix such as crude plant extracts, identification based on the UV detection and the retention time of standards can lead to a wrong identification of the compounds.

In this context, hyphenation of LC with MS considerably improves the characterization of polyphenols, exploiting the power of separation of the HPLC and structure elucidation of MS.

Liquid chromatography–mass spectrometry (LC–MS) techniques are nowadays the best analytical approach to study polyphenols from different biological resources, and are the most effective tool in the study of the structure of phenolic compounds.

6.1.3 High-Speed Counter-Current Chromatography (HSCCC)

HSCCC is a continuous liquid–liquid partition chromatography with no solid support matrix, the stationary phase of which is retained in the separation columns by gravity and centrifugal force field. Therefore, HSCCC avoids the disadvantages arising from the interaction of samples with the solid support such as adsorption and denaturation of target products, tailing of solute peaks, and contamination [125–127].

In HSCCC, the stationary phase is immobilized by a centrifugal force and the solvent system used in the case of polyphenols is usually a mixture of ethyl acetate,

Table 67.2 HPLC condition for characterization of different classes of phenolic compounds

Compounds	Column	Solvent system	Detection	References
Benzenoid derivatives	Agilent	Methanol–water with 2 % acetic acid (1:1, v/v)	DAD 280, 360 nm	[73]

n-butanol, *n*-hexane, water, methanol, chloroform, or acetonitrile (Table 67.3). HSCCC has the unique features of high recovery, high efficiency, and the ease to scale-up. Industrial HSCCC is in the course of development. It has widely been used in the separation and purification of natural products from complex matrix [128–130].

6.2 Spectral Methods for Structure Elucidation

6.2.1 Mass Spectrometry

Using mass spectrometry to determine molecular weights and fragmentation patterns is a widely used method of identifying plant polyphenols because it has the potential to eliminate some of the ambiguities associated with other methods.

The high sensitivity and possibilities of hyphenation with chromatographic techniques (GC/MS, LC/MS) sets MS among the most appropriate physicochemical methods for the study of natural products from biological material. Mass spectrometry coupled with chromatography can provide selective molecular weight detection of biological active compounds in vegetal samples. Molecular ions and characteristic fragment ions obtained from the mass spectrometer are used to identify the desired constituents. These molecular ions, sometimes with or without reference to authentic standards, have been successfully used to identify polyphenols [112, 115, 118, 138].

Mass spectrometers use the difference in mass-to-charge ratio (m/z) of ionized molecules to separate one from another. This requires first that the various molecular species of interest have been charged (often by loss or addition of protons) and transferred into the gas phase, and that they are then separated as a function of their m/z values [106, 107, 139]. Various instruments based on different sources and analysers are available, and the various combinations made from them provide a large range of analytical possibilities more or less suitable for a given application according to the specificity of the source and analyser.

The main sources used to analyze phenolic compounds are: electron impact (EI), chemical ionization (CI), fast atom bombardment (FAB,) atmospheric pressure ionization (API) including atmospheric pressure chemical ionization (APCI) and atmospheric pressure photo-ionization (APPI), electrospray ionization (ESI), and in parallel to the advent of electrospray ionization, matrix-assisted laser desorption ionization (MALDI) [104–107, 112].

The electron impact (EI) and chemical ionization (CI) are considered relatively harsh techniques involving the volatilization of the sample into gas phase by heating in a vacuum, then bombarded by a stream of electrons in order to cause ionization of the sample. The differences between EI and CI are that in the case of CI, the sample is ionized by a strong acid produced by the ionization of the reagent gas, usually ammonia or methane.

Polyphenols are thermally labile compounds and their evaporation without decomposition is impossible even in the ion source of mass spectrometer, where high vacuum exists. In this situation, soft ionization methods have to be applied for

Table 67.3 Counter-current chromatography: conditions for separation of different classes of phenolic compounds

Phenolic classes	Samples	CCC mode	Solvent system	Detection	References
Isomeric polyphenols	*P. laetevirens*	CCC	Light petroleum –ethyl acetate–methanol–water *n*-hexane–ethyl acetate–methanol–water	ESI-MS, ^{1}H-RMN, ^{13}C-RMN	[131]
Gallocatechins, alkaloids	*Camellia sinensis*	HSCCC	BME–CH3CN– TFA	UV-VIS	[129]
Flavonol glycosides, phenolic acids	Sea buckthorn fruits	HSCCC	*n*hexane– *n*-butanol–water	ESI-MS	[125]
Procyanidins	Grape seed	HSCCC	Ethyl acetate/2-propanol/water and ethyl acetate/1-butanol/water	UV-VIS	[132]
Ursolic acid and methyl ursolate	*Malus domestica*	HSCCC	n-hexane: AcOEt:MeOH:water	ESI- MS	[133]
Catechins	*Camellia sinensis*	HSCCC	Hexane, EtOAc, MeOH and water	UV -VIS	[134]
Flavanoids	*Patrinia villosa*	CCC	*n*-hexane–ethyl acetate–methanol–water	UV, IR, high resolution (HR)-electrospray ionization (ESI)-MS	[135]
Anthocyanins	*Vaccinium myrtillus*	HSCCC	Methyl *tert*-butyl ether–*n*-butanol -acetonitrile–water–trifluoroacetic acid	UV-VIS ESI-MS	[136]
Anthocyanins	Purple sweet potatoes	HSCCC	*n*-butanol/ethyl acetate/acetic acid Trifluoroacetic acid/n-butanol/methyl tertiary butyl ether/acetonitrile	UV-VIS, ESI-MS/MS, and NMR	[137]
Caffeic acid, chlorogenic acid,quercetin glucoside/quercetin-galactoside and phloridzin	Apple pomace	HSCCC	Hexane–ethyl acetate–aqueous acetic acid	UV, ESI -MS	[73]

analysis of this group of compounds, and the analyte molecules are ionized without evaporation in high vacuum (FAB, MALDI) or under atmospheric pressure (ESI, APCI) [2, 6, 8, 22].

APCI and ESI are the most widely used ionization methods for characterization of phenolic compounds, and they can be used to establish polyphenol fingerprints of complex extracts.

The advantage of these techniques is that they produce stable ions and low spontaneous fragmentation and allow being operated under both positive (molecular species $[M + H]^+$)and negative ion modes (molecular species $[M\text{-}H]^-$) [108].

Table 67.4 summarizes the fragment ions observed for several phenolic classes in negative and positive ionization modes.

ESI is more often used to ionize polar and nonvolatile molecules, like condensed tannins and anthocyanidins, and APCI is used for less polar and nonionic compounds especially flavonols, flavones, flavanones, and chalcones [67, 105, 139].

The matrix-assisted laser desorption/ionization time-of-flight (MALDI–TOF) technique is suitable to determine the presence of molecules of higher molecular weight with high accuracy, and it has been applied with success to study procyanidin oligomers and other complex phenolic mixtures [67, 141].

Sensitivity and selectivity of detection can be increased using tandem mass spectrometry(MS/MS), that is, two (MS/MS) or more (MS^n) mass analyzers coupled in series. MS/MS and MS^n produce more fragmentation of the precursors and daughter ions, therefore providing additional structural information for the identification of flavonoids.

6.2.2 NMR Spectroscopy

NMR spectroscopy is nowadays one of the most promising spectroscopic techniques for the analysis of complex systems, such as food matrices.

Advantages such as simplicity of the sample preparation and measurement procedures, the instrumental stability, and the ease with which spectra can be interpreted have contributed to the growing popularity of the technique.

Another advantage of this technique is the simplicity of samples preparation. The solid samples can be extracted in a deuterated solvent while liquid or freeze-dried extracts are often prepared by adding 5–10 % of deuterated solvent D_2O [1, 6].

Deuterated solvents provide a signal for magnetic field stabilization and allow optimization of the resolution of the NMR peaks. Standard procedures should be followed to ensure repeatability and comparability when preparing a series of samples.

Although sensitivity reasons rendered the ^1H nucleus as the most exploited, other nuclei such as ^{13}C and ^{31}P gained popularity lately, because of their ability to attack specific problems in food science [142, 143].

^1H-NMR and ^{13}C NMR spectroscopy shows a number of advantages relative to other analytical techniques: They are fast (less than 5 min is required to record an one-dimensional spectrum); sometimes they need no calibration with internal standards or separation of the various components prior to the analysis; they show remarkable selectivity, it is possible to identify unknown compounds at

Table 67.4 Fragment ions detected for phenolic compounds

Compounds	MS mode	MW	Fragment ions m/z	References
Gallic acid	–	170	125, 79, 81	[72, 78]

Resveratrol		227	185	[22, 33]
Cyan-3,5-diglu	+	773	449, 287	[75]
Cyan-3-soph-5-glu	+	611	611, 449, 287	[75]
Procyanidin B1	–	577	451, 425, 407, 289	[78]
Procyanidin B2	–	577	451, 425, 407, 289	[78]
Procyanidin 3	–	577	451, 425, 407, 289	[78]

a molecular level; they also give a wealth of information in a single experiment and they provide quantitative results with excellent repeatability and reproducibility [14, 22, 141].

^{31}P NMR has a long history in food science and it is successfully applied for the structure elucidation of lignins [144].

This technique based on the derivatization of the samples by phosphytilation allows both quantitative and qualitative characterization of all the labile OH groups, namely, the aliphatic OH, different phenolic OH, and carboxylic OH. This method is based on the replacement of the acidic hydrogens of the hydroxyl and carboxyl groups with the phosphorus reagent 2-chloro-4,4,5,5-tetramethyphospholane and the use of ^{31}P-NMR spectroscopy to identify the phosphitylated compounds [142, 144, 145].

This facile magnetic resonance method supplements ^{1}H and ^{13}C NMR techniques, especially in cases where severe overlapped signals in ^{1}HNMR spectra or long relaxation times of the insensitive ^{13}C nuclei render the analysis a difficult task [145].

Disadvantages of NMR spectroscopy may be considered such as low sensitivity compared with chromatographic and mass spectrometry techniques and the high cost of the analysis, since the NMR spectrometers are quite expensive.

In the last few years, much effort was devoted to the development and improvement of LC-NMR.

The application of LC-NMR provides valuable structural information in studies of mixtures of natural phenolics and allows for a proper identification of compounds indistinguishable using other methods [146].

In LC-NMR, separation is usually performed on an RP C18 column and broad acetonitrile or methanol gradients are applied, using D_2O instead of water [14, 22].

The LC-NMR uses mainly the simple ^{1}H-NMR spectra or ^{1}H-^{1}H correlation experiments. Access to ^{13}C-NMR information is possible but is restricted only to a very limited number of cases where the concentration of the LC-peak of interest is very important and ^{13}C-NMR data can be deduced indirectly from inverse detection experiments. Indeed, due to the low natural abundance of the ^{13}C isotope (1.1%), the sensitivity for direct measurement in the LC-NMR mode is not sufficient [1, 2, 146].

6.2.3 Final Considerations

Plant phenolics are structurally diversified class of phytochemicals. This makes the development of standardized procedures for simultaneous analysis of all phenolics a very difficult task.

The discussion in this chapter focused on the developments of analytical techniques in the field of polyphenols separation and fractionation and provided at the same time an overview on the methods developed to enable identification of these compounds.

Selection of the extraction conditions (sample preparation, types of solvents, further purification steps, etc.) is crucial to ensure complete extraction of phenolics from vegetal material without losses or modifications of their chemical structure.

The analytical procedures outlined above have been applied during the last few years to enable further progress in the determination and characterization of important classes and subclasses of food phenolics.

Spectrophotometric methods provide valuable information concerning quantification of total phenolics and their classes even if they do not separate or give quantitative measurement of individual compounds.

HPLC with UV–Vis detection is the most widely utilized for separation of polyphenols, although other chromatographic methodologies such as GC, CCC, have also been used with success.

Spectral methods like MS and RMN are powerful and highly sensitive techniques successfully applied for structure elucidation of phenolics. Hyphenated techniques combine chromatographic and spectral methods to exploit the advantages of both, and they are the most extensively used to achieve good isolation and characterization of polyphenols from complex matrices.

Abstract

Catharanthus roseus (L.) G. Don is one of the most important medicinal plants, mainly due to the presence of anticancer alkaloids. For many years, the phenolic composition of this species remained largely unstudied. Recently, detailed

phytochemical studies using the latest analytical techniques have helped understand the complex phenolic profile of this species. Several highly glycosylated flavonoids have been found, mainly quercetin, kaempferol, and isorhamnetin derivatives. Other classes of phenolic compounds, namely benzoic acids and phenylpropanoids have also been described. Additionally, the high content in phenolic compounds turned this plant an interesting source of antioxidants whose activity has already been shown.

In this chapter, the tissue-dependant distribution of phenolics, as well as their concentrations and antioxidant activity, will be presented.

1 Introduction

Catharanthus roseus (L.) G. Don is a member of the Apocynaceae and was described for the first time in Madagascar. Although initially sorted in the *Vinca* genus (*Vinca rosea*), with time this species has been classified in a distinct one. The species was taken to France in the seventeenth century and, nowadays, it has acquired a pantropical distribution, mainly due to its easy cultivation and use as an ornamental plant [1].

In late 1940s, the plant received considerable attention mainly due to the antidiabetic properties claimed in its ethnopharmacological use. The discovery of the anticancer agents of *C. roseus* was made almost simultaneously by two independent groups – the group of Noble and collaborators in Canada [2, 3] and the group of Svoboda and colleagues from the Eli Lilly Company (Indianapolis) in the United States [4, 5].

In the 1950s, this species was included in a screening project to find new antidiabetic drugs by Professor Noble, University of Western Ontario, with little success. As a final resort, oral administration was abandoned and a concentrated extract was injected intraperitoneally in rats, which died in 5 days as a consequence of severe leukopenia. The attention was shifted from antidiabetic to anticancer activity, and subsequent fractionation of the extract rendered the isolation of vinblastine (vincaleukoblastine) [6].

At the same time, Svoboda and co-workers started a screening assay with 240 plant species to find new anticancer molecules. In the course of these experiments, the team realized that leukemic rats treated with *C. roseus* had an over-life quite superior to untreated subjects. With this, the interest was set on *C. roseus*, and vincristine (leurocristine) was isolated.

A few years later, two drugs based on these molecules entered the market: vinblastine, under the name Velban®, and vincristine as Oncovin®. The first anticancer molecules of natural origin were making their way.

2 Phenolics

Phenolic compounds are a class of metabolites that can be found in all plant species. These compounds can range from simple compounds bearing just one phenolic hydroxyl, to some more complex ones, like flavonoids, which are often polyphenols.

Given the chemical diversity of these compounds, they are usually classified in different groups. As so, the simplest phenolics are arranged in a C_6–C_1 skeleton, displaying at least one hydroxyl group attached to an aromatic ring. This class is frequently addressed as benzoic acids, given the fact that benzoic acid is the simplest member of this class.

Phenylpropanoids, which display a C_6–C_3 arrangement, are frequently, but not always, phenolic compounds. From a biosynthetic point of view, these compounds derive from phenylalanine and tyrosine and some examples are ferulic, cinnamic, caffeic acids, among others.

Finally, the third group of phenolics found in *C. roseus* is that of flavonoids, which have a C_6–C_3–C_6 skeleton and comprise several different classes, including flavonols, flavanols, flavones, anthocyanins, among others. It should be highlighted that, regarding flavonoids in *C. roseus*, only flavonols and anthocyanins have been described.

In this chapter, we will only focus on compounds found in plants, thus leaving studies performed in cell cultures out of the scope of this work. For a review on this subject, please see the work of Mustafa and Verpoorte [7].

3 Extraction and Purification

Sample preparation is a critical step for the analysis of phenolics in natural matrices and is far more critical for quantification than for identification.

The conditions employed should be as mild as possible to avoid chemical artifacts arising from hydrolysis, oxidation, and isomerization [8]. The addition of an antioxidant, such as *tert*-butyl-4-hydroxyanisole, *tert*-butylhydroquinone, or sodium fluoride, can prevent some of these interferences.

Hydrolysis of the extracts may be a useful approach for decreasing the number of compounds to be identified/quantified, thus resulting in a better resolution and better characterization of the matrix. Acid hydrolysis is employed to remove the sugar moiety, yielding the aglycones. Differently, alkaline hydrolysis is applied for deacylation of sugars and breaking of the covalent bond that phenolic acids may establish with the matrix. For an example, please see the work by Ferreres et al. [9].

4 Detection and Identification

4.1 LC-UV/LC-DAD

All flavonoid aglycones contain at least one aromatic ring and, therefore, absorb UV light. The A-ring is responsible for the first maximum, found in the 240–285-nm range, and the second maximum, observed at 300–550 nm, is due to the substitution pattern and conjugation of the C-ring [10].

When using an UV detector at a fixed wavelength, the obtained information is still very limited. In these situations, co-cromatography with authentic standards is recommended. Diode array detectors (DAD) are much more useful because they yield the full record of the UV-Vis spectrum of each molecule. Due to the fact that each class of phenolic compound has a characteristic spectrum, identification is facilitated, although a definitive characterization requires a standard to compare retention time and UV spectrum (see Fig. 68.2 for an example).

When two compounds with very close, or even superimposable, retention times and identical UV spectra are found in a chromatogram, more sophisticated detectors that can yield much more structural information are required. Liquid chromatography-diode array detection (LC-DAD) is still the main technique used for phenolics quantification, a parameter not usually determined by other techniques, such as liquid chromatography-mass spectrometry (LC-MS), given its poor sensibility.

Because of the great number of different flavonoid glycosides in nature, quantification using authentic standards is often impossible as they are not commercially available. However, given the fact that sugar moieties are poor chromophores, with small effect in the UV spectra, it is a common practice to quantify glycosides using standards of the corresponding aglycone or a similar one.

Regarding phenolic acids, most compounds are commercially available and can thus be positively identified by comparison of their retention time and UV spectra with those of reference compounds. Hydroxycinnamic acids absorb at two regions of the UV spectrum, presenting a maximum at 225–235 nm and two other, very near from each other, by 290–330 nm. The double absorption in this region arises from the presence of *cis* and *trans* isomers, and the ratio between these two forms contributes to the final spectrum.

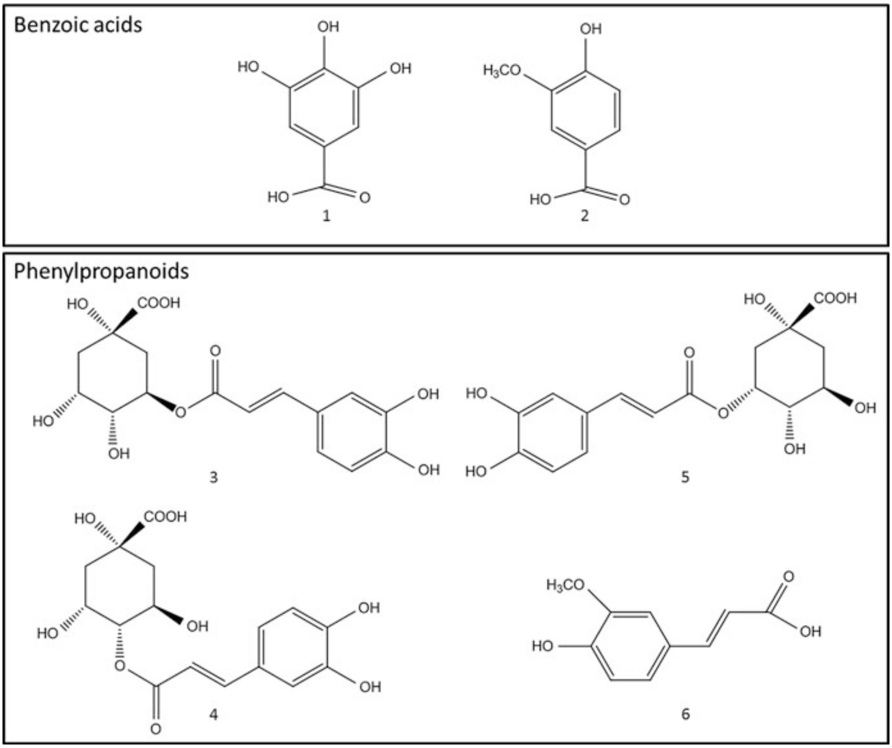

Fig. 68.1 Benzoic acids and phenylpropanoids described in *C. roseus*. Identity of compounds as in Table 68.1

In alkaline medium, all three maxima suffer a bathochromic shift. The different esters of the same acid present similar spectrum, regardless of the molecule conferring the alcohol function (quinic acid, sugar, or tartaric acid) [11].

The UV spectrum of benzoic acids is more influenced by the hydroxylation degree of benzenic moieties than that of hydroxycinnamic acids. Methylation of hydroxyl groups has almost no effect on the UV spectrum. Only dihydroxylated benzoic acids present two maxima [11].

4.2 LC-MS

MS is a powerful technique in the analysis of flavonoids and phenolic acids, mainly due to its high sensitivity and the possibility of coupling with different chromatographic techniques, especially with LC. In addition, the characteristic fragmentation pattern of some phenolics can aid in their identification [12].

The amount of information obtained by multisignal MS or MS/MS renders two levels for identification of compounds: positive and provisional. Positive identification can be achieved when reference compounds are available, thus allowing comparison of both retention time and spectra. When no standards are available, a common

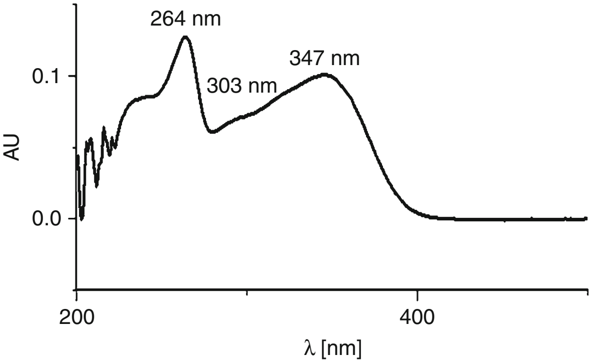

Fig. 68.2 UV spectrum of flavonol-3-*O*-glycosyl derivative present in the leaves of *C. roseus*

situation in natural product chemistry, provisional identification takes place. In this case, although the identity of subunits such as aglycones, sugars, and acyl moieties is elucidated, the positions of glycosidic and acyl linkages remain sometimes unknown, with the exception of some fragmentation patterns that allow a positive identification of the glycosidic bonds [13].

Spectroscopy by UV-Vis and MS in total ion mode can render detection limits for flavonoids in the range of 10 ng. When single ion monitoring (SIM) mode is used, MS analysis provides better detection limits, usually below 1 ng. SIM mode, however, causes loss of valuable information concerning fragmentation pattern, which is very important for the identification of many compounds. Among all ionization sources available, electrospray ionization (ESI) in negative ion mode is the one most suitable for the analysis of phenolics.

5 Benzoic Acids

Simple benzoic acids are synthesized in plants *via* the shikimate pathway, which is derived from shikimic acid, which is itself derived from quinic acid *via* 3-dehydroquinic and 3-dehydroshikimic acids (Scheme 68.1). In fact, shikimic, but not quinic, acid has been described in the leaves and stems of this species [14]. The simplest benzoic acids are protocatechuic acid (3,4-dihydroxybenzoic acid) and gallic acid (3,4,5-trihydroxybenzoic acid). The latter proved to be present in the tissues of *C. roseus*, in addition to vanillic acid (4-hydroxy-3-methoxybenzoic acid) [15]. The quantitative composition of *C. roseus* in benzoic acids can be seen in Table 68.1, and the structures of these compounds are represented in Fig. 68.1.

6 Phenylpropanoids (Hydroxycinnamic Acids)

Phenylpropanoids are a class of C_6–C_3 phenolics with a widespread distribution in nature. These compounds can be derived either from phenylalanine, like cinnamic acid,

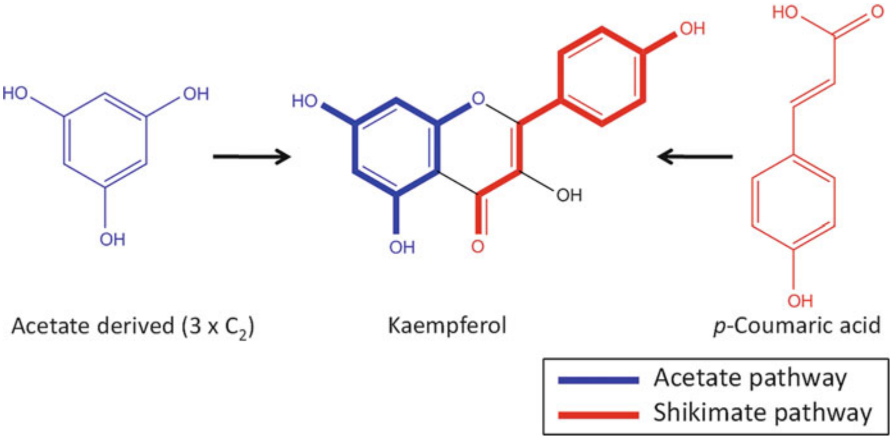
or from tyrosine, like *p*-coumaric acid (Scheme 68.1). In the particular case of hydroxycinnamic acids, the most common ones are ferulic and sinapic acids, which can be found in plants either in their free or esterified form. In *C. roseus*, several reports have described the presence of hydroxycinnamic acids esterified with quinic acid, namely 3-*O*-caffeoylquinic, 4-*O*-caffeoylquinic, and 5-*O*-caffeoylquinic acids (3-CQA, 4-CQA, and 5-CQA, respectively) [16]. The distribution of these compounds has been shown to be dependent on the tissue, as they can be found only in some plant parts, namely, in the stems and leaves. Seeds and petals were also investigated for the presence of these compounds, but they were not found. This tissue-dependent distribution of caffeoylquinic acids in leaves and stems can be related with their recognized action as protectors against herbivores and infection [18], a function particularly relevant for the organs involved in vegetative growth (stems and leaves). In what concerns compounds in their free form, hydroxytyrosol and ferulic acids have been described. The amount of these compounds in the plant can be found in Table 68.1, and their structures can be seen in Fig. 68.1.

7 Flavonoids

Among natural products, phenolics are one of the most studied classes due to their broad range of biological activities, which include antioxidant, anticancer, antiallergy, among others [19].

From a biosynthetic point of view, flavonoids derive from both the shikimate and the acetate pathways. A detailed discussion on the biosynthesis of these compounds is beyond the scope of this work; however, a simplified representation of the biosynthetic pathway can be seen in Scheme 68.2.

The phenolic composition of *C. roseus* has remained unknown for a long period of time. Early reports in the 1950s on the flavonoids of *C. roseus* described the presence



Scheme 68.2 Combination of acetate and shikimate pathways in flavonoids biosynthesis

of quercetin and kaempferol, by using paper chromatography, which are the only flavonoid aglycones found in this species to these days [20]. Although this study is remarkably important from a historical point of view, due to the fact that it was the first study on the phenolics of this species, the chromatographic methodology used is prone to some errors because of the lack of specificity and sensitivity. In 1996, Nishibe et al. isolated two flavonoids from *C. roseus* leaves: mauritianin (kaempferol-3-*O*-α-L-rhamnopyranosyl-(1 → 2)-α-L-rhamnopyranosyl(1 → 6)-β-D-galactopyranoside) and also quercetin-3-*O*-α-L-rhamnopyranosyl-(1 → 2)-α-L-rhamnopyranosyl-(1 → 6)-β-D-galactopyranoside [21]. In 1999, the same compounds were also isolated from stems, in addition to another one that was described in this species for the first time: syringetin-3-*O*-robinobioside [22]. As so, until early 2008, the only flavonoids reported in this species were reduced to five. Recently, an in-depth study of the phenolic composition of *C. roseus* was performed using high-performance liquid chromatography-diode array detection-electrospray ionization-mass spectrometry (LC-DAD-ESI-MS/MS) [23]. Leaves, stems, seeds, and flowers were studied in order to understand the distribution of these metabolites within the different plant tissues. Fifteen glycosides of quercetin, isorhamnetin, and kaempferol were found, with the latter constituting the majority. UV spectra characteristic of flavonol-3-*O*-glycosyl derivatives were found (Fig. 68.2). The identity and quantity of these compounds, as well as their tissue distribution, can be found in Table 68.2. It is worth mentioning that the above-referred syringetin-3-*O*-robinobioside [22] was not found in this latter study, which could mean that the presence of this compound may depend on the agricultural practices, climate, or the stadium of the plant's life cycle.

Anthocyanins in *C. roseus* are highly dependent on the cultivar under study, which can result in different petal color. As so, Little Bright Eye, a white variety, seems to be disposed of these compounds [16], while other varieties have been shown to contain this class of flavonoids. In particular, the 3-*O*-glucosides of malvidin, hirsutidin, and petunidin have been described, as well as their

30	Hirsutidin-3-O-(6-*O*-*p*-coumaroyl) glucoside	–	–	49.3	–	[24]

6-*O*-*p*-coumaroyl derivatives, totalizing six anthocyanins (Fig. 68.3, Table 68.3) [24]. As it can be seen, all flavonols are highly glycosylated, bearing no acylation, while anthocyanins display only one sugar moiety, being some of them acylated with *p*-coumaric acid.

Roots of *C. roseus* were also investigated for the presence of phenolic compounds, but no such metabolites were found [25].

Recently, the vacuoles of *C. roseus* leaves were isolated and analyzed by LC-DAD-ESI-MS/MS and the presence of three caffeoylquinic acids, a quercetin triglycoside, a kaempferol triglycoside, and two anthocyanins was demonstrated [26]. As expected for a class III peroxidase, CrPrx1 was capable of oxidizing the phenolic compounds tested, which included kaempferol, quercetin, ferulic acid, among others. By comparing the several standards, the highest apparent affinity was observed for kaempferol (0.018 mM) and the lowest for ferulic acid (1.606 mM). In fact, higher affinities were observed for kaempferol, 5-CQA, quercetin, and caffeic acid, while lower ones were noticed for ferulic acid and coniferyl aldehyde. 5-CQA, which is close to the major phenolic compound accumulated in the vacuoles of *C. roseus* leaves, presented one of the lowest Kms, indicating a high affinity of CrPrx1 for this compound.

In addition, it was concluded that glycosylation of the aglycone significantly lowers CrPrx1 affinity for the substrate since the Km increased from 0.045 mM for quercetin to 1.589 mM for quercetin-3-*O*-arabinoside.

8 Antioxidant Activity

The rich phenolic composition of *C. roseus* has led to the hypothesis that this species could present good antioxidant activity. Recently, aqueous extracts of leaves, stems, flowers, and seeds were tested for their antiradical capacity against the synthetic radical DPPH and the physiological radicals superoxide anion and nitric oxide. All tissues tested exhibited a concentration-dependent effect against superoxide radical, with the order of activity being seeds ($IC_{50} = 74$ μg/mL) > leaves ($IC_{50} = 90$ μg/mL) > stems ($IC_{50} = 202$ μg/mL) > petals ($IC_{50} = 260$ μg/mL) [23].

Regarding nitric oxide radical, the scavenging capacity was much lower and the order of activity was distinct from that found against superoxide anion: petals (IC_{25} = 232 μg/mL) > seeds (IC_{25} = 320 μg/mL) > leaves (IC_{25} = 505 μg/mL) > stems (IC_{25} = 546 μg/mL).

The order of antiradical activity against DPPH revealed to be similar to the one observed for nitric oxide, with the best material being petals (IC_{50} of 197 μg/mL) [23].

The antioxidant activity of *C. roseus* roots was also assessed in another work [25], and this material showed to have higher antioxidant potential than all of the previously studied plant materials. Although no phenolics were found in the roots, the organic acids present in the extract proved to contribute to a strong antioxidant activity against DPPH, superoxide, and nitric oxide radicals.

9 Conclusion

In the last few years, there has been a great evolution in the knowledge of the phenolic composition of *C. roseus*. While only five compounds were described in this species by 1996, today this number has risen to over 25, most of which are flavonoids. This is a consequence of recent studies that were undertaken, using more advanced analytical techniques like LC-MS, which is a powerful approach for chemically complex extracts. As *per* the state of the art, three classes of phenolics are known to occur in *C. roseus*: benzoic acids, phenylpropanoids, and flavonoids. Benzoic acids are limited to gallic and vanillic acids, and phenylpropanoids include ferulic acids and isomers of caffeoylquinic acid. The group of flavonoids represents the majority of the phenolics reported in *C. roseus* and is mostly constituted by quercetin, kaempferol, and isorhamnetin derivatives, all of them highly glycosylated and bearing no acylation. Anthocyanins deriving from malvidin, hirsutidin, and petunidin are also described. The rich composition in phenolics has turned *C. roseus* an interesting source of antioxidants.

identification of flavonoids in plant, food, and biological samples. This chapter provides an overview of flavonoid analysis by HPLC, including extraction of flavonoids in both aglycones and glycosides, separation by a selection of stationary and mobile phases, and finally, detection and identification by UV–VIS, fluorescence, electrochemical, mass spectrometry, and NMR spectroscopy.

Flavonoids • Foods • HPLC • Medicinal plants • Quantitation

1 Introduction

Flavonoids are polyphenols and function as secondary metabolites in plants. Their biological importance in plants, animals, and microorganisms stems from their diversity in chemical substitution of the C6–C3–C6 framework (Fig. 69.1), giving over 10,000 known compounds [1, 2]. The rapid increase of new flavonoids reported in the last decade is partly due to the intense research on rationalizing of the molecular contribution of health benefits in traditional herbal medicine and food and on using flavonoid molecular entities in chemosystematics of plants. The improved bioassay-guided separation technology and the advance in the development of the HPLC system, especially the detection modality, have also contributed to the growth of identification of new flavonoids. A number of reviews have been published on analytical methods for flavonoids and polyphenols in plant, food, and biological samples [3–9].

In this chapter, we focus on the analysis of flavonoids strictly based on the C6–C3–C6 framework (i.e., excluding the isoflavonoids). The chemical diversity, size, three-dimensional shape, and physical properties of flavonoids are reviewed in recognition of their importance in determining the extraction and separation strategy. Various detectors coupled to the HPLC with different stationary and mobile phases are discussed for the feasibility of aiding the full identification of flavonoids. In addition, the challenges of using two-dimensional HPLC in the screening of flavonoids for their bioactivity in herbal medicine or food are highlighted.

2 Structure and Physicochemical Properties

Flavonoids are characterized by a C6–C3–C6 framework and typically with a phenylbenzopyran chemical structure. The heterocyclic benzopyran ring is known as the C ring. An aromatic ring (A ring) fused with the heterocyclic benzopyran ring (C ring) and linked to a phenyl moiety (B ring) as shown in Fig. 69.1. The A and B rings can be hydroxylated, and the hydroxyls can be *O*- and *C*-glycosylated, methylated, acetylated, pyrenylated, or sulphated. Sugar units can be D-glucose, L-rhamnose, D-galactose, L-arabinose, D-xylose, D-allose, D-apose, D-mannose, D-glactouronic acids, D-glucuronic acids, di- or trisaccharides.

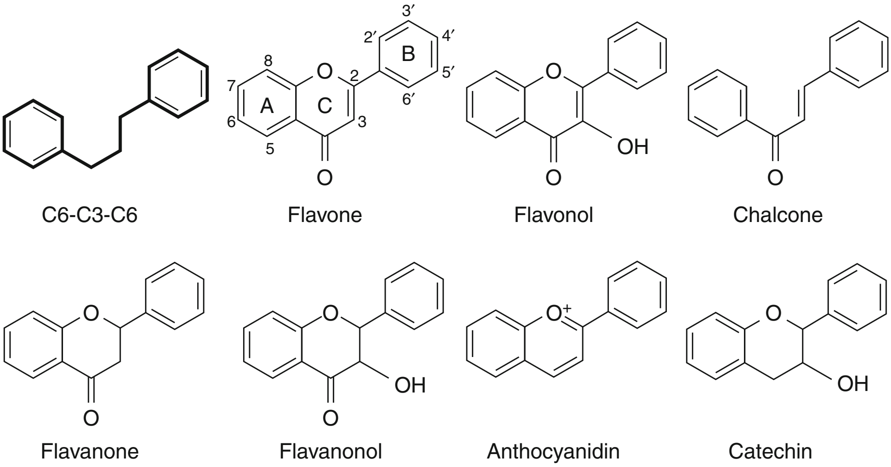

Fig. 69.1 Skeleton of a C6–C3–C6 defining the flavonoid class and structures of the main flavonoid subclasses

The center heterocycle is either pyran, pyrilium, or γ-pyrone. The main subclasses of flavonoids are flavone, flavonol, flavanonol, flavanone, anthocyanidin, and chalcone (Fig. 69.1). The latter subclass does not have a heterocycle B ring structure. Both flavanonol and flavanone have a chiral center at C2 position and they are stereoisomers.

The solubility of a flavonoid is a crucial factor in controlling its interaction with the mobile phase in HPLC. Therefore, the properties of these flavonoids such as hydrophobicity, dipole moment, hydrogen bonding, ionization, and steric effects are important to take into account when choosing a mobile phase for an effective separation. Flavonoids without sugar units attached tend to have low solubility in water and are pH dependent. The solubility of quercetin, isoquercitrin, rutin, chrysin, naringenin, and hesperetin was quantified in three different organic solvents (acetonitrile, acetone, and tert-amyl alcohol), and the data did not give a clear correlation between the solubility of flavonoids and their thermodynamic properties [10].

The number and the position of hydroxyl groups attached even in the same class of flavonoids can influence the lipophilicity of the flavonoids. Octanol–water partition coefficient (log P) values were reported for flavonoids from the flavone, flavonol, and flavanone [11], showing that aglycones are more lipophilic than any glycosylated or sulfated conjugates. However, there is not a trend of retention time of the flavonoid with respect to the log P (Table 69.1). Despite having the same number and position of hydroxyl substituents in luteolin (flavone) and eriodictyol (flavanone), they have different log P values but similar retention times.

The acidity of hydroxyl groups in flavonoids has been studied by theoretical calculations [12]. Interestingly the 4′-OH on the B ring and the 7-OH on the A ring

Quercetin-7-sulfate	0.74 ± 0.02	14.72
Quercetin-3-rhamnoglucoside	−0.64 ± 0.05	10.88
Quercetin-3-sulfate	−1.11 ± 0.01	11.23

are identified as the most suitable deprotonation sites because of the favorable delocalization of the electron pair. Therefore, the most acidic flavonoids are those characterized by a high degree of π-electron delocalization, for which deprotonation gives anionic species that can be readily stabilized by resonance structure.

3 Extraction

The structural complexity of flavonoids has prohibited a single extraction method for all classes of flavonoids. Sample handling strategies (pretreatment, extraction, and clean-up) are important prior to the determination of flavonoids by HPLC. Sample pretreatment is required in most of the flavonoid-containing matrices, such as plant materials, food products, and biological samples. Work-up routines before extraction processes can involve freeze-drying, homogenization, centrifugation, and/or filtration. The pretreatment for liquid food products and biological samples is simply centrifugation and for solid plant materials and food products is homogenization.

Solvent extraction of flavonoids is commonly used after pretreatment. The factors that contribute to the efficiency of solvent extraction are polarity of solvent or solvent mixtures, pH, temperature, and particle size. The acidity of the extraction medium can influence the degree of solubility for soluble flavonoids and their conjugates, for example, glycones in plants and glucuronide and sulfate conjugates in biological samples. Solvent such as aqueous, methanol, ethanol, ethyl acetate, acetone, acetonitrile, or their mixture is commonly used to isolate flavonoids from powdered plant materials [13]. In anthocyanin extraction, acidified aqueous methanol or ethanol is used to denature the cell membrane and to solubilize the analyte. The use of weak organic acids and low concentrations of strong acids was reported to prevent the hydrolysis of anthocyanins to anthocyanidins [14–17]. Since flavonoids can exist as various conjugated forms, sample treatment with acid [18–20] or enzymatic [21, 22] hydrolysis is required to facilitate the identification of the aglycones.

Flavonoids can be extracted by solvent extraction through Soxhlet extraction, ultrasound-assisted extraction (USAE), microwave-assisted solvent extraction (MASE), accelerated solvent extraction (ASE), or supercritical fluid extraction (SFE) methods [23]. The latter two methods are based on using compressed fluids as extracting agents [24]. A comparative extraction study of flavonoids from dry cell cultures of *Saussurea medusa* Maxim by Soxhlet extraction, USAE, and MASE showed that MASE is more efficient in terms of yield and time for extraction. Another comparative study, using the compressed fluid techniques, accelerated solvent extraction (ASE) using water, and supercritical fluid extraction (SFE) using CO_2 and 10 % EtOH as modifier versus standard hot water or 70 % ethanol extraction of flavonoids from *Scutellaria lateriflora*, was reported [25]. The use of ASE at 85 °C with water as solvent gave the best results for flavonoid glycosides, whereas SFE gave higher yields of flavonoid aglycones.

Liquid–liquid extraction (LLE) and solid-phase extraction (SPE) are usually performed on liquid samples, such as beverages or biological fluids. These two extraction methods are used to concentrate flavonoid analytes based on their solubility in different solvents and their polarity. Unwanted lipids or lipophilic materials in crude extract can be eliminated by washing it with nonpolar solvents, such as hexane or dichloromethane.

Column chromatographic and SPE methods are used in the clean-up step before injection to the HPLC system. The polar nonphenolic compounds such as organic acids can be removed by SPE method using a preconditioned C_{18} cartridge. Apart from the commonly used C_{18} cartridge, a variety of adsorbent materials such as Amberlite, C_8, and HLB have also been used successfully for extracting flavonoid compounds from wine [26]. SPE method has been found useful in enhancing the extraction of glabridin from licorice (from 0.23 % to 35.2 % after SPE) [27].

4 Separation

Reversed-phase (RP) liquid chromatography is used for separation of analytes that dissolve in mixed aqueous–organic solvents. Separation of flavonoids is therefore commonly carried out in the reversed-phase mode, on C_8- or C_{18}-bonded silica columns with mixed aqueous–organic mobile phase. The aqueous mobile phase is usually acidified water using a mild organic acid such as formic or acetic acid. The organic mobile phase is typically either methanol or acetonitrile. Normal-phased liquid chromatography is seldom used for flavonoid analysis because the analyte often retains on the column. However, peracetylated flavonoids can be separated on a cyano-silica column using *n*-hexane-ethyl acetate mobile phase under isocratic conditions [28].

4.1 Stationary Phases

A complete separation of naturally occurring mixtures of flavonoids poses problems due to the wide range of polarities and the tendency for flavonoids of similar polarity to elute in groups. C_{18} is normally the stationary phase of choice. Typically columns have an internal diameter ranging from about 2–5 mm with particle sizes 3–5 μm with a length of 75–250 mm. C_8 stationary phase is also used for the separation of more polar flavonoids. A comparison of HPLC capacity factors of 27 flavonoids have been reported using Zorbax SB (250 × 4.6 mm) analytical columns containing C_{18}, C_8, and CN stationary phases [29]. The results showed that the hydrophobic flavonoids (usually aglycones) had similar capacity factors in C_{18} and C_8 columns and were much reduced in CN column (Table 69.2). However, for polar flavonoids, the capacity

Table 69.2 Capacity factors of flavonoids in chromatography columns with different stationary phases [29]

	Coefficients of retention		
Compound	C_{18}	C_8	CN
Apigenin (5,7,4′-trihydroxyflavone)	34.24	39.23	22.37

3-Methylkaempferol-7-*O*-glucoside	7.23	7.03	4.65
Myricetin-3-*O*-galactoside	1.12	1.17	1.44
Myricetin-3-*O*-rhamnoside	1.96	2.01	2.12
Patuletin (patuletin-7-*O*-glucoside)	2.30	2.23	2.23
Pectolinarin (5-hydroxy-6,4′-dimethoxyflavone-7-*O*-(6-*O*-α-L-rhamnopyranosyl)-β-D-glucopyranoside)	17.97	16.42	7.59
Scoparin (chrysoeriol-8-C-β-D-glucopyranoside)	2.46	2.44	2.52
Scutellarein-7-rhamnoxyloside (5,6,4′-trihydroxyflavone-7-*O*-β-rhamnoxyloside)	2.74	3.12	2.74
Hirsutrin (quercetin-3-*O*-glucoside)	2.19	2.22	2.31
Eriodictyol (5,3′-dihydroxy-4′-methoxyflavone-7-*O*-glucoside)	2.24	2.24	1.85

factors were similar in all columns. Optimum separation of flavonoids also depends on column types of C_{18}; for example, the separation of 51 flavonoids in a Chinese herbal prescription of Longdan Xiegan Decoction using a Symmetry column from Waters was better than that of Zorbax (Agilent) and LiChroCART (Merck) [30].

The anthocyanins are most often separated by HPLC on a C_{18} column with long gradients to achieve the best chromatographic resolution [31–33]. A new approach using a HPLC column that combines both ion-exchange and reversed-phase (RP) separation mechanisms showed significant improvement in chromatographic

Fig. 69.2 HPLC anthocyanin profiles (520 nm) of Concord (*Vitis labrusca*) skin extracts (MeOH–H_2O–HCOOH = 70:28:2). Magnified regions focus on acylated anthocyanins. (**a**) Mixed-mode column (Primesep, SIELC). (**b**) C_{18} RP column (Zorbax SB-C_{18}, Agilent) [34]

performance, especially for the separation of 3,5-diglucoside anthocyanins from 3-monoglucoside anthocyanins in analyzing grape anthocyanins. A total of 37 anthocyanin peaks were detected in the Concord skin extract using a Primesep column, i.e., a mixed ion-exchange and reversed-phase mode column [34]. In Fig. 69.2a, the separation of different anthocyanin subgroups using a Primesep mixed mode column is achieved avoiding overlaps found with a C_{18} column (Fig. 69.2b). A total of 25 compounds were clearly identified. Other column such as monolithic or rod column has been used to separate 24 anthocyanins in a red cabbage sample in 18 min [35]. The advantages of using monolithic columns over the conventional particulated columns are shorter run times, higher flow rates, and faster column equilibration [36, 37].

A porous polyamide resin is shown to possess hydrogen bond acceptor properties suitable for the separation of polyphenolic solutes such as phenolic acids, flavonols, and flavonoids. The separation is achieved in the presence of solvent mixtures of acetic acid and ethanol. The extent of hydrogen bond adsorption is reviewed based on data obtained from the elution behavior of a variety of simple polyphenolic solutes. Polyamide adsorption chromatography was applied for the purification of resveratrol and polydatin from *Polygonum cuspidatum* Sieb. & Zucc [38].

The highly cross-linked 12 % agarose gel, Superose® 12 HR 10/30, possesses hydrogen bond acceptor properties suitable for the separation of polyphenolic solutes such as phenolic acids, flavonols, and flavonoids. The separation is achieved isocratically in the presence of solvent mixtures of acetic acid and ethanol. The extent of hydrogen bond adsorption is reviewed based on data obtained from the elution behavior of a variety of simple polyphenolic solutes including dihydroxybenzoic acids [39, 40].

Columns of HPLC with monolithic supports generally enable faster separations, for example, a 4 mL/min elution flow could be utilized achieving an HPLC analysis [35]. However, the high flow rate makes this type of column not suitable for mass spectrometry detection. Alternatively, smaller dimension columns packed with smaller particle sizes than the conventional ones achieve a faster separation while maintaining resolution. A Zorbax SB C_{18} column (1.8 μm particle size) has been used for the determination and identification of flavonoids and isoflavonoids (genistin, genistein, daidzein, daidzin, glycitin, glycitein, ononin, formononetin, sissotrin, and biochanin A) in fmol quantities in submicroliter sample volumes by HPLC/UV–VIS DAD separation method (which takes <1 min) [41].

Immobilized artificial membrane (IAM) stationary phase consists of a monolayer of phospholipid covalently immobilized on an inert silica support. The IAM stationary phase mimics the lipid environment found in cell membranes, and it can be used for elucidating drug-membrane interactions. The interaction of catechins, flavones, flavonols, anthocyanidins, and anthocyanins with phosphatidylcholine was investigated by HPLC with an IAM column. The IAM partition coefficients of the flavonoids correlated well with the amounts flavonoids incorporation into the liposomes [42].

4.2 Mobile Phases

One of the most important parameters for well separation of flavonoids is the composition of the eluent. Controlling the solubility of the flavonoids in the eluent is a crucial factor for determining the combination of solvents used. In RP-HPLC, analytes are retained on the stationary phase based on their hydrophobicity. Elution of flavonoids in RP-HPLC is therefore in the order of decreasing polarity. Polarity increases most by hydroxyls at the fourth position, followed by those at the second and third positions. Loss of polar hydroxyl groups or additions of methoxy groups reduce polarity and hence increase retention times.

In 1974, the first application of HPLC to flavonoid analysis was published [43], and 2 years later, 12 flavonoids were separated by RP-HPLC in a methanol–water–acetic acid (30:65:5) mobile phase system [44]. In 1994, Nogata et al. reported a separation of 25 naturally occurring *Citrus* flavonoids (flavones, flavonols, and flavanones) simultaneously with a gradient system of 0.01 M phosphoric acid (A) and methanol (B), in three steps: (1) 0–55 min, 70–55 % (v/v) A in B, (2) 55–95 min, 55-0% A in B, and (3) 95–100 min, isocratic, 100 % B, measured at 285 nm, Fig. 69.3 [45].

Both isocratic and gradient elution methods have been successful in separating flavonoids from extracts. However, isocratic elution is less used than that of gradient because it tends to resolve better of members of the same class of flavonoids but works well with monolithic columns. An RP-HPLC method using a monolithic column was developed and validated for the separation and quantification of three flavonols, myricetin, quercetin, and kaempferol, in Rhus coriaria L. The method employed the isocratic mobile phase acetonitrile-10 mM potassium dihydrogen orthophosphate buffer adjusted to pH 3.0 using orthophosphoric acid at a flow rate of 4.0 mL/min, a Chromolith Performance RP-18e (100 × 4.6 mm) monolithic column kept at 40 °C, and UV detection at 370 nm [46]. Successful attempts in simultaneous determination of different classes of flavonoids (quercetin, naringenin, naringin, myricetin, rutin, and kaempferol) using a commercially available monolithic column and isocratic elution were also achieved [36].

Gradient elution is more often employed in recognizing the complex flavonoid profiles of plants, food, and drinks. Rutin, quercetin-3-arabinoside, naringin, myricetin, quercetin, apigenin, and quercetin dimethyl ether in beer samples were separated by gradient elution using a multichannel electrochemical detection with a CoulArray detector [47]. A step linear gradient method using a mixture of methanol and 0.1 % formic acid as a mobile phase was validated for the simultaneous determination of five flavonoids (rutin, quercitrin, quercetin, kaempferol, and isorhamnetin) in rat plasma [48]. Another example is the analysis of rat urine, bile, and plasma after the oral dose administration of rhubarb extract using a gradient of 0.1 % formic acid (A) and methanol (B) starting with 5 % B at 0–10 min, 5–20 % B at 10–30 min, 20–25 % B at 30–40 min, 25–45 % B at 40–160 min, 45–60 % B at 160–180 min, 60–80 % B at 180–200 min, and 80 % at 200–220 min (Fig. 69.4) [49].

Multisolvent gradient elution conditions have been suggested to tackle materials that are difficult to separate. Three-component solvent system, methanol–acetonitrile–water, is commonly used in separation of natural products [50, 51]. Recently, a detailed study on the ratio of acetonitrile to methanol in a three-component solvent system for achieving improved separation capabilities of 11 flavonoids (flavanols, biflavanol, triflavanol, and flavanones) was made [52].

Ionic strength and pH of mobile phase is known to influence the retention of flavonoids on the column depending on if there is protonation dissociation or a partial dissociation. An increase of pH enhances the ionization of flavonoids and could reduce the retention in a reversed-phase separation. Thus, small amounts of HOAc (2–5 %), H_3PO_4, or TFA (0.1–1 %) are normally included in the solvent to suppress ionization of phenolic or carboxylic groups and hence improve resolution

and reproducibility of each separation [53]. Both acetate and phosphate buffers have been used as part of the mobile phase for optimizing the analysis time and enhancing separation [29, 54].

5 Identification

Choosing an appropriate detector in an HPLC analysis of flavonoids is as crucial as the stationary and mobile phase. The detector reports the chemical composition of the column effluent via a recorded or digitized signal. The chemical information can be processed differently depending on the type of detectors used. The selection of a detector in flavonoid analysis is normally based on the chemical properties and the sensitivity of the analytes. The two detection techniques widely used in flavonoid analysis are UV–VIS spectrophotometry and mass spectrometry. Multiple-wavelength detection, such as diode array detection (DAD), can be used for positive identification by comparing the retention time and UV spectrum with authentic standards. However, if no reference standard is available, detections such as tandem mass spectrometry and NMR spectroscopy have proved useful in the identification of flavonoids.

5.1 Detection

5.1.1 UV–VIS and Photodiode Array Detection (UV-DAD)

UV–VIS spectrophotometry offers a routine detection and quantitation of flavonoids in HPLC. The two common solvents used as mobile phase in flavonoid analysis are acetonitrile and methanol, and their UV cut-off λ_{max} are 190 and 205 nm, respectively. They do not interfere with the two UV–VIS absorption bands at 240–285 nm and 300–560 nm corresponding to two aromatic rings (A and B) of the flavonoid aglycones [55]. For flavones, the substitution of OH or OMe positions in aglycones and the type of glycosides (either *C*- or *O*- glycosides) give a slight change of the λ_{max} of both bands [30]. The hydrolyzed anthocyanins, anthocyanidins, show a characteristic absorbance in the visible region between 515 and 540 nm [3, 56]. On the other hand, there is little or no conjugation between the A- and B-rings of flavanones and isoflavaones, and hence they only exhibit a low intensity in band I which often appears as a shoulder to the peak of band II [57].

Multiple-wavelength absorbance detection offers advantages over single-wavelength absorbance detection in flavonoid analysis of plant and food products by HPLC. These products normally contain flavonoids of different subclasses and variable substitutions in the same subclass. Two compounds may elute very close together within one peak, but they may be identified by the differences in their spectra. For example, catechins in tea infusions were identified by comparing peak retention times and online DAD spectra of authentic standards, (−)-epigallocatechin, (−)-epigallocatechin gallate, (−)-epicatechin, (−)-epicatechin gallate, (−)-epigallocatechin 3-*O*-(3-*O*-methyl) gallate, and (−)-3-*O*-methyl epicatechin gallate [58]. The total flavonoid content of leaves of *Passiflora incarnata* L., Passifloraceae harvested from plants cultivated or collected under different conditions was evaluated by high-performance liquid chromatography with ultraviolet detection (HPLC-UV-DAD) [59]. Figure 69.5 shows an HPLC-UV-DAD chromatogram measured at $\lambda = 337$ nm of leaves and the UV-DAD spectra of flavonoids: orientin, homoorientin, vitexin, and luteolin.

5.1.2 Electrochemical Detection (ECD)

Electrochemical detectors measure chemical properties of a compound and rely on chemical reactions in which electrons are transferred from one compound to another. There are two types of electrochemical detectors, amperometric or coulometric detectors. The latter one is commonly used because of its high surface of contact with a structure of porous graphite working electrodes giving 100 % of the analyte. The magnitude of the current is therefore directly proportional to the injected compounds, and conveniently the peak areas in an HPLC chromatogram represent the total current as a function of time.

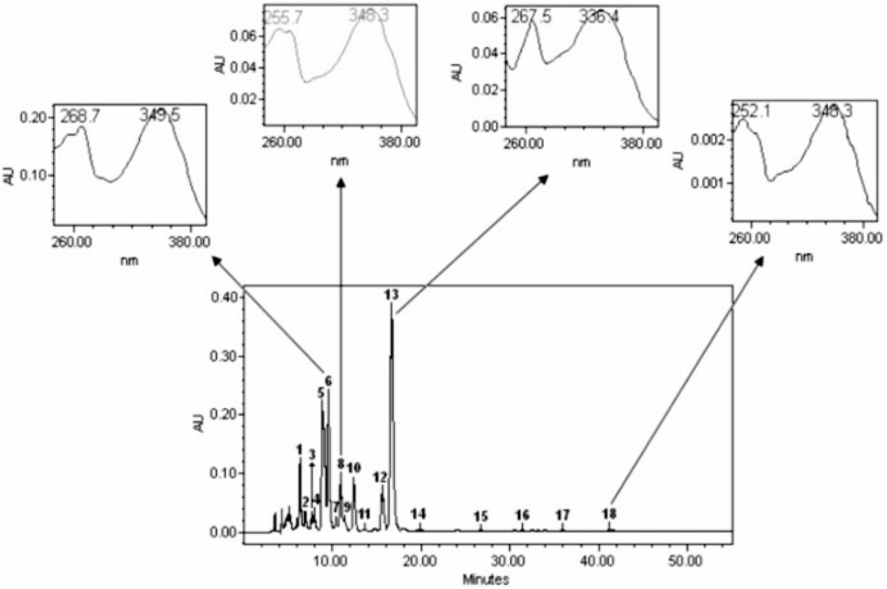

Fig. 69.5 Representative HPLC-UV-DAD ($\lambda = 337$ nm) chromatogram of leaves of *Passiflora incarnata* L. and UV-DAD spectra of flavonoids peaks identified as (**6**) orientin, (**8**) homoorientin, (**12**) vitexin, and (**18**) luteolin [59]

Coulometric detectors are particularly suited to the analysis of flavonoids since the electroactive hydroxyl group present in rings A and B often has a low potential of oxidation. The capabilities of electrochemical detection techniques were demonstrated on 11 compounds belonging to three different classes of flavonoids: flavanone glycosides, flavone and flavonol aglycones. Separation of all compounds examined has been carried out under reversed-phase conditions on a C_{18} standard-bore column and using a porous graphite electrode for electrochemical detection. Instrumental precision in terms of relative standard deviation was found to be between 0.6 % and 10 % [60]. Another example of HPLC-ECD using a microbore column analyzing 15 flavonoids in bottled Japanese green tea samples were reported. The flavonoids were divided into two groups according to their hydrophobicity and were resolved by two isocratic systems: methanol–water (1:1 and 3:7, v/v) containing 0.5 % phosphoric acid. The retention factor (k) of each flavonoid linearly correlated with the log P values. The detection limits (S/N = 3) of the flavonoids tested were in the range of 2–25 fmol, that is, 600 times more sensitive than conventional HPLC with UV detection [61].

Multichannel electrochemical coulometric detection or coulometric array detection has been developed so that different potentials are applied on the electrodes. A number of chromatograms (8, 12, or 16) can be recorded simultaneously. Flavonoids can have several oxidation processes across the array of potentials, giving characteristic profiles for identification. Methods were developed for the analysis of flavonoids in beverages and plant extracts using gradient HPLC with multichannel electrochemical coulometric detection. Eight-channel CoulArray detection offers high selectivity and sensitivity with limits of detection in the low $\mu g\ L^{-1}$ range, at least an order of magnitude lower than single-channel coulometric detection using the Coulochem detector [62]. An example is given in Fig. 69.6 showing the chromatogram of a mixture of standard phenolic and flavonoid compounds, at 0.25 $mg\ L^{-1}$ each, at the optimized HPLC separation selectivity and CoulArray sensitivity under gradient conditions on a Purospher Star column.

5.1.3 Fluorescence Detection (FD)

Fluorescence detection in conjunction with HPLC post-column treatment is commonly used to fulfill the requirements of sensitivity and specificity needed for the study of flavonoids in body fluid. The number of flavonoids that exhibit native fluorescence is limited, and derivatization of flavonoids with reagents such as Al^{3+} [63] and Tb^{3+} [64] is needed before detection. If a hydroxyl group is replaced by a methoxy group, fluorescence becomes considerably more intense as demonstrated by a study using luteolin flavones [65].

Another example of post-column liquid chromatographic reaction system for the determination of flavonoids in orange juices is based on the use of the long-wavelength fluorophore cresyl violet and cerium (IV) in a cetyltrimethylammonium bromide micellar medium [66]. Two flavone aglycones (quercetin and kaempferol), a flavanone aglycone (naringenin), one flavone-*O*-glycoside (rutin), and two flavanone-*O*-glycosides (hesperidin and naringin) were used as analyte models. The reaction process involves the interaction between the analyte, cerium(IV), and cresyl violet giving rise to a decrease in the fluorescence, measured at λ_{ex} 585, λ_{em} 625 nm, which is proportional to the analyte concentration.

5.1.4 Mass Spectrometry Detection

Improvements in the instrumentation, ionization sources, high-resolution mass analyzers, and detectors [67–69], in recent years have taken mass spectrometry to a different level of HPLC-MS for natural product analysis. Mass spectrometry detection offers excellent sensitivity and selectivity, combined with the ability to elucidate or confirm chemical structures of flavonoids [70–72]. Both atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI) are most commonly used as ionization sources for flavonoid detection [73–76]. Both negative and positive ionization sources are applied. These sources do not produce many fragments, and the subsequent collision-induced dissociation energy can be applied to detect more fragments. Tandem mass spectrometry (MS^n, $n \geq 2$) provides information about the relationship of parent and daughter ions, which enables the confirmation of proposed reaction pathways for fragment ions and is key to identify types of flavonoids (e.g., flavones, flavonols, flavanones, or chalcones) [77–80].

Anthocyanins are in glycosylated forms, and their aglycones are known as anthocyanidins. The positive charge in the tetravalent oxygen makes anthocyanidins more suitable for MS analysis in positive mode at low voltages [81]. MS detection of catechins and gallocatechins, which are proanthocyanidins,

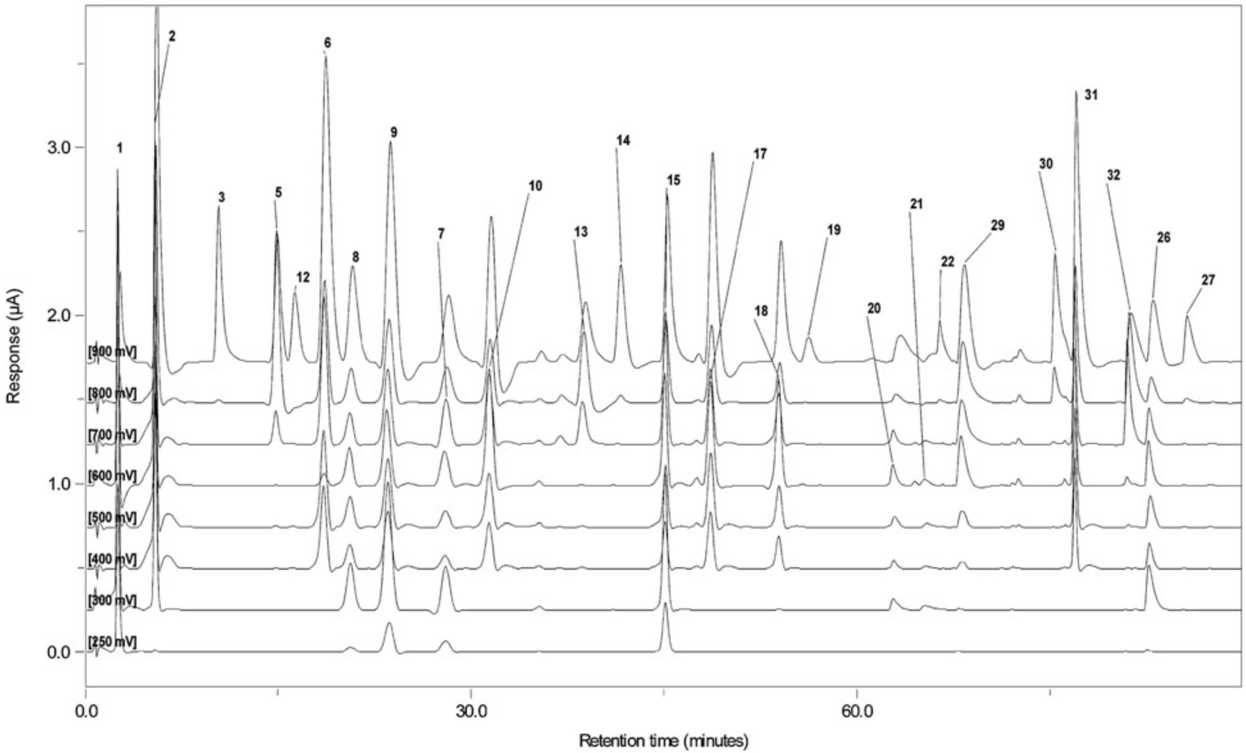

Fig. 69.6 Chromatogram of a mixture of phenolic and flavonoid antioxidant standards. Column (Purospher STAR, RP-18e,150 × 2.9 mm, 5 µm), gradient condition, 0 min: 2 % MeCN; 20 min: 2 % MeCN; 50 min: 9 % MeCN; 65 min: 19 % MeCN; 90 min: 50 % MeCN, pH = 3.14, flow rate 0.4 mL min^{-1}. (Flavonoids: **7**, (+)-catechin; **15**, (−)-epicatechin; **20**, rutin; **21**, quercetin-3-arabinoside; **22**, naringin; **23**, myricetin; **24**, quercetin; **25**, apigenin; **26**, quercetin dimethyl ether; **30**, naringenin; **31**, hesperetin) [62]

can solve the problem suffered from the interferences caused by co-eluting phenolics in UV detection [82]. In the fragmentation of catechins, a loss of 152 mass unit (168 mass unit for gallocatechins) is produced due to their retro-Diels–Alder fission. The characteristic signals in mass spectra of catechins and gallocatechins enable identification of their polymerization [83].

Further details on mass spectrometric analysis of flavonoids are discussed in ► Chap. 66, "Mass Spectrometric Detection of Phenolic Acids."

5.2 Combination of Detection

Multiple detections, such as HPLC-UV-MS^n, HPLC-UV-NMR, HPLC-DAD-FD-UV, and HPLC-DAD-FD-MS, have been adopted to identify and characterize the structure of flavonoids and also used to evaluate the bioactivity of components [72, 84–87]. In most cases, single-stage MS is used in combination with UV detection to facilitate the confirmation of the identity of flavonoids in a sample with the help of standards and reference data (an example is given in Fig. 69.7, [88]). For the identification of unknowns, tandem mass spectrometry is used.

A recent example of using the multiple detection system elegantly by incorporating a simultaneous bioactivity screening into a three-detection system (photodiode array and fluorescence detectors and an electrospray ionization tandem mass spectrometer, DAD-FD-MS^2) [87] demonstrated that 25 flavonoids could be characterized and/or tentatively identified in an aqueous infusion of leaves of *Ficus deltoidea* (Moraceae). The main constituents are flavan-3-ol monomers, proanthocyanidins, and C-linked flavone glycosides. The proanthocyanidins were dimers and trimers comprising (epi)catechin and (epi)afzelechin units. The antioxidant activity of *F. deltoidea* extract was analyzed using HPLC-DAD-FD-UV$_{\text{antioxidant}}$ detection, showing 85 % of the total antioxidant activity of the aqueous *F. deltoidea* infusion was attributable to the flavan-3-ol monomers and the proanthocyanidins. The data obtained from the online HPLC-ABTS antioxidant detection system are shown in Fig. 69.8 along with absorbance traces at 280 and 365 nm. The chromatographic profiles after 34 min did not exhibit antioxidant activity. The peaks contributing the main antioxidant activity were the flavanonol monomers gallocatechin (peak 1), catechin (peak 3), and epicatechin (peak 9), and the flavone apigenin-6,8-*C*-diglucoside (peak 11).

HPLC-UV-NMR is a powerful technique for the identification and characterization of flavonoids. However, there are drawbacks, as NMR remains rather insensitive because of the need for solvent suppression, which has restricted the observable NMR range. Recently, two major research developments in HPLC-UV-NMR are post-column solid-phase extraction (HPLC-UV-SPE-NMR) and combination of HPLC-UV-SPE with capillary separations and NMR detection [89]. A post-column treatment of analyte focusing and multiple trapping through a SPE has solved the problem of sensitivity and solvent suppression. The separation and elucidation of three *C*-methylated flavanones and five dihydrochalcones from *Myrica gale* seeds have been achieved by HPLC-DAD-SPE-NMR and

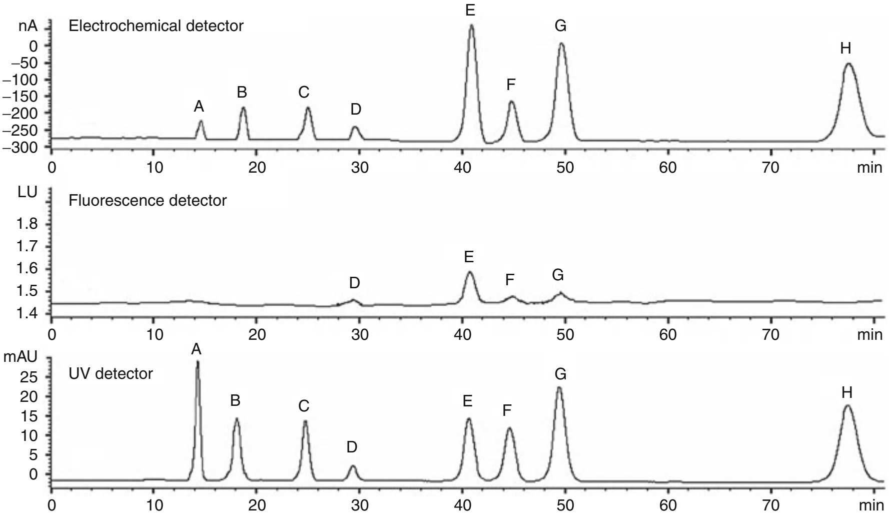

Fig. 69.7 Chromatograms of the flavonoid standards; rutin (*A*), isoquercitrin (*B*), luteolin-40-glucoside (*C*), quercetin-40-glucoside (*D*), quercetin (*E*), naringenin (*F*), luteolin (*G*), and apigenin (*H*) with electrochemical, fluorescence, and UV detectors [88]

HPLC-DAD-MS [90]. Analysis of flavonoids in Wormwood (*Artemisia absinthium* L.) and in the leaves of 12 Litsea and Neolitsea plants has been also achieved by HPLC-DAD-SPE-NMR and HPLC-DAD-MS [91, 92].

6 Two-Dimensional (2D, LC × LC) HPLC

Online 2D LC × LC separation is achieved by a direct coupling of primary and secondary columns through switching valves. Two approaches are used. In the first, eluent containing peaks of interest and monitored during the first dimension of separation is redirected to the second dimension of separation. In the second, a comprehensive 2D setup, the whole sample is subjected to both separations. The advantage of 2D chromatographic techniques over 1D methods is the increase in peak capacity (resolving power) but the timescale for achieving it is comparatively long [93]. Separation of flavonoids in plants and foods requires comprehensive 2D LC × LC approach for full separations. RP-HPLC is normally used in the 1D separation, and hence RP × RP systems, perhaps with different selectivity stationary phases, is selected for 2D analysis.

A review on the use of different stationary phases in polyphenols, polycarboxylic acids, and flavonoids has highlighted the differences in selectivity of these classes of polar or possibly ionized compounds [94, 95]. Figure 69.9 shows the contour plot and the elution conditions of the comprehensive 2D separation of phenolic acids and flavones using parallel gradients of acetonitrile in a 5 mM ammonium acetate buffer on a PEG microcolumn in the first dimension and

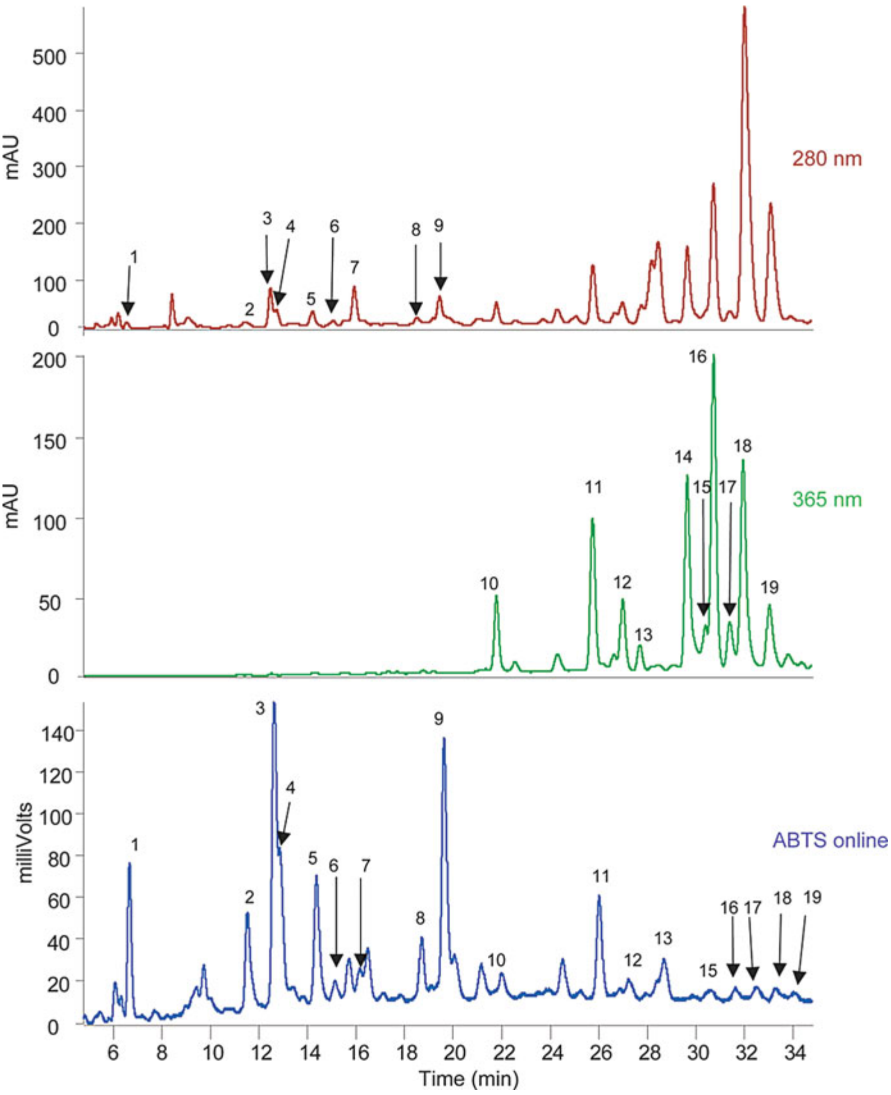

Fig. 69.8 Reversed-phase HPLC of an aqueous infusion of *F. deltoidea* leaves with absorbance detection at 280 and 365 nm and online ABTS$^+$ antioxidant detection at 720 nm [87]

a short monolithic C_{18} column in the second [95]. In this study, flavonoids included for separation are **19** (+)-catechin, **20** (−)-epicatechin, **21** rutin, **22** naringin, **23** myricetin, **24** quercetin, **25** apigenin, **27** luteolin, **28** naringenin, **29** 7-hydroxyflavone, **30** hesperidin, **31** morin, **32** hesperetin, and **33** flavone. There is a clear separation of compounds **19** and **33**.

In addition, from the same group has developed a comprehensive 2-D LC × LC system for the separation of phenolic and flavone antioxidants, using a PEG-silica

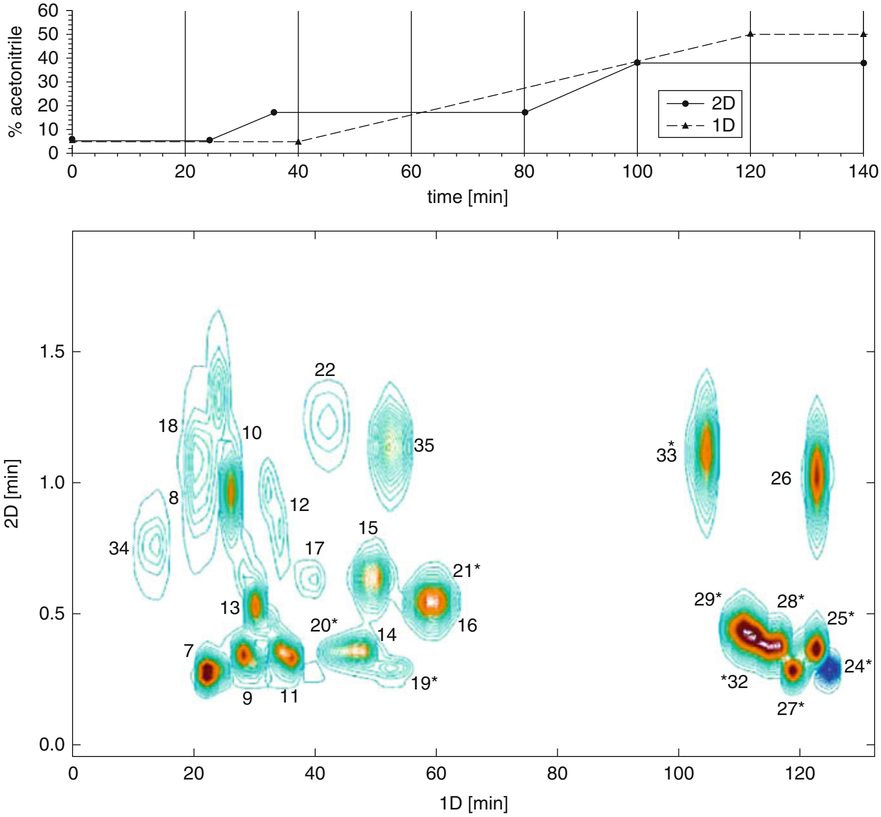

Fig. 69.9 Contour plot and elution conditions (*top*) showing comprehensive LC × LC separations of phenolic acids and flavones on a PEG column in the first dimension and on a Chromolith RP-18e column in the second dimension with parallel gradients of acetonitrile in the two dimensions. Compounds that are flavonoids in this figure (*) are **19** (+)-catechin, **20** (−)-epicatechin, **21** rutin, **22** naringin, **24** quercetin, **25** apigenin, **27** luteolin, **28** naringenin, **29** 7-hydroxyflavone, **32** hesperetin, and **33** flavone [95]

column in the first dimension and a C-18 column with porous-shell particles in the second dimension and the use of electrochemical coulometric detection to compensate the effects of the baseline drift observed in UV during the gradient elution [96]. Superficially porous columns with fused core particles improve the resolution and speed of second dimension separation in comparison to a fully porous particle C_{18} column. The developed system has been applied to the analysis of flavonoids and phenolic acids in beer samples.

A comprehensive two-dimensional HPLC system, with an RP column as a primary column and an immobilized liposome chromatography (ILC) column as a secondary column, was developed for the screening and analysis of the membrane-permeable compounds in the traditional Chinese medicine

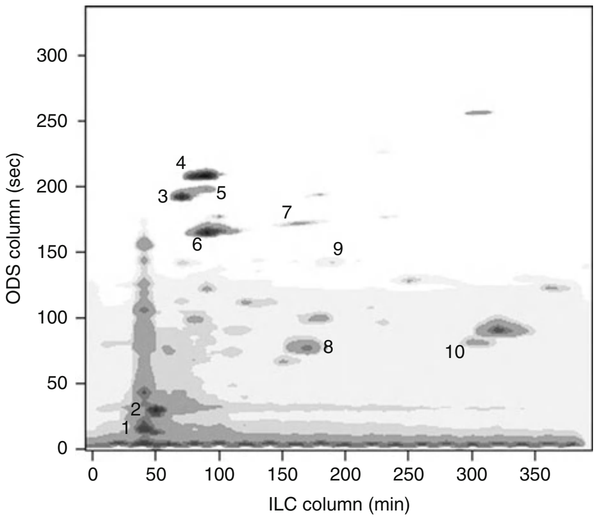

Fig. 69.10 2D chromatogram of Longdan Xiegan Decoction. Chromatographic conditions for the ILC column: isocratic elution with 10 mM ammonium acetate solution (pH 6.8); flow rate, 0.05 mL/min. Chromatographic conditions for the ODS column: linear gradient elution from 10 % MeCN to 70 % MeCN in 7 min, and then returning to the initial mobile phase and holding for 3 min for re-equilibration; flow rate, 2.0 mL/min; injection volume, 5 μL; detection wavelength, 210 nm. Cycle time for the second dimension is 10 min. Compounds (1–10): geniposide, gentiopicroside, oroxylin A-7- *O*-glucuronide, wogonoside, 7-*O*-β-D-glucuronopyranosylchrysin, baicalin, ononin, liquiritin apioside, 3′,4′-dihydroxy-5,6-dimethoxy-7-*O*-glucosideflavone, liquiritin [97]

prescription Longdan Xiegan Decoction (LXD) [97]. More than 50 components in LXD were resolved using the developed separation system. Eight flavonoids and two iridoids were identified interacting with the ILC column, a system that mimics biomembranes (Fig. 69.10). The results show that the developed comprehensive two-dimensional chromatography system can be used for identifying membrane permeable flavonoids in complex matrixes such as extracts of traditional Chinese medicine prescriptions. A similar system with an RP column and a silica-bonded human serum albumin (HSA) column was developed for the biological fingerprinting analysis of bioactive components in LXD [98].

7 Quantitation

Quantitative analysis of flavonoids in plant, food, and biological samples is important because these compounds are partially responsible for the biological activity and medical benefits in these products. Flavonoids are commonly used as chemical markers for quality control purpose of plant and food products.

Flavonoids can be determined quantitatively by direct (in glycoside or conjugated form) or indirect (after hydrolysis) analysis. However, sample preparation (e.g., particle size) and solvents used in extraction steps can significantly affect the results [99]. Method development for quantitation is often validated in terms of selectivity, accuracy, precision, recovery, calibration curve, and reproducibility. Biological sample methods have to comply with the Food and Drug Administration (FDA) guidelines for validation of bioanalytical method [100].

With the coupling of HPLC to different sensitive detection techniques, quantitation of flavonoids in all types of samples has been explored whenever the reference standards are available for calibration [101–103]. Furthermore, the quantitation potentials of analytes (regardless of the type of compounds) rely mainly on the sensitivity limits of the coupled detection system. To date, HPLC coupled to a UV–VIS detector is the most popular quantitation technique used in flavonoid analysis especially for samples with high flavonoid concentrations. The wavelengths used to quantify anthocyanins are at the range 510–520 nm, flavanonols at 280 nm, flavones and flavanols at 270 and 360–370 nm. However, DAD is the other detection mode for quantitation but only slightly more sensitive than UV, and it is still not as sensitive as MS. The detection limits of LC-UV/DAD are usually in the region of μg/mL to the ng/mL levels, while for LC-MS, it is in the region of ng/mL to the pg/mL levels. The ability for the analysis to attain the lowest possible limit of detection, characteristic of the detector, depends on the chromatographic and detection method development, as well as the sample preparation/clean-up method. These are important factors to consider in order to prevent interferences, which could cause inaccurate and misleading measurements. A good review on quantitative analysis of flavonol glycosides, biflavones, and proanthocyanidins in *Ginkgo biloba* leaves, extracts, and phytopharmaceuticals has been published highlighting the different factors from extraction, separation to detection on the quantitative analysis of one subclass of flavonoid [104].

Quantitative methods using the HPLC-electrospray ionization-tandem mass spectrometry method (HPLC–MS^2) facilitates the achievement of adequate sensitivity for pharmacokinetic and metabonomic studies with flavonoids. Matrix effects on signal intensity are important in biological samples, especially during the preparation of calibration curves, to avoid errors from nonlinear range at high concentration [50]. Flavonoid kaempferol, for example, is mainly present as glucuronides and sulfates, and small amounts of the intact aglycone in rat plasma. A validated HPLC–MS^2 method following FDA guidelines has been reported for determination of kaempferol and its major metabolite glucuronidated kaempferol in rat plasma in a study of the pharmacokinetics after oral administration of kaempferol with different doses [103]. The separation of kaempferol and its metabolites was carried out on a C_{18} column (150 × 2.1 mm, 4.5 μm, Waters Corp.) with isocratic elution at a flow rate of 0.3 mL min^{-1}, and a mobile phase consisting of 0.5 % formic acid and acetonitrile (50:50, v/v). The quantitative determination was from a Quattro Premier mass spectrometer operating under a multiple-reaction monitoring mode (MRM), using the electrospray ionization technique.

8 Selected Examples of Flavonoids Analysis by HPLC

Some examples of more flavonoid analyses by HPLC have been selected and detailed as presented in Tables 69.3–69.5. These examples are divided into plant (Table 69.3), food (Table 69.4), and biological (Table 69.5) samples. Notably, these examples are mainly from work published from 2008 onward, except for three papers in 2006 and 2007. These examples have been the selected ones due to the research article details including good representation(s) of chromatogram(s) to assist other researchers to easily validate their studies. These examples show the application of this chapter's aforementioned types of extractions, separations (in terms of column chemistry, dimensions), and the detection systems.

9 Conclusion

The number of flavonoids (9,000 in 2004 [105], 9,600 in 2007 [1], 10,380 in 2009 [2]) identified from 2004 to 2009 indicates the high level of interest of this class of secondary metabolites in plant. The achievements are a result of the advance in the technology of detection. In 1994, the separation of 25 flavonoids reference standards was made comfortably relying on the stationary phase technology and the knowledge of the interaction of mobile phase and analytes. The improvement of sensitivity and target-specific detection, for example, tandem mass spectrometry detection, has compensated the inability of complete resolution of peaks in a chromatogram and assisted the identification of sugar units, which partly contributed to the boom of newly identified flavonoids in recent years. In certain ambiguous circumstances, for example, the position of substitutions, NMR spectroscopy can provide a fuller picture of the identity of the flavonoids. HPLC-MS has been used to screen compounds for drug discovery programs [106]. In flavonoids, HPLC-UV-MS has been used for screening the antioxidant activities in teas [87] and using the 2D (LC × LC) system in an herbal decoction [97, 98].

In many examples, with little regard of the sample type, the analyses of flavonoids are usually done in the reversed-phase HPLC mode using nonpolar C_{18} (in few cases, C_8) columns and polar mobile phase (mixed aqueous–organic solvents) due to their structural and physicochemical properties. Conversely, with more regard of the sample type, different extractions and sample pretreatments including Soxhlet, LLE, SPE, USAE, ASE, and SFE have been used prior to HPLC flavonoid analysis.

Table 69.3 Selected examples of flavonoid analysis by HPLC in plant (*SLE* solid liquid extraction, *aq*. aqueous, *Q-TOF* quadrupole-time of flight, *TQ* triple quadrupole)

Plant	Flavonoid sub-class	Extraction	Stationary phase	Mobile phase	Detector(s)	References
Glycyrrhiza L. (Leguminosae family): licorice	6 chalcones	SLE (ultrasonification, 70 % aq. MeOH)	Agilent Zorbax SB-C_{18} column (50 × 4.6 mm, 1.8 μm)	Gradient: 0.2 % formic acid (aq.) and MeCN	UV-MS (+ve, Q-TOF MS^2)	[107]
Bupleurum species	1 catechin, 2 flavones, 8 flavonols	SLE (ultrasonification, MeOH)	Shimpack ODS C_{18} column (150 × 4.6 mm, 5 μm)	Gradient: 0.1 % formic acid (aq.) and MeCN	UV	[108]
Orostachys japonicus	7 flavonols, 7 catechins	SLE (reflux, 70 % aq. MeOH; hexane; EA)	Agilent Zorbax SB-C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.05 M ammonium formate (aq.) and MeOH	UV-MS (+ve, Q TRAP)	[71]
Hypericum japonicum	1 flavanonol, 4 flavonols	SLE (ultrasonification, 70 % aq. MeOH)	Agilent Zorbax SB-C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.5 % formic acid (aq.) and MeCN	UV-MS (+ve, Q-TOF MS^2)	[109]
Iris tectorum Maxim. (Iridaceae)	2 flavanones, 1 flavonol, 1 flavanonol	SLE (ultrasonification, MeOH)	Agilent Eclipse Plus™ C_{18} column (150 × 3.0 mm, 3.5 μm)	Gradient: 0.05 % acetic acid (aq.) and MeCN	DAD-MS (−ve and +ve MS^2)	[110]
Murraya paniculata (L.) Jack	14 flavones, 2 chalcones	SLE (ultrasonification, 70 % aq. MeOH)	Agilent Zorbax Eclipse Plus C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.1 % formic acid (aq.) and MeCN	DAD-MS (+ve MS^2)	[111]
Ziziphus jujuba Mill. and *Z. jujuba* var. spinosa (Bunge) Hu ex H.F	3 flavonols	SLE (ultrasonification, 80 % aq. MeOH)	Waters Sunfire C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.2 % acetic acid (aq.) and MeCN	DAD-MS (−ve, Q-TOF MS^2)	[112]

Scutellaria baicalensis Georgi (*S. baicalensis*)	27 flavones, 1 flavanol, 2 flavanones, 1 flavanonol, 1 biflavone	SLE (reflux, 60 % aq. MeCN; CH_2Cl_2)	Welch Materials Ultimate XB C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.06 % acetic acid (aq.) and MeCN	UV-MS (−ve LCQ Ion trap MS^n)	[113]
Chrysosplenium (Turn.) L. (aerial parts) of flowering *C. alternifolium*	4 flavonols	SLE (reflux, MeOH)	Agilent Hypersil C_{18} column (125 × 4 mm, 5 μm)	Gradient: 0.5 % phosphoric acid (aq.) and MeCN	DAD	[114]
Glycin tomentella Hayata (leaves and roots)	3 flavones, 7 flavonols, 6 flavanones	SLE (reflux, 95 % aq. EtOH)	Thermo Hypersil GOLD C_{18} column (250 × 4.6 mm, 5 μm).	Gradient: 9 % acetic acid (aq.) and MeOH	DAD	[115]
Houttuynia cordata Thunb	4 flavonols	Pressurized liquid extraction or hot soaking with shaking (70 % EtOH)	Kromasil Turner YWG C_{18} column (250 × 4.6 mm, 10 μm)	Gradient: water–MeCN–phosphoric acid (400:100:0.2) and MeCN–MeOH–water–phosphoric acid (375:75:50:0.1)	UV	[116]
Artemisia annua L.	5 flavonols, 1 flavone	SLE (Maceration, DCM or hexane)	Merck Eurosphers Star RP-18 column (200 × 4.6 mm, 5 μm)	Gradient: formic acid aq. (pH 3.2) and MeCN	DAD-MS (+ve, ion trap, MS)	[117]

Table 69.4 Selected examples of flavonoid analysis by HPLC in foods (*SLE* solid liquid extraction, *LLE* liquid–liquid extraction, *aq*. aqueous, *Q-TOF* quadrupole-time of flight, *TQ* triple quadrupole)

Food	Flavonoid subclass	Extraction	Stationary phase	Mobile phase	Detector(s)	References
Black currant juice	3 flavones, 2 flavonols, 3 flavanones	None (direct injection)	Agilent Zorbax Rapid Resolution C_{18} column (50 × 2.1 mm, 1.8 μm)	Gradient: 0.1 % formic acid (aq.) and 0.1 % formic acid in MeCN	MS (−ve, LTQ-Orbitrap, MS^2)	[118]
Tomato (*Lycopersicon esculentum* Mill.)	8 flavonols, 11 flavanone, 2 dihydrochalcones	SLE (Homogenization, sonication, and centrifugation); SPE	Phenomenex Luna C_{18} column (50 × 2.0 mm, 5 μm)	Gradient: 0.1 % formic acid (aq.) and 0.1 % formic acid in MeCN	DAD-MS (−ve, LTQ-Orbitrap and TQ, MS^n)	[119]
Passiflora edulis fruit pulp	2 flavones, 1 flavonol	LLE (sonication 60 % or 100 % MeOH or EtOH); SPE	Waters Symmetry C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.2 % formic acid (aq.) and 0.2 % formic acid in MeCN	DAD-MS (−ve, TQ, MS^2)	[120]
Ripe red paprika (*C. annuum*) and yellow habanero (*C. chinense*) peppers	3 flavonols, 2 flavones	LLE (homogenization, EtOH); 3 M HCl	Phenomenex Gemini C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.03 M phosphoric acid (aq.) and MeOH.	DAD-MS (−ve or +ve, Q-TOF, MS)	[121]
Citrus grandis, Citrus paradise (flavedos "external layer of peel" and juices)	15 flavonols, 13 flavanones	LLE (sonication, MeOH)	Agilent Zorbax SB C_{18} column (250 × 4.0 mm, 5 μm)	Gradient: 1 % acetic acid (aq.) and 1 % acetic acid in MeCN	DAD-MS (−ve, Ion trap, MS^2)	[122]
Rooibos tea from *Aspalathus linearis*	4 flavones, 8 flavonols, 2 dihydrochalcones	SLE (boiled, water)	Phenomenex Luna Phenyl–Hexyl (250 × 4.6 mm, 5 μm)	Gradient: 2 % acetic acid (aq.) and MeCN	DAD	[123]

Ocimum gratisimum L., *Vernonia amygdalina* L., *Corchorus olitorius* L., *Manihot utilissima* Pohl.	6 flavonols, 10 flavones	SLE (MeOH; 70 % aq. EtOH, pH 2.5)	Phenomenex Synergi max C_{12} column (150 × 4.0 mm, 4 μm)	Gradient: formic acid aq. (pH 3.2) and MeCN	DAD-MS (−ve, Ion trap, MS)	[124]
Sugarcane raw juice (*Saccharum sinense* Roxb.)	1 flavone, 1 anthocyanin	LLE (n-butanol (1:1 v/v); MeOH)	Waters Symmetry C_{12} column (150 × 4.6 mm, 4.6 μm)	Gradient: 0.1 % formic acid (aq.) and MeOH	DAD	[125]
Slovenian honeys: *Robinia pseudoacacia*, *Tilia spp.*, *Castanea sativa*, *Abies alba* Mill., *Picea abies* (L.) Karst	4 flavonols, 3 flavones, 3 flavanones, 1 flavanonol	LLE (acidified water pH 2); SPE, MeOH–MeCN (2:1, v:v). Biological sample	Flavonoid subclass	Extraction	Stationary phase	Mobile phase	Detector(s)	References
Ginkgo biloba in rat plasma	3 flavonols	Acid hydrolysis (sample: 10 M HCl: MeOH 2:1:2 v:v: v); neutralized with 15 M NH_3; LL (MeOH)	Waters C_{18} column (150 × 4.6 mm, 5 μm)	Isocratic: MeCN-0.02 M NaH_2PO_4 (0.2 % H_3PO_4), pH = 2.0, (35:65)	DAD	[133]
Aspalathus linearis in human urine and blood plasma	8 flavones, 4 flavonols, 2 dihydrochalcones	Urine: SPE (Oasis WCX cartridges) Blood: centrifugation (2,000 g for 10 min at 4 C) – plasma: (LLE, EtOAc)	Phenomenex Luna Phenyl–Hexyl (250 × 4.6 mm, 5 μm)	Gradient: 2 % acetic acid (aq.) and MeCN	UV-MS (−ve, ion trap, MS^2)	[123]
Herba Epimedii in dog plasma	7 flavonols	SLE (Vortex, centrifugation MeOH, 70 % EtOH aq.)	Agilent Zorbax Eclipse SB-C_{18} column (50 × 2.1 mm, 1.8 μm)	Gradient: 0.3 % acetic acid (aq.) and 0.3 % acetic acid in MeCN	MS (+ve, TQ, MS^2)	[134]
Hawthorn leaves in rat plasma	2 flavones	SLE (Vortex, centrifugation MeOH)	Dikma Diamonsil TM C18 column (200 × 4.6 mm, 5 μm)	Isocratic: MeOH–MeCN–THF–0.5 % acetic acid (1:1:19.4:78.6)	UV	[135]
Vitis labrusca vines (Concord grapes) in human urine and blood	25 anthocyanins	Acidify with 50 % formic acid aq., SPE (Phenomenex Strata C_{18} (6 mL/500 mg), 1 % formic acid containing 10 % MeOH)	Phenomenex Synergi (250 × 4.6 mm, 4 μm)	Gradient: 1 % formic acid (aq.) and MeOH	DAD-MS (+ve or −ve, ion trap, MS^n)	[131]

(*continued*)

Table 69.5 (continued)

Biological sample	Flavonoid subclass	Extraction	Stationary phase	Mobile phase	Detector(s)	References
Dalbergia odorifera in rat urine	4 neoflavones, 2 flavanones, 2 chalcones	LLE (Vortex, centrifugation EtOAc)	Agilent Zorbax SB C_{18} column (250 × 4.6 mm, 5 μm)	Gradient: 0.3 % acetic acid (aq.) and MeCN	UV-MS (−ve, MS)	[136]
Eriobotrya japonica (Thunb.) Lindl.	9 flavonols	SLE (EtOH)	Hanbon Kromasil C_{18} column (200 × 4.6 mm, 5 μm)	Gradient: 1 % acetic acid (aq.) and 1 % acetic acid in MeOH	DAD-MS (−ve, Ion Trap, MS)	[137]
Vaccinium macrocarpon cranberry concentrate in rats urine and blood	2 flavonols, 7 anthocyanins	Tissue: LLE (homogenization, 80 % MeOH containing 0.1 % acetic acid; vortex, centrifugation 80 % MeOH aq.)	Phenomenex Fusion (150 × 2.0 mm, 1.8 μm)	Gradient: 0.1 % formic acid (aq.) and 0.1 % formic acid in MeCN	MS (−ve, TQ, MS^2)	[132]
		Urine, plasma: Hydrolysis, LLE (diethyl ether)				

Indeed, with the development of separation techniques for HPLC to the ultra-HPLC leading to faster analyses and high throughput, coupled with the advancement of the detection technique, even more flavonoids would both be identified and quantified quicker in the future.

Abstract

In recent years, there has been an increased interest in the use of solid support-free liquid–liquid chromatographic techniques for the purification of polyphenols from natural plant sources. These methods include mainly high-speed countercurrent chromatography (HSCCC) and centrifugal partition chromatography (CPC). This chapter presents a summary of all recent HSCCC and CPC studies investigating the fractionation or purification of phenolic compounds from complex plant extracts. This synopsis, covering the last 5 years and comparing over 90 studies, demonstrates that solid support-free liquid–liquid

separation techniques offer distinct advantages for the isolation of polyphenols in terms of analyte preservation, solvent consumption, and run duration while the purity and recovery values remain equivalent to or even higher than those obtained with conventional chromatographic methods using solid supports. Crucial parameters affecting the separation of different polyphenol classes will be discussed, particularly the nature of the solvent system, the chromatographic development modes, the flow rate, and the column capacity.

1 Introduction

A wide range of methods can be used for the purification of phenolic compounds from natural sources. The most common procedures are based on “solvent extraction,” a simple and efficient process applicable to a wide range of raw materials. The starting material is partitioned between at least two liquid phases in order to obtain fractions enriched in the target compound(s). This step is generally followed by macroporous resin separation, silica gel, Sephadex or polyamide chromatography, and preparative thin layer chromatography or preparative high-performance liquid chromatography [1, 2]. These procedures are usually tedious as well as solvent- and time-consuming because of multiple chromatographic steps. In addition, low recoveries are usually obtained, and a large amount of organic solvent waste is often generated [3].

In recent years, there has been an increased interest in the use of solid support-free liquid–liquid chromatographic methods for the separation and purification of flavonoids and other phenolic compounds from natural sources [4, 5]. High-speed countercurrent chromatography (HSCCC) and centrifugal partition chromatography (CPC) are the two main variants of support-free liquid–liquid chromatographic systems being used today. In the development of a HSCCC or CPC separation method, a least two immiscible liquid phases (solvent system) are required. One phase is maintained into the column (stationary phase) by a centrifugal force field, while the other phase (mobile phase) is pumped through it. The principle of both methods relies on the partition of solutes between the two immiscible liquid phases of the solvent system according to their distribution coefficient K_D. Due to the liquid nature of the stationary phase, these techniques are an excellent alternative to more traditional solid support chromatography. Irreversible adsorption of samples on the solid support is avoided, and the chemical integrity of mixtures subjected to fractionation or purification is preserved. Additional benefits include total sample recovery, high sample mass loading capacity, good selectivity, and versatility while consuming low solvent quantities.

This chapter presents an overview reporting over than 90 studies conducted between 2007 and 2012 and dedicated to the fractionation or purification of polyphenols from natural sources using HSCCC or CPC. It is clear that solid support-free liquid–liquid separation techniques have acquired a significant place among the chromatographic techniques commonly used for the purification of natural products. In particular, HSCCC and CPC are extremely promising for the purification of polyphenols. Efficient procedures are currently being developed to allow either the direct purification of phenolic compounds from complex plant extracts, their partial purification for a further combination with an orthogonal solid support-based technique, or for bioassay-guided fractionation strategies investigating the bioactivity of particular polyphenol classes.

2 The Technology of Solid Support-Free Liquid–Liquid Chromatographic Systems (HSCCC and CPC)

2.1 General Principles

High-speed countercurrent chromatography (HSCCC) and centrifugal partition chromatography (CPC) refer to particular types of hydrodynamic and hydrostatic solid support-free chromatographic systems, respectively. Countercurrent chromatography was firstly introduced by Ito, Harada, and Aoki in 1966 [6], while centrifugal partition chromatography was introduced by Nunogaki in 1982 [7]. In HSCCC, hydrodynamic instruments are used where the separation takes place in a so-called "multilayer coil" made of a long piece of continuous tubing wrapped around a holder in multiple layers (Fig. 70.1). The resulting multiple coils can be connected in series to increase the total volume of the instrument. The coil is submitted to a centrifugal force field and rotates around its own axis while simultaneously rotating around the central axis of the system. This results in stationary phase retention and partitioning of the analytes between the two liquid phases. In contrast, CPC is hydrostatic and uses a spinning rotor, comprised of a series of interconnected cells circumferentially engraved on stacked disks in rotation around a single axis. In CPC, the centrifugal force field applied to maintain one phase stationary inside the column remains constant in intensity and direction. In both systems, the mobile phase is pumped through the stationary phase, and the hydrodynamic equilibrium between phases depends on the intensity of the centrifugal force (generated by the rotation speed), on the flow rate of the mobile phase, and on the physicochemical properties of the biphasic solvent system (density, viscosity, interfacial tension, *etc*....). HSCCC and CPC are very interesting in terms of selectivity, sample loading capacity, and scale-up ability [8, 9] and have both been successfully applied to the purification of natural products [4, 5]. They also allow total recovery of injected samples (up to 100 %) and consume low solvent quantities.

The column capacity of HSCCC or CPC instruments ranges from 200 to 1,000 mL for semi-preparative or preparative-scale separation processes. Analytical columns have also been recently developed (25 mL for CPC and 18 mL for HSCCC). Pilot and industrial instruments for large-scale applications are progressively appearing on the market (5–15 L for CPC and up to 18 L for HSCCC). Development of solid support-free liquid–liquid separation instruments is currently focused on the improvement of coil and column design, scale-up capacities, and operating conditions to guarantee industrial applications with high productivity.

2.2 Crucial Parameters for Efficient Separations in HSCCC and CPC

One of the key factors for a successful HSCCC or CPC separation relies on the choice of a suitable biphasic solvent system. A good solvent system should ideally both dissolve as well as efficiently partition the target compounds between the two immiscible phases while displaying a sufficient stability at the hydrodynamic equilibrium of the two liquid phases during the experiment. Generally, the distribution coefficient (K_D) of a compound in a biphasic solvent system should range between 0.5 and 2 [10], and the selectivity ($\alpha = K_b/K_a$) between any pair of compounds to be separated should be greater than 1.5 (with $K_b > K_a$). It should be noted that a high K_D value results in broad chromatographic peaks and long elution duration, while a low K_D value results in poor separation resolution. The stability of a solvent system is reflected by its settling time, which should ideally be shorter than 30 s when measured in a test tube, in order to ensure a sufficient retention of the stationary phase. Finally,

the selected solvent system should result in similar volumes of each immiscible phase in order to optimize their use and avoid solvent waste.

A large choice of biphasic solvent systems is available in the literature, and sometimes several systems can be suitable for the purification of the same compound. Solvent systems composed of an organic and an aqueous phase are the most popular in conventional HSCCC or CPC processes [10]. For instance, the Arizona liquid system, which combines *n*-heptane/ethyl acetate/methanol/water in different possible proportions, is widely used for the purification of natural products and especially of phenolic compounds [11]. Other solvent systems composed of chloroform/methanol/water or ethyl acetate/*n*-butanol/water have also been widely used for HSCCC and CPC applications. More recently, another kind of solvent system composed of water-soluble hydrophilic organic solvent and inorganic salt solution, first designed for peptide and protein separation, has been used for the purification of natural products including salvianolic acid [12]. These aqueous two-phase systems present the advantage of being low cost and environmentally safe, providing higher polarity compared to the conventional organic/aqueous systems and being suitable for the separation of highly polar natural products. Another original solution consists in the use of salting-out gradients in CPC (chloroform/*n*-butanol/LiCl solution and/or phosphate buffer) for the isolation of chlorogenic acid derivatives [13].

After optimization of the biphasic solvent system, a suitable pumping mode must be selected. When the lower phase of the biphasic solvent system is used as the stationary phase, the experiment is performed in the “ascending mode” in CPC or “tail to head” in HSCCC. When the lower phase is used as the mobile phase, the experiment is performed in the “descending mode” in CPC or “head to tail” in HSCCC. Another interesting aspect of these techniques is the ability to change the role of the two phases during the run, the stationary phase becoming mobile and *vice versa*, to operate in dual mode or in multiple dual mode [14].

In addition to the classical elution mode (isocratic or gradient) where the selectivity depends only on the affinity of the analytes for the two liquid phases, other development strategies based on displacement methods can be applied. Basically, the displacement mode is performed by adding a retaining agent or ion exchanger in the stationary phase and a displacer in the mobile phase. In the pH-zone-refining displacement mode, an acid or a base is dissolved in the stationary phase as retainer. Depending on the nature of the target compound, displacement by pH-zone-refining can be suitable for the separation and purification of ionizable compounds whose electric charge and solubility properties depends on the pH value [15]. This is the case for some polyphenols. In the ion-exchange displacement mode, a cationic exchanger is, for instance, dissolved in the stationary phase in order to capture all anionic analytes present initially in the crude sample via the formation of ion pairs. This method mainly concerns ionic compounds whose charge is invariant and independent of the pH in aqueous solution. Then a displacer agent presenting a stronger affinity for the exchanger is added to the mobile phase, resulting in a step-by-step selective transfer of the analytes from the stationary to the mobile phase [16]. This ion-exchange displacement mode has been previously developed in combination with CPC for the purification of glucosinolates from white mustard and broccoli seeds [17] and rosmarinic acid from *Lavandula vera* cell cultures [18].

3 Applications of HSCCC and CPC for the Purification of Polyphenols

3.1 Direct Purification, Orthogonal Purification, or Bioassay-Guided Fractionation?

Due to their wide injection capacity and absence of solid support, crude samples from several milligrams to several grams can be injected in HSCCC and CPC without extensive preparation. This overview reports a large panel of studies carried out from 2007 to 2012 applying solid support-free liquid–liquid separation methods for the direct purification of polyphenols starting from crude plant extracts. In this literature survey, the purification of phenolic compounds from complex plant extracts was achieved in three ways: either totally by HSCCC or CPC without need for another complementary technique (Table 70.1-A), partially with a further orthogonal solid support-based purification procedure required (Table 70.1-B), or in a bioassay-guided fractionation perspective for the biological investigation of particular polyphenol classes (Table 70.1-C).

3.2 Direct Purification or Orthogonal Purification

Among these studies, HSCCC has been by far the most widely used technique for the purification of polyphenols as compared to CPC. This is probably because HSCCC is becoming a popular and very useful technique for people working in pharmacognosy, particularly in Asian and North American laboratories. Most of the studies presented in Table 70.1 have been performed in Asia and concern the preparative isolation of active compounds from traditional Chinese medicinal herbs [19–22]. For instance, several isoflavones were recently isolated with high purity by HSCCC from the rhizomes of *Belamcanda chinensis*, a plant traditionally used in Eastern Asia to treat inflammation, asthma, or pharyngitis [23]. The phenolic compounds of *Halimodendron halodendron*, a Fabaceae species distributed in Northwest China [24]; the prenylflavonoids of *Artocarpus altilis* whose leaves are used in Indonesia for the treatment of liver cirrhosis, hypertension, and diabetes [25]; the flavanones of *Poncirus trifoliata*, a fruit widely used in oriental traditional medicine to treat digestive ulcers, gastritis, or inflammation [26]; or the rotenoids of *Millettia pachycarpa*, a famous Chinese herb used as an antihelminthic [21] are only a few examples of phenolic compounds which have been efficiently purified by HSCCC starting from crude extracts of Asian medicinal plants.

High-performance countercurrent chromatography (HPCCC) is another recent development of HSCCC enabling higher flow rates and thus shortening the separation time while maintaining good resolution [27]. HPCCC was used for the purification of several flavonol glycosides and flavones from the Chinese herb *Flaveria bidentis* at the preparative scale [28].

Table 70.1 Recent applications of HSCCC and CPC in the purification of polyphenols from complex plant extracts

Targeted compound(s) (purity %)	General method column capacity	Starting material	Solvent system	Flow rate, Rotation speed, run duration	Refs
A – Direct isolation of highly pure polyphenols					
Phloroglucinol: hyperforin (98 %)	HSCCC (220 mL) gradient elution	*Hypericum perforatum* (1 g)	Hept:MeOH:ACN (1.5:0.5:0.5 v/v), Hept:MeOH (1.5:1 v/v)	2 mL/min; 800 rpm; DM; 480 min	[48]

Flavonols: hyperoside, quercitrin (>98 %)	HSCCC (260 mL)	*Osteomeles schwerinae* (160 mg)	Hex:EtOAc:MeOH:H_2O (0.5:5.5:1.5:4.5 v/v)	1.5 mL/min 800 rpm DM; 300 min	[63]
Flavanones (>97 %)	HSCCC (300 mL) 2 steps	*Citrus aurantium* (1.42 g)	EtOAc:BuOH:H_2O (2 :1 :3 v/v) and $CHCl_3$:MeOH:BuOH:H_2O (4:3:0.5:2 v/v)	2 mL/min 800 rpm DM; 24 h (continuous injection mode) + 7 h	[64]
Phloretin (98.2 %)	HSCCC (260 mL)	phloretin extract of apple tree (767.3 mg)	Hex:EtOAc:EtOH:H_2O (2:2:1:2 v/v)	2 mL/min; 850 rpm; DM; 500 min	[47]
Flavonols, biflavonoids	HPCCC (146 mL) Gradient elution	*Apocynum venetum* (*n.i.*)	Hex:EtOAc:ACN:H_2O (1.5:3.5:2:5 and 0:5:3:7 v/v), EtOAC:MeOH:H_2O (5:2:5 v/v) and BuOH:MeOH:H_2O (5:1:5 v/v)	2 mL/min 1,000 rpm AM; 130 min	[65]

(*continued*)

Table 70.1 (continued)

Targeted compound(s) (purity %)	General method column capacity	Starting material	Solvent system	Flow rate, Rotation speed, run duration	Refs
Prenylflavanones (>94 %)	HSCCC (300 mL): stepwiseelution	Biotransformed extract of kurarinone (520 mg)	Hex:EtOAc:MeOH:H_2O (1:1:0.7:1 v/v) and (1:1:1.2:1 v/v)	1.5 mL/min; 900 rpm; DM; 700 min	[66]
Flavonoids: Spinosin derivatives (>90 %)	HSCCC (80 mL)	*Ziziphus jujubam* (50 mg)	EtOAc:BuOH:H_2O (3:2:5 v/v)	1.5 mL/min; 1,500 rpm; DM; 240 min	[43]
Kaempferol-3,7-dirhamnopyranoside	HSCCC (300 mL)	*Siraitiagros venori* (90 mg)	EtOAC:BuOH:H_2O (4:1:5 v/v)	1.5 mL/min; 850 rpm; DM; 5.5 h	[67]
Homoisoflavones (>85 %)	HSCCC (300 mL)	*Caesalpinia sappan* (120 mg)	$CHCl_3$:MeOH:H_2O (4:3:2 v/v)	1 mL/min; 900 rpm; DM; 550 min	[45]
Senkyunolide I and H (>93 %) and ferulic acid (99 %)	CCC (230 mL)	*Ligusticum chumanxiong* (400 mg)	Hex:EtOAc:MeOH:H_2O (3:7:4:6 v/v)	2 mL/min; 800 rpm; DM; 300 min	[68]
Prenylflavonoid: xanthohumol (>95 %)	HSCCC (280 mL)	*Humuluslupulus* (607 mg)	Hex:EtOAc:MeOH:H_2O (5:5:4:3 v/v)	2 mL/min; 850 rpm; DM; 300 min	[39]
Chromones (>90 %)	HPCCC (132 mL)	*Saposhnikoviadivaricata* (300 mg)	EtOAc:BuOH:EtOH:H_2O (1:1:0.1:2 v/v)	6 mL/min; 1,600 rpm; DM; 150 min	[69]
Punicalagin (>92 %), gallic acid (75 %)	HSCCC (250 mL)	*Punica granatum* (350 mg)	BuOH:TFA:H_2O (100:1:100 v/v)	2 mL/min; 800 rpm; AM; 360 min	[70]
Phenolic acids (>94 %)	HSCCC (200 mL)	*Salvia miltiorrhiza* (*n.i.*)	Hex:EtOAc:MeOH:AA:H_2O (1 :6 :1.5 :1.5 :8 v/v)	1.5 mL/min; 850 rpm; DM; 350 min	[44]
Luteolin (91.2 %), apigenin (97.4 %), 3′-hydroxygenkwanin (94.3 %), genkwanin (95.8 %)	HSCCC (240 mL) elution	*Daphne genkwa* (*n.i.*)	Hex:EtOAc:MeOH:H_2O (5:7:5:5 v/v)	1.2 and 2 mL/min; 850 rpm; DM; 450 min	[20]
Flavonols (>97 %)	HSCCC (200 mL)	*Flos Gossypii* (80 mg)	Hex:EtOAc:MeOH:H_2O (1:2:0.8:0.9 v/v)	1.5 mL/min; 800 rpm; DM; 300 min	[71]
Flavones glycosides: Camellianins A and B (*n.i.*)	HSCCC (260 mL) elution	*Adinandra nitida* (200 mg)	EtOAC:EtOH :H_2O (5:1:5 v/v)	2 mL/min; 900 rpm; DM; 150 min	[72]

Flavonoids, biflavonoids (>85 %)	HPCCC (Midi-DE 915.5 mL)	*Selaginella tamariscina* (400 mg)	Hept:EtOAc:MeOH:H_2O (2:3:2:3 v/v)	50 mL/min; 1,250 rpm; DM; 75 min	[27]
Rotenoids and isoflavones (>93 %)	HSCCC (290 mL) elution	*Millettia pachycarpa* (400 mg)	Hex:EtOAc:MeOH:H_2O (1:0.8:1:0.6 v/v)	2 mL/min; 850 rpm; DM; 400 min	[21]
Flavonoid glycosides (>97 %)	HSCCC (230 mL) elution	Sugarcane juice (250 mg)	EtOAc:BuOH:H_2O (9:1:10 v/v)	1.5 mL/min; 900 rpm; DM; 400 min	[73]
Phenolicacids (96 %) and flavonoids (>82 %)	HSCCC (230 mL) Stepwise elution	*Eupatorium denophorum* (378.5 mg)	EtOAc:MeOH:H_2O (10:1:10 and 5:1:5 v/v)	2 mL/min; 800 rpm DM; 720 min	[50]
Flavonols glycosides (>90 %)	HSCCC (40 mL)	*Ginkgo biloba* (40 mg)	Hex:BuOH:EtOAc:MeOH-0.5 % AA (1:0.5:3.5:1:4 v/v)	1 mL/min; 1,600 rpm; AM; 250 min	[74]
Rutin (61.4 %), quercitrin (76.7 %) [75]	CPC (200 mL)	*Panicum virgatum* (600 mg)	EtOAc:EtOH:H_2O (2:1:2 v/v)	3 mL/min; 1,100 rpm; DM; 140 min	[75]
Flavonol glycosides and (+)-catechin (>92 %)	HSCCC (240 mL)	*Byrsonima basiloba* (1 g)	EtOAc:BuOH:H_2O (2:1:3 v/v)	1 mL/min; 850 rpm; DM; 240 min	[76]
Flavonol glycosides (>95 %)	HSCCC	*Hedyotis diffusa* (200 mg)	Hex:EtOAc:BuOH:MeOH:1% AA (1:1:3.5:1:4.5 v/v)	2 mL/min; DM; 130 min	[77]
Myricetin, quercetin, kaempferol (>93 %)	CPC in 2 steps	*Rhododendron mucronulatum* (500 mg)	Hex:EtOAc:MeOH:H_2O (3:5:3:5 and 4:5:4:5 v/v)		[78]
Isorhamnetin (94 %), irigenin (95 %), hispidulin (90 %)	HSCCC (230 mL)	*Belamcanda chinensis* (100 mg)	Hex:EtOAc:MeOH:H_2O (4:5:5:5 v/v)	1.2 mL/min; 800 rpm; DM; 400 min	[22]
Quinines, phenolic acids and flavonols (>85 %)	CPC (275 mL)	*Senecio giganteus* (500 mg to 1 g)	EtOAc:ACN:H_2O (5:1:4 v/v)	10 mL/min; 900 rpm; AM	[79]
Flavonols (>95 %)	HSCCC (300 mL)	*Nelumbo nucifera* (80 mg)	Hex:EtOAc:MeOH:H2O (1:5:1:5 v/v)	1.8 mL/min; 800 rpm; DM; 350 min	[80]
Flavonoids: Epimedin A, B and C (>90 %), icariin (96.8 %)	HSCCC (320 mL) dual mode	*Epimedium brevicornum* (300 mg)	BuOH:EtOAc:H_2O (3:7:10 v/v)	1 and 2 mL/min; 1,000 rpm; DM; 660 min	[81]

Table 70.1 (continued)

Targeted compound(s) (purity %)	General method column capacity	Starting material	Solvent system	Flow rate, Rotation speed, run duration	Refs
Flavanone glycosides: naringin, neoponcirin, poncirin (>90 %)	CPC (230 mL)	*Poncirus trifoliata* (524 mg)	EtOAC:ACN:H_2O (3:2:5 v/v)	2 mL/min; 1,200 rpm; DM; 250 min	[26]
Prenylflavonoids (>95 %)	2D-CCC (1,600 and 210 mL)	*Artocarpus altilis* (500 mg)	Hex:EtOAc:MeOH:H_2O (5:5:7:3 and 5:5:6.5:3.5 v/v)	5 and 1.5 mL/min; 500 and 800 rpm; DM; 500 min	[25]
Phenolic acids and flavonols	HSCCC (280 mL)	*Halimodendron halodendron* (700 mg)	$CHCl_3$:MeOH:H_2O:AA (4:3:2:0,05 v/v)	3 mL/min; 850 rpm; DM; 200 min	[24]
Didymin, narirutin, clinopodiside A (>96 %)	HSCCC 2 steps	*Clinopodium chinensis*	EtOAc:BuOH:H_2O (5:0.8:5 and 5:1:5 v/v)		[82]
B- HSCCC or CPC used as orthogonal technique for the purification of polyphenols					
Nevadensin (98 %)	MAE + HSCCC elution	*Lyeicnotuspauciflorus* (3 g)	Hex:EtOAc:MeOH:H_2O (7 :3 :5 :5 v/v)	2 mL/min; 800 rpm; DM; 720 min	[83]
Erionic acids (*n.i.*)	CPC + preparative HPLC	*Eryodictyon augustifolium* (60 mg)	Hept:EtOAc:MeOH:H_2O (5:4:4:5 v/v)	8 mL/min AM, 10 mL/min DM; 1,100 rpm; 70 min	[84]
Neohesperidin (97.5 %)	Macroporous resin + HSCCC (260 mL)	*Citrus reticulata* (60 mg)	EtOAC:BuOH:H_2O (4:1:5 v/v)	2 mL/min; 800 rpm; DM; 300 min	[85]
Naringenin-7-*O*-β-*D*-glycoside, isoquercitrin, astragalin (>93.6 %)	Sephadex LH-20 + HSCCC (200 mL)	*Helichrysum arenarium* (160 mg)	EtOAc:H_2O (1 :1 v/v)	1.5 mL/min; 800 rpm; DM; 350 min	[86]
6-hydroxyluteolin-7-O-β-glucoside and quercetagetin-7-O-β-glucoside (*n.i.*)	pH-ZR HSCCC (144 mL) + semiprep-HPLC	*Athrixia phylicoides* (100 mg)	M*t*BE:ACN:H_2O (2:2:3 v/v) (formic acid, NH_3)	5 mL/min; 1,600 rpm; DM; 40 min	[87]
Flavonols : isoquercitrin, quercetin glycosides (>98.7 %)	HSCCC (260 mL) + Sephadex LH-20	*Poacynum hendersonii* (240 mg)	BuOH:petroleum ether:H_2O + 0.5 % AA (5:3:5 v/v)	1.5 mL/min; 850 rpm; DM	[88]
Anthraquinones (>96 %)	HSCCC (230 mL) + prep-HPLC	*Morinda officinalis* (300 mg)	Hex:EtOAc:MeOH:H_2O (6 :4 :5 :5 v/v)	1.5 mL/min; 800 rpm; DM; 300 min	[29]

Polymethoxyflavones : tetramethyl-o-isoscutellarein and nobiletin (>97 %)	HSCCC (1,200 mL) + prep-hplc	*Citrus reticulata Blanco* (5 g)	Hex:EtOAc:MeOH:H_2O (1:1:1:1.5 v/v)	5 mL/min 700 rpm DM; 330 min	[52]
Silydianin (95 %), silychristin (99 %), taxifolin (98 %)	HSCCC (260 mL) after removal of silybin	Silymarin extract (1,463 mg)	Hex:$CHCl_3$:MeOH:H_2O-0.5 % AA (0.5 :11:10:6 v/v)	2 mL/min; 850 rpm; DM; 600 min	[89]
Flavonol glycosides (*n.i.*)	polyamide chromatography + HSCCC (230 mL)	*Nelumbo nucifera* (125 mg)	EtOAc:MeOH:H_2O:AA (4:1:5:0.1 v/v)	1 mL/min; 800 rpm; DM; 480 min	[90]
Flavonoids: apigemin (98.8 %), 3-hydroxyl-genkwanin (97.7 %) and genkwanin (93.5 %)	macroporous resin + CCC (4,800 mL)	*Daphne genkwa* (3 g)	Hex:EtOAc:EtOH:H_2O (4 :5 :4 :5 v/v)	30 mL/min; 480 rpm; DM; 320 min	[53]
Flavonol glycosides (>98 %)	HSCCC (260 mL) + Sephadex LH-20	*Poacynum hendersonii* (240 mg)	BuOH:petroleum ether:0.5 % AA (5:3:5 v/v)	1.5 mL/min; 850 rpm; DM; 400 min	[88]
Kaempferol triglycosides (>95 %)	macroporous resin + HSCCC (260 mL)	*Actinidia valvata* (*n.i.*)	EtOAc:BuOH:H_2O (2:1:3 v/v) and (4:1:5 v/v)	1.5 mL/min; 800 rpm; DM; 400 + 450 min	[91]
Isorhamnetin-3-gentiobioside, rutin and narcissin (>95 %)	silica gel column + HSCCC (290 mL)	*Astragalus altaicus* (200 mg)	EtOAc:BuOH:H_2O (2:1:6 v/v)	1.5 mL/min; 800 rpm; DM; 500 min	[92]
Chlorogenicacid (85 %), flavonol glycosides (>70 %)	HSCCC (220 mL) + gel chromatography	apple pomace (2.1 g)	Hex:EtOAc:1 % AA (1:9:10 v/v)	2 mL/min; 800 rpm; DM; 420 min	[93]
Hydroxytyrosol (90 %)	CPC (1 L) after filtration and resin adsorption	Olive oil mills waste water residue (30 g)	CycloHex:EtOAc:MeOH:H_2O (4:6:4:6 v/v)	18 mL/min; 900 rpm; AM; 450 min	[94]
Flavonoid glycosides (*n.i.*)	HSCCC (325 mL) + resin chromatography	*Radix astragali* (100 mg)	Hex:EtOAc:BuOH:MeOH:H_2O-0.5 % TFA (1:2:1:1:5 v/v)	2 mL/min 800 rpm DM; 250 min	[95]
Naringin (98.3 %)	macroporous resin + HSCCC (260 mL)	*Fructus aurantii* (600 mg)	EtOAc:BuOH:H_2O (2:0.8:3.2 v/v)	1.5 mL/min 850 rpm DM; 500 min	[96]
Alquds (98.8 %), hesperidin (98.1 %)	C18 column + HSCCC (420 mL)	*Taraxacum mongolicum* (600 mg)	Hex:BuOH:H_2O (1:1:2 v/v)	1.5 mL/min; 800 rpm; DM; 350 min	[97]

Targeted compound(s) (purity %)	General method column capacity	Starting material	Solvent system	Flow rate, Rotation speed, run duration	Refs
Polymethoxyflavanones (>96 %)	HSCCC (230 mL) + prep-HPLC	*Pogostemon cablin* (300 mg)	Hex:EtOAc:MeOH:H_2O (11:5:11:5 v/v)	1.5 mL/min; 800 rpm; DM; 330 min	[98]
Quercitrin (97 %), quercetin (93 %)	HSCCC (230 mL) + prep-HPLC	*Hypericum Perforatum* (900 mg)	EtOAc:MeOH:H_2O (10:1:10 v/v)	2 mL/min; 800 rpm; DM; 360 min	[99]
Flavonols and flavonol glycosides (>97 %)	HSCCC (290 mL) + prep-HPLC	black currant (100 mg)	Hex:EtOAc:MeOH:H_2O (1:10:1:10 v/v)	1.5 mL/min; 800 rpm; DM; 250 min	[100]
Flavones (*n.i.*)	HSCCC (310 mL) + Sephadex, silica gel	*Lantana trifolia* (3 g)	Hex:EtOAc:BuOH:H_2O (0.4:1:X:1 v/v) where X=0.1, 0.3, 0.5, and 0.7	3 mL/min 850 rpm AM	[101]
Isoflavones (>92 %)	HSCCC (1 L) 2 steps + Flash column	*Belamcanda chinensis* (2 g)	Hex:EtOAc:isopropanol:MeOH:H_2O (5:6:2:3.5:6 v/v) and (0:10:0:2:9 v/v)	5 mL/min 400 rpm DM; 350 min	[23]
Flavonoid glycosides (>98 %)	polyamide resin + HSCCC (420 mL)	*Taraxacum mongolicum* (500 mg)	EtOAC:BuOH:H_2O (2:1:3 v/v)	1.5 mL/min 800 rpm DM 350 min	[102]
C- Bioassay-guided fractionation and rapid characterization of plant-derived polyphenols by HSCCC or CPC					
Flavonols	CPC (200 mL) antimicrobialactivity	*Kalanchoepinnata* (350 mg)	EtOAc:EtOH:H_2O (4.5:1.5:4.5 v/v)	4 mL/min; 1,200 rpm; DM; 125 min	[30]
Isoflavones	HSCCC (260 mL) antioxidant activity	*Puerarialobata* (210 mg)	Petroleum ether:EtOAc:MeOH:H_2O (2:3:2:3, 2:3:5:4, 1:5:2:5 and 1:1.3:1:1.3 v/v)	1.2 mL/min; 850 rpm; DM; 625 min	[31]
Flavonoids : Butrin, isobutrin	CPC (200 mL) antioxidant activity	*Butea monosperma* (*n.i.*)	Hept:EtOAc:MeOH:H_2O (1:4:1:4 v/v) and BuOH:H_2O (1:1 v/v)	3 mL/min; 1,300 rpm; AM; 280 min	[32]
Phenolicacids, anthocyanins	HSCCC (100 mL) antioxidant activity	Red wine extract (1 g)	MtBE:BuOH:ACN:H_2O + 0.1 % TFA (2:2:1:5 v/v)	3 mL/min; DM	[103]

Isoflavones, flavonols	HSCCC (500 mL) antioxidant activity	*Mucunasempervirens* (600 mg)	Stationary phase: H_2O saturated with BuOH and EtOAC. Mobile phase: *n*-Hex:EtOAc (1:1 to 1:4 v/v) and BuOH:EtOAc (1:4 to 2:1 v/v)	3 mL/min; 1,000 rpm; AM; 640 min	[104]
Flavonoids and coumarins	HSCCC (300 mL) antioxidant activity	*Psoralea coryfolia* (250 mg)	Hex:EtOAc:MeOH:H_2O (1:1.1:1.3:1 v/v)	1.3 mL/min; 1,000 rpm; DM; 600 min	[105]
Flavonoids and biflavonoids	HSCCC (420 mL) antioxidant activity	*Selaginella sinensis* (*n.i.*)	Hex:EtOAc:MeOH:H_2O (8:8:9:7 v/v)	1.2 mL/min; 1,000 rpm; DM; 400 min	[106]
Prenylated flavones	HSCCC (1,000 mL) antibacterialactivity	*Sophora flavescens* (8 g)	Hex:EtOAc:MeOH:H_2O (1:1:1:1 v/v)	8 mL/min; 500 rpm; DM; 270 min	[35]
Flavonols	CPC (200 mL) hyphenated with HPLC	*Hippophaërhamnoides* (1.5 g)	Hept:EtOAc:MeOH:H_2O (1:4:1:4 v/v)	3 mL/min; 1,300 rpm; AM; 180 min	[36]
Flavonol glycosides	CPC (200 mL) hyphenated with ESI-MS	Apple peel extract (350 mg)	EtOAC:EtOH:H_2O (4.5:1:4.5 v/v)	4 mL/min; 2,000 rpm; DM; 400 min	[107]
Flavonol glycosides	HSCCC (850 mL) combined to ESI-MS	Sea buckthorn juice concentrate (4.1 g)	Hex:BuOH:H_2O (1:1:2 v/v)	3 mL/min; 800 rpm; DM; 600 min	[108]
betacyanins	Ion-pair HSCCC (850 mL) combined to HPLC/ESI-MS	*Bougainvilleaglabra* (755 mg)	M*t*BE:BuOH:ACN:H_2O-0.7 % TFA (2:2:1:5 v/v)	3 mL/min; 850 rpm; DM; 360 min	[37]
Phenolic acids and flavonoids	HSCCC (850 mL) combined to HPLC/ESI-MS	Rum aged in oak barrels (800 mg)	Hex:EtOAc:MeOH:H_2O + 0.1 % FA (1:1:1:1 v/v)	3 mL/min; 900 rpm; DM	[51]

n.i. non indicated

In general, the objective when isolating natural polyphenols from complex plant extracts is to obtain compounds in sufficient quantities and with high purities for structural elucidation, for further use in bioactivity studies, or as standard reference substances for chromatography. The studies reported in Table 70.1 clearly demonstrate that HSCCC and CPC are efficient in directly purifying polyphenols from crude plant extracts without additional clean-up. Other studies have concentrated their efforts on the rapid but partial purification of polyphenols by HSCCC or CPC. In these cases, an additional orthogonal technique such as preparative HPLC, Sephadex, or open silica gel column chromatography was required to achieve the full purification of the target compound(s). This strategy combines the advantages of HSCCC or CPC and those of solid support-based chromatographic techniques to improve purification efficiency. This can be particularly appropriate for the rapid preparative isolation of complex polyphenolic structures. For example, HSCCC was combined with preparative HPLC for the rapid separation and purification of anthraquinones from *Morinda officinalis* [29].

3.3 Bioassay-Guided Fractionation and Characterization of Plant-Derived Polyphenols

Plant extracts normally contain a large number of chemical components among which polyphenols can be present in various amounts. These complex mixtures are not easily characterized, and sometimes bioassay-guided fractionation is preferentially used in order to focus only on the compounds providing a biological or pharmacological interest. In this field, HSCCC and CPC have a high potential due to their inherent characteristics. Classical bioassay-guided fractionation methods based on solid support materials are generally time-consuming. In addition, multistep purification procedures sometimes result in drastic sample or activity loss during the isolation of target compounds because of sample degradation, irreversible adsorption on solid support, or dilution.

Due to the absence of solid support, both HSCCC and CPC circumvent these problems by maintaining the integrity of all compounds present in the initial crude sample during the separation process. They also provide high sample recovery and thus offer an excellent alternative for the rapid screening of bioactive compounds in complex plant extracts.

As presented in Table 70.1-C, several studies investigating the biological effects of polyphenols have developed bioassay-guided fractionation methods using HSCCC or CPC. Generally in a first step, the initial crude extract is fractionated into individual polyphenols or into highly simplified polyphenol-enriched fractions. The biological activity of each collected fraction is then evaluated on a specific model. This strategy allows the rapid identification of structures responsible for the observed activity. For example, a *Kalanchoe pinnata* extract was fractionated by CPC, and each fraction was evaluated for its antimicrobial activity and cytotoxicity [30]. In another work, HSCCC was combined with DPPH-chemical tests in order to screen and separate several antioxidant isoflavones from a *Pueraria lobata* extract [31]. In a similar way, the different flavonoids present in a crude extract of *Butea monosperma* flowers were fractionated by CPC according to their molecular family and polarity, and each fraction was evaluated for its antioxidant activity [32].

Antioxidant activity tests are by far the most commonly used models for bioassay-guided fractionation of plant-derived polyphenols. This is mainly because there has been considerable research on natural antioxidants, particularly for their potential use as additives in pharmaceutical or cosmetic formulations. Polyphenols are the major well-recognized natural antioxidants consumed in the human diet [33]. A range of in vitro and in vivo methods have been developed to evaluate their antioxidant properties and mechanisms of action on human metabolic pathways [34]. However, antioxidant screening in complex mixtures of plant origin requires simple and rapid in vitro models for a possible combination with chromatographic techniques such as TLC, HPLC, HSCCC, or CPC. The reduction of the stable free-radical DPPH$^{\bullet}$ (1,1-diphenyl-2-picrylhydrazyl) by antioxidant substances is currently the most widely used chemical test for the screening of plant extracts. Only a few bioassay-guided fractionation processes have also evaluated the antimicrobial, antibacterial activity, or cytotoxicity of fractions enriched in specific flavonoids by using HSCCC or CPC liquid–liquid systems [30, 35].

HSCCC or CPC fractionation of complex plant extracts containing polyphenols has also been employed in a number of studies in order to rapidly obtain information on sample composition without purifying each individual compound (Table 70.1-C). In these cases, each simplified fraction obtained from the HSCCC or CPC separation procedure is usually monitored by high-performance liquid chromatography (HPLC), thin layer chromatography (TLC), or mass spectrometry (MS), either by off-line or direct coupling with the appropriate detectors. In a recent study, CPC was directly associated with HPLC to separate and on-line guide the fractionation of flavonols (quercetin and isorhamnetin derivatives) from *Hippophaë rhamnoides* berries [36]. In another study, HSCCC was coupled to HPLC-MS/MS in order to fractionate and resolve the highly complex mixture of betacyanins present in purple bracts of *Bougainvillea glabra* [37].

3.4 Solvent System Selection

Due to the versatility of HSCCC and CPC instruments, various solvent systems have been tested for the purification of polyphenols according to their structure, polarity, or other physicochemical properties. As illustrated in Fig. 70.2, the solvent system composed of *n*-hexane, ethyl acetate, methanol, and water is by far the most commonly used solvent system for the purification of polyphenols despite the large number of other possibilities. Generally, this solvent system (related to the Arizona liquid system) is particularly adapted for the purification of polyphenols with moderate polarity [38]. As shown in Table 70.1 and Fig. 70.2, *n*-hexane can be replaced by *n*-heptane or petroleum ether, and methanol can be replaced by acetonitrile or ethanol. The proportions of each solvent can vary greatly with

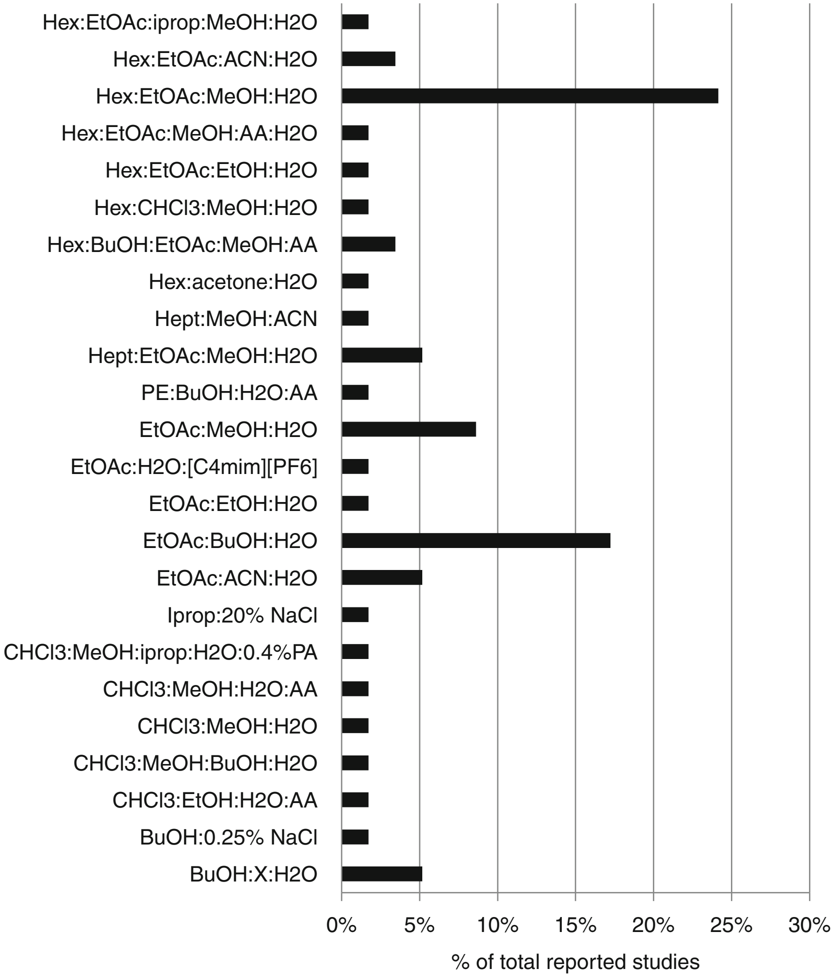

Fig. 70.2 Solvent systems commonly used for the purification of polyphenols from crude plant extracts (55 studies reported over the five last years)

respect to the structures to be purified, but globally, all these variants have also proven to be efficient in the purification of moderately polar phenolic compounds such as flavonoid aglycones. For example, xanthohumol and related prenylflavonoids have been successfully isolated from a hops extract in only one step by HSCCC using the quaternary biphasic solvent system Hex/EtOAc/MeOH/H_2O in the proportions 5:5:4:3 (v/v) [39]; bioactive cajaflavanones have been purified from *Derris ferruginea* by CPC using the biphasic solvent system Hept/EtOAc/MeOH/H_2O in the proportions 4:1:4:1 (v/v) [40], while resveratrol dimers (quadrangularin A and parthenocissin A) have been purified from the roots of *Parthenocissus laetevirens* by HSCCC in the elution mode using Hex/EtOAc/MeOH/H_2O as biphasic solvent system in the proportions 1:2:1:2 (v/v) [41].

Ternary biphasic solvent systems composed of EtOAc/BuOH/H_2O have also been used to purify polyphenols by solid support-free liquid–liquid chromatography. Because they do not contain apolar solvents like *n*-heptane, *n*-hexane, or petroleum ether, these systems are more appropriate for the separation of compounds exhibiting higher polarities such as flavonoid glycosides. For instance, several flavonol glycosides have been isolated with purities over 97 % from a *Flaveria bidentis* extract by HSCCC with a two-phase solvent system composed of EtOAc/MeOH/H_2O in the proportions 10:0.4:10 (v/v) [42]. Similarly, three spinosin derivatives have been isolated with purities over 90 % from *Ziziphus jujuba* by HSCCC using a biphasic solvent system composed of EtOAc/BuOH/H_2O in the proportions 3:2:5 (v/v) [43].

Different variants of these systems have also been tested by adding a small amount of organic acid. The presence of an acid in the solvent system can significantly influence the distribution coefficient of negatively charged analytes such as phenolic acids. They become more hydrophobic in acid medium and thus provide a better affinity for the organic phase. Three polyphenols (3,4-dihydroxyphenyllactic acid, salvianolic acid B, and protocatechualdehyde) were, for example, efficiently purified from *Salvia miltiorrhiza* in a one-step HSCCC experiment using the biphasic solvent system Hex/EtOAc/MeOH/AA/H_2O in the proportions 1:6:1.5:1.5:8 (v/v) [44]. In addition, the presence of an acid in the solvent system can reduce its settling time and thus improve the hydrodynamic properties of the stationary and mobile phases during the separation experiment. A reduction of the settling time induces an increase of the stationary phase retention volume inside the HSCCC or CPC column. This results in an improvement of separation resolution.

Other solvent systems composed of $CHCl_3$/MeOH/H_2O have been successfully tested and proposed for the separation of free and glycosylated flavonoids. The use of chloroform instead of ethyl acetate can be helpful when the initial crude sample is more soluble in chlorinated solvents [38]. Homoisoflavonoids were purified from *Caesalpinia sappan* by HSCCC in the descending mode using the biphasic solvent system composed of $CHCl_3$/MeOH/H_2O in the proportions 4:3:2 (v/v) for a total elution duration of 550 min [45]. Solvent systems containing methyl *tert*-butyl ether (M*t*BE) have also been suggested for the purification of anthocyanin derivatives [37].

3.5 HSCCC and CPC Chromatographic Development Modes

Most of the purification procedures presented in our literature survey were conducted in the classical elution mode. In this case, the column is first filled by one of the two liquid phases of the biphasic solvent system, playing the role of stationary phase, while the other is used as the mobile phase and pumped through it. This classical elution mode can be effective if the number of target compounds is not too high or if the starting plant extract is not too complicated. A simple elution mode was used in HSCCC for the efficient purification of ellagic acid and

3-*O*-methylellagic acid 4′-*O*-β-D-glucopyranoside from an *oil tea camellia* extract. The purification was achieved in 240 min in the descending mode by using a biphasic solvent system composed of $CHCl_3$/EtOH/H_2O/AA in the proportions 4:3:2:0.01 (v/v) [46]. Similarly, phloretin was isolated with high purity from an apple tree bark extract by an elution HSCCC procedure using the solvent system Hex/EtOAc/MeOH/H_2O in the proportions 2:2:1:2 (v/v) [47]. When the target polyphenolic compounds present in the initial crude extract are numerous, structurally highly different or if they exhibit a broad range of polarities, it can be difficult to purify each of them in a single elution-step procedure by HSCCC or CPC. To circumvent this problem, a stepwise elution or a gradient elution method can be performed to achieve a more efficient separation. The gradient elution mode, mostly applied with ternary solvent systems, has been often used to cover a large polarity range of flavonoids [48, 49].

The combined use of two different solvent systems in stepwise elution can also be useful to obtain an excellent purification of polyphenols within a short period of time. For example, a stepwise elution was applied to the preparative purification of caffeic acid and quercetagetin glycosides from a crude extract of *Eupatorium adenophorum* by using a pair of solvent systems composed of EtOAc/MeOH/H_2O in the proportions 10:1:10 (v/v) and 5:1:5 (v/v) [50].

It should also be mentioned that the flow rate of the mobile phase plays a significant role in the efficiency of HSCCC or CPC separations. As illustrated in Fig. 70.3, the flow rate values used in the HSCCC studies reported in our literature survey were globally comprised between 1 and 5 mL/min for column capacities up to 500 mL. In CPC-based studies, the flow rates were slightly higher, ranging from 3 to 10 mL/min for column capacities up to 275 mL. Increasing the flow rate usually allows a significant productivity gain. However, reducing the flow rate can sometimes improve resolution. Recent developments in HSCCC and CPC column designs have particularly focused on the scale-up of separation processes. For the separation of polyphenols from crude plant extracts, only a few studies have used pilot-scale HSCCC coils of 850-mL [37, 51], 1,000-mL [23, 35], 1,200-mL [52], 1,600-mL [25, 41], and 4,800-mL [53] capacities. A 1,000-mL CPC rotor was used for the fractionation of prenylated flavonoids from a licorice root extract [54]. In this study, the flow rate was set at 25 mL/min, resulting in separation duration of only 55 min. Increasing the column capacity allows not only the application of higher flow rates but also the injection of higher crude sample mass. As shown in Fig. 70.3b, however, there is no clear linear relationship between the sample mass and the column capacities used in studies investigating polyphenol purification from plant extracts by HSCCC or CPC. Globally the quantities of crude samples were lower than 2 g for column capacities up to 500 mL. In only one study, 5 g of a crude *Derris ferruginea* stem extract were injected into a 275-mL CPC rotor for the fractionation of bioactive cajaflavanones [40]. Such multi-gram quantities of crude sample are normally loaded into HSCCC or CPC column capacities higher than 800 mL. Nevertheless, it should be noted that the amount of injected sample is generally small compared with the column capacities used. This can be explained by the negative effects of mass overloading when purifying phenolic compounds by solid support-free liquid–liquid chromatographic techniques. Indeed, the π-stacking

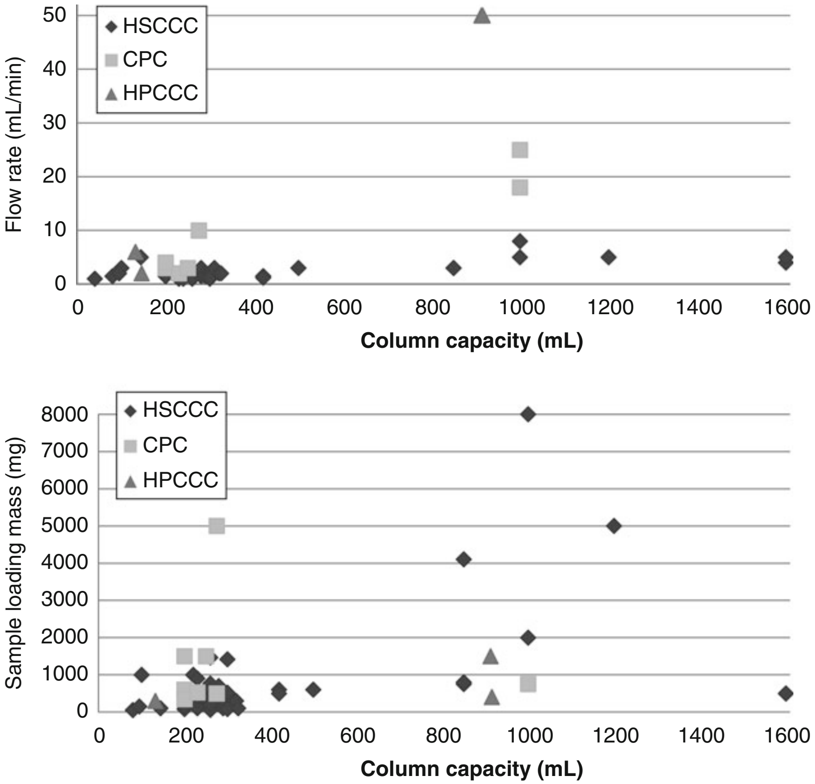

Fig. 70.3 Flow rate application and sample loading as a function of HSCCC, HPCCC or CPC column capacities for the separation of polyphenols from crude plant extracts

phenomena occurring in the aqueous phase can disturb the polyphenol behavior in the biphasic system, thus decreasing the resolution of the separation. This phenomenon has been observed, for example, in the case of the anthocyanins purification by gradient elution CPC on a column of 5 L. Thus, if the absence of solid support often permits very high selectivities and limited adsorption phenomena or irreversible degradations, these advantages are partially counterbalanced by the phenomena of aromatic ring associations. One solution would be to use the displacement mode (ion exchange or pH-zone refining), exchange or acid–base reactions generating interactions of higher energy than those governing the π-stacking phenomena.

4 Conclusion

High-speed countercurrent chromatography (HSCCC) and centrifugal partition chromatography (CPC) are two very promising chromatographic techniques which have been successfully applied to the purification of natural products.

The number of studies presenting HSCCC or CPC applications for the purification of phenolic compounds remains low as compared to other classes of secondary metabolites like alkaloids. However, the increasing number of papers published the last 5 years confirms the potential of these techniques for the separation and purification of different polyphenol classes including flavonoids and phenolic acids.

Abstract

Emerging evidences from extensive laboratory research backed by epidemiological data lead credence to a family of natural origin compounds with putative chemopreventive potential to intervene ontogeny and progression of cancer. This family of natural compounds called “polyphenols” has more than one phenol unit or building block per molecule and considered beneficial if not critical to human health. Major dietary sources contributing to total polyphenol intake include fruits, vegetables, cereals, chocolates, dry legumes and beverages such as fruit juice, tea, coffee and red wine. Polyphenols have captivated great attention because of their pleiotropic actions including antioxidative, xenobiotic detoxification, anti-inflammatory, and therapeutic benefits including antitumor and chemosensitizing potential to several common cytotoxic chemotherapeutic agents. Mechanistically, polyphenol-rich diet has shown to modulate transcription factors and interrupt the complex cell signaling pathways and their component enzymes, microRNAs, with common aim to thwart tumor cell proliferation while sparing normal cells and inhibits angiogenesis, invasion, and metastasis considered as hallmarks of cancer. This chapter presents a succinct global overview of deregulated signaling pathways, antioxidant status and enzymes exacerbated in tumors and the role of polyphenols in modulating the end results in different site-specific cancers citing representative examples. We conclude highlighting chemosensitization of cancer with select polyphenol compounds – genistein, epigallocatechin-3-gallate, curcumin, quercetin, silibinin, and resveratrol – along with appraisal on ongoing clinical trials with primary objective of better clinical management of cancer patients with long-term survival benefits and designing novel analogs with improved bioavailability for future use.

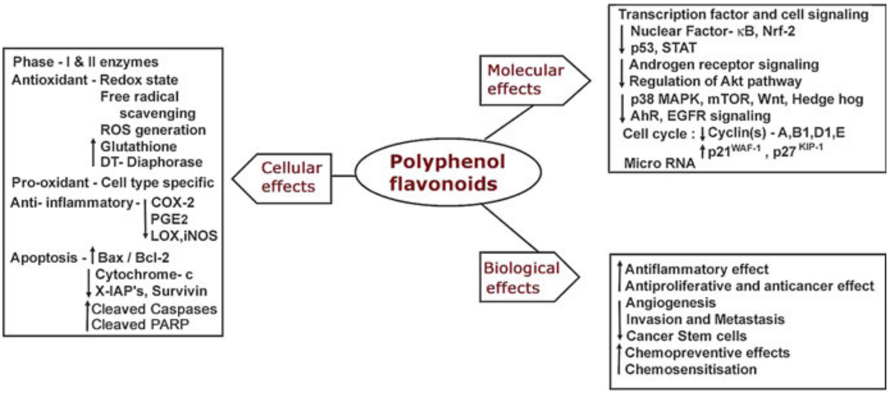
1 Introduction

Polyphenols are a family of promising phytochemical compounds mainly derived from natural sources and considered beneficial if not critical to human health [1]. Their origin and persistence within edible plant parts and products is largely accountable as secondary metabolite ostensibly to protect against UV radiation and aggression to pathogens and predators [2, 3]. As functional nonnutritive food component, polyphenols are considered important because, in addition to their contribution to color, astringency, flavor, and oxidative stability, their antioxidant potential has been predicted to be higher than dietary antioxidants such as vitamin C and E. Major dietary sources contributing to total polyphenol intake include fruits, vegetables, cereals, chocolates, dry legumes, and beverages such as fruit juice, tea, coffee, and red wine. It has been estimated that approximately 100 g of fresh weight fruits such as grapes, apple, pear, cherries, and berries contains approximately up to 200–300 g of polyphenols, whereas a glass of red wine or a cup of freshly brewed tea or coffee typically contains approximately 100 mg of polyphenols. As a class, polyphenols are receiving increasing attention because emerging evidence strongly attests their role in prevention of cancer and other avenues related to health-promoting properties such as antimicrobial including antiviral effect, cardioprotective effect, antidiabetic effect, antiaging, neuroprotective effects, and protection against many other pathological events. This credence led to foundation in 2003 by Augustin Scalbert in Vichy, France, “1st International Conference on Polyphenols and Health.” This biennial conference includes sessions on range of relevant health-promoting effect topics including bioinformatics, metabolomics, biomarkers, cancer, and discussion on the issue of polyphenols in inflammation and oxidative stress.

Major insights and current knowledge on environmental factors associated with increased risk of developing cancer in humans include chemical and physical mutagens, e.g., cigarette smoke, exposure to heterocyclic amines, nitrosamines, polycyclic aromatic hydrocarbons (PAHs), tamoxifen, nickel, chromium, arsenic, chloromethyl ethers, asbestos, radon, and UV irradiation. Existing knowledge from appreciation of their mechanistic detail led to emergence of the field of “chemoprevention” which is defined as application of interventions (nutrients, drugs, and biologics) that inhibit or reverse the multistage carcinogenic process. This contributing chapter presents a global overview of our current knowledge relating to health-promoting effects of polyphenols focusing on pleiotropic and multitargeted mechanism of their action contributing to chemopreventive and anticancer effects (Fig. 71.1). We conclude with brief prologue on select polyphenol compounds underscoring clinical trials integrating these compounds either as mono- or adjunct therapy in cancer treatment strategy.



Phase - I & II enzymes
Antioxidant - Redox state
Free radical scavenging
ROS generation
↑ Glutathione
DT- Diaphorase
Pro-oxidant - Cell type specific
Anti- inflammatory - ↓ COX-2

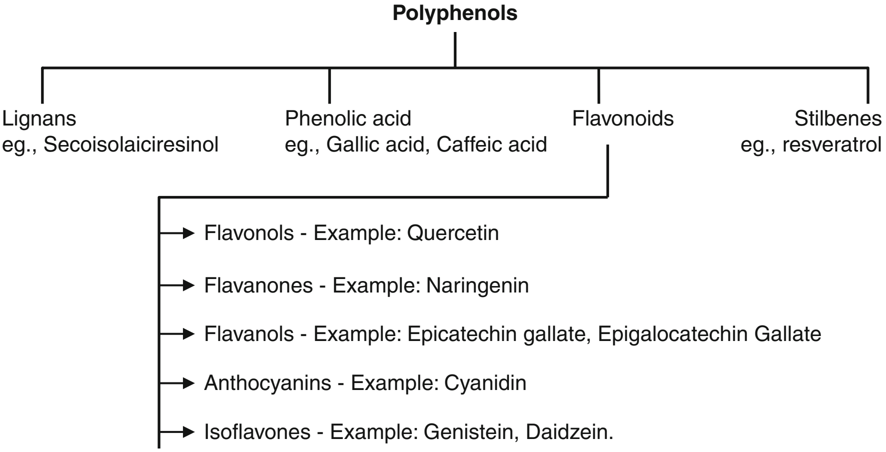
2 Chemistry and Classification of Polyphenols in Food

Polyphenols are derived from phenylalanine and characterized by the presence of several reactive hydroxyl groups on aromatic rings presenting great diversity in structures, ranging from rather simple molecules (monomers and oligomers) to polymers. As a chemical family, more than 8,000 distinct structures have been identified that can arbitrarily be classified into 10 different classes based conditionally on the existing number of phenol rings that they contain and on the basis of structural elements that bind these rings to one another [1, 4] (Fig. 71.2). The most abundant and common polyphenols in foods are the low-MW phenolic compounds such as flavonoids and phenolic acids, along with less common stilbenes (e.g., resveratrol) and lignans (e.g., secoisolariciresinol). Flavonoids comprise the most studied group of polyphenols, and based on variation in the type of heterocycle group within this class, flavonoids have been further divided into six subclasses: flavones (e.g., apigenin), flavonols (e.g., quercetin, myricetin, and rutin), flavanones (e.g., naringenin), anthocyanins (e.g., cyanidin), flavan-3-ols (e.g., catechin, epicatechin, and epigallocatechin-3-gallate), and isoflavones (e.g., genistein) [1, 5]. An overview on pilot studies and trials from viewpoint of cancer prevention-related rationale, in which either healthy individuals or patients with premalignant conditions or cancer received polyphenol phytochemicals, has been reviewed and published by Thomasset et al. [6].

3 Polyphenols and Modulation of Phase I and II Biotransformation Enzymes

According to seminal scheme proposed by Lee Wattenberg, modulation of phase I drug-metabolizing enzymes and induction of phase II detoxifying enzymes have been inferred as an important strategy largely responsible for detoxification of



Polyphenols
Lignans
eg., Secoisolaiciresinol
Phenolic acid
eg., Gallic acid, Caffeic acid
Flavonoids
Stilbenes
eg., resveratrol
Flavonols - Example: Quercetin
Flavanones - Example: Naringenin
Flavanols - Example: Epicatechin gallate, Epigalocatechin Gallate
Anthocyanins - Example: Cyanidin
Isoflavones - Example: Genistein, Daidzein.

Fig. 71.3 Schematic representation of phase I and II reactions and its modulation by chemodietary polyphenol compounds

chemical carcinogens and by extension, cancer chemoprevention [7]. Essentially, phase I enzyme according to Wattenberg's perception catalyzes "functionalization reactions" mediated by the superfamily of heme-containing monooxygenase (cytochrome P450 (CYP) enzymes that metabolize inert chemical (pro)carcinogen to biologically inactive or chemically reactive electrophilic metabolites) (Fig. 71.3). The later undergoes additional metabolism by phase I or phase II enzyme systems (glutathione S-transferase (GST) isoenzymes, uridine diphosphate-glucuronosyltransferase, sulfotransferase, and catechol-O-methyltransferase) resulting in increased detoxification; these biochemical reactions generally increase water solubility, enhancing removal of harmful xenobiotic agents/carcinogens from the body, precluding them from attacking cellular DNA and initiating tumorigenesis [8, 9]. Further, within this conceptual framework, another observational paradigm classifying chemopreventive phytochemicals (including polyphenol compounds) primarily on the stage they effectively contribute to preventive effects has emerged and accordingly classified as: (a) inhibiting carcinogen formation, (b) blocking agents inhibiting tumor initiation, or (c) suppressing agents that specifically act as inhibitors of tumor promotion/progression.

Of interest to human health, it is now well established that some common dietary polyphenols – curcumin, resveratrol, genistein, epigallocatechin-3-gallate (EGCG), quercetin, silibinin, ellagic acid, etc. – show evidence of inhibiting carcinogen activation and being potent inducers of GST inhibit carcinogen-induced tumorigenesis in vivo in a number of animal models. Resveratrol, a polyphenol present in wine at concentration between 1 and 10 μM, restrains bioactivation of polycyclic aromatic hydrocarbons (PAHs), a class of ubiquitous environmental chemicals, through reduced expression of CYP1A1 and CYP1B1 genes in human bronchial epithelial cells [10]; increased CYP1A1 expression and activity are associated with a high risk of lung and colorectal cancer [11, 12]. Likewise, CYP1B1 activates procarcinogens and their elevated levels are associated with estrogen carcinogenesis [13]. Normal human breast and breast tumor tissues are known to express CYP1B1, leading to the generation of an carcinogenic entity – 4-hydroxyestrogen; hence, inhibition of CYP1B1 affects the production of this and other mutagenic estrogen 3,4-catechols [14]. Quercetin, found abundantly in fruits and vegetables, significantly inhibits benzo[a]pyrene (B[a]P)-induced CYP1A1 mRNA and protein expression within tumor cells [15]. Isoflavone – biochanin A (from red clover) and genistein (from soybean) have been found effective in inhibiting DMBA-induced DNA damage in cells by inhibiting CYP1A1 and CYP1B1 enzymes [16]. Furthermore, genistein and isoflavone analogs (daidzein and glycitein) show evidence of the potential to decrease the side effects of tamoxifen via inhibition of CYP1A2 that inhibits the formation of α-hydroxy tamoxifen and its sulfate conjugate believed to be responsible for DNA adduct formation [17, 18]. Baicalein, a flavone from the root of the *Scutellaria* species, reduces the CYP1A1/CYP1B1 mRNA expression induced by DMBA [19]. Other examples include flavones (chrysin, baicalein, and galangin), flavanones (naringenin), and isoflavones (genistein, biochanin A). All these compounds harbor the potential to inhibit the activity of aromatase (CYP19) enzyme diminishing estrogen biosynthesis and producing antiestrogenic effects vital in breast and prostate cancers [20]. Ellagic acid inhibits N-nitrosobenzylmethylamine (NBMA) metabolism in vitro and in vivo inhibiting NBMA-induced esophageal tumors [21, 22]. Further, the effect of dietary ellagic acid on hepatic and esophageal mucosal cytochromes P450 and phase II enzymes has been reported [23]. Another important plant polyphenol – curcumin – significantly affects CYP1A2 and CYP2A6 activity in humans [24]. Tea polyphenols exhibit an inhibitory effect on microsomal CYP enzyme system [25, 26]. Epigallocatechin-3-gallate (EGCG) has a strong inhibitory effect on CYP1A1 at the transcriptional level [27].

(−)-Epicatechin-3-gallate (ECG) – another catechin and major antioxidative phenolic constituent of green tea – inhibits inducible CYP450 isoforms and shown to abrogate up to 50 % benzo[a]pyrene-diol epoxide-DNA adduct formation in benzo [a]pyrene (B[a]P)-treated cells [28, 29]. Furthermore, in mouse model of transplacental induction of lymphoma, lung, and liver cancer by the polycyclic aromatic hydrocarbon – dibenzo[a,l]pyrene (DBP) – induction of cytochrome P450 (CYP1B1) in maternal liver by EGCG reduced the bioavailability of DBP to the fetus demonstrating that maternal ingestion of green tea during pregnancy and nursing may provide protection against transplacental carcinogenesis [30].

Glutathione S-transferase (GSTs) and NAD(P)H:quinine oxidoreductase 1 (NQO1)/quinone reductase (QR) have a considerably important role in the detoxification of carcinogens, and their induction above basal level by flavonoids and vegetable diets is associated with chemopreventive effects [31]. GST has been identified as one of the main detoxifiers of dihydrodiol and epoxide forms of benzo [a]pyrene (a known mutagen in tobacco), and GST-Pi plays a critical role in the development of lung carcinogenesis following exposure to tobacco-related carcinogens and urethane [32, 33]. EGCG enhances the activity of GST and NQO1 enzymes in mouse liver and small intestine and in breast and prostate cancer cells [34–37]. The effect of a biologically active flavonoid – silibinin derived from milk thistle (*Silybum marianum*) on phase II enzymes – reveals moderate to highly significant increase in both GST and QR activities in liver, lung, stomach, skin, and small bowel in a dose- and time-dependent manner demonstrating the bioavailability and phase II enzyme induction by systemically administered silibinin [38]. Genistein and daidzein have been testified to increase QR activities in murine hepatoma and human colon cancer cell line, and the inhibition of benzo[a]pyrene metabolite-DNA binding by genistein results from QR induction [39–41]. Topical applications of soy isoflavones (mixture of 33 mg of genistein and 67 mg of daidzein), 30 min prior to the application of tumor promoter – 12-O-tetradecanoylphorbol-13-acetate (TPA) on mouse skin – prevented decrease in GST activity [42]. Other studies reported that dietary genistein and daidzein are able to elevate the activities of phase II and antioxidant enzymes in rat liver and kidney and QR in the colon of rats in vivo [43, 44]. Thus, promotion of detoxification of chemical carcinogens by select polyphenol class of phytochemicals represents a promising rationale-based pharmacological approach for chemoprevention in susceptible individuals.

4 Anti-inflammatory Effect

In 1863 Rudolf Virchow envisaged a connection between inflammation and cancer that later supported the hypothesis that inflammatory process is a cofactor in carcinogenesis. Although inflammation under normal physiological conditions is beneficial for host’s defense, prolonged inflammation by chemical and physical agents and inflammatory reactions of uncertain etiology cause various chronic disorders including cancer. The complex circuitry of inflammation and cancer is less well understood. It is currently believed that at the site of inflammatory stimulation, the production of pro-inflammatory and immunosuppressive cytokines and diverse reactive oxygen species (ROS) and reactive nitrogen species (RNS) by locally recruited inflammatory cells induces genetic alterations which lead to malignant transformation and stimulate proliferation of initiated cells. Among the myriad of changes that occurs within the inflammatory environment, cyclooxygenase-2 (COX-2), lipoxygenase (LOX), and inducible nitric oxide synthase (iNOS) are important enzymes involved in provocating inflammatory processes; their improper upregulation has also been linked with the pathophysiology of certain types of human cancers as well as inflammatory disorders [45]. Thus, blocking inflammation signaling is usually recognized as potential mode for chemoprevention, and constellation of polyphenols targeting anti-inflammatory signaling pathways is described in the following sections. The natural occurring polyphenols – curcumin and resveratrol – are being recognized as one of the most promising nontoxic natural molecules to abate colitis and potentially colon cancer associated with colitis. Cui et al. reported that the polyphenol resveratrol significantly improves inflammation score and downregulates markers of inflammation and inflammatory stress (p53 and p53-phospho-Ser(15) reducing tumor incidence from 80 % to 20 % in mice [46].

4.1 Cyclooxygenase

The cyclooxygenase pathway converts arachidonic acid released by membrane phospholipids into eicosanoids such as prostaglandins, prostacyclins, and thromboxanes with cyclooxygenase-2 (COX-2) being the key regulatory enzyme for prostaglandin synthesis. Inhibition of COX-2 expression in malignant tumors is considered vital in clinical management of cancer since overexpression of COX-2 activity has been observed in practically every premalignant and malignant condition involving the colon, liver, pancreas, breast, lung, bladder, skin, stomach, head and neck, and esophagus [47]. Transcription factors – AP-1 and NF-κB – have been found to stimulate COX-2 transcription [48, 49]. Published studies indicate several classes of polyphenol compounds inhibit COX activity at transcriptional as well as enzyme level [50]. Polyphenol curcumin has an effect opposing TPA-induced tumor promotion by effectively inhibiting cyclooxygenase and lipoxygenase activities [51]. Theaflavin-2 (TF-2), a major component of black tea extract, suppresses inflammatory pathways in vitro and in vivo by modulating COX-2 gene expression at the transcriptional level alleviating inflammatory effect [50]. Mechanisms relating to anti-inflammatory effect by resveratrol targeting prevention and amelioration of carcinogenesis have been reported. Resveratrol treatment attenuates COX-2 induction stimulated by lipopolysaccharides (LPS), 12-O-tetradecanoylphorbol-13-acetate (TPA), or superoxide [52]. Resveratrol directly binds with COX-2 and this binding is absolutely required for resveratrol inhibition of the ability of human colon adenocarcinoma HT-29 cells to form colonies in soft agar [53]. Dietary resveratrol also antagonizes pro-inflammatory cytokines TNF-alpha and IL-1β and augments anti-inflammatory cytokine IL-10. Also, resveratrol reduces prostaglandin E synthase-1 (PGES-1), COX-2, and iNOS protein expression via downregulation of p38 mitogen-activated protein kinases (MAPK) signaling pathway [54]. Quercetin effectively suppresses COX-2 promoter activity in colon cancer cells [55]. Genistein inhibits COX-2 expression via LPS-mediated tyrosine kinase signaling pathway [56]. It has been reported that EGCG affects activity of COX-2 following interleukin-1β stimulation of human chondrocytes and also in LPS-induced macrophages [57, 58]. Green tea extract enriched with EGCG downregulated COX-2 expression induced by TPA in mouse skin and human mammary cells (MCF-10A) in culture [49]. It is currently being emphasized that chemopreventive compounds, capable of inhibiting COX-2 expression without affecting COX-1, needs prioritization for cancer prevention and therapy.

4.2 Lipoxygenase

Lipoxygenases (LOXs) are enzymes involved in biochemical events leading to generation of pro-inflammatory mediators such as leukotrienes and conjugated hydroxyeicosatetraenoic acids (HETEs) from arachidonic acid of membrane phospholipids. On basis of regiospecificity during interaction with substrates, lipoxygenases have been designated as 5-LOX, 8-LOX, 12-LOX, and 15-LOX [59]. Several lines of evidence comply that 5-LOX pathway interacts with multiple intracellular signaling pathways that control cancer cell proliferation [59]; thus, inhibiting 5-LOX pathway has been predicted useful in inhibiting ontogeny of tumor development in a number of animal model systems. A variety of polyphenol compounds have been evaluated for their ability to either inhibit the synthesis or action of leukotrienes in context of anticancer properties. Nordihydroguaiaretic acid (NDGA) is a well-characterized nonselective LOX inhibitor from resinous extracts of the creosote bush *Larrea divaricata*; it blocks cysteinyl leukotriene (CysLT) synthesis. It has been used for centuries by native North Americans as a remedy for diverse illnesses and inhibits the growth of various tumors both in vitro and in animals [60–64]. Curcumin inhibits COX and LOX activities as well as TPA-induced promotion in mouse skin [51]. Polyphenols in red wine and grape seed extracts inhibit colon adenocarcinoma cell proliferation concomitant with increased apoptosis accompanying inhibition of 5-LOX activity [65]. The beneficial effects of cocoa polyphenols – flavan-3-ols and procyanidins – have been ascribed to their ability to inhibit mammalian LOX enzyme leading to decline in the plasma concentrations of cysteinyl leukotrienes which are metabolites of the 5-LOX pathway of arachidonic acid metabolism [66]. Green and black tea polyphenols – (−)-epigallocatechin gallate, (−)-epicatechin-3-gallate, and theaflavins – reportedly inhibit LOX-dependent activity by 30–75 % in colon tumors [67].

4.3 Inducible Nitric Oxide Synthase (iNOS)

As the name suggests, iNOS is an inducible enzyme induced by various stimuli including pro-inflammatory cytokines, hypoxia, and redox transcription factor

NF-κB leading to production of high amounts of nitric oxide ($NO^{\bullet}$) upholding it for an extended period of time. The production of $NO^{\bullet}$ under inflammatory milieu induces oncogenic mutations in p53 genes invigorating pro-tumorigenic effects. Polyphenol compounds exhibit promise for their ability to inhibit this pathway. As an example, resveratrol suppresses iNOS expression and COX-2 in murine macrophage cell line (RAW 264.7) stimulated with LPS and interferon-γ (INFγ) [68, 69]. Quercetin obstructs the generation of LPS-induced NO through the suppression of iNOS expression and attenuates LPS-induced prostaglandin E(2) production both in vitro and in vivo [70]. In murine RAW 264.7 macrophages, genistein, apigenin, and kaempferol inhibited the production of nitric oxide and induction of iNOS by LPS probably via inhibition of the activity and expression of iNOS [71–73]. EGCG also blocks LPS- and IFNγ-activated iNOS expression and enzyme activity in vitro [74, 75]. iNOS is overexpressed in colon tumors, and selective iNOS-specific inhibitors are speculative of providing a selective and safe chemopreventive strategy for colon cancer. A comprehensive review article highlighting mechanisms underlying endotoxin-induced iNOS expression in macrophages and promising natural agents that may be useful for anti-inflammatory and anticarcinogenesis strategies has been published [76].

5 Antioxidant Potential of Polyphenols

The most well-known benefit of polyphenols on human health is ascribed to their antioxidant property. This is attributable to direct scavenging of various radicals due to their chemical substructure containing labile phenolic hydroxyl group as well as their ability to upregulate the expression of free radical scavenging and cytoprotective antioxidant enzymes – superoxide dismutase, catalase, and peroxidases. These enzymes under basal conditions do not operate at maximal capacities but are upregulated (induced) to much higher levels by polyphenol compounds, thereby markedly enhancing the capacity of cells and host to endure oxidative stress and related forms of toxicity. A great deal of research has evaluated the antioxidant effect of various classes of polyphenols.

Under normoxic conditions in an aerobic organism, ROS [mainly superoxide radicals ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), hydroxyl radicals ($OH^{\bullet}$)] and RNS (like nitric oxide (NO) and peroxynitrite anions ($ONOO^{-}$)) are generated as by-products of metabolism notwithstanding exposure to hazardous xenobiotics [77, 78]. These ubiquitously generated radicals not only potentially damage DNA and induce mutations but also partake in most carcinogenic processes by activating oncogene products and/or inactivating tumor suppressor proteins [79, 80]. The presence of a high level of H_2O_2 reported in several carcinomas including melanoma, neuroblastoma, colon, and ovarian carcinoma cell lines functions in triggering signaling leading to transcriptional activation of cell proliferating genes [81–83]. Thus, a surrogate paradigm – abrogating signaling events and the expression of responsive genes stimulating cell proliferation – resides in scavenging of *ROS* by phenolic antioxidants. Additionally, oxidative stress induced by ROS has also been linked to tumor promotion in many tissues and implicated as playing a significant role in the promotion of carcinogenesis [84–87]. Green tea polyphenols by virtue of its action as strong antioxidant function in trapping and preventing the formation of reactive species including superoxide radical, singlet oxygen, hydroxyl ROS, nitric oxide, nitric dioxide, and peroxynitrite and additionally are found to reduce hydrogen peroxide (H_2O_2)-induced cytotoxicity [88, 89]. Quercetin, present in many commonly consumed fruits and vegetables, is a powerful antioxidant and potent scavenger of ROS and RNS through increased Nrf2 expression in vitro [90–92]. Quercetin protects cells from ultraviolet A (UVA)-induced intracellular damage. Quercetin pretreatment strongly suppressed UVA-induced apoptosis in human keratinocyte HaCaT cells by markedly inducing the expression of antioxidative gene and reduced production of reactive oxygen species following UVA irradiation by increasing protein levels of the transcription factor Nrf2; these beneficial effects were greatly compromised by downregulating Nrf2 expression [93]. Genistein belonging to the isoflavone group of compounds also exhibits strong antioxidant activity, particularly through the increased expression of antioxidant and phase II detoxifying enzymes at physiological concentrations [94]. Mangiferin, a polyphenol found in mango, exerts cytoprotective effect on benzo[a]pyrene-induced lung carcinogenesis in mice by rescuing enzyme activities of catalase, superoxide dismutase, glutathione peroxidase, and glutathione reductase [95]. It has recently been documented that stilbene piceatannol induces cytoprotective heme oxygenase-1 expression in human mammary epithelial cells [96]. In addition to the aforementioned effects, the efficacy of other tea polyphenols, theaflavin-3,3′-digallate and (−)-EGCG, in inhibiting xanthine oxidase enzyme (a prooxidant) suppressing intracellular ROS and exerting antioxidative effect has been reported [97]. The effect of resveratrol to inhibit free radical formation has been validated in human promyelocytic leukemia cells treated with TPA [98]. Similarly, in mouse model of tumor induction, the epidermal hyperplastic response to TPA was inhibited by resveratrol through interference with pathways of reactive oxidants and, possibly, through the modulation of the expression of the proto-oncogene *c-fos* and TGF-β1 [99]. Furthermore, resveratrol (and other non-polyphenol antioxidants) tends to inhibit the development of adenomas and preneoplastic atypical hyperplasias in mice that are deficient in the 8-hydroxyguanine DNA glycosylase 1 (Ogg1) gene; this gene encodes an enzyme that repairs oxidative DNA injury by 8-oxoguanine (8-oxoG) [100]. Ogg1 gene deficiency enhances lung adenocarcinogenesis in mice by virtue of accelerated oxidative stress along with mutations of EGFR and K-Ras gene similar to that found in human lung cancer [100].

Intriguingly, in contrast to above mentioned scenario, emerging evidence suggests the accumulation of ROS at low to moderate concentrations could short-circuit signaling events that favor the induction of apoptosis by stimulating cytochrome c release (into cytosol) that triggers caspase activation in many biological systems [101]. In DU145 prostate cancer cells, ECG increases ROS formation and mitochondrial depolarization causing apoptosis induction [102]. Additionally, EGCG induces H_2O_2 formation in human lung adenocarcinoma (H661) and in Ha-ras gene-transformed human bronchial (21BES) cells to cause apoptosis; the effect seems to be abolished by addition of exogenously added catalase (CAT) confirming the involvement of H_2O_2 in provoking the induction of apoptosis upon treatment [103, 104]. Stilbene resveratrol has been shown to interact with mitochondria of cancer cells and induce an imbalance in cellular antioxidant activities, leading to a significant increase in the levels of both intracellular reactive oxygen species (ROS) and lipid peroxides. Resveratrol sensitizes colon cancer cells to 5-fluorouracil chemotherapy by inducing a state of increased oxidative stress mechanistically linked to the inhibition of Akt and STAT3 proteins, which are known to have oncogenic potential in colorectal carcinomas [105].

6 Polyphenols and Cell Cycle

The hyper-proliferation of tumor is a highly regulated process that progresses like normal cells through the four phases of cell cycle – G1, S, G2, and M – which are controlled by cell cycle regulatory proteins. These include cyclins (cyclin A, B, Ds, or E), cyclin-dependent kinase (CDK; CDK1, 2, 4, or 6), and associated CDK inhibitors (CKI) such as $p27^{KIP1}$, $p21^{CIP1/WAF1}$, p53, and phosphorylated retinoblastoma (pRb). In retrospect, cell cycle arrest occurs in response to cellular stress preventing the replication of damaged DNA and/or segregation of damaged chromosomes during mitosis through intricately balanced signaling ensuring completion of phase-specific events and maintaining genetic integrity [106]. Increasing experimental data therefore suggest that cell cycle control, particularly at the G1/S and G2/M transitions, represents a major task for the cell to ensure an accurate cell division. Accumulated evidence indicates the potential of polyphenol phytochemicals to induce growth inhibition of cancer cells by interfering with cell cycle checkpoints particularly at the G1/S and G2/M transitions through modulation of the expression and/or activities of key proteins.

The natural phytoalexin resveratrol was shown to result in inhibition in the expression of regulators of the G1/S transition of the cell cycle in particular cyclin D1, CDK4, and cyclin E in human breast cancer cells [107]. Benitez et al. found that treatment of androgen receptor-positive and androgen receptor-negative prostate cancer cells with resveratrol causes not only a significant reduction in the levels of expression of cyclins D1, E, and CDK4 but also a reduction in cyclin D1/CDK4 kinase activity compromising cells' capability to proliferate and causing an increase in apoptosis in time- and dose-dependent manner [108]. In HL-60 cells resveratrol induced apoptotic cell death in cells preferentially arrested in the G0/G1 phase concomitant with a gradual decrease in the anti-apoptotic Bcl-2 oncoprotein expression [109]. Quercetin exerts its antitumor effect through blocking cell cycle progression at the G0/G1 interface, parallel with CDK inhibition [110]. Many recent studies demonstrate that EGCG causes a predominant G1 cytostatic cell cycle arrest through regulation of cyclin D1, CDK4, CDK6, $p21^{CIP1/WAF1}$, and $p27^{KIP1}$ [111, 112].

We earlier reported that curcumin can completely downregulate cyclin D1 expression through both transcriptional and posttranscriptional mechanism(s) and showed a decrease in the formation of cyclinD1/CDK4 enzyme complex, resulting in suppression of proliferation and induction of apoptosis [113]. Corollary to our findings, several other independent studies reported that curcumin upregulates CDK inhibitors such as p21$^{CIP1/WAF1}$ and p27^{KIP1} and downregulated cyclin B1 and CDC2 [114]. CDK inhibitors (CDKIs) such as the p21$^{CIP1/WAF1}$ and p27^{KIP1} proteins abrogate formation of the enzyme complexes and block cell cycle progression. 3',4',7-Trihydroxyisoflavone, a metabolite of the soybean isoflavone daidzein, is a direct inhibitor of CDK2 and CDK4 [115].

In an in vivo model of intestinal tumorigenesis in Apc$^{Min/+}$ mice, feeding of grape seed extract reduced the total number of intestinal polyps compared to control mice [116]. The findings paralleled with decreased cyclin D1 and c-Myc protein levels in the small intestine along with downregulation in expression of other important molecules such as COX-2, iNOS, and β-catenin and increased expression of p21$^{CIP1/WAF1}$ with reduced cell proliferation and increased apoptosis [116]. Thus, the suppression of cell cycle components by natural polyphenol compounds could be an effective strategy in abating the proliferation of tumor cells in vivo.

7 Polyphenols, Transcription Factors, and Cell Signaling

Extensive research efforts to gain a better appreciation of molecular pathways have revealed the presence of a complex network of signaling pathways overtly active in cancer cells augmenting proliferation and suppressing apoptosis. The molecular basis of pleiotropic action of flavonoids and other class of polyphenols is emerging through examination of discreet regulatory pathways including Akt, NF-κB, mitogen-activated protein kinase (MAPK), p53, COX-2, Ras, and many other molecules that are known to regulate apoptosis without entailing unacceptable side effects (Fig. 71.4). Published studies reveal that insidious manipulation of multiple signaling cascades by dietary polyphenol compounds therapeutically interferes with signaling up- or downstream of target pathway contributing to the pleiotropic effects of these agents in chemoprevention strategy. We present a comprehensive indication of deregulated signaling mechanisms prevailing within tumor cells along with few select examples of polyphenol compounds so as to convey a broad overview relating to their biological and molecular basis of action in chemoprevention strategy. Furthermore, this highlights some noteworthy rationale of including cytoprotective polyphenol compounds in sensitizing tumors to improve the efficacy of chemotherapy in the clinics and warrants further examination to improve patient survival.

7.1 Polyphenols and Nuclear Factor-κB

The nuclear transcription factor-κB (NF-κB) signaling is one of the most vital components in the control of cell proliferation synchronizing survival of tumor cells, tumor invasion, metastasis, drug resistance, and stress response. Elevated levels of NF-κB have been detected in a number of human malignancies, and the subsequent activation

Fig. 71.4 A schematic summary of the molecular targets and cell signaling pathways altered by polyphenol compounds. Multiple growth factor receptors are activated at the cell surface during cancer. Polyphenol compounds promote transcriptional activation of a battery of detoxification and antioxidant proteins. The P13K–Akt, NF-κB, AhR, and STAT-3 pathways are of significance and targets of polyphenol compounds. By dephosphorylating these molecules, polyphenol compounds modulate downstream signaling pathways impinging on proliferation, angiogenesis, and apoptosis. NF-κB pathway is inactive as a result of the binding of p50 and p65 to IκBα. When IκBα is phosphorylated by IKKs and degraded, p50 and p65 are set free and are translocated into the nucleus to activate a specific set of genes. This pathway has been shown to be inhibited both in vitro and in vivo. Polyphenols inhibit COX-2 enzyme and reduce PGE2 levels

has been shown to suppress apoptosis and induce proliferation, invasion, metastasis, and chemoresistance signifying that activated NF-κB regulates downstream genes to promote cancer cell growth [117]. Therefore, NF-κB has emerged as a target for the prevention and/or treatment of cancer. Under non-stimulating conditions, NF-κB is sequestered in the cytoplasm through tight association with NF-κB inhibitory protein IκB. Following stimulation including cytokine binding to its receptor, activation of IκB kinase (IKK) complex occurs. This leads to phosphorylation and subsequent degradation of the inhibitory protein IκB, allowing NF-κB to translocate into the nucleus and bind to its target DNA to regulate the expression of NF-κB target genes (Fig. 71.4).

A number of studies reported in the literature reveal wide array of polyphenol compounds derived from common dietary sources and medicinal plants wield antitumor effects through the suppression of NF-κB DNA binding activity in myeloid, lymphoid, and several solid tumor cell lines derived from prostate, breast, head and neck, and pancreatic cancer cells resulting in the inhibition of downstream target genes that are critical for the establishment of aggressive cancers. This ultimately leads to the inhibition of cell growth and induction of apoptotic cell death [118–120].

Polyphenols such as curcumin, resveratrol, genistein, and tea components have also been found to potentiate the antitumor activity of chemotherapeutic agents through regulation of NF-κB. We and other investigators have reported that chemotherapeutic drugs such as cisplatin, Taxol, gemcitabine, oxaliplatin, and docetaxel could result in the activation of NF-κB in tumor cells, contributing to drug resistance in cancer cells [121–125]. Further, we have shown that pretreatment of cancer cells with isoflavone genistein followed by treatment with low concentrations of docetaxel, gemcitabine, cisplatin, or oxaliplatin elicited significantly greater inhibition of cell growth concomitant with induction of apoptosis compared to either agent alone [121–123, 126, 127]. The results could be recapitulated in established in vivo animal models. Collectively, our results and studies reported from other laboratories clearly suggest that polyphenol compounds, which inactivate NF-κB activity along with other cellular effects, may contribute to increased cell growth inhibition and apoptosis with suboptimal doses of chemotherapeutic agents.

7.2 Aryl Hydrocarbon Receptor (AhR)

The AhR is a ligand-dependent transcription factor belonging to the basic helix–loop–helix/Per–ARNT–Sim family of proteins responsible for the induction of drug-metabolizing enzymes. Induction of cytochrome P4501A1 (CYP1A1) expression has been studied extensively as a model of AhR action. A variety of structurally diverse xenobiotic compounds such as halogenated and polycyclic aromatic hydrocarbons (dioxins, benzo[a]pyrene, and 3-methylcholanthrene) bind to the AhR as ligands and cause toxicological effects including cancer by activating this transcription factor [128]. In AhR$^{-/-}$ mice, benzo[a]pyrene fails to induce skin carcinogenesis [129]. Substantial data reported in literature from cultured cells and animal models indicate that naturally occurring compounds such as flavonoids, curcumin, resveratrol, EGCG, and genistein can effectively suppress biological events related to AhR-mediated signaling [130–133]. An in-depth mechanism of flavonoids on aryl hydrocarbon receptor-mediated signal transduction has been reported recently [134]. Curcumin suppresses phosphorylation of the AhR and AhR nuclear translocator (ARNT) through the inhibition of PKC; the later can directly phosphorylate AhR [131]. EGCG inhibits AhR signal transduction by interacting with its partner protein heat shock protein 90 [135]. Resveratrol, being an AhR antagonist, decreases 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)-induced expression of CYP1B1 expression and induces NAD(P)H:quinone oxidoreductase 1 (NQO1) expression [136, 137]. Such effects are important in breast cancer because estrogen genotoxicity may be initiated by cytochrome P450 (CYP1B1)-mediated oxidation of catechol estrogens to metabolites that react with DNA to form estrogen-DNA adducts [136]. Thus, by modulating AhR regulatory pathways, polyphenol compounds can influence breast cancer initiation and progression and other cancers as well.

7.3 Nuclear Factor E2 p45-Related Factor (Nrf2)

Nuclear factor E2 p45-related factor 2 (Nrf2) is a 1 (Bzip) transcription factor 2 sequestered in the cytoplasm by a cysteine-rich cytoskeleton-binding protein named Kelch-like ECH-associated protein-1 (Keap-1). After activation it translocates into the nucleus and binds to the “antioxidant response element” (ARE) in conjugation with small Maf proteins. Nrf2 plays a central role in the regulation (basal and/or inducible expression) of several phase 2 genes (e.g., *GST* and *NQO1*) by binding to the ARE in their promoters and portrayed as an important target for achieving chemoprevention (Fig. 71.4). ROS also activates the Nrf2–ARE pathway to activate antioxidant and detoxifying enzymes [138]. Most polyphenol compounds with chemopreventive status serve as transcriptional activators for the expression of glutathione S-transferase, NAD(P)H:quinone oxidoreductase 1 (NQO1), heme oxygenase-1(HO-1), γ-glutamyl cysteine synthetase (γ-GCS), and antioxidant enzymes by coordinately regulating Nrf2-antioxidant/electrophile response element (ARE/EpRE) [139]. To cite a few cases in point, EGCG-rich green tea polyphenol treatment to human mammary epithelial cells results in the expression of glutamate-cysteine ligase, manganese superoxide dismutase, and heme oxygenase-1 antioxidant enzymes by Nrf2-mediated signaling upregulating antioxidant enzyme expression [140]. The antioxidant efficacy of quercetin is also reportedly mediated through increased Nrf2 expression [141]. Quercetin protects cells from ultraviolet A damage mainly by elevating intracellular antioxidative activity via the enhanced accumulation of this transcription factor for antioxidant genes [93]. Furthermore, it has been reported that quercetin upregulates the expression of Nrf2 mRNA and protein by inhibiting ubiquitination and proteasomal turnover [141]. EGCG upregulates the expression of γ-glutamyltransferase, glutamate-cysteine ligase, and heme oxygenase 1 in the liver and colon of mice [142]. Increased levels of glutathione S-transferase (GST)-P activity were detected in lymphocytes of volunteers with lower baseline GST-P activity when treated with 800 mg Polyphenon E per day for 4 weeks [143]. Flavonoids have been shown to induce the expression of NQO1 and GST following the release of Nrf2 from Keap-1 [144]. Curcumin supplementation resulted in increased expression of detoxification enzymes glutathione S-transferases, glutathione reductase, epoxide hydrolase, HO-1, catalase, and NQO1 in the liver, small intestine, and kidney tissues of mice [145]. These examples as “proof of concept” validate molecular basis for the action of polyphenols in cancer chemoprevention strategies.

7.4 Regulation of the Akt Pathway

Most human cancers display reduced expression of the Akt inhibitor *PTEN* (the tumor suppressor phosphatase and tensin homologue deleted on chromosome 10). Hence, proteins regulating signaling through the phosphatidylinositol 3-kinase (PI3K)/Akt pathway are frequently activated in tumors because of the loss of PTEN. Activated Akt phosphorylates downstream substrates involved in the regulation of cell survival, cell cycle progression, and cellular growth (Fig. 71.4). A wide array of polyphenolic compounds derived from dietary sources including genistein, resveratrol, EGCG, silibinin, curcumin, and quercetin and whole plant extracts have been reported to inhibit cancer cell growth and induce apoptosis through the inhibition of the Akt pathway in tumor cells [146–152]. Kaempferol found in tea, propolis, and grapefruit inhibits UVB-induced phosphorylation of Akt signaling attesting kaempferol as a putative antitumor promoting agent [153]. EGCG promotes apoptosis in T24 human bladder cancer cells by inhibiting PI3K/Akt activation that, in turn, results in modulation of Bcl-2 family proteins, leading to enhanced apoptosis [154]. In Apc$^{Min/+}$ mice, oral administration of the green tea component EGCG reveals marked chemopreventive effects in association with inhibition of Akt signaling [155]. Furthermore, it has been reported that EGCG and other green tea polyphenols (GTP) decrease Akt phosphorylation along with reduction in nuclear β-catenin level in human breast cancer cells, leading not only to induction of apoptosis but also compromised their invasive capacity [156, 157]. Recently Dave et al. showed that the isoflavone genistein prevents cancer by inducing apoptosis in target cell concurring with increased PTEN expression both in vivo and in vitro [158]. We and others have found that isoflavone genistein inhibits cancer cell growth and induces apoptosis through the downregulation of Akt in breast, lung, ovarian, prostate, and pancreatic cancer cells [126, 149, 159–161].

The existence of a potential crosstalk between Akt, NF-κB, and androgen receptor (AR) has been reported, and genistein could interrupt these crosstalks resulting in downregulation in the expression of AR and prostate-specific antigen (PSA) [159]. In pancreatic and ovarian cancer with constitutively active Akt, the ability of genistein to induce apoptosis and sensitization to cytotoxic chemotherapy (cisplatin/Taxotere) implies importance of the inhibition of phosphorylated Akt signaling as a clinically significant strategy [126, 162]. In spot of clinical drug development, Deguelin, a retinoid of flavonoid family with chemopreventive activities, has been found to decrease tumor incidence in animal models for lung, colon, mammary, and skin carcinogenesis through Akt inhibition [163–167]. Deguelin is also effective in reducing pAkt levels in the lung of Akt-inducible transgenic mice stimulating apoptosis and suppressing proliferation of premalignant and malignant human bronchial epithelial cells at doses in which only minimal effects were observed in normal bronchial cells [163, 168]. Collectively, these results reflect that Akt is an important target for action of chemopreventive agents not only in cancer prevention but also towards therapeutic approach.

Emerging evidence reveals that activated Akt is also critical for acquiring drug resistance in multiple cancers types [169–173]; therefore, one may anticipate downregulation of Akt by chemopreventive polyphenol agents would sensitize cancer cells to chemo- or radiotherapy. We and other investigators reported enhanced chemotherapeutic or radiation effects by isoflavone genistein being partially mediated by the inhibition of Akt signaling [121, 174, 175]. It has been found that genistein also enhanced necrotic-like cell death with the significant inhibition of Akt activity in breast cancer cells treated with genistein and adriamycin, suggesting that the enhanced growth inhibition by combination treatment is through the inactivation of the Akt pathway [176]. Phenoxodiol, one of the synthetic derivatives of genistein, inhibits Akt signaling pathway and subsequently activates the caspase system inhibiting X-linked inhibitor of apoptosis protein (XIAP) which in turn leads to increased chemosensitization [177]. Curcumin, the polyphenol from the plant *Curcuma longa*, downregulates Taxol-induced phosphorylation of Akt (and its interaction with NF-κB), revealing insight into antitumor effect of curcumin being mediated through the inactivation of the Akt and NF-κB pathways [178]. It is currently assumed that Akt inhibition is likely to emerge as a prognostic marker for patient risk stratification.

7.5 Polyphenols and MAP Kinase

Mitogen-activated protein kinases (MAPK) are a family of serine–threonine kinase proteins that essentially amplify and integrate signals from a variety of extracellular stimuli from the cell membrane to the nucleus. Accumulating evidence indicates constitutive and inappropriate activation of MAPK due to amplified or overexpressed growth factor receptors and oncogenic Ras as a critical component in a number of solid malignancies such as breast, prostate, and gastric cancers [179, 180]. Evidence from various studies has shown that modulation of this pathway by polyphenol compounds confers advantage for the prevention and/or treatment of human cancer [181]. In mammalian cells, three distinct but parallel MAPK cascades have been identified that lie downstream of the membrane-associated RTK: the extracellular signal-regulated kinase (ERK), the c-Jun N-terminal kinase (JNK), and the p38 MAPK. Although ERKs can be activated by mitogens and growth factors, JNK and p38 can be activated by many environmental stress stimuli such as UV and γ-irradiation as well as many inflammatory cytokines, which are frequently associated with the induction of apoptosis; therefore contextually, p38 and JNK have been generally linked to cell death and tumor suppression, whereas ERK pathway is thought to play a prominent role in conferring a survival advantage to cells and tumor promotion.

Modulation of MAPKs by flavonoid polyphenols such as kaempferol and genistein has been shown [182]. Huang et al. reported that genistein inhibited TGF-β-mediated p38 MAP kinase activation, matrix metalloproteinase type 2, and cell invasion in human prostate epithelial cells at concentrations associated with dietary consumption [183]. In other studies, genistein has been found effective in preventing cytokine-induced ERK1/2 activation and promoting apoptotic cell death [184]. Since genistein is a well-known inhibitor of tyrosine kinase, it is possible that genistein inhibit tyrosine kinase upstream of p38 MAPK and subsequently inhibit the phosphorylation of tyrosine on p38 MAPK, leading to the inactivation of MAPK pathway. EGCG has shown to inhibit 12-O-tetradecanoylphorbol-13-acetate and epidermal growth factor-induced transformation of mouse epidermal cell line JB6 which parallel with the inhibition of AP-1 transcription factor DNA binding and transcriptional activity [185, 186]. In Ha-ras-transformed human bronchial cells, treatment with EGCG inhibited c-Jun, ERK1/2 phosphorylation, and the phosphorylation of ELK1 and MEK1/2 [104, 187]. In prostate cancer, decrease in the MAPK signaling may contribute to the reduction in cell proliferation and induction of apoptosis and provide a cellular mechanistic basis for EGCG suppressing prostate cancer growth without toxicity [188]. In human gastric cancer cells, EGCG blocked tumor promoter-induced MMP-9 expression by suppressing MAPK signaling and AP-1 activation and in addition has shown to abrogate PMA-induced activation of extracellular-regulated protein kinase (ERK) and c-Jun N-terminal kinase (JNK) which is an upstream modulator of AP-1 [189]. In anaplastic thyroid carcinoma (ATC), one of the most lethal cancers because of its aggressiveness and the lack of efficacious therapy, EGCG showed potency towards growth inhibition and apoptosis by suppressing the phosphorylation of EGFR, ERK1/2, JNK, and p38 [190].

Paradoxically, contrary to above-mentioned findings, Bhattacharya and colleagues reported oxidation-triggered generation of intracellular reactive oxygen species leading to activation of JNK and p38 MAPK but not ERK in inducing apoptosis by theaflavins (TF) and thearubigins (TR) – the major polyphenols of black tea [191]. Phase II enzyme induction by green tea polyphenols involves the activation of MAPK [139, 192]. Curcumin inhibits the activation of MAPK and shown to inhibit JNK activation induced by various agonists, including PMA, ionomycin, anisomycin, UVC, gamma radiation, TNF, and sodium orthovanadate [193, 194]. Curcumin attenuates experimental colitis through a reduction in the activity of p38 MAPK and causes decrease drug resistance by its inhibitory effect on MAPK signaling [195–197]. Resveratrol significantly inhibits mitogen-activated protein kinase (MAPK) activities and immunoblot analyses revealed consistent reduction in the phosphorylation of extracellular signal-regulated kinases 1/2 (ERK1/2), Jun N-terminal kinase (JNK-1), and p38 MAPK [198]. Resveratrol reduced prostaglandin E synthase-1 (PGES-1), COX-2, and iNOS protein expression via downregulation of p38 MAPK signaling pathway [54]. p38 MAPK pathway is involved in the mechanisms of the cell response to quercetin through the modulation of Nrf2 and glutathione-related enzymes [199]. Transcriptome and proteome profiling of colon mucosa of quercetin-fed rats point to tumor-preventive mechanism through downregulation of the potentially oncogenic MAPK in vivo [200]. Silibinin inhibits invasion of cancer cells by suppressing the MAPK pathway [201, 202]. Silibinin inhibits UVB-induced and regression of established skin tumors via modulation of MAPK and Akt signaling enhancing p53 in mouse skin, leading to decrease in UVB-caused proliferation and increased apoptosis, which might in part, be responsible for its overall efficacy against photocarcinogenesis and effectiveness both in prevention and intervention of human skin cancer [151, 203].

7.6 Wnt and Hedgehog Signaling and Polyphenol

In adult life Wnt signaling plays important homeostatic task, but inappropriate regulation and activation of this pathway is reportedly associated with several pathological disorders including cancer [204, 205]. In 60 % of the cases of colorectal cancer, either mutation or abnormalities in components of the Wnt/β-catenin signaling pathway are evident [206]. Other site-specific cancer with abnormal Wnt signaling has been reported for melanoma, hepatocellular carcinoma, gastric carcinoma, glioblastoma, leukemia, and pancreatic and breast cancer [207]. The antitumor effect of flavonoids in relation to their ability to modulate the Wnt/β-catenin signaling pathway has been reviewed by various authors [208–210].

Apigenin was the first described flavonoid as regulator of the Wnt pathway affecting the levels of β-catenin and Dsh proteins resulting in cell cycle arrest [207, 211]. EGCG inhibits Wnt signaling in breast, lung, and colon cancers by elevating transcriptional repressor protein levels (HBP1) which suppresses Wnt signaling [212]. Another mechanism reported in lung cancer cells includes promotion of demethylation of Wnt antagonist, WIF-1 (Wnt inhibitory factor 1), that inhibits Wnt signaling by direct binding to Wnt molecules [213]. The effect of green tea extract in reducing tumor multiplicity in the Apc$^{\mathrm{Min/+}}$ mouse has been linked to inhibition of translocation of Wnt mediator β-catenin to the nucleus [214, 215]. In rat mammary gland tumors, Su and colleagues demonstrated using Affymetrix rat 230A GeneChip arrays that soy isoflavone genistein inhibits Wnt expression through increased secretion of Wnt inhibitor (sFRP2) and decreased expression of Wnt5a attenuating Wnt signaling, without affecting β-catenin levels indicating noncanonical effect of genistein on mammary tumor [216]. In colon cancer, genistein inhibits β-catenin-mediated WNT signaling through increased expression of Wnt pathway antagonist sFRP2 gene expression by demethylating its silenced promoter [217]. Additionally, genistein has been reported to suppress GSK-3β and Akt phosphorylation which are upstream components of the β-catenin/Tcf pathway leading to suppression of β-catenin/Tcf transcriptional activity [218]. Other polyphenolic flavonoids – kaempferol, isorhamnetin, and baicalein – have been found and reported as negative regulators of β-catenin/Tcf signaling, and their inhibitory mechanism is related to the decreased binding of β-catenin/Tcf complexes to consensus DNA [218].

Flavonoid silibinin treatment decreased nuclear and cytoplasmic levels of β-catenin triggering growth inhibition and apoptosis in colon tumor cell lines such as SW480 where the Wnt pathway is altered [219]. The effect of resveratrol in colon cancer cells which do not have a basally activated Wnt pathway is due to significant decrease in the amount and proportion of β-catenin in the nucleus due to reduced expression of the two regulators (lgs and pygoI) of β-catenin localization [220]. The in vitro growth and apoptosis of several leukemia and lymphoma cell lines by quercetin are molecularly driven by inhibiting components of the Wnt signaling pathway [221]. Also, quercetin inhibits human SW480 colon cancer growth in association with inhibition of cyclin D1 and survivin expression through Wnt/beta-catenin signaling pathway [222].

The in vitro and in vivo effect of isoflavone genistein, EGCG, and resveratrol in the regulation of Hedgehog (Hh) signaling has also been reported [223]. Inhibition of Hh signaling correlates with delayed prostate tumor growth in vivo in TRAMP mice [223]. In transgenic LADY model of prostate cancer (alternative to TRAMP model), tumors rarely produce metastasis due to lack of increased Hh signaling during tumor development, evidence that strengthens the importance of Hh signaling in the process of metastasis [224].

7.7 Regulation of the STAT Pathway

Of the 7 STAT family members identified till date, aberrant constitutive activation of STAT3 family of cytoplasmic latent transcription factors has been identified in a number of human cancers including breast, lung, ovarian, pancreatic, skin, prostate, and in multiple myeloma, leukemia, and lymphomas. Active STAT3 dimers bind to consensus sequences in the promoters of genes regulating cell proliferation and anti-apoptotic behavior in cooperation with other transcription factors to regulate expression of genes such as Bcl-2 and Bcl-xL, Mcl-1, $p21^{CIP1/WAF1}$, and cyclin D1 [225–227]. Under normal conditions, multiple STAT3 endogenous negative regulators attenuate STAT3 signaling such as suppressors of cytokine signaling (SOCS) proteins, protein inhibitors of activated STATs (PIAS), and protein tyrosine phosphatases such as SHP-1 and SHP-2 that dephosphorylate active STAT3 complexes [228–230].

Natural chemopreventive agents such as green tea, resveratrol, and curcumin have shown to modulate STAT activation in tumor cells. In transgenic TRAMP mouse prostate cancer model, green tea polyphenol inhibited STAT3 expression inhibiting tumor growth and promoting apoptosis [231]. Polyphenon E (a standardized mixture of green tea polyphenols) suppresses STAT3 activation in breast cancer cells concurrent with inhibition of markers of angiogenesis [232]. Resveratrol inhibits Src tyrosine kinase activity blocking STAT3 activation [233, 234]. Bharti et al. demonstrated that curcumin inhibited IL-6-induced STAT3 phosphorylation abrogating nuclear translocation of activated STAT [235]. Administrating curcumin to athymic nude mice bearing ovarian tumors resulted in significant inhibition of STAT3 phosphorylation [236]. Luteolin, a flavonoid abundant in green vegetables, such as broccoli, cabbage, celery, green pepper and spinach, inhibits phosphorylation of STAT3 and targets it for proteasomal degradation, in this manner inhibits the expression of cyclin D1, survivin, Bcl-xL, and VEGF [237]. Thus, suppressing STAT signaling pathway by dietary polyphenol is expected to provide a window of opportunity for prevention and treatment of cancer.

7.8 Androgen Receptor (AR)

As a member of the steroid receptor superfamily of transcription factors, AR and its cognate natural ligand, androgen, are intimately associated with normal prostate development as well as in the growth and maintenance of hormone-resistant prostate cancer (HRPC) for which there is no curative therapy [238]. Most HRPC express AR and the androgen-inducible PSA. Studies have shown that polyphenol-rich food items such as soy products are associated with reduction of prostate cancer risk. The soy isoflavone genistein functions as a novel AR disrupting compound utilizing intracellular signaling pathways to alter AR nuclear accumulation and degradation by the ubiquitin proteasome pathway modulating androgen-dependent transcription program in prostate [239]. Furthermore, isoflavones have shown to modulate other regulatory molecules such as FOXO3a, GSK-3β, and β-catenin – these function as AR coregulators regulating the activity of AR. Experimentally, it has been demonstrated that isoflavone inhibits FOXO3a binding to the promoter of *AR*, but instead it promotes FOXO3a binding to the $p27^{KIP1}$ promoter, resulting in alteration of AR and $\mathrm{p27^{KIP1}}$ expression leading to the inhibition of cell proliferation and the induction of apoptosis in both androgen-sensitive and insensitive prostate cancer cells [240]. Using microarray techniques, it has been shown that resveratrol downregulates the expression of both AR and AR target genes by repressing AR transcriptional activity and not due to changes in nuclear translocation or DNA binding [241–243].

7.9 Mammalian Target of Rapamycin (mTOR) Signaling

The mTOR signaling is one of the major downstream signaling targets of PI3K/Akt and plays a critical role in promoting cellular proliferation and survival by phosphorylating two major targets – the eukaryotic translation initiation factor 4E (eIF4E)-binding protein 1 (4E-BP1) and the ribosomal protein S6 kinases (S6K1 and S6K2) that are required for cell cycle traverse from G1 to S phase [244]. Thus, inhibition of mTOR results in accumulation of cells in the G1 phase of the cell cycle and potential apoptosis. mTOR exists as two functionally distinct complexes, mTORC1 and mTORC2 differing in subunit compositions and biological functions. Dysregulated mTORC1 signaling is often observed in human tumors, and emerging evidence suggests that inhibition of mTOR signaling can be exploited as a potential tumor-selective therapeutic strategy. Initially, Rapamycin and its derivatives, CCI-779 and RAD001, showed much promise in clinical setting but later due to drug-mediated hyperactivation of Akt and ERK–MAPK pathways subsequently increased tumor cell viability accompanied by drug resistance [245]. Due to such negative clinical activity in a limited number of tumor types, it has now been rationalized to combine drugs which inhibit both (Akt and mTOR) signaling networks in therapeutic front. Recently, it was found and reported that the combined use of resveratrol and rapamycin resulted in modest additive inhibitory effects on the growth of breast cancer cells, mainly through suppression of rapamycin-induced Akt activation [246]. Similar findings have been reported in human glioma cells wherein rapamycin enhanced resveratrol-induced apoptosis [247]. Resveratrol inhibits insulin-stimulated Akt, S6 kinase, and 4E-BP1 phosphorylation and surges the association between mTOR and its inhibitor, DEPTOR, one mechanism by which resveratrol negatively regulates mTOR activity [248]. A combination of dietary grape polyphenols, resveratrol, quercetin, and catechin (RQC), at low concentrations induced apoptosis in gefitinib-resistant breast cancer cells and inhibited mammary tumor growth and metastasis in nude mice through mechanism involving inhibition of Akt and mTOR and activated AMP-dependent protein kinase (AMPK) even in the presence of gefitinib [249]. This emphasizes that anti-EGFR therapy can be potentiated by inhibition of Akt/mTOR signaling. Curcumin inhibits phosphorylation of the mTOR and its downstream effector molecules by dissociating raptor (a protein component of mTORC1 complex) from mTOR [250]. Silibinin from milk thistle plant inhibits translation initiation by inhibiting the mTOR signaling pathway [251]. Genistein modifies 4E-BP1 (Ser65) phosphorylation in tumor lines [252]. The antitumor activity of cisplatin by genistein is enhanced among others with reduced p-mTOR, p-p70S6K1, p-4E-BP1, and p-Akt [253]. EGCG, as key nodal ATP-competitive inhibitor of both phosphatidylinositol-3-kinase (PI3K) and mTOR (with K(i) values of 380 and 320nM), inhibits cell proliferation [254]. By targeting VEGF-R2-regulated Akt/mTOR/P70S6K signaling pathway, quercetin inhibits tumor growth and angiogenesis which in the future can be used as a potential drug candidate for cancer therapy [255].

7.10 Regulation of the Growth Factor Signaling Pathway

Over the past decade, extensive research has elucidated the functional relationship and molecular characterization between growth factor receptors (GFR) and their ligands that drive cell proliferation and tumor growth. Several chemopreventive phytochemicals including curcumin, genistein, resveratrol, and catechins have been shown to be potent inhibitors of several growth factor signaling pathways. Curcumin inhibits the ligand-stimulated activation of EGF (epidermal growth factor) receptor (EGFR) including an inhibitory effect on EGFR phosphorylation indicating that it has the potential to break the autocrine loops that are established in several advanced cancers and enhances the growth inhibitory effects of FU and oxaliplatin through EGFR and insulin-like growth factor receptor (IGFR) pathways [256–258]. Blocking EGF receptor directs the cancer cells to enter apoptosis, and this inhibition also abrogates the invasive potential of the cancer cells. The molecular effects and the mechanism by which EGCG and other catechins exert their protective effects towards dysregulated receptor tyrosine kinases (RTKs) in cancer cells have recently been summarized by Larsen et al. [259]. From ligand binding assays, it has been concluded that EGCG blocks the binding of EGF to its receptor to cause inhibition of EGFR phosphorylation [260]. In addition, it has been found that tea catechins inhibit receptor expression through a complex circuitry by inhibiting the activity of ERK, which regulates the transcription factor Egr-1, and that Egr-1 controls the expression of EGFR [260]. Inhibition of EGFR signaling has also been shown to decrease the production of vascular endothelial growth factor (VEGF) in cancer cells [261]. Adachi et al. demonstrated that EGCG disrupts lipid order and membrane organization; this causes internalization of EGFR such that EGF could no longer bind [262]. EGCG has also been shown to bind directly to EGF, VEGF, and platelet-derived growth factor (PDGF) ligands [263–265]. EGCG treatment potentiated the effects of the tyrosine kinase inhibitor erlotinib in head and neck tumors [112, 266]. In pancreatic cancer, growth inhibition and apoptosis was associated with inhibition of EGFR tyrosine kinase activity by flavonoid luteolin, present abundantly in several green vegetables [267]. Luteolin also inhibits VEGF-induced angiogenesis and tumor growth in a murine xenograft model [268]. Quercetin is reported to be a potent inhibitor of EGFR tyrosine kinase activity; it however does not directly inhibit EGFR but instead interferes with different signaling pathways downstream of EGFR that regulate cell proliferation and survival [269, 270]. In prostate cancer cells, growth inhibitory and apoptotic effects of silibinin could be achieved by targeting EGFR signaling. Silymarin and silibinin are also effective in inhibiting transforming growth factor-α (TGF-α) and EGF-mediated tyrosine phosphorylation of EGFR and its adapter protein Shc in androgen-independent human prostate cancer cells harboring constitutively active EGFR [271, 272]. IGFs are mitogenic ligands and their activity is firmly controlled by the presence of IGF-binding proteins (IGFBPs); similar to EGFR, IGF receptor (IGFR) signaling also promotes growth and survival of cancer cells. It has been shown that silibinin, apigenin, and EGCG downregulate IGF-IR signaling and significantly increase the levels of IGF-binding protein-3 (IGFBP-3) in prostate cancer inhibiting cell growth both in vitro and in vivo [273–275]. The anticancer properties of NDGA in breast cancer cells in vitro and in vivo relate to direct inhibition of the function of two receptor tyrosine kinases, the insulin-like growth factor receptor (IGF-1R), and the c-erbB2/HER-2/neu receptors resulting in inhibition of cellular anti-apoptotic signaling pathway [64].

8 Apoptosis

Apoptosis is an important defense mechanism against tumor development and major mechanism of anticancer action of chemopreventive and chemotherapeutic agents. At the molecular level, premalignant and tumor cells tend to skirt apoptosis by deregulating genes that bring about programmed cell death, and therefore, regulating apoptosis is considered as a relevant target in reducing the incidence of cancer. Contextually, overexpression of growth-promoting oncogenes and anti-apoptotic proteins such as Ras and Bcl-2 family members has been linked with promotion of cell proliferation which is fundamental to tumor growth. Additionally, in humans, the induction of apoptosis is closely related to normal p53 functioning since lack of its expression or function is associated with increased risk of tumor development. Two principal groups of Bcl-2 family proteins are anti-apoptotic proteins such as Bcl-2, Bcl-xL and Mcl-1 and proapoptotic proteins, which are further subdivided into multidomain proteins (Bax, Bak) as well as BH3-domain-only molecules such as Bim, Bid, Bik, Noxa, or Puma.

Fig. 71.5 Potential pathways of apoptosis (extrinsic and intrinsic) and intracellular signaling elements modulated by polyphenols in chemoprevention and sensitizing cancer cells to cytotoxic chemotherapies

Most bioactive dietary polyphenols demonstrate potent apoptosis signaling in cancer cells as single agent augmenting the core apoptotic pathway that involves interference with mitochondrial integrity (intrinsic pathway) or synergize with death receptor of extrinsic pathway (Fig. 71.5). The extrinsic pathway is regulated by cytokines (mainly CD95L and TRAIL) secreted by cytotoxic T cells or natural killer (NK) cells and considered as important endogenous anticancer immunosurveillance agent inducing apoptosis selectively in tumor cells. Both these pathways converge through executioner caspases to cleave the death substrates (like poly (ADP-ribose) polymerase (PARP)) and eventually result in the classical morphological and biochemical hallmark of apoptosis such as chromatin condensation, translocation of phosphatidyl serine across plasma membrane, membrane blebbing, nuclear DNA fragmentation, and formation of apoptotic bodies [276]. As mentioned earlier, ROS contributes to mitochondrial depolarization and plays an important role in execution of intrinsic proapoptotic pathway.

Evidence for polyphenol-induced apoptosis has been observed in breast, colon, bone, leukemia, larynx, prostate, ovary, and pancreatic cancer cells. In most instances, the tested compounds have been documented to modulate apoptosis signaling through a number of targets in several cancer cell lines [277]. These targets include downregulation of the expression of apoptotic suppressor proteins such as Bcl-2 and Bcl-xL and upregulation of proapoptotic Bax expression, proteolytic activation of caspase-3, decrease in mitochondrial potential with subsequent release of apoptotic generating proteins cytochrome *c* and inhibitor of apoptosis (IAP) family.

Studies reported by us and several other laboratories have shown that isoflavone genistein induces apoptosis in breast, prostate, non-small cell lung cancer, head and neck squamous cell carcinoma, and pancreatic cancer cells [120, 121, 126, 278–281]. Phenoxodiol, the genistein derivative, under phase II clinical trials has been reported to bind to the tumor-associated NOX (tNOX) receptor and block its function and subsequently inhibits the anti-apoptotic proteins XIAP (X-linked inhibitor of apoptosis) and FADD-like ICE (FLICE) inhibitory protein, eventually inducing apoptotic cell death [177]. Bronikowska et al. tested and reported the cytotoxic and apoptotic activities of isoflavones – genistein, biochanin A, and neobavaisoflavone – in combination with TRAIL on HeLa cancer cells [282]. Isoflavone enhanced TRAIL-induced apoptosis indicating that isoflavones augment TRAIL cytotoxicity in cancer cells. In another study, the suppressive effect of genistein and resveratrol, alone and in combination in a transgenic model of spontaneously developing prostate cancer, revealed increasing evidence of apoptosis in the prostate along with reduced cell proliferation as core mechanism for the observed additive and synergistic effects in suppressing tumor growth. Furthermore, in this model genistein as a single agent induced apoptosis and found to decrease steroid receptor coactivator-3 (Src-3) in the ventral prostate [283].

Resveratrol has been shown to induce cell death in some tumor types expressing high CD95 (Fas, APO-1) by augmenting CD95 (FasL) expression, thereby manipulating CD95–CD95L system as “apoptotic trigger” to induce cell death [109]. The in vivo antitumor activity of grape-derived polyphenols against colon carcinoma cell xenograft in BALB/c mice and azoxymethane-induced aberrant crypt foci (preneoplastic lesions) has been viewed owing to increased apoptosis as indicated by TUNEL staining and active caspase-3 levels in tumor cells consistent with efficacy of these class of polyphenols in stimulating apoptosis under in vitro conditions [284]. Additionally, red wine polyphenols has been reported efficacious in reducing the number of azoxymethane-induced aberrant crypt foci (preneoplastic lesions) in colon by 49 % by mechanism involving inhibition of proliferation and promotion of apoptosis within tumor cells subsequent to upregulation of tumor suppressor genes. Resveratrol has been described to interfere with mitochondrial functions by inhibiting mitochondrial ATP synthesis through its binding to F1-ATPase [285]. The efficacy of treatment with polyphenolic extract of *Solanum nigrum* L. (SNPE) against hepatocellular carcinoma (HCC) was reportedly remarkable with almost complete inhibition of tumor weight as well as tumor volume at 2 μg/ mL. In vitro studies revealed sub-G(1) phase accumulation and caspase-3, 8, and 9 cleavages induced by SNPE attesting apoptosis induction as one of the underlying phenomenon in achieving cell growth inhibition [286].

In vitro, EGCG has been shown to cause growth inhibition and apoptosis in a number of human cancer cell lines including leukemia, melanoma, breast cancer, lung, bladder, and colon [47, 287–289]. Yamauchi (2009) reported EGCG in green tea polyphenols (GTP) as a potent apoptosis inducer that functions exclusively through a p53-dependent pathway in A549 cells [290]. Treatment with GTP and EGCG to nude mice bearing highly invasive estrogen receptor-negative human breast cancer cell line (MDA-MB-231) showed an effect in delaying the tumor incidence as well as reduction in tumor burden compared to control. Immunohistochemistry performed on tumors showed evidence of apoptosis induction that inhibited proliferation of cells strengthening proclamation that GTP and EGCG treatment inhibit proliferation and induce apoptosis cells in vitro and in vivo asserting antitumor properties [157].

In U-937 leukemia cells and mice harboring xenografts of this cell line, the proapoptotic effects of quercetin resulted in both the increased expression of the proapoptotic factor Bax and the inhibition of anti-apoptotic Mcl-1 [291]. Quercetin causes apoptosis in both transformed and primary leukemia cells but not in normal blood peripheral mononuclear cells at concentrations up to 50 mM [292]. Further, quercetin has been shown to be a potent enhancer of TRAIL-induced apoptosis in prostate and hepatocellular carcinoma cells [293, 294].

9 Invasion and Metastasis

A great deal of research has evaluated the effect of polyphenol compounds in inhibiting the invasive and metastatic behavior of cancer cells that represents the primary source of clinical morbidity and mortality in large majority of solid tumors. Currently, it is widely accepted that epithelial–mesenchymal transition (EMT) – a process that converts an epithelial cell to a mesenchymal cell by promoting the loss of cell–cell adhesion – leads to enhanced cancer cell migration and invasion. Gene expression analyses of human cancer specimens have identified cell migration genes, whose characteristic expression patterns can predict the risk of metastasis, and closely related to this phenomenon, high endogenous levels of uPA (urokinase-type plasminogen activator) and its receptor, uPAR, and matrix metalloproteases (MMPs) have been found in advanced metastatic cancers. Matrix metalloproteinases are proteolytic enzymes believed to provide cancer cells with their invasive potential by degrading the extracellular matrix. It is currently believed that inhibition of the activities of MMP-9 and uPA and levels of ERK and Akt might be one of the molecular mechanisms involved in the anti-invasive activity by polyphenols along with inhibition of AP-1 and NF-κB to block secretion of uPA. An in-depth molecular mechanism for anti-invasive and anti-metastatic activity of polyphenol and their related derivatives in various types of cancers has been recently reported by Weng and Yen [295]. In the following narrative, we summarize some key events associated with (select) polyphenol compounds such as EGCG, genistein, and resveratrol.

The pleiotropic anticancer effects of EGCG are linked with modulation of key elements in signaling pathways, which phenotypically retard invasion and metastasis of tumor cells from primary site including liver, lung, breast, prostate, colon, pancreatic, gastric, and oral site [296]. It has been reported that EGCG-mediated alterations in the expression of key regulators of EMT pathway including upregulation of E-cadherin, gamma-catenin, MTA3, ERα, and FOXO3 and downregulation of Snail reduce the invasive phenotype [297]. EGCG also increases the expression of the tissue inhibitor of MMPs (TIMP1 and TIMP2) at lower concentrations (1 μM) providing an additional mechanism and means to suppress the activity of MMPs [298]. Other investigators reported that EGCG significantly inhibits tumor cell invasion into basement membranes by reducing the expression of the MUC1, MMP-2, and MMP-9 proteins [299]. The invasion of lung carcinoma cells was attenuated by EGCG-mediated repression in expression of MMP-9 and nuclear localization of NF-κB [300]. The invasion and migration of human oral cancer cells, OC2, may partially be attributed to the decreased production of MMP-2/MMP-9 and uPA by EGCG [301]. Additionally, it has been shown that EGCG significantly suppresses the invasive ability of a variety of oral cancer cells by demethylating and enhancing RECK (an MMP inhibitor) and consequently inhibiting MMP-2/MMP-9 levels [302].

The effect of one of the most widely studied flavonoids – genistein on anti-metastatic properties on various types of cancer – has been reported. Genistein effectively inhibited the invasive potential of hepatocellular carcinoma (Bel7402 cells) by inhibiting focal adhesion kinase (FAK) signaling [303]. In breast cancer, the cell–matrix adhesion and migration of MDA-MB-231 cells are suppressed by genistein through inhibition of NF-κB and AP-1 and decreased titers of uPA secretion along with downregulation of MMP-2/MMP-9; MT1-, MT2-, and MT3-MMPs; and the chemokine receptors – CXCR4 and CXCL12 [304–307]. In melanoma, genistein suppressed adhesion-induced protein tyrosine phosphorylation to interrupt cell–ECM interactions contributing to inhibition of melanoma cell invasion [308]. The motility potential of melanoma cells is also decreased by genistein [309]. Genistein inhibits matrix metalloproteinase type 2 (MMP-2) activity in six out of seven prostate cell lines tested, blocks MMP-2 induction by TGF-β, and inhibited cell invasion. Efficacy was seen at low nanomolar concentrations, corresponding to blood concentrations of free genistein attainable after dietary consumption [183]. In orthotopic murine model of human prostate cancer metastasis, dietary genistein (before implantation) led to 96 % decrease in lung micrometastasis by 4 weeks along with nuclear morphometric changes in tumor cells indicative of increased adhesion (i.e., decreased detachment) and increased tumor levels of FAK, p38 MAPK, and HSP27 "promotility" proteins; however, the ratio of phosphorylated to total protein trended downward, indicating a failure to increase relative amounts of activated protein supporting the notion of cellular compensatory responses to antimotility effects induced by genistein [310].

In our laboratory, the effect of dietary genistein and purified soy extract [G2535, containing $\geq$97 % total unconjugated isoflavones and daidzein in a 2:1 ratio (G2535:daidzein)] on the growth of metastatic prostate cancer cells in an SCID-human experimental model of prostate cancer bone metastasis is being investigated. The findings demonstrate that genistein effectively inhibits prostate cancer cell growth in the bone environment and downregulates the transcription and translation of genes critically involved in the control of tumor cell invasion and metastasis in vitro and in vivo, suggesting possible therapeutic role of genistein and G2535 for metastatic prostate cancer [311, 312]. Other investigators have also demonstrated similar results showing that isoflavones inhibit bone metastasis of human breast cancer cells in a nude mouse model and metastasis of androgen-sensitive human prostate tumors in mice [313, 314]. Furthermore, studies reported from our laboratory have earlier documented that genistein intervenes in the regulation of the osteoprotegerin/receptor activator of NF-κB (RANK)/RANK ligand/MMP-9 signaling in prostate cancer, suggesting that isoflavone genistein could be a promising nontoxic agent that may synergize in augmenting the therapeutic outcome of metastatic prostate cancer with chemotherapeutic drugs [315]. Other reports indicate that genistein has the potential to therapeutically compensate endoglin deficiency – a key regulator of cell motility and induces metastatic suppressor kangai-1 (KA11) suggesting that genistein could be used for anti-metastatic therapies [316, 317].

Several studies have reported the anti-invasive and anti-metastatic effect of resveratrol as a potent arsenal in chemoprevention strategy. In hepatoma, Kozuki et al. and Miura et al. revealed that resveratrol can suppress the ROS-stimulated invasive capacity of the tumor cells by preventing rise of peroxide level and expression of HGF [318, 319]. Resveratrol inhibits MMP-9 expression in SMMC-7721 cells [320] and TNFα-mediated MMP-9 expression in HepG2 cells by downregulation of the NF-κB signaling pathway [320]. In lung cancer, anti-metastatic effect of resveratrol has been documented by a decrease both in the number and the weight of Lewis lung carcinoma (LLC) metastases in animal models via inhibition of LLC-induced angiogenesis [321, 322]. The migratory and invasive ability of A549 lung cancer cells is compromised by resveratrol treatment inhibiting the expression of heme oxygenase-1 (HO-1) and subsequently MMP-9 and MMP-2 expressions [323]. Resveratrol inhibits the migration of MDA-MB-231 breast cancer cells by inducing a rapid global array of filopodia and decreasing focal adhesions (also called cell–matrix adhesions) along with decrease in focal adhesion kinase (FAK) activity in these cells [324]. Quercetin, by downregulating uPA and its receptor uPAR and mRNA, culminates in inhibition of invasion, migration, and signaling molecules involved in survival and proliferation of cancer cells [325]. Apigenin substantially upregulated in colon cancer cells the anti-metastatic multifunctional cell-surface protein, CD26, which is downregulated in various cancers including colorectal carcinoma [326]. Thus, polyphenol compounds have the propensity to alter the metastatic behavior of tumor cells emphasizing their potential in chemoprevention armentorium.

10 Angiogenesis

Angiogenesis is the formation of new blood vessel from existing vasculature, an adaptive process to compensate tissue and cellular requirement for oxygen and nutrient import as much as the need to export metabolic wastes, and thus considered critical for growth and survival of tumors. Angiogenesis is also a prerequisite for metastatic tumor spread. As a result, intervention of the angiogenic process by polyphenol class of compounds has been viewed as a novel strategy for cancer control and therapy. Emerging evidence reveals tumor cells produce potent angiogenic factors such as vascular endothelial growth factor/vascular permeability factor (VEGF/VPF) and fibroblast growth factor-2 (FGF-2) and concurrent downregulation of angiogenesis inhibitors (thrombospondin-1, angiostatin, endostatin) which sets in angiogenic phenotype within tumor [327, 328]. TGF-β signaling is known to upregulate angiogenesis. It has also been established that the α-subunit of potent tumorigenic factor, hypoxia-inducible factor-1 (HIF-1α), becomes elevated in tumors due to hypoxia and that HIF-1α transcriptional activity contributes to tumor angiogenesis, invasion, and progression [329]. The antiangiogenic properties of a number of naturally derived phytochemicals are essentially accomplished by inhibiting VEGF-mediated signaling and biological effects in endothelial cells and modulation of HIF-1α levels [330–332].

Great deal of evidence indicates the antiangiogenic effect of green tea extracts (GTE) and its main catechin EGCG. In in vitro model of cultured human umbilical vein endothelial cells (HUVECs), EGCG has been reported to disrupt VEGF-induced receptor dimerization inhibiting angiogenic signaling [333]. In human colorectal cancer cells, EGCG has also been shown to inhibit growth and activation of VEGF/VEGFR axis [334]. The effect of EGCG in heterotopic tumors induced by subcutaneous injection of gastric cells in nude mice recapitulates the in vitro data showing reduction in tumor microvessel density (MVD) by the treatment [335]. In breast cancer xenografts, green tea extract decreased the tumor blood vessel density, reducing the size of the tumor [336]. The antiangiogenic effect of other polyphenol compounds – genistein, resveratrol, quercetin, curcumin, and silibinin – has also been reported. Genistein has been shown to inhibit TGF-β signaling, impacting angiogenesis by suppressing TGF-β-induced expression of VEGF [337, 338]. Experiments conducted in nude mice xenograft and chick chorioallantoic membrane bioassay confirm genistein as a potent inhibitor of angiogenesis [339]. Mechanistically, genistein inhibits expression of angiogenesis-related factors, vascular endothelial growth factor [165], platelet-derived growth factor, tissue factor, and urokinase plasminogen activator (uPA), while, on the other hand, it upregulates angiogenesis inhibitors – plasminogen activator inhibitor-1, endostatin, angiostatin, and thrombospondin-1 [339]. Genistein significantly reduces nuclear accumulation of HIF-1α affecting angiogenesis by suppressing VEGF-mediated autocrine and paracrine signaling pathways between tumor cells and vascular endothelial cells [340]. Resveratrol suppresses tumor angiogenesis by blocking capillary-like tube formation induced by VEGF and also by intercepting the binding of VEGF to human umbilical vein endothelial cells [321]. Deguelin significantly reduces in vivo tumor angiogenesis and vascular tumor growth by interfering with several points in the angiogenic process, including inhibition of endothelial cell migration, invasion, and metalloprotease production and also inhibited HUVE cells' growth by inducing cell cycle arrest in the G0/G1 phase associated with induction of p21 and p53 and reduced survivin levels [341]. Deguelin anticancer activity in gastric, lung, and hepatocellular cancers also correlated with the inhibition of angiogenesis and induction of apoptosis [342–344]. Silibinin has been shown to strongly inhibit growth and survival of endothelial cells and inhibits VEGF- and IGF-1-induced cell proliferation and survival of endothelial cells [345]. Apigenin has been reported to inhibit hypoxia-induced or HIF-1α-mediated expression of VEGF in cancer cells [346]. Quercetin inhibits endothelial functions and in vivo angiogenesis induced by VEGF and inhibits tube formation by human microvascular dermal endothelial cells and HUVECs [347, 348]. Polyphenols of human interest need to be further analyzed in depth for their potential benefit in restricting neovascularization since blocking angiogenesis is a promising emerging therapeutic strategy to block or reverse tumor progression.

11 Polyphenols and MicroRNA

MicroRNAs (miRNAs) are a class of endogenous small noncoding RNA molecules of 20–25 nucleotides in length cleaved from ~70 to 100 nucleotide hairpin pre-miRNA precursors [349]. Emerging evidence reveals pivotal role of miRNAs in a wide array of biological processes including their role as regulatory molecules targeting multiple signaling pathways found dysregulated in cancer and affecting approximately 30 % of human genes. The mechanism underlying miRNA dysregulation in cancer is not fully understood, although several lines of evidence suggest the involvement of an epigenetic mechanism. The miRBase Version 16.0 has 1,048 miRNA sequences annotated in the human genome with likelihood of further additional miRNA to be validated in the future [350, 351]. miRNAs represent two opposing roles – it can behave either as oncogenes or tumor suppressors depending on tissue type and presence of specific targets [352]. Increasing evidence attests that overexpressed miRNAs may function as oncogene and promote cancer development by negatively regulating tumor suppressor genes and/or genes that control cell differentiation or apoptosis [353, 354]. Such concept evolved from studies reporting upregulation or downregulation of specific miRNAs in various types of cancer and identifying their molecular targets. A good example is let-7, which negatively regulates expression of Ras oncogenes, and its downregulation in tumors contributes to activation of Ras signaling pathway [355]. Recently, Parasramka and colleagues and other investigators evaluated miRNAs as target for cancer chemopreventive agents along with information relating to miRNA biogenesis and mechanistic insight on epigenetic modifications in context of cancer [353, 356]. In the following sections, we present a broad overview with few representative examples of miRNAs as targets for action of polyphenols. Despite many of the published studies being descriptive, there exists much optimism in scientific community for future development of miRNA for use in therapy. Li et al. from our laboratory examined and reported genistein treatment upregulated miR-146a in pancreatic cancer cells subsequently, consequently impacting their invasive potential by downregulating EGFR, NF-κB, IRAK, and MTA-2 [357]. Further, in isogenic pancreatic cancer cells, isoflavone treatment led to upregulation of miRNAs belonging to miR-200 and let-7 families that were downregulated in gemcitabine-resistant cell lines relative to sensitive cell lines amending EMT-related transcription factors such vimentin, slug, and ZEB1 [354]. In human uveal melanoma cells (C918), genistein downregulated the expression of miR-27a in vitro and reduction in the size of xenografted tumors parallel with upregulation of its target tumor suppressor gene, *ZBTB10* [358]. The effect of EGCG treatment in altering the microRNA expression has been described in human hepatocellular carcinoma (HepG2), breast (MCF-7), and in lung cancer cells. In HepG2 cells, miR-16 which targets the anti-apoptotic Bcl-2 protein becomes upregulated by EGCG [359]. In MCF-7 cells, Polyphenon-60 treatment resulted in alterations of 23 miRNAs including downregulation of *miR*-21 and *miR*-27 which is generally overexpressed in these cells, with *miR*-21 being associated with downregulation of a tumor suppressor gene [360]. Resveratrol reportedly impairs several signature miRNAs in colon, lung, and prostate cancer cells with miR-21, miR-155, and miR-663 being recognized as the major miRNAs modulated by resveratrol with their targets linked to apoptosis induction and inhibition of cell proliferation and cell cycle regulation. MicroRNAs as promising molecular target for curcumin, and its synthetic analog with improved bioavailability (CDF, difluorinated curcumin), have been reported by us in pancreatic cancer cells and other investigators [361–363]. In a multidrug-resistant lung cancer cell line (A549/DDP), 342 miRNAs mainly targeting various oncogenic and tumor suppressors were altered (>2.5 fold) by curcumin treatment [363]. In pancreatic cancer, miRNA-199a, an oncogenic miRNA, was significantly decreased after curcumin treatment [361]. CDF in combination with gemcitabine attenuated the expression of miR-21 and miR-200 in tumor tissue and in parallel leads to the induction of tumor suppressor gene *phosphatase and tensin homologue* (*PTEN*) [362]. We recently reviewed the role of miRNAs in the regulation of cancer stem cell (CSC) phenotype and function during tumor development and progression and the potential role of naturally occurring agents believed to function by targeting CSC-related miRNAs [364].

12 Polyphenol and Cancer Chemoprevention

According to the American Cancer Society estimate, out of 1,638,910 numbers of new cancer cases diagnosed in the year 2012, a total of 577,190 deaths have been projected to occur in the United States in the current year [365]. Central to their mission and year 2015 goals, a 50 % reduction in age-adjusted cancer mortality rates and a 25 % reduction in age-adjusted cancer incidence rates along with a measurable improvement in the quality of life of all cancer survivors have been envisioned. Pertinent to the attainment of their goals in the foreseeable future, cancer prevention and early detection are deemed as promising strategy especially for people at high risk of cancer, and emerging evidence indicates polyphenol compounds strategically hold promise for cancer intervention. Based on accumulated information on their multitargeted mechanism of action, translational implications in preventing growth and metastasis of cancer are currently being actively investigated. Although the list is not complete, we report studies from literature highlighting the effect of few select polyphenol compounds – such as EGCG from tea, the flavonoids quercetin and genistein from onions and soya, curcumin in curry spice, flavanone silibinin from artichoke, and resveratrol from red grapes on some most common site-specific cancers in preclinical models of carcinogenesis.

12.1 Gastointestinal Cancers

The estimated new cases of gastrointestinal (GI) cancers in the USA in the current year are expected to be around 284,680, out of which 142,510 will succumb in the near future. Experimental studies reported over the past decade support the contention that bioactive polyphenol compounds show promise in inhibiting tumorigenesis in the digestive tract including esophagus, stomach, small intestine, and colon associated with increased apoptosis and reduced cell proliferation. The widely investigated model polyphenol compounds such as resveratrol, curcumin, silymarin, quercetin, and tea polyphenol(s) have been found effective in inhibiting colon tumorigenesis in Apc$^{Min/+}$ mouse model which are genetically predisposed to develop intestinal tumors as a result of mutation of the *APC* gene. As reported earlier, β-catenin plays an important role in the Wnt signaling that is most commonly dysregulated in colorectal cancer, and most polyphenol compounds exhibit efficacy in reducing the expression of β-catenin. EGCG added in drinking water (0.02–0.32 %, wt/vol) made accessible to Apc$^{Min/+}$ mice inhibited the development of small intestinal tumors along with inhibition of tumor multiplicity in a dose-dependent manner associated with increased expression of the signaling protein E-cadherin and decreased levels of nuclear *β*-catenin, c-Myc, phospho-Akt, and phospho extracellular signal-regulated kinase 1 and 2 (ERK1/2) [155]. Resveratrol administration through drinking water also inhibited intestinal tumorigenesis in Apc$^{Min/+}$ mouse model by about 70 % alongwith reduction in expression of genes that are directly involved in the progression or cell proliferation such as cyclin D1, D2 and DP-1 transcription factor and Y-box binding protein, and decrease in TGF-β levels [366]. Flavonone silibinin administered orally (750 mg silibinin/kg body weight) for 6 weeks decreased the total no of intestinal polyps by 55 % alongwith decrease in expression of signaling molecules such as beta-catenin, cyclin D1, c-Myc and phospho-glycogen synthase kinase-3β expression. Silibinin treatment was also effective in downregulating phospho-Akt, COX-2, iNOS, nitrotyrosine, and nitrite levels in polyps which are well-known precursors of intestinal/colon carcinogenesis [367]. Others have reported that silibinin inhibits DMH-induced colon carcinogenesis by modulating the Wnt/beta-catenin pathway and glutathione redox system [368]. In similar lines of development, the effect of Polyphenon E (PPE, a standardized green tea polyphenol preparation) made accessible through the diet (0.24 %) for 34 weeks on the development of azoxymethane (AOM)-induced adenocarcinoma in colon of rats revealed reduction in the incidence (57 % vs. 23 %) and multiplicity of adenocarcinoma, and adenoma was decreased by 80 % and 45 %, respectively [369]. Recently, Shimizu and colleagues demonstrated the inhibition of AOM-induced ACF formation in male C57BL/KsJ-db/db mice by EGCG (0.01 % and 0.1 % in drinking water) by suppressing the activities of the insulin-like growth factor (IGF)/IGF-1R axis [370]. Resveratrol also inhibits AOM and 1,2-dimethylhydrazine (DMH)-induced colon cancer in rats reducing the number of aberrant foci (ACF) by modulation in the expression pattern of p21 and Bax [371–373]. Other gastrointestinal-related site-specific effect of tea polyphenols includes diethylnitrosamine (DEN) and benzo[a]pyrene-induced forestomach cancer in A/J mice and N-methyl-N'-nitro-N-nitrosoguanidine (MNNG)-induced gastric cancer in rats [374]. Resveratrol has been reported to be effective in inhibiting N-nitrosomethylbenzylamine (NMBA)-induced esophageal tumor in rats [375], wherein upregulated expression of COX-2 and PGE-2 levels was all significantly lowered by resveratrol treatment [375]. Ellagic acid inhibited esophageal cancer incidence in rats (66.7 % vs. 100 % in controls) when administered following carcinogen–NMBA treatment [376].

12.2 Hepatocellular Cancer

Hepatocellular carcinoma (HCC) is the most common type of primary hepatic tumor, and the incidence of hepatocellular carcinoma is increasing in the United States and Western Europe [377]. Liver cirrhosis is acknowledged as a premalignant condition for developing HCC. Other risk factors include tobacco and alcohol consumption, aflatoxins, and sex hormones. Chemoprevention of liver cancer has been suggested as an alternative to current treatment modalities because of limited therapeutic advantage to present protocols of therapy. In line with this concept, the cancer-preventive effect of dietary polyphenols on liver cancer is supported by results from cell culture, animal, and clinical studies. In vitro cell culture studies show that polyphenols potently induce apoptotic cell death and cell cycle arrest in tumor cells but not in their normal cell counterparts. The major polyphenol of green tea – EGCG – was studied in C3H/HeNCrj mice spontaneously developing hepatoma. EGCG (0.1 % in drinking water) reduced the incidence of hepatoma-bearing mice from 83.3 (control) to 52.2 % and also reduced the average number of hepatomas per mouse from 1.83 (control) to 0.91 (0.1 % EGCG) at week 65. EGCG inhibited the growth and secretion of alpha-fetoprotein by human hepatoma-derived PLC/PRF/5 cells without decreasing their viability [378]. Preventive effects of EGCG on diethylnitrosamine-induced liver tumorigenesis in obese and diabetic C57BL/KsJ-db/db mice have been reported wherein EGCG prevented obesity-related liver tumorigenesis by inhibiting the IGF/IGF-1R axis leading to improvement in hyperinsulinemia and attenuating chronic inflammation [379]. According to author's speculation, EGCG may prove useful in the chemoprevention of liver tumorigenesis in obese individuals. In another study, the inhibitory effect of tea polyphenols in development of precancerous liver lesions in rats was deduced based on its inhibitory effect on GST-Pi overexpression, both at mRNA and protein levels [380]. It is believed that EGCG suppresses the growth of human hepatocellular carcinoma cells by inhibiting activation of the vascular endothelial growth factor–vascular endothelial growth factor receptor axis [381]. The efficacy of EGCG as monotherapy regimen and co-treatment with EGCG and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) in HCC cells and xenograft tumors revealed synergistic apoptosis-inducing effect by downregulation of Bcl-2 and Bcl-xL caused by inactivation of NF-kappaB, supporting the notion that EGCG treatment may be useful for improving the prognosis of HCCs [382].

The effect of resveratrol in chemoprevention and treatment of hepatocellular carcinoma has been compiled and presented by Bishayee et al. [383]. Dietary resveratrol has been shown to prevent DEN-initiated and phenobarbitone-promoted hepatocarcinogenesis in rats possibly through anti-inflammatory effects by suppressing elevated levels of HSP70, COX-2, and NF-κB [384]. These beneficial effects combined with an excellent safety profile encourage the development of resveratrol for chemoprevention and intervention of human HCC that remains a devastating disease. Dietary resveratrol (50 ppm) has shown to inhibit proliferation and metastasis of tumor cells subcutaneously implanted with an ascites hepatoma cell line, AH109A in Donryu rats [385]. Treatment of H22 hepatoma cell-bearing mice with resveratrol (15mg/kg b wt) inhibited the growth of transplantable liver cancer by ~49 % along with decrease in the expression of cyclin B1 and CDC2 proteins [386]. The efficacy of other natural chemopreventive polyphenol compounds in inhibiting HCC such as ellagic acid administered concurrently with chemical carcinogen, N-2-fluorenylacetamide (FAA), in male ACI/N rats has been recorded. Ellagic acid treatment led to 30 % decline in tumor incidence relative to untreated control group [387]. Another report indicates significant decline in gamma-glutamyl transpeptidase-positive foci induced by aflatoxin B1 (AFB1) following treatment with ellagic acid (0.005 %) [388]. Silymarin also reduced the number of liver tumor nodules induced with carcinogen NDEA in rats along with elevated antioxidant enzymes in nodules [389]. Flavonoid quercetin exerts preventive effect on hepatic cancer development in rats via significant decrease of oxidative stress and antioxidant activity relative to untreated controls with several cancer-induced features being clearly observed in carcinogen-treated control group [390].

12.3 Prostate Cancer

Prostate cancer is the most common malignancy occurring in men and accounts for 29 % of all cancer diagnosed in the year 2012 in North America. Although polyphenol compounds have been found to inhibit growth and promote apoptosis of cultured prostate cancer cells, the conclusion thus far from preclinical models of prostate cancer complements polyphenols for primary prevention and preventing the progression of prostate cancer development. In transgenic mouse model of prostate cancer (TRAMP mice), resveratrol in the diet significantly reduced the incidence of poorly differentiated prostatic adenocarcinoma (by 7.7-fold) [391]. Mechanistically, this was found associated with decline in cell proliferation and growth factor, IGF-1 levels, along with downregulation of downstream effectors, phospho-ERKs 1 and 2, and increase in putative tumor suppressor estrogen receptor-beta [391]. Resveratrol has also been reported to be effective in inhibiting growth of advanced human prostate cancer xenograft in nude mice and those induced by chemical carcinogen 3,2'-dimethyl-4-aminobiphenyl in male rats.

In experimental models of prostate cancer, dietary genistein inhibited metastasis of human prostate cancer in mice [310]. In TRAMP mice, lifelong exposure to dietary genistein suppressed the development of cancerous lesions by 50 % and advanced prostate cancer by 35 % [392]. It is currently believed that genistein consumption is associated with reduced risk of prostate cancer by modulating androgen-dependent transcription program within prostate [239].

Mukhtar et al. showed that administration of a green tea polyphenol infusion (0.1 % in drinking fluid) to transgenic adenocarcinoma of the mouse prostate (TRAMP mice) for 24 weeks markedly inhibited prostate cancer development and distant site metastases [393, 394]. Conceivably, the inhibition of VEGF, MMPs, and IGF-1 signaling pathways contributed to the cancer prevention activity of green tea polyphenols although it is not clear whether tea polyphenols inhibit prostate carcinogenesis by direct action of tea polyphenols in the prostate or by an indirect action, such as by affecting circulating serum IGF-1 levels or by affecting androgen levels [369]. It has been speculated that green tea catechins inhibit prostate tumor formation in the TRAMP model through sustenance in the levels of clusterin (a protein involved in apoptosis and downregulated in the prostate during cancer progression) [395].

Oral silibinin has been reported to block prostate cancer growth and progression at PIN (prostatic intraepithelial neoplasia) stage in TRAMP mice via modulation within tumor IGF–IGFBP-3 axis and cell cycle regulation, and therefore, it has practical and translational potential in suppressing growth and neoplastic conversion of PIN to prostate cancer in humans [396]. Additionally, suppression of advanced human prostate tumor growth in athymic mice by silibinin feeding has been reported associated with reduced cell proliferation, increased apoptosis, and inhibition of angiogenesis [397].

12.4 Lung Cancer

Lung cancer has been rated as the second most site-specific cancer in males and females and is expected to account for 26 % of all female and 29 % of all male cancer deaths [365]. Mesothelioma represents 1.5 % of these cases, and small cell lung cancer (SCLC) accounts for approximately 13 %, with non-small cell lung cancer (NSCLC) being the rest. The potential of phytoalexin resveratrol treatment to mice bearing highly metastatic Lewis lung carcinoma cells (LLC) revealed significant reduction in the tumor volume (42 %), tumor weight (44 %), and metastasis to lung (56 %) which may be due to the inhibition of DNA synthesis in LLC cells and through the inhibition of tumor-induced neovascularization by resveratrol [321]. The anti-metastatic potential of resveratrol has been validated in another study reporting reduction both in the number and the weight of the lung metastases [322]. The inhibitory effect of resveratrol on enzyme-heme oxygenase-1 (HO-1) which is involved in angiogenesis and HO-1-mediated inhibition of MMP-9 and MMP-2 expression may account for the anti-invasive mechanism of resveratrol in lung cancer [323]. Matrix metalloproteinases (MMPs) are key enzymes in the degradation of extracellular matrix, and their expression is dysregulated in lung cancer metastasis. The chemopreventive potential of curcumin and resveratrol during promotional phase of benzo[a]pyrene (B[a]P)-induced lung carcinogenesis has been portrayed by Malhotra and colleagues. Although treatment with resveratrol and curcumin given separately to B[a]P-treated mice showed appreciable improvement in the histoarchitecture of the lung with improved antioxidant parameters, combined treatment resulted in a significant improvement in lipid peroxide and reduced glutathione levels, as well as in the activities of SOD along with noticeable improvement in the lung histoarchitecture [398].

Another commonly occurring polyphenol compound – ellagic acid – shows efficacy in the prevention of lung tumors induced by benzo[a]pyrene and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK)-induced pulmonary adenoma formation. In N-nitrosodimethylamine (NDMA)-induced model of lung cancer, ellagic acid treatment reduced the incidence of lung tumors to 20 % from the control value of 72 % concomitantly with increased level of antioxidant glutathione in the lungs of mice [399]. The effect of other classes of polyphenol compounds with reference to chemoprevention and therapy of lung cancer has been investigated. Quantification of micro-CT data in real time revealed that silibinin significantly decreases urethane-induced tumor number and size in B6/129 wild-type mice through inhibition of iNOS expression in lung [400]. Another study reported urethane-injected mice exposed to silibinin had statistically significantly low lung tumor multiplicity and reduced lung tumor expression of vascular endothelial growth factor (VEGF) and the two enzymes, inducible nitric oxide synthase and cyclooxygenase-2, that promote lung tumor growth and progression by inducing VEGF expression [401]. Oral silibinin repressed human non-small cell lung carcinoma A549 xenograft growth and enhanced the therapeutic response of doxorubicin in athymic BALB/c nu/nu mice with strong protective efficacy against doxorubicin-mediated adverse health effects.

A spectrum of chemoprotective effect of tea preparations (including green tea, black tea, EGCG, and theaflavins) in the inhibition of initiation, promotion, and progression stages of NKK-induced lung tumorigenesis in rat, mice, and hamsters has been reported [369]. Additionally, in metastasis model, oral administration of green tea infusion reduced the number of colonies of Lewis lung carcinoma cells in lung [402]. It has been recorded that administration of GTP prior to challenge with carcinogen B[a]P significantly reduces internal body tumor incidence in susceptible A/J mice [403]. The inhibitory effect of a standardized green tea polyphenol preparation containing 65 % (−)-epigallocatechin-3-gallate (Polyphenon E) administered through drinking fluid at 0.5 % concentration on NKK-induced lung tumor in A/J mice revealed an inhibition in the progression of lung adenomas to adenocarcinoma and reduced the lung tumor incidence by 52 % and tumor multiplicity by 63 % in tumor-bearing mice [404]. These favorable and protective changes at the cellular level were reflected by alterations such as increased apoptosis and alterations in the levels of c-Jun and extracellular signal-regulated kinase (ERK1/2) phosphorylation [404]. Additionally, black tea polyphenols have also been reported to be effective in inhibiting the pathogenesis of carcinogen (NKK and B[a]P)-induced lung cancer in mice despite the fact that bioavailability of GTP is higher than the high-MW polyphenols in black tea [405–407].

12.5 Breast Cancer

Studies reported in literature show inverse correlation between high intake of total dietary polyphenol and the incidence of breast cancer proclaiming cost-effective approach to control incidence of breast cancer. We earlier reported that resveratrol inhibits the tumor burden and multiplicity of 7,12-dimethylbenz(a)anthracene (DMBA)-induced mammary tumors in Sprague Dawley rats [408]. Resveratrol also reduced N-methyl-N-nitrosourea-induced breast tumors in rats [409]. It has been reported that combination of polyphenols (resveratrol, quercetin, or catechin) at physiologically relevant concentrations is more effective than individual compounds in inhibiting ERα(−), ERβ(+) MDA-MB-231 breast cancer cell proliferation, cell cycle progression, and primary mammary tumor growth [410]. Additionally, it has been shown by the same research group that combined dietary grape polyphenols are effective in inhibiting not only mammary tumor growth but also site-specific metastasis especially to the liver and bone [411]. As a single agent in xenograft mouse model, resveratrol treatment culminated in a significantly lower tumor growth, decreased angiogenesis, and increased apoptotic index in ERα(−), ERβ(+) MDA-MB-231 tumors [412]. In HER-2/neu transgenic mice, resveratrol supplementation delayed the development of tumors and reduced the mean number, size, and metastasizing capacity of spontaneously developing tumors, an effect that was associated with downregulation of HER-2/neu expression and apoptosis within mammary tumors of these mice [413]. The flavonoid biochanin A (BCA) inhibits the growth of human breast cancer cells (MCF-7) in a murine xenograft animal model and is considered as a breast cancer-preventive agent [414]. The critical role of isoflavone genistein in inhibiting breast cancer has been thoroughly reviewed and presented [415–417]. The timing of exposure to genistein appears critical for its mammary protective effects. It has been reported that genistein early in life causes enhanced mammary gland differentiation, alterations in cell proliferation and apoptosis, and upregulation of tumor suppressor genes [418]. Neonatal administration of genistein had a protective effect against the subsequent development of mammary cancer induced by DMBA in Sprague Dawley rats [419]. Flavonolignan silibinin with chemopreventive activity in preclinical models of prostate and colorectal cancer failed to show similar effect on tumor development when tested in the C3(1) SV40 T,t antigen transgenic multiple mammary adenocarcinoma mouse model [420]. However, the effect of treatment with a complex of silibinin and phosphatidylcholine (IdB 1016) on the development of spontaneous mammary tumors was seen delayed in HER-2/neu transgenic mice along with reduction in the size and number of primary tumor masses and diminished lung metastases in these mice [421].

Ellagic acid inhibits 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP)-induced mammary cancer in female F344 rats [422, 423]. The effect of tea catechins on the progression or late promotion stage of mammary gland carcinogenesis is not robust due to low bioavailability of tea polyphenols in the mammary tissues. Intriguingly, black tea was found to reduce the tumor number and size in rats that were high on high-fat diets; it is thought that black tea affects tumorigenesis indirectly by affecting fat absorption and metabolism, which may subsequently influence estrogen metabolism and mammary tumorigenesis [369, 424].

12.6 Oral Cancer

Several experimental studies reported till date document the efficacy of polyphenol compounds in inhibiting chemical carcinogen-induced oral cancer. Studies reported in literature reveal naturally occurring plant phenolics such as caffeic, ellagic, chlorogenic, and ferulic acid(s) modestly influence the spectrum of pathological changes occurring within squamous epithelium concurrently with reduction in tumor incidence during in 4-nitroquinoline 1-oxide (4-NQO)-induced tongue carcinogenesis in rats [425]. Silymarin treatment during stages of tumor induction decreased the polyamine content and prostaglandin levels in tongue mucosa [426]. The modulatory efficacy of green tea polyphenols on 4-NQO-induced oral carcinogenesis showed a significant increase in the levels of expression of glycoconjugates (hexose, hexosamine, sialic acid, fucose) similar to that observed for immunological markers culminating in regression of oral cancer [427]. The antimutagenic effects of green tea catechins, (-)-epicatechin gallate (ECG), and EGCG on induction of 6-thioguanine (6TG)-resistant mutations induced by 4-NQO were observed only when these cells were post-treated with catechins during the mutation expression time after treatment with 4-NQO; this is suggestive that catechins may act intracellularly as antimutagenic blocking agent or suppressive agent. In preclinical model, EGCG efficiently inhibited phorbol-12-myristate-13-acetate (PMA)-induced cell invasion and MMP-9 expression, corroborating inhibition of growth of SCC-9 cell xenograft tumors in nude mice model [428]. According to the authors, the results hold promise that EGCG could reduce invasion and cell growth of tumor cells, and such a characteristic may be of great value in developing a potential cancer therapy. Resveratrol or a combination of resveratrol and quercetin, in concentrations equivalent to that present in red wines, is an effective inhibitor of oral squamous carcinoma cell (SCC-25) growth and proliferation [429]. Further, the effect of tea polyphenol constituents on growth of oral squamous carcinoma cells in vitro revealed a significant dose-dependent inhibition in cell growth including dose-dependent changes in cell morphology [430].

12.7 Bladder Cancer

Bladder cancer is another important health problem, and according to current estimate this ranks as the fourth most commonly diagnosed malignancy in males accounting 7 % of all cancer diagnosed at different sites [365]. Transitional cell carcinoma is the most common prevalent histological type of bladder cancer in Western population. From literature preview, one concludes that some classes of investigated polyphenols show promise in inhibiting bladder cancer. Studies reported thus far show that silymarin inhibits bladder cancer induced by tobacco smoke carcinogen N-butyl-N-(4-hydroxybutyl) nitrosamine in ICR mice [431]. In another study, green tea polyphenol (Polyphenon E) was evaluated for chemoprotective efficacy against 4-hydroxy butyl(butyl)nitrosamine-induced bladder cancer. Administration of Polyphenon E to rats caused dose-dependent decrease in palpable urinary bladder cancer relative to control group of animals [432]. The effect of several soy components including genistein and isoflavone-rich soy phytochemical concentrate (SPC) on growth and metastasis in clinically relevant model of orthotopic bladder cancer and subcutaneously growing tumors in mice resulted in the induction of tumor cell to undergo apoptosis along with inhibition of tumor angiogenesis [433]. Furthermore, SPC, but not genistein, significantly inhibited lung metastasis in this model, in part, by its effect on modulating the expression of NF-κB and IGF-1 [433].

Overall, these information support interest of dietary natural polyphenol in chemoprevention of important site-specific cancers which can be exploited further in sensitizing therapy to anticancer agents as discussed in the following sections.

13 Polyphenols and Chemosensitization of Cancer Therapy

Overwhelming evidence from numerous preclinical studies and clinical trials provides increasing evidence that some polyphenol has more benefit in clinical therapy of cancer than chemotherapy alone, rendering this class of phytocompounds highly attractive for therapeutic interventions. The majority of patients diagnosed with cancers receive chemotherapy and or radiotherapy under multimodal treatment protocol. Unfortunately, findings from many clinical studies reveal the emergence of drug-resistant phenotypes. Reversal of such resistance, whether intrinsic or drug induced, is critical for the success of cancer treatment. Even though association has been found between diet and cancer risk, polyphenols have not been established as a direct cause or cure for cancer. From foregoing myriad of biological responses due to pleiotropic effect of polyphenol compounds on cellular and molecular events, a rationale for combining polyphenol compounds with conventional therapeutics can be expected to have higher efficacy because of inactivation of survival signaling and simultaneous activation of multiple death pathways. Conceptually, this may sensitize tumor cells to therapeutics. Furthermore, clinical studies suggest that a common form of multidrug resistance (MDR) in human cancers results from the expression of the MDR1 gene that encodes P-glycoprotein (P-gp), a member of

ABC transporter family that has been described for drug resistance and low bioavailability of drugs by pumping drugs out of the cells at the cost of ATP hydrolysis [434]. Various P-gp inhibitors have been synthesized and studied extensively to reverse MDR. Of interest, a few select polyphenol compounds have shown to intensify action of chemotherapeutic drugs by suppressing the MDR phenomenon [435–439]. Studies reported thus far combining polyphenol compounds with cytotoxic anticancer therapies augmenting chemosensitization in a variety of preclinical murine model of human cancers reinforce biological basis towards underlying potential therapeutic application of polyphenols. This concept has been summarized in the following description exemplifying polyphenol phytochemicals such as EGCG, genistein, curcumin, resveratrol, quercetin, and silibinin. These compounds beside dietary component exhibit notable efficacy in preclinical models of carcinogenesis.

We reported that isoflavone genistein potentiated growth inhibition and apoptotic cell death caused by cisplatin, erlotinib, docetaxel, doxorubicin, gemcitabine, and CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) in cancers of prostate, breast, pancreas, lung, and lymphoma [122, 123, 127, 440–442]. We have also found that dietary genistein in vivo could enhance the antitumor activities of gemcitabine, cisplatin, oxaliplatin, and docetaxel in a tumor model, resulting in apoptotic cell death and the inhibition of tumor growth [121, 124, 126, 312]. Similar observations have been reported by other investigators showing that the antitumor effects of chemotherapeutics, including 5-fluorouracil (5-FU), adriamycin, cytosine arabinoside, tamoxifen, and perifosine, could be potentiated by genistein [176, 443–447]. Genistein enhanced the antitumor effect of bleomycin in HL-60 cells, but not in normal lymphocytes in an in vitro study [448]. The synergistic action of genistein and cisplatin or carmustine (BCNU) on the growth inhibition of glioblastoma and medulloblastoma cells has also been observed [449]. In ovarian cancer, genistein potentiated the antiproliferative and proapoptotic effect of antibodies directed against the cell adhesion molecule L1-CAM [450]. Furthermore, despite limitations in the cytotoxic effect of the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL/Apo2L) in gastric and pancreatic adenocarcinoma cell lines, subtoxic concentrations of genistein sensitized these TRAIL-resistant cells to TRAIL/Apo2L-mediated apoptosis [451, 452]. In radiotherapy, experimental studies from Dr. Hillman's laboratory have demonstrated that the combination of genistein and radiation exerts enhanced inhibitory effects on tumor growth and progression of renal cell carcinoma and prostate tumor in orthotopic models [453, 454]. Genistein also enhanced radiosensitivity in human esophageal and cervical cancer cells, suggesting the beneficial effects of genistein in cancer radiotherapy [174, 175].

Studies have viewed resveratrol could be potentially useful in chemosensitization when used in combination with a variety of anticancer drug treatment mainly due to its effect on apoptosis augmenting therapeutic efficacy. Combination of resveratrol with platinum drugs, cisplatin and oxaliplatin, has been reported to sensitize the ovarian cancer cells to platinum-induced apoptosis providing a mode of overcoming drug resistance [455]. In another study resveratrol has been found to augment the growth inhibitory effects of cisplatin and doxorubicin on human ovarian (OVCAR-3) and uterine (Ishikawa) cancer cells diminishing cardiac toxicity of doxorubicin [456]. Significant antitumor synergistic cytotoxicity by combination of resveratrol with dexamethasone, fludarabine, and bortezomib in Waldenström macroglobulinemia (a rare, slow-growing non-Hodgkin lymphoma) has been reported [457]. Furthermore, in drug-sensitive promyelocytic leukemia HL-60 cell line and its multidrug-resistant variant HL-60/VCR (P-gp positive), resveratrol exhibited proapoptotic activity when combined with multiple anticancer drugs – doxorubicin, cycloheximide, busulfan, gemcitabine, and paclitaxel – resulting in enhancement of the combination therapy [458]. The antitumor effect of combination of resveratrol with 5-fluorouracil (5-FU) on transplantable murine hepatoma 22 model has been reported with inhibition up to 77 % in combination treatment group compared to 53 % in 5-FU alone antagonizing its toxicity markedly [459]. Furthermore, in pancreatic cancer, the potential of resveratrol regarding therapeutic efficacy was recapitulated in a relevant preclinical orthotopic model wherein the response outcome between only gemcitabine treatment versus resveratrol plus gemcitabine was significantly greater compared to monotherapy [460]. Resveratrol sensitizes human melanoma cells that were sensitive or resistant to temozolomide and to paclitaxel in lung cancer cells [461, 462]. Additionally, resveratrol sensitizes leukemic cells to proteasome inhibitors via regulation of FOXO1 transcriptional activity and accumulation of $p27^{KIP1}$ and protects against cisplatin-induced cardiotoxicity by alleviating oxidative damage [463, 464]. In ER positive breast cancer explants, the efficacy of combination of cyclophosphamide and resveratrol revealed enhanced antiproliferative actions along with differential expression of cell cycle, apoptosis, and stress factors encouraging clinical trial of the regimen in the future [465].

The chemosensitizing effect of green tea and its constituents has been reported both in vivo and in vitro. EGCG, the most potent constituent among catechins present in green tea, downregulates P-gp and BCRP in a tamoxifen-resistant MCF-7 cell line and induced apoptosis and growth inhibition when combined with tamoxifen in human breast cancer MDA-MB-231cells [466, 467]. Furthermore, in a murine model of breast cancer, EGCG synergistically sensitized the tumor cells to paclitaxel by diminishing the expression of endoplasmic reticulum chaperone GRP78 (*g*lucose-*r*egulated *p*rotein *78*) augmenting apoptosis [468]. EGCG reversed doxorubicin resistance in solid human carcinoma xenograft model [469]. In orthotopic mouse glioblastoma models, EGCG significantly enhanced therapeutic efficacy of temozolomide by lessening expression of GRP78 known to be responsible for chemoresistance to temozolomide [470]. Additionally, sensitization of glioma cells to cisplatin and tamoxifen by tea catechin has been reported to be associated with decreased expression of telomerase improving drug sensitivity [471, 472]. In human prostate cancer, EGCG sensitizes carcinoma cells to TRAIL-mediated apoptosis and synergistically inhibits the biomarkers associated with angiogenesis and metastasis such as VEGF, uPA, angiopontin, and MMPs [231, 472]. Stearns et al. reported that combination therapy of EGCG and doxorubicin inhibits prostate tumor metastasis and tumor growth in SCID mice [473]. In an in vivo mouse model for chemoresistant liver cancer, green tea catechin, EGCG, augmented the antitumor activity of doxorubicin by markedly enhancing the intracellular accumulation of doxorubicin along with downregulation of MDR1 and HIF-1α expression [439]. In a mouse model of human melanoma, EGCG sensitizes melanoma cells to interferon-induced growth inhibition with increase in Fas protein levels and decrease in NF-κB [474]. A synergistic inhibitory action of a combination of Polyphenon E with the cholesterol-lowering agent, atorvastatin, against NNK-induced lung cancer in A/J mice resulting from downregulation of anti-apoptotic protein (Mcl-1 and Bcl-xL) has been reported [475]. The synergistic growth inhibitory effect of EGCG and erlotinib in cell culture and nude mouse xenograft model of squamous cell carcinoma of head and neck suggests that erlotinib treatment activates the tumor suppressor protein p53, which dictates synergistic growth inhibition outcome by inhibiting NF-κB signaling pathway [476]. A comparative study evaluating the efficacy of mitomycin C and polyphenolic catechins (Polyphenon E®) in rat bladder tumor model revealed similar efficacy of both substances in preventing intravesical tumor growth [477].

A comprehensive review by Raina et al. on the efficacy and mechanisms of combinatorial strategies for cancer eradication by silibinin and cytotoxic agents has been published [478]. Silibinin restored paclitaxel sensitivity to paclitaxel-resistant human ovarian carcinoma cells [479]. Quercetin greatly improved therapeutic index of doxorubicin against breast cancer by its opposing effects on HIF-1alpha in tumor and normal cell, and combining intratumoral doxorubicin injection and quercetin synergistically induced rejection of established breast cancer in mice [480, 481]. In human leukemia, colon, prostate, hepatoma, and non-small cell lung cancer cell lines, quercetin enhanced TRAIL-mediated apoptosis [293, 294, 482–484]. Curcumin has been shown to inhibit the growth of cancer cells in vitro with strong anticancer outcome in animal models of carcinogenesis. The reported benefit of curcumin in combination with taxane chemotherapy for hormone refractory prostate cancer (HRPC) treatment suggests that curcumin in combination with taxane could be useful in HRPC patients. Curcumin also sensitizes TRAIL-resistant xenografts of human prostate tumor cells, suggesting that combination of curcumin and TRAIL could be useful for the prevention and treatment of human prostate cancer [485]. In lung cancer, the synergistic effect of curcumin and cisplatin via downregulation of thymidine phosphorylase and excision repair cross-complementary 1 (ERCC1) protein levels has been reported [195]. Sreekanth et al. reported that liposomal curcumin augments the anticancer therapy of paclitaxel in experimental mouse model of cervical cancer by downregulating anti-apoptotic factors and survival signaling molecules such as NF-κB, Akt, and MAPK that play key roles in cell proliferation, survival, angiogenesis, and metastasis [196]. The effect of curcumin on multidrug resistance-associated protein 5 (MRP5) in pancreatic cancer sensitized these tumor cells to the cytotoxic effects of 5-fluorouracil and gemcitabine [486]. Combination of curcumin and chemotherapeutics as a novel strategy for the treatment of breast and colon cancer has been reported by us and others [125, 487]. Several clinical trials using curcumin in combination treatment are being conducted to test the effects and toxicity of the combination in patients with multiple myeloma, rectal, colon, and pancreatic cancers.

From preceding account, it thus becomes clear that chemopreventive polyphenol compounds as efficient multitargeted agents could be considered for the design of anticancer therapy. Preclinical studies reported till date supports their inclusion to achieve favorable increase in the efficacy of chemotherapeutic index.

14 Clinical Trials for Cancer Therapies by Polyphenols

Based on information available at http//www.clinicaltrials.gov several clinical trials are under way which mirror the clinical usefulness of individual class of polyphenols in cancer patients (Table 71.1). Much of these ongoing trials or yet to open for participant recruitment relating to polyphenols are focused on investigating the effects of genistein, isoflavone, EGCG, resveratrol, curcumin, and silibinin. We believe that in the future these compounds will prove valuable in combination with conventional therapeutics or together with radiation therapy for the treatment of human malignancies. Thomasset et al. reviewed and published results of pilot studies and trials, in which either healthy individuals or patients with premalignant conditions or cancer received polyphenol compounds from the viewpoint of chemoprevention-related rationale. Their conclusion based on collected evidences surmises that tea polyphenols should tentatively move forward into phase III clinical intervention trials, while in the case of curcumin and soya isoflavones more studies in premalignant conditions are warranted [6]. Later a prospective study ($n = 383$) found that plasma genistein levels inversely correlate with subsequent incidence of breast cancer in both pre- and postmenopausal Dutch women supporting the hypothesis that high isoflavone and, in particular, genistein intake may be associated with reduced breast cancer risk [488]. Additional, meta-analysis of 18 published epidemiological studies supports the hypothesis that soy isoflavones may reduce breast cancer risk.

The beneficial effects of isoflavone on early stage prostate cancer draw closer from a clinical trial demonstrating that supplementing early stage prostate cancer patients with soy isoflavones alters surrogate markers of proliferation such as serum prostate-specific antigen (PSA) and free testosterone in large number of subjects than the group receiving placebo [489]. Currently, a clinical trial is being conducted using AXP107-11 (a crystalline form of genistein) in combination with gemcitabine in patients with locally advanced or metastatic, unresectable adenocarcinoma of the pancreas (stage III–IV) (NCT01182246; Table 71.1). Phenoxodiol™ one of the isoflavone analogs (derived from equol) has shown a broad-spectrum anticancer effect [472, 490]. In phase I trial, phenoxodiol delivered by intravenous infusion continuously for 7 days every 2 weeks in cohort of patients with solid tumors was well tolerated up to a dose of 27mg/kg/day [491]. Another phase I and pharmacokinetic study involving either repeated weekly infusions of phenoxodiol administered over 1–2 h or as single bolus intravenous dose in patients with advanced cancer with no treatment-related death has been reported [472, 492]. Phenoxodiol is

Table 71.1 Current ongoing clinical trials

Genistein/isoflavone	
NCT01028001	Phase II trial of preoperative soy isoflavone supplementation and molecular markers in the prevention of head and neck squamous carcinoma
NCT01036321	Phase II clinical trial of purified isoflavones in prostate cancer: comparing safety, effectiveness, and mechanism of action between African, American and Caucasian men
NCT01174953	High-risk prostate cancer prevention study
NCT01126879	Phase 2 trial of genistein in men with circulating prostate cancer cells
NCT00499408	Phase II trial of vitamin D and soy supplementation for biochemically recurrent prostate cancer following definitive local therapy
NCT01489813	Phase II randomized placebo-controlled clinical trial of genistein in reducing the toxicity and improving the efficacy of intravesical therapy
NCT01538316	Clinical trial on the effectiveness of the flavonoids genistein and quercetin in men with rising prostate-specific antigen
NCT01325311	Phase IIa, randomized placebo-controlled trial of single high-dose cholecalciferol and daily genistein (G2535) versus placebo in men with early stage prostate cancer undergoing prostatectomy
NCT01182246	Safety, pharmacokinetics, and efficacy of AXP107-11 in combination with standard gemcitabine (Gemzar®) treatment in patients with locally advanced or metastatic, unresectable adenocarcinoma of the pancreas, stage III–IV: a prospective, open-label, multicenter, sequential phase Ib/IIa study (the drug substance, AXP107-11, is a crystalline form of genistein)
Green tea/EGCG	
NCT01317953	Phase study of oral green tea extract as maintenance therapy for extensive-stage small cell lung cancer
[a]NCT01589887	Clinical and biologic evaluation of Polyphenon E, an extract of green tea containing EGCG, in plasma cell dyscrasias – pilot study
[a]NCT00942422	The clinical and biologic evaluation of Polyphenon E, an extract of green tea containing EGCG, in plasma cell dyscrasias – pilot study
[a]NCT00262743	A phase I/II study of daily oral Polyphenon E in asymptomatic, Rai stage 0–II patients with chronic lymphocytic leukemia
NCT00917735	Phase II, randomized, double-blind, placebo-controlled study of the efficacy of green tea extract on biomarkers of breast cancer risk in high-risk women with differing catechol-O-methyltransferase (COMT) genotypes
NCT01060345	A pilot study of chemoprevention of green tea in women with ductal carcinoma in situ (DCIS)
[a]NCT00676793	Phase II clinical trial to determine if Polyphenon E inhibits c-Met signaling and activation of pathways contributing to breast cancer progression
[a]NCT00516243	Phase IB randomized, double-blinded, placebo-controlled, dose escalation study of Polyphenon E in women with a history of hormone receptor-negative breast cancer
NCT01360320	Minimizing the risk of metachronous adenomas of the colorectum with green tea extract MIRACLE
NCT00596011	Phase II, randomized, double-blind, multicentered study of Polyphenon E in men with high-grade prostatic intraepithelial neoplasia (HGPIN) or atypical small acinar proliferation (ASAP)
[a]NCT00233935	Phase IB randomized, double-blinded, placebo-controlled, dose escalation study of Polyphenon E in patients with Barrett's esophagus

(*continued*)

Table 71.1 (continued)

[a]NCT01606124	Randomized phase II trial of Polyphenon E versus placebo in patients at high risk of recurrent colonic neoplasia
NCT01116336	Phase I chemoprevention study with green tea and erlotinib in patients with premalignant lesions of the head and neck
NCT01032031	The effect of dietary bioactive compounds on skin health in humans in vivo
Curcumin	
NCT01160302	An exploratory biomarker trial of the food substances curcumin C3 Complex® in subjects with newly diagnosed head and neck squamous cell carcinoma
NCT01294072	Phase I clinical trial investigating the ability of plant exosomes to deliver curcumin to normal and malignant colon tissue
NCT00927485	Use of curcumin for treatment of intestinal adenomas in familia adenomatous polyposis (FAP)
NCT00641147	Curcumin for treatment of intestinal adenomas in familial adenomatous polyposis (FAP)
NCT00689195	Evaluation of curcumin formulation and Ashwagandha root powder extract in the management of advanced high-grade osteosarcoma
[a]NCT00969085	Phase II trial of curcumin in cutaneous T-cell lymphoma patients
[a]NCT01490996	A phase I/IIa study combining curcumin (Curcumin C3-Complex, Sabinsa) with standard care FOLFOX chemotherapy in patients with inoperable colorectal cancer
[a]NCT01238198	Oral curcumin for radiation dermatitis in breast cancer patients
[a]NCT01608139	Pilot study of curcumin, vorinostat, and sorafenib in patients with advanced solid tumors
[a]NCT01219673	A study of reducing the symptom burden produced by chemoradiation treatment for head and neck cancer
[a]NCT01269203	A phase II randomized study of the efficacy of curcumin for reducing symptoms during maintenance therapy in multiple myeloma patients
Resveratrol	
NCT01476592	A biological study of resveratrol's effects on Notch-1 signaling in subjects with low-grade gastrointestinal tumors
NCT01489319	Evaluation of the ovarian dynamic response and the inflammatory response to oral lipid challenge in relation to body composition in polycystic ovary syndrome
Silibinin	
[a]NCT01129570	Phase I trial of Siliphos in patients with advanced hepatocellular carcinoma

[a] Study is not yet open for participant recruitment

currently undergoing in phase II/III clinical trials to investigate its effect combined with docetaxel in patients diagnosed with ovarian, fallopian tube, or primary peritoneal cavity tumors (NCT003038880). Phase II results on safety and efficacy of intravenous phenoxodiol in combination with cisplatin or paclitaxel in women with platinum/taxane-refractory/resistant epithelial ovarian, fallopian tube, or primary peritoneal cancers have recently being published [493].

Pilot clinical studies relating to administering EGCG at dose of 800 mg/day to healthy individuals were reportedly well tolerated with minimal toxicity ($\leq$ grade I) [494]. Subsequent studies revealed that EGCG delivered in the form of capsule

(200 mg p.o. for 12 weeks) was effective in patients with human papillomavirus-infected cervical lesions [495]. A 1-year "proof-of-principle" study by Bettuzzi et al. in volunteers with high-grade PIN suggested that green tea polyphenol may reverse or delay prostate carcinogenesis [496]. Later, a follow-up update by Brausi et al. confirmed the benefit of green tea intake is limited only in precancerous stage of the disease and those with high-grade prostatic intraepithelial neoplasia (HGPIN) on biopsy, but in studies involving men with more advanced prostate cancer, green tea consumption did not show benefits, confirming the conclusion from mouse prostate cancer model that the effect of green tea polyphenol decreases with advancing age [497].

Polyphenon E, a highly characterized green tea extract standardized to EGCG and other green tea polyphenols received IND (*i*nvestigational *n*ew *d*rug) status and is currently undergoing pilot trials for plasma cell dyscrasias (NCT01589997; NCT00942422) and in men with HGPIN or atypical small acinar proliferation (ASAP) (NCT00596011). The results of a randomized, double-blind, placebo-controlled trial of Polyphenon E in prostate cancer patients before prostatectomy have recently been reported [498]. The primary aim of this study was to determine the bioavailability of green tea polyphenols in prostatic tissue with secondary end points being measurement of modulation of systemic and tissue biomarkers related to prostate carcinogenesis. Phase I and II clinical trial of Polyphenon E in patients with asymptomatic Rai stage 0 to II chronic lymphocytic leukemia revealed that chronic daily oral administration of the preparation is well tolerated with signs of clinical activity accompanied by reduction in absolute lymphocyte count (ALC) and/or lymphadenopathy in majority of the patients [499, 500]. Recently, a phase III clinical trial is being conducted using combination of EGCG and erlotinib to chemoprevent head and neck cancer with premalignant lesion (NCT 01116336).

Clinical trial using formulated resveratrol SRT501 combined with bortezomib in patients with multiple myeloma has to be terminated because of the failure of kidney function. Nonetheless, one currently ongoing clinical trial relates to biological study of resveratrol effect on Notch-1 signaling in subjects with low-grade gastrointestinal tumors (NCT01476592). Polyphenol curcumin has a wide margin of safety. Table 71.1 summarizes the ongoing clinical trials of curcumin in cancer of different sites and origin. However, pharmacokinetics and bioavailability studies of curcumin revealed its poor absorption and rapid elimination from the body. A study that investigated the safety and feasibility of combination therapy using curcumin and gemcitabine treatment in pancreatic cancer patients revealed no dose-limiting toxicities in the phase I study and recommended a dose for oral curcumin as 8 g/day for phase II study [501]. Further investigation into efficacy of treatment outcome using this recommended dose in pancreatic cancer patients is awaited. Siliphos (main component being silibinin) is being tested for intervention in advanced hepatocellular carcinoma (NCT01129570).

From above discussion, it is obvious that including polyphenol compound or its derivates either as monotherapy or in combination may synergize the efficacy of current therapy supporting further therapeutic interest of using polyphenol or its derivatives in clinical application.

15 Prologue on Select Polyphenol Compounds from Natural Dietary Sources

15.1 Genistein

Genistein (4,5,7-trihydroxyisoflavone) is the predominant isoflavone in soybean-enriched foods and related products such as tofu and soy drinks. Its consumption in Asian countries varies between 20 and 80 mg/day, whereas it is only 1–3 mg/day in the USA [502]. The soy isoflavone genistein has been well studied and is found to inhibit cancer cell growth in vivo and in vitro. It has multiple molecular targets including various receptor, enzymes, and pathway interactions affecting cell growth by inducing apoptosis and reduces invasiveness by downregulation of matrix metalloproteinase expression [94, 239, 415]. Genistein is also a tyrosine kinase inhibitor, but inhibition of receptor tyrosine kinase requires higher circulating genistein levels in humans; a dose of 10/mg/kg soy-rich diet yields circulating genistein concentration of about 1μM, which is far below that required for significant inhibition of tyrosine kinase [503]. Isoflavone genistein was originally identified as having a close similarity in structure to estrogens and harboring weak estrogenic activity and, as such, was labeled as a phytoestrogen; nonetheless, review of data from literature and clinical trials suggests an inverse correlation between genistein intake and risk of breast and other hormonally related reproductive organ cancers. A study among women in Shanghai, China, found that plasma isoflavone concentration was inversely associated with the risk of nonproliferative and proliferative benign fibrocystic conditions as well as breast cancer [504]. Clinical studies in osteopenic and osteoporotic postmenopausal women support breast and uterine safety of purified naturally derived genistein administered for up to 3 years accompanied by attenuation of postmenopausal problems [415, 505]. Genistein has close structural similarity to 17β-estradiol and shown to compete with 17β-estradiol in interaction with estrogen receptor (ER) and preferentially binds and activates ER-β isoform. The latter has been shown by cluster analysis to upregulate the expression of genes that are important in the negative regulation of cellular proliferation and affect the expression of genes associated with signaling events that repress ER activities including cellular proliferation, thus exerting a potential favorable role in the prevention of hormone-related cancers [415].

In parallel with its effects on estrogen-sensitive cancer, relatively high levels of soy isoflavones have been found in the serum, urine, and prostatic fluid of Asian men who consume a soy-rich diet presumably contributing in lowering the risk and incidence of prostate cancer in several cohorts and case-controlled studies [506–509]. Genistein affects androgen receptor-mediated gene expression in vivo and is classified as an androgen antagonist in prostate tissue at a concentration relevant to human exposure on a soy-rich diet. However, other different tissue- and tumor-specific concentration of genistein in human population has not been determined.

15.2 Resveratrol

The phytoalexin resveratrol (3,5,4′-trihydroxy-trans-stilbene) is a non-flavonoid polyphenol compound found enriched in dietary items such as grapes, peanuts, plums, pines, blueberries, and cranberries. Red wine constitutes a major source of human consumption of resveratrol. Jang et al. first reported cancer chemopreventive potential of this bioactive compound effectively intervening at all three discrete and overlapping major stages of carcinogenesis [510]. This led other researchers to evaluate its potential to suppress tumor growth in context of cancer chemoprevention and as therapeutic adjunct; their assessment revealed that resveratrol suppresses the growth of a variety of cancers including lymphoma; multiple myeloma; breast, prostate, colon, and pancreatic cancer; melanoma; head and neck squamous cell carcinoma; ovarian carcinoma; and cervical carcinoma [511, 512]. Further, the diverse bioactivity associated with resveratrol stimulated its investigation in several human clinical trials. A myriad of molecular events that decrease tumor size and volume in preclinical models associated with resveratrol intake have been compiled and presented [5, 513]. Their anticancer properties can be summarized as (a) growth inhibitory and cell proliferation activity; (b) cell cycle arrest in the S, G1/S, or G2/M phase of cell cycle depending on cell and tissue specificity through a mechanism involving the downregulation of activator molecules and upregulating their inhibitors and tumor suppressor p53 transcription factor and their responsive genes; (c) induction of apoptosis by suppressing expression levels of anti-apoptotic proteins; and (d) antiangiogenic, anti-invasion, and anti-metastatic characteristics.

15.3 (−)-Epigallocatechin Gallate

The cultivation of green tea (*Camellia sinensis*) dating more than 5,000 years ago was initially associated with medicinal usage, until its current status as one of the most popular consumed beverage worldwide along with purported recognition of its beneficial health effects including anticancer properties. Relative to other tea, the chemistry of green tea has been well characterized, and the chemopreventive effect of green tea is mainly attributed to its polyphenol content known as catechins. (−)-Epigallocatechin-3-gallate (EGCG) is the most abundant catechin in green tea and represents 50–80 % of the catechins by weight in a typical 200–300 mg per brewed cup of green tea [289, 514]. Besides EGCG, other major catechins in green tea are (−)-epicatechin-3-gallate (ECG), (−)-epigallocatechin (EGC), and (−)-epicatechin. Recently, the molecular targets that could account for the chemopreventive effect of EGCG and other tea compounds have been reviewed and succinctly presented [289, 369, 515, 516]. Overall, its broad-spectrum pleiotropic effects on cellular proteins and signaling pathways attribute in curtailing tumor growth and constitute underlying mechanism by which EGCG and other tea polyphenol constituents protects against cancer reflecting its chemopreventive efficacy. In addition the ability of green tea polyphenols to inhibit matrix metalloproteinases, cyclin-dependent kinases, ubiquitin/proteasome degradation pathways, DNA methyltransferase, and receptor tyrosine kinase (RTK) pathways has been proposed as promising avenues for enhancing therapeutic efficacy [259]. Additionally, the antioxidant activity of green tea polyphenols and, more recently, prooxidant effects of these compounds have been suggested as cellular basis for cancer prevention [88, 517]. Several evidences point to the effect of tea polyphenol in inhibiting tumor incidence and multiplicity in different organ sites such as the skin (UV radiation and chemically induced), lung, liver, breast, prostate, stomach, pancreas, bladder, and colon based on preclinical, observational, and clinical trial data [289, 516]. Besides cancer, EGCG has demonstrated beneficial effects in other diseases such as diabetes, Parkinson's disease, Alzheimer's disease, stroke, and obesity.

15.4 Silibinin

The flavonolignan silibinin is a purified polyphenolic compound derived from the seeds of herb milk thistle (*Silybum marianum*). It was originally used as a remedial hepatoprotective agent being capable of scavenging both free radicals and reactive oxygen species by enhancing the antioxidant defense machinery of cells. Additionally, silibinin has effects on multiple targets including abrogation of mitogenic and survival signaling and cell cycle regulation. Silibinin has been reported to target the receptor tyrosine kinase (EGFR, IGF-1), MAPK, and NF-κB pathways in various cancers [518]. It has been vigorously evaluated in different animal species and models with no signs of adverse effects, and thus, its consumption as a drug or dietary supplement appears to be safe with no systemic toxicity. Silibinin has been examined against different cancers (lung, oral, colon, prostate, and pancreas) for over a decade with outcome suggesting its further evaluation in large cohort of patient population harboring different site-specific cancer.

15.5 Quercetin

The flavonoid quercetin derived from fruits and vegetables (apple, onion, tomatoes) has been considered as prototype chemopreventive agent targeting key molecules due to its antioxidant, anti-inflammatory, antiproliferative, proapoptotic, and antiangiogenic effects interfering against the "initiation" to invasion and metastasis of tumor progression. As reported, multitargeted cancer prevention by quercetin includes modulation of several signal transduction pathways including those associated with the processes of inflammation and carcinogenesis [519]. Further, a number of investigators have examined and reported that quercetin is effective in inducing cell death and cell cycle arrest in tumor cells through downregulation of selective oncogenes. Recently, Russo et al. reviewed the status of quercetin in disease prevention and therapy concluding the necessity of further research on possible use of quercetin in adjunct cancer therapy [92].

15.6 Curcumin

As diferuloylmethane, is a polyphenolic compound extracted from the dried ground rhizome of the perennial herb *Curcuma longa*. Curcumin has been extensively researched and reviewed with regard to its mechanism of action that mediates its chemopreventive and therapeutic effects. Several known pleiotropic effects of curcumin action have emerged including inhibition of signaling pathways at multiple levels such as transcription factors NF-κB, STAT (constitutively and drug induced), enzymes (COX-2, MMPs), cell cycle arrest with downregulation of cyclin D1 and cyclin E and upregulation of p21$^{\text{CIP1/WAF1}}$ and p27$^{\text{KIP1}}$ cyclin-dependent kinase inhibitors, inhibitory effect on oncogenic proliferation (EGFR and Akt), anti-invasive pathway-related molecules (β-catenin and adhesion molecules), and anti-metastatic effect. Curcumin upregulates caspase family proteins and downregulates anti-apoptotic genes (Bcl-2, Mcl-1, and Bcl-xL). The effect of curcumin is not only limited to cancer but also reported to display therapeutic effect against various human disorders such as metabolic and infectious diseases, diabetes, psoriasis, rheumatoid arthritis, atherosclerosis, and Parkinson's and Alzheimer's diseases. In animal models, the anticarcinogenic effects of curcumin include a spectrum of cancers such as leukemias, lymphomas, multiple myeloma, brain cancer, and melanoma as well as skin, cervix, lung, prostate, breast, ovarian, bladder, liver, gastrointestinal tract, pancreatic, and colorectal cancers. However, on the downside, therapeutic applications of curcumin in humans are limited by its high metabolic instability as well as poor absorption and bioavailability. To overcome this shortcoming, many research laboratories including ours, are focussing on developing novel, synthetic analogs and formulations of curcumin including its complexation with polymeric micelles or nanoparticle-based encapsulation towards greater chemical stability, systemic bioavailability, and antitumoral activities than naturally occurring curcumin [520, 521].

16 Conclusion and Perspective

Emerging scenario from multifaceted preclinical and clinical studies reveal that polyphenol class of compounds have the potential to intervene and modulate many strategic targets predicted in ontogeny of tumor initiation and progression. Many of these events are currently believed to result from the high frequency of mutations prevailing in cancer cells along with multiple deregulated signaling mechanisms. This knowledge is paving way to explore novel approaches for "preventive intervention" at a time point where it can be most effective to therapeutic modules. Drugs that are currently in clinical practice have shown response in clinics, but still most patients diagnosed with cancer succumb to recurrence or advanced disease that lacks effective therapy. With farfetched knowledge gained with respect to cancer prevention research and chemopreventive phytochemicals, superimposing conventional dogma of cancer treatment with new testament of "chemosensitisation" by multitargeting phytochemicals into continum of cancer care and therapy holds promise for the future. Dietary intake of fruits, vegetables, beverages, and edible plant parts rich in polyphenol contents is proposed to help in preventing and lowering the risk of cancer in susceptible population. This chapter summarized a prognostic overview of the potential of polyphenol compounds covering multitargeted mechanism including modulation of inflammation, antioxidant status, regulation of key intracellular signaling events pertaining to cancer cell proliferation and other biological events such as apoptosis, cell cycle arrest, angiogenesis, and metastasis. Collectively, all these evidences reinforce our conviction that polyphenol compounds could be ideal candidates for further exploration and incorporation in "prevention intervention." Much of what we know presently, the realization of bioavailability of bioactive polyphenol in context of therapeutic response remains a challenge that need to be vigorously addressed. Another important issue relates to recommended dose range associated with optimal biological activity and maximal therapeutic indices. Further, using computer modeling and other modules such as systems biology approach, development of novel stable semisynthetic derivatives and formulation of natural polyphenol compounds needs to be prioritized and further evaluated in genetically modified transgenic and knockout models in setting of prevention and sensitization to therapy. This can later be extended into clinic either as monotherapy or in combination with current cancer therapies in patients leading to improvement in health care.

Abstract

The occurrence of tannins and anthocyanins from grapes and wines is well documented. Various chemical reactions involving anthocyanins and/or flavanols have been demonstrated to occur during red wine aging. Current knowledge regarding the reaction mechanisms involved in some of these processes and the structures of the resulting products is reviewed. Their effects on wine organoleptic quality are also discussed.

1 Introduction

Phenolic compounds are products of secondary metabolism of plants; they are particularly important in grape wine because of their effects on wine color and it's organoleptic properties [1]. Polyphenols are defined as a wide range of chemicals including at least one aromatic nucleus and one or more hydroxyl groups, in addition to other constituents [2]. Tannin has been defined by as follows: "water-soluble phenolic compounds, molecular weight of between 500 and 3,000 Da, which, in addition to the properties of usual phenols, have the ability to precipitate alkaloids, gelatine and other proteins." Anthocyanins are defined as water-soluble vacuolar pigments that may appear red, purple, or blue according to pH. They belong to a parent class of molecules called flavonoids. Anthocyanins are glucoside of anthocyanidins. Anthocyanins have been shown to act as a "sunscreen," protecting cells from high-light damage by absorbing blue-green and UV light, thereby protecting the tissues from photoinhibition or high-light stress.

Tannins belong to the flavan-3-ols and can be considered as the most diverse category of flavonoids. These compounds range from simple monomers, (+)-catechin and its isomer (−)-epicatechin, to oligomers and polymers called proanthocyanidins. The proanthocyanidins are formed of catechin and epicatechin by oxidative coupling between the positions C4 and C6 or C8 of the adjacent monomer. The oligomers of procyanidins are formed by 2–5 units of (+)-catechin or (−)-epicatechins, the polymers being formed by 6 or more units [3, 4]. In addition, flavan-3-ols may be esterified with gallic acid (i.e., epicatechin gallate) or hydroxylated to form prodelphinidin (i.e., gallocatechins, epigallocatechin). The flavan-3-ols, present in grapes, are mostly in the form of polymers. The seed tannins are made up of procyanidins (polymers of catechin and epicatechin), partially galloylated, while those of skins also contain prodelphinidins (polymers of gallocatechin and epigallocatechin) [5]. The average number of monomeric units, defined as the mean degree of polymerization (mDP), may go up to 18 in tannin fraction from seeds and around 30 units in skin tannin extract. The anthocyanidins are widely present in the plant kingdom, mainly in the form of glycosides, especially in black/red grape skins, where they are responsible for the colors red, blue, and purple depending on the pH of the cell compartment [6]. The most common anthocyanidins are the pelargonidin, cyanidin, delphinidin, peonidin, and malvidin, but these compounds are only present under their glycosylated forms, called anthocyanins. The anthocyanidins are also capable of conjugation with hydroxycinnamic acids (e.g., *p*-coumaric acid, caffeic acid) and other organic acids (e.g., malic and acetic acids). Unlike other species, North American *Vitis* species have significant levels of diglycosylated anthocyanins in positions C3 and C5; *Vitis vinifera* contains only traces of these and is characterized by the presence of a majority of anthocyanin monoglucosides, particularly the malvidin-3-*O*-glucoside and its acylated derivatives. The anthocyanins are present in the red grapes at about 500–3,000 mg/kg, but can reach higher values in cultivars called "dyers" as Alicante Bouschet (5,000 mg/kg) in which the anthocyanin concentration in pulp is also high.

Table 72.1 Anthocyanin and tannin content in the different parts of the grape berry

	Pulp	Skins	Seeds

The grape berries also contain large amounts of tannins mainly concentrated in the seeds and skins and large amount of anthocyanins concentrated in skins (Tables 72.1 and 72.2).

2 Tannins and Anthocyanins in Grape Berries

The major phenolic compounds are the anthocyanins and tannins (proanthocyanidins or condensed tannins) [9–12]. The identification of these compounds and their distribution in the grape berry have been investigated.

2.1 Structure of Tannins

Tannins are abundant in grapes and wine, and in the grape, they are found in both the seed and skin. These are often specifically called the flavan-3-ols to identify the location of the alcohol group on the C ring. The flavan-3-ols are the most reduced form of the flavonoids, since both positions 2 and 3 on the C ring are saturated, stereoisomers exist, and two are found in grapes (Fig. 72.1). The *trans* from is (2R,3S) (+)-catechin, and the *cis* form is (2R,3R) (−)-epicatechin. Both catechin and epicatechin have the 3′,4′ catechol substitution on their B ring. The only other

	Flavan-3-ols	R_1	R_2	C-2	C-3
	(+)-Catechin	H	H	*R*	*S*
	(+)-Gallocatechin	OH	H	*R*	*S*
	(+)-Gallocatechin gallate	OH		*R*	*S*
	(–)-Epicatechin	H	H	*R*	*R*
	(–)-Epigallocatechine	OH	H	*R*	*R*
	(–)-Epicatechine gallate	H		*R*	*R*

Fig. 72.1 Chemical structure of principal flavanol monomers of grapes and wine

B ring substitution pattern found in wine flavan-3-ols is the 3′,4′,5′-trihydroxy form, appropriately called the gallocatechins. Epigallocatechin is found in grape skin, but gallocatechin is not found in significant amounts. Gallate esters are also found, and the gallic acid is esterified at position 3 of the epi-series only. Epicatechin gallate represents a small but significant proportion of the flavan-3-ol pool in grapes in the seeds. Thus, for the simple series of monomeric flavanols, there are four different ones found in wine. These monomeric flavan-3-ols are sometimes referred as the "catechins." The levels of total monomeric flavan-3-ols in typical red wine ranged from 40 to 120 mg/L with the majority usually being catechin [13]. The levels are strongly affected by seed extraction techniques and are higher when extended maceration techniques are used. The majority of phenolic compounds in red wine are from the condensation of flavan-3-ol units to yield the oligomers (proanthocyanidins) and polymers (condensed tannins). The condensation occurs to form covalent bonds between flavan-3-ol units, the most common linkages being 4 → 8 and 4 → 6 positions (Fig. 72.2). On average, epicatechin is the predominant unit in condensed tannins from grapes and wine; catechin is the next most abundant (often found at the end or terminal units – those with no bonds at position 4). In typical red wines, the amount of polymer plus oligomer is a sizable fraction of the total phenolic level, being in the range of 20–50% in new wines and a higher proportion in older wines. Levels are between 0.5 g/L and 2 g/L or higher for some red wines in function of the grape variety, while in white wine, levels are lower ranging from 10 to 50 mg/L and highly dependent on pressing techniques [11]. The monomeric catechins are bitter and astringent, while in polymer, the bitterness is minimal, but the astringency remains [14]. Over several years of aging, a disproportionation reaction can occur, perhaps with some oxidation, so the polymers continue to increase in size until they are no longer soluble in wine and form the precipitate commonly observed in older red wines. During aging, the amount of phenolics in a wine decreases.

Fig. 72.2 Procyanidin dimers of flavanols from grapes and wines

The proanthocyanidins form a considerable portion of the tannins found in wine and in particular contribute heavily to the color and flavor of red wines. Proanthocyanidins are high-molecular-weight polymers formed from flavan-3-ol monomeric unit (i.e., (+)-catechin and (−)-epicatechin). Oxidative condensation occurs between carbon C-4 of the heterocycle C ring and carbons C-6 or C-8 of the attached aromatic A rings (Fig. 72.3) [15]. The procyanidins B1–B4 are the most

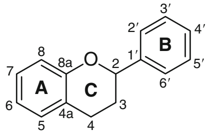

Fig. 72.3 Basic structure and numbering system of flavonoids

common dimers and are characterized by the C4–C8 linkage; they are occasionally accompanied by corresponding C4–C6-linked isomers (B5–B8) (Fig. 72.2).

It was reported that esterification of (−)-epicatechin and procyanidin B2 by gallic acid can occur and that these gallate esters are only found in the grape seed extract. Grape seed extract contains oligomer procyanidins made up of dimers or trimers of (+)-catechin and (−)-epicatechin.4-6 The procyanidin dimers are comprised of procyanidins B1, B2, B3, B4, B5, B6, B7, and B8. There are six procyanidin trimers which include procyanidins C1 and C2.

Furthermore, several galloylated procyanidins, which are most commonly the gallate esters of the dimeric procyanidins, and some free gallic acid are present [16, 17]. Tetramers or greater of these flavonols would be known as polymeric proanthocyanidins, and the astringency of the molecule would increase accordingly. Therefore, oligomeric proanthocyanidins are less astringent, bind less strongly to proteins, and are more soluble [17].

2.2 Structure and Impact of Anthocyanins

Anthocyanins belong to the flavonoid group of polyphenols. They have a C6C3C6 skeleton typical of flavonoids. Anthocyanins are glycosylated polyhydroxy and polymethoxy derivatives of 2-phenylbenzopyrylium cation, i.e., the flavylium cation [18]. The main part of anthocyanins is its aglycone, the flavylium cation (Table 72.3), which contains conjugated double bonds responsible for absorption of light around 500 nm causing the pigments to appear red to human eye. The aglycones are called anthocyanidins, which are usually 3,5,7,3′,4′-penta- or 3,5,7,3′,4′,5′-hexasubstituted. Different anthocyanidins are known today (Tables 72.1 and 72.2), but only six of them are significant and most common from food point of view [19]. The most important anthocyanidins are pelargonidin, cyanidin, peonidin, delphinidin, malvidin, and petunidin (Fig. 72.4). These aglycones differ in the number of hydroxyl and methoxyl groups in the B ring of the flavylium cation.

Winemakers observed sensory differences in Cabernet Sauvignon wines made from three pruning treatments in a single vineyard, particularly in mouthfeel characteristics. The relationships between wine composition and wine sensory characteristics were examined and then compared to berry weight and composition and wine quality scores. Cabernet Sauvignon from three pruning treatments – machine, cane, and spur – was harvested at commercial harvest date, and replicate wines were made from each for three vintages [20]. The composition of the wines from all three pruning systems was generally similar. Differences in individual descriptive attributes did not separate the wines from the three treatments, or across vintages, despite

differences in overall quality scores. Principal component analysis (PCA) could separate the wines by pruning and by vintage using wine composition or sensory parameters. Higher concentrations of anthocyanins, tannins, and phenolics in berries did not always result in higher concentrations in wines. In this study, higher wine tannin or wine phenolic concentrations did not result in higher wine astringency, and wine color measures and phenolic composition were not good indicators of individual wine sensory properties or wine quality. Wine composition was not necessarily directly influenced by berry composition. Few studies focus on the berry to wine sensory continuum, particularly over more than one vintage or in a commercial

context. This study highlighted how complex the relationships among berry qualities, wine sensory properties, and wine quality can be, particularly within a single vineyard. In another work, the authors [21] try to determine how changes in grape composition brought about by artificial shading (sunlight exclusion) influence wine properties including color, flavonoid composition, and sensory attributes. Prior to flowering, bunches of Shiraz grapes were enclosed in boxes designed to eliminate light without altering bunch temperature and humidity. This artificial bunch shading had little effect on berry ripening and accumulation of sugar, but at harvest, the shaded bunches had smaller berries and higher seed weight, juice pH, and titratable acidity. The amount of anthocyanins in the fruit was not significantly changed, but anthocyanin composition in the shaded berries was shifted toward dioxygenated anthocyanins (i.e., glucosides of cyanidin and peonidin). Shaded fruit shows an increased in seed tannin level and a decreased in skin tannin concentration, but the largest relative change in flavonoid composition was a marked decrease in flavonols in the shaded fruit, similar to previous studies. Wines made from shaded fruit had lower wine color density, total phenolics, anthocyanins, and tannins when the wine was bottled and after aging for up to 3 years. Sensory analysis of the wines indicated no significant difference in aroma attributes, but the wines made from shaded fruit were rated lower for astringency, fruit flavor, and flavor persistence in-mouth sensory attributes. The results indicate that extreme shading of Shiraz fruit can decrease wine color, anthocyanins, and tannins as well as altering sensory attributes.

3 Tannins and Anthocyanins in Wines

Anthocyanin pigments and tannins are particularly important for red wine quality. Their extraction depends on their location in the berry and their solubility.

All phenolic compounds are unstable and undergo numerous enzymatic and chemical reactions. Color and taste changes during red wine aging have been described as anthocyanin–tannin reactions. The structures and properties of tannins and pigmented tannins from these reactions are often misunderstood. Wine phenolic composition is subject to evolve in wine during aging and storage [22]. Five key points have to be taken under consideration: (1) reactions of tannins yield both larger polymers and smaller species; (2) anthocyanin reactions can generate colorless species as well as polymeric and small various pigments; (3) some polymeric pigments undergo sulfite bleaching, while some low-molecular-weight pigments do not; (4) polymers are both soluble and astringent, so the astringency loss during aging may involve cleavage rather than polymerization; and (5) sensory properties of anthocyanins and tannins are modulated by interactions with other wine components.

The effect of the use of SO_2 and pectolitic enzymes in the prefermentative phase, maceration time, and oak aging on color, anthocyanins, tannins, (+)-catechin, (−)-epicatechin content of Aglianico wine has been realized [23]. The addition of SO_2 and pectolitic enzymes before fermentation caused an increase in color intensity, color stability, total phenolics level, anthocyanins, (+)-catechin, and (−)-epicatechin content in Aglianico wine. Longer maceration times made wines richer in total phenolics and gave them better chromatic characteristics. Storage in oak caused a decrease in anthocyanins, (+)-catechin, (−)-epicatechin content, but an increase in total phenolic content, and a stabilizing effect on color also occurred.

4 Organoleptic Properties of Tannins

Grape phenolics are nonvolatile, and therefore, they cannot be smelled. Anthocyanins provide the visual component in wines. Flavan-3-ol monomers are bitter and thus have taste. That is because some hydroxyl groups of polyphenols bind to salivary proteins that some of them as tannins are defined as astringent giving a sensation of dryness in the mouth. The tannins or proanthocyanidins are astringent, but the perception is complex. Tannins are compounds to be deterrents to herbivores and fungi. Tannins can accomplish this property because of their ability to bind strongly to proteins [24]. Considering wine, it is generally considered that we observe this as a loss of lubrication due to the tannins binding and precipitating salivary proteins. To put it simply, tannins are astringent, terribly astringent [25, 26]. Astringency is a tactile sensation, and therefore, we feel it. This gives rise to the common term used to describe tannins in wine: mouthfeel. Beyond astringency, tannins can also possess bitterness, which is a taste sensation and is brought about by the lowest-molecular-weight tannins [14, 27–29]. It is generally considered that too much bitterness in wine is not desirable, and based upon the reduction in the lowest-molecular-weight tannins observed during berry maturation, this may provide a structural explanation for why tannin quality improves with fruit maturity. Considering tannin perception in total, the astringency of tannins has a distinct temporal aspect to their perception [30]. When wines have an excess quantity of tannins, the astringency of the wine can linger beyond that of other components. This persistence is generally thought of as being undesirable. Although bitterness and astringency are found in red wines, it is not a descriptor that is often used in a production setting. Instead, winemakers tend to describe tannins in terms that provide subquality information. Sensory scientists and chemists have tried to understand these more subtle aspects of tannin perception [29, 31–40]. From these investigations, it is clear that the perception of astringency in wine could be influenced by many components in wine including ethanol [29, 41], acidity [29, 41, 42], viscosity [43], simple sugars[44], polysaccharides [45, 46], and anthocyanins [45]. The major difficulty to conduct this type of study results in the influence of the variation in human response to astringency and bitterness [41]. Some complex interaction between tannins and other macromolecules found in wine occurs and modifies the mouthfeel perception [29, 46–49].

How can different grape components influence tannin perception? Tannins and acid are balanced with ethanol sugar and polysaccharides. The goal to get an optimized red wine quality is to balance these components. When the grape berry is mature, the composition should be balanced. The enologist has the ability to modulate wine perception by adjusting the balance particularly with the decision of the harvest date and with adapted winemaking and aging process. To simultaneously explore the primary and interactive effects of proanthocyanidin (“tannin”), ethanol, anthocyanin, and wine polysaccharide concentrations on the mouthfeel perception of wine-like media, a sensory study based on an incomplete factorial design was conducted [50]. Two grape polyphenol fractions, i.e., grape seed tannins and anthocyanins, and two fractions of wine polysaccharides (mannoproteins + arabinogalactan proteins and rhamnogalacturonan II) were prepared and analyzed. A panel of 15 trained judges generated a series of mouthfeel descriptors and rated their intensities while samples containing various levels and combinations of the components were held in mouth and after expectoration. The sensory perception was primarily determined by tannin concentration. However, the attribute ratings were also strongly influenced by all other factors both directly and through interactions. The intensities of all astringency descriptors increased with tannin concentration and were reduced when rhamnogalacturonan II was added. Bitterness increased with ethanol level and decreased in the presence of proteoglycans. Secondary effects observed included both masking and enhancement of the primary effects but also specific interaction effects. The latter are probably related to differences in the structural organization and properties of molecular assemblies involving polyphenols, polysaccharides, and ethanol.

The taste and mouthfeel properties of three different types of tannin-like polyphenolic compounds, representative of some of the tannin-like polyphenolic compounds found in red wines, were determined using descriptive sensory analysis [50]. Ethyl-bridged flavan-3-ols were produced by reaction of (+)-catechin with acetaldehyde under acidic conditions. Red-colored tannin-like polyphenolic compounds from wine and from wine pomace were isolated by multilayer coil countercurrent chromatography (MLCCC). Mouthfeel attributes and bitterness of the fractions dissolved in a model wine (MW) medium were rated while the fractions were held in the mouth and after expectoration. The sensory properties of the fractions described above were compared to those of apple procyanidins (tannins) with degree of polymerization (dp) 3 and 9. Both wine and pomace-derived colored tannin-like polyphenolic compounds were rated as significantly less astringent when compared to both the apple tannin fractions but were similar to the MW. The ethyl-bridged flavanols (with mean dp of 5) were rated significantly more bitter than both the apple procyanidin fractions. Astringency of the ethyl-bridged flavanols was lesser than the apple procyanidin fraction with dp9 and more than that with dp3. Highly purified grape anthocyanidin monoglucosides and coumaroylated monoglucoside, prepared either by solid-phase extraction or by multilayer coil countercurrent chromatography, were rated similarly to the MW indicating that free anthocyanins, like the colored tannin-like polyphenolic compounds from wine and pomace, do not contribute astringency or bitterness to wine.

Storage conditions that may influence the chemical and sensory properties of young bottled Cabernet Sauvignon and Merlot wines have been also studied [51]. Low- and high-tannin wines ($\leq$400 mg/L and $\geq$ 800 mg/L catechin equivalents, respectively) stored at 23 °C for 0 day (baseline) and at either 27 °C or 32 °C for 40, 55, and 70 days were used for chemical and sensory analyses. In both low- and high-tannin wines, storage at 32 °C resulted in significant increase in small polymeric pigment ($p \leq 0.05$) with a corresponding decrease in anthocyanin concentrations over time, which was more pronounced in Cabernet Sauvignon. In both varieties, high-tannin-content wines contained larger polymeric pigment than the low-tannin-content wines ($p \leq 0.05$). A trained sensory panel ($n = 21$) gave higher astringency ratings to high-tannin-content wines than low-tannin-content wines for both varieties, which remained constant throughout the study. An increased perception of bitterness was associated with storage at 32 °C storage for 70 days, while alcohol burn intensity was comparable in Cabernet Sauvignon. No significant differences in bitterness and alcohol burn intensity were found in Merlot. These results indicate that storage temperature and storage time contributed to change the chemical composition of typically aging red wines but did not impact perceived astringency. Tannin concentration was positively correlated with perceived astringency ($r = 0.882$) in Cabernet Sauvignon, while small polymeric pigment and low polymeric pigment had lower correlation with perceived astringency for both varieties.

5 Organoleptic Properties of Anthocyanins

The relationships between the levels of polyphenols, acidity, and red pigments in Shiraz wines and their perceived textural profiles as quantified by a trained sensory descriptive analysis panel were explored [52]. A “chamois-like” feeling when the wine was held in the mouth appeared to be related to an absence of polyphenols. The in-mouth “chalklike” texture was strongly associated with anthocyanin concentration and was negatively associated with alcohol level and acidity. The astringent subqualities of “velvetlike” and “emery-like” roughing were mostly related to polyphenol levels, but these attributes could not be adequately differentiated by the compositional variables under study. Wines that elicited a “puckery” sensation were characterized by relatively low anthocyanin levels, high acidity, and high pigmented polymer and tannin concentrations. The results of the study suggest that the in-mouth textural properties of Shiraz red wine are associated not only with their tannin composition and concentration but also with their acidity and anthocyanin and alcohol concentrations.

Two fractions containing the major polysaccharides present in wine have been isolated, one comprising a mixture of neutral polysaccharides, mannoproteins, and arabinogalactan proteins and the other containing the acidic polysaccharide rhamnogalacturonan II. A grape anthocyanin fraction was also prepared (Vidal et al. [36]). A trained sensory panel, using formal sensory descriptive analysis methods to rate the intensity of mouthfeel attributes while the samples were held in the mouth and after expectoration, individually assessed the fractions dissolved in a model wine at levels commonly encountered in red wines. Both polysaccharide fractions significantly increased the "fullness" sensation above that of the base wine. The rhamnogalacturonan II fraction significantly decreased the attribute ratings associated with the astringency of the model wine, whereas the neutral wine polysaccharide fraction had less affect on reducing the ratings for these attributes. The anthocyanin fraction tended to increase "fullness" although the effect was not great enough to be statistically significant. Unlike the polysaccharides, this fraction also increased perceived astringency, but this effect could be due to the presence of some derived tannins in the sample.

The contribution of anthocyanins or tannin–anthocyanin reaction products to the mouthfeel properties of wines prepared from both red and white berries with and without pomace contact and anthocyanin addition was also investigated [53]. A trained sensory panel rated mouthfeel and taste attributes in wines after 6 months of bottle storage, and phenolic measures were obtained. A white wine made in the same manner to how a red wine is made did not exhibit the same mouthfeel sensory attributes of a red wine: it was lower in viscosity, less particulate in nature, and lower in intensity for the astringency descriptors fine emery, dry, and grippy. It was found that differences in ratings of mouthfeel attributes could not be related closely to phenolic composition or structure. This study has shown that the presence of anthocyanins during fermentation increases the intensity of astringency attributes. Using the mouthfeel wheel, the differences between a white wine made like a red wine and a red wine could be quantified. It was also shown that the presence of anthocyanins in red wine can explain the differences perceived between the mouthfeel properties of a white and a red wine.

6 Tannin Evolution and Organoleptic Perception

Many wines are consumed after a period of aging. Aging modifies various organoleptic wine properties and implies a significant financial cost in the wine final price. The present-day wine consumers expect wine from a particular vintage and age to possess unique qualities that differentiate it from other wines of the other vintages.

Flavan-3-ols are the most abundant phenolic compounds, with oligomeric and polymeric procyanidins (condensed tannins) in red wine often representing 25–50% of the total phenolic constituents [54]. As these attributes contribute so much to overall red wine quality, an understanding of the relationship between proanthocyanidin composition, sensory perception, and age of red wine is critically important. It was possible to correlate a chemical parameter describing wine structure such as proanthocyanidin mean degree of polymerization (mDP) and a sensory parameter describing proanthocyanidin mouthfeel characteristics such as astringency with the age of vintage of Bordeaux Cabernet Sauvignon wines for 23 wine samples of known aging periods from Chateau Mouton Rothschild (*premier grand cru classé Pauillac*) kept under similar conditions during and after the winemaking process. An extended aging period was considered, covering a time frame of 27 years. The dates of production of these wines range from 1978 to 2005. The oligomeric and polymeric proanthocyanidins were depolymerized in the presence of a nucleophilic agent (phloroglucinol) in acid medium [55]. Reversed-phase HPLC analysis of the products formed allows determination of the structural composition of proanthocyanidins, which are characterized by the nature of their constitutive extension units (released as flavan-3-ols phloroglucinol adducts) and terminal units (released as flavan-3-ols). To calculate the apparent mDP, the sum of all subunits (flavan-3-ol monomer and phloroglucinol adducts, in moles) was divided by the sum of all flavan-3-ol monomers (in moles). Regarding sensory analysis, fifteen judges were trained to evaluate astringency intensity using a 0–7-point scale (0 = amorphous, 1 = hollow, 2 = soft, 3 = mellow, 4 = slight astringency, 5 = tannic, 6 = hard, 7 = rough). A solution of 1.0 g/L aluminum sulfate was presented to judges as an astringency marker. We found that the mDP decreases with aging [55], with values of R^2 above 0.8 (Fig. 72.5a). This regression model behaves fairly well in the range of years explored; the lowest values of mDP were measured for 1978 vintage, whereas the highest were found for the 2001 followed by the 2005 vintage. If the wine is included between vintages 1978 and 1998, its DPm will vary from 1.81 to 3.68. The wine DPm fluctuates between 3.94 and 7.13 for the vintages 1999–2005. During aging, rearrangement reactions between phenolic compounds may explain decreases in the mDP. In particular, the presence of oxygen in wine will lead to the formation of acetaldehyde via the coupled oxidation of oxygen and phenolic compounds [56]. In young wines, free sulfur dioxide is present; formed acetaldehyde is considered as the bisulfite adduct and therefore would not be available for reaction with phenolic compounds [57]. Concerning astringency intensity, Fig. 72.5b suggests that astringency decreases during aging ($R^2 = 0.598$, $p = 0.000$). Wine aging is a process in which the organoleptic properties are modified as the result of a series of reactions whose effect is to strengthen certain desired characteristics while reducing or eliminating other unwanted ones. This change of perception could be attributed to mDP, since the higher the mDP is, the higher the overall astringency is perceived [50]. The correlation between astringency intensity and mDP ($R^2 = 0.509$, $p = 0.049$) permits the qualitative assessment of tannins. Scale patterns between wine mDP and tannin perception are proposed (Fig. 72.6). The judges perceived wines having an mDP inferior to 2 to be soft and mellow, while wines with an mDP between 2 and 4

were characterized as mellow and slightly astringent, and wines with an mDP bigger than 4 were perceived rather tannic. The function of this scale pattern is not the identification of anonymous wines, but the exercise of astringency quality evaluation, to give sensory information taking into consideration a specific wine chemical analysis. This might classify its value for consumption and to see whether it has the optimized astringency required prior to consumption. mDP and astringency intensity parameters are critically required for the wine industry in order to judge wine quality.

7 Mechanisms of Polymerization and Condensation of Tannins and Anthocyanins During Aging

Oxidative reactions in wine have been subject to thorough review with the oxidation of ethanol to acetaldehyde (via hydrogen peroxide) widely accepted as a major factor [58, 59]. This reaction followed by subsequent reactions of the acetaldehyde with tannins and anthocyanins to form ethyl-linked structures is very complex [60–62]. It is affected by a range of wine parameters including phenolic content, temperature, pH, sulfur dioxide concentration, and light penetration. In addition to the oxygen mediated reactions, other reactions involving phenolics but not oxygen can also take place in wine [63]. These reactions include polymerization and condensation of tannins, breakdown and condensation of anthocyanins, and precipitation of larger polymers. In addition to reactions that affect color and tannin structure, the presence or absence of oxygen also influences wine aroma evolution and improvement [64–66]. The acetaldehyde formed during wine aging reacts with anthocyanins. It can react with anthocyanins either alone to form ethylidene-bridged anthocyanin dimers [67–70] (Fig. 72.7, reaction 5) and vitisin B [71, 72] (Fig. 72.7, reaction 6) or in combination with Fl (flavan-3-ols) to form ethylidene-bridged copolymers (Fig. 72.7, reaction 7). Previous studies have shown that acetaldehyde addition increased the rate of anthocyanin-flavan-3-ol copolymerization [57, 69, 73]. Ethylidene-bridged copolymers up to tetramers were synthesized in model wine containing malvidin-3-*O*-glucoside and (−)-epicatechin. The obtained oligomers contained at most two anthocyanins units, which were always in the terminal position [61, 74]. The copolymers formed are transient and may evolve into substances with higher degrees of condensation, which may finally precipitate [61, 74]. The depolymerization of ethylidene-bridged Fl or the dehydration of ethyl alcohol-flavan-3-ol adduct formed during acetaldehyde-flavan-3-ol condensation may lead to the formation of *p*-vinylphenols (Fig. 72.7, reaction 4). These compounds may react with anthocyanins and pyranoanthocyanins to form more complex compounds such as *p*-vinylpyranoanthocyanin-flavan-3-ol [61, 74–78] in which the ethylidene bridges are rearranged and are no longer quantifiable as EDP ethylidene-diphloroglucinol with the EDP phloroglucinolysis (Fig. 72.7, reaction 8). Clearly, more research on microoxygenation as well as on the effect of oxygen on red wine composition in general needs to be carried out in order to get a better understanding of all the mechanisms and species formed in the complex media.

8 Conclusions

Tannins and anthocyanins are key wine component groups. Since the skins and seeds contain the most of the phenolics, red wine is a whole berry extract. In addition, because of the significant sensory effects of these substances on bitterness and astringency, they are controlled by winemakers. The methods of control involve the manipulation of extraction as well as fining with protein to precipitate and remove tannin from finished wine; technological enological process as nano- or ultrafiltration is now seeing some use. While many studies have examined astringency, the lack of a clear, accepted definition that delineates the oral sensations it encompasses makes it difficult to effectively compare results. The potential interaction of astringency with basic tastes in many complex foods and beverages suggests that the physiological and psychological mechanisms underlying the perception of astringency should be further studied. However, it is essential to ensure that consumer expectations created by the vintage information on the wine label are not mismatched by the sensory experience of consuming the wine. Scale pattern between wine aging and both mDP and astringency intensity is a first answer to these expectations.

Abstract

Vine and wine are an abundant source of stilbenoids that constitute a large class of compounds, including a series of monomers and oligomers (dimers, trimers, tetramers). Stilbenoids can reach a level of over 100 mg L^{-1} in red wine. Several epidemiological studies have correlated the consumption of grapes and wines with significant health benefits. The most studied stilbenoid, resveratrol, exhibits multiple biological activities across multiple diseases including cancer and cardiovascular and neurodegenerative diseases. This compound shows promise in both the prevention and the treatment of these diseases. Moreover, resveratrol mimics calorie restriction and extends the lifespan in species ranging from yeast to multicellular animals (not in normal mammals) by a sirtuin-dependent mechanism. Resveratrol is well absorbed yet rapidly metabolized; however, the tissue concentrations found in some studies in animals and humans are compatible with its biological activities. Resveratrol is well tolerated at doses of up to 1 g day^{-1} in human and does not cause serious adverse events up to 5 g day^{-1}. Interestingly, other wine and grape stilbenoids such as piceatannol, pterostilbene, viniferins, and vitisins also have beneficial activities. In this chapter, we have discussed chemistry and protective role of stilbenoids in general, and resveratrol in particular, during various pathological conditions such as neurodegeneration, neuroinflammation, cancer, cardiovascular diseases, and antiaging process. Works related to bioavailability and clinical trials of resveratrol are also presented.

Keywords

Biological activities • polyphenols • resveratrol • toxicity • *Vitis vinifera*

Abbreviations

AA	Arachidonic acid
AD	Alzheimer’s disease
ADI	Acceptable daily intake
AP-1	Activator protein 1
APP	Amyloid precursor protein
Aβ	β-Amyloid peptide
COX	Cyclooxygenase
HDL	High-density lipoprotein
IGF	Insulin-like growth factor
IL	Interleukin
iNOS	Inductible nitric oxide synthase
LDL	Low-density lipoprotein
LPS	Lipopolysaccharide
MAPK	Mitogen-activated protein kinase
NF-κB	Nuclear factor-kappa B
NO	Nitric oxide
NOAEL	No observed adverse effect levels
PGE_2	Prostaglandin E_2

ROS	Reactive oxygen species
SIRT	Sirtuin
TNF	Tumor necrosis factor
TxA2	Thromboxane A2

1 Introduction

Vitis vinifera L. is a perennial woody vine belonging to the Vitaceae family. It is a productive plant, considered the world's premier fruit, occupying 7.6 million hectares of viticultural land in 2010. It is used mainly for wine (6.8 million hectares) but also for juice, fresh consumption (table grapes), dried fruit, and distilled liquor.

Polyphenolics are important constituents of grapes in determining the color, taste, and body of wines. Unlike other alcoholic beverages, red wine, which is obtained after about 10 days of maceration, contains phenolic compounds in substantial concentrations of up to 4 g L^{-1}. Due to the lower maceration time, white and rosé wines contain about a tenth of the polyphenol levels of red wines [1]. Among these compounds, stilbenoids constitute an important subclass, whose overall levels can reach over 100 mg L^{-1} in red wine. Resveratrol is one of the major stilbenoids of red wine with numerous promising biological activities.

Several epidemiological studies have shown a correlation with red wine consumption and significant health benefits. According to the statistics of the World Health Organization (1995), the reduction in the mortality rate from coronary heart disease in France as compared to the USA was 61% for men and 69% for women. As compared to the UK, the reduction was 68% and 71%, respectively [2, 3]. This finding constitutes the "French paradox" since the saturated fat intakes and serum cholesterol levels are similar in these three countries. This paradox has been attributed, in part, to moderate wine consumption [2]. A prospective cohort study by Renaud et al. was performed on the health effects of wine and beer drinking in 36,250 middle-aged men from eastern France [4]. Compared to abstainers, a moderate daily intake of wine, defined as 22–32 g of alcohol or two to three glasses, was associated with a lower risk of death due to cardiovascular diseases (40%), cancer (22%), other causes (42%), and all causes (33%). Similar results were found in a large Danish cohort [5].

Many epidemiological studies in different countries have examined the relationship between alcohol consumption and the risk of other diseases, including neurodegeneration. In prospective studies in the United States, Mukamal et al. observed a pronounced reduction in the risk of incident dementia among older adults (5,900 subjects) with moderate alcohol consumption (one to six drinks per week) [6], and Stampfer et al. found that in women (12,000 participants; 70–81 years old), up to one drink per day decreases the risk of cognitive decline of about 20% [7]. In these two studies, no significant difference was found according to the type of beverage. Additional cross-sectional (French men and women and

African and Japanese Americans) and prospective studies examined cognitive performance among moderate drinkers and abstainers, with the majority of these studies showing a beneficial effect [7, 8].

In regard to wine consumption, a number of studies have looked at its impact on neurodegenerative disease risks by examining cognitive performance and rates of dementia. The most frequent age-related degenerative disease is Alzheimer's disease, which accounts for approximately 70% of the cases of dementia. In the Tromsø study from Norway, light-to-moderate wine consumption was associated with better performance on cognitive tests after a 7-year follow-up of 5,000 subjects [9]. Moreover, a protective effect of wine against the occurrence of dementia was found in the Aquitaine region of France (the French Paquid cohort) in a prospective study that involved approximately 4,000 subjects aged 65 and over [10]. The risk of developing a dementia was decreased by about a factor of 2 in moderate drinkers (250–500 mL per day) compared to nondrinkers and light drinkers. In the Copenhagen City Heart study and the Chongqing study in China, authors found also that light-to-moderate drinking of wine is associated with a lower risk of dementia in elderly people [11, 12]. Similar results were obtained in two studies performed in Canada and New York, where a lower risk for dementia was correlated with wine consumption but not with spirits and beer consumption [13, 14]. In these last four studies, the consumption of wine was from one serving a week to three servings a day.

While epidemiology studies show wine to be protective against the development of many diseases, this correlation is complicated by other factors. For instance, some self-reporting studies have found that wine drinkers have a healthier diet than people who drink beer or spirits. In Danish supermarkets, wine buyers made more purchases of healthy food items such as olives and other fruits and vegetables than people who buy beer [15]. Other recent studies in Scotland and in China suggest that prior intelligence (defined by childhood IQ scores), socioeconomic status and general lifestyle moderation may partly explain the association between moderate alcohol intake and better cognitive function [16, 17].

It is prudent to note that only the moderate consumption of wine has shown a potential decrease in the risk of certain diseases, whereas excessive consumption is harmful and associated with increased mortality. Recently, supplementation with Concord grape juice for 12 weeks has been found to improve memory function in older adults (sample of 12 persons) in pre-dementia conditions [18].

2 Chemistry of Stilbenoids

Over the last 100 years, the grapevine *Vitis vinifera* L. (Vitaceae), the primary source of wine, has been the subject of numerous chemical studies. While stilbenoids are found in a number of plant species [19], grapes and related products are the most significant dietary source of these substances [20]. Stilbenoids are non-flavonoid polyphenols with an essential structural skeleton of two aromatic rings joined by an ethylene bridge (C_6–C_2–C_6). Over 1,000 stilbenoids have been structurally characterized in the plant kingdom, which primarily vary in the number and position of hydroxyl groups and various substitutions with sugars, methyl, and methoxy groups in addition to the structural conformations of the molecules and oligomerization patterns.

Within the grapevine, *V. vinifera*, including all parts of the plant and cell cultures, there are a little over 60 known stilbenoids. However, the majority of these have not been identified as wine constituents. Of the total known *V. vinifera* stilbenoids, 17 are monomers, all resveratrol and piceatannol derivatives, with eight having been identified in wine. The majority of the stilbenoids are dimers, with 24 dimers known in the plant, but just 9 of these have been reported in wine. In addition to these dimers, there are six trimers in *V. vinifera*; none have been identified in wine. While 16 tetramers are known *V. vinifera* plant part constituents, only one, hopeaphenol, has been found in wine [21].

2.1 Distribution of Stilbenoids

In *V. vinifera*, stilbenoids can either be constitutively expressed or induced through an abiotic or biotic stress. While there are exceptions, the stilbenoids are primarily constitutively expressed in the lignified organs (roots and stems) and are mainly induced substances, serving as phytoalexins, in leaves and berry skins [22, 23]. Within the roots and stems, stilbenoids are found as major constituents. In leaves, stilbenoids have been shown to be highly inducible, and a number of stilbenoids have been identified in infected and treated leaves. The stilbenoids in roots, stems, and leaves have been widely studied due to their importance in disease resistance. While these plant parts are not commonly utilized in the diet, they may be sources of novel stilbenoids with potent biological activities.

2.1.1 Grape Berries

In the berry, stilbenoids are produced primarily in the skin and to a lesser extent, the seeds. The stilbenoid monomers, *E*-resveratrol and *E*- and *Z*-piceid (Fig. 73.1) are

	R_1	R_2	R_3
E/Z-resveratrol	H	H	H
E/Z-piceid	Glc	H	H
E/Z-piceatannol	H	H	OH
E/Z-astringin	Glc	H	OH
E-pterostilbene	CH_3	CH_3	H

E-cis-miyabenolC

Fig. 73.2 Stilbenoids dimers and trimer

found in grapes, with the concentration of the glucosides usually being significantly higher than the aglycone [1]. An additional monomer, pterostilbene, has also been detected in healthy and immature grape berries, but in low levels [24].

2.1.2 Leaves

Stilbenoids are highly inducible in leaves using a number of chemicals, UV-C treatment, and infectious agents [25]. To date, the majority of stilbenoids from leaves have been identified from stressed leaves. In some of the preliminary studies by Langcake and Pryce using leaves infected by *Botrytis cinerea*, the main stilbenoids detected were *E*-resveratrol, *E*-ε-viniferin (Fig. 73.2), and α-viniferin [26]. The resveratrol dehydrodimer, *δ*-viniferin, and piceids were detected in leaves induced by UV irradiation [27, 28]. More recently, Mattivi et al. isolated and identified 14 stilbenoids from the leaves of a hybrid *V. vinifera* infected with *Plasmopara viticola* [23]. These compounds included two new dimers and two new to *V. vinifera*: *E*-ω-viniferin,

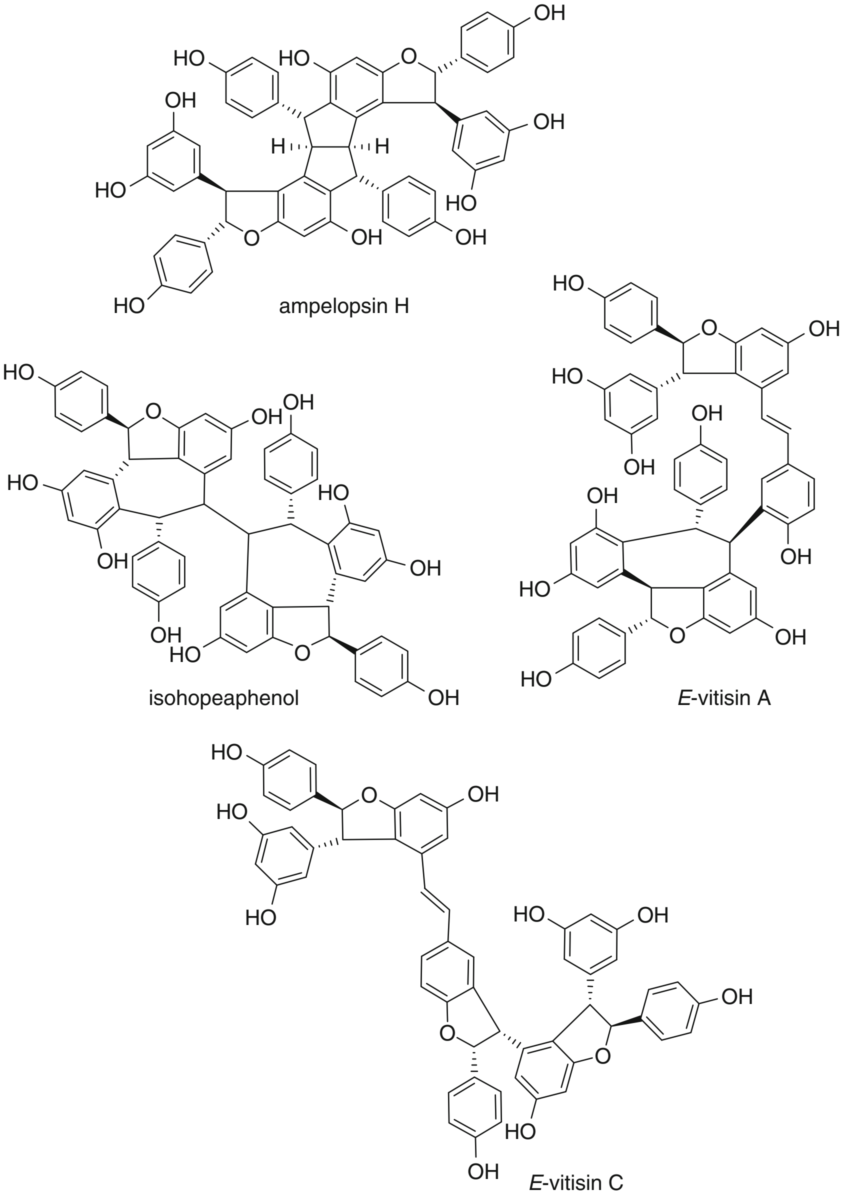

Fig. 73.3 Stilbenoids tetramers

Z-ω-viniferin, ampelopsin D, quadrangularin A, respectively, together with the known dimers: *E*- and *Z*-ε-viniferin, and pallidol. In addition, four trimers were found, *Z*-miyabenol C and *E*-*cis*-miyabenol C new in *V. vinifera*, along with α-viniferin and *E*-miyabenol C. Three tetramers new to grapevine, isohopeaphenol, ampelopsin H, and a vaticanol C-like isomer, were also characterized (Fig. 73.3, [23]).

2.1.3 Stems

In the stems, a greater number of stilbenoids have been isolated and identified than in other plant parts. These include the monomers and dimers *E*- and *Z*- resveratrol, piceatannol, *E*-piceid, (+) − ampelopsin A [29], pallidol [30], scirpusin A [31], ε-viniferin [29], ε-viniferin glucoside [32], viniferifuran [33], and (−)-malibatol A [34], along with the trimers *E*-miyabenol C [35] and (+)-viniferol D [36] and tetramers viniferol A, hopeaphenol, isohopeaphenol [34], viniferol B and C [37], *E*-vitisin A, B, and C [38], and vitisifuran A and B (Fig. 73.3, [33]).

2.1.4 Roots

From the roots, five stilbenoids have been isolated, including resveratrol, ε-viniferin (dimer), gnetin H (trimer), hopeaphenol, and r-viniferin (tetramers) [39].

2.2 Determination of Stilbenoids in Wine

Of the 18 stilbenoids identified in various wines, 13 have been quantified. These molecules include *E*- and *Z*-resveratrol, *E*- and *Z*-piceid, *E*- and *Z*-piceatannol, and *E*- and *Z*-astringin, hopeaphenol, pallidol, parthenocissin A, *E*-ε-viniferin, and *E*-*δ*-viniferin.

Since the first report of the presence of *E*-resveratrol in wine by Siemann and Creasy in 1992, the quantification of these stilbenoids, especially resveratrol, has been carried out by a variety of analytical methods, primarily with HPLC-UV [40] and GC/MS [41–43]. These methods often require prior sample treatment before injection. Nevertheless, HPLC with UV detection has been the most frequently used technique due to its widespread availability. Other quantification techniques include HPLC with a fluorescence detector and LC-MS often with little or no sample preparation required [44].

Resveratrol occurs in wine in free (*E* and *Z*) and glycosidically bound forms. *E*-resveratrol is present in concentrations ranging from trace amounts to 36 mg L^{-1}, averaging 2 mg L^{-1}, in red wines and has been found up to 8 mg L^{-1} in white wines [45]. For the bound forms of resveratrol (piceids), concentrations are reported to be in a range of 0.3–9 mg L^{-1} in red and 0.1–2.2 mg L^{-1} in white wines [41, 46]. Ribeiro de Lima et al. determined piceids and *E*-astringin in Portuguese red wines in concentrations up to 68 mg and 36 mg L^{-1}, respectively [47].

Besides the stilbene monomers, some resveratrol dimers have been characterized from wines. From German commercial Riesling white wines, ε-viniferin diglucosides and pallidol mono- and diglucosides have been identified at very low levels (<0.05 mg/L) [48]. From French commercial red wines, low levels (from 0.5 to 4.8 mg L^{-1}) of *E*-ε-viniferin, parthenocissin A, and pallidol have been isolated [44, 49]. From Brazilian red wines, *trans*-*δ*-viniferin was found, but only in one of the vintages tested (2002), with an average level of 11.7 mg L^{-1} [50].

The only known tetramer to be unambiguously identified in wine, hopeaphenol, has been quantified in Pinot Noir wines from Burgundy in addition to a range of North African wines, where their concentrations have ranged from undetectable levels to 2.1 mg L^{-1} [51, 52].

HPLC-MS has now become the analytical method of choice for the quantitation of stilbenoids in the grapevine and wine. Buiarelli et al. developed a method for the quantitation of several stilbenoid monomers (*E* and *Z* forms of resveratrol, piceid, piceatannol, and astringin) in 19 red and 3 white Italian wines by HPLC-MS-MS using a triple quadrupole mass spectrometer without the need for sample preparation [53]. The detection limits were about 50 ng mL^{-1} for all these monomers.

Red wines contain larger amounts of stilbenoids than white wines, regardless of the enological technology applied. The extent of maceration with skins during fermentation is the main factor determining the concentration of stilbenoids in wines. They generally require long maceration times to be extracted efficiently [42, 54]. The increase of alcohol, due to fermentation during maceration, also promotes the extraction of stilbenoids from the grape skins.

3 Pharmacological Applications and Mechanisms of Action

3.1 Neurodegenerative Diseases

For demographic reason, the percentage of neurodegenerative diseases is increasing. These disorders, which result from deterioration of neurons, are classified into two categories: (1) movement disorder pathologies such as Parkinson's disease and (2) cognitive deterioration pathologies and dementia such as Alzheimer's disease (AD). The majority of neurodegenerative studies have focused on AD, which is the most common type of neurodegenerative disorder, accounting for 65% of all dementias. The prevalence of AD is estimated to be between 1% and 5% among people aged 65 years and doubles approximately every 4 years, where it reaches about 30% at 80 years [55]. The number of people with AD could rise from about 26 million today to more than 100 million worldwide by 2050 [56].

Histopathology studies reveal that one of the major characteristics of AD is the excessive accumulation of two types of proteins, tau proteins and β-amyloid peptide (Aβ) (Fig. 73.4, [57]). β-amyloid originates from proteolytic cleavages of the transmembrane amyloid precursor protein (APP) [58]. APP can be cleaved by different proteases, called α-, β-, and γ-secretases. The α-secretase cleaves APP into a nontoxic amyloid form, whereas β-secretase, followed by γ-secretase, cleaves the APP to form Aβ peptide. Normally, this Aβ peptide is quickly removed from the brain through clearance mechanisms. However, buildup of the Aβ peptide can occur by either overproduction or defective clearance. This buildup can lead to extracellular self-aggregation into assemblies, ranging from soluble high-molecular-weight Aβ oligomers to fibrils and amyloid plaques. These different assemblies promote inflammation and activate neurotoxic pathways, leading to dysfunction and subsequent death of brain cells [56, 59]. Recent studies suggest that the small Aβ oligomers cause more damage to synaptic and cognitive functions than larger amyloid plaques [56]. Moreover, these Aβ oligomers can interact with cell surface receptors which stimulate NF-κB signaling in microglia (resident immune cells) and astrocytes, triggering the release of inflammatory and neurotoxic mediators [60].

Fig. 73.4 Main key players involved in AD

Proinflammatory cytokines can interact with the processing and production of Aβ peptide in neurons, suggesting that chronic, unresolved inflammation may be the initial steps in AD in certain individuals [61]. Indeed, the inflammatory activity of immune cells (macrophages and microglia) and of astrocytes increases with age, which is the most important risk factor for AD [56]. The accumulation of soluble Aβ oligomers is also accompanied by markedly increased intracellular calcium, due to the upregulation of calcium channels expression, leading to neuronal cell dysfunction and death [62]. The second major protein implicated in Alzheimer's pathology, tau protein, is a microtubule binding protein, which can become detached from microtubules after abnormal hyperphosphorylation and also self-aggregate into oligomers and inclusions, known as neurofibrillary tangles, within neurons. The presence of inclusions gradually filling the intracellular space, combined with destabilization of the microtubules, can seriously impair neuronal function and kill neurons [63]. Studies support that Aβ peptide can facilitate tau pathology [64], but Small and Duff hypothesize an alternative model that links Aβ elevations and tau hyperphosphorylation by separate mechanisms driven by a common upstream molecular defect [65].

3.2 Wine and Neurodegenerative Diseases

To test the ability of red wine consumption on the development of an Alzheimer's disease, two different wines were administered to mice in two separate studies.

For both studies, the transgenic mice (Tg2576), a model of Alzheimer's disease was used. These mice manifest Aβ peptide accumulation in the brain after 7 months of age. In the first study, Wang et al. used a Cabernet Sauvignon in drinking water with a final ethanol concentration of 6%, from 4 to 11 months [66]. Red wine consumption was compatible with general good health of the mice and attenuated spatial memory decline and Aβ neuropathology. The concentration of Aβ peptides and amyloid plaque burden in the neocortex and hippocampus of treated mice was notably reduced in comparison with ethanol controls. Red wine promoted the non-amyloidogenic pathway, through an increase in α-secretase activity, which may prevent the synthesis of toxic Aβ peptides. The quantity of red wine consumed by mice was equivalent to a human daily intake of two to three glasses, which is a moderate consumption. The role of resveratrol in this study was not well established because the wine used contains only a very low level of resveratrol (0.2 mg/L) and the analysis of additional stilbenoids was not performed. In a second study, these authors tested a wine from another species, Muscadine wine made from *V. rotundifolia*. Muscadine wine has been found to contain resveratrol, but very little additional chemical studies have been performed on this plant. Using HPLC-UV and comparison with known standards, the authors demonstrated a distinctive chemical profile of major compounds from the previously used Cabernet Sauvignon wine [67]. Muscadine treatment also attenuated AD phenotype in AD mouse model but through a different mechanism. Both treatments inhibited the aggregation of Aβ peptides, but the α-secretase pathway was not promoted by Muscadine. These studies suggest that specific polyphenols from the different red wines may beneficially modulate AD phenotypes through multiple Aβ-related mechanisms. Consuming a combination of multiple polyphenols with complementary activities, present in foods and/or drinks, may be optimal for AD prevention. These authors also tested a grape seed polyphenol extract comprised of catechins in monomeric (8%), oligomeric (75%), and polymeric (17%) forms, using the same transgenic mouse model of AD [68]. When orally administered to the mice at a dose equivalent to 1 g day^{-1} in humans, this extract significantly reduced the level of Aβ peptides in the brain, mainly the soluble extracellular high-molecular-weight oligomeric Aβ species, considered a major risk factor for the onset and the progression of AD dementia. The extract might exert this effect through the prevention of Aβ oligomerization, as shown in vitro [68]. A reduction in amyloid plaque burden was also found. These beneficial effects were correlated with the attenuation of cognitive impairments.

3.3 Stilbenoids and Aβ peptides

Several studies have investigated the effects of resveratrol and of several other stilbenoids on AD for their ability to modulate multiple mechanisms of AD pathology [60]. In vitro studies have shown that resveratrol may protect against the Aβ peptide-induced toxicity in PC12 neuronal cells or primary neurons by influencing apoptotic signaling pathways, reducing changes in mitochondrial membrane potential, and inhibiting the accumulation of reactive oxygen species [69–72]. The stilbenoid tetramer, vitisin A, and piceatannol exert much stronger protective effects than resveratrol on Aβ-induced PC12 cell death [71, 73]. Marambaud et al. also showed that resveratrol markedly lowers the levels of secreted and intracellular Aβ peptide produced in different APP-transfected cell lines, but resveratrol did not reduce Aβ synthesis due to its lack of effect on the β- and γ-secretases [74]. The treatment of these cells with selective proteasome inhibitors significantly blocked the resveratrol-induced decrease of Aβ, which demonstrated a potential proteasome-dependent anti-amyloidogenic activity of resveratrol. In another study, however, Jeon et al. reported that resveratrol and scirpusin A have a relatively specific inhibitory activity on β-secretase [75]. These results all together suggest that resveratrol and other stilbenoids may protect neurons against Aβ injuries.

Recently, a therapeutic approach that interferes directly with the neurodegenerative process in AD, particularly the accumulation and the aggregation of Aβ, is considered one of the most promising targets to alter the progression of the disease, rather than merely treating the symptoms [76]. Several studies suggest that polyphenols could prevent AD or delay its onset by directly inhibiting the Aβ aggregation and the formation of Aβ fibril deposits in the brain [77, 78]. This would be particularly advantageous since monomeric Aβ could act as natural antioxidant that prevents neuronal cell death caused by oxidative stress, whereas Aβ oligomers and fibrils are neurotoxic [79]. Using in vitro assays, we recently reported that resveratrol derivatives inhibit the aggregation of the peptide (25–35 fragment) and destabilize the preformed oligomers and fibrils [80–82]. Initial screening of 4 monomers, 4 dimers, and 6 stilbenoid oligomers from grapevine for inhibition studies was performed at a concentration of 10 μM, with curcumin as the positive control. Five stilbenoids exhibited peptide aggregation inhibition activity better than that of curcumin. These were further tested to determine their IC_{50} values. The IC_{50} values of all compounds are summarized in Table 73.1.

Among all the compounds tested, resveratrol, piceid, and the dimers, scirpusin A and ε-viniferin glucoside, exhibited the most significant inhibition of Aβ aggregation. Of the monomers tested, resveratrol and its glucoside (piceid) showed the strongest inhibition of the peptide aggregation. Examination of the inhibitory data for the stilbene monomers suggests some potential structure-activity relationships (Table 73.1) [82]. The presence of a single hydroxyl group in the *para* position on ring B and at least one hydroxyl group on ring A is essential for the protective activity against Aβ aggregation, suggesting that hydrogen bonds might play an important role in the binding process. Of the three stilbene dimers, two had considerable inhibitory activity: scirpusin A (0.7 ± 0.3 μM) and ε-viniferin glucoside (0.2 ± 0.3 μM). These two compounds differed only by two substituents. Scirpusin A had an additional hydroxyl group, whereas ε-viniferin glucoside has a glucose unit. It is very difficult to draw any conclusions on the structure-activity relationship using this limited data set. Nevertheless, their strong inhibitory activity in vitro warrants further investigation into their

potential as therapeutic agents in AD treatment and prevention. Unlike the stilbene dimers, the stilbene oligomers, both the trimers and tetramers, were weak inhibitors. These results suggest that spatial constraints are critical in the binding process. However, other oligomers need to be tested to confirm that bulkier compounds lack activity since results indicate that the inhibitory effect depends not only on the specific ring substituents but may also depend on the overall 3D structure [81].

Since the full-length Aβ (1–40) and Aβ (1–42) peptides are more biologically relevant than the fragment Aβ (25-35) peptide, we then investigated the effects of ε-viniferin glucoside on their aggregation and cytotoxicity [83]. ε-Viniferin glucoside inhibited the fibrillization and the toxicity in PC12 cells of both full-length peptides with the same level as the fragment peptide. Using mass spectrometry (Fig. 73.5), we observed non-covalent complex between ε-viniferin glucoside and Aβ (1–40) peptide at 2/1 stoichiometry. Therefore, ε-viniferin glucoside could act on Aβ polymerization at an early stage in the process. The binding may lock the peptide conformation and thus prevent nucleation. NMR experiments will be conducted to extend the molecular knowledge of this interaction.

When orally administered to a transgenic mouse model (Tg19959) of Alzheimer's disease at a dosage of 300 mg/kg for 45 days, resveratrol reduces plaque formation mainly in medial cortex (−48%), striatum (−89%), and hypothalamus (−90%) without alterations in APP processing or SIRT-1 activation [84].

However, resveratrol was not detectable in the brain, but the precise mechanisms by which it reduces Aβ pathology was not elucidated; however, it did alter brain glutathione levels. Using a scaling factor of 0.08, the authors find a human equivalent of 1.68 g per day for a 70-kg person.

3.4 Resveratrol and Tauopathies

To test the effect of resveratrol on Alzheimer's disease and tauopathies, the inducible p25 transgenic mouse model [85, 86] was used. For this study, resveratrol was dosed via intra-cerebroventricular injection for 3 weeks, which prevented neurodegeneration in the hippocampus and cognitive decline [87]. Moreover, resveratrol reduced the extent of cell death caused by p25 in transfected primary neurons. SIRT-1 deacetylase was found to be involved in these resveratrol's neuroprotective effects in both the in vitro and in vivo studies.

3.5 Stilbenoids and Neuroinflammation

Inflammatory processes within the nervous system are driven by mononuclear microglial cells and are thought to play an important role in the pathogenesis of neurological disorders, including meningitis, encephalitis, and Alzheimer's and Parkinson's diseases [88]. Microglia are normally quiescent but can be activated by exposure to bacterial lipopolysaccharide (LPS) or Aβ [89, 90]. Thus, activated microglia are capable of producing a variety of proinflammatory mediators including proinflammatory cytokines such as interleukins (IL-1β, IL-6) and tumor necrosis factor (TNF)-α, reactive oxygen species (ROS), nitric oxide (NO), and prostaglandin E_2 (PGE_2) [91, 92]. Although NO and ROS contribute to the killing of microbial pathogens, they also interact to form peroxynitrite, which is toxic to the neurons when cocultured with LPS- or Aβ-stimulated microglia [93]. In addition, they can exacerbate proinflammatory cytokine production in response to these stimuli [94]. Since proinflammatory cytokines can, in turn, contribute to the synthesis of NO, this may lead to a self-propelling circle of NO, ROS, and proinflammatory cytokine production and uncontrolled inflammation [91].

A number of stilbenoids have been tested using an activated microglia model. In vitro studies show that resveratrol inhibits LPS-induced TNF-α, NO, iNOS expression, and ROS production in microglia [72, 95–97] by inhibiting IκB degradation, which prevents the nuclear translocation of the transcription factor NF-κB [96]. This activity was also found with piceatannol and pterostilbene [92, 97]. Resveratrol also potently inhibited prostaglandin E_2 production in LPS-activated primary rat microglia without affecting COX-2 expression in this model [98]. In our lab, we have evaluated the effect of several stilbenoids from grapevine and wine at 10 μM concentration on NO, TNF-α, and ROS production by LPS-activated BV2 microglia (Table 73.2). Hopeaphenol, and *E*-vitisin A were found to be toxic to BV-2 cells, whereas *Z*-piceid, ampelopsin A, quadrangularin A, and *E*-miyabenol C were not active. Ten stilbenoids were effective in reducing LPS-induced nitrite production at 10 μM, with the percentage of inhibition ranging from 10.9% to 89.1%. The IC_{50} values of *E*-vitisin B, *E*-piceatannol, *E*-ε viniferin, *E*-δ-viniferin, and *E*-resveratrol were all less than 15 μM, at 6.4, 7.8, 8.3, 12.4, and 13.9 μM, respectively. Among these compounds, only *E*-vitisin

B significantly reduced LPS-induced ROS (29.0%) and TNF-α (41.9%) production. Our findings indicate that glycosylation decreases the activity of *E*-resveratrol monomers. Similarly, the presence of an *ortho*-hydroxy structure on ring B is relevant for monomer activity, if we compare those of *E*-resveratrol and *E*-piceatannol. Interestingly, the stilbenoid tetramer, *E*-vitisin B, was more effective than the other stilbenoids tested. However, as stated previously, *E*-vitisin A, which only slightly differs from *E*-vitisin B, was found to be cytotoxic at 10 μM to BV-2 microglia. We therefore investigated the effects of a lower concentration of *E*-vitisin A and found that 5 μM reduced NO production by LPS-activated BV-2 cells (71%) without being cytotoxic. These findings are in accordance with those obtained in the RAW 264.7 macrophage cell line [99]. Since *E*-vitisin B and *E*-vitisin A are both tetramers derived from *E*-resveratrol, they may exert anti-inflammatory effects similar to resveratrol through decreased activation of the NF-κB signaling pathway, thus reducing the expression of TNF-α and iNOS.

Vitisin B is a stilbenoid with promising antioxidant and anti-inflammatory effects that may prove effective in slowing down microglia-driven neuroinflammatory processes.

In vivo studies show that dietary supplementation of resveratrol reduced the LPS-induced deficits in spatial working memory in aged mice and also the production of interleukin-1β (a proinflammatory cytokine) in the periphery and the brain. In addition, resveratrol was shown to inhibit interleukin-1β production by LPS-stimulated microglia in vitro [100]. In healthy volunteers, the activation of NF-κB in circulating peripheral mononuclear cells was prevented by the moderate consumption of alcohol drinks containing polyphenols such as red wine during a fat-enriched diet [101]. In a gerbil ischemia model, administration of resveratrol during the early stage of cerebral ischemia protects against neuronal cell death in the hippocampal CA1 area and concomitantly inhibits glial cell activation [102]. Again, in a colchicine-induced Alzheimer's disease model, chronic treatment with orally administered resveratrol (10–20 mg kg^{-1}) greatly reduced the cognitive impairment and oxidative stress markers in the rat brain [103].

Stilbenoids, and resveratrol in particular, appear to interact with various molecular mechanisms involved in AD and thus exert neuroprotective properties.

4 Toxicity of Resveratrol

Safety studies have been conducted on *E*-resveratrol synthesized by DSM Nutritional Products Ltd. in multiple in vitro and in vivo animal studies (>99% purity) [104]. It was shown in this work that resveratrol is nonirritating to the skin and eyes of rabbits and non-sensitizing. It was non-mutagenic in the Ames test with *Salmonella typhimurium* and *Escherichia coli*. A positive clastogenic activity was found in a chromosome aberration test with human lymphocytes, but in an in vivo micronucleus test in rats, with a dose up to 2 g kg^{-1}, resveratrol was not genotoxic. To evaluate the possible oncogenicity of resveratrol, p53 knockout mice were treated daily by gavage for 28 consecutive days [105]. These mice deficient in the tumor suppressor gene p53 showed no increase in the incidence of malignant or benign tumors at the maximum tolerated dose, 1 g kg^{-1} day^{-1}. No evidence of oncogenicity was found with this model. Higher doses (2 or 4 g kg^{-1} day^{-1}) induced toxicity and mortality. The target organ was mainly the kidney [105, 106]. Histopathology showed hydronephrosis and also urothelial hyperplasia [105].

Some studies have found that resveratrol exhibited a weak estrogenic activity in vitro [107]. Indeed, resveratrol was shown to have a low affinity for the estrogen receptor, about 5 orders of magnitude lower than diethylstilbestrol and estradiol [104]. However, a recent in vivo uterotrophic assay with immature female rats was negative [108]. Moreover, the administration of resveratrol at a dose of 0.75 g kg^{-1} day^{-1} to pregnant rats did not induce any adverse effects on embryo-fetal survival and development [104]. The no observed adverse effect levels (NOAEL) for resveratrol obtained in different general toxicity studies in rats, rabbits, and dogs, from subacute to chronic in duration, 1–6 months, are always dosed between 0.25 and 0.75 g kg^{-1} day^{-1} [104, 108, 109]. These data show a good interspecies concordance, and no increase in the toxicity of resveratrol has been observed with the increase of the treatment duration. Due to these studies, the 0.75 g kg^{-1} day^{-1} dose was defined as the NOAEL for resveratrol [108]. To calculate the acceptable daily intake (ADI) in human, a standard default safety factor of 100 is often applied to data from toxicity studies, which gives an ADI of 0.45 g^{-1} day^{-1} for a 60-kg individual. However, the adverse effects in humans have been investigated in some studies after ingestion of higher doses of resveratrol, up to 5 g^{-1} day^{-1} for a single dose and for chronic administration [110–112]. The consumption of resveratrol by humans at these doses did not cause serious adverse events in these studies. For example, after 29 daily doses of 0.5, 1, 2.5, or 5 g resveratrol, healthy volunteers exhibited mild adverse effects only for the doses in excess of 1 g per day [112]. The majority of the participants on the two highest dose levels presented at least one adverse effect. The most common toxicity possibly due to resveratrol was gastrointestinal including nausea, flatulence, abdominal discomfort, and diarrhea. Typically, the onset of gastrointestinal symptoms was 1 h after ingestion with improvement throughout the day. It was also found that resveratrol at a dose of 1 g day^{-1} might manifest adverse metabolic drug interactions in inhibiting certain cytochrome P450 isoenzymes, which could potentially lead to increased adverse drug reactions or altered drug efficacy in people on medication [113].

5 Bioavailability and Metabolism

5.1 In Vivo and In Situ Studies in Rodents

Since 1995, several studies have contributed to the clarification of *E*-resveratrol bioavailability. The first experiments on absorption and distribution of resveratrol in vivo were performed by Bertelli and coworkers in rats [114]. They evaluated the concentration of resveratrol in the plasma, urine, heart, liver, and kidney after oral administration of 4 mL of red wine containing 6.5 mg L^{-1} of resveratrol. The result shows that resveratrol is quickly absorbed, reaching its peak concentration (20 ng mL^{-1}) approximately 60 min after wine ingestion, with initial resveratrol concentration observed after 30 min. In the liver and kidneys, the highest concentrations were reached after 1 h. A second group of rats was given a daily dose of 2 mL of red wine containing 6.5 mg L^{-1} of resveratrol for 15 days. The values obtained indicate a higher concentration in the different organs, particularly in the liver. However, the authors suggest that the amount of resveratrol found in these different tissues was lower than that required for pharmacological activity.

Numerous studies have shown that dietary polyphenols are subjected to metabolic conversion in the liver and also during their absorption in the intestine before reaching the systemic circulation. Andlauer et al. investigated the absorption of resveratrol using an isolated preparation of luminally and vascularly perfused rat small intestine [115]. They showed that 46% of the luminally administered resveratrol was extracted by the small intestine and 21% appeared on the vascular side. The majority of the absorbed resveratrol was two glucuronide derivatives (80%). However, they did not identify the glucuronidation sites of these stilbenoids. In our laboratory, we identified two monoglucuronides of resveratrol using human liver microsomes, which corresponded to glucuronidation at positions 3 and 4′ [116].

Several studies describe the bioavailability of labeled resveratrol in vivo. Soleas et al. used tritiated resveratrol and showed that 77–80% of this stilbenoid may be absorbed in the rat intestine [117]. However, only trace amounts of radioactivity were detectable in the liver, kidney, heart, or spleen. In our laboratory, Vitrac et al. investigated the absorption and tissue distribution of ^{14}C-resveratrol following oral administration to mice [118]. The concentrations of drug-related radioactivity in the various organs are measured. Three hours after administration, radioactivity was found in the brain, lung, heart, liver, kidney, spleen, duodenum, colon, and testis. The highest concentration of radioactivity per organ was found in the duodenum. The kidneys contained the second highest amount of labeled resveratrol, followed by the lungs and liver. Substantial amounts were present in the colon and spleen, while moderate radioactivity was present in the heart, testis, and brain. The low concentration of radioactivity in the colon suggested that there are low levels of fecal elimination. On the contrary, decreasing concentrations of radioactivity in kidney over time indicates that renal excretion might be one of the major modes of elimination of the ^{14}C labeled resveratrol, which was also supported by the high concentrations found in urine. We also found that the concentration of radioactivity in whole blood was relatively low and constant during the experiment period (6 h). The observations were consistent with the recent results found by Juan et al. [119]. Ninety minutes after intravenous administration of 15 mg kg^{-1}, resveratrol and its conjugates were widely distributed in all the tissues studied (liver, kidney, lungs, testis, and brain). The highest concentrations were found in kidney and the lowest in brain.

5.2 Studies in Human

After these in vivo and in situ experiments in animals, the absorption of resveratrol by humans was performed. Soleas et al. [120] was the first to measure free and conjugated resveratrol in plasma and urine. Volunteers were given 25 mg of resveratrol orally in 120 mL of white wine. The plasma concentrations of free resveratrol and glucuronide and sulfate conjugates peaked at 30 min. At this time, the concentration of resveratrol conjugates was 48-fold higher than the free resveratrol (338 μg L^{-1} vs. 7.1 μg L^{-1}). Over the 24-h collection period, 24.6% of the resveratrol was recovered in the urine, predominantly in conjugated form. Walle et al. evaluated the absorption after oral administration of 25 mg of ^{14}C-labeled resveratrol [121]. They determined a peak plasma resveratrol equivalent concentration, based on total radioactivity, of 491 μg L^{-1} at 1 h after the dose.

In these two studies, the plasma concentration of the free resveratrol aglycone was less than 2% of the total resveratrol concentration. Walle et al. showed that most of the radioactivity after oral dosing was recovered in urine (53–85%) but also in feces (0.3–38%) [121]. For the structure identification of resveratrol metabolites in urine, a larger unlabeled dose (100 mg) was given to one subject. Five major metabolites were identified, including two resveratrol monoglucuronides, a dihydroresveratrol monoglucuronide, a resveratrol sulfate, and a dihydroresveratrol sulfate. The sulfate conjugates excreted in urine were the major metabolites. Intestinal microflora was suggested as the potential source of hydrogenated resveratrol metabolites formed by saturation of the aliphatic double bond. Boocock et al. determined six major conjugated metabolites in the plasma and urine of human volunteers after administration of an oral dose of 1 g: two monosulfate conjugates, one disulfate, two monoglucuronides, and one glucuronide sulfate [122]. Two more conjugates (one disulfate and one diglucuronide) were identified in plasma and urine from nine volunteers after oral administration of 85.5 mg of piceid, the major resveratrol glucoside found in wine and grapes, by Burkon and Somoza [123].

Some studies aimed to characterize the effect of matrix and food on the absorption of resveratrol. Golberg et al. reported no major differences among the three matrices used, grape juice, white wine, and V-8 homogenized vegetable cocktail, containing 25 mg of resveratrol [124]. It appears that the biggest impact on resveratrol pharmacokinetics occurs when administered with a high-fat source. La Porte et al. who investigated the pharmacokinetics of 2 g of resveratrol administered twice daily with food, showed that a high-fat breakfast decreased the area under the plasma concentration–time curve from 0 to 12 h and maximum plasma concentration by 45% and 46%, respectively, when compared with the standard breakfast [125]. These data suggest that food has an important effect on the systemic exposure of resveratrol.

In a dose escalation study, Boocock et al. evaluated the safety and pharmacokinetics of resveratrol administered as a single dose (0.5, 1, 2.5, or 5 g) [111]. The peak plasma concentration of the parent molecule across the four dose levels ranged from 73 to 539 ng mL^{-1} (0.3–2.4 μM). The authors suggest that these concentrations are markedly below the resveratrol concentration required in in vitro experiments to elicit pharmacological effects associated with cancer chemoprevention (>5 μM). The most abundant metabolites were resveratrol 3-sulfate and two resveratrol monoglucuronides, with area under the plasma concentration curve values up to 23 times greater than those of resveratrol.

Since the first investigations on the bioavailability of resveratrol, the improvement of analytical techniques has allowed increasingly lower detection limits of resveratrol, in addition to allowing the identification and measurement of its metabolites. While there is great heterogeneity in the experimental conditions used in research on resveratrol in humans, a few conclusions can be made. Upon oral administration, resveratrol is rapidly absorbed, yielding peak plasma concentration between 0.5 and 2 h post dose. Resveratrol has a low bioavailability even with high doses. The low concentration of the free form in plasma is due to a rapid and extensive metabolism in the intestine and liver before distribution to various tissues. The main metabolites described in plasma and urine are the conjugated metabolites of resveratrol (glucuronic acid and/or sulfate), but some authors also identified conjugates of dihydroresveratrol.

5.3 Levels of Resveratrol and Its Metabolites in Target Tissues

Currently, some questions remain unanswered. For example, in vivo studies in rodents report the parent compound and metabolites in target tissues. Abd El Moshen et al. described the tissue distribution of ^{3}H-resveratrol in rat following oral administration of 50 mg kg^{-1} [126]. They detected resveratrol and its glucuronide conjugate in plasma and tissues (kidney, liver, heart, lung, testis, and brain). More recently, Juan et al. reported that resveratrol glucuronide was identified as the major metabolite after an intravenous administration of resveratrol (15 mg kg^{-1}), but the sulfated form was also widely distributed (in lower levels than resveratrol or the glucuronide) [119]. In humans, only one study has quantified resveratrol and its metabolites in target tissue, where it was examined in tumor and normal colon tissues [127]. In this study, 20 patients with histologically confirmed colorectal cancer consumed eight daily doses of resveratrol at 0.5 or 1 g before surgical resection. Parent compounds plus two monoglucuronides, two sulfates, one disulfate, and one resveratrol sulfate glucuronide were identified. The highest mean concentrations of resveratrol and metabolites are found in normal tissue localized proximal to the tumor. These concentrations reached 674, 86, 67 nmol g^{-1} for resveratrol, resveratrol-3-glucuronide, and resveratrol-3-sulfate, respectively. These authors suggested that daily oral doses of resveratrol produce levels in the human gastrointestinal tract at a level sufficient to elicit anticarcinogenic effects. Even if some quantitative differences exist between human and rodent studies, it seems that resveratrol and its glucuronide and sulfate conjugates are present in organs. Recent data suggests that the 3- and 4′-sulfates engage several mechanisms consistent with anticancer activity [128, 129]. However, more investigations are needed in the evaluation of the potential biological activity of resveratrol metabolites. On the other hand, some authors have suggested that sulfatases and ß-glucuronidases could convert the metabolites back to resveratrol in human target tissues and that other stilbenoids, such as piceid and oligomers of resveratrol, may represent alternative forms of resveratrol administration [123, 130].

6 Other Biological Activities

Stilbenoids have a wide range of pharmacological and biological actions, primarily in regard to cancer and cardiovascular diseases. Moreover, resveratrol appears to mimic calorie restriction and extend lifespan in certain species.

6.1 Cancer Chemoprevention

Clifford et al. reported that a diet with red wine solids delayed the onset of tumors in transgenic mice, which spontaneously develop externally visible tumors without carcinogen pretreatment [131]. Systemic administration of resveratrol has been shown to inhibit the initiation and the development of tumors in about 30 rodent cancer models, but there are a few exceptions in which no benefit has been found [132]. Moreover, the study of tumorigenesis in a mouse skin cancer model showed that topical application of resveratrol reduced the number of skin tumors per mouse by up 98% and lowered drastically the percentage of mice with tumors [133]. Resveratrol also exerts protective effects against ultraviolet radiation, mediating oxidative stress and cutaneous skin damage, including skin cancer [134].

Additionally, several reports indicate that *E*-resveratrol inhibits the proliferation of a wide variety of human cancer cells including breast, prostate, colon, gastric, lung, pancreatic, liver, thyroid, and ovarian cancers, leukemia, lymphoma, osteosarcoma, squamous cell carcinoma, multiple myeloma, and medulloblastoma [135]. Among the other stilbenoids, piceatannol, α- and ε-viniferin, hopeaphenol, pallidol, ampelopsin A, vaticanol B and C, and pterostilbene also showed cytotoxicity and/or antiproliferative effect on different tumor cell lines [136–145].

The cancer chemopreventive activity of *E*-resveratrol was established in various assays reflecting the three major stages of carcinogenesis [133, 146]. Indeed, resveratrol may inhibit carcinogenesis by affecting the initiation, promotion, and progression of cancer through several different mechanisms, via the modulation of signal transduction pathways that control cell division, apoptosis, inflammation, angiogenesis, and metastasis [135, 147–149]:

- The anti-initiation activity was demonstrated by its antioxidant and antimutagenic effects, inhibition of carcinogen bioactivation, induction of phase II drug-metabolizing enzymes, and the stimulation of DNA repair.
- The anti-promotion activity was shown by its blocking action of the stimuli-mediated MAPK pathway activation, inhibition of polyamine synthesis and increase of polyamine catabolism, and inhibition of the production of proinflammatory mediators via cyclooxygenase-2 and lipoxygenase pathways. Resveratrol may also inhibit NF-kB and AP-1 activation.

Resveratrol can modulate the major cell cycle mediators, including cyclins, cyclin-dependent kinases, and inhibitor proteins which lead to arrest the cell cycle through mechanisms varying with the cancer cell type, in G1, S, or G2/M phase; and can induce apoptosis through the p53-dependent mechanism in several cancer cell lines. Previously, we described a cell surface resveratrol receptor on the extracellular domain of integrin αVβ3 in breast cancer cells. Binding of resveratrol to integrin, principally to the β3 monomer, was essential for transduction of the stilbene signal into p53-dependent apoptosis of these cells [150]. Resveratrol may also act through p53-independent mechanism in some cell types.

- The inhibition of progression and invasion mechanisms has also been reported. Resveratrol can affect the expression of the inducible nitric oxide synthase gene, which is partly controlled by NF-kB and thus reduces the abnormal level of NO, which contributes to inflammation and angiogenesis. Moreover, resveratrol can inhibit angiogenesis through the inhibition of polyamine synthesis, the vascular endothelial growth factor, and of the expression of adhesion molecules and matrix metalloproteinases, which is also involved in tumor invasion and metastasis. In vivo studies show the inhibition of tumor-induced neovascularization and metastasis by resveratrol. *E*-Resveratrol markedly reduced proliferation and migration of liver myofibroblasts, major actors in the development of liver fibrosis and cancer progression. It can also deactivate human liver myofibroblasts [151]. From numerous studies using various liver cancer cell lines, chemically induced tumors, as well as implanted cancer in animal models, it now appears that resveratrol is one of the most promising molecules for the prevention and also the therapy of metastatic diseases of the liver [152].

Resveratrol could also affect cancer stem cells based on cancer stem cell theory [153]. This theory asserts that several human cancers are initiated from and maintained by a very small population of tumorigenic cells that are capable of continuous self-renewal which produces the tumor mass. Indeed, resveratrol modulates two major pathways playing a pivotal role in cancer stem cell self-renewal [153].

Resveratrol can be converted to piceatannol by cytochrome P450 enzymes in the liver [154] or overexpressed in a wide variety of human tumors [155]. Piceatannol has a known antileukemic activity and is also a tyrosine kinase inhibitor [156]. Piceatannol can also induce apoptosis in human tumor cell lines [144], inhibit the lipopolysaccharide-induced production of critical mediators of the inflammatory response in different models [157, 158], and suppress NF-kB activation induced by various inflammatory agents [159]. Moreover, piceatannol has antimetastatic activities which might be due to the inhibition of angiogenesis [137]. Recently, Kwon et al. studied the mechanisms underlying these effects [160]. They demonstrated that piceatannol inhibits migration and invasion of prostate cancer cells by the inhibition of interleukin-6/STAT3 signaling. STAT3 is a transcription factor controlling several oncogenic processes.

Several other stilbenoids also have promising cancer chemopreventive activities. The dimer ε-viniferin displayed a more potent inhibitory effect than resveratrol on human cytochrome P450 enzymes involved in bioactivation of numerous carcinogens [161]. ε-Viniferin also possesses anti-inflammatory properties [162], as well as vaticanol B, α-viniferin, vitisin A, vitisifuran A, and hopeaphenol [163, 164]. An orally administered extract containing bergenin, hopeaphenol, vaticanol B and C, and ε-viniferin, exhibited an antitumoral effect against subcutaneously allografted sarcoma in mice [140]. Analysis of structure-activity relationships showed that the substitution of hydroxyl groups of resveratrol to methoxy groups potentiated cytotoxic activity [165, 166]. Pterostilbene exerts various effects including antiproliferative, proapoptotic, antioxidant, anti-inflammatory, anti-invasive, and antimetastatic activities.

6.2 Cardiovascular Protection

Resveratrol and other stilbenoids could be beneficial to cardiovascular health by acting on multiple targets, such as lipoproteins and oxidative stress, platelet aggregation, vasodilation, and myocardial infarction [132, 167, 168].

6.2.1 Antioxidant Activity

The oxidation of low-density lipoproteins (LDL) plays a critical role in the initiation of atherogenesis. Oxidized LDLs are a key component in endothelial injury. They may directly injure the endothelium and play an initial role in the increased adherence and migration of monocytes and lymphocytes into the subendothelial space [169]. Oxidized LDL may bypass the normal tight control exercised by the classical LDL receptor in the macrophages and be endocytosed via nonregulated scavenger receptors. This leads to a rapid accumulation of cholesterol and cholesteryl esters and subsequent foam cell formation. Hence, it is conceivable that oxidative stress accelerates atherogenesis by enhancing LDL oxidation and increasing its accumulation into foam cells. The presence of antioxidants can interfere with the peroxidation process by removing the alkoxyl or peroxyl radicals.

In our laboratory, we have studied the antioxidant activities of pure stilbenoids found in wine [170]. On Cu^{2+}-induced lipid peroxidation on LDL, we showed that three stilbenoids (resveratrol, astringin, and piceatannol) were more effective than Trolox, the water soluble vitamin E analogue. No significant difference was found between *E* and *Z* structures of each molecule, except for resveratrol, with a better activity for *trans*-resveratrol. The glycosylation of *trans*-stilbenoids reduces their activity when compared to the corresponding aglycones, whereas a catechol structure in the B ring increases it. Among these molecules, the most potent antioxidant is piceatannol (aglycone, catechol structure) which was two times more efficient than Trolox. These results are in agreement with other reported data concerning structure-activity relationship studies of resveratrol and its analogues [171]. These compounds can also act by another mechanism, i.e., their complexation with metal ions (iron, copper), which are involved in the generation of free radicals and lipid peroxidation [172]. Moreover, α-tocopherol (the principal form of vitamin E) which functions as a major antioxidant in human LDL can be recycled from its free radical form (α-tocopheryl) by a phenolic compound.

Resveratrol can also prevent the initial events of atherosclerosis in endothelial cells by inhibition of the enzymatic systems producing reactive oxygen species, such as NADPH oxidase and hypoxanthine/xanthine oxidase, and by the inhibition of both the expression of adhesion molecules and the monocyte adhesion to endothelial cells [167]. Moreover, red wine polyphenols, in particular *E*-resveratrol, have been shown to inhibit the proliferation and the migration of vascular smooth muscle cells in intima, notably involved in the formation of atherosclerotic plaques [173]. In fact, resveratrol specifically blocks the mTOR pathway, which is activated by oxidized LDL, and regulates the proliferation of smooth muscle cells [174]. Other stilbenoids have been shown to exert an activity on this target as well. For example, pterostilbene inhibits vascular smooth muscle cell proliferation with an IC_{50} value less than 1 μM [175], whereas vitisin B, a resveratrol tetramer, enhances their proliferation but exhibits an anti-migratory effect [176].

Using a hamster model of atherosclerosis, Auger et al. showed aortic fatty streak area was significantly reduced (76%) in the group receiving resveratrol at a level corresponding to a moderate consumption of red wine [177]. Orally administrated resveratrol in rats maintained on a hypercholesterolemic diet improves the plasma lipid levels altered such as total cholesterol, triglycerides, LDL cholesterol, and HDL cholesterol [178].

6.2.2 Antithrombotic and Vasoprotective Effects

Studies suggested that *E*-resveratrol is particularly active on human platelet aggregation by inhibiting the synthesis of certain eicosanoids [179]. We screened various stilbenoids for their antiplatelet properties on human platelet-rich plasma in which aggregation was induced either with arachidonic acid (AA), ADP, collagen, or the TxA2 mimetics U-46619 [180]. Significant inhibition of AA-induced aggregation was only observed for the aglycones, *E*- and *Z*-resveratrol and piceatannol, with IC_{50} values similar to that of acetylsalicylic acid. These aglycones also showed an antiplatelet activity when collagen or ADP was used as stimulating agent, but only at much higher concentrations. In addition, all derivatives were found to be inactive when U-46619 was tested as aggregation inducer. Based on these findings, the anti-aggregating profile observed for stilbenoids points to an interaction of the compounds with the platelet arachidonic acid pathway through a mechanism consistent with an inhibition of cyclooxygenase. Significant inhibition of AA-induced aggregation was also observed for the tetramer, vitisin A, with an IC_{50} value inferior to that of acetylsalicylic acid, but ε-viniferin (a dimer) had no inhibitory effect [181]. Moreover, *E*-resveratrol was found to modulate intracellular free calcium in stimulated human platelets, which is an essential component of the aggregation process [167]. Interestingly, orally administrated resveratrol prevents in vivo platelet aggregation and thrombus formation in hypercholesterolemic rabbit and mice, respectively [132]. Clinical study showed that resveratrol can inhibit aggregation of platelets from high-risk cardiac patients who are aspirin resistant [182].

Several studies have shown that the extent of coronary artery stenosis due to atherosclerotic plaque formation and expansion into the arterial lumen is not sufficient to explain the incidence of clinical events associated with atherosclerosis [183]. It appears that the generation of clinical events involves plaque rupture, resulting in thrombus formation and arterial occlusion. This rupture is induced by vasomotor disturbances in which oxidized low-density lipoproteins may be involved. Resveratrol is able to regulate vasomotion, which is impaired in atherosclerosis. The key regulators of the vasomotor function are the vasodilator NO and the vasoconstrictor endothelin-1 [167]. A number of in vitro and in vivo studies have shown improved vascular function in response to resveratrol [184, 185]. Resveratrol enhances expression and activity of endothelial nitric oxide synthase [186] and inhibits endothelin-1 secretion and endothelin-1 gene expression in human umbilical vein endothelial cells [187]. Intragastric administration of resveratrol for 12 weeks to hypercholesterolemic rabbits improved the endothelial function, reduced plasma endothelin-1 levels, and induced a significant elevation in NO levels [188, 189]. It was also reported that coronary flow velocity reserve and flow-mediated dilatation of the brachial artery increased specifically after the intake of a red grape polyphenol extract by patients with coronary heart disease [190]. This extract contained mainly flavanols and phenolic acids in addition to *E*-resveratrol and ε-viniferin. These effects may be due to the improvement of endothelial function and the vasorelaxing effects of polyphenols.

6.2.3 Myocardial Infarction

Numerous data in animals strongly suggest that resveratrol might protect against ischemic damage during myocardial infarction [132, 178]. Perfusion of rat hearts with resveratrol before ischemia leads to a better recovery of developed pressure and aortic flow, reduction of malondialdehyde concentrations and of infarct size, and increase of functional recovery of the coronary flow. Hung et al. found a positive correlation between the antioxidant activity of stilbenoids and their cardioprotective efficacy, with piceatannol being notably more active than resveratrol [191]. While the antioxidant properties of stilbenoids are at least partially involved in this myocardial protection, the implication of NO-dependent mechanisms has also been shown [192]. These authors showed that rats receiving drinking water containing a low concentration of resveratrol for 15 days have the heart protected from ischemic reperfusion injury. Resveratrol can also enhance neovascularization in infarcted rat myocardium [193].

Some studies in animals suggest that resveratrol might be useful to protect against brain damage following cerebral ischemia [132].

6.3 Aging and Longevity

Calorie restriction is a very effective nutritional intervention inducing slow metabolism that can extend the lifespan in species ranging from yeast to primates and also protect against obesity, diabetes, and cardiovascular disease [194, 195]. Calorie restriction is believed to extend lifespans, in part, by increasing the activity of sirtuins, NAD^+-dependent deacetylases, although their physiological role may be more complex than expected [195]. Under calorie restriction, the altered oxygen consumption modifies the NAD^+/NAD ratio and leads to an NAD^+-dependent activation of sirtuin, an evolutionary conserved enzyme family which acts by deacetylating histones and nonhistone proteins such as transcription factors, NF-kB, and the p53 tumor suppressor involved in longevity [167, 196]. In a famous paper by Howitz et al. [197], it was shown that resveratrol mimics calorie restriction by stimulating a sirtuin and extending *Saccharomyces cerevisiae* lifespan by 70%, piceatannol lacking any activity. Then, this activity of resveratrol was also found in multicellular animals (short-lived invertebrates), the worm *Caenorhabditis elegans* and the fly *Drosophila melanogaster*, with an increase of longevity of 14% and 29%, respectively, through sirtuin activation [198]. Likewise, this effect was also observed in a short-lived vertebrate, the fish *Nothobranchius furzeri*; resveratrol added to the food caused an extension of the maximum lifespan by up to 59% [199]. In addition, resveratrol delays the age-dependent decay of locomotor activity and cognitive performance in the fish and prevents age-dependent neurodegeneration by decreasing aggregated proteins in the brain [199]. Some controversial results have been found as no increase in lifespan of different yeast strains and *C. elegans* in the presence of resveratrol and no direct activation of a mammalian sirtuin (SIRT1) was observed [195, 200–202]. However, resveratrol has proven to be a valuable tool for mammalian cells in vitro, in which it has been shown to produce SIRT1-dependent effects, but this may occur through an indirect mechanism [203]. No extension of the normal lifespan by resveratrol has been found in mammals, as in mice on a standard diet. However, Baur et al. showed that resveratrol improves health and survival of mice on a high-calorie diet, preventing the early mortality associated with obesity [203]. In fact, resveratrol shifts the physiology of mice consuming excess calories toward that of mice on a standard diet affecting favorably a variety of parameters such as motor function, insulin sensitivity, organ (liver) pathology, mitochondrial number, and 144 of the 153 pathways significantly altered in high-caloric mice (whole-genome microarrays on liver) [203]. Sirtuin activation may constitute a potential strategic target in aging associated diseases such as neurodegenerative diseases and cardiovascular and metabolic diseases [196].

7 Clinical Trials

There is little published evidence of pharmacodynamic effects of resveratrol in humans demonstrating protective or therapeutic effects. The database "clinicaltrials.gov" of the US National Institutes of Health shows a total of 32 clinical studies with resveratrol. Of these studies, seven are examining the effects of this compound on brain functions, five are either active or recruiting, and two are completed. The results from one of these clinical trials are currently available [204]. These authors assessed the effects of resveratrol on cerebral blood variables and cognitive performance in 22 healthy adults by a double-blind, placebo-controlled, crossover study. Cerebral blood flow was evaluated by measure of total and deoxygenated hemoglobin levels in the prefrontal cortex using near-infrared spectroscopy. Single doses of orally administered resveratrol, 250 or 500 mg, led to a significant increase of the cerebral flow in dose-dependent manner during task performance, but cognitive function was not affected. This beneficial action can be due to the vasorelaxatory properties of resveratrol, likely due to an induction of the NO synthesis. A reduced cerebral blood flow is observed in primary neurodegenerative diseases, and in natural aging, which is associated with impaired NO-mediated vasodilatation [204, 205]. In this study, the bioavailability data show the presence of low levels of resveratrol and its metabolites in the plasma, mainly the sulfated conjugate. The second completed study, currently not published, carried out by the same authors was similar to the first one, except the co-supplementation with piperine. The aim was to investigate whether this alkaloid from black pepper may be able to enhance the bioavailability of resveratrol, as previously demonstrated for other phenolic compounds through inhibition of their metabolism [206, 207].

In other pharmacological domains such as cancer, a few studies have been carried out in humans. In the UK study described by Patel et al. [127], twenty patients with confirmed colorectal cancer consumed eight daily doses of resveratrol (0.5 or 1 g) before surgical resection. A small, 5%, reduction in cell proliferation in colorectal tissue after resveratrol consumption was observed, which suggests that these doses are sufficient in the human gastrointestinal tract to favorably alter cell proliferation. Resveratrol (parent) was recovered from tumor tissue and proximal to tumor at maximal levels of 94 and 674 nmol/g, respectively, where it represents the major form, although its conjugates, sulfates, and glucuronides were the dominant forms present in the plasma. These tissue concentrations are compatible with cancer chemopreventive activity of resveratrol because resveratrol has been shown to exhibit growth inhibition and apoptosis induction in human-derived colon cells in vitro with IC_{50} values of about 20 nmol mL^{-1} [127, 208]. The same team also showed that ingestion of resveratrol at 2.5 g day^{-1} for four weeks by healthy volunteers caused a decrease in a circulating insulin-like growth factor (IGF) and an IGF binding protein, which might contribute to chemopreventive activity. Indeed, the IGF signaling system can significantly influence the development of malignancies. In this study, the repeated ingestion of high doses of resveratrol leads to micromolar concentrations of parent and much higher levels of conjugates in the plasma [112].

8 Conclusion

Vine and wine are abundant sources of polyphenolic compounds, including flavonoids and stilbenoids. The latter appear to constitute a large class of compounds, and a number of stilbenoids have exhibited potent biological activities on multiple targets in rodent models and cells in vitro. Within wine, there are almost 20 known stilbenoids, and over 60 in grapevine, a number of which have demonstrated promising biological activities, yet many others have undergone little or no biological evaluations. The sum of these stilbenoids in wine may help explain the health benefits of wine reported in epidemiological studies.

Among the stilbenoids in grapevine, *E*-resveratrol is the most studied due to its promising biological activities in regard to the prevention and treatment of leading diseases, including cancer, cardiovascular diseases, and neurological diseases. Currently, resveratrol is the subject of over 30 clinical trials in the USA alone, including studies on its bioavailability and pharmacokinetics.

In regard to neurological diseases, resveratrol and several other stilbenoids can modulate multiple pathways in neurodegenerative disease pathologies. In Alzheimer's disease, several stilbenoids, including resveratrol, have shown several different activities against the fibrillization of Aβ peptide and prevention of toxicity-induced damage in neuronal cells, including the microglia-driven neuroinflammatory processes. Some data are now available on its bioavailability, biological effects, and toxicity in humans, which have shown the absorption levels based on multiple dosing and acute and chronic side effects of high dosages. Additionally, further investigations are still necessary as to the identification of the endogenous compounds responsible for the biological activity within target tissues and the precise mechanism of its indirect interaction with sirtuins.

Abstract

Cocoa and dark chocolate contain many active compounds, which seem to play some pharmacological roles both in vitro and in human. Many studies have focused their attention on polyphenol content, which is elevated in cocoa beans and in some kind of dark chocolate, depending on harvest and postharvest handling. Procyanidins monomers and oligomers modulate a large quantity of biological mechanisms. Indeed, scientists might be more interested to better understand pharmacological aspects of such compounds in vivo and their

mechanisms of action and interactions with other molecules as well as new medicines. Moreover, some potential adverse effects have to be taken into prompt consideration. This chapter, which is not the result of a specific experimental work but only a short study of recent bibliography on the specific subject, might help in understanding some aspects connected with the chemistry of cocoa and chocolate.

Keywords
Chocolate • cocoa • proanthocyanidins • human health • adverse effects

Abbreviations

APP	Amyloid precursor protein
Aß	Amyloid beta
AUC	Area under the curve
BBB	Blood-brain barrier
COX-2	Cyclooxygenase 2
EDR	Endothelium-dependent relaxation
EGCG	Epigallocatechin gallate
HDL-c	High-density lipoprotein cholesterol
iNOS	Nitric oxide synthases
LDL-c	Low-density lipoprotein cholesterol
mDP	Mean degree of polymerization
NFCS	Nonfat cocoa solids
NF-kB	Nuclear factor kappa-light-chain-enhancer of activated B cells
NO	Nitric oxide
NOAEL	No observed adverse effect level
ORAC	Oxygen radical absorbance capacity
pKa	Acidity constant
UGT	Uridine 5′-diphospho-glucuronosyltransferase

1 Introduction: Health Benefits of Cocoa

Over the last two decades, the scientific community has become aware of the potential health-related benefits of antioxidants and the properties of polyphenols-rich dark chocolate and cocoa. More than 200 studies were reported on bioactive compounds, chemical compositions, and health benefits of cocoa and cocoa products. Many of the proposed health-protective activities associated with the consumption of cocoa and chocolate have been attributed to flavan-3-ols, including monomers. Reported pharmacological activities of procyanidins include antioxidative and anticancer effects, protection against cardiovascular disease, risk reduction of blood clotting, protection against urinary tract infections, decrease of LDL-c, decrease of blood pressure, and improvement of endothelium vasodilatation. Moreover, there is some scientific evidence about an increase in blood flow and perfusion of the brain by

Fig. 74.1 Cocoa beans in a cacao pod

polyphenols, and experimental data suggests that flavanols may delay the onset of neurodegenerative diseases such as Alzheimer's disease through a number of different mechanisms. Preliminary in vitro and ex vivo investigations suggested that cocoa flavanols and procyanidins might possess immunoregulatory effects [1–3]. The potential mechanisms through which flavanols and cocoa might exert their beneficial activity on cardiovascular health include: activation on NO, antioxidant, anti-inflammatory, and antiplatelet effects, which in turn might improve endothelial function, lipid levels, blood pressure, and insulin resistance [4–6].

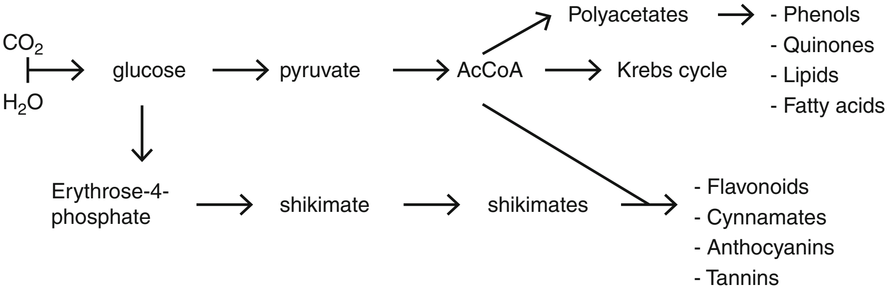
More recently, studies begin to emphasize the bioactivities of flavonoids through modulating several cellular signaling pathways involved in cell apoptosis, proliferation, survival, and inflammatory responses.

Procyanidins seem to represent the second most abundant natural phenolic after lignin and, with other substances, they might be responsible for the oral sensation of astringency in ripening fruits (apples, peaches, grapes, berries), beverages (tea, wine), cocoa and chocolate [7, 8].

It has been showed that chocolate is one of the most polyphenol-rich foods. According to Lee et al. [9], cocoa contains a higher content of flavonoids per serving than teas or red wine. Moreover cocoa powder is one of the richest dietary sources of flavanols (on a weight basis) identified so far, exceeded only by a few food ingredients such as buckwheat hulls, sorghum, cinnamon, and some "superfruit" [10]. Cocoa is also one of the richest dietary sources of polyphenols listed in the Phenol-Explorer database [11] and one of the richest sources of procyanidins in the USDA Database for the Proanthocyanidin Content of Selected Foods [12] (Fig. 74.1).

2 Proanthocyanidins in Cocoa and Cocoa-Derived Products

Polyphenols are common antioxidants present in a wide range of foods and beverages of plant origin. Although still debated and with many differences depending from the studied population, a mean intake of about 1 g per day has been proposed [13, 14].



Scheme 74.1 Secondary metabolism of plants. Glucose metabolism: the shikimate and the acetate pathway

Phenolic compounds or polyphenols constitute one of the most abundant and widely distributed groups of substances in the plant kingdom with more than 8,000 phenolic structures currently known. They are products of the secondary metabolism of plants and arise biogenetically from two main primary synthetic pathways: the shikimate pathway and the acetate pathway. Both acetic acid and shikimic acid are derived from glucose metabolism [15] (Scheme 74.1).

Moreover, according to chemical structure, polyphenols can be divided in classes as simple phenols, benzoquinones, phenolic acids, acetophenones, phenylacetic acids, hrodroxycinnamic acids, phenylpropenes, coumarins, isocoumarins, chromones, naphthoquinones, xanthones, stilbenes, anthraquinones, lignans, neolignans, lignins, and flavonoids. The latter allow to consider 13 subclasses with more than 5,000 compounds (Fig. 74.2).

The absolute structure of flavonoids can vary dramatically; however all plant flavonoids share a common 15-carbon structural backbone designated as C_6–C_3–C_6. Flavonoids share a common structure consisting in two aromatic rings (A and B); differences in the structure of the heterocyclic C ring result in distinct classes of flavonoids, including flavanols, flavanones, flavones, isoflavonols and anthocyanidins (Figs. 74.3, 74.4).

In nature, many flavonoids exist as glycosides, making characterization of compounds even more complex.

Cocoa is a source of many polyphenolic compounds, including hydroxybenzoic acid (gallic, syringic, protocatechuic, vanillic acids), hydroxycinnamic acids and analogues (caffeic, ferulic, p-coumaric, phloretic acids, clovamide, dideoxyclovamide), flavonols (quercetin), flavones (luteolin, apigenin), flavanones (naringenin), and flavan-3-ols monomers ((+)-catechin, (−)-catechin), oligomers and polymers (proanthocyanidins) [18, 19].

Epicatechin and catechin (Fig. 74.4) represent the basis on which to build more complex molecules such as procyanidin polymeric forms. Proanthocyanidins are polymer chains of flavonoids such as flavan-3-ols. Mainly, two primary forms of procyanidins occur in plants: A-type and B-type, which differ by the linkage between individual compounds. A-type procyanidins form 4–8 and 2–7 cross-links and has

been described in cranberries. The B-type procyanidins form 4–8 cross-links. Moreover, B-1-B-4-types differ only in the arrangement of catechin and epicatechin units, with predominant forms being procyanidin B-1 found in grape, sorghum, cocoa, and cranberry, type B-2 found in apple, cocoa, and cherry, type B-3 found in strawberry and hops, and finally type B-4 found in raspberry and blackberry [20]. Kelm et al. [21] indicated that unfermented cocoa beans contain monomers up to 14 subunits (tetradecamer).

2.1 Factors Affecting the Quantity and Quality of Proanthocyanidins

The amount of flavonoids and flavanols in cocoa and chocolate might be highly variable and this variability is multifactorial. For example, plant's genetic predisposition dictates the biosynthesis of the primary (sugars, amino acids, etc.) and secondary metabolites (proanthocyanidins, saponins, alkaloids, etc.) while genetics can cause as much as a fourfold difference in flavan-3-ol content of fresh cocoa beans [22, 23]. Variability with respect to secondary metabolites exists between varieties (or cultivars) of the same species. However, various environmental factors determine the extent to which genetic potentialities are

achieved. Ecology, drought, soil type/structure, disease, herbivore damage, and farming practices (i.e., pruning, application of pesticides, etc.) do have an influence on secondary plant metabolism. The postharvest handling (storage time, temperature, modified atmospheres, etc.) of fruits and vegetables can also impact metabolite levels. Processing effects, such as heating, fermentation, roasting, alkaline treatment (Dutch processing), shearing, and baking, have been shown to reduce both the level of total procyanidins and the level of low molecular weight flavanols. Finally, variability in food component values may be attributable to the differences in analytical methods used to determine the values [12].

Various type of dark chocolate with high flavonoid contents are today available in the market. These chocolates are produced by controlling postharvest processes: fermentation, heating, and alkalization treatments. By controlling the process involved in preparing the chocolates, high-flavonoid chocolate can be produced that preserves up to 70 % of the flavonoids present in the final product. Current regulations do not require that antioxidant capacity and/or polyphenol content be provided on food labels. Inclusion of this information has been suggested [24, 25].

3 Properties of Proanthocyanidins

The discovery of flavan-3-ols and their procyanidin polymeric forms in cocoa can be traced back to the beginning of the last century and are now identified as catechins [26–28]. In 1939, leucoanthocyanin phenolic compounds were identified [29] and, in 1955, fractionation and characterization of these compounds were reported [30]. Procyanidins in cocoa have more recently been fractionated into monomers through decamers with even higher forms existing [31].

Proanthocyanidins have been the subject of more than 2,700 bibliographic entries in the last 65 years [8].

The chemical structures of flavonols and procyanidins might be important for antioxidant activity because of free radical trapping and chelation of redox-active metals properties. Adamson et al. [32] indicated that polyphenol content positively correlated with antioxidant properties as measured by ORAC. All polyphenols possess antioxidant properties in vitro but this activity is not well characterized in human.

Procyanidin-rich chocolate increased the antioxidant capacity, decreased the oxidative stress, and decreased the leukotriene-prostacyclin ratio in humans and human aortic endothelial cells [33, 34]. Procyanidins extracted from cocoa exhibited EDR through activation of nitric oxide synthase activity in rabbit aortic rings in vitro [35]. The results were reported to be due to the tetramers and higher polymers of epicatechin, and monomers, dimers, and trimers were not capable of contributing to EDR. In vivo studies, both in human and animals, indicated that epicatechin from cocoa could enhance the antioxidative activity in plasma. In theory, these antioxidant actions can result in a reduction of the steady-state concentration of free radicals and other oxidants, diminishing the following oxidation of target molecules such as lipids, proteins, and nucleic acids. However, plasma concentrations of flavanol and procyanidin observed after consumption of foods rich in such compounds were relatively low. The actual concentrations that can be

reached in plasma of humans subjected to realistic polyphenol consumption are believed to be in the nanomolar range [36, 37]. This low bioavailability leads to a kinetically unfavorable condition with respect to other compounds with similar free radical scavenger capabilities present in blood in significantly higher micromolar concentrations, that is, tocopherols and ascorbate. According to Galleano et al. [38], a function of flavanols as direct free radical scavengers is unlikely to be relevant, and could be limited to the blood and other tissues directly exposed after consumption, that is, gastrointestinal tract. Moreover, it has been suggested that other mechanisms, compatible with the concentration at target site reached by flavanols, may explain the observed changes in cell or tissue oxidation levels after flavanol consumption. These mechanisms are beyond the ability of flavanols and other flavonoids to directly prevent free radical-mediated tissue damage [37].

Procyanidins have been reported at concentrations from 370 to 23,710 mg/kg in various cocoa products [19, 20, 39] (Table 74.1). Besides other proanthocyanidins, (−)-epicatechin has been reported as the major monomeric flavanol in cocoa, representing ca. 35 % of the total phenolic content [40].

Catechin and epicatechin have been found at concentrations of 150–1,580 mg/kg in chocolate and 2,530–3,170 mg/kg in cocoa liquor [39, 41–44].

Many phenols are found as glycosides in cocoa, mainly glucoside, galactoside, and arabinose. Miller et al. [45] showed that there is a strong degree of correlation between flavanols, with the possible exception of catechin, and % NFCS in chocolate and cocoa-containing products, with cocoa powder being highest and chocolate syrup being lowest in these compounds.

Supplementation of cocoa for 4 weeks significantly improves platelet function among healthy subjects [1]. However, there was no correlation between cocoa intake and plasma antioxidant status. Similarly, cocoa intake decreased LDL oxidation without changes in antioxidant potentials and oxidative stress level in plasma [46]. Dark chocolate supplementation for 3 weeks in healthy subjects significantly increased HDL-c compared to their unsupplemented counterparts [47]. However, there were no changes in total antioxidant capacity and oxidative stress biomarker (8-isoprostane). Similarly, Wan et al. [48] demonstrated that cocoa powder and dark chocolate supplementation improved HDL levels by 4 % compared to control diet, but there were no changes in oxidative stress biomarkers. Milk chocolate bar consumption increased HDL levels compared to high carbohydrate snacks among young men [49]. These studies clearly indicated that cocoa administration did not exert their antioxidative properties in plasma of healthy subjects, although there were significant health outcomes. This could be due to the status of subjects recruited in the study. Cooper et al. [44] reported that healthy subjects may already have optimum dietary status and supplementation will not produce meaningful outcomes.

Cocoa powder exerted anticancer properties in in vivo studies. Amin et al. [50] indicated that cocoa liquor extract lowered the activity of tumor marker enzymes (alkaline phosphatase, gamma-glutamyl transpeptidase, glutathione-S-transferase, and glutathione reductase activities) in plasma and/or liver of hepatocarcinogenic male Sprague-Dawley rats, which were induced with diethylnitrosamine and 2-acetylaminofluorene.

Cocoa powder supplementation significantly reduces the incidence of prostate carcinogenesis compared to positive controls using the *N*-methylnitrosourea and testosterone propionate prostate tumor model on 60 male Wistar-Unilever rats [51]. The supplementation also increased the life span of the tumor-bearing rats. Bisson et al. [52] reported that cocoa powder dose-dependently decreased prostate hyperplasia through reducing dihydrotestosterone level and prostate size ratio. To a greater extent, long-term supplementation of cocoa powder improved cognitive performance in aged rats compared to unsupplemented rats [53]. Daily cocoa extract administration prevented the overproduction of free radicals after heat exposure and thus protect from cognitive impairments [54, 55].

3.1 The Promising Role of Proanthocyanidins

In a mice model of Parkinson's disease, catechins are thought to chelate metal ions such as copper (II) and iron (II) and therefore prevent the generation of potentially damaging free radicals, to suppress the translation of APP mRNA, to reduce holo-APP, and to decrease Aβ levels. After the oxidation of catechins by free radicals, a dimerized product is formed with an increased iron-chelating potential and ability to scavenge superoxide anions [56–58].

In vivo studies on mice have shown that 0.33 % of an EGCG administration can reach the brain and that frequent consumption enables the body to maintain a high level of catechins [59].

Other properties of catechins monomers and oligomers can be summarized as follows:

- Increase antioxidant enzymes such glutathione peroxidase and reductase, superoxide dismutase, and catalase.
- Increase the total plasma antioxidants, whereas decrease the plasma peroxide level.
- Decrease oxidative stress by inhibiting the activity of xanthine oxidase, a ROS-generating system.
- Protect lipids from oxidation in the liver, serum, and brain. For instance, it has been demonstrated that catechins could protect against lipid peroxidation induced by 6-hydroxydopamine, hydrogen peroxide, and iron.

These antioxidant effects are observed in vitro with concentrations ranging from 1 to 50 μM. Interestingly, higher concentrations (100–500 μM) and in the presence of copper (II) or iron (III), EGCG exacerbated oxidative stress, cytotoxicity, and DNA damage induced by hydrogen peroxide. Moreover, EGCG promotes cell survival by restoring the protein kinase C activity, a critical regulator of cell proliferation and survival [57, 60–68].

3.2 Bioavailability and Metabolism of Proanthocyanidins

When discussing the biological activity of flavonoids in general, and flavanols in particular, there are some major factors to be considered: bioavailability from food, matrix effects, absorption and metabolism in the gastrointestinal tract, tissue and cellular distribution after absorption, possible interactions and/or accumulation, which are the chemical form(s) biologically available to the cell/tissue and their potential metabolism at cellular level [3, 42, 69, 70].

Recently, there have been two major approaches commonly used to determine the availability of phenolic compounds either by measuring their concentration in plasma and urine after ingestion of known amount of foodstuffs or ingestion of the pure compounds [71].

Factors that influence the extent and rate of absorption of ingested compounds by the small intestine include molecular size, lipophilicity, solubility, pKa, gastric and intestinal transit time, membrane permeability, and first-pass metabolism [72, 73].

The procyanidins that cross the intestinal barrier are conducted to the liver via the portal vein, where they further degrade into metabolites by methylation, glucorination, and sulfation, which result in the potential antioxidants capacity of flavanols. These metabolites can possibly reach all tissues within hours following consumption as described in radiolabeled experiments with rats. Further modification in the colon gives rise to other bioactivities that are attributed to flavanols. Urine and feces analysis confirmed the presence of low molecular weight metabolites, which indicates that polymeric procyanidins are absorbed through the intestinal barrier after degradation in low molecular weight metabolites, most probably by gut microflora [74, 75].

Although it has been suggested that the metabolism of procyanidin polymers (specifically dimer B-3 and trimer C-2) by intestinal microflora is limited [76], human fecal microflora, grown under anaerobic conditions in vitro, have the ability to degrade procyanidins (mDP = 6) to low molecular weight metabolites within 48 h.

In vitro studies showed that procyanidin oligomers (dimers and trimers) passed through the human epithelial Caco-2 cell monolayer, whereas polymers did not [77].

Epigallocatechin gallate enter the brain after a gastric administration and methylated flavonoids cross the BBB more readily, whereas glucuronide or glycoside conjugates have greater difficulty [59, 78, 79].

It is well recognized that orally administered flavonoids would undergo extensive presystemic first-pass metabolism. Substantial intestinal and hepatic glucuronidation have been found in a number of structurally diverse flavonoids.

Glucuronides of phenolic compounds have generally been assumed to be rapidly excreted in vivo and to be pharmacologically inactive, but several studies are demonstrating that some drug glucuronides may be pharmacologically active [80, 81].

Studies on the stability of procyanidins oligomers isolated from *Theobroma cacao* L. has shown that these compounds are unstable under acidic conditions and decompose to epicatechin monomeric and dimeric units, but also to other oligomeric units [81].

During digestion and transfer across the small intestine, and in the liver, flavanols are rapidly metabolized in phase I and phase II biotransformations to various *O*-sulfated, *O*-glucuronidated and *O*-methylated forms. Various UGT isozymes, expressed in the intestine and in the liver, have been identified to catalyze the glucuronidation of flavonoids. In humans consuming cocoa, plasma levels of non-methylated epicatechins such as epicatechin-7-sulfate and methylated metabolites such as 3′-*O*-methylepicatechin have been reported to occur in micromolar concentrations within 1 h after intake. Metabolic studies have confirmed the presence of these conjugates in the plasma and urine of rodents and humans, as well as in the bile and brain of rats. It has been reported that colonic microflora can break flavonoids flavan structure to form simple phenolics and rig-fission metabolites that may be physiologically relevant.

Studies incubating EGCG with intestinal fluid (pH 6.5) for only 5 min resulted in a significant decrease (81.6 %) in the amount of EGCG, whereas a similar incubation in plasma (pH 7.4) resulted in only a 29.3 % decrease [82].

In summary, non-metabolized flavanols or metabolites of flavanols can exert biological effects depending essentially on flavanol metabolism and presence at target tissue. Certain monomers may be better absorbed than others. For example, in humans consuming a cocoa beverage containing equal amount of epicatechin and catechin, epicatechin was identified to be the predominant plasma flavanol absorbed, with plasma catechin levels reaching less than 10 % of epicatechin concentrations. Part of these differences in plasma flavanol concentrations, could be due to procyanidin degradation: dimers have been shown to form epicatechin and methylated epicatechin under certain conditions, although the physiological relevance of such degradation remains to be confirmed. Although it is uncertain whether the trimers and higher polymers of the flavanols are readily absorbed, it has been suggested that over prolonged exposure, bacterial breakdown and colonic absorption of smaller molecules may occur. Both absorption and metabolism of cocoa-derived catechins appear to be influenced by chocolate matrix [17, 38].

In fact, in a complex food matrix, the pH changes are likely to be buffered on the inside for long periods of time, thus limiting flavanol oxidation during intestinal transit.

Several studies have been performed regarding the influence of milk protein on the bioavailability of epicatechin from cocoa beverages and chocolate. Serafini et al. [83] reported that milk resulted in a reduced AUC for epicatechin relative to control in chocolate confections, while others reported no statistical difference between the AUC of epicatechin from cocoa beverages consumed with water or milk. Recently Mullen et al. [84] reported that milk decreases urinary excretion but not plasma pharmacokinetics of cocoa flavan-3-ol metabolites. Ortega et al. [85] observed that the fat content of certain cocoa samples enhances the digestibility of some phenolic compounds, especially procyanidins during duodenal digestion. Recently, Neilson et al. [86] suggested that chocolate confections containing high levels of sucrose might enhance plasma level of the predominant catechin and epicatechin metabolites as compared to milk chocolate confections, while confections containing moderate levels of sucrose and no milk deliver intermediate plasma levels of these compounds. However, the physical state of the product may significantly modulate this effect.

3.3 Human Studies

According to Donovan et al. [87], the concentration of (–)-catechin was higher to that of (+)-catechin in chocolates. However, bioavailability of (–)-catechin was less than the (+) form of catechin, resulting in low plasma concentration of (–)-catechin. On the other hand, Fraga et al. [88] reported that (+)-catechin was 100 times more efficient than quercetin in an in vivo oxidative stress model [55].

In a human clinical trial, the administration of 148 mg of procyanidins had increased plasma epicatechin at 2 h compared to baseline (0 h) [33]. In addition, plasma epicatechin concentration increased to 21.2 nmol/L after consumption of the procyanidins and then returned to normal levels [33]. Similarly, plasma procyanidin dimer, (–)-epicatechin and (+)-catechin can be detected as early as 0.5 h and reach maximal concentrations by 2 h after acute consumption of cocoa [36]. Murphy et al. [1] indicated that administration of procyanidins increased plasma (–)-epicatechin and (+)-catechin by 81 % and 28 %, respectively. Moreover, (–)-epicatechin was detected as early as 0.5–1 h after chocolate or cocoa consumption and they are present mainly as sulfate conjugates, glucuronides, or methylated forms [89]. A study related to plasma kinetics of epicatechin in men after consumption of 40 and 80 g of dark chocolates, detected that epicatechin increased markedly after chocolates consumption, reaching a maximum between 2 and 3 h [90]. The maximal concentration and AUC of plasma kinetics correlate well with the dose of chocolates. This indicates that epicatechin is absorbed from chocolates and is rapidly eliminated from plasma. Attainable plasma levels were 0.7 μmol/L (free epicatechin and epicatechin conjugates) from 80 g of black chocolates, which contain 164 mg of epicatechin. To a greater extend, Baba et al. [91] indicated that administration of procyanidins B2 [epicatechin-(4β-8)-epicatechin] (Fig. 74.4) extracted from cocoa powder was absorbed in the plasma and excreted in the urine. The compounds appeared maximally in the plasma at 30 min and decreased gradually from 30 to 300 min [55].
