Baba et al. [89] reported that (–)-epicatechin from chocolate or cocoa is present in plasma of human volunteers as sulfate, glucuronide, and sulfate-glucuronide (mixture of sulfate and glucuronide) conjugates, rather than methylated forms. It was reported that plasma concentration of glucuronide conjugates of non-methylated and methylated (–)-epicatechin were higher compared to other forms. Using a pure (–)-epicatechin compound, Da Silva showed that (–)-epicatechin is present in plasma in the forms of glucuronide and sulfate-glucuronide conjugates (free and *O*-methylated) [92]. The glucuronidation of (–)-epicatechin occurs at the position 3′ of the B ring in humans [93]. Natsume et al. [93] found that (–)-epicatechin metabolites present in human plasma are different than the forms present in rats. The glucuronidation of (–)-epicatechin occurs at the 7 position of the A ring and the 3′ position of the B ring in rats and humans, respectively. This glucuronidation compound showed low antioxidant activity compared to intact compounds as it has lost the catechol structure of the B ring responsible for the antioxidative effects. (–)-Epicatechin metabolites are present in urine within 24 h in the range of 25–30 %. There is a significant reduction in total (–)-epicatechin metabolites after 6 h and the remaining conjugates are mostly present as the *O*-methylated form. Excretion of (–)-epicatechin metabolites in urine was observed to be dose dependent [94]. Moreover, it was observed that the level of (–)-epicatechin metabolites excreted in urine was in the close range after equivalent ingestion of pure (–)-epicatechin and (–)-epicatechin from cocoa powder. Hence, the bioavailability of (–)- epicatechin was not influenced with the presence of other compounds present in cocoa powder [55].

4 Bioactivity of Proanthocyanidins

Proanthocyanidins are the principal vasoactive polyphenols in red wine that are linked to a reduced risk of coronary heart disease and to lower overall mortality [95]. The French Paradox introduced the idea that flavonoids found in red wine and fresh fruit may be responsible for the lower rates of cardiovascular diseases in France. In fact, red wine was the first polyphenol-rich food (year 1979) to be inversely associated with ischemic heart disease deaths in industrialized countries [96] and with deaths from coronary heart disease in segments of the French population [97]. Hertog et al. [98] linked a lower mortality from cardiovascular disease in an elderly population of Dutch males with a high flavonol intake, principally with the consumption of onions, apples, and tea.

Today, there is much epidemiological evidence that diets rich in fruits and vegetables can reduce the incidence of different diseases such as cardiovascular diseases, diabetes, cancer, and stroke. These protective effects are attributed, at least in part, to phenolic secondary metabolites. Initially, the protective effect of dietary phenolics was thought to be due to their antioxidant properties, which resulted in a lowering of the levels of free radicals within the body. However, there is now more evidence that the metabolites of dietary phenolics, which appear in the circulatory system in nmol/L to low mmol/L concentrations, exert modulatory effects in cells through selective actions on different components of the intracellular signaling cascades vital for cellular functions such as growth, proliferation, and apoptosis. In addition, the intracellular concentrations required to affect cell signaling pathways are considerably lower than those required to cause an antioxidant effect [99].

4.1 Redox Activity

Several studies indicate that catechins and procyanidins are powerful scavengers of ROS. Some findings regarding the antioxidant activity of proanthocyanidins are listed in Ref. [100]. Other antioxidant mechanisms are the chelation of transition metals, as well as the mediation and inhibition of enzymes. The metal-chelating activity of proanthocyanidins is thought to be due to their capacity to reduce the concentration, and thus the oxidative activity, of hydroxyl radicals formed by Fenton reaction catalyzed by iron or copper. Flavanols also influence oxidative stress via enzyme modification and modulation of cell signaling pathways; the extent of the effect relies greatly on flavanol structure-related protein reactivity [101].

4.2 Nonredox Activity

Nonredox mechanism of actions of flavonoids might also be relevant in vivo. It has been suggested that flavonoids metabolites could interact with cell signaling cascades, influence the cell at a transcriptional level, or downregulate pathways leading to apoptosis [102].

Epigallocatechin gallate have been shown to inhibit COX-2 and iNOS expression by preventing NF-kB activation [103]. Oligomers of 5–12 subunits, with the most powerful pentamers, are active on different human cancer cell lines [104].

Moreover, monomers and dimers were shown to repress NO production, TNF alpha secretion, and NF-kB-dependent gene expression induced by interferon γ, whereas the trimeric procyanidin C2 and Pycnogenol enhanced these parameters. In addition, in unstimulated RAW 264.7 macrophages, both procyanidin C2 and Pycnogenol increased TNF gamma secretion in a concentration and time-dependent manner. These results demonstrate that procyanidins act as modulators of the immune response in macrophages [105].

Results from Vestraeten et al. [106] indicate that dimers and trimers isolated from peanut and cocoa interact with lipid membranes and thus can modulate membrane fluidity. The alteration of membrane fluidity can per se affect numerous cellular processes influencing, among others, the functionality of membrane-associated enzymes and certain intracellular transport mechanisms and membrane receptors. In addition, procyanidins may reduce the incorporation into the bilayer of hydrophobic compounds that can affect, either directly or indirectly, the integrity of the membrane.

With respect to the physiological relevance of dimers and trimers, it has been reported that dietary procyanidins are relatively stable during gastric transit [40]; thus, high micromolar concentrations of both dimers and trimers can be predicted to occur throughout the gastrointestinal tract following the consumption of procyanidin-rich foods. While absorption of trimers from the gut is thought to be very limited, monomers and dimers can be readily detected in the plasma pool within 2 h after the consumption of flavonoid-rich foods or beverages. Thus, while the potential protective effects of dimers and trimers are probably most relevant for the gastrointestinal track, the dimers may also provide some protection to cells in circulation, as well as vascular endothelial cells [106].

4.3 Atherosclerosis, Cytotoxicity, Carcinogenicity, Platelet Aggregation, Vasodilatation, Vasoconstriction, Reperfusion, and Cellular Adhesion

Other nonredox mechanisms of actions of proanthocyanidins are involved in amelioration of several steps in the process of atherosclerosis [107].

Procyanidin B2 (dimer), isolated from loquat leaves, was found to inhibit the 12-*O*-tetradecanoylphorbol-13-acetate (TPA)-induced activation of Epstein-Barr virus early antigen in Raji cells [108]. Animal studies and cell models suggest that flavonoids act as anticarcinogens through influencing molecular events in the initiation, promotion, and progression stages of cancer [109].

Regarding cytotoxic activities, the 3,3′-di-*O*-gallate derivative of procyanidin B2 was found to be active against human leukemic cells (HL-60) and a melanoma cell line but was inactive toward several other tumor cell lines. Several other galloylated procyanidin dimers were also shown to inhibit the growth of human lung and colon carcinoma cell lines [7, 108].

In vitro experiments with whole blood showed that cocoa procyanidin trimers and pentamers increased expression of platelet activation markers (fibrogen binding conformation of GPIIb-IIIa and P-selectin) in unstimulated platelets but suppressed platelet activation response to epinephrine [110]. Both short-term (2–6 h) studies and a long-term (28 day) study with human subjects demonstrated that consumption of proanthocyanidin-rich cocoa beverage lowered P-selectin expression and platelet aggregation (ADP-, collagen-, epinephrine induced) in ex vivo experiments [110, 111].

The inhibition of Ca^{2+} influx through Ca^{2+} channels thereby activating NO release is a proposed mechanism in nitric oxide–dependent vasodilation by proanthocyanidins [112].

Angiotensin II is a vasoconstrictor that is produced in the pulmonary capillaries by angiotensin-converting enzyme and can be involved in the development of hypertension and atherosclerosis [113]. Several proanthocyanidins and preparations containing them inhibited angiotensin-converting enzyme activity in both in vitro and in vivo experiments. These included pycnogenol, proanthocyanidins isolated from red grapes, and extracts of *Erythroxylum laurifolium* (endemic species on Reunion Island in the Indian Ocean) and of fruits of *Cupressus sempervirens* L. (Italian cypress) [107].

Hearts from red wine proanthocyanidin-fed rats were more resistant to ischemia-reperfusion injury than hearts from control animals [114, 115]. Blood flow parameters were improved, whereas infarct size, formation of hydroxyl radicals, and malondialdehyde levels of heart perfusate were all modulated as a result of feeding animals proanthocyanidins or proanthocyanidin-containing ingredients. These same dietary treatments also reduced the levels of proapoptotic factors JNK and c-Jun, as well as the proportion of apoptotic cardiomyocytes.

Proanthocyanidins and/or their metabolites [116] containing high proportion of A-type linkages are beneficial in the case of urinary tract infection. The primary effect is inhibition of cellular adherence of P-type (mannose-resistant) uropathogenic strains of *Escherichia coli* [117, 118].

4.4 Water-Insoluble Polyphenols

Among the dietary constituent, cocoa highly contributes to the intake of water-insoluble polyphenols. Recent studies [119] have demonstrated that procyanidin content in food is largely underestimated. Authors suggested that the measurement of non-extractable polyphenols may be crucial in assessing reliable dietary intake of polyphenols and this is of particular importance when the benefits exerted by polyphenols bound to dietary fiber throughout the gastrointestinal tract are investigated. Fogliano et al. [120] have shown that insoluble polyphenols are able to exert antioxidant activity through the whole gastrointestinal tract; despite being still bound to other macromolecules and that the human digestive process solubilizes a significant part of the bound polyphenols and it increases their bioaccessibility.

4.4.1 Potential Adverse Effects

Procyanidins have been considered antinutritional compounds because they can interact with proteins, starch, essential amino acids, and carbohydrates and inhibit certain enzymes [121–123]. This binding depends on the degree of polymerization: the larger molecules tend to bind more efficiently [7]. However, at the dose present in cocoa no adverse effect has been observed [124, 125]. In addition, the level of flavonoids required to induce mutations and cytotoxicity may not be physiologically achievable through dietary sources; however the use of flavonoid supplements could result in exposure to potential toxic levels [126]. Reported flavanol-related health detrimental effects include activation of pro-carcinogens, pro-oxidant activity, hemorrhage formation, initiation of hepatotoxicity, genotoxic effects, interference with thyroid hormone biosynthesis, alteration of pharmacokinetics of therapeutic drugs, increased estrogenic tumor formation, mutagenicity, modification of plasma biochemistry, instigation of gastroenteritis, antinutritive activity, and weight loss [100, 127–129].

Proanthocyanidin-rich products have been reported to possess the ability to cause cell toxicity to normal, healthy tissue [129] and although generally considered safe, ingestion of higher concentration of proanthocyanidins instigates destruction of mucosal lining of the digestive tract, gastroenteritis, and congestion of the intestinal wall in rats, hemorrhagic gastroenteritis in rabbits [130], and striking lesions in the digestive tract of sheep [131]. Structurally similar to endogenous steroid hormones, flavonoids may also promote estrogenic activity by initiating increased expression of aromatase (CYP19), which correlates with tumor initiation, promotion, and progression [132, 133]. Different studies on rats have found approximately the same NOAEL for procyanidins, which correspond to an average of 12 g daily by an adult for 3 months. Moreover, a grape seed proanthocyanidins extract is under study in a Phase I pilot chemopreventive study in healthy women at high risk of developing breast cancer [8, 134, 135].

5 Conclusion

Regarding the general healthy population, the intake of moderate quantities of chocolate might be considered as safe. Some kind of chocolate, in particular dark chocolate, contains high amounts of polyphenols and proanthocyanidins, which are actually believed to possess different pharmacological activities. The most studied activity is undoubtedly the antioxidant, but some nonredox mechanism of actions could be also relevant in vivo: some flavonoids and flavonoids metabolites could interact with cell signaling cascades, influence the cell at a transcriptional level, or downregulate pathways leading to apoptosis.

Although the scientific evidence on the antioxidant properties of polyphenols and proanthocyanidins is relevant, this is not yet the case for the pharmacokinetic and pharmacodynamic aspects of such compounds and their metabolites, in particular when considering mechanisms other than the antioxidant. Interactions with other compound and food matrix could alter the effects. Moreover the health status of the subject could explain the differences in clinical outcomes.

Abstract

Beer phenols issued from malt and hop can contribute directly to several characteristics of beer, mainly flavor, astringency, haze, body, and fullness. Some phenolic structures can also impart very interesting health properties. Yet phenolic structures also evolve through storage. Low-molecular-weight phenols like 4-vinylsyringol can impart off-flavors in aged beer, while oxidized

1 Introduction

Beer phenols issued from malt and hop can contribute directly to several characteristics of beer, mainly color, flavor, astringency, and haze. As antioxidants, they can also protect raw materials from oxidative degradation throughout the process, minimizing therefore off-flavors such as *trans*-2-nonenal.

In this chapter, all phenolic structures that have been found in beer will be described.

2 Catechins and Proanthocyanidins

Even compared to grapes, hop emerges as an exceptional source of catechins and proanthocyanidins. Therefore, although added in 100 times lesser quantity than malt, it can account for 30% of total beer polyphenols. Among hop cultivars, the lower the bitterness, the higher the flavonoid level (up to 1% “total flavanoids” in Saaz pellets, as expressed in terminal unit weight [1]). During mashing, malt flavonoids are progressively dissolved in the wort (monomers dissolve much faster than oligomers). From mash filtration to boiling, a great proportion of them will be lost through oxidation, adsorption to spent grains, linkage to coagulated proteins, etc. According to the type of hop conditioning used (CO_2 extracts are much poorer in polyphenols than pellets and cones) and the stage of addition, more or less flavonoids will be brought into the wort in the boiling kettle [2].

In dried hop cones or pellets, (+)-catechin and (−)-epicatechin monomers can reach up to 2,821 and 1,483 ppm, respectively [3–7]. Malt contains only 10–100 ppm (+)-catechin (and no epicatechin at all) [3, 5, 8–10]. The main monomeric unit identified in beer is (+)-catechin (0.5 to 6.9 mg.L^{-1}), but (−)-epicatechin (0.8–1.9 mg.L^{-1}), (−)-catechin gallate, (−)-epicatechin gallate, and two glycosides have also been detected (Table 75.1) [8, 11–21].

Hop is also an excellent source of flavonoid oligomers (proanthocyanidins, known as anthocyanogens in the brewing field). For instance, B3 and B4 procyanidin dimers have been detected at levels up to 0.1% [3, 5–7]. Malt contains two B3 dimers (prodelphinidin and procyanidin) at lower levels than in hop, but with higher amounts of gallocatechin units [3, 5, 10, 22]. Many trimers have also been detected in malt (catechin and gallocatechin units) and hop (catechin, epicatechin, and gallocatechin units, but always a catechin unit at the terminal position). Thiolysis hyphenated to RP-HPLC-ESI(−)-MS/MS was recently optimized by our group to investigate beer polyphenolic oligomers [17]. Thiolysis indicated that most beer dimers are procyanidins B3 (two catechin units), while most trimers are prodelphinidins (catechin in terminal units and gallocatechins or catechins in extension units). Despite the absence of chromatographic peaks corresponding to oligomers above trimers, an apparent degree of polymerization (mDP) close to 6 was calculated in a total LH20 extract. Detailed structures were determined by RP-HPLC-ESI(−)-MS/MS [16]. Four dimers were identified: three procyanidins (B1, B3, and B4) and one prodelphinidin (B3) (Table 75.1). Previously detected in hop or malt, three trimers (the procyanidin C-4∝-8-C-4∝-8-C and two prodelphinidins, GC-4∝-8-C-4∝-8-C and GC-4∝-8-GC-4∝-8-C), were distinguished for the first time in beer. As expected, according to previous thioacidolysis data, most beer proanthocyanidins carry a catechin as terminal unit.

2.1 Colloidal Instability

Colloidal instability due to interactions between polyphenols and proteins limits the shelf life of beer. A lag phase is usually observed in lager beers before chill-haze development [23–25]. The time needed to form critical amounts of tanning polyphenols leading to visible chill-haze particles corresponds to the lag phase. As described by Leemans et al. [25] for different batches, the longer the lag phase, the better the colloidal stability.

Chill haze (or reversible haze), defined by non-covalent bonds between polyphenols and active proteins, can eventually turn into permanent haze that no longer dissolves as the beer warms.

Catechin does not rapidly induce strong haze. Upon storage, however, it does. Likewise, colloidal instability caused by dimers and trimers is enhanced after oxidation (not true for tetramers and pentamers) [26–28]. Free radicals are known to enhance haze [29]. Tannoids have been defined by Chapon [30] as intermediates in the oxidation of simple flavanoids to tannins, forming complexes with proteins. On the other hand, according to O'Rourke et al. [28], oxidized flavanols cause chill haze, but only subsequent polymerization leads to tannoids and permanent haze [28, 31].

Leemans et al. [25] have proposed a model in which aldehydes and oxygen play key roles in tanning polyphenol formation [25, 31]. Not only dissolved oxygen but also shaking, higher temperature, polyphenol-rich raw materials, light, and heavy metals will significantly increase colloidal instability [25, 31].

Beer contains less haze-active polyphenols than haze-active proteins. Derived from barley hordeins, haze-active proteins (10–30 kDa) are acidic hydrophilic polypeptides, rich in both proline and glutamic acid [26] and glycosylated [32]. Much more haze is produced near pH 4.0 than at pH 3.0 or above pH 4.2. At the beer pH, ethanol at low concentration causes a modest decline of haze, while strong haze is observed at higher concentrations [33].

To preserve beer colloidal stability, brewers usually remove haze-active materials [34]. To get rid of haze-active proteins, precipitation with tannic acid, hydrolysis with papain and adsorption to bentonite [35] or silica gel [36, 37] are very effective, but unfortunately in some cases, such procedures also remove foam proteins. To remove haze-active polyphenols, the most usual way is adsorption to polyvinylpolypyrrolidone-PVPP. Because of the structural analogy between these compounds and proline [38], pyrrolidone rings bind polymerized flavanoids through hydrogen and ionic bonds.

New combined absorbents are now proposed to brewers, such as PVPP mixed with silica xerogel, PVP bound onto silica, and tannin linked to silica [23, 39]. Another innovative way is the use of flavan-3-ol and proanthocyanidin-free malt which allows affording an excellent colloidal stability [40].

2.2 Astringency

In beer, flavanoids could be also responsible for astringency [41, 42]. Catechin and epicatechin thresholds lie between 1 and 20 ppm [41, 42], with higher values for the beer matrix (20 ppm). Astringency is intensified at low pH, especially near 4.0–4.2 [43], but a higher astringency has been measured by François et al. [44] in beers with a pH close to 5. In this case, it was suspected that the pH of the samples fell in the mouth before polyphenol/protein interactions occurred. Sensory analyses applied to top-fermented beers have shown that storage (20°C or 40°C with air in the headspace) decreases bitterness and post-bitterness but intensifies astringency [45]. On the other hand, no significant astringency-related deterioration was measured in lager beers aged for 5 days at 40°C (with or without oxygen) [44]. In both cases, an increase in DP (global assay) and a decrease in total flavanoids were mentioned, especially at higher temperature or pH, in the presence of air [44, 45].

2.3 Color

Beer color increases through storage, especially in the presence of oxygen and at higher temperature. At pH 3, colorless catechin-derived products are formed after enzymatic oxidation, whereas at pH 6 after chemical degradation, yellow products including dehydrodicatechin A dimers differing by their interflavan linkages can be detected in model media (Fig. 75.1) [46, 47]. Recently, Callemien and Collin [15] detected dehydrodicatechin A in a beer spiked with catechin after storage.

2.4 Health Properties

Flavan-3-ols induce cardioprotective effects, including antioxidant effects (protection against LDL oxidation) and inhibition of platelet activity and vasodilatation [48, 49]. Flavonoids might reduce the risk of cancer, although some procarcinogenic activities have also been reported [48, 50]. Flavonoids alter the synthesis of eicosanoids (mediators of inflammation). They decrease the leukotriene/prostacyclin ratio by modifying lipoxygenase activity [51, 52]. Immune regulation has also been observed [53]. Hop proanthocyanidins can help prevent nitric oxide-related disorders such as Alzheimer's and Parkinson's diseases [7].

3 Prenylchalcones and Derived Flavanones

More than twenty prenylchalcones and derived flavanones, studied mainly for their biological effects, have been identified in hop [54]. Concentrations higher than 0.6%, with a predominance of xanthohumol and desmethylxanthohumol, are usually found (Fig. 75.2) [55]. Levels of 80 and 90 ppm have been reported for the corresponding flavanones, isoxanthohumol and hopein. The higher the α-acid content (bitter acids in hop), the higher the xanthohumol level [56].

Since hop is the only source of these compounds in beer, a relation can be established between their concentration and the rate of hopping. Xanthohumol isomerizes easily during the brewing process into isoxanthohumol [57]. Only 15–50% hop xanthohumol remains in the final beer [58, 59], leading to concentrations often below 1 mg.L^{-1} [18, 55, 60, 61]. Stout- and Porter-style beers are characterized by slightly higher levels because dark malts contain compounds inhibiting xanthohumol isomerization [57]. The use of xanthohumol-enriched hop products (obtained by ethanol-CO_2 extraction) combined with late hopping makes

it possible to increase significantly the xanthohumol and isoxanthohumol potential of beer (close to 10 mg.L^{-1}).

3.1 Health Properties

Xanthohumol is a "broad-spectrum" cancer chemopreventive agent acting on all three stages of carcinogenesis. Xanthohumol and isoxanthohumol are both active ROS scavengers, while only the former is active in superoxide scavenging assays. Isoxanthohumol, 8-prenylnaringenin, and xanthogalenol may also exert chemopreventive effects [18, 61–64].

Prenylflavanones have mainly been studied for their estrogenic activity. Hopein is a very potent phytoestrogen. The authors recommend its application in prevention or treatment of (post)menopausal symptoms and osteoporosis [61, 63, 65]. Weak estrogenic activity has been observed for close analogs like 6-prenylnaringenin, 8-geranylnaringenin, 6,8-diprenylnaringenin, and isoxanthohumol. Prenylchalcones like xanthohumol and xanthogalenol also show low activity [66].

4 Flavonols

Sixteen flavonol glycosides (mainly mono-, di-, and triglycosides of quercetin and kaempferol) have been detected in hop [31]. Although boiling can extract 91% of the kaempferol and 88% of the quercetin glycosides, only a few ppms of flavonols are found in the final beer (Fig. 75.3) [8, 11, 13, 67, 68].

4.1 Bitterness

In beer, flavonols could be responsible for bitterness but do not participate in beer haze formation [31].

4.2 Health Properties

Flavonols induce cardioprotective effects, including antioxidant effects (protection against LDL oxidation) and inhibition of platelet activity and vasodilatation [48, 69], while very little information is available on their potential anticancer effects.

5 Hydroxybenzoic Acids, Hydroxycinnamic Acids, and Derived Compounds

Malt and hop contain various hydroxybenzoic acids, which are retained at least partially up to the final beer (Fig. 75.4). Total hydroxybenzoic acids – mainly *p*-hydroxybenzoic, vanillic, and gallic acids – usually reach a few ppms in beer. They have also been found as glycosides or other bound forms [8, 11–14, 70–74].

Hydroxycinnamic acids are partially recovered in beer (Fig. 75.4). Most of them are in combined forms in the raw materials, either with quinic acid, glucose, or cell-wall constituents [8, 11–14, 70–78]. In malt, *p*-coumaric and ferulic acids are esterified with arabinoxylans [79]. They can be both water extracted and enzymatically solubilized by cinnamoyl esterases [80]. After mashing, an additional release of ferulic acid may occur during fermentation due to yeast cinnamoyl esterases [81].

Three coumarins issued from orthohydroxycinnamic acid cyclization have also been found in beer (Fig. 75.5) [8, 73].

5.1 Flavor

Hydroxybenzoic and hydroxycinnamic acids are characterized by relatively high flavor thresholds (> ppm, mainly bitter taste and astringency) [82]. On the other hand, their decarboxylated derivatives (Fig. 75.5) can impart very strong phenolic/clove/smoked flavors to beer because of their low threshold values (ppb order).

Decarboxylation can occur either by thermal degradation [83] during malt kilning and in the boiling kettle [77, 84], or during fermentation. In this last case, decarboxylation is catalyzed by the phenylacrylic acid decarboxylase found in *Saccharomyces cerevisiae* strains displaying the Pof^{+} phenotype (phenolic off-flavor) [85, 86] and in some contaminating microorganisms like *Brettanomyces*/*Dekkera* spp. [87] or *Enterobacteriaceae* [88]. In this way, 4-vinylguaiacol is issued from ferulic acid, while 4-vinylphenol derives from *p*-coumaric acid. 4-Vinylguaiacol has been also found in hop [89].

Fig. 75.4 Hydroxybenzoic acids and hydroxycinnamic acids and range of concentrations in beer (Adapted from [31])

In Belgian white beer production, enzymatic decarboxylation of ferulic acid occurs linearly through fermentation at a rate close to 140 ppb/day (Fig. 75.6). The rate decreases strongly during secondary fermentation, down to 20 ppb/day. Compared to *p*-coumaric acid, ferulic acid is preferentially degraded by yeast (*p*-coumaric acid remains unmodified until the ferulic acid concentration reaches 2 ppm) [31]. Concentrations up to 6.2 ppm in 4-vinylguaiacol and up to 3.2 ppm in 4-vinylphenol have been reported in wheat beers [8, 77–79, 81, 90–97]. For instance, 4-vinylguaiacol contributes to the specificity of Belgian white beers (made with unmalted wheat) and German rauch and weizen beers (made with malted wheat) [92, 94, 97, 98]. According to its concentration, 4-vinylguaiacol can lead either to strong pharmaceutical off-flavor defects [91] or to pleasant clove flavors [79], while 4-vinylphenol is always considered to be an off-flavor [79]. These vinyl compounds can be further oxidized or reduced into smaller molecules like vanillin, 4-ethylguaiacol, guaiacol, and 4-ethylphenol through chemical reactions [99] or through the activity of wild yeasts like *Brettanomyces*/*Dekkera* spp. [87].

Fig. 75.5 Hydroxybenzoic- and hydroxycinnamic acid-derived compounds and range of concentrations in beer (Adapted from [31])

Degradation of 4-vinylguaiacol through natural aging (25% after 20 days) or at 40°C (50% after 20 days) has been reported [77, 94, 100]. This compound could be partially transformed to 4-ethylguaiacol, vanillin, and guaiacol [79, 101].

By using the AEDA methodology on aged lager beers, 4-vinylsyringol was identified as a strong old-beer-like phenolic odorant (FD value as high as that of *trans*-2-nonenal, responsible for the cardboard off-flavor in aged beer) [102, 103]. Its release through aging should be due to acidic hydrolysis of a glycoside, since sinapic acid decarboxylation occurs much earlier in the process, either in the boiling kettle or during fermentation.

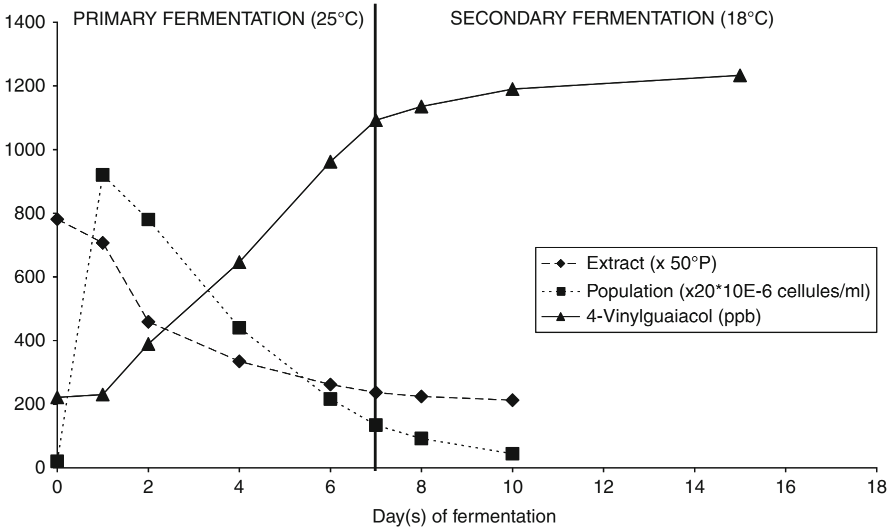

Fig. 75.6 Evolution of extract, cell population, and 4-vinylguaiacol concentration through fermentation of a Belgian white beer

5.2 Color

Phenolic acids do not participate in beer haze formation [27, 104], but vinylphenol and cinnamic acid have been described as potential pigments [105–108].

6 Stilbenes

Our group recently discovered three stilbenes in hop: *trans*-resveratrol, *trans*-piceid, and *cis*-piceid [4, 109]. Concentrations ranging from 0.7 to 11 ppm *trans*-piceid and from 0.03 to 2.3 ppm *trans*-resveratrol have been reported in hop cones [110]. A strong influence of geographic origin and harvest year has been shown [110], but American aromatic cultivars like Willamette and Cascade emerge in all cases as the best sources of stilbenes. Resveratrol is very sensitive to heat and light [110]. Even during hop storage, a significant loss occurs, especially in highly oxygen-sensitive varieties, leading to new analogs like *cis*-resveratrol and dimers [111]. Likewise, hop pelletization induces strong degradation [111, 112]. *trans*-Resveratrol and glycosides are absent from malt [113], so one should not be surprised to find only traces of stilbenes in beer (Fig. 75.7). Up to 5 μg.L^{-1} *trans*-resveratrol was detected by our group in Belgian commercial beers [114].

Taking into account a concentration of 1–10 ppm stilbenes in hop and hopping close to 200 g.hL^{-1} in wort, a maximum of 2–20 μg.L^{-1} stilbenes could be

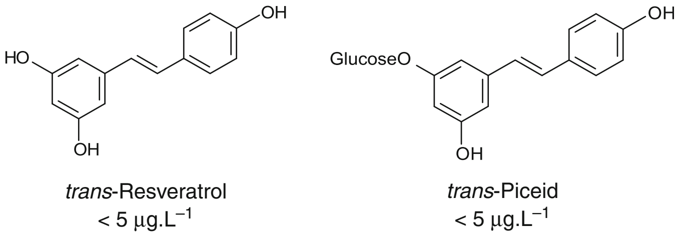

Fig. 75.7 Stilbenes and range of concentration in beer [114]

expected in beer. Moreover, massive degradation of *trans*-resveratrol is known to occur in the boiling kettle (60% degradation after 7 min of boiling – Fig. 75.8a). *trans*-Piceid is much more stable during heat treatment, and it can be converted to free resveratrol through wort fermentation (only 60% recovered from a beer prepared by spiking an industrial wort at 10 mg.L^{-1} before fermentation – Fig. 75.8b). When the wort was not pitched, *trans*-piceid remained stable, suggesting that yeast enzymes catalyze this hydrolysis to free resveratrol, as previously described for wine [114]. On the other hand, the *trans*-resveratrol concentration decreased even in the absence of yeast (40% degradation), most likely because of reactions with wort components (apparent degradation of 17% in the presence of yeast due to the equilibrium with piceid).

In order to increase the stilbene level, stilbene-enriched hop products and brewery process modifications are needed (e.g., adding a stilbene-enriched ethanolic hop extract after fermentation significantly increases the beer stilbene potential).

6.1 Health Properties

trans-Resveratrol shows an impact on platelet aggregation and vasodilatation, and through its effect on the antioxidant status, regulates gene expression and decreases the total lipid concentration (cholesterol and triglycerides) [115]. Although less potent, *cis*-resveratrol, *trans*-, and *cis*-piceid also improve the antioxidant activity [116, 117].

Piceid absorption is enhanced by the presence of its sugar [118].

trans-Resveratrol inhibits the initiation and growth of tumors. It inhibits cyclo-oxygenase, ornithine decarboxylase, and angiogenesis [119, 120]. *trans*-Piceid is a weaker inhibitor of ROS production [121]. As flavonoids, *trans*-resveratrol alters the synthesis of eicosanoids (mediators of inflammation) and decreases the leukotriene/prostacyclin ratio by modifying lipoxygenase activity [120–122]. Estrogenic activity has recently been reported for some stilbenes, especially *trans*-resveratrol. *cis*-Resveratrol appears less potent [120, 123].

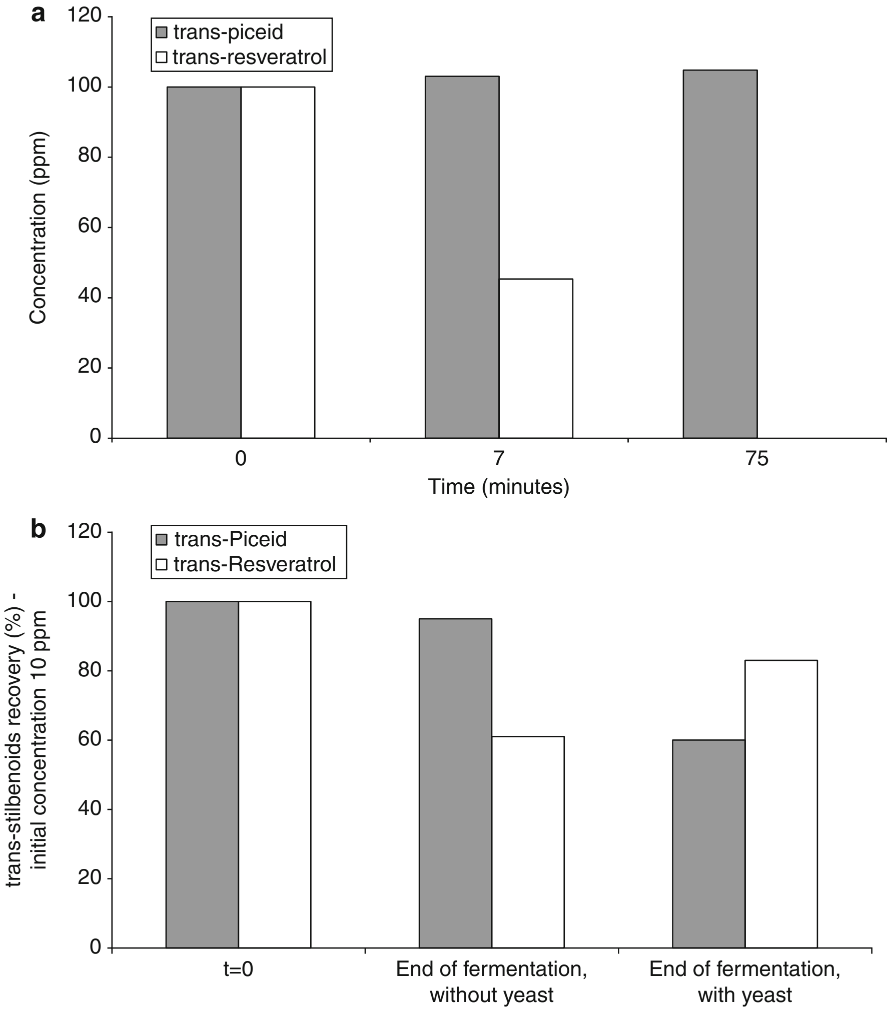

Fig. 75.8 Follow-up of the degradation of *trans*-resveratrol and *trans*-piceid (**a**) in an aqueous model medium previously flushed by nitrogen-mimicking wort ebullition (**b**) through wort fermentation [112, 114]

7 Conclusion

The aim of the present chapter was to review all phenolic structures that have been found in beer. Each family was discussed according to its properties and stability through storage. However, at the end of this chapter, it is very difficult to advice brewers as to which phenols should be kept in the final beer and at what levels.

Beer phenols issued from malt and hop can contribute directly to several characteristics of beer, mainly flavor, astringency, haze, body, and fullness. Some phenolic structures also impart very interesting health properties. However, degradation of such compounds will inevitably lead to alteration of fresh beer. On the other hand, as antioxidants, these compounds can considerably protect raw materials from oxidative degradation throughout the process.

Abstract

Numerous studies indicate that regular intake of polyphenol-rich food and beverages such as red wine is associated with a protective effect on the cardiovascular system. In addition to the antioxidant property, polyphenols may also induce a beneficial effect on the cardiovascular system by several other mechanisms including the improvement of the vascular function. Indeed, experimental and clinical studies indicate that polyphenols are potent inducers of two major endothelial vasoprotective mechanisms, the formation of nitric oxide (NO) and the induction of endothelium-derived hyperpolarization (EDH).

1 Introduction

Diet is one of the major risk factors of mortality by cardiovascular diseases associated with lifestyle [1–3]. For example, the Mediterranean diet has been reported to have a favorable effect on lipid profile, endothelium-dependent vasodilatation, insulin resistance, metabolic syndrome, antioxidant capacity, and myocardial and cardiovascular mortality [4, 5]. Moreover, a recent meta-analysis of epidemiological studies showed that greater adherence to a Mediterranean diet is associated with a significant reduction (9 %) in mortality from cardiovascular diseases [6]. The Mediterranean diet is defined in part by its high content in polyphenols coming from fruits, vegetables, and the regular and moderate consumption of red wine. Numerous epidemiological studies have shown a protective effect against cardiovascular diseases of various rich sources of polyphenols such as red wine [7–9], vegetables and fruits [10–13], green tea [14, 15], as well as chocolate and cocoa [16, 17].

Endothelial function is a key regulator of the vascular health, and its alteration has been shown to be an independent predictor of cardiovascular outcome in subjects with cardiovascular risks [18]. Numerous polyphenols and polyphenol-rich sources have been shown to improve the endothelial function; thus, polyphenol-rich sources such as red wine might prevent the development of cardiovascular diseases, at least in part, by improving the endothelial dysfunction.

This chapter summarizes experimental and clinical evidence suggesting that red wine and other sources rich in polyphenols and flavonoids improve the endothelial function in health and diseases.

2 Mechanism of Endothelium-Dependent Vascular Protection

The endothelium is a monolayer of cells covering the lumen of all blood vessels. While the endothelium has been considered for a long time as an inert barrier between the vessel wall and the blood, studies in the late 1970s revealed that endothelial cells play a major role in the regulation of vascular tone [19, 20]. Indeed, Furchgott and Zawadzki first reported that acetylcholine induced relaxations of rabbit aortic rings suspended in organ chambers only in the presence of an intact endothelium [19]. Further investigations indicated that the endothelium plays a key role not only in the control of vascular tone but also in the adhesion and aggregation of platelets and leucocytes to the blood vessel, in endothelial permeability, smooth muscle cell proliferation, and blood coagulation [21–26].

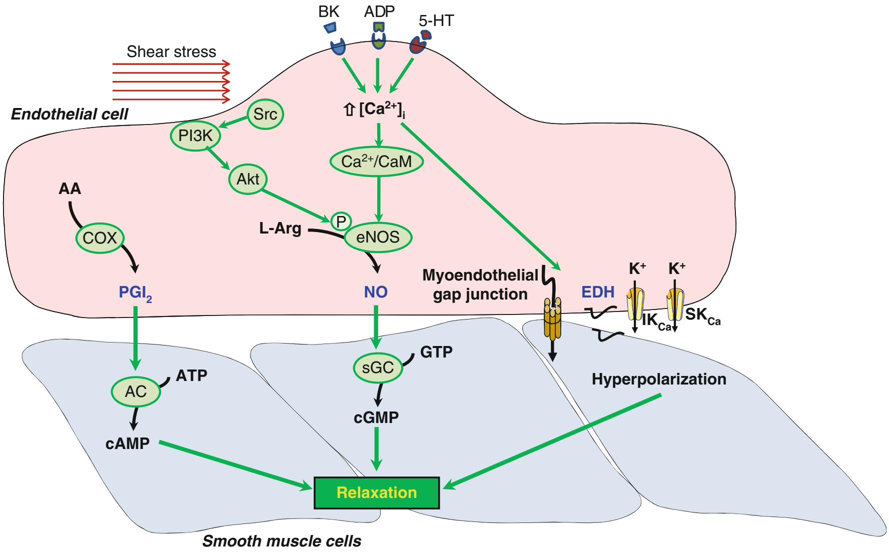

Fig. 76.1 *Endothelium-derived relaxing factors*. Endothelial nitric oxide synthase (eNOS) generates nitric oxide (NO) from L-arginine (L-Arg) after its activation by shear stress via the Src/PI3-kinase/Akt pathway or by a variety of agonists (*5-HT* serotonin, *BK* bradykinin, *ADP* adenosine diphosphate) via the calcium/calmodulin pathway (Ca^{2+}/CaM). NO induces relaxation of the vascular smooth muscle by the activation of soluble guanylyl cyclase (sGC). Endothelium-derived hyperpolarization (EDH) often involves the activation of endothelial SK$_{Ca}$ and IK$_{Ca}$ channels (small and intermediate conductance Ca^{2+}-activated K$^+$ channels, respectively) inducing hyperpolarization (⁓) of the endothelium, which is, thereafter, transmitted, in part, to the underlying vascular smooth cells via myo-endothelial gap junctions with subsequent relaxation. Prostacyclin (PGI$_2$) is also a potent vasodilator, which has potent platelet inhibitory effects. Abbreviations: *Src* Src family kinase, *PI3K* phosphatidylinositol 3-kinase, *ATP* adenosine triphosphate, *cAMP* cyclic adenosine monophosphate, *GTP* guanosine triphosphate, *cGMP* cyclic guanosine monophosphate, *AC* adenylyl cyclase, *AA* arachidonic acid

The regulation of the vascular tone by the endothelium is due predominantly to the endothelial formation of several potent vasorelaxing factors involving nitric oxide (NO), endothelium-derived hyperpolarizing factor (EDHF), and prostacyclin (PGI$_2$) (Fig. 76.1).

2.1 The Endothelium-Derived Nitric Oxide

The main relaxing factor produced by the endothelium is nitric oxide or NO. After the first report by Furchgott and Zawadzki in 1980 that described an endothelium-derived relaxing factor (EDRF), it took 7 years to identify the EDRF as NO [19, 27, 28]. NO is a labile gas produced by the conversion of L-arginine to L-citrulline by NO synthases, a group of heme-containing dimeric enzymes. Among the three isoforms, one is induced by several pro-inflammatory cytokines such as interleukin and is named inducible NO synthase (iNOS or type II NOS), while the other two are constitutively activated and observed mainly in neural tissue (neuronal NOS, nNOS, or type I NOS) and in endothelial cells (endothelial NOS, eNOS, or type III NOS). The eNOS is a 135 kDa protein that is primarily found in the Golgi apparatus as well as in caveolae, the membrane association requiring myristoylation and palmitoylation [29]. Several physiological stimuli including shear stress, bradykinin, serotonin, and ADP have been reported to induce the activation of eNOS by both calcium/calmodulin-dependent and -independent events. Indeed, shear stress induces a sustained NO formation in native endothelial cells that is dependent on an initial increase of the intracellular concentration of free calcium, while the sustained phase is not sensitive to chelation of calcium or inhibition of calmodulin [30, 31]. Under basal conditions, eNOS is mostly in an inactivated state due to its association to caveolin 1, the caveolae scaffold protein, and to HSP90 (heat-shock protein). The calcium-dependent activation of eNOS is mainly due to the increase of the intracellular concentration of free calcium followed by the association of calcium with calmodulin. The calcium-calmodulin complex then interacts with HSP90, which directly activates eNOS by allowing its phosphorylation by kinases and the dissociation of eNOS from caveolin 1 [32]. The activated eNOS will then relocate to the Golgi apparatus where it will generate NO [33].

In addition to the calcium-dependent activation, the activity of eNOS can also be regulated positively or negatively by the phosphorylation of the enzyme. Indeed, it has been reported that phosphorylation of the residues serine 1177 or 615 activates eNOS while the phosphorylation of the residue threonine 495, tyrosine 657, or serine 114 causes an inhibitory posttranslational modification [34]. Activation of eNOS subsequent to its phosphorylation on serine 1177 in endothelial cells has been observed in response to shear stress, bradykinin, and VEGF [34]. Several kinases are involved in the phosphorylation of serine 1177 including the protein kinase A (PKA), protein kinase B (Akt), or Ca^{2+}/calmodulin-dependent protein kinases II (CaMKII) (for review, see [34]). On the other hand, eNOS is constitutively phosphorylated on threonine 495. This phosphorylation is associated in endothelial cells with a reduced binding ability of the calcium-calmodulin complex to eNOS [35].

While eNOS can be activated by both the calcium signal and phosphorylation, the availability of the substrate and the presence of endogenous inhibitors might also contribute to regulate the activity of eNOS and the endothelial formation of NO. Indeed, several studies indicate that cardiovascular diseases are often associated with an increased expression and/or activity of arginase, an enzyme which competes with eNOS for its substrate L-arginine, and also with a reduced L-arginine transport in endothelial cells leading to a reduced availability of the substrate and, thus, to a reduced formation of NO [34, 36].

After its activation, eNOS converts its substrate L-arginine into NO and L-citrulline. NO can diffuse freely in the vascular wall and reach the smooth muscle cells where it activates soluble guanylyl cyclase, an enzyme-transforming guanosine-5′-triphosphate (GTP) into guanosine 3′,5′-cyclic monophosphate (cGMP).

The increase in cGMP activates the cyclic-dependent protein kinase (PKG), which reduces the intracellular concentration of calcium and activates the myosin light chain phosphatase (MLCP), leading to relaxation of the vascular smooth muscle. In addition, NO can also exert a large number of effects such as inhibition of platelet adhesion and aggregation, smooth muscle proliferation, monocyte adhesion, as well as activation of glucose uptake, glycolysis, and fatty acid oxidation (for reviews, see [23, 37]).

2.2 The Endothelium-Derived Hyperpolarizing Factor (EDHF)

The EDHF is an endothelium-derived relaxing factor which importance increases with the decrease of the size of the artery. Indeed, EDHF-mediated relaxations are not observed in the aorta, the largest conductance artery, while it is the main endothelium-derived relaxing factor in small resistance arteries [38]. Initially, EDHF responses were defined as the relaxations that persisted in the presence of inhibitors of eNOS and cyclooxygenases and were associated with the hyperpolarization of the vascular smooth muscle (for review, see [39]). The classical EDHF pathway has been described as an increase in the intracellular free calcium concentration in endothelial cells inducing the opening of two calcium-dependent potassium channels, the small and intermediate conductance calcium-dependent potassium channels (SK_{Ca} and IK_{Ca}, respectively). Activation of these channels induces the hyperpolarization of endothelial cells, which will be transmitted to the underlying smooth muscle cells either by myo-endothelial gap junctions or activation of inwardly rectifying potassium channel (K_{IR}) and ouabain-sensitive Na^+/K^+-ATPase. In addition, an EDHF pathway independent of the endothelial hyperpolarization has also been described. This EDHF pathway seems to depend on the hyperpolarization of smooth muscle cells by opening of various potassium channels such as ATP-sensitive and large-conductance potassium channels (K_{ATP} and BK_{Ca}, respectively$_{)}$, most likely subsequent to the release of several factors by endothelial cells. These endothelial factors have not been totally elucidated and seem to vary depending on the species and the vascular bed studied, but include so far NO, hydrogen peroxide, prostacyclin, epoxyeicosatrienoic acids (EETs), vasoactive peptides, and carbon monoxide (for review, see [39]). Due to this complex and multifaceted origin, it has been recently suggested that the term EDHF was no longer adequate and should be replaced by EDH for endothelium-derived hyperpolarizations.

2.3 The Prostacyclin (PGI_2)

In 1976, Moncada et al. reported that microsomes isolated from rabbit and pig aortas were able to convert endoperoxides into a factor which has strong vasorelaxant and anti-aggregant properties [40]. The product was later identified as the prostacyclin PGI_2, which is the major prostanoid produced by endothelial cells. Its synthesis starts by the conversion of arachidonic acid into endoperoxides by the action of the two isoforms of cyclooxygenases, before the subsequent conversion of endoperoxides into prostacyclin by the PGI_2 synthase. After diffusion toward the underlying smooth muscle, PGI_2 activates the adenylyl cyclase, which converts adenosine-5′-triphosphate (ATP) into 3′,5′-cyclic adenosine monophosphate (cAMP). cAMP, in turn, activates protein kinase A leading to a decrease in the free calcium concentration and inhibition of the myosin light chain kinase, an enzyme responsible for phosphorylating smooth muscle myosin, thus inducing relaxation of the vascular smooth muscle.

3 Vascular Protection by Wine Polyphenols: In Vitro and Ex Vivo Studies

The first study on the potential of red wine and grape-derived polyphenols to inhibit the vascular tone was reported in 1993 by Fitzpatrick et al. using rat aortic rings suspended in organ chambers [41]. Following this first study, numerous other groups have studied the polyphenol-induced activation of the eNOS leading to an increased formation of the vasoprotective NO using in vitro, ex vivo, and in vivo approaches. In addition, several studies have reported that polyphenols are able to induce vasorelaxations through EDH in isolated arteries, suggesting that polyphenols can activate both pathways in the endothelium (Fig. 76.2).

3.1 Red Wine Polyphenols Induce the Activation of eNOS In Vitro

The in vitro characterization of the vascular effects of polyphenols from red wine has focused mainly on the potency of red wines to activate the NO pathway in endothelial cells. In 2002, Leikert et al. reported that exposure of cultured endothelial cells (HUVECs and EaHy926 cells) to a red wine extract for several hours resulted in the induction of eNOS expression and subsequent formation of NO [42]. This effect was later confirmed using French red wine by Wallerath et al. [43, 44]. The characterization of the pathways involved indicated that red wine polyphenols activate a redox-sensitive mechanism. Indeed, using the redox-sensitive probe dihydroethidine, it has been shown that red wine polyphenols cause the intracellular formation of superoxide anions in cultured coronary artery endothelial cells [45]. Moreover, the activation of eNOS in endothelial cells induced by a red wine polyphenolic extract is significantly inhibited by intracellular antioxidants like *N*-acetylcysteine, membrane-permeant analogs of superoxide dismutase (SOD), such as Mn(III)tetrakis(1-methyl-4-pyridyl)porphyrin (MnTMPyP) and polyethylene glycol-SOD (PEG-SOD). The formation of superoxide anions in endothelial cells, in turn, triggers a Src/PI3-kinase/Akt pathway, which ultimately causes eNOS activation by increasing the phosphorylation level of Ser 1177, a positive regulatory site, and the dephosphorylation of Thr 495, a negative regulatory site [46, 47]. Moreover, it has been reported that the formation of NO in cultured endothelial

cells induced by a red wine polyphenolic extract requires calcium in the extracellular medium and is associated with an increased intracellular calcium signal [48]. However, the calcium signal is rather small and short lasting; therefore, it has been suggested that the calcium signal is most likely acting in synergy with the Src/PI3-kinase/Akt pathway to induce a rapid and sustained eNOS-dependent NO formation in endothelial cells.

The activation of eNOS in endothelial cells by red wine polyphenols involves several classes of phenolic compounds (Fig. 76.3). Indeed, the fractionation of a red wine polyphenolic extract indicated that the activation of eNOS and subsequent formation of NO are mainly associated with anthocyanins and procyanidins [49, 50]. Moreover, the activation of eNOS by anthocyanins appears to be strongly related to the structure of the compounds. Indeed, two closely related anthocyanins have been isolated from a red wine extract, malvidin-3-coumaroylglucoside and petunidin-3-coumaroylglucoside, which differ only by a single substituent: a methoxyl function on position 5′ for the malvidin-3-coumaroylglucoside and a hydroxyl function on position 5′ for the petunidin-3-coumaroylglucoside. While petunidin-3-coumaroylglucoside strongly activated eNOS by phosphorylation on serine 1177, malvidin-3-coumaroylglucoside did not have such an effect, indicating a critical role for the hydroxyl function on position 5′ of the B ring for eNOS

activation by anthocyanins [50]. In addition, petunidin-3-glucoside and petunidin aglycone, two closely related compounds differing by the nature of the substitution attached in position C3, were not able to induce activation of eNOS in endothelial cells [50]. These results indicate that the nature of the substitution on position C3 is also critical for the induction of eNOS activation by anthocyanins.

3.2 Red Wine Polyphenols Induce Endothelium-Dependent Relaxations Ex Vivo

The study by Fitzpatrick et al. using rat aortic rings suspended in organ chambers indicated that addition of increasing volumes of several wines and grape juices induced pronounced relaxations in precontracted rings with an intact endothelium, while rings where the endothelium was mechanically removed showed little or no relaxation [41]. The endothelium-dependent relaxation was associated with an increased formation of cGMP, and competitive inhibitors of NO synthase (N^{ω}-nitro-L-arginine and N^{ω}-monomethyl-L-arginine) prevented both the relaxation and the increase in cGMP, indicating that red wine and grape polyphenols induce endothelium-dependent relaxations through an increased formation of NO leading to the subsequent vascular formation of cGMP. These results were confirmed by Andriambeloson et al. using a red wine polyphenolic extract, which caused relaxations in endothelium-intact rings with concentrations 1000-fold lower than those inducing relaxations in rings without a functional endothelium [51]. The endothelium-dependent relaxations were strongly inhibited by a competitive inhibitor of NO synthase (N^{ω}-nitro-L-arginine methyl ester) but not those in arterial rings without endothelium. Moreover, the measurement of NO formation by electron paramagnetic resonance provided direct evidence that red wine polyphenols induce the formation of NO in endothelium-intact arterial rings [51]. The ability of red wine to induce endothelium-dependent relaxations in arteries has been attributed to its polyphenolic fraction rather than its alcohol content since it has also been observed with other grape-derived polyphenol-rich products such as red wine without alcohol [52, 53], red wine extracts [54, 55], purple grape juice [56], and grape extracts [57–61]. However, the comparison of different wines for their ability to induce endothelium-dependent relaxations has indicated that some red wines are potent inducers while others have little effects [62–64]. The phenolic content of red wine is strongly correlated to the ability to induce vasorelaxation [62]. The identification of the molecules responsible for the vasorelaxant effect of red wines is a difficult task since wines are complex mixtures of several hundreds of polyphenolic compounds [65]. However, fractionation of red wine polyphenolic extracts has indicated that a great variety of compounds, in particular procyanidins and anthocyanins, are able to stimulate the endothelial formation of NO [49, 50]. The importance of polyphenols, and in particular procyanidins and anthocyanins, is also suggested by the fact that grape skin and grape seed extracts, products rich in such polyphenolic compounds, induce strong endothelium-dependent relaxations [41, 59–61, 66] while white wines, which contain less than 10 % of the phenolic content of red wines and only traces of procyanidins and no anthocyanins, cause little or no endothelium-dependent relaxations [64].

Grape-derived products have been shown to induce endothelium-dependent relaxations in a great variety of blood vessels including conductance arteries such as the rat and rabbit aorta [41, 51, 63], the porcine coronary artery [45, 46], the rat mesenteric artery [67], and the human coronary and internal mammary arteries [64, 68]. It has also been reported that grape-derived products are able to induce endothelium-dependent NO-mediated relaxation in resistance arteries such as the rat mesenteric bed and cerebral arterioles [66, 69], and the porcine retinal artery [70].

The investigation of the signaling pathway involved in the endothelium-dependent NO-mediated relaxation induced by red wine polyphenols indicates that, surprisingly, polyphenols act through an intracellular redox-sensitive mechanism. Indeed, in coronary artery rings, the relaxation induced by a red wine polyphenolic extract was markedly reduced by membrane-permeant analogs of either superoxide dismutase (MnTMPyP or polyethyleneglycol-SOD) or catalase (polyethyleneglycol-catalase) but remained unaltered by native superoxide dismutase and catalase which are unable to cross the cell membrane [46]. Interestingly, NO-mediated relaxations to bradykinin, a physiological agonist, were not affected by MnTMPyP indicating that red wine polyphenols and bradykinin activate distinct signaling pathways leading to eNOS activation [46]. The endothelial source of superoxide anions induced by polyphenols remains unclear, as it does not seem to involve major enzymatic sources such as NADPH oxidase, xanthine oxidase, cytochrome P450, or the mitochondrial respiratory chain [61, 71]. Studies using a grape seed extract or an isolated green tea catechin (epigallocatechin-3-gallate) have shown that the methylation of the hydroxyl groups resulted in the loss of the vasorelaxant activity, suggesting a key role of the polyphenol hydroxyl moieties, probably through autoxidation, a mechanism known to generate semiquinones and then quinones with the concomitant formation of superoxide anions [57, 71]. The further characterization of the signaling pathway has indicated that the prooxidant response in endothelial cells triggers the activation of the Src/PI3-kinase/Akt pathway leading to the activation of eNOS by phosphorylation and the subsequent NO-mediated relaxation of isolated arteries [46]. A similar eNOS activation pathway has been identified for other grape-derived products such as grape juice and a grape skin extract [56, 61].

Some studies have investigated the role of estrogen receptors in the polyphenol-induced NO-mediated relaxation of isolated arteries since estrogens have been shown to activate eNOS via the PI3-kinase/Akt pathway and polyphenols can interact with estrogen receptors [72]. A recent study by Chalopin et al. indicated that a red wine extract caused small endothelium-dependent relaxations in aortic rings from estrogen receptor alpha wild-type mice but not in estrogen receptor alpha knockout mice [73]. However, other studies have reported that fulvestrant, a selective antagonist of estrogen receptor alpha, did not affect endothelium-dependent NO-mediated relaxations to a different red wine extract and also to two major red wine polyphenols, kaempferol and rutin, in the rat aorta [47, 74]. Taking together, these findings suggest that the estrogen receptor alpha may contribute to some extent to the NO-mediated relaxation of isolated arteries in response to some red wine polyphenols.

While the NO-mediated relaxation is a predominant event in large-conductance arteries, red wine has also been reported to induce EDH-mediated relaxations in smaller arteries. Indeed, in porcine coronary artery, a red wine polyphenolic extract induced concentration-dependent EDH-mediated relaxations as well as hyperpolarizations of the vascular smooth muscle [45]. A similar effect has been reported in the rat mesenteric bed with an alcohol-free freeze-dried red wine from Brazil [75]. The activation of the EDH-mediated relaxation by red wine seems to involve also the redox-sensitive PI3-kinase/Akt pathway like the NO-mediated relaxation [45, 76].

3.3 Red Wine Polyphenols Have Beneficial Effects on the Endothelial Function In Vivo

In vitro and ex vivo studies are useful for characterizing the effect of red wine on the endothelium. However, the major limitation of such studies is that most of the phenolic compounds applied to cells and artery rings are not those present in the blood circulation after oral absorption. Indeed, most polyphenols are circulating in blood in form of metabolites such as glucuronides, methyl, and sulfo-conjugates [77–79]. Noteworthy, some polyphenols like procyanidin oligomers may be absorbed in the intact form since they have been identified in blood and urine following ingestion of a procyanidin-rich grape seed extract by humans and rats [80, 81]. In addition, procyanidin oligomers have been estimated to reach the nanomolar range in human plasma after consumption of procyanidin-rich cocoa and grape seeds [81, 82].

The in vivo evaluation of the beneficial effect of red wine polyphenols on the endothelium has mostly been assessed in experimental models of hypertension, which are associated with an endothelial dysfunction. Indeed, oral ingestion of red wine has been shown to reduce blood pressure in spontaneously hypertensive rats, a genetic model of hypertension [83]. The same effect has also been reported after ingestion of a grape seed extract [84]. Moreover, red wine has been shown to lower blood pressure in several other experimental models of hypertension including the angiotensin II-induced hypertension [85], the N^{ω}-nitro-L-arginine-induced hypertension [75, 86, 87], and the DOCA salt-induced hypertension [88] in rats. Taken together, these experimental studies indicate that ingestion of red wine products is associated with a beneficial effect in several experimental models of hypertension associated with an improved endothelial function.

Several studies have indicated that the endothelial dysfunction is often associated with an increased oxidative stress in the vascular wall due, at least in part, to an increased expression and activity of the NADPH oxidase, a major vascular source of superoxide anions [89–93]. The vascular oxidative stress is also likely to involve other enzymatic sources such as cyclooxygenases, mitochondria, cytochrome P450, or uncoupled eNOS [93, 94]. Red wine polyphenols have been shown to reduce strongly the level of oxidative stress in the arterial wall of pathological arteries in association with a reduced vascular expression of NADPH oxidase [91–94]. In addition, polyphenols may reduce vascular oxidation stress due to their direct antioxidant properties and also to their ability to inhibit the activity of NADPH oxidase [95]. Moreover, the angiotensin system appears to be a potent inducer of the endothelial dysfunction and vascular oxidative stress by activation of NADPH oxidase [96, 97]. In ageing rats, the endothelial dysfunction is associated with an increased vascular expression of both angiotensin II and its receptors AT1R and AT2R, and these responses are normalized by intake of red wine polyphenols [93, 94]. Taken together, these data suggest that polyphenols are able to exert their beneficial effects on the endothelium, at least in part, by reducing the vascular oxidative stress through several mechanisms including direct antioxidant properties, inhibition and downregulation of NADPH oxidase, and downregulation of the vascular angiotensin system.

4 Clinical Studies on the Beneficial Effects of Wine Polyphenols

Several epidemiological studies have linked a protective effect against cardiovascular diseases and regular consumption of either red wine [7, 8, 98] or polyphenol-rich sources such as green tea [14, 15, 99], cocoa, or chocolate [16, 17]. Since many cardiovascular diseases are associated with an impaired endothelial function, the evaluation of the endothelial function is of great importance. In humans, the endothelial function is often assessed by the flow-mediated dilatation (FMD). For this purpose, reactive hyperemia is induced after a transient ischemia in the upper arm using an inflatable cuff like that used for the measurement of blood pressure, while the diameter of the brachial artery is monitored continuously at the elbow level by ultrasound. The cuff is inflated until the occlusion of the brachial artery, which is maintained for 5 min before the blood flow is released. The reperfusion then induces an endothelium-dependent dilatation of the brachial artery due to the increased shear stress, the most important physiological activator of eNOS. Impaired endothelial function, assessed by FMD, has been reported as an independent predictor of cardiovascular outcome in subjects with cardiovascular risk factors or established cardiovascular diseases [18].

FMD and blood pressure have been often used for the evaluation of the effect of the dietary intake of polyphenols on the protection of the cardiovascular system. Indeed, the basal FMD is increased in healthy subjects after two glasses of red wine with or without alcohol [100] or after consumption of 3 ml/kg of red wine [101]. Similarly, intake of red wine has been shown to restore a normal endothelial function in hypercholesterolemic patients with impaired FMD [99, 102]. A study by Papamichael et al. has also shown that acute intake of two glasses of red wine with or without alcohol is able to reduce the endothelial dysfunction induced by the smoking of one cigarette by healthy nonsmokers [103]. Moreover, acute intake of two glasses of red wine without alcohol improves FMD in patients with coronary artery disease, while intake of regular red wine was less effective, suggesting that the beneficial effect is due to the polyphenol content rather than the alcohol component of red wines [104].

The beneficial effect of polyphenols on the endothelial function has also been observed for other dietary polyphenol-rich sources. Indeed, intake of purple grape juice has been shown to improve the endothelial function in hypercholesterolemic patients with impaired FMD similarly to red wine [102]. Moreover, purple grape juice intake improved FMD in teenagers with metabolic syndrome [98]. In addition, a grape-derived product has been shown to improve the impaired FMD in healthy subjects subsequent to the intake of a high-fat meal [77]. Similarly, intake of cocoa

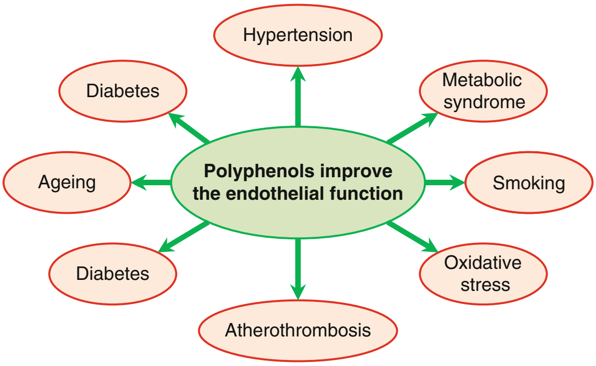

Fig. 76.4 Potential health beneficial effects of polyphenols

and chocolate, sources rich in epicatechin and procyanidin that are also present in red wine, has been associated with an improved FMD. Indeed, basal FMD has been increased after ingestion of a single dose of 46 g of dark chocolate or a low dose of purified epicatechin, 1 or 2 mg/kg body weight in healthy adults [105, 106]. Similarly, intake of dark chocolate improved FMD in patients with heart failure [32], habitual smokers [107], and overweight adults [108]. Taken together, these studies indicate that the intake of polyphenol-rich sources has a beneficial effect on the endothelial dysfunction associated with several pathologies and physiological situations such as ageing, which are associated with an increased prevalence of cardiovascular diseases (Fig. 76.4).

5 Conclusion

The endothelium plays a key role in the maintenance of vascular health, and the alteration of its function will promote the development of cardiovascular diseases. A large number of experimental and clinical studies indicate that polyphenols are potent activators of the endothelial cell leading to the formation of major vasoprotective factors including NO and EDH and that they contribute to delay the development of an endothelial dysfunction and to improve also an established endothelial dysfunction, in part, by reducing the vascular oxidative stress. All these effects will contribute to a better perfusion of target organs and, hence, improve vascular health.

Abstract

In the early 1930s, some isoflavonoid compounds were discovered to exhibit estrogenic activities that were found to be deleterious at high doses for cattle reproduction. Later, several toxicological studies on these compounds were performed between the 1940s and 1980s using mainly rodent models. These same compounds were discovered in edible plants and in human biological fluids, and a large body of scientific work was then dedicated to their putative impact on human health.

Because estradiol is a natural hormone with ubiquitous effects in mammals, nearly all biological functions can be influenced by isoflavonoids that have estrogenic activities. Their effects are significantly affected by their biological concentrations in body fluids and by their affinity to known estradiol receptors. Our knowledge of the biological effects of estrogenic isoflavonoids progresses the more we learn about the effects of estradiol and of endocrine disruptors. In this respect, the latest information concerns the discovery of both new pathways for cellular action and epigenetic effects. In addition, the two latest issues involve the factors influencing the metabolism of phytoestrogenic compounds and their bioavailability, and this confirms the importance of the efficient doses and of their affinities for the estradiol receptors.

After a general introduction on the classical molecular effects of estradiol, this chapter presents the main isoflavones with estrogenic activities that have been investigated so far, with their plant sources and forms as well as their role in plants. Their presence in human food and their bioavailable forms in human and in animal models are then evoked. Next, this chapter presents the latest data concerning their mechanisms of action and explains how these processes can influence more highly integrated physiological functions. The data from animal studies and epidemiological studies are discussed as an introduction to pharmacological applications demonstrated in clinical trials. Because estradiol in mammals can have both beneficial and harmful effects, depending on the dose, the physiological status, and the target organ, the dark side of the story of phytoestrogenic compounds is also exposed.

1 Introduction

The isoflavonoid family represents a distinct group among the flavonoid compounds. Within this group, some of the most potent estrogenic molecules of the plant kingdom can probably be found. Only one coumestane, namely coumestrol, and one prenyl-flavanone, namely 8-prenyl naringenin (8-PN), are known to be more estrogenic in some in vitro tests [1]. Coumestrol is present in alfalfa [2], sometimes in soy, and in some fruits and beans together with isoflavones (**Isofl**) [3], whereas 8-PN has been found so far only in hop (*Humulus* sp.) [4] and in *Sophora flavescens*, a fabaceae used in Chinese traditional medications [5]. However, although coumestrol and 8-PN can be more estrogenic in vitro, their bioavailability in plasma is usually low [6, 7]. Meanwhile, the **Isofl** usually exhibit a higher plasma bioavailability, resulting in a higher estrogenic effect in vivo. This is particularly the case in humans [8].

The estrogenic effects of all these compounds are based on their chemical structures, which share some similarities with that of the estradiol molecule. Indeed, there are several natural estrogens in vertebrate animals, among which 17β-estradiol (17β-E_2) is the most potent. 17β-E_2 is an aromatized C18 steroid with hydroxyl groups at the 3- and 17-β positions (Fig. 77.1a). In humans, it is produced primarily by the cyclic ovaries and the placenta. It is also produced by the brain, the adrenal cortex, and the adipose tissue of men and postmenopausal women. As shown in Fig. 77.1a, 17β-E_2 is a three-dimensional molecule with its two hydroxyl groups at a distance of 10 Angstroms (Å) and bearing a phenolic ring. The hydroxyl groups form an angle allowing the best interaction with the specific estradiol receptors (ERs) [9]. These receptors, namely ERα and ERβ, derive from two different genes: ESR1, located in humans on chromosome 6, and ESR2, located on chromosome 14 (Fig. 77.1b). These receptors have nuclear transcriptional effects and present a ligand binding domain (LBD) with a hydrophobic pocket constituted by the E/F domain (C-terminal domain) of the protein and a part of the A/B domain (N-terminal domain) folded in its vicinity (Fig. 77.1b). The E/F domain is constituted of several helix structures (Fig. 77.1c, d).

The position of the H12 helix is crucial for the transcriptional effect of the ERs (Fig. 77.1c, d). Whether or not the transcription factors are recruited depends on the spatial position of the H12 helix in the LBD. This, in turn, allows or does not allow the estrogen-dependent gene transcription [10]. The 17β-E_2 spatial structure is so relevant for the ligand–receptor interaction that the natural 17-α-isomer of estradiol binds only weakly to the ERs and exhibits little estrogenic genomic activity in estrogen-responsive tissues [11]. 17β-E_2 physiological plasma concentrations in women usually vary from 10 to 20 pg/mL (i.e., from 36 to 72 pM) in the metestrus phase of the female cycle to 500–600 pg/mL (i.e., 2 to 4 nM) in the estrous phase of the female cycle. During pregnancy, these 17β-E_2 levels can reach values over 30 ng/mL (i.e., over 110 nM). In the meantime, 17β-E_2 levels in men are below 50 pg/mL and are below 40 pg/mL in postmenopausal women (i.e., below 200 pM in both cases).

Despite the great specificity of the ERs for their natural steroidal mammalian ligands, since the 1970s, many molecules have been found to be able to bind to the ERs [12]. They were first called xeno-estrogens and now are regularly encompassed under the general name of endocrine disruptors [13]. Isoflavones with estrogenic activities can be classified in this category [14]. Their chemical structures are presented in Fig. 77.2a. As for 17β-E_2, the molecules exhibit two

hydroxyl groups on the opposite sides of the molecule at a distance of 10 Å and they also exhibit phenolic rings. Their main differences reside in their spatial shape. Indeed, whereas 17β-E_2 is a three-dimensional molecule (Fig. 77.2b), **Isofl** are planar compounds because of the double bond existing between the C_2 and C_3 carbons and therefore the spatial position of their hydroxyl groups into the hydrophobic pocket of the LBD are not strictly stackable to those of 17β-E_2. As a result, the affinities of **Isofl** for the ERs are much lower than that of 17β-E_2. Usually, the affinities of the **Isofl** with estrogenic activities are considered to be better for ERβ and to range from genistein (**Gen**) to kievitone according to the following order: **Gen**>daidzein >glycitein>biochanin A>formononetin>phaseolin>kievitone [12, 15]. Other compounds like glyceolin were also found to exhibit estrogenic activity. However, these activities are not yet fully characterized [16].

The affinity of **Isofl** with estrogenic activities for ERs can change according to the system used. Indeed, the solubilized receptors extracted from an estrogen target tissue usually exhibit lower affinity to non-steroidal estrogens than recombinant proteins (1/100–1/10,000 vs. 1/10–1/1,000, respectively) and even less than the recombinant LBD of those receptors [15, 17] (1/1–1/1,000). Although, these affinities are low, especially in the most physiological systems, the **Isofl** with estrogenic properties can reach plasma concentrations 10,000–100,000 times higher than those of 17β-E_2. Namely, **Isofl** can reach micromolar concentrations in plasma, whereas 17β-E_2 is currently found at picomolar to nanomolar concentrations in those same plasmas. In vitro tests, performed on estrogen reactive cells, can also show discrepancies in their response to phytoestrogens according to their equipment in ERs [18], to their molecular context (i.e., their ability to synthesize the transcription factors) [19], and to their proper enzymatic equipment [20]. Indeed, according to their function and tissue origin, cells are either able or unable to transform conjugated estrogens (steroidal or not) into free estrogens based on their equipment in phase 1, 2, and 3 enzymes, ABC-binding cassettes, and multidrug resistance (MDR) enzymatic complexes [20]. To add another level of complexity, it must be mentioned that the affinity of xeno-estrogens for the ERs does not strictly reflect their transcriptional activities. It was shown that, although soy estrogenic **Isofl** exhibit a greater affinity for ERβ, their nuclear transcriptional efficiency is greater via ERα [19]. However, in vivo, both ERs can possibly act together, forming heterodimers [21].

2 Plant Origin

The estrogenic isoflavonoids including **Gen**, daidzein (**Daid**), formononetin (Form) biochanin A (Bioch), and glycitein (**Gly**) are secondary metabolites from plants. Isoflavones can mainly be found in great concentrations in Leguminosae. Some of them contain high amounts of **Isofl** with estrogenic properties (i.e., up to several hundred mg/100 g of dry matter [22]). The most concentrated Leguminosae are red kidney beans (*Phaseolus vulgaris*) [15], soy (*Glycine max*) [23], kudzu (*Pueraria lobata* or *tuberosa*) [24], alfalfa (*Medicago* sp.) [3], clover (*Trifolium* sp.) [25], and so on. Estrogenic **Isofl** are also found in a smaller quantity in Leguminosae traditionally edible in Western countries like beans, lentils, favas, chickpeas, and potatoes, but in these vegetable sources the concentrations are about 500 times lower than in the plants previously cited [26, 27]. See Table 77.1 for more details.

In addition, Farnsworth et al. [28, 29] also detected these compounds in more than 300 different plants, including many species of Leguminosae like *Baptisia*, *Cytisius*, *Dalbergia*, *Genista*, *Lupinus*, *Medicago*, *Phaseolus*, *Teline*, *Trifolium*, and *Ulex* and in several species of Rosaceae like *Prunus*. In Western countries, these plants were traditionally used as sources of antifertility agents.

There is evidence that **Isofl** act as phytoalexin [15]. They are antimicrobial and may have a role in plant protection. As an example, the antifungal activity of lupin **Isofl** has been demonstrated [30]. In soybean cultivars, an increase in **Isofl** concentrations was shown to be a specific response to the attack of a saprophytic fungi

Mucor ramosissimus. In the soybean strains resistant to the fungus, **Isofl** (including glyceollins I, II, and III; glycinol; glyceocarpin; **Gen**; isoformononetin; and N-acetyltyramine) were induced by the fungal attack, all compounds possessing antifungal activity with the exception of **Gen** [31]. A contamination of a soy strain with the fungus *Diaporthe phaseolorum f.* sp. *Meridionalis*, induced the accumulation of **Isofl** (**Gen**, **Daid**), pterocarpans (glyceolins), and flavones (apigenin and luteolin) via a nitric oxide synthase pathway [32]. To go on with interactions of the plants with microorganisms, there is some evidence that the symbiotic relationship between *Rhizobium lupine* and *Lupinus albus* stimulates an increase in production of prenylated **Isofl** in the root nodules [33]. These prenylated **Isofl** possess in vitro activities against a number of other *Rhizobium* species. Zhang and Smith [34] also showed that **Gen** plays a major role in the establishment of the symbiosis between *Bradyrhizobium japonicum* and its host, that is, soy (*Glycine max*). **Gen** is the soy recognition molecule inducing the greatest plant-to-bacterium signal. In fact, the binding of **Gen** to *B. japonicum* activates many of the bacteria nod genes.

There is solid proof that farming practices directly influence the levels of **Isofl** in soy. As a matter of fact, irrigation was shown to enhance **Isofl** content in soybeans by as much as 2.5 fold [35]. A deficit in nitrogen fertilizer increases the estrogenic activity of a clover pasture [36]. On the other hand, a supplementation in the same fertilizer decreases the occurrence of **Isofl** with estrogenic activity in a clover pasture [36]. A study where soy cultivars (*Glycine max*) were bred for 3 years demonstrated that levels of **Isofl** were related to both environmental and genetic characteristics and could be susceptible to selection [37]. The genomic regions implicated in this process have been identified [38]. Vyn and coworkers [39] showed that **Gen**, **Daid**, and **Gly** contents in soy are correlated with potassium in roots and leaves and with crop management using potassium-rich fertilizers. Lindner in [22] gave an evolutionist theory about the ability of Leguminosae to produce estrogenic **Isofl**. Indeed, it appears that isoflavonoid compounds are synthesized by the plants in response to bacterial or fungal attacks or to water stress. Estrogenic **Isofl** can then be considered as protective compounds. In the case of over-grazing of a pasture by mammalian predators, the production of great quantities of estrogenic compounds that could impair predator reproduction would result in the reduction of the predator pressure. Finally, because estrogenic **Isofl** are also specific attractants for symbiotic bacteria of the *Rhysobium* gender, and because these bacteria can fix the atmospheric nitrogen, human selection against the production of **Isofl** in Leguminosae would result in the loss of one of their greatest interests in crop management.

3 Food Content and Intake

Isoflavones with estrogenic activities are present in significant amounts in food processed from soy (see Table 77.2 and [40]) and in food supplements containing soy, clover, alfalfa, and kudzu extracts [41–44] and (see Table 77.3). Isoflavones, under a glycosylated form in plants (Fig. 77.2b), are generally soluble in water and uncovalently linked to proteins rather than present in the lipid phase of the crude matter. Consequently, there is almost no **Isofl** in soy oil or soy lecithin preparations (see [40, 41, 44] and Table 77.2). Isoflavones with estrogenic activities are present in several mg per 100 g of processed soy-based food, or several tenths of mg per 100 mL of liquid soy-based food [3, 40, 45–50]. This leads to food intakes from a few milligrams of **Isofl** up to 50 mg per portion of soy-based food [40, 41]. Soy-based food-supplements usually contain **Isofl** in the same range of quantities, even though several laboratories producing food supplements have developed formula containing up to 100 mg per capsule [40, 41, 44]. In parallel, several soy-based infant formulas were designed and commercialized to address lactose intolerance in babies. Although they are generally prepared from the best quality concentrated soy protein, and because soy is used as the major protein source, these formula contain large amounts of **Isofl** [48, 51–53].

In this specific case, infants, before diet diversification, can be exposed to **Isofl** amounts 5–11 times higher than those encountered in adulthood in a diversified regimen [51] or by menopausal women on soy-based food supplements [44]. Cooking or other food transformation processes can generate acetyl or malonyl conjugates of the phytoestrogenic glycosylated **Isofl** [54]. However, the aglycone compounds are thermally highly resistant except in highly acidic conditions. Therefore, common cooking transformations including extrusion do not considerably affect the **Isofl** content of soy-based-food [55]. It should be noted that crude soy was usually not considered to be edible by humans or animal species because it contains several anti-nutritional factors including anti-trypsin agents, saponins, and sapogenins [56]. Initially, in Asian countries, soy was essentially used in crop rotations based on its ability to fix atmospheric nitrogen in the soil. Asian people learned subsequently how to use it as an edible crop, empirically submitting it to traditional Asian food transformation processes. These traditional processes include cooking, precipitation with magnesium chloride from Nigari, and pressing after seven aqueous extractions (tofu, miso, and traditional Asian-derived products), or fermentation with specific bacteria (tempeh, soy sauce, and traditional Asian-derived products) [57]. These traditional forms of processing reduce the amount of anti-nutritional agents and of **Isofl** with estrogenic activities in the food matrix. Western processing used in the preparation of soy “milk” (i.e., tonyu) and derived products (including yogurts, ice creams, desserts, cheese, etc.), but also Western-made tofu and derived products do not follow the traditional Asian recipes. Consequently, the **Isofl** with estrogenic activities may remain, in some cases, in the diet at high concentrations [41, 45, 55]. However, as mentioned earlier, the **Isofl** concentration in a plant varies greatly depending on its genetic background and on its cultivating conditions and/or fungi or bacterial attacks. Therefore, the

amounts of **Isofl** with estrogenic activities are highly variable from one batch of the same food trademark to another. Soy consumption is regular and moderate in Asia, currently 2–7 soy dishes/week. The **Isofl** intake in China is 25 mg/day on average [58] and in Japan from 45 to 60 mg/day [59]. However, there is a great variability in the intake, especially in the various regions of China. In Western countries, soy is usually consumed anecdotally and European **Isofl** intake is considered to be below 2 mg/day [60–62]. However, in the past few years there has been effective publicity on the health benefits of soy consumption. As a consequence, some Western consumers have exaggerated their soy intakes, leading to cases of over-consumption of **Isofl** with estrogenic properties. The health effects of such behaviors will be detailed below.

4 Bioavailability and Metabolism

In plants and vegetables, isoflavones are present mainly as glycosides (Fig. 77.2b). Glycosidases linked to the enterocyte layer are present in the gut and can quantitatively hydrolyze the **Isofl** glycosides from the food. This has been deduced since no glycosides can usually be found in human feces, urine, or blood [63]. Once deglycosylated into aglycone compounds, estrogenic **Isofl** can enter the enterocyte barrier, where they can be subjected to the action of detoxification enzymes. These enzymes, called phase

1, 2, and 3 enzymes, are, respectively, responsible for the hydroxylation, glucuronidation or sulfatation, and finally expulsion of the conjugated polyphenols from the cells. The actions of these enzymes are incomplete at the gut level. They are completed in the liver and kidney [63]. The phase 2 enzymes encompass, among others, sulfotransferase (SULT) and glucuronosyltransferase linked to uranyldiphosphate molecules, namely UDPGT or UGT. There are many isoforms of these enzymes, which can be highly specific of certain substrates. However, again the structural similarities between $17\beta\text{-}E_2$ and **Isofl** lead to cross activities of the UGT enzymes. Indeed, UGT1A is responsible for the glucuronidation of $17\beta\text{-}E_2$ in the C3 position in men's liver microsomes, whereas UGT2B7 is responsible for the glucuronidation of $17\beta\text{-}E_2$ in the 17β position [64]. It was shown that UGT1A can also use **Gen**, **Daid**, Bioch, Form, and **Gly** as substrate [65]. In addition, the same study showed that, at physiological doses, UGT1A9 is also able to conjugate **Isofl**. Isoflavone sulfation was demonstrated in the gastrointestinal tract and in the liver [66]. For **Gen** at least, SULT1A is involved. Usually, a substrate can also modulate the activity of its proper enzyme. Consequently, it was shown in rodents that high doses of **Isofl** can modulate the activities of several phase 2 enzymes known to be implicated in the 17β-E_2 conjugation [67, 68]. Because the soy **Isofl** can act differently on the different enzymes studied, they can influence 17β-E_2 bioavailability in a complex manner, including at the tissue level [20]. As an example, Sun and coworkers [69] showed that **Isofl** can modulate the activity of these enzymes in the LNCap cells (prostate cancer cell line) probably playing a role on 17-βE_2 bioavailability in tissues. The relative affinity of **Isofl** and 17β-E_2 is crucial when considering the respective effects of one to the other. Isoflavones are likely to exert an estrogenic activity if 17β-E_2 is absent or only present at low concentrations, that is, in the young, in men, and in post-menopausal women. On the other hand, in premenopausal or in pregnant women where 17β-E_2 is high in plasma, **Isofl** are likely not to exhibit an effect unless **Isofl**-containing-foods are consumed in exaggerated amounts. This will be discussed later. Because of this, there are small differences of **Isofl** bioavailability between men and women [41].

Isoflavones undergo metabolic transformation in the gut. Namely, **Daid** is known to be transformed into *o*-desmethyl-angolensin and **Gen** into *p*-ethylphenol [70] by gut bacteria. These compounds can enter the blood stream but are not estrogenic. In contrast, **Daid**, can be biotransformed by the gut bacteria into *S*-equol (***S*-Eq**) [71, 72]. Unlike in humans, this conversion is highly efficient in animal models including mice [73], rats [74], monkeys [75], and hamsters [76], but not in pigs, which seem to be rather close to humans on this point [77]. In human consumers, ***S*-Eq** occurs only in about 20–45% of the tested populations [78].

Contrary to the **Isofl**, ***S*-Eq** possesses an asymmetric carbon in position C_3. This gives it a three-dimensional shape closer to that of 17β-E_2 (Fig. 77.2c, d). Thanks to this, ***S*-Eq** exhibits a greater affinity for the ERs than its precursor **Daid** [72], and has a greater effect on bone resorption prevention [79]. This also raises the question of the relevancy of animal models when considering the putative effect of soy or a soy extract on human health.

Considering the data mentioned above, isoflavonoids in plasma are mainly under a conjugated form and, in humans under moderate soy-food intake, essentially under a glucuronide conjugated form [80]. As mentioned earlier, **Isofl** exhibit the best bioavailability among the known polyphenols [8]. At a dietary relevant rate, their absorption ranges between 60 and 80 % according to the compounds and the studies [8, 81]. Their T_{max} is usually obtained between 6 and 8 h after ingestion depending on the compound considered [41]. Their elimination half-life ($T_{½}$) is rather long, from 10 to 24 h, since it can sometimes be influenced by a recirculation phenomenon involving biliary excretion of liver-targeted absorbed **Isofl** [41]. The residence time of **Isofl** in plasma increases from **Daid** to **Gen** with **Daid**<**Gly**<**Gen**, and chronic ingestion can lead to plasma steady-state levels. As a consequence, under chronic ingestions, although **Gen** is usually ingested in a greater amount via soy-food, the urinary levels contain more **Daid** and do not reflect the ingestion rate of **Isofl**. They do not reflect the plasma levels either [78]. The T_{max} of ***S*-Eq** is usually reported to be between 16 to 18 hours since its absorption occurs in the colon. It was also shown that **Isofl** with estrogenic activities can bind to the specific proteins binding 17β-E_2 and testosterone (T) in plasma, with a low affinity and in a nonspecific manner. These sex hormone binding globulins, namely SHBG, are present in plasma from adults and α-fetoprotein (AFP) of fetuses and neonates [82]. This binding can influence **Isofl** and 17β-E_2 excretion. This is particularly relevant since it was shown in vitro that **Gen** significantly induces SHBG production in HepG2 cells [83]. Several authors reported plasma **Isofl** concentrations ranging from 150 ng/mL to 219 ± 330 ng/mL in Asian consumers under a traditional diet [84–86]. In the meantime, other authors reported plasma **Isofl** levels ranging from 177 ± 104 ng/mL to 941 ± 370 ng/mL in Western consumers with a significant soy-food intake [41, 87, 88]. The measures were performed in similar conditions (doses and time between ingestion and collection). These differences can be linked to the ethnic origin of the subjects and possibly to a peculiar effect of the respective bacterial flora of the two groups [89]. Isoflavones from food supplements are more bioavailable than those from a soy-food matrix [41]. In the following paragraphs, the in vitro tests cited will be those involving molecules known to be present in plasma and therefore susceptible to being in contact with the target cells. The glycosylated precursors of plants will not be considered.

5 Mechanisms of Action

Isoflavones with estrogenic activities can exhibit nuclear actions involving the classical ER pathways. They have been shown to bind to the classical receptors ERα and ERβ and also to induce transcriptional activities via these receptors [19]. Via these pathways, their activity is between 1/100 and 1/10,000 that of 17β-E_2. This depends on the compounds considered. Genistein is by far the most studied **Isofl** with estrogenic effects. The investigations were mainly undertaken to prove the beneficial effects of isoflavonoids on breast cancer risk after having found the presence of **Isofl** and **Eq** in the human diet and in human biological fluids [90, 91] after soy consumption. Recently, it was shown that the natural form of **Eq** found in humans is the isomer S, that is, ***S*-Eq**, which presents in vitro a strong affinity for ERβ, almost 50 times higher than for ERα [92]. Many of the mechanisms of action described below will be illustrated with **Gen**, although all its effects are not strictly stackable to the other members of the **Isofl** family. In the last decade, classic ERs were shown to be present in the cell membranes under a palmitoylated form [93]. Under this form they are also embedded in other membranes such as those of endoplasmic reticulum [94] and those of mitochondria [95]. The cell membrane estradiol receptors (mERs) can be blocked by ICI 182,780, as can nuclear ERs [96]. Membrane classical ERs are known to establish a cross-talk with the insulin-like growth factor 1 (IGF-1) receptor [97] and via these pathways to induce breast cancer cell proliferation. The actions of **Gen** on ERs and mERs are blocked similarly by ICI 182,780 [96]. Genistein is also known to increase IGF-1 receptor gene expression via an IGF-1 dependent mechanism, and this mechanism is probably involved in the proliferative effect of **Gen** at low concentrations (from 0.5 to 10 μM) on breast cancer cell lines. However, there are discrepancies in the literature concerning the effect of **Gen** on breast cancer cell growth. While Chen and coworkers [96] say that **Gen** induce the ER/IGF-1 cross-talk, Anastasius and coworkers [98] showed that long-term exposures to very low doses of **Gen** (i.e., 10 nM) reduce the expression of AKt and phosphorylated AKt in MCF-7 when **Gen** is applied for 10–12 weeks. This reduces proliferation of MCF-7 cells. The AKt pathway is induced via the IGF-1 receptor. According to these two studies, **Gen** could then act in opposite ways on the same pathways. Indeed, the authors of these two studies argue for different doses of exposure of the same line of cells. To highlight this issue, one must remember the following: (1) When soy is ingested, **Gen** is present with other compounds including **Daid**, **Gly**, and in some cases ***S*-Eq**; these three compounds do not exhibit the same mechanisms of action. (2) **Gen** plasma concentrations vary widely and plasma concentrations can reach up to 1–2 μM at C_{max} after a soy-based food intake, however, these concentrations do not remain for long. (3) Breast contains adipose tissue known to fix **Isofl** differently with a predominance of ***S*-Eq** [99]. (4) The E-screen test involving MCF-7 cells conducted in vitro and in which **Isofl** with estrogenic activities induce cell proliferation is the one chosen by the OECD to check for potential adverse effects of chemicals on breast cancer [100]. In the last decade, a new membrane estrogen receptor, a G-protein coupled ER, the so-called GPCR or GPR-30, has been discovered. It belongs to the rhodopsin-like receptor family and is coupled to a G protein. It mediates very rapid estrogenic effects, that is, effects occurring within a delay ranging from a few seconds to several minutes. Its estrogenic action is mediated by cytoplasm cascades of phosphorylations and de-phosphorylations. These cascades can involve the PI3K – MAPK – ERK 1/2 and SF-1 pathway. Recently, **Gen** was found to bind GPR-30 and to induce the kinase activations induced by both 17β-E_2 and tamoxifen [101]. This led to activation of endometrial cell proliferation. As far as we know, neither **Daid**, ***S*-Eq**, nor the other **Isofl** with estrogenic properties have been tested yet on this newly discovered membrane ER. In addition to the membrane receptor GPR-30, orphan estrogen-related receptors (ERRα, ERRβ, and ERRγ) were discovered in the nuclear compartment [102]. These receptors, whose physiological ligands have not yet been identified, are closely related to classical ERs but they do not respond to 17β-E_2. The ligand-binding pockets of ERRα and ERRγ are extremely small compared with those of the classical ERs because the ERR ligand-binding pockets are partly filled by lipophilic side chains. As a consequence, the classic agonists or antagonists of the ERs act differently on ERRs. 4-OH tamoxifen binds ERRβ and ERRγ without initiating transcription when diethylstilbestrol (DES, known as a potent estrogen) acts as an antagonist on all ERR isoforms [103–105]. Recently, **Eq** was shown to bind to ERRγ and to significantly induce dependent-gene transcription [106]. Previously, Suetsugi and coworkers [107] showed that Bioch was able to bind and to induce transcription via the three ERR isoforms while **Gen** and **Daid** were active only through ERRα and β. At the same time, **Isofl** were tested on many targets for anti-estrogenic action. Genistein was then shown to exhibit anti-proliferative effects at high doses (>20 μM) via a specific anti-protein tyrosine kinase (PTK) effect [108], affecting Bcl-2 availability in breast cancer cells [109] and inducing cell apoptosis. This effect is not elicited by either **Daid** or **Eq**. Daidzein was shown to exert an anti-protein kinase C (PKC) effect at doses higher than 60 μM [110]. Isoflavones were shown to exhibit anti-angiogenesis effects in vitro at doses higher than 50 μM. Recently, it was shown that **Gen** acts via an anti-PTK route decreasing the activation of JNK and p38MAPK in Huvec cells [111]. **Gen** and **Daid** were also shown to inhibit the 5α-reductase (5-AR) and the 17β-hydroxysteroid dehydrogenase enzymes implicated, respectively, in the biotransformation of T into dihydroT (DHT) and of estrone into 17β-E_2. Inhibitors of these enzymes are used in the treatment of breast and prostate cancers. However, the effects are only recorded using doses higher than 10 μM with IC_{50} values over 50 μM [112]. These doses are much higher than the doses available in the plasma of soy consumers. Isoflavones were also shown to have slight anti-aromatase effects [113]. Aromatase is the key enzyme for 17β-E_2 production. Drugs with anti-aromatase activities are used in breast cancer treatments. However, this time again the IC_{50} in vitro are very high (i.e., over 100 μM). On the other hand, **Isofl** at dietary concentrations were shown to antagonize anti-aromatase treatments in athymic nude mice implanted with MCF-7 cells [114]. This leads to a proliferative estrogenic effect. Flavonoids are usually considered as potent antioxidants. In this respect, and because of their specific chemical structure that prevents a total delocalization of the electrons on the carbon skeleton of the molecule, isoflavonoids are poor antioxidants, even though they were shown to have such an effect in vitro at extraphysiological concentrations [115]. In 2002 and 2006, it was reported that **Gen** can have epigenetic effects. The demonstration was obvious since **Gen** altered the epigenome of offspring in viable yellow agouti mice [116, 117]. In this study, involving dietary doses, **Gen** appeared as a methylating agent. Epigenetic effects that result in the modulation of gene expression can be achieved via the DNA methylation of CpG islands and via the acetylation or the methylation of histones. These effects can be transferred from one cell generation to the other. Several studies showed that high doses of **Gen** or other **Isofl** may have demethylating effects on the promoters of metastases or tumor suppressor genes and induce their expression [118–120]. However, the active doses are not always relevant to the nutritional situation and may induce PTK inhibition. Gupta and coworkers [121] studied the effects of 24 nutraceuticals including **Gen** on various epigenetic modulations of genes implicated in the inflammatory process. They also studied their consequences on tumor cell viability, proliferation, invasion, and angiogenesis. However, the active doses were usually extraphysiologic. Epigenetic effects are interesting to consider for **Isofl**, since they fit with epidemiological data showing an environmental protection of Asian populations against some cancers after early, moderate, and continuous exposure to soy food, that is, from childhood to old age. Such a protection is absent if soy is consumed later in life. These epigenetic effects, if achieved with low doses and on genes implicated in early tumorization processes, may be particularly relevant to study in the context of cancer prevention by nutritional factors.

6 Animal Studies

In animals, the bioavailability of **Isofl** is different from that observed in humans. Globally in rodents, **Isofl** bioavailability is 10 times lower than in humans; the oral doses must be 10 times higher to lead to the plasma doses recorded in humans. Indeed, 20 mg/kg/day of **Isofl** leads to 610 ng/mL **Isofl** in rat plasma [122], while 1.4 mg/kg/day leads to 599 ng/mL **Isofl** in human plasma [123]. However, as mentioned earlier, rodents are intensive ***S*-Eq** producers. This is not always the case in humans. Because ***S*-Eq** exhibits specific health effects, soy consumption in animals may not induce the same health effects as in humans. In addition, one must remember that soy consumption leads to significant plasma levels of **Gen**, **Daid**, ***S*-Eq**, and **Gly**. Therefore, the test of a pure compound cannot be transposed to soy consumption.

6.1 Breast Cancer

There are two major types of results that were obtained in rodent models concerning breast cancers. The first category encompasses those obtained on nude athymic mice implanted with human breast cancer cell lines. Globally, these experiments using MCF-7 implanted cells show a proliferative effect induced by ingested soy [124], or by ingested isolated soy **Isofl** [125, 126]. These experiments also show a negation of the effects of the anti-aromatase letrozole [114] or of the effect of the anti-estrogen tamoxifen [127] by the dietary **Isofl**. Note that processed soy does not induce the same response [128]. Recently, Onoda and coworkers [129] tested pure **Eq** and a fermented preparation, namely SE5-OH containing large proportions of ***S*-Eq** on the proliferation of MCF-7 cells transfected with a luciferase gene (MCF-7-E10) in athymic nude mice. They found no proliferation at a dietary dose of 250 and 500 ppm. However, in this paper **Gen** was not active either and this is in discrepancy with previous works. In addition, the same treatments induced proliferation of the cell lines in vitro. Therefore, these results need confirmation. Although MCF-7 is a widely recognized breast cancer cell type it presents specificities (that is, ERα and sometimes ERβ positive with a full context for 17β-E_2 action). Consequently, it is not surprising to find that **Gen** exhibited no proliferative effects on mice implanted with ER-negative tumor cells (MDA-MB-231). In this case, soy inhibited cell growth [130]. This advocates for an estrogenic and a proliferative effect of **Isofl** and their plasma metabolites at dietary relevant plasma concentrations on ER-positive cells. The other type of results show, on the contrary, a preventive effect on chemo-induced tumors. Indeed, **Gen** was shown to prevent proliferation of chemo-induced breast tumor cells [131]. This effect was only obtained when **Gen** was administrated prior to the tumor inductor dimethylbenz[a]anthracene (DMBA) [132]. Daidzein and its metabolite ***S*-Eq** do not exhibit the same pattern of activity [133].

These effects are mediated by the ERs and not by the MEK 1-2 or ERK 1-2 pathways [134]. Taken together, these results were long considered as discrepant. However, in the first case we observed an estrogenic effect on cells already transformed in tumor cells, and in the second case, the effect of **Gen** is examined before cell tumorization and appears to prevent it. It was first thought that the preventive effect of **Gen** on the transformation of normal cells into tumor cells was due to its capacity to induce mammary development and differentiation [135]. That said, the differentiation process is in opposition with the dedifferentiation process occurring in cancer cells. Nowadays, the hypothesis of a protective effect of **Gen** through epigenetic pathways is attracting attention [136]. The epigenetic effects seem probable, although they have to be shown with relevant **Isofl** dietary plasma concentrations.

6.2 Colon Cancer

Although it is hypothesized that soy may have a preventive effect on colon cancer (CCa), the role of **Isofl** in soy is still unclear and the demonstration is not conclusive in animal studies undertaken with males. This time again, two different types of studies were performed. Some tried to check the effects on tumor cell proliferation and others tested the potential role of soy or **Isofl** from soy on the prevention of chemo-induced tumors. Some studies tried to sort out the effect of **Isofl** compared with that of other compounds of soy protein. As an example, Vis and coworkers [137] checked for the effects of several components of soy food on colon cell proliferation.Neither methionine nor **Isofl** were found to influence colon cell proliferation. However, soy saponins may exert a protective effect on colon cell proliferation by reducing the lytic activity of cholic acid. When fish oil and **Isofl** in soy were tested on the proliferation of colon and breast cells [138], it was found that **Isofl** in soy had no effect on apoptosis in either tissue, but reduced mitosis in the colon ($P < 0.001$) while increasing it in the mammary gland ($P = 0.001$). These changes were associated with contrasting modifications in the ER expression. **Isofl** in soy increased ERα and decreased ERβ expressions only in the colon. In parallel, Xiao and coworkers [139] examined the chemo-preventive effects of soy protein with **Isofl** and of **Gen** versus casein on the prevention of CCa induced by azoxymethane (AOM). There were no effects of either treatment when limited to gestational exposure. However, soy protein fed to male rats at weaning and until the end of the AOM exposure reduced the colon tumor incidence by 47 %. It is not clear from this study whether **Isofl** are responsible for this preventive effect. More recently, a study [140] examined the effects of a life-time exposure (including pregnancy and lactation) to soy **Isofl** of male rat treated with AOM to induce CCa. Two doses of **Isofl** were tested (40 and 1,000 mg/kg diet). Soy **Isofl** did not affect incidences or multiplicities of colon aberrant crypts or tumors but the lowest dose of **Isofl** decreased tumor burden and size ($P < 0.05$). ERβ expression in colon tumors was increased by soy **Isofl**.

Controls were made in vitro on DLD-1 cells. Their proliferation was decreased dose dependently by **Isofl** and the expression of ERβ was increased. Note that in mammary tumor cells the ERβ positive cells that are not ERα positive do not grow under **Isofl** treatments [18]. Lately, the epigenetic effects of **Gen** and of a soy protein extract (SPE) were examined on three different cell lines [118] together with their anti-proliferative activity. It was found that **Gen** and SPE regulated the expression of WNT5a. The WNT signaling pathway plays a critical role in normal epithelial regeneration and tumorigenesis in the human colon. This regulation was accompanied by a decrease in DNA methylation in the CpG islands of the WNT5a promoter. However, the doses used (75 μM) were far higher than the dietary relevant doses and can inhibit the PTK pathway. Therefore, these results are not fully convincing and may be reanalyzed with lower and dietary relevant doses.

6.3 Prostate Cancer

Animal studies indicate that **Isofl** and **Eq** can have beneficial effects on prostate growth and cancer since they decrease prostate serum antigen (PSA) production, and they bind and prevent the synthesis of 5α-DHT [141, 142]. Several data would indicate that **Isofl** and especially **Gen** at high doses may prevent and cure prostate cancers. The cell action determined on chemo-induced prostate tumors or in LNCap cells implanted in nude athymic mice leads either to cell apoptosis via the IGF/Src/Bax-BCl_2 pathway already described, or via a direct induction of caspase 3 [143, 144]. The other pathway that is thought to be involved in PCa protection is the prevention of the pro-oncogene MDM2 synthesis, this pro-oncogene being common to several cell types including breast cells. However, it was shown using reporter transgenic mice models coupling androgen responsive elements and luciferase that **Gen** administrated orally at a dose of 5 mg/kg is agonist of the androgen receptor (AR) in the prostate of intact males and antagonist in castrated males [145]. Because androgens are tumorotrophic agents in PCa, this result indicates that the effect of **Gen** on PCa is far from being simple. To add to the controversy, Nakamura and coworkers [146] recently developed a patient-derived prostate cancer xenograft model. They grafted clinical prostatectomy samples into nude athymic mice fed 0, 2, or 10 mg/kg **Gen**. For these doses they showed dose-dependent increases in lymph nodes and secondary organ metastases (liver, lungs). They also showed the aggregation of invasive malignant cells in the secondary organs of the **Gen**-treated groups and not in the control. Their data suggest that this effect is due to the enhanced activities of PTK, EGFR, and their downstream Src in **Gen**-treated groups. They underlined that the effect of **Gen** may depend on the kind of tumor considered. In addition, Hillman and coworkers [147] reported that **Gen** combined with irradiation was remarkably efficient in the induction of PC-3 cell apoptosis in nude athymic mice when ingested at a rate of 5 mg/day (PC-3 are human prostate cancer cells). However, **Gen** alone significantly induces PC-3 proliferation and lymph node dissemination in secondary organs.

6.4 Osteoporosis

Bone is in constant remodeling, with accretion and resorption phenomena occurring at the same time [148]. During growth the accretion overcomes resorption. During adulthood the two mechanisms are balanced. In women, during and after menopause, the resorption mechanisms take precedence over bone formation. Two cell types are involved in these phenomena: osteoblasts take part into bone formation while osteoclasts are responsible for bone resorption. At the physiological level, bone health can be measured directly by physical measurements of bone mineral density (BMD) or bone mineral content (BMC). Other indirect measurements can be performed on urine or plasma samples for resorption or accretion biomarkers, that is, BTM (for Bone Turn-over Markers) like deoxypyridinoline (DXP) or *n*-telopeptide (NTx). Hormonal, mineral, and vitamin measurements including parathyroid hormone (PTH), calcium, and vitamin D can also predict the bone turn-over efficiency. However, BMD and BMC are not the best predictors of the bone fracture risk. The bone architecture has to be conserved to avoid fractures. In animal studies, bone resistance to fracture can be measured and is a good marker of osteoporosis. Osteoblasts derive from stromal cells and their differentiation is under the control of estrogens and growth factors. Osteoclasts derive from monocytes. Their differentiation requires the activation of the RANK receptor by its ligand RANK-L. RANK-L is produced by the osteoblasts. However, osteoblasts also produce osteoprotegerin (OPG), which interferes with RANK-L in its binding to RANK. OPG, when present, prevents osteoclast differentiation. Therefore, the bone accretion is the result of a finely balanced synthesis of RANK-L and OPG by the osteoblastic cells. This balance is tightly controlled by endocrine, paracrine, and nutritional factors. Estrogens are one among other factors controlling bone accretion [149]. Isoflavones with estrogenic activities were tested on this function in animal models. All published data are positive with either soy or individual **Isofl** [122, 148, 150, 151]. Equol and ***S*-Eq** seem to exhibit a particularly favorable effect on bone accretion [79, 152]. These effects were examined using diets containing relevant concentrations of **Isofl** on ovariectomized rats, which may mimic the menopausal situation in humans. Bone physiology was assessed by measuring bone markers of resorption in plasma (DXP, TLx), osteocalcin, and BMD and BMC. In animals at sacrifice the bone resistance to fracture was also measured. In all cases the results published in the literature showed a positive effect of **Isofl** or soy on bone physiology. These results are sustained by in vitro data showing that pure **Isofl**, when tested at relevant doses, activate osteoblastic differentiation [153, 154], osteoblastic proliferation, and cytoskeleton protein secretion [155, 156]. Isoflavones also increase alkaline phosphatase production and that of OPG [157–159]. Isoflavones also decrease the production of inflammatory cytokines like IL-6, which are known to activate the osteoclasts [158]. These effects are dependent on the nuclear ERE pathways being blocked by ICI 182,780 [160] and also by membrane pathways leading to CREB activation [161].

6.5 Memory

Estrogens are known to be neuroprotective and neurotrophic agents [162]. Their mechanisms of action include direct effects on neurons, actions on astroglial cells, and vascular effects [162]. On vessels, estrogens were shown to induce vasodilatation, improving oxygen perfusion of the surrounding cells [163]. Estrogens also reduce the production of inflammatory molecules such as IL-6 [164] by glial cells. Finally, in neurons, they increase the dendritic spine density known to be involved in neuronal plasticity [165]. They activate glutamate receptor mobility and target them at the synapses [166]. They are involved in mitochondria maintenance and activity [95]. At physiological doses they are beneficial for the calcium balance involved in the long-term potentiation (LTP) phenomenon [165]. LTP is the best cellular model so far that has been connected to memory functioning. 17β-E_2 is also synthesized in neurons and especially in the pre- and post-synaptic compartments [167]. ERs, mER, and GPR-30 [168] are present in many brain territories, including some involved in the memory process like the hippocampus [169], amygdala, striatum, and prefrontal cortex [170]. They are also present in other brain areas projecting onto or into these territories like median septum or basal forebrain [170], which are involved in the cholinergic activation of the hippocampus. In rodents, seven studies describing the effects of **Isofl** used either pure compounds or soy-based-food [171–177]. All studies, except that of Lund and Lephart [172], which involved very high doses of **Isofl** (600 mg/kg), showed a positive effect on working, reference, or spatial memory and even anxiety. The study by Lund and Lephart [173] showed beneficial effects on spatial memory in females but deleterious effects in males. These results are sustained by in vitro data obtained using pure **Isofl**. At high doses (>10 μM) **Gen** may induce an inhibition of PTK and exhibit deleterious effects, including the disruption of calcium homeostasis and induction of apoptosis via the Bax-BCl_2 pathway [178]. At lower doses, **Isofl** induce dendritic spine growth [171], cholinergic activation of the hippocampus [176], and neurotrophic effects on hippocampal neurons [179]. They exert anti-inflammatory effects on glial cells [180]. In addition, some of their effects seem to prevent the deleterious effects of β-amyloid [181–183].

In summary, except for bone health, all data obtained on animal models are not fully conclusive. The doses tested must be considered carefully and the compounds available in plasma should be taken into account when a parallel is to be drawn with humans.

7 Epidemiological Studies

Epidemiological studies suggested that soy consumption with **Isofl** presenting estrogenic activities in Asian countries may prevent several disorders and diseases, some of them being hormone dependent, such as menopausal symptoms; cardiovascular diseases; breast, prostate, and colon cancers; fractures; and memory defects. Asian populations, known as regular consumers of soy and **Isofl**, were carefully analyzed for their susceptibility to various diseases and compared with those existing in Western populations. The diseases studied were mainly breast, prostate, and colon cancers as well as osteoporosis. Some recent studies examined the effects of soy intake on memory. The first studies relied on dietary surveys linked to an estimation of phytoestrogen intake, which could be incomplete [184]. Some studies then linked the relative risk or incidence of disease to urinary **Isofl** levels [185]. Then, menopausal, health, BMI, or age status were taken into account [186]. Finally, some environmental, genetic, and cultural factors were considered in these comparisons [187, 188]. There are other factors that can possibly act on diseases incidence: dietary factors, oral contraception and hormone replacement therapies (HRT), morphology and posture, and gene polymorphism. Recent studies have tried to sort out these different factors.

7.1 Menopausal Symptoms

Menopausal symptoms encompass hot flushes, night sweats, vaginal dryness, mammary density, and mood fluctuations. They are considered as adverse effects of menopause but not as a disease. In Western countries, they have been treated for more than 20 years using HRT. However, several studies, including the famous Women's Health Initiative (WHI). showed that the deleterious effects of the US treatments on breast and endometrial cancers as well as on the cardiovascular pathologies may overcome their benefits [189]. A few epidemiological studies tried to examine whether the consumption of soy and **Isofl** with estrogenic activities may prevent hot flushes. This is relevant since it is known that hot flushes and night sweats are controlled by the hypothalamus preoptic area implicated in body core temperature regulation. This area induces shivering or sweating when it records a body temperature over a lower and an upper threshold. Between these thresholds is a thermal neutral zone. The amplitude of this neutral zone is under serotonin and noradrenergic control.17β-E_2 is known to induce the local synthesis of these two neuromediators as well as their respective receptors [190]. The study of Nagata and coworkers [191] showed a reduction in hot flushes with increased soy consumption. Note that, in this case, the highest quartile consumed 50.2 mg of **Isofl** per day (115 g of soy per day) and in this case the Hazard ratio was 0.42 with a $CI_{95\%}$ between 0.25 and 0.72. In Hawaii, Sievert and coworkers [192] showed that the incidence of hot flushes based on self-declarations was higher in the European-American ($n = 203$) versus the Japanese-American ($n = 249$) participants (72% vs. 53% $P < 0.01$). In China, in a population of 1,399 participants, consumption of soy three times a week reduces the incidence of hot flushes but not significantly (OR = 0.67 $CI_{95\%}$ = (0. 38,1.20), P value = 0.18) [193]. A recent study performed in China on 4,842 women with non-metastatic breast cancer and aged between 20 and 75 did not show a correlation between hot flushes, night sweats, and vaginal dryness on one side and soy consumption on the other [194]. The **Isofl** consumption ranged from less than 20 to more than 62.3 mg/day. As far as we know, no observational epidemiological studies were performed on the effect of either soy consumption or of **Isofl** on hot flushes incidence in women from Western countries.

7.2 Breast Cancer

Breast cancer can be a hormone-dependent disease when malignant cells possess ERs (ER-positive tumors, about 80 % of the post-menopausal breast cancers). It has been hypothesized that **Isofl** could exert both estrogenic and anti-estrogenic activities. From the previous discussion it appears that at dietary doses the effects in vitro or in relevant animal models are mainly estrogenic and proliferative in ER-positive cells [124]. However, the two ERs, ERα and ERβ, may play different roles, and according to the cell equipment in ERs, **Isofl** can induce the proliferation of ERα-positive cells and can be anti-estrogenic and anti-proliferative in ERβ-positive cells, which do not express ERα [18]. In the epidemiological studies conducted so far and considering soy or **Isofl** effects, the precise status of the tumor cells are usually not stated in detail. This adds confusion to the results. In addition, we will see later that cycles and 17β-E_2 production in premenopausal women can be impacted by **Isofl** consumption. This would suggest a difference between the premenopausal status when 17β-E_2 is synthesized under the pituitary stimulation, and post-menopause when **Isofl** with estrogenic activities can be the major estrogens in plasma. A recent review, presenting a meta-analysis of the relative risk of breast cancer with **Isofl** consumption, showed that Asian women may be protected to a slight extent but not Caucasian women living in Western countries [195]. This can be explained by two main facts. Firstly, in Western countries the **Isofl** intake is usually low (below 5 mg per day). Secondly, a high **Isofl** consumption is mostly related to food-supplement intake, which usually occurs late in life at peri-menopause and during menopause and post-menopause. Another recent study established that differences exist between menopausal and postmenopausal women regarding soy **Isofl** effect on breast cancer [196]. When soy is consumed moderately from childhood in an Asian context, protection is observed in premenopausal women who generally mainly present ER-negative tumors. It is not the case in menopausal women [197]. Other recent analyses tried to find a link between soy intake and breast cancer recurrence. The relationship remains unclear, with some studies showing a reduction in the recurrence of breast cancer [198] and others no effect [199]. However, the study by Shu [198] has to be considered with caution since it included volunteers who all had bilateral breast surgery. Finally, when the intake duration is taken into account, it seems that a limited protection can be associated with early, regular, and moderate soy intake from childhood to menopause [200]. In very few studies the ER status of breast tumors was considered. When it was done it appeared that **Isofl** could be slightly protective as could other polyphenols on ER-negative tumors, but that this "protection" by estrogenic **Isofl** is lost when ER-positive tumors are considered [201].

7.3 Colon Cancer

Colon cancer (CCa) is thought to be influenced by estrogens. However, a recent re-analysis of the WHI results has shown that HRT may not be beneficial, but vitamin D may be [202]. A meta-analysis was recently done analyzing the results of studies performed to associate soy or **Isofl** consumption to the incidence of CCa [203]. Eleven studies tried associating soy intake with CCa incidence, and four looked at CCa mortality with soy consumption. The incidence was reduced by soy consumption only in two studies and only in women. The mortality rate was never associated with soy consumption except for one inverse correlation in Chinese women from Hong Kong. Six case–control studies have analyzed the intake of **Isofl** with CCa risk. Among them, three showed no effect and three showed a significant reduction of the risk. Among the positive studies, only one showed the effect of significant **Isofl** intake (20 mg/day) [204]. In the others, the intake was below 1.5 mg/day [205, 206] raising the question of confounding factors. The authors of the meta-analysis [203] concluded that soy consumption may lead to a reduction of CCa in women but not in men. However, other studies are needed to take into account possible confounding factors.

7.4 Prostate Cancer

The incidence and mortality rate of prostate cancer (PCa) varies largely worldwide. The lowest rates are observed in Japan and other Asian countries [207], but the efficiency of the detection program is not the same as in Western countries [208]. In addition, the incidence of latent PCa discovered at autopsy is not substantially different between Japan and the US. This suggests that the differences are related to cancer progression and not cancer appearance. Several factors, including genetic and environmental, may play a role in the development of PCa. It was shown that the risk for PCa increased dramatically in Japan concomitantly to the introduction of a Western-like diet [207]. Migrant studies have shown an increase in PCa incidence in Asian men after emigration to the US [209]. Western lifestyle presents many differences from the Asian one, including several dietary habits among which soy and tea consumption have drawn much attention so far. In addition, the Mormon and Seventh-day Adventists communities in the US, which are not genetically different from the White Americans but have different lifestyles (no tobacco, no drugs, more vegetables and fiber, more polyphenols with antioxidant activities) exhibit lower incidence of many cancers, including PCa [210]. Recently, a meta-analysis indicated that tofu consumption and urinary **Gen** and **Daid** were associated, in Asian people, with a lower incidence of PCa [211]. The odd ratios (OR, 95 %) were 0.69 for total soy foods with a confidence interval ($CI_{95\%} = 0.57–0.84$) and 0.75 ($CI_{95\%} = 0.62–0.89$) for non-fermented soy foods. The consumption of miso, nato, or tonyu was not associated with this incidence. These data have not been confirmed so far by clinical trials [212].

7.5 Osteoporosis

Ecological studies showed that the incidence of osteoporotic fractures in Chinese women is lower than that observed in Caucasian women in Western countries [213]. This was attributed by some authors to the dietary intake of estrogenic **Isofl** by the Asian populations. Among 10 epidemiological studies that examined the correlation between soy-food consumption and bone loss based essentially on BMD, Lagari and Levis [214] indicated that 7 showed a positive association and 3 no association. It is difficult to draw out a definitive opinion from these data since, in most cases, pre-, post-, and menopausal women were included. In addition, the number of subjects was greatly different (from 24,403 to 15). However, in the three negative studies, two involved Caucasian women from Western countries whose soy consumption is generally low.

7.6 Memory

The WHIM study which dealt with the memory assessment of the US HRT on memory lead to confusion about the role of 17β-E_2 on memory. WHI (1995–2002) was stopped prematurely because a higher rate of vascular incidents was observed in the HRT-treated group. In addition, in the WHIM sub-population, a slight deterioration of the "Minimal Mental Scores" was detected in treated women versus placebo. However, the figures were far from alarming: 40/2,245 versus 21/2,245, respectively [215]. Later, it was understood that the type of HRT combined with the age of the volunteers and with their body weight most probably favors the deleterious effect of HRT on the vascular function and secondarily on the brain function. There are few epidemiological studies connecting soy consumption and memory and none connecting **Isofl** and memory. Previously, one study had reported an adverse effect of high tofu intake on dementia incidence in old men [216]. Another independent study reported a deleterious effect of tofu consumption on memory characteristics in old men but a positive effect of tempeh (containing vitamin B9) [217]. Hogervorst noted that the deleterious effects he observed at first on a large cohort of Indonesian subjects were no more significant on a smaller group of subjects living in the same district and after a stratification based on age [218]. Note that the tofu consumption that was considered in that study varied from 0 servings per week to 21 per week (three times per day). The largest group had one tofu serving per day. From these data no firm conclusion can be drawn on the effect of either soy or **Isofl**.

Epidemiological and ecological studies are of great interest, especially when they involve large populations of subjects. However, when different populations are compared, abusive correlations can be made between different items that are not always relevant because of the many existing confounding factors that are not always considered. Comparisons of Asian and Caucasian populations each in their own contexts must take into account cultural, socio-economic, medical, and environmental factors that include diet. When health disorders are considered it must be remembered that medical surveys are not the same in all countries and that, in some cases, figures can be misestimated for that reason. For example, menopausal symptoms or prostate cancers may not be declared equally in developed and emerging countries. Exposure to persistent pollutants (radioactivity or chemicals) or to specific climate factors (long nights in northern countries) can greatly influence several health parameters. When Asian and Western diet habits are compared it must be remembered that there are great regional variations, especially in emerging countries where local habits based on traditional food availability is a major factor in foodstuff consumption. Therefore, epidemiological and ecological data must be sustained by clinical interventions and mechanistic explanations.

8 Clinical Trials

8.1 Menopausal Symptoms

Many studies exist in the literature dealing with the clinical effects of soy **Isofl** with estrogenic activities on menopausal symptom relief. Two recent reviews were retained here to illustrate this specific point. The first one by Bolaños and co-workers [219] analyzed 19 previous studies. They tried to separate the studies, and their conclusions were based on the source of **Isofl** used. They observed more convincing results than the previous meta-analysis. They sorted **Isofl** sources between soy concentrates, soy-based food supplements, and soy extracts. The general tendency is a reduction of hot flush incidence, but the greatest heterogeneity of the results was observed with soy-based food supplements. The other recent meta-analysis is that of Keeley and Caroll [220]. These authors examined the effects of preparations based on several plant extracts. They selected studies conducted in treated versus placebo clinical trials and using pure extracts not mixed with other plant extracts or with vitamins or minerals. Their conclusions are drawn for each preparation type. Considering **Isofl** preparations, they conclude that a lack of well-designed-studies cannot lead to the conclusion of a beneficial effect of soy-based food supplements on menopausal symptoms. They underlined the great variability in the study designs and the lack of control over the plant extracts. From our point of view, **Isofl** preparations are likely to have a beneficial effect on the occurrence of hot flushes even though the great heterogeneity of the studies did not show it conclusively. We argue for a positive effect of the **Isofl** preparations based on the popularity of such preparations among peri- and menopausal women. Indeed, many other types of preparations were proposed to relieve these symptoms and none have been as popular as the soy-based food supplements so far. It is difficult to believe that women would have wasted money for years without any relief. However, there is a crucial need for well-designed studies testing homogenous groups of women. These studies need to use fully characterized extracts and avoid interaction with other chemicals or plant extracts. **Isofl** bioavailability and metabolism should be evaluated among women during these trials since several metabolites may have greater effects than others. The incidence of hot flushes needs to be evaluated more precisely and to be based on more than self-declaration. The occurrence of placebo effects on such a symptom is undisputed, but several studies showed that **Isofl**-containing preparations may have a better effect than placebo, although the improvement could be moderate [221, 222]. For now, the market is highly heterogenous with a large choice of doses, products not claiming any **Isofl** content, and products making false claims. This anarchic offering [41] combined with the great inter-individual differences in **Isofl** bioavailability and metabolism among women [78] can only result in conflicting opinions on the benefits of **Isofl** on menopausal symptoms.

8.2 Breast Cancers

Some clinical trials designed to examine the effect of **Isofl** on menopausal symptoms, on bone resorption, or on vascular risk factors tried to determine whether these treatments could influence the occurrence of breast cancer. To date, no study has reported an effect of **Isofl** on breast cancer proliferation because no ethics committee would ever authorize the test of such compounds on women with a proliferating ER-positive tumor. The only data that are available were collected some time ago on women with benign breast hyperplasia, and the examination was usually done on samples collected on healthy tissue. Three studies match these characteristics, that of Petrakis and coworkers [223], that of McMickael-Philipps and coworkers [224], and that of Hargreaves and coworkers [225]. All three studies are concordant, which gives their results an undisputed power. The authors used daily administrations of either 45 or 60 mg of **Isofl** in soy-based food supplements or in soy-based-food. These doses are common in the market. The treatment was done from 2 weeks to 1 month prior to the biopsies, on premenopausal women. All studies looked for an estrogenic effect of the **Isofl** on the healthy breast tissue without clear statement on volunteers' ovarian cycles. All found an effect that went from the secretion of breast fluid to the increased production of estrogen-dependent proteins, like PS-2 and progesterone receptors (PR). Some clearly showed breast epithelial cell proliferation. From these studies, it can be said that an oral intake of **Isofl**, at doses from 45 to 60 mg per day, has an estrogenic effect on healthy breast tissue. This means that the **Isofl** bioavailable concentrations and their circulating forms are adequate for an estrogenic effect in the breast tissue. More recently, the study of Qin and coworkers [226] tried to find epigenetic effects of **Isofl** on genes implicated in breast cancer progression. Although their approach is interesting, their results are not fully conclusive. The doses they used were 37.2 and 128.8 mg **Isofl** on premenopausal women aged between 19 and 54 treated for an ovarian cycle. However, contrary to the previous studies, they found no estrogenic effect based on C3 and cell morphology measurements. They interpreted some of their results as anti-estrogenic effects. Conversely, they found different effects according to the doses they used on the hypermethylation of some genes' promoter. As an example, *RAR*β*2* methylation decreased for **Gen** plasma levels below 600 ng.mL^{-1} and increased for **Gen** plasma levels above 600 ng.mL^{-1}. This correlation, which excludes the other **Isofl**, likely needs additional analysis. In addition, the great variability in the age of the recruited subjects probably requires discussion. Because all of these studies were performed involving premenopausal women who presented significant 17β-E_2 plasma levels, the hypothesis of a synergy between **Isofl** and 17β-E_2 cannot be rejected. Therefore, the transposition to the menopausal or post-menopausal situation must be considered cautiously.

8.3 Colon Cancer

There are few clinical trials involving **Isofl** with estrogenic activities and colorectal cancer (CCa). Their results are not consistent. Adams and coworkers [227] found no effect of a 12-month dietary soy intervention with 81 mg/day of **Isofl** on three sites in the colon on the basis of five different measurements in a population of mostly men aged

50–80 with previous adenomatous polyps. Soy consumption on the contrary may have a preventive effect on CCa [203], but this needs to be confirmed by supplemental studies.

8.4 Prostate Cancer

Prostate cancers (PCa) are hormone-dependent diseases. The proliferation of prostate cancer cells is under the positive control of both androgens and estrogens. Testosterone and DHT induce PCa growth, and AR are the main targets of current therapies. However, ERs are differentially expressed in the prostate tumors and during cancer progression and Aromatase KO (ARKO) mice had a lower incidence of PCa showing that the local production of 17β-E_2 from T plays a role in cancer progression. While the proliferative effect of 17β-E_2 seems to be essentially mediated by ERα, ERβ on the other hand seems to be protective since it is either absent or not detectable in 40 % of the tumors [228]. Therefore, the combination of anti-5-AR, ERα antagonist. and ERβ agonist seems to be a promising treatment option for PCas. Although the exact implication of this ERβ receptor is not yet well defined, **Isofl** are thought to prevent clinical PCa because they exhibit a better affinity for ERβ than for ERα. As mentioned above, affinity does not mean transcription activity, and heterodimers can possibly be active. There are unconvincing results from clinical trials involving **Isofl** with estrogenic activities on PCa [143]. One study evaluating red clover **Isofl** supplements on the progression of PCa before surgery found a significant elevation of apoptosis in radical prostatectomy specimens [229]. The doses were 160 mg/day and there were 20 cases versus control. On the contrary, many studies did not find any effect on tumors. The study of de Vere White and coworkers [230] found a partial reduction of PSA in 17 % of their patients (up to 50 % reduction) with the administration of 900 mg of **Isofl** for 6 months. Lazarevic and coworkers found a modest reduction of PSA (7.8 %) with 30 mg of pure **Gen** in 54 % of their subjects treated for 3–6 weeks prior to prostatectomy [231]. Because PSA is not an absolute marker of PCa tumor progression, there is no pure evidence of a protective effect of **Isofl** with estrogenic activities on PCa [232], although soy may be protective [233].

8.5 Osteoporosis

Osteoporosis is a disease characterized by osteopenia and a higher risk of bone fracture. Because bone architecture is as essential for bone resistance as BMD, BMD cannot reflect, on its own, the osteoporosis prevention. In addition, although bone is in constant remodeling, its evolution is slow and a preventive effect cannot be demonstrated in short-term trials. Therefore, at the same time as the epidemiological studies involving soy-based-food, some clinical trials were performed involving soy-based food supplements. They allow compliance with higher-dose-treatments for long periods of time. Among the 17 studies cited by Lagari and Levis [214], 12 were performed in peri- and menopausal women between 40 and 65 years of age. The inclusion of peri-menopausal women is likely to have reduced the significance of the results since these women with significant circulating 17β-E_2 are likely not to respond to the **Isofl** treatments in the same way as menopausal women. Three studies only lasted for several weeks and measured BTM. One involving pure **Gen** did not show any effect and the two involving **Isofl** mixtures showed a reduction of BTM. To complete these data, note that when ***S*-Eq** is analyzed on its own in clinical studies, it seems to exert a specific lowering effect on bone turnover. The other studies lasted from 6 months to 4 years. Generally, when BMD was measured it improved, as well as BTM. It must be emphasized that these effects were all obtained using high doses of either **Gen** or mixed **Isofl**. These doses ranged between 40 and almost 700 mg **Isofl** per day. Efficient doses were commonly over 54 mg per day and their effects were essentially limited to the lumbar spine and sometimes to the femoral neck; effects were not observed on peripheral bones. It must be specified that several studies associated **Isofl** with calcium and/or vitamin D supplements as well as physical exercise. In addition, it is well known now that other dietary factors including alkaline components, proteins, vitamins [148], and polyphenols [234] can prevent bone loss, and that colas and acidified food should be avoided [235].

8.6 Memory

Some studies showed maintenance of several types of memory performance in post-menopausal women under soy supplementations compared with other food supplementations. A moderate intake of **Isofl** produces positive effects and spatial and verbal memory are usually improved or at least maintained, compared with controls [236, 237]. Three other experiments were performed using soy. In young volunteers a 10-week soy consumption with 100 mg of **Isofl** improved cognition [238]. In post-menopausal women, 99 mg of **Isofl** in soy for 12 months did not improve the cognitive performances tested [237]. Conversely, 72 mg of **Isofl** daily in soy milk had no effect on different memory tests and was deleterious to verbal working memory performances [239]. When these results are considered in parallel with the epidemiological studies, soy may not be beneficial to memory. When **Isofl** are considered in soy-based food supplements, eight studies should be included. They were performed on young or aged subjects, on Caucasian or Asian subjects, and on either men or women. Five studies exhibited positive results on either memory tests or on mood tests whereas three studies led to no improvement. Duffy and coworkers [240] showed, in 33 post-menopausal women treated for 12 weeks with 60 mg soy **Isofl**, a significant improvement in recall of pictures and in a sustained attention to tasks. Casini and coworkers [241] treated post-menopausal women for 6 months with 60 mg of soy **Isofl** and showed an improvement of mood disorders. Gleason and coworkers [242] tested 100 mg of soy **Isofl** for 6 months on 34 elderly men and women. They found that **Isofl**-treated subjects improved their performance on tests of visual-spatial memory ($P < 0.01$), construction ($P = 0.01$), and verbal fluency ($P < 0.01$) and speeded dexterity ($P = 0.04$). Islam and coworkers [243] tested a supplementation of 100 mg soy **Isofl** for 3 days at various periods of the menstrual cycle in 28 premenopausal women and compared their effect to that of naturally synthesized 17β-E_2. They showed that **Isofl** supplementation during menses (low 17β-E_2 plasma levels) led to an improvement in working memory and verbal memory when 17β-E_2 in the luteal phase seemed only to affect verbal memory. Thorp and coworkers [244] tested 116 mg of soy **Isofl** on 34 men in a 12-week double-blind, placebo-controlled cross-over trial. They found that **Isofl** supplementation significantly improved spatial working memory ($P = 0.01$) but did not affect auditory and episodic memory. On the contrary, Ho and coworkers [245] found no effect of 80 mg supplementation of soy **Isofl** in healthy Chinese post-menopausal women. However, nothing is said in this study on the soy consumption of the subjects and this may have induced a bias in the results. Maki and coworkers [246] found no effect of 120 mg **Isofl** from clover fed to 14 women for 12 months. Finally, Pilsáková and coworkers [247] tested the mental rotation in 20 men and 16 women. They found a negative effect of 0.34 mg **Isofl** administrated for 1 week. From these studies, it appears that soy **Isofl** as supplements may have a positive effect on spatial working memory. However, the treatment needs to be done at doses from 60 to 120 mg for 12 weeks to 12 months with a correct management of confounding factors including diet factors.

9 Pharmacological Applications

The pharmacological use of **Isofl** with estrogenic activities is an undisputed fact today. In 2005, our team identified 136 different preparations from 67 different laboratories available in French shops or presented in French on the web. Our partial analysis of this market presented notably in [41] led to the same conclusions as those expressed by Setchell and coworkers [248], Nurmi and coworkers [249], and Kelley and Carrols [220]. In all cases, it was considered that the selection was greatly heterogeneous with **Isofl** content claims varying from 2 to 120 mg per units (capsules, tablets, etc.) with preparations with no claimed doses and with discrepancies between the claimed doses and those found after analysis. Moreover, in several cases when different batches were analyzed, variations in the **Isofl** composition were observed, indicating that the soy extract was not the same from one batch and the other. This market must be monitored to avoid misleading consumers. Several preparations like Bonistein® containing pure synthetic **Gen**, vitamin D, K1, and fish oil are sold today. The claim is bone protection, although the results are not yet fully convincing. Soy-germ-based food supplements containing a high amount of **Gly** are also sold by various manufacturers. Note that **Gly** does not induce MCF-7 proliferation in vitro [250]. Recently, a fermented soy extract enriched in ***S*-Eq**, namely SE5-OH, appeared on the market [251].

9.1 Menopausal Symptoms

The major claim for **Isofl** containing food supplements is the relief of menopausal symptoms. There is still much controversy around this effect. However, the popularity of these preparations around the world suggests a positive effect in at least some of the users. Because of the large variability in the preparations available on the market, the placebo effect, and the large inter-individual variations on **Isofl** bioavailability it seems highly logical that there should be a conflict of opinions on this issue.

9.2 Breast Cancer

Because of the controversy around the effects of **Isofl** on breast cancer proliferation and risks, the soy or clover-based food supplements advertised in the 1990s for breast cancer prevention have disappeared from the market today. They were proposed to children and teenagers in a preventive strategy. Because soy contains many compounds that are as interesting as **Isofl**, like phytosterols, soya saponins, abd protease inhibitors, the reduction of the beneficial effect of soy to that of **Isofl**, especially in the case of breast cancer prevention, seems illogical. It is more sensible to advise a regular and moderate soy-food intake from childhood to adulthood as part of a well-balanced and diversified diet.

9.3 Colon Cancer

There is no clear effect of **Isofl** on CCa in men, even though some data would advocate for a protecting role in women. However, soy may be protective through other soy components like saponin, sapogenin, or Bowman-Birk inhibitor [252, 253]. These compounds only have limited blood availability. However, they are in contact with gut cells at a significant rate. Marketing **Isofl** in food supplements for the prevention of CCa does not rely on consistent scientific data.

9.4 Prostate Cancer

There are **Isofl**-containing food supplements on the international market claiming to be healthy for the prostate health. Usually, **Isofl** are associated with other ingredients with anti-oxidant properties. The efficacy of these preparations is unclear.

9.5 Osteoporosis

Despite the concordance of positive results in vitro, in animal models, and sometimes in clinical studies, estrogenic **Isofl** are not considered to exert a clear preventative effect on human osteoporosis. As mentioned earlier, the reduction of the excretion of BTM or maintenance of BMD does not strictly indicate a reduction of the risk of bone fracture. In France and in Europe, the food and health agencies have not so far allowed a health claim on osteoporosis prevention. A claim on the prevention of bone loss with daily doses over 60 mg, preferably in two intakes per day, may be more easily obtained. However, as mentioned earlier, such a preventive effect can be achieved only with high doses of **Isofl**, which are susceptible to affect the proliferation of ER-positive breast cancer cells in menopausal women with breast cancer. Therefore, this use must be monitored carefully.

10 Toxicity

The effects of 17β-E_2 are numerous and tightly regulated through a precise balance of its bioavailable concentrations in fetuses, in infants, during childhood, in adult men and women, and during senescence. Therefore, a slight modification of the estrogens in an individual can lead to so-called endocrine disruptions. The adverse effects presented here are essentially demonstrated in animals with high doses of **Isofl**, and usually only suspected in humans where it is ethically difficult to experiment on toxicological effects.

10.1 Reproduction

The potential adverse effects on reproduction are sustained by the historical data from the 1940s obtained on Australian ewes grazing clover pastures and presenting an infertility syndrome [254] and also by the work of Farnworth and coworkers [28, 29] identifying **Isofl** with estrogenic activities in many plants traditionally used in our countries as sources of anti-fertility agents. In addition, the classical definition of estrogens as having uterotrophic characteristics [255] may lead to a suspicion of adverse effects on women's reproductive system. We are now examining the potential adverse effects of high doses of **Isofl** with estrogenic activities during in utero exposure, during infancy and in adult life.

10.1.1 In Utero Exposures

An effect of **Isofl** with estrogenic activities can be considered if their concentrations combined with their affinity overcome that of 17β-E_2, or if these concentrations induce a modification of the endogenous 17β-E_2 bioavailability in fetuses by interfering with the AFP. In both cases, considering the affinity ratio for the ERs and the AFP of steroidal and non-steroidal estrogens respectively, the **Isofl** concentrations must be very high in the fetus plasma and therefore ingested at very high levels by the mother. In Western women, who do not consume soy significantly, the **Isofl** levels in the amniotic fluid are on average 40 nM [256]. In contrast, it was shown that in Asian women under regular and moderate soy consumption with an intake of **Isofl** in the range of 20 mg per day, the **Isofl** level in the amniotic fluid was 250 nM [257] or about 10 times that of 17β-E_2 [258]. These concentrations are not sufficient to induce an adverse effect on the fetuses as seen in Asian populations.

In parallel, it was shown that 45 mg of **Isofl** per day affect LH secretion in premenopausal women, lengthening the menstrual cycle in American Caucasian women [259] to the duration commonly observed in Japanese women, that is, 30 days instead of 28 days in Western countries. During pregnancy, LH secretion required for progesterone production is essential. An adverse effect of **Isofl** during pregnancy may be observed through this mechanism but only at high doses. This was observed in ewes on clover pastures by Findlay and coworkers [260]. This disruption of LH and progesterone levels was shown to lead to miscarriages. However, according to Sharpe and Skakkebeck [261], an estrogenic contamination can also affect the sex differentiation in males via a complex mechanism. The estrogens can reduce the GnRH secretion of the fetuses affecting their in utero secretion of FSH and LH and consequently their secretion of T by Leydig cells and of 17β-E_2 by Sertoli cells. This can lead to a hyposecretion of anti-Mullerian hormone (AMH) and consequently to cryptorchidism and hypospadias. If a regular and moderate intake of soy is safe in this mechanism, it must be pointed out that two independent studies reported a significant elevation of the incidence of hypospadias in babies whose mothers had a vegetarian diet during pregnancy [262, 263]. The results are remarkably concordant on hypospadias risk with OR = 4.99; $IC_{95\%}$ = 2.10–11.88 in [262] and OR = 4.6; $IC_{95\%}$ = 1.6–13.3 in [263]. However, some confounding factors, like a lack of crucial nutrients or an elevated intake of herbicides or pesticides with estrogenic effects due to the consumption of vegetables, prevent the conclusion that there is a direct effect from soy **Isofl**.

10.1.2 Neonatal Exposure

As mentioned previously, only high **Isofl** intakes can possibly cause adverse effects. However as seen in Table 77.2, babies fed soy-based infant formula exclusively during their first months of life experience a tremendous intake of **Isofl**, 5–11 times higher than that occurring in adults under normal soy consumption or in adults using soy-based food supplements [51] (Table 77.2). The report by Rozman and coworkers [51], who worked on behalf of the US Department of Health and Human Services, mentioned **Isofl** plasma levels in babies under this specific diet ranging from 3.5 to 6.5 μM. As mentioned previously, **Isofl** at a plasma concentration of about 1 μM decrease LH production in premenopausal women. Therefore, it seems sensible to fear a decrease of LH production in babies under an exclusive intake of soy-based infant formulas. As a matter of fact, in male babies it is known that a LH surge occurs naturally around 4 months of age [264, 265]. This is before teething and before diet diversification. This LH surge is responsible for the masculinization of the sexually dimorphic nucleus of the preoptic area (SDN-POA). It must be noted that the masculinization of the SDN-POA is obtained after LH induced T production in the testes and after the aromatization of T into 17β-E_2 in the SDN-POA. This means that the masculinization effect itself is under estrogen stimulation. This process leads to an increase in the size of the SDN-POA in males. If the neonatal LH surge is prevented in male neonate macaque rhesus using a GnRH analog, for example, a smaller SDN-POA is observed, a devirilization of adult behavior [266, 267], a reduction in adult testicular size [266], a reduction of sperm production in adults [266], osteopenia [268], and a partial immunodeficiency [269] affecting specifically the T $CD4^+$ lymphocytes. In female infants the LH surge is not as pronounced and usually occurs later, on average after 6 months of age usually after diet diversification.

Now, what could be expected from an overloading of **Isofl** with estrogenic activities in infants? Isoflavones can exert two major effects an anti-LH effect and an estrogenic effect. In marmosets, it was shown that partial feeding of male infants with human soy-based infant formulas leads to a decrease in the neonatal T levels induced by the normal LH neonatal surge [270]. It seemed that this effect was probably compensated later since the cellular composition of testes with respect to Leydig and Sertoli cells was finally not affected at the adult stage [271]. Note that in that specific experiment the feeding was not exclusive and therefore no rigorous comparison can be made with a human situation where a mother conscientiously feeds her baby several times a day (and night) with a soy-based infant formula. If the feared decrease in LH production is achieved, one could expect a reduction in the testicular size, a reduction in the sperm production later in life, but no disruption of the sexual behavior since at the SDN-POA level, the lack of T and consequently of aromatized 17β-E_2 could be compensated by **Isofl**. On the other hand, in female infants LH is not expected to be produced before 6 months of age or the estrogens induced by such a synthesis. Then the SDN-POA remains normally of a small size. In that context, a contamination by xeno-estrogens, including **Isofl** with estrogenic activities, may induce a masculinization effect on the SDN-POA leading to a masculinization of the behavior later in life. This has been observed in rats using treatments with high doses of coumestrol and **Gen** [272]. Up to now, only one study has given data on the effects of exclusive soy-based formula intake during infancy versus cow's milk-based formula on adult reproductive parameters, including sexual behavior, and that is the study by Strom and coworkers [273]. They claimed that no effect was observed. However, they did not examine testicular size or sperm production in men fed soy formula in their infancy, or the women's social behavior under the same diet. Conversely, they found a significant and higher incidence of acne spots during menstruation and of painful menstruations in women fed a soy-based formula during infancy. In addition, there were 3 stillborns out of 79 births in the soy-formula group versus 0 out of 148 births in the cow's milk group. These results were not significant because the population size was not large enough. Because acne spots and painful menstruations are under hormonal control, it seems abusive to conclude an absence of endocrine disruption with exclusive soy-based infant formula feeding in neonates. Indeed, several pediatric societies around the world, in the United State, Great Britain, France, and New Zealand, clearly advise against the use of these formulas at an early age unless there is a clear health indication (galactosemia or lactase deficiencies, which are very rare) or unless it corresponds to the parents' convictions [51]. Finally, a recent review advises care with soy-based infant formulas considering the recent growing data on the effects of soy **Isofl** on male sperm count and male fertility [274].

10.1.3 Over-loading in Adults

Cases Reported in Women

Chandrareddy and coworkers [275] reported three cases of endometrial disruptions correlated to high soy consumption. The consumers were American women. One was a 56-year-old postmenopausal woman, one was a 43-year-old pre-menopausal woman, and the third was a 35-year-old woman; all declared having high soy consumption for periods varying from 2 to 14 years. The pre-menopausal women were taking contraceptive pills based on norethisterone, which blocks menstrual bleeding, this bleeding being very painful. Despite this treatment, they both exhibited bleeding and associated pains. All three women had endometrial polyps and fibroids. They exhibited endometriosis patterns that were recurrent even after adequate surgery. Pharmacological doses of **Gen** were shown to induce endometriosis patterns in rats [276]. All symptoms disappeared in these women after the interruption of soy consumption. The youngest got pregnant after soy and contraception arrest. In this case, the **Isofl** intake in pre-menopausal women was so high that it counteracted the norethisterone treatment, establishing an estro-progestational contraception where a progestational contraception was intended. In his study, Chandrareddy did not detail the levels of the **Isofl** intake. However, we observed (unpublished data) the case of a 31-year-old pre-menopausal woman under norethisterone contraception who had painful menstruations even when under treatment. In her case, the soy and **Isofl** intake could be evaluated. She declared having a soy-based yogurt, a soy-based-dessert cream, and soy-based cereals every day, 30 mg **Isofl** on average. She also had tofu once a week and also 1 L of soy milk (tonyu) two or three times a week. According to our measurements and considering the great variability of **Isofl** content in tonyu (80–280 mg/L) her **Isofl** consumption could then vary from 30 to 333 mg of **Isofl** per day when she had a tofu and a tonyu drink highly concentrated in **Isofl**. The highest dose is about 15 times higher than the habitual exposure in China and five times higher than the highest consumption considered in Japan. In these circumstances, the symptoms observed could be easily explained.

Cases Reported in Men

Again, only high soy consumption or the specific potentiating effects of **Isofl** are under discussion here. Chavarro and coworkers [277] presented the effect of soy and **Isofl** consumption on sperm count in men. They recruited 99 men who were male partners from subfertile couples with complete dietary and semen analysis data. They constituted four groups according to the soy food and **Isofl** intake. Age, abstinence time, BMI, smoking status, caffeine, and alcohol intakes were considered. Seventy-two percent of the men were overweight, with BMI > 25 kg/m^2. The authors observed that soy-food and **Isofl** intakes were inversely related to sperm concentration. Men with the highest intake level of soy foods (≥ 2 times per week) had 35 million sperm.mL^{-1} less than men who did not consume soy foods ($CI_{95\%} = -67, -3$), and there was a significant trend toward decreasing sperm concentration with increasing soy food intake (P, trend $= 0.03$). The adjusted difference in sperm count was significant, $P < 0.05$ for obese volunteers under the highest soy food intake, with a decrease of 50.45 million sperm.mL^{-1}. There was a strong trend in non-obese volunteers still on the highest soy food intake, with a decrease of 48.2 million sperm.mL^{-1}. The difference between obese and non-obese volunteers can be explained by a synergy in the obese subjects between **Isofl** and 17β-E_2 produced by adipose tissues. More recently in Japan, Toshima and coworkers [278] analyzed the urine concentrations of cadmium, 3-PBA (an insecticide with endocrine disruption effects), and **Daid** and ***S*-Eq** of 42 Japanese men. They were male partners of couples who had infertility problems. Semen parameters (volume, concentration, and motility) were examined. After multiple regression analysis it was found that fruit and coffee consumption as well as urinary **Daid** explained a reduction in sperm concentrations ($P < 0.001$, $P < 0.01$, and $P < 0.001$, respectively). In addition, coffee consumption, ***S*-Eq** production, and 3-PBA detection in urine explained a reduction in sperm motility ($P < 0.001$, $P < 0.05$, and $P < 0.01$, respectively). This pilot study suggested that apyrethroid exposure through fruit consumption and other dietary habits, including coffee and soy intake, were significant contributors to poorer semen quality. These studies may be considered with that of Fisch et al. [279], who reported that sperm count was significantly lower in Asian people than in men from Western populations without fertility disruption. These data are also supported by results recently reported in male mice exposed to soy containing food from conception to adulthood versus a soy free diet [280]. The authors observed a reduction of haploid germ cells in testes with a 25 % decrease in epididymal sperm counts and a 21 % reduction in litter size. Transcripts coding for androgen-response genes in Sertoli cells and Gapd-s, a specific spermatid marker, were significantly reduced. In addition, dietary soy decreased the size of the seminal vesicle without affecting its proteolytic activity. There was no effect on male behavior. From this study it can be said that dietary soy and phytoestrogens may affect male reproductive function resulting in a small decrease in sperm count and fertility.

10.2 Estrogen-Dependent Cancers

There are no data available on humans, except those obtained from studies conducted for other scientific purposes, regarding the incidence of cancer during soy or **Isofl** supplementation. As a consequence, there are no significant results or data. However, the US National Toxicology program checked for the toxicological effects of **Isofl** in a comprehensive 2-year study [281]. Sprague–Dawley rats were exposed for five generations to 0, 50, 100, 500, and 1,250 ppm of **Gen** in their diet. Different conditions of exposure were tested. None revealed a carcinogenic activity of **Gen** in males whatever the dose. On the contrary, the different exposures showed some evidence of the carcinogenic activity of **Gen** in female Sprague–Dawley rats, especially for the 500 ppm dose, based on increased incidences of mammary gland adenoma or adenocarcinoma (combined) and pituitary gland neoplasms. In addition, exposure to **Gen** was shown to accelerate the onset of aberrant estrous cycles. The effects of **Gen** on estrous cycling and the incidence of common hormonally related spontaneous neoplasms in female Sprague–Dawley rats are considered by the authors to be consistent with an estrogenic mechanism of toxicity.

10.3 Hypothyroidism

Links have already been made between alterations in thyroid function and soy consumption. In the 1960s when the first soy-based infant formulas were commercialized, hypothyroidism goiters were observed and led to iodine supplementation in these formulas. However, when hypothyroidism is detected it still is difficult to manage in babies under soy-based infant formulas [282, 283]. In parallel, the case of a woman who was treated with levothyrox for hypothyroidism showed that the intake of soy-based food supplements interacts with drug absorption [284]. As a result, the doses required to balance her thyroid function had to be increased when soy-based food supplement was taken simultaneously with levothyrox treatment. The mechanism of action is not fully characterized but **Gen** was found to bind to thyroid hormone receptors [285] and to compete with T3 at concentrations of 1 μM, which are dietarily relevant. Many other studies, however, showed no adverse effects from soy or isoflavones on thyroid function of healthy subjects [286–291]. In addition, in Japan, where soy is consumed at the highest rate on earth, no adverse effects were consistently reported. However, the traditional Japanese diet is based on a large variety of sea foods that are rich in iodine. They may compensate for the effect of soy and/or isoflavones on an alteration of the thyroid function. Taking all these data together, it seems that the adverse effects of soy or of soy **Isofl** may occur only in persons with previous hypothyroidism. In that case, a balance in the thyroid function may be more difficult to achieve medically.

10.4 Myeloid Leukemia

Gen also exhibit anti-DNA topoisomerase II effects at high doses [292]. DNA topoisomerase II is a nuclear enzyme involved in DNA repair. Its inhibition can lead to increased consequences for DNA damage. This effect was advocated in the late 1990s to favor infant myeloid leukemia via a fetal exposure from mothers consuming soy [293]. Although this effect has not been proved, one study pointed out the highest prevalence of this pathology in Chinese populations with a relation to genetic influence [294].

11 Conclusion

Sometimes the effects of **Isofl** with estrogenic activities are wrongly associated with those of soy. This has to be considered with caution inasmuch as soy contains many other compounds with potential health impacts, like saponins, sapogenins, protease inhibitors, and phytosterols. Because of their low efficiency of transfer through the enterocyte barrier, their actions are most probably relevant for gut health. The effects of **Isofl** with estrogenic activities are relevant to consider for soy extracts enriched in **Isofl** and for pure compounds. Again, because the different **Isofl** do not exhibit the same properties at the cellular level, the effects of a pure compound cannot necessarily be extrapolated to an **Isofl** extract or to the intake of a vegetable source of **Isofl**. That said, soy is a plant that is most probably good for our health because it is rich in protein, low in cholesterol, and contains phytosterols known to prevent cholesterol absorption. However, soy also contains high amounts of **Isofl** with estrogenic activities and high bioavailability in mammal plasmas. Potential estrogenic effects can be expected from high soy consumption. The health effects of **Isofl** with estrogenic activities, although highly probable on bone preservation or on prostate cancer progression, are not yet fully demonstrated because many biases can interfere in the epidemiological or clinical studies undertaken so far, including the effects of other nutrients. Only meta-analysis, taking into account these biases, may help with deciphering what truly happens. Isoflavones with estrogenic activities have demonstrated their estrogenic effects only at high doses in accordance with their low affinities with ERs. The only effects on estrogen-dependent pathologies that could be consensual so far are those related to mammalian reproduction or to interferences with thyroid function in occasional cases of hypothyroidism. As mentioned in the abstract, only chronic intakes of high doses of **Isofl** can lead to significant bioavailable plasma doses because, contrary to anthropoid endocrine disruptors, these molecules only have a short plasma residence time in mammalian organisms. Because of a strong advertising campaign, essentially led by soybean producers and manufacturers, the health effects of soy, which are most probably real, have been largely disseminated. In some cases, they have led to the over-consumption of soy and of **Isofl** with estrogenic activities. If soy consumed on a moderate and regular basis can most certainly lead to disease prevention, high consumption of soy or of **Isofl** with estrogenic activities are most probably not safe. It must be kept in mind that in Western countries, estrogens are only prescribed by doctors via either contraceptive pills or via hormonal replacement therapies. This means that the use of estrogens must be controlled and reserved to particular situations involving specific doses. Indeed, medical drugs are developed for our health and are not designed to be poisonous. However, they are designed to be used in specific doses and for specific symptoms. These considerations must be kept in mind when considering **Isofl** with estrogenic activities. If there is almost a general consensus on their effects on bone health (although strong in vivo scientific evidence is still missing in humans) it is not a reason to administer them in high doses to newborns. Likewise, although **Isofl** with estrogenic activities may be beneficial to prostate cancer, this does not mean that they can be consumed without limit by patients with breast cancer. We think that **Isofl** extracts and **Isofl**-containing-foods are more than simple functional foods. Their estrogenic effects lead them to be classed as food-drugs, because, in Western countries, estrogens are delivered as medical drugs. As such, they must be consumed cautiously, as they are in Asia. This means that they can be consumed on a moderate and regular basis but that consumers must be careful not to over-consume them through frequent daily intake. The limit in humans should be 1 mg/kg/day. According to the food item consumed and to the body weight this should be from one (in children) to a maximum of three normal portions (in adults) of soy items per day. To date, food manufacturers have refused to mention the **Isofl** content of their foodstuffs. Yet, this would be the best way to widen soy food consumption in the community. In the nutrition domain, like in others, excess is never good. In addition, the consumption of **Isofl** or **Isofl**-containing-foods should be mentioned to medical practitioners, who are the people who are best placed to advise about a significant estrogen supplementation.

properties can act, is markedly influenced by metabolism and absorption in the gastrointestinal tract. Indeed, our intestine is the primary metabolically active site of absorption of exogenous factors in our body and harbors trillions of microbial cells with a vast metabolic potential, referred to as the intestinal microbiota. The aim of the present book chapter is to give insights into the role of phenolic compounds in human health. We will focus our attention on two families of polyphenols of importance in human nutrition, namely, the isoflavones and lignans, and will discuss in detail the role of intestinal microorganisms in regulating their metabolism and thereby health effects.

1 Introduction

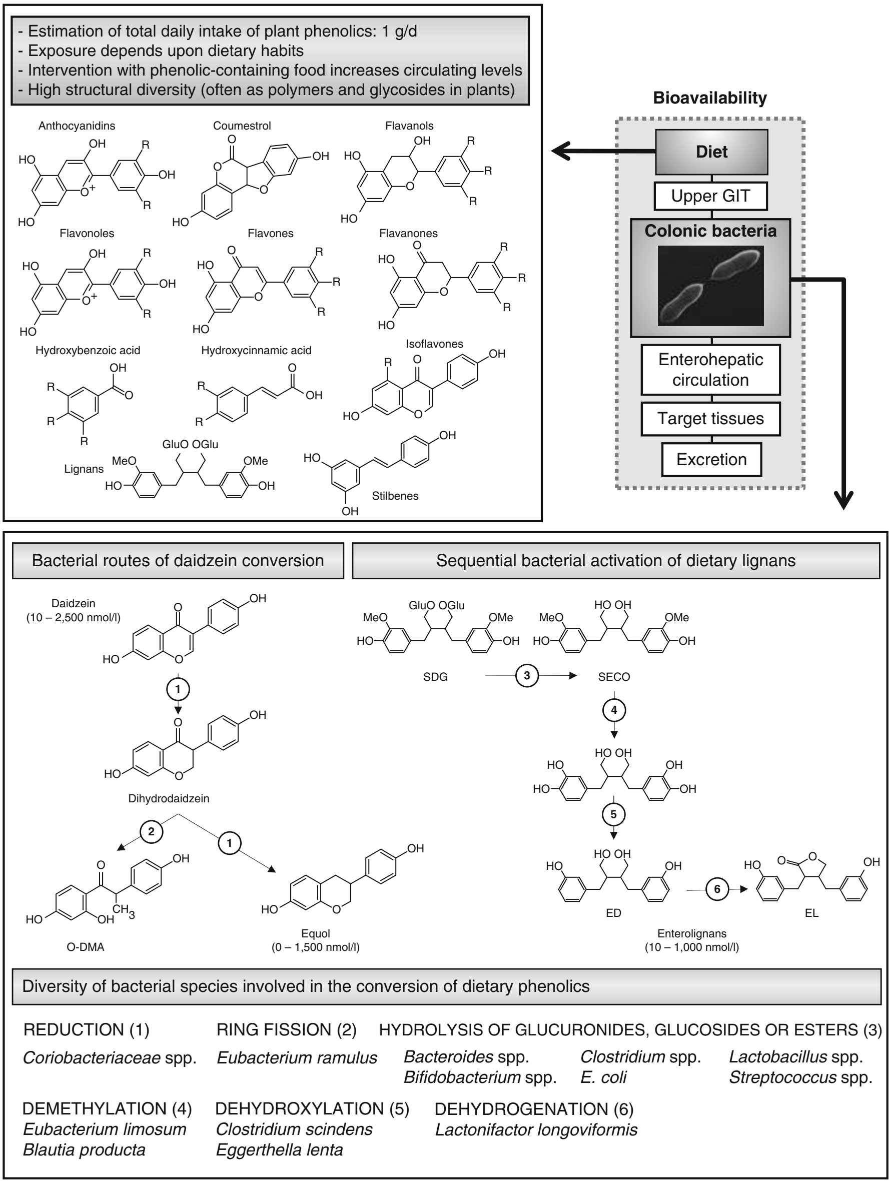
Nutrition, in combination with other environmental factors such as climate shifts and changes in ecosystem structure, has played a key role in evolutionary processes that made us what we are: *Homo sapiens*. Our brain must be constantly fueled with energy in the form of glucose, and essential nutrients such as fatty acids are required for proper brain development. Thus, selectively advantageous eating behaviors have certainly favored essential nutrient supply, efficient energy harvest from food stuff and effective mechanisms of energy storage, contributing to nutritional stability and thereby to more rapid development of cognitive functions and the emergence of our species [1]. Beyond evolutionary issues, it is nowadays acknowledged that nutrition, along with physical activity, are important factors influencing human health. In westernized countries, the long-term deleterious health effects of diets rich in calories, simple sugars, saturated fat, and red meat with respect to the development of cardiovascular diseases, colorectal cancer, and the metabolic syndrome are as much recognized as the virtue of eating enough portions of fruits and vegetables, although underlying mechanisms of actions remain to be described [2–4]. Positive effects of fruits and vegetables are usually attributed to high content of fiber, vitamins, and phenolic compounds (hereon defined as plant secondary metabolites with a backbone structure made of one or several phenol groups). Assuming that a substantial proportion of the dietary intake of common ancestor species consisted of plant materials, it is not surprising that, over millions of years of evolution, our body has inherited an efficient metabolic machinery to dispose of the large quantity of phenolic compounds that we still ingest daily as part of our omnivorous diet. Intestinal microorganisms are intrinsic parts of this metabolic machinery. Indeed, from an evolutionary perspective again, the human body can be considered as a supra-organism made of not only own eukaryotic cells, but also the hundred trillions of microorganisms that colonize various body sites such as the skin and the genital, respiratory and, most importantly with respect to nutrition, the gastrointestinal (GI) tract [5]. The intestinal microbiota is referred to as the assemblage of microbial communities and associated genomes (the metagenome) primarily colonizing the distal GI tract. Due to its highly diverse metabolic potential, the intestinal microbiota greatly alters the fate of phenolics in the human body by changing their structure and absorption rates in the gut, thereby influencing their biological effects.

In that context, the present chapter gives insights into the relevance of phenolic compounds in human nutrition. We will primarily discuss bioavailability and biological properties of isoflavones and lignans in the context of human health and disease, our main focus being the metabolic activities of intestinal bacteria.

2 Phenolics in Human Nutrition

Concoctions of plant products for the purpose of curing disease or sustaining health in human subjects have a long history of use, especially in traditional Chinese medicine. However, molecular mechanisms underlying positive effects have yet to be defined and traditional medicine therefore faces intense criticism [6]. Nevertheless, the emergence of systems biology approaches may help shedding light on host responses toward treatment with plant products that obviously contain a wealth of phenolic compounds [7–9]. Beyond these issues on the role of herbal treatment for improvement of human health, there is a plethora of epidemiological data highlighting beneficial effects associated with intake of food items rich in phenolic compounds. A well-known example of such food items is soy (or soy products) which contain elevated concentrations of the isoflavones daidzein and genistein as well as their glycosylated and methylated precursors (Fig. 78.1).

Biological properties of isoflavones were first coined in the 1940s, after infertility problems started to occur in female sheep grazing on clover pastures containing high amounts of isoflavones, and later in the 1980s in captive cheetahs fed a soy-based diet [10, 11]. These data already suggest that dietary phenolics or corresponding metabolites, such as equol, one of the two end metabolites produced



- Estimation of total daily intake of plant phenolics: 1 g/d
- Exposure depends upon dietary habits
- Intervention with phenolic-containing food increases circulating levels
- High structural diversity (often as polymers and glycosides in plants)

Fig. 78.1 Phenolics in human nutrition: A microbiological perspective. Bioavailability of dietary compounds depends on the sum of molecular mechanisms underlying liberation of the compounds from dietary matrices, absorption, distribution into body tissues via blood circulation, metabolism (in the GI tract or target tissues), and elimination from the body. The keypad shows parameters of relevance to phenolic bioavailability. The two enlarged windows illustrate the diversity of both phenolics in food and microbial functions involved in phenolic conversion, with a focus on isoflavones and lignans. Estimates of blood concentration of daidzein, equol, and enterolignans are

by bacteria from the plant isoflavone daidzein, have the potential to interfere with highly sensitive host hormonal pathways. Since then, numerous meta-analyses and epidemiological studies including Asian populations consuming soy products on a daily basis have reported positive effects of soy intake on the development of breast cancer, bone disorders, and cardiovascular diseases [12–14].

The lignans, a family of polyphenolic compounds with a dibenzylbutane structure (Fig. 78.1), are another example of major plant phenolics relevant to human nutrition. Dietary lignans are converted to the enterolignans enterodiol (ED) and enterolactone (EL) by bacteria in the GI tract [15]. In contrast to isoflavones that occur in high concentrations almost exclusively in soy, a vast variety of food items such as flaxseeds, sesame seeds, berries (blackberry and strawberry), cereals (rye and wheat), and beverages (coffee, tea, and wine) contain detectable concentrations of lignans, which are therefore of importance in westernized diets [16]. Importantly, lignins have also been shown to be dietary precursors of enterolignans [17]. Of note, researchers originally proposed in 1980 that enterolignans were new mammalian hormones after they detected them in urinary extracts from female primates and human adults via spectrometric measurement [18, 19]. This shows that lignans share structural features with steroid hormones and are, as isoflavones, also referred to as phytoestrogens. Two years later, in 1982, the same authors reported that urinary lignans originate from food precursors [20]. Thereafter, enterolignan production has been associated with positive effects on the incidence of heart diseases as well as breast and prostate cancer [21–23].

Besides isoflavones and lignans, human food contains a wealth of phenolic compounds (Fig. 78.1). Rapid improvement in the sensitivity of analytical tools, together with the development of specific databases such as Phenol-Explorer and the USDA Flavonoid Database, have substantially contributed to the understanding of human exposure to phenolics [24]. Table 78.1 provides a non-exhaustive list of major groups of dietary phenolics and representative food sources. Depending on dietary habits, total intake of phenolics in European populations can reach up to 1 g/day or higher [26, 28, 30]. By studying dietary intake in 4,942 French adults, Scalbert et al. showed that the most dominant dietary phenolics are hydroxycinnamic acids, flavonols, and anthocyanins [30]. However, there is a direct positive association between ingested amounts of specific food products and blood concentrations of corresponding metabolites, showing that one can easily and rapidly modulate exposure to specific phenolics by modulating dietary intake. In Asian populations for instance, isoflavones intake is nearing 100 mg/day due to high intake of soy products [35]. Nevertheless, health effects of dietary phenolics do not depend solely on ingested amounts, but rather on the concentration of active compounds that reaches target tissues. In that respect, what makes lignans and isoflavones outstanding is that plant precursors are usually less biologically

Fig. 78.1 (continued) given in brackets (large interindividual differences are observed due to various dietary habits and ability to metabolize polyphenols). Table 78.1 Dietary intake and example food sources of phenolic compounds[a]

Compound	Intake[b]		Food	Content[c]
Phenolic acids				
Hydroxybenzoic acids (e.g., gallic acid)	10–30		Blackberry	8–27
			Tea leaves	Up to 450
Hydroxycinnamic acids (e.g., caffeic and ferrulic acid)	25–800	(68 %)	Coffee	35–175
			Blueberry	Up to 200
Flavonoids				
Anthocyanidins (e.g., cyanidin, peonidin)	20–80		Blackberry	100–400
			Black currant	130–400
Flavanols (e.g., epicatechin)	10–20		Chocolate	45–60
			Apricot	10–25
Flavanones (e.g., naringenin, hesperitin)	25–50		Orange juice	22–69
			Grapefruit juice	10–65
Flavones (e.g., apigenin, luteolin)	5–30		Parsley	24–185
			Celery	2–14
Flavonols (e.g., quercetin, kaempferol)	10–20		Yellow onions	35–120
			Curly kale	30–60
Isoflavones (e.g., daidzein, genistein)	<1–60		Boiled soybean	20–90
		(0–82 %)	Soy milk	3–20
		(3–30 %)	Whole grain bread	0.3–0.8
Lignans[d]	0.5–2	(10 %)	Flaxseed	300
		(3 %)	Sesame seed	39
		(16 %)	Broccoli	1.3
		(0.7 %)	Strawberry	0.3
		(7.4 %)	Wheat bread (whole grain)	0.1
		(3 %)	Beer	0.03
		(11 %)	Coffee	0.02–0.03

[a] Compiled using data from Phenol-Explorer (www.phenol-explorer.eu), the USDA Flavonoid Database (www.nal.usda.gov/fnic/foodcomp/Data/Flav/flav.html) and the following Refs. [16, 25–32]

[b] Given as ranges (in mg/day aglycone equivalent) for each of the listed families of phenolics (e.g., isoflavones). Ranges reflect fluctuations of mean dietary intake depending on population origin (Asia, Denmark, Finland, France, Germany, Holland, Italy, Spain, UK, or USA) and dietary habits. Values in brackets indicate mean contribution of some of the given food items to dietary intake in European populations

[c] In mg/100 g or 100 ml. Of note, concentration of phenolic compounds in food can be altered by food processing [33]. During production of tempeh for instance, a traditional soy product from Indonesia, isoflavone glycosides are hydrolyzed to aglycones [34]

[d] Refers to lariciresinol, matairesinol, pinoresinol, and secoisolariciresinol

active so that enterolignans and equol can be seen as paradigm metabolites highlighting the relevance of bacterial activation of dietary components in the intestine. Hence, no matter which phenolics are of interest and what health effects they have, bioavailability and bacterial metabolism are matters of primary importance.

3 Bioavailability: Importance of the Intestinal Microbiota

Bioavailability refers to the proportion of absorbed doses of a molecule, and eventually metabolites thereof, which reaches sites of physiological activity. Our GI tract is of course at the front line of metabolic events regulating bioavailability due to its primary role in nutrient absorption and because oral intake is the major voluntary route of exchange with our environment (compared with passive exposure to exogenous factors via the skin and the respiratory tract). The liver and kidneys play a central role in bioavailability as well. Efficient conjugation of phenolics for the purpose of increasing water solubility, and eventually excretion, occurs in all three organs (gut, liver, kidneys) mainly via the activity of *O*-methyl transferases, UDP-glucuronosyltransferases, and sulfotransferases [26]. The bioavailability of dietary phenolics is thus tuned by the sum of molecular mechanisms underlying liberation from dietary matrices, absorption, metabolism (by both host and microbial cells), distribution, and excretion (Fig. 78.1).

In upper parts of the GI tract, there is a paucity of data on the fate and role of polyphenols. Their effects have been discussed in the context of oral cancer prevention [36]. Their fate in the stomach has not yet been systematically studied. Quercetin has been shown to be absorbed in the rat stomach, but only as aglycone [37]. Fast plasma appearance of anthocynins may also be explained by rapid absorption in the stomach [38]. Concerning lignans, we found that secoisolariciresinol diglucoside (SDG) (the main enterolignan precursor in flaxseed) is resistant to acid hydrolysis in vitro [39], which confirmed previous findings [40]. In the jejunum, there is good evidence that isoflavones and flavonols can be deglycosylated via lactase-phlorizin hydrolase activity and rapidly absorbed in the brush border membrane of enterocytes [41, 42]. Rat in vitro perfusion models have also been useful in demonstrating absorption of phenolic acids as well as quercetin and phloretin in the small intestine [43, 44]. However, the flavanol epigallocatechin-3-gallate can inhibit hydrolase activity in vitro, yet this inhibition is regulated by salivary proline-rich proteins [45]. This raises the question of the effect of chewing on polyphenol bioavailability via indirect or direct mechanisms such as salivary hydrolysis [46]. Plant phenolic substrates can be detected in blood and urine samples shortly after intake, which speaks in favor of rapid absorption, albeit, in low amounts. For instance, only about 2 % of the ingested dose of plant lignans was found in plasma of four individuals 1 h after intake of 50 g sesame seeds [47]. In some individuals however, plant lignans may occur in higher concentrations than enterolignans in blood samples [48]. This is also true for the isoflavone daidzein, which occurs at higher concentrations than its metabolite equol in blood samples [49], most likely because bacterial production of equol in the gut is a limiting reaction (see details in Sect. 5.1). Altogether, characterization of the metabolic network regulating phenolic bioavailability in the upper GI tract requires further investigation. In particular, very little is known about phenolic transport from gut lumen into blood stream. A recent pharmacokinetic study in human adults based on the use of equol isotopes revealed peak plasma concentrations 2–3 h after oral intake of the isotopes (350–500 ng/ml after administration of a single bolus of 20 mg) [50]. One may interpret that transport mechanisms in the gut are not region-specific, since equol is supposed to be primarily produced in distal parts of the intestine. Absorption rates of phenolics and kinetics of appearance in blood vary greatly depending on chemical structure. For instance, glucosides of quercetin (but not rhamnoglucosides) are more efficiently absorbed than aglycones [51]. However, underlying molecular mechanisms of absorption are not known. So far, only monocarboxylic acid transporters and the plasma membrane carrier bilitranslocase have been discussed for transport of phenolic acids and anthocynins, respectively [52–55]. Independently of what exactly happens in the upper GI tract, it is acknowledged that a substantial proportion of ingested polyphenols can reach the colon, where lower transit time favors bacterial conversion.

The first piece of evidence demonstrating that distal parts of the GI tract are crucial for the metabolism of phenolics is the so-called second plasma peak observed after 6–8 h postprandial when measuring phenolic metabolites in plasma samples overtime after ingestion of plant substrates [56]. Indeed, a substantial proportion of absorbed phenolics is efficiently conjugated in enterocytes and later in the liver prior to secretion back into the small intestine via the bile (enterohepatic circulation) [57]. Enterohepatic circulation thereby contributes to bacterial "re-feeding" since the bulk of glucuronidated and sulfated phenolic metabolites released in the bile can be hydrolyzed by various bacterial species [58]. Bacterial hydrolysis thus allows reabsorption of otherwise lost conjugated phenolics to be excreted in feces and thereby to delayed appearance of phenolic metabolites in the blood (second plasma peak). Another piece of evidence showing that distal gut microorganisms are crucial for phenolic metabolism is the drop in plasma and urinary concentrations of phenolics associated with alteration of intestinal microbial communities following oral antibiotic treatment [56, 59, 60]. Finally, the use of germfree mice, that is, mice that are bred in isolators under sterile conditions and are thus deprived of any living microorganisms, has provided major insights into the important role of intestinal microbial communities in shaping host physiology, including the ability to metabolize food substrates such as phenolics. To some extent, one can consider germfree mice as knockout mice, in which a multifunctional set of genes (the microbiome) has been disrupted, leading to loss of functions. Indeed, besides alteration of immune cell development [61], the absence of microorganisms in germfree animals has major impacts on energy balance [62], nutrient supply via production of short-chain fatty acids, and degradation of mucin [63] as well as phytoestrogen conversion. Enterolignans and equol, for instance, are not detectable in the intestine and body fluids of germfree rats fed phenolic-rich diets, yet gnotobiotic rats colonized with fecal suspensions from phenolic-converting human donors or with isolated active bacterial consortia regain the ability to produce active metabolites [64–67]. Taking into account that the intestinal microbial ecosystem in mammals harbors a total of up to 10^{14} cells belonging to more than 1,000 different species per host, each bearing approximately a few thousands of genes, it is not surprising that the absence of such diverse microbial communities is linked to disturbances in metabolic functions. In the following two sections, we will highlight specific features of intestinal microbiota that are of importance for phenolic conversion.

4 Microbial Diversity: Relevance for Phenolic Conversion

As seen above in Sect. 2, a broad array of food items contain various phenolic compounds in a wide range of concentrations (from a few micrograms up to a few hundred milligrams per 100 g), which highlights the rationale for "eating a little of everything each day" to cover supplies yet avoid adverse effects due to long-term excessive intake of a limited number of food items. With respect to chemical structure, the variety of phenolics is also quite large and the amounts ingested are driven by dietary habits, which differ markedly between individuals (Fig. 78.1). Hence, the mixture of phenolics in the intestinal lumen is determined by multiple levels of complexity and is thus highly diverse and variable.

Diversity is also a major attribute of intestinal microbial communities in mammals. Indeed, although our intestinal microbiota consists dominantly of only four of the 30 known bacterial phyla (highest taxonomic level within the superkingdom *Bacteria*; www.ncbi.nlm.nih.gov/Taxonomy; www.bacterio.cict.fr), namely, the *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, and *Proteobacteria*, the diversity at low taxonomic levels (≤ genus) is very high. Most recent molecular studies refer to a few thousands different bacterial species being present in the human gut, and accordingly even more individual strains [68]. Although bacteria make up the majority of intestinal microbial populations, our intestine harbors also *Archaea* (two dominant methane-producing species, *Methanobrevibacter smithii* and *Methanosphaera stadtmanae*, have been described to date), eukaryotic microorganisms, such as fungi and protozoa, as well as viruses. However, the role of these microorganisms in the metabolism of phenolics is unknown (bacteriophages may, for instance, influence phenolic conversion by regulating the density of specific active bacterial populations).

As often in biology, the efficacy of one complex system (the intestinal microbiota) is greater than the sum of its biologically active parts (bacterial strains). Indeed, one key asset of the high diversity of our intestinal microbiota is that several different bacterial species can carry out one given function, such as cleaving glucose moieties of phenolics. This is referred to as "functional redundancy" (one bacterium can take over the function of another if for some reason the latter disappears). This ensures flexibility and is crucial to achieve stability and ecosystem equilibrium over time upon influence of various environmental stimuli [69]. Hence, the high diversity of our intestinal microbiota helps us cope with the high diversity of exogenous chemical compounds that we ingest. Nevertheless, in spite of this high diversity, there are a few bacterial species (50–100), and by extension a few associated bacterial functions, that make up the so-called core microbiome [70], that is, the assemblage of species/functions that are dominant (occur in high numbers) and show a high prevalence (they are found in most individuals).

Despite the notion of a core microbiome and the stability of the gut microbial ecosystem over time without major changes in dietary habits, each individual person harbors their own characteristic intestinal microbiota (in the sense of a personalized fingerprint). Indeed, there are large interindividual differences in both intestinal bacterial composition (proportion of taxa) and diversity (qualitative pattern of taxa); there is marked quantitative variation and low similarity indexes between gut samples from different individuals, even for dominant bacterial groups [68, 71, 72]. Individualized intestinal microbial patterns in adulthood are highly dependent upon a dynamic sequence of events affecting the ecosystem throughout life, especially in early life. At birth, the human body is colonized by microorganisms from the environment. Primary colonizers (aerobic or facultative anaerobic bacteria) help establish a reduced environment that is suitable for subsequent colonization by strictly anaerobic species, which largely dominate the ecosystem in adulthood. In infants below 1 to 2 years of age, the human intestinal microbiota is unstable and composition fluctuates greatly [73]. The infant gut microbiome seems not to be well equipped for efficient conversion of polyphenols. For example, equol is not detected in urine and blood samples from infants below the age of 12 months who are fed cow or breast milk [74, 75]. Delivery mode at birth (vaginal delivery vs. caesarian section) and breast versus formula milk feeding have been shown to influence microbial colonization patterns [76–79]. In early life, and very often thereafter, the intestinal ecosystem is challenged by infectious agents and antibiotic therapies. In most cases, the ecosystem shows resilience, thanks to its diversity, that is, it rapidly returns to its original state after a challenge. However, in some cases, and more likely and frequently during infancy where microbial populations are not yet fully stabilized, the ecosystem or at least specific community niches can be permanently affected [80]. Altogether, this variety of colonization and challenging events can partly explain why certain individuals harbor specific bacteria and others do not, and why the latter group therefore lacks the functions expressed by absent or subdominant bacterial species. For instance, it is well known that only about 30–50 % of human subjects produce equol from the isoflavone daidzein, meaning that one half to two thirds of human populations do not harbor equol-producing bacteria in their intestine, at least not in high enough densities [81, 82]. Likewise it has been shown that bacteria capable of catalyzing the production of enterolactone from plant lignans belong to subdominant populations, that is, they occur at densities below 10^8 cell/g content (compared to a total cell density of approximately 10^{12} cell/g) [83, 84].

In summary, our intestinal microbiome encodes numerous core functions of importance for the conversion of dietary phenolics, yet interindividual differences in the makeup of bacterial species that colonize our gut underlie interindividual differences in phenolic metabolism and thereby in possible health effects. In Sect. 5, we will give more details on active bacterial members and central metabolic reactions involved in phenolic conversion prior to focusing on health effects of isoflavones and lignans.

5 The Gut Microbiota Influences Health Effects of Phenolics

5.1 Core Bacterial Reactions and Conversion of Isoflavones and Lignans

Exceptions prove the rules: the functional diversity of intestinal microbiota implies that all plant phenolics that we ingest can be converted by microorganisms.

However, there are exceptions, such as the isoflavone irilone, which seems to be resistant to bacterial conversion [85]. Gut bacteria catalyze an array of dominant core reactions that play key roles in the metabolism of a large panel of phenolic compounds, including isoflavones and lignans: (I) hydrolysis of esterified and conjugated bounds, (II) deglycosylation (removal of sugar moieties), (III) demethylation (substitution of a methyl by a hydroxyl group), (IV) dehydroxylation (reduction of hydroxyl groups), (V) dehydrogenation, (VI) reduction. Figure 78.1 gives a brief overview of the so far identified bacterial species that catalyze these reactions [86, 87]. It is noteworthy that several species occur in proximal parts of the bowel (*Enterobacteriaceae*, lactobacilli, lactococci, and streptococci in the stomach and small intestine), showing that bacterial metabolism of phenolics may be crucial not only in the colon, but already before, for example, for hydrolysis of conjugated metabolites secreted in the bile. Most dietary phenolics occur as biologically inert polymers or glycosides, meaning that reaction type I and II are crucial for phenolic activation and influence downstream reactions such as demethylation. As a matter of fact, the production of one given active metabolite often results from sequential reactions involving several bacterial species. For instance, production of enterolignans from SDG requires four reactions, among which demethylation and dehydroxylation are catalyzed only if the substrate has been previously deglycosylated and demethylated, respectively [15, 88]. Reaction type III (demethylation) is also crucial with respect to biological activities since most plant phenolics are methylated and are less active than hydroxylated metabolites. This is obvious, for instance, in the case of caffeic acid phenyl ester (an active phenolic constituent of honeybee propolis), for which we found that methylation of catechols markedly reduces anti-inflammatory activities [89].

The physiological advantage for bacteria to convert phenolic compounds is easily understandable in the case of deglycosylation (active species can utilize released glucose moieties as carbon and energy sources) or demethylation (acetogenic bacteria, for instance, are capable of producing energy by incorporating methyl groups into the Wood-Ljungdahl pathway of acetogenesis). In contrast, it is more difficult to identify driving forces that led to the establishment of complex phenolic-converting metabolic chains involving various distantly related bacterial species. One simplistic way to assess such a complex system is to try gaining access to individual bacterial components of the metabolic chain by means of anaerobic cultivation for subsequent in vitro characterization. Indeed, the isolation of pure bacterial cultures, in combination with the use of biochemical techniques (high performance liquid chromatography and mass spectrometry), for the purpose of metabolite identification allows description of key bacterial players in phenolic metabolism, including subdominant bacterial populations [15, 90]. Microbiologists have been culturing microorganisms for a long time, rapidly leading to major breakthroughs in biomedical research such as the identification of *Mycobacterium tuberculosis* by Robert Koch in 1876 or the discovery of the antibiotic penicillin by Alexander Fleming in 1928. In contrast, it is only from the 1950s onwards that the development and use of anaerobic tools by pioneers such as René Dubos, Sydney Finegold, Lillian Holdeman, Robert Hungate, Edward Moore, and Russel Schaedler

Table 78.2 Cultivable bacteria capable of converting the isoflavone daidzein[a]

Bacterial strain	End metabolite	Origin	References

			Zhao et al. [112]
Strain SY8519	*O*-desmethylangolensin	Human feces	Yokoyama et al. [113]
Strain TM-40	Dihydrodaidzein	Human feces	Tamura et al. [114]

[a] These strains are also able to produce 5-hydroxy equol from the isolflavone genistein
[b] From dihydrodaidzein only (this strain does not convert daidzein)

gave rise to extensive culture-based work dealing with commensal bacterial communities from human intestinal samples [91–93].

In 1985, Borriello et al. were the first to study the conversion of plant lignans by fecal slurries in detail [94], yet active bacterial strains were first isolated in 2000 [88]. In the case of phenolic acids, which as mentioned above are dominant phenolics in human diet, knowledge of bacterial conversion and involved species is scant. Hydroxycinnamates (e.g., *p*-coumaric, ferulic, and sinapic acid) as well as benzoic acids (e.g., gallic, syringic, and vanillic acids) are rapidly degraded by intestinal bacteria and a few members of the *Firmicutes* are known to demethylate a variety of phenolic acids [39, 86]. Actually, this is the case of isoflavones that rapidly drew most of the attention of microbiologists working in the field of polyphenols. Reasons for this are the low proportion of equol producers among humans (30–50 %) and the fact that equol is the most potent known isoflavone metabolite. Researchers have thus embarked on a microbial “Gold Rush” attempting to isolate and identify those rare equol-producing bacteria that colonize the human gut. The first evidence for microbial equol production was published in 1995 [81], however the first equol-producing bacterium, strain Julong 732, was isolated in 2005 (and so far this isolate is still not taxonomically classified) [95]. To date, a total of 16 daidzein-converting strains have been identified (Table 78.2).

From this listing, it is obvious that proper taxonomic description is needed, as some of the isolates could belong to the same species. It is also striking that all equol-producing bacteria with a validly published name are members of the family *Coriobacteriaceae*. This hints at functional specialization in the gut, maybe contributing to the better survival of this bacterial group in the competitive intestinal milieu. Interestingly, some *Coriobacteriaceae*, such as *Eggerthella* spp., are dominant intestinal bacteria and can convert steroid hormones and biliary acids [58]. This shows again that core functions such as dehydroxylation are relevant to various substrates and raises the question on the influence of host hormonal status on polyphenol metabolism [115].

A major advantage of culture-based approaches is that isolated strains can be used in vivo to assess physiological roles of phenolic-converting bacteria (in e.g., germfree mice) or in vitro for isolation and characterization of active enzymes. So far, very few corresponding data have been published. Crude enzyme extracts from *Asaccharobacter celatus* converts daidzein to dihydrodaidzein under anaerobic conditions and a dihydrodaidzein-producing reductase from lactococci has already been cloned (UniProtKB E1CIA4 and E7FL40/1) [103, 116]. However, culturing is per definition restricted to the study of microorganisms able to be isolated and to grow in the laboratory (most recent estimation refers to a proportion of 60 % cultivable bacteria in the mouse intestine) [62]. Again, it is important to remember that one given reaction can be catalyzed by several phylogenetically distantly related bacteria, which highlights the notion of functional bacterial groups and the importance of considering intestinal microbiota as a dynamic pool of functions rather than an assemblage of taxonomic entities. A more comprehensive way to assess the bacterial conversion of phenolics at the level of the entire ecosystem (the pool of microbial functions) than culturing is to use metagenomic techniques, i.e., molecular tools dedicated to the study of the metagenome (the sum of genomes originating from the thousands of bacterial species colonizing the intestine) [68, 117]. For instance, culture- or PCR-based screening of gut metagenomic clone libraries can give direct access to bacterial genomic information involved in conversion of phenolics, metagenomic libraries being defined as collections of >10,000 *Escherichia coli* clones where each clone expresses functions encoded on one large DNA fragment (commonly 40,000 bp) from the gut metagenome. As an example, metagenomic clones can be cultured on agar plates containing a glucosylated phenolic substrate as sole carbon and energy source, an approach that has been already used with other kinds of substrates such as β-glucans [118]. In such an assay, only clones capable of utilizing the substrate would grow and could be further analyzed by sequencing for determination of active gene sequences. Alternatively, colorimetric reactions may also be used for detection of for instance phenolic-demethylating clones [119].

One additional key issue in the field of bacterial enzymatic conversion of polyphenols is enantiospecificity. Many polyphenols, such as isoflavones and lignans, are optically active molecules that display several asymmetric carbon atoms. So far, only *S*-equol has been detected as a bacterial product of daidzein conversion [95, 120]. In the case of lignans, both (+)- and (-)-enantiomers occur in plants and bacterial conversion in the gut seems to be enantiospecific and preserve absolute configuration [121]. There is strong evidence that biological activity depends upon chirality of equol [122, 123], stressing the need for stereochemical analysis of other phenolic metabolites produced by intestinal bacteria. This serves as further proof of the necessity to isolate phenolic-converting bacterial enzymes for potential biotechnological production of active metabolites [103]. Finally, the search for new bacterial metabolites (and determination of corresponding biological properties) is also of primary interest. Considering the diversity of both dietary phenolics and intestinal bacterial species, it is likely that the panel of intermediate and end metabolites produced by intestinal bacteria is much larger than hitherto observed. For instance, we have found that the lignan-dehydrogenating bacterium *Lactonifactor longoviformis* does not only produce enterolactone, but also the novel metabolite 2,3-bis(3,4-dihydroxybenzyl)butyrolactone, the occurrence of which in vivo along with biological activities is still to be determined [121].

In summary, the array of enzymatic reactions catalyzed by the gut microbiome alters the structure of ingested phenolics. In view of the notion of structure/activity relationship, we conclude that intestinal bacteria greatly influence the biological activities of dietary phenolics. In the case of the isoflavone daidzein the route of bacterial conversion (i.e., the production of equol or *O*-desmethylangolensin depending on gut bacterial composition), is key to downstream health effects (Fig. 78.1). In the following two sections, we will give detailed information on biological activities and potential health effects of isoflavones and lignans.

5.2 Health Effects of Isoflavones and the Bacterial Metabolite Equol

In recent reports, the European Food Safety Authority (EFSA) refuted claims about the role of isoflavones in body function effects (article 13.1) such as maintenance of normal blood LDL-cholesterol concentrations in the general population [124, 125]. This has two main implications (also true beyond the sole case of isoflavones): first, even when scientific rationale is sound and there is a substantial number of well-conducted studies showing an overall significant trend toward positive effects of a defined dietary compound, a major problem in nutrition research is that intake of definite food stuff may need to stretch over long life periods before one can observe significant effects, when compared, for example, with pharmacological products usually associated with instant target effects (even though long-term effects of pharmacological therapies are often also not determined, yet beneficial immediate effects indeed prevail). Thus, the preventive aspect of nutritional strategies implies to carry out studies at scales (both in terms of time and cohorts) virtually impossible to manage in order to substantiate beneficial effects. This very often hampers closing the gap between scientific evidence and clear recommendations for consumers. The second implication is that, whereas it is very difficult to corroborate findings for the "general population," it makes sense to look at health effects of isoflavones in sensitive target groups, like infants. For these reasons, this is not our intention to provide here an exhaustive review of possible health effects of isoflavones. Instead, we will focus our attention on osteoporosis affecting menopausal women and on the effect of early exposure to isoflavones, thereby highlighting the biological properties of the bacterial metabolite equol.

Infants make up a study population of particular interest for several reasons: (1) they have not yet necessarily acquired a fully functional phenolic-metabolizing machinery (at least from a microbiological perspective), (2) the use of soy-based infant formula has become a rather common feeding alternative in westernized countries, and (3) a growing human body may be particularly sensitive to the biological properties of isoflavones. There are several published papers showing that early exposure to isoflavones has the potential to influence hormone levels and organ differentiation in the offspring of various animal species [126–129]. For instance, male marmoset twin monkeys fed soy formula milk for 30–40 days from the age of 5 days were characterized by lower mean testosterone levels in blood samples [129]. However, long-term effects must be further investigated. Furthermore, caution must be taken when interpreting results obtained using doses higher than the estimated intake of 2–10 mg isoflavones per day per kilogram body weight in infants fed soy-based formula [130, 131]. Exposure of human infants to dietary isoflavones has drawn attention of researchers since the mid-1990s. Depending on studies, isoflavone concentrations in soy-based infant formula range from 30 to 280 mg/kg [131–133]. Setchell et al. found that mean plasma concentrations of both genistein and daidzein in seven infants fed soy-based formula were 979 ng/ml (approximately 4 μmol/l) [131]. This concentration was markedly higher than in infants fed either cow-milk formula (5.3 ng/ml) or human breast milk (4.2 ng/ml), and is also higher than in adults on their usual diet. Interestingly, infants can also be exposed to isoflavones via breast milk during lactation. In seven breastfeeding mothers, ingestion of 55 mg/day isoflavone glucosides for 2–4 days increased isoflavone concentrations significantly in breast milk (from ca. 5 to 70 nmol/l) and in infant urine (from ca. 30 to 110 nmol/mg creatinine) [134]. Hence, it is clear that infants can be exposed to relatively high isoflavone concentrations and experimental work shows some significant effects of early exposure to isoflavones in animals. However, there is an obvious lack of physiological evidence in humans, as underlined in recent review papers and human infant trials [135–139].

The rationale for considering possible health effects of dietary isoflavones in infants is substantiated by in vitro and in vivo work on their biological properties. Especially, the estrogenic-like properties of isoflavones have been studied as early as in the 1950s based on the mouse uterine weight method [140], 30 years before equol was first detected in human urine [141]. Among daidzin metabolites, equol has the strongest binding affinities to estrogen receptors (ER), especially for ER-β [122, 142, 143]. Nevertheless, 17β-estradiol is 10–100 times more potent than equol. Interestingly, the *R*- and *S*-enantiomer of equol exhibit different binding affinities for ER-α (0.5 vs. 2 % of 17β-estradiol binding, respectively) or ER-β (1 vs. 20 %) [122]. Beyond binding affinities, equol can also modulate ER transcriptional activity [142, 144, 145]. Very recently, induction of estrogenic responses by equol has been demonstrated in vivo using the 3xERE-luciferase mouse model, which allows detection of estrogen activity by light production [146]. On the other hand, isoflavones have the potential to reduce estradiol bioavailability by increasing levels of circulating sex hormone–binding globulin [147, 148]. Obviously, the pro- or anti-estrogenic activities of equol depend on circulating concentrations of estradiol, which markedly vary during puberty, menstrual cycle, and menopause. Isoflavones concentrations in blood may reach up to a maximum of 10 μmol/l after ingestion of phenolic-rich food, which exceeds blood concentration of estradiol by a factor of $> 10{,}000$ [149]. Interestingly, tissue accumulation of polyphenols (including isoflavones and lignans) has been reported, which likely contributes to modulation of biological properties in target tissues [150–153].

In spite of the aforementioned properties of equol, its direct contribution to health effects is unclear. From the complex metabolite mixtures found in blood and target tissues after soy intervention, it is impossible to relate effects to only one specific molecule. Still, discoveries from the last decade may form the basis of future research to assess the exact role of equol in mediating health effects. Indeed, the fact that single equol-producing bacterial strains are now available allows the design of gnotobiological experiments using animal model of diseases. In such experiments, germfree animals colonized with an equol-producing or non-producing bacterium (a closely related inactive species or a mutant strain in which active enzymes have been knocked-out) could be compared with respect to the development of, for instance, tumors in various tissues or bone disorders in response to ingestion of daidzein-rich diets. In addition, large-scale production of pure enantiomers of equol for use in experimental or even clinical studies will surely help in deciphering direct health effects and underlying molecular mechanisms (US Patent no. 7528267 and 6716424).

To follow up on phytoestrogenic activities of isoflavones in vivo, a number of studies have looked at the effect of soy consumption on fertility parameters in adults. Again, there is evidence in animal species [154, 155], but very few data in human [156]. Alteration of semen quality by soy food or isoflavones is questionable [157, 158] and a recent meta-analysis of 15 placebo-controlled studies concluded that soy or isoflavone consumption is not associated with changes in testosterone levels in healthy men [159]. In contrast, peri- and postmenopausal women represent a target population of particular relevance. We will here focus only on the effect of isoflavones on osteoporosis, which has been intensively studied in postmenopausal women and represent a major public health problem [160]. Readers interested in the effects of isoflavones on cardiovascular risks and breast cancer may refer to already published comprehensive papers [13, 14, 161–163]. Osteoporosis is characterized by low bone mass, deterioration of bone tissue, and disruption of bone microarchitecture resulting in compromised bone strength and increased fracture risk [160]. The diagnosis of osteoporosis is primarily established by measurement of bone mineral density (BMD) [164]. Of course, genetic factors determine peak bone mass. However, studies involving twins indicate that environmental factors, including dietary habits, play a substantial role in the pathogenesis of osteoporosis [165].

Again, the EFSA refuted claims related to the use of soy isoflavones for maintenance of BMD [125]. This highlights the difficulty to reach consistency in experimental setups required for drawing conclusion on definite intake of isoflavones associated with long-term health benefits. Nevertheless, there is a growing body of valid scientific data showing overall that beneficial effects of isoflavones on bone disorders in elderly women are promising [161]. In two recent meta-analyses [166, 167], Ma et al. selected randomized controlled trials (RCT) investigating the effects of soy isoflavones on BMD and markers of bone turnover in peri- and postmenopausal women. Based on a total of 19 RCT with an intervention period of 1–24 months and isoflavone intake of 4–150 mg/day, the authors concluded that isoflavone intervention significantly attenuates bone loss of the spine in menopausal women, inhibits bone resorption, and stimulates bone formation. These results were confirmed by even more recent meta-analyses [168, 169]. However, it must be acknowledged that most studies are not appropriate for assessment of soy isoflavone consumption for more than 1 year [12]. Thus, one major remaining challenge is to characterize long-term clinically relevant effects of isoflavones prior to making statements on their use in hormone replacement therapies [170]. In a very recent double-blind RCT, Tai et al. found that treatment with 300 mg/day isoflavones for 2 years did not prevent decline of BMD in lumbar spine and proximal femur in postmenopausal Taiwanese [171].

5.3 Health Effects of Enterolignans

As for isoflavones, there is a vast number of studies investigating various biological properties and potential health effects of lignans [115]. There is good experimental evidence that lignans are beneficial with respect to the development of cardiovascular diseases and breast cancer. It is obvious however that RCT in human subjects are lacking. Interventions based on the use of flaxseeds as main lignan source have revealed promising effects with respect to reduction of prostate cancer proliferation [172, 173], tumor growth in breast cancer patients [174–176], and low-density lipoprotein (LDL) cholesterol levels [22, 177]. In addition, recent data from the EPIC study (European Prospective Investigation into Cancer and Nutrition) suggested that lignan intake decreases colon cancer risk in women [178]. However, because flaxseeds contain substantial amounts of fibers and oil, it is not possible to distinguish between direct effects of lignans and confounding or synergistic effects of fibers and oil. We will thus focus hereafter only on studies assessing health effects that can be attributed to pure lignans converted in vivo to the enterolignans ED and EL by gut bacteria. Unfortunately, viewed from that perspective, the number of human intervention trials shrinks further away. We found only two different double-blind RCT, in which authors analyzed the effect of flaxseed extracts enriched in SDG (ca. 30 % dry mass). Hallund et al. found that an intervention with 500 mg/day SDG equivalent for 6 weeks in 22 healthy postmenopausal women marginally reduced C-reactive protein concentrations and had no effect on endothelial function and plasma lipid concentrations [179–181].

In another trial involving 78 subjects with benign prostatic hyperplasia, ingestion of a flaxseed lignan extract (>300 mg/day SDG equivalent) over a 4-month period significantly improved International Prostate Symptom and Quality of Life Scores [182]. It is thus again in laboratory animals that most of the beneficial effects of pure lignans have been reported. In rodents, Lilian Thompson and colleagues found that SDG reduces or delays mammary tumor growth [183–185], affects mammary gland structure [186, 187], reduces metastasis in the lung [188] as well as colon carcinogenesis (number of aberrant crypt foci after azoxymethane treatment) [189]. In contrast, matairesinol and secoisolariciresinol did not protect against intestinal tumor formation in Min mice [190]. More recently, lariciresinol was found to attenuate mammary tumor growth in xenograft- and carcinogen-induced rat models [191]. With respect to cardiovascular risks, SDG was found to reduce the incidence of atherosclerosis in rabbits and to induce neovascularization-mediated cardioprotection in rats [192–194].

Biological properties underlying the aforementioned protective effects of lignans are not well characterized, especially in vivo. As stated in Sect. 2, plant lignans are usually less active than enterolignans, which are thus seen as paradigm metabolites for the relevance of bacterial conversion. In vitro studies showed that EL has slightly higher binding affinity for the human pregnane X receptor, which mediates induction of enzymes involved in steroid metabolism and xenobiotic detoxification, than its precursor secoisolariciresinol [195]. Moreover, EL binds to estrogen receptors, with a preference for ER-α [142, 196], and can activate estrogen responsive elements [197]. Both ED and EL modulate ER-α mRNA and protein contents and compete dose dependently with estradiol and the unsaturated fatty acid arachidonic acid for binding site on rat and human α-fetoprotein, an estradiol-binding protein [198, 199]. However, binding affinities of enterolignans appear to be 10–10,000-fold lower than those of other phytoestrogens or sex hormones. Both enterolignans and plant lignans also bind to sex hormone–binding globulin, with possible consequences on circulating levels of the sex hormones testosterone and estradiol [200]. The estrogen-dependent properties of ED and EL include as well inhibition of aromatase, 5α-reductase, and 17β-hydroxysteroid dehydrogenase, three enzymes involved in the metabolism of growth-promoting steroid hormones [201–204]. Besides, EL was found to induce the expression of the estrogen-responsive protein pS2 in human breast cancer MCF-7 cells [205]. This and other in vitro studies showed that ED and EL alter cell proliferation of various breast, colon, and prostate cell lines, as well as endothelial cells derived from bovine brain capillaries [206–210]. In vitro, both ED and EL have also higher antioxidant activities than plant precursors [211, 212]. In vivo, short-term feeding of SDG to rats only led to minor changes in the antioxidant status of hepatic tissue [213].

To conclude on the last two sections on health effects, one can say that polyphenols are generally regarded as safe and there are only a few reports on possible toxic effects (yet not in the case of isoflavones and lignans in humans) [214–217]. However, polyphenols have the potential to interact with sensitive hormonal systems. Moreover, as implied above when discussing bioavailability, efficient conjugation and excretion mechanisms as well as relatively low phenolic concentrations in blood

(<200 nmol/l without intervention [51, 218, 219]), when compared with other molecules of dietary origin (sugars, amino acids, acetate, etc ...), are hallmarks of efficient host metabolism dedicated to the elimination of exogenous molecules. Thus, one should not presume that biological properties of phenolics are solely synonyms of beneficial effects, for example, equol may trigger hyperplasia of rat uterine tissue [220] and lignans have been shown to affect pregnancy outcome, reproductive development, and estrous cycling in rats and women [221–223].

Isoflavones are promising with respect to improvement of osteoporosis in postmenopausal women, but long-term effects and dose/activity relationship must be further investigated. Regarding lignans, data obtained using animal models of cancer and cardiovascular disorders are promising too. However, there is a paucity of data in human subjects. In both cases (isoflavones and lignans), direct in vivo effects of bacterial metabolites is a future research area of particular interest.

6 Impact of Phenolics on Intestinal Microbiota

One fundament of intestinal ecosystems is the trialog between dietary components, intestinal microorganisms, and the host. Over the last century, medical microbiology had been a dominant field of research and the focus was mainly placed on the study of bacteria-host interactions. However, over the last 20 years, the impact of nutrition on human health and the intestinal microbiome has gained a lot more attention in westernized countries [5]. This is mainly due to: (1) research-founded breakthroughs (molecular mechanisms underlying benefits or deleterious effects of specific dietary molecules are being described); (2) shifts in public health challenges and mentalities (while many bacterial infections are no major threat anymore, chronic disorders such as allergies, obesity, and inflammatory diseases in an ever-aging population represent an increasing social and economical burden; meanwhile, many people are concerned about self-improvement of well-being via nutrition); and (3) market-driven issues (global food companies are lured by profits associated with massive consumption of functional foods and nutraceuticals).

There is nowadays strong evidence that diet greatly influences the composition of intestinal microbiota. The most studied dietary components having striking effects on microbial diversity are fat and fibers [224, 225]. In contrast, the effect of dietary microcomponents like polyphenols on intestinal microbiota is much less known, in spite of various possible mechanisms of actions. First of all, the fact that the conversion of phenolics is under the control of bacterial metabolic chains means that any substrate affecting one chain link has the potential to alter the entire system. Secondly, there is good indication that phenolic extracts and pure phenolics have antimicrobial properties and may thereby alter the growth of intestinal bacteria like clostridia, bacilli, and members of the *Enterobacteriaceae* [226–229]. In addition, since gene expression of enzymes catalyzing, for instance, dehydroxylation can be induced by matching substrates [230], it is possible that polyphenols directly influence core gut microbial functions. At the same time, the growth of phenolic-metabolizing bacteria may be favored if conversion provides a net energy input for the bacteria. This could lead in parallel to increased competitive advantage and thus indirect growth inhibition of other bacterial groups. Finally, certain polyphenols or metabolites thereof may interfere with quorum sensing, a molecular system that coordinates gene expression of, for instance, virulence factors according to bacterial cell density [226–229]. In spite of these mechanisms, which must still be substantiated by further investigations, there is to the best of our knowledge only 11 papers reporting effects of phenolic compounds on intestinal microbiota. In vitro experiments showed that incubation of fecal slurries with tea extracts prevented growth of clostridia [231]. Possemiers et al. showed that the hop prenylflavonoid isoxanthohumol increased the abundance of members of the *Clostridium* cluster XIV as well as bifidobacteria in a continuous culture system [232]. In rats, Hanske et al. found that xanthohumol does not affect the diversity of dominant fecal microbial communities, as analyzed by denaturing-gradient gel electrophoresis [233]. Smith et al. reported that a diet rich in proanthocyanidins increased the occurrence of *Enterobacteriaceae* and *Bacteroides* in rat feces [234]. The remaining papers relate to human intervention trials. Tea polyphenols increased viable counts of bifidobacteria and decreased counts of *Clostridium perfringens* in eight Japanese healthy adults [235], but had no major impact on fecal microbiota in six hypercholesterolemic volunteers [236]. We found in 2005 that a dietary treatment with 100 mg isoflavones per day for 1 month altered the bacterial diversity and composition in fecal samples from 39 postmenopausal women [71]. Very recently, Tzounis et al. found that a diet rich in cocoa-derived flavanols (494 mg/day) consumed for 4 weeks by 22 healthy human volunteers increased the proportion of lactic acid bacteria by a factor of two, as measured by in situ hybridization [237]. The same authors had previously reported that 150 mg/l of the flavanol monomers epicatechin and catechin stimulated growth of bifidobacteria, *E. coli* and members of the *Firmicutes* in vitro [238]. With respect to bacterial activities, Wiseman et al. found that soy consumption for 10 weeks increased beta-glucosidase activity in feces from 76 healthy young adults [239]. Finally, Hoey et al. reported two- to tenfold lower counts of bacteria in feces from ten infants (aged 4–12 months) fed a soya- versus milk-based formula [74]. However, the fecal concentration of total short chain fatty acids (ca. 45 μmol/g) as well as beta-glucosidase and glucuronidase activities (both ca. 10–25 μmol/h per g) were unchanged.

Bottom line is that the amount of data is too limited to draw firm conclusions on the impact of phenolics on intestinal microbiota. The task ahead is challenging due to the diversity of phenolics in food as well as interindividual intestinal microbial profiles. The use of next generation molecular approaches will be crucial for the identification of core responses to dietary phenolics at the level of the entire gut microbial ecosystem. High-throughput 16 S ribosomal RNA sequencing allows for instance in-depth characterization of changes in bacterial diversity. However, it will be essential to translate the meaning of such structural changes for host health development, since microbial functions are the driving force of bacteria-host interactions and changes in diversity are not necessarily linked to changes in ecosystem functions. Ecological approaches, such as metatranscriptomic or metabolomic, for gene or metabolite expression profiling could be used for identification of core microbial functional markers under the influence of dietary phenolics [240].

7 Can We Potentiate Intestinal Microbial Metabolism?

The pace of research involving phenolic compounds has rapidly increased over the last two decades (Fig. 78.2). One obvious underlying reason is the wish to prevent or cure diseases by means of natural products. Since intestinal bacteria are essential for phenolic bioavailability and associated health effects, nutritional strategies favoring production of active metabolites via the microbiome look very attractive. As seen above, the use of antibiotics is the best proof-of-concept that influencing metabolite production by targeting intestinal microbial communities is promising [56, 60, 241–244]. However, there is to date no valid data substantiating the theory of diet-driven optimization of microbial phenolic conversion.

The link between intake of specific dietary components and phenolic metabolite production is unclear. Although increased excretion of equol has been associated with increased consumption of fat, meat, and fruits, for instance [82, 152, 245–247], and enterolignans excretion seems to correlate well with dietary intake of fibers [248–250], more work is needed to reach consensus in results. Nonetheless, it is clear that ingestion of isoflavone and lignan food substrates enhance production of equol and enterolignans [33, 251–253]. An intriguing question is however to know whether the activity or growth of phenolic-activating bacteria can be specifically induced, that is, in the case of equol, for example, whether non-equol producers on

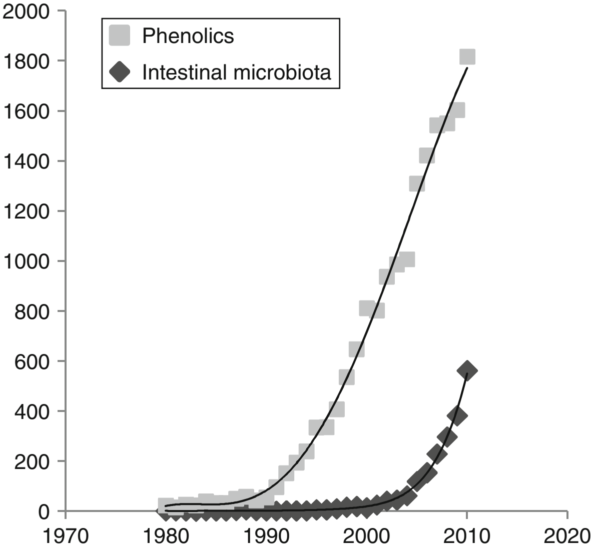

Fig. 78.2 Publication output in the field of phenolic research and intestinal microbiota. The PubMed database of the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov/pubmed) was searched for the number of articles per year (from 1980 until 2010) responding to the following queries: "intestinal microbiota" (*black diamond*) and "phenolics OR phytoestrogens OR polyphenols" (*gray squares*)

their usual diet can become producers, thanks to ingestion of appropriate plant substrates. In 12 Caucasian postmenopausal women, Védrine et al. found that isoflavone intervention (100 mg/day) increased plasma equol concentrations from 0.31 to 0.99 μmol/l in equol producers, but that the seven volunteers classified as non-equol producers did not acquire the ability to produce equol after 1 month exposure [251]. In contrast, another study in China revealed a higher proportion of equol producers among 200 healthy adults challenged with a soy-isoflavone supplement for 3 days (60 % equol producers after supplementation vs. 27 % at baseline) [254]. Here too, more work is needed to draw firm conclusions on equol phenotype changes and influence of demographic origin on phenolic bioavailability [245, 255, 256].

Probiotics are defined as live microorganisms that, when administered in adequate amounts, confer a health benefit to the host [257]. Their use has drawn quite some attention for improvement of phenolic activation in the gut based on the rationale that glucosidases from probiotic lactic acid bacteria (mainly lactobacilli and bifidobacteria) may enhance phenolic bioavailability by increasing concentrations of aglycones. However, the dominance of endogenous phenolic-deglycosylating *Bacteroides*, *Bifidobacterium*, and *Clostridum* spp. in the intestine suggests that deglycosylation is not a limiting step in the in vivo production of active metabolites. Moreover, while there are many reports on the fermentation of soy products by probiotic bacteria, all ten intervention trials based on soy and probiotic treatment in human subjects failed to demonstrate any positive effects of probiotic bacteria [258–267]. Concerning lignans, the only one study available also failed to show any beneficial probiotic effects [268]. More interestingly, researchers in the group of Willy Verstraete at Ghent University have successfully used phenolic-converting bacteria originating from the human intestine, such as *Eubacterium limosum* catalyzing demethylation, to enhance the activation of isoflavones and isoxanthohumol in continuous culture systems and in rats [269, 270].

Functional food products also include prebiotics like fructooligosaccharides (FOS) and inulin, which are nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacterial species already resident in the colon [271]. The prebiotic concept was first coined in 1995 by Glenn Gibson and the bifidogenic effect of FOS and inulin has since then been confirmed by many studies. In contrast, there are only a few reports on the influence of prebiotics on isoflavone bioavailability. Steer and colleagues showed in vitro that 10 g/l FOS in combination with soyabean isoflavones significantly prevented genistein breakdown in continuous culture system vessels [272]. Similar results were obtained by Piaza et al. using inulin in a randomized double-blind crossover study enrolling 12 healthy postmenopausal women [273]. The authors found increased plasma concentration of daidzein and genistein after inulin treatment (approximately 7 g/day) for 21 days. Possible synergistic effects of combined isoflavone and prebiotic intervention are of particular interest with respect to health parameters such as blood lipid profiles or bone density and calcium homeostasis [274–276].

8 Conclusion

The issue of phenolics in human nutrition bears resemblance to industrialized production factories, where input of raw materials is important, yet processing strategies determine the quality of final products. That is, the amount of phenolics that we eat makes of course a difference, but metabolism within the body determines their fate and health effects. Future prospects related to phenolic bioavailability (especially bacterial metabolism) that have been evoked throughout the chapter are summarized in Table 78.3.

Intestinal microbial functions are essential for conversion of a vast majority of dietary phenolics, for example, isoflavone and lignan activation. The main future

Table 78.3 Take home messages and future challenges[a]

Facts	Perspectives
Human diet contains a wealth of highly diverse phenolic compounds	Implementation of phenolic databases is crucial for good estimation of intake depending on dietary habits
Plant phenolics can be absorbed in the upper GI tract	Transport mechanisms and kinetic of appearance in blood must be characterized in detail, especially in relation to chemical structure
The intestinal microbiota is highly diverse and has a vast metabolic potential	Functional metagenomic screening is a promising approach for characterization of bacterial genes involved in phenolic conversion
Bacterial culture allows isolation of phenolic-converting bacteria	Identified strains can now be used for colonization of experimental animal models and for large-scale production of pure phenolics
Isoflavones may improve osteoporosis in postmenopausal women, and lignans can protect against tumor growth and atherosclerosis in animal models	More clinical data are needed; long-term effects must be defined
	Studies in gnotobionts or using pure substances are required for assessing direct health effects of equol and enterolignans in vivo
Health effects depend on the type of bacterial metabolites produced	Effort must be put into studying enantiospecificity of bacterial conversion
There are large interindividual differences in the ability to metabolize plant phenolics in the gut	High-throughput sequencing and metabolite analysis will allow dynamic characterization of the gut microbial ecosystem in human intervention trials
Intestinal microbiota is sensitive to dietary changes	Impact of phenolics on gut microbial diversity and activities must be further studied
	Use of pre- and probiotics to increase bacterial production of active metabolites is not yet scientifically founded
Infants can be exposed to substantial amounts of phenolics and colonization events determine the metabolic potential of intestinal microbiota	Epidemiological data on the impact of chronic early exposure to phenolics are warranted and effort should be put in characterizing the establishment of intestinal microbiota in large infant cohorts

challenge for microbiologists working in the field of phenolics and human nutrition is to characterize metabolic networks at the level of the entire intestinal ecosystem, in relation to host functions. New generation molecular techniques will certainly help taking on this challenge, although computer analysis of the colossal amounts of data generated by high-throughput methods is a high hurdle for most microbiologists. It would be valuable, for instance, if large-scale human intervention trials on phenolics were designed so as to include microbiological analysis of intestinal samples via, for instance, sequencing or spectrometry analysis to characterize bacterial diversity and identify core functions of relevance to phenolics. This could lead to the discovery of phenolic-specific enterotypes, as in the sense of specific clusters of microbial species associated with functional profiles of relevance [277], thereby allowing detailed characterization of interindividual differences. The long-term objective is the ability to generate personalized meta-metabolic profiling for development of individualized nutritional strategies [278].

In view of individualized nutritional strategies, we must also say that, even though the focus of the present chapter is the metabolic potential of intestinal microorganisms, host genotype strongly determine health effects of phenolics too. Thus, a challenging task is also to assess the role of host genotype in controlling phenolic health effects, either directly via differential expression of specific key genes (coding for ER or intestinal transporters for instance) or indirectly via alteration of microbiota [279].

Finally, it is important to remember that early life periods are critical for shaping the intestinal microbiome. More effort should be put into characterizing intestinal microbiota development in infants and the implication of early dietary exposure to phenolics for health homeostasis later in life. To date, it is also not possible to provide clear recommendations with respect to dietary intake of isoflavones or lignans for treatment or prevention of diseases. Nevertheless, good evidence has been accumulating regarding improvement of bone disorders in postmenopausal women by isoflavones and cardiovascular risks as well as breast cancer by lignans. More clinical and epidemiological data are mandatory and effort should be put into performing experiments in gnotobiotic animal models of disease to draw firm conclusions on the direct role of bacterial metabolites, such as equol and enterolignans, in host health.

Acknowledgments We are grateful to Prof. Hannelore Daniel (TU München, Molecular Nutrition Unit), Dr. Laura Hanske (German Institute of Human Nutrition Postdam-Rehbrücke, Department of Gastrointestinal Microbiology), Dr. Gemma Henderson (Grasslands Research Centre, AgResearch) and Dr. Augustin Scalbert (Clermont University, Department of Human Nutrition) for critically reading the manuscript and giving helpful recommendations.

Abstract

Anthocyanins are naturally occurring compounds widespread in plant-derived foodstuffs and therefore abundant in our diet. There are evidences regarding the positive association of their intake with healthy biological effects displayed in vivo. This chapter aims to review some concepts regarding anthocyanins' bioavailability. It summarizes the latest advances on the ingestion, absorption, bioavailability, and biotransformation of these compounds through different approaches. Attention is also given to the role of microbiota in anthocyanin metabolism and bioavailability.

Keywords

Absorption • anthocyanins • bioavailability • metabolism • microbiota

1 Introduction

Anthocyanins belong to the large group of flavonoids that occur in nature arising from plant secondary metabolism. They constitute the largest group of water-soluble pigments widespread in the plant kingdom, being responsible for the colors displayed by many flowers, fruits, and leaves of angiosperms. These pigments are usually associated with fruits, but they also occur in vegetables, roots, legumes, and cereals [1, 2].

The scientific community has become more aware of the importance of anthocyanins in a regular diet as different experiments have been performed aiming to support and explain some biological and health-promoting features attributed to these molecules.

The antioxidant capacity of anthocyanins has been demonstrated by radical scavenging of reactive oxygen species, reducing capacity, inhibition, or delaying of lipoprotein oxidation and platelet aggregation. Anthocyanins as individual compounds or present in a more complex extract have been found to play a role in the prevention of cardiovascular diseases and to be involved in several different events like the prevention of DNA damage, estrogenic activity, enzymatic inhibition, anti-inflammation response, lipid peroxidation inhibition, etc. [3–7].

Over the last years, more attention has been paid to the putative antitumoral properties of anthocyanins and anthocyanin extracts [8]. The induction of apoptose in tumor cells as well as the suppression of cell proliferation and angiogenesis have been pointed out as possible mechanisms where anthocyanins may play their anticarcinogenic role [9–11]. Although there are several works reported in the literature dealing with in vitro antioxidant and biological properties of anthocyanins, there is a lack of more in vivo evidences. This is mostly due to bioavailability issues as it will be further discussed in this chapter.

2 Anthocyanin Chemistry and Stability

Polyphenolic compounds share the presence of an aromatic ring with two or more hydroxyl groups. Currently, more than 8,000 compounds belonging to this family are known. Depending on the presence of the flavan nucleus, polyphenols are usually divided in flavonoids and non-flavonoids. The basic flavonoid structure, the flavan nucleus, consists of a C6-C3-C6 structure constituted by two aromatic rings linked by an heterocyclic ring, labeled A, B, and C (Fig. 79.1).

The various classes of flavonoids differ in the level of oxidation and substitution pattern of ring C, while individual compounds within a class differ in the arrangements of hydroxyl, methoxyl, and glycosidic side groups. Dietary flavonoids exist primarily as 3-*O*-glycosides and polymers [12].

Anthocyanins, a particular class of flavonoids, naturally occur as glycosides of flavylium (2-phenylbenzopyrylium) salts but differ from them by structural variations in the number of hydroxyl groups in the molecule, the degree of methylation of these hydroxyl groups, the nature and number of sugar moieties attached to the phenolic molecule, and the position of the attachment, as well as the nature and number of aliphatic or aromatic acids attached to the sugars [1]. The sugar moieties vary but are usually a mono- or disaccharide unit, frequently glucose, galactose, rhamnose, arabinose, or xylose [13].

Most commonly known anthocyanins are based on six anthocyanidins: cyanidin, delphinidin, malvidin, pelargonidin, peonidin, and petunidin (Fig. 79.2), but there are 539 anthocyanins reported to be isolated from plants [14].

The more widespread anthocyanins in fruits are glycosylated in the 3-OH position (3-O-monoglycosides) and, in less extension, in both position 3-OH and 5-OH (3,5-*O*-diglycosides).

Physicochemical properties of anthocyanins, particularly their color, structural characteristics, and stability, are unique. Anthocyanins are highly reactive molecules and thus sensitive to degradation reactions. Several factors such as oxygen, temperature, light, enzymes, and pH affect anthocyanin chemistry and consequently their stability and color. The degradation of anthocyanins may occur during their extraction, food processing, and storage. A critical factor that is strictly related to the color displayed by anthocyanins is the fact that they coexist in equilibrium

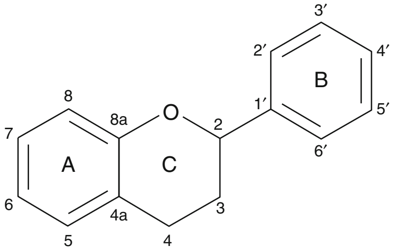

Fig. 79.1 Basic structure of flavan nucleus

Anthocyanin	R1	R2
Delphinidin	OH	OH
Petunidin	OCH_3	OH
Malvidin	OCH_3	OCH_3
Cyanidin	OH	H
Peonidin	OCH_3	H
Pelargonidin	H	H

between five species: flavylium cation, carbinol base, chalcone, quinonoidal base, and anionic quinonoidal base (Fig. 79.3). In aqueous solution, anthocyanins occur between those different structures depending on pH [15–17].

As a result of these features, in solution, these natural compounds present little color expression above pH 3.5. On the other hand, in nature, the same pigments may display more color as a result of copigmentation phenomena [18, 19]. This ability of anthocyanins to establish noncovalent interactions with colorless copigments is extremely relevant as it has been considered to be the first step in the formation of new anthocyanin-derived pigments [20].

Concerning temperature, anthocyanins become paler after heating as the equilibrium is displaced toward the colorless carbinol and chalcone forms. The stability of anthocyanins (or other derived pigments) regarding pH and temperature variations and their degradation pathways are reported in the literature [21].

The complex biochemistry of these compounds is a particular important point during passage through gastrointestinal (GI) tract where the exposition of anthocyanins to different pH and temperature conditions may alter anthocyanin chemical forms and, consequently, their potential bioactivity.

2.1 Occurrence and Intake

Polyphenols are widespread, virtually present in all foods and beverages of plant origin, such as fruits, vegetables, tea, cocoa, and wine. It is extremely difficult to estimate the daily average intake of polyphenols for several reasons such as the extensive diversity of chemical structures that makes the estimation of polyphenol content in foods complex, the analytical methods used for these estimations, variation of content with geographical region, cultivar, and season, as well as dietary habits. Progresses are currently being made through the construction and application of a database on polyphenol content in foods [22].

Scalbert and Williamson have proposed for the total dietary intake about 1 g/day, which is much higher than that of all other known dietary antioxidants,

about 10 times higher than that of vitamin C and 100 times higher than those of vitamin E and carotenoids [23]. Recently, Pérez-Jiménez and colleagues, using a French cohort and a phenolic food content database, have confirmed that the daily intake of polyphenols is about 1 g/day. Nevertheless, the authors point out a possible underestimation due to insufficient data or lack of accurate data on the content in foods of some complex polyphenols [24].

Anthocyanins are found in the human diet as part of red wine, certain varieties of cereals, and certain leafy and root vegetables (aubergines, cabbage, beans, onions,

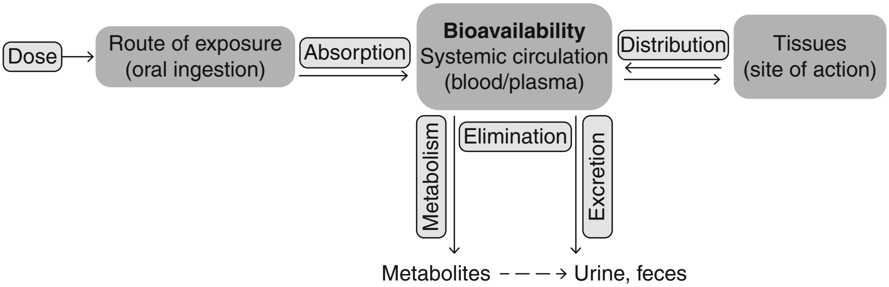

Fig. 79.4 Simplified diagram illustrating common biokinetic concepts (Adapted from [32])

radishes), but they are most abundant in red fruit such as cherries, plums, strawberries, raspberries, blackberries, grapes, red currants, and black currants. Cyanidin is the most common anthocyanidin in foods. Food contents are generally proportional to color intensity and reach values up to 2–4 g/kg fresh wt in black currants, black elderberry, or black chokeberry [25–27]. These values increase as the fruit ripens. Anthocyanins are found mainly in the skin, except for certain types of red fruit, in which they also occur in the flesh (cherries and strawberries). Red wine contains up to 1 g anthocyanins/L, and these anthocyanins can be transformed into various complex structures as the wine ages [26–31].

3 Bioavailability: Basic Concepts

The basic kinetic concepts in the body system initially came from the study of drug actions, or pharmacokinetics. Nowadays, these principles are usually applied to study or predict the movement of a substance in the organism, such as a toxin, an environmental pollutant, or even a phytochemical, constituting what is called biokinetics.

There are some general but essential concepts that are important to remind and are illustrated on Fig. 79.4 [32].

Dose is the amount of chemical delivered to the body. The means and location by which the chemical is delivered to the body is the *route of administration*. The most common routes of administration include intravenous (IV), oral ingestion (po), subcutaneous (sc or sq), and intramuscular (IM).

Absorption is the movement of chemical molecules from the site of delivery to the systemic circulation. For some routes of administration, a portion of the chemical dose may never reach the systemic circulation. The fraction of the administered dose that reaches the systemic circulation is called the bioavailable fraction or *bioavailability*.

Once absorbed into the systemic circulation, blood flow delivers the chemical to the body tissues. In some cases, specific body tissues act as storage depots, with chemical initially collecting in the tissues while plasma concentrations are high, then later being released back into the bloodstream after plasma concentrations lower with time. This back and forth movement of a chemical between circulating plasma and tissues (including the target tissue) is called *distribution*.

Enzymatic conversion of the drug molecule into a different chemical form is called metabolism, or *biotransformation*, with the converted molecules labeled metabolites. *Excretion* is the process by which chemicals or metabolites are discharged into body wastes, typically in the urine or feces. *Elimination* is a collective term for all processes that decrease the amount of chemical in the body, which includes both biotransformation and excretion.

Biokinetic, or *disposition*, is the term for everything that happens to a chemical in the body. Thus, disposition of a chemical, or xenobiotic, is defined as the composite actions of its absorption, distribution, biotransformation, and elimination.

Throughout all these processes, there are tissue barriers made of one or more cell types that collectively form a distinct boundary between two different physiological environments. Chemicals movement through tissue barriers implies passage through biological membranes. Biological membranes are composed by a phospholipid bilayer, the polar head groups of phospholipids being oriented toward the outer and inner surfaces of the membrane. Numerous proteins are embedded at irregular intervals, but only some are transmembrane proteins, traversing the entire lipid bilayer. At physiologic temperatures, membranes have a fluid character which is largely determined by the structure and relative abundance of unsaturated fatty acids. Unsaturated fatty acids and cholesterol are positively and negatively related with membrane fluidity, respectively.

There are several mechanisms by which a chemical can cross biological membranes. It can pass by passive processes; it can involve a carrier (carrier-mediated process) or a specialized transport process. Passive processes are only possible if chemicals are small, lipid soluble, and nonionized and if there is a concentration gradient between the two sides of the membrane (principle of Fick's law). Chemicals pass from regions of higher concentration to regions of lower concentration, without energy expenditure, according to a concentration gradient. Carrier-mediated transport involves one or more transporter(s), and it can be either influx or efflux of substances. The transport can be uniport (transport of a single molecule), symport (transport of two or more different molecules or ions in the same direction), or antiport (transport of two or more different molecules or ions in opposite directions), and because it uses a transporter, it is saturable and specific. Specialized transport includes endocytosis, with and without the interaction with membrane receptors. This form of chemical distribution is more likely for larger molecules and proteins. Endocytosis includes phagocytosis, pinocytosis, and potocytosis, depending on the nature of transported compound.

The bioactivity of a substance is directly dependent on the concentration, which makes the disposition of any compound a major contributor to its potential bioactivity. Therefore, because the disposition of a chemical determines its concentration at the site of action, the concerted action of absorption, distribution, and elimination dictates the potential for biological events to occur.

3.1 Factors Affecting Bioavailability

Regarding phytochemicals, polyphenols and flavonoids in particular, their major route of entry is by oral ingestion, since they are consumed as part of a normal diet. Their bioavailability, similarly to what happens with other xenobiotics ingested orally, can be influenced by several factors. The physicochemical characteristics of the compound, such as the size of the molecule, its lipid/water solubility, or its pKa, can dictate its ability to cross a membrane by simple diffusion or not. For example, due to its size, larger molecules may imply other transport processes rather than diffusion. If the compound is hydrophilic, it is unlikely to cross a membrane freely, but if it is too lipophilic, it may not be completely soluble in gastric secretions which can also make its absorption difficult. In addition, if the compound has ionic charge, it is not probable to cross biological membranes by diffusion and may involve other process to enter the cell.

There are several additional factors relating to the GI tract itself that influence the absorption of xenobiotics such as pH, the presence of food, digestive enzymes, bile acids, bacterial microflora of the GI (microbiota), and the motility and permeability of the GI tract.

Gastric motility and emptying time may influence bioavailability since a higher contact time is usually related with higher absorption. The same principle applies to intestinal motility and transit time. Higher permanence time of the compounds on absorptive surfaces is usually related with higher absorption and consequently with higher bioavailability.

Considering flavonoids, food matrix is a very important issue because it can influence the availability of the compounds to be absorbed in several ways: first, the flavonoid must be liberated from the food matrix where it is inserted, and the difficulty of this process is dependent on the type of matrix; second, if the food matrix has a more lipophilic environment, it can facilitate flavonoids' solubilization and absorption. Ethanol seems to exert crucial effects on anthocyanin intestinal bioavailability, favoring its transport across intestinal epithelia. Also, interaction between different compounds may occur and interfere with absorption; as well, competition or interactions for specialized transport systems are likely to occur due to the variety of molecules present in GI tract after a meal. Another important concept should be the frequency of the consumption. For anthocyanins, it is known that intestinal epithelial cells chronically exposed to anthocyanins are more prone to their own transport [33]. This is an important finding, justifying dietary recommendations, highlighting chronic consumptions of fruits and vegetables as healthy food habits.

Additionally, there are other factors such as age, interindividual and sex differences, biotransformation, and protein binding that may insert variations in xenobiotic absorption between two different individuals. Here, the role of microbiota on biotransforming flavonoids has to be emphasized because it is critical for flavonoid bioactivity. This issue is developed later in this chapter.

When taken together, these factors can cause large interindividual and intraindividual variations in bioavailability, but the knowledge about disposition of flavonoids and their metabolites is a critical determinant to understand its biological effects upon a particular organism. Although flavonoid antioxidant activity in vitro is well established and supported under different circumstances of oxidative stress, antioxidant potential of these compounds in vivo is still an unclear issue. Flavonoids from different classes have different chemical properties which make the study of flavonoid bioavailability difficult as a whole. Each flavonoid class has particular features that make it unique and with characteristics that can make a difference on the extent of the absorption and on their bioactivity. Anthocyanins are a class of flavonoids with very special features, for example, in nature, anthocyanins are glycosylated with different types of sugar moieties, have a positive charge at lower pHs, and are chemically unstable with pH variations [34]. These particular features affect anthocyanin absorption, biotransformation, bioavailability, distribution, and, as a consequence, their bioactivity.

Several animal and human studies have already associated biological effects with anthocyanin consumption, but for that to happen, the compounds or their metabolites must reach target tissues. Bioavailability is sometimes taken as guaranteed, and the mechanisms by which molecules are available, the factors that modulate this bioavailability and the chemical forms that may have bioactivity are not adequately explored. These questions still remain with few, unclear, and broad informations as an answer.

4 Bioavailability of Anthocyanins

Despite the remarkable progress achieved in the field of flavonoid bioavailability and flavonoid-mediated cellular effects, the whole task remains quite complex [35].

From the perspective of preventive nutrition, dietary flavonoids are expected to act at low concentrations following daily intake and in long term. Cell studies typically make use of much higher concentration of flavonoids and often in the biologically irrelevant form of aglycones or native glycosides so that the relevance of the conclusions as to their nutritive effects remains speculative.

In the case of anthocyanins, this is even more complex as they coexist under different structural forms at physiological pH. Extensive knowledge of the bioavailability of anthocyanins is thus essential if their health effects are to be understood (Fig. 79.5).

4.1 Oral Cavity, Stomach, Small Intestine, and Colon

Studies involving individual anthocyanins revealed that their amount in plasma is generally 1% of consumed quantities, due to limited intestinal absorption, although additional factors may contribute to the proposed low anthocyanin bioavailability, such as high rates of cellular uptake, metabolism, and excretion [36].

Upstream to gastrointestinal absorption, a variety of binding processes can take place, namely, interaction with food proteins or with salivary proteins and digestive enzymes [37–39].

In a recent work with healthy volunteers, black raspberry anthocyanins could be detected under their hydrolyzed aglycone form in the oral cavity, resulting from the activity of ß-glycosidase derived both from bacteria and oral epithelial cells [40]. In the same study, parent anthocyanins and cyanidin-3-glucoside microbiota metabolite, protocatechuic acid, were detected in the saliva. Furthermore, saliva samples contained glucuronidated anthocyanin conjugates, consistent with intracellular uptake and phase II conversion of anthocyanins [40].

Still, whether these oral transformation reactions will be of importance for local effects in the oral epithelium is difficult to assess considering the relatively short residence time of most foods in the oral cavity.

Anthocyanins, for consumers that eat berries and drink red wine on a routine basis, are major dietary components. The key difference compared to the other flavonoid glycosides, however, is that anthocyanins undergo rearrangements in response to pH and temperature [15]. Physiological temperatures are highly suitable both thermodynamically and kinetically for observing the chalcone tautomer [15]. The limited available experimental evidence indicates that in the acidic conditions that prevail in an empty gastric compartment, anthocyanins are in the red flavylium form, while all the other dietary flavonoids remain neutral.

After ingestion, anthocyanins are readily detected in plasma, in their parent forms, possibly as a result of their absorption through the gastric wall [41–44].

Oppositely to other extrahepatic organs, such as the intestine and kidneys, the stomach has been widely ignored as a metabolizing organ although it has been identified as a site of absorption for different compounds [45, 46].

The contribution of the gastric mucosa to the metabolism of anthocyanins should not be ruled out because the stomach possesses conjugative enzyme activities (UDP-glucuronosyltransferase, sulfotransferase, and catechol-*O*-methyl transferase) [47–50]. Besides, in vitro studies showed that some flavonoids could be metabolized into glucuronidated and sulfated metabolites by the gastric wall [45, 51].

The anthocyanin fraction that is not absorbed in the stomach reaches the small intestine. Once anthocyanins enter more basic conditions in the small intestine, the carbinol pseudobase and the chalcone forms are likely to predominate. Unlike flavonoids where glycosides are hydrolyzed, anthocyanin glycosides are rapidly and efficiently absorbed from the small intestine [52–54]. Furthermore, anthocyanins are quickly metabolized and appear in the circulation or are excreted into bile and urine as both intact and metabolized forms (glucuronidated, sulfated, or methylated derivatives) [52, 53, 55–59].

Unabsorbed anthocyanins reach the colon where they undergo substantial structural modifications. Previous studies have suggested that this is likely due to the spontaneous degradation under physiological conditions [60] or following microbial metabolism. In fact, colonic microbiota hydrolyzes glycosides into aglycones and degrades them to simple phenolic acids.

According to Vitaglione and coworkers, protocatechuic acid is the major human metabolite of cyanidin-3-glucoside in humans [61]. In particular, protocatechuic acid accounts for almost 73% of the ingested anthocyanins. This metabolite was detected in plasma 2 h after blood orange juice ingestion, indicating that perhaps it was formed through chemical degradation at the physiological conditions of the systemic circulation or in the intestinal mucosa. This metabolite is recovered in fecal samples, which suggests that the gut extensively metabolizes anthocyanins [62].

The metabolism of berry anthocyanins resulting in phenolic acids in humans was recently studied [63]. The main anthocyanin metabolites detected were homovanillic and vanillic acids.

In another recent study, blueberry anthocyanin absorption and metabolism in rats was accomplished, and the main metabolite detected in urine was hippuric acid, which may be produced in liver through a conjugation of glycine with aromatic phenolic acids [64].

Since anthocyanin phenolic acids can be further absorbed in colon [65], it is possible that they are additionally metabolized by hepatic cells [66]. Health benefits associated with anthocyanin-rich foods may also be explained by a slow and continuous release of phenolic compounds through the gut into the bloodstream.

Despite low apparent bioavailability, plasma concentrations of anthocyanins appear sufficient to induce changes in signal transduction and gene expression in vivo [67, 68] in a manner that suggests their putative role in physiological functions and health outcomes.

Some of the human studies investigating anthocyanin bioavailability are summarized in Table 79.1.

In the studies listed, anthocyanins are administrated from different sources varying from beverages (red wine, fruit juices) to the ingestion of fruits, like blood orange, grapes, and different berry extracts or concentrates. The data values from all studies are summarized in the next data ranges:

- Anthocyanin dose administrated, 56–3.570 mg
- Duration of the assay, 3–48 h
- % urinary recovery, 0.003–5
- Maximal plasma or serum concentration, 1.4–592 nmol/L
- Time to reach maximal plasma concentration, 0.3–4 h
- Half-life of elimination, 1.5–3.0 h

The overall analysis of the biokinetic parameters has facilitated some main assumptions in what anthocyanin bioavailability is concerned. The most important one is that although there is a considerable variability in the values for the biokinetic parameters, anthocyanins appear to be rapidly absorbed and eliminated, reaching low maximal concentrations in plasma and urine.

Several factors including variations in the dose, anthocyanin chemical composition in the different sources, food or beverage matrix or processing, age and gender of the individuals, and the analytical methodology used can have a huge effect on the bioavailability and metabolism of anthocyanins.

4.2 Tissue Distribution of Anthocyanins

It has been only recently that studies were conducted to determine tissue concentrations of anthocyanins. The stomach exhibited only native anthocyanins, while in other organs (jejunum, liver, and kidney), native and methylated anthocyanins as well as conjugated anthocyanidins (monoglucuronides) were identified [69].

In another work, pigs were fed diets supplemented with blueberries for 4 weeks. Although no anthocyanins were detected in the plasma or urine of the fasted animals, intact anthocyanins were detected in liver, eye, cortex, and cerebellum. The results suggest that anthocyanins can accumulate in tissues, including tissues beyond the blood–brain barrier [70].

In a more recent work, proportions of anthocyanin derivatives (methylated anthocyanins and glucurono-conjugated derivatives) were identified in various organs (bladder, prostate, testes, heart, and adipose tissue) in rats fed with a blackberry anthocyanin-enriched diet for 12 days [71]. In this study, the bladder contained the highest levels of anthocyanins, followed by the prostate. Prostate, testes, and heart contained native cyanidin-3-glucoside and a small proportion of cyanidin monoglucuronide. Cyanidin-3-glucoside and methylated derivatives were present in adipose tissue.

Moreover, two recent works report the capacity of dietary anthocyanins from grape and berries to reach the brain [69, 72].

4.3 Mechanisms of Anthocyanin Absorption

The mechanisms responsible for the gastrointestinal absorption of anthocyanins are not fully understood. Whether anthocyanins are absorbed through passive diffusion or via a facilitated transport remains to be elucidated.

Recently, Passamonti and coworkers have suggested that an organic anion carrier, bilitranslocase expressed in the gastric epithelium, could be involved in the absorption of anthocyanins at the gastric level [73]. The administration of high amounts of anthocyanins, far from diet levels, could induce saturation of this transport and contribute to the lower anthocyanin bioavailability reported in those particular studies [55].

The potential mechanisms of anthocyanin glycosides absorption in the small intestine may involve a specific glucose transporter, such as SGLT1, as previously suggested for the flavonoids [74].

A recent work points for the putative involvement of GLUT2 transporter in anthocyanins' absorption at the intestinal level [33].

Another possible mechanism may involve the hydrolyzation of anthocyanins by brush border enzymes such as lactase phloridzin hydrolase, prior to passive diffusion of the aglycone, as already proved for other flavonoids [74, 75].

The health benefits associated in epidemiologic studies with the consumption of anthocyanin-rich foods contradict the apparent low bioavailability of these compounds. More subtle scenarios may exist, and detailed information is unlikely to be forthcoming until ring-labeled ^{14}C-anthocyanins [76] and anthocyanin metabolite conjugate standards become available [77].

4.4 Microbiota Impact on Anthocyanin Availability and Bioactivity

Microbiota keeps an important role in human metabolism. It must be considered a metabolizing "organ," with impact on endo- and xenobiotic metabolism, beyond its metabolic relevance for vitamin B12 synthesis, and carbohydrate breakdown, between other important functions.

As it has been known, no systematic reviews have been undertaken to assess the role of xenobiotic biotransformation in colon, in particular in what concerns anthocyanins.

Colonic microbiota could now be considered as a "microbial organ" placed within a host organism. In addition to the obvious role of the intestine in the digestion and absorption of nutrients, the human GI tract contains a huge collection of microorganisms. Microbiota has not been fully described, but it is clear that the human gut is home for an ecosystem of around 10^{13}–10^{14} bacterial cells. As a whole, the microorganisms that live inside humans are estimated to outnumber human cells by a factor of ten. And the microbiome represents overall more than 100 times the human genome [78].

The diet anthocyanins (parent compounds) that reach the microbiota are those not absorbed in the upper GI level and, also, their metabolites excreted in the bile and/or from the enterohepatic circulation (Fig. 79.5). In the microbiota, anthocyanins are extensively metabolized, especially by genera and species able to do that.

Anthocyanins are metabolized since part of the absorbed amounts have been found as methylated, sulfated, or glucuronidated forms. Anthocyanin metabolization includes the cleavage of glycosidic linkages and breakdown of the anthocyanin heterocycle [79–81].

For this kind of biotransformation, β-D-glucosidases, β-D-glucuronidases, and alpha-L-rhamnosidases that release aglycones from their glycoside or glucuronidate forms will be necessary [82–84]. There is a lack of information about this, but, probably, Bacteroides could be the genus mostly involved in these biotransformation reactions since this genus expresses those enzymes. For this reason, one could also consider, based on a specificity for substrate, that anthocyanins have a prebiotic effect upon Bacteroides, allowing them to grow. This is a new concept but important to consider, especially in an occidental diet pattern that needs to increase Bacteroides number. There is evidence from studies that compare microbiota from lean and from obese individuals that the last ones have an increase on Firmicutes genera and a Bacteroides decrease (about 50% reduction) in comparison with lean ones [85].

Furthermore, it is important to highlight that anthocyanin bioavailability may vary according to: (1) the food source and, consequently, by the matrix of the food source, and (2) the individual characteristics of the microbiota that strongly depends on dietary habits [86].

Depending on food source, anthocyanins can be chemically different, mainly as glucosides or rutinosides. However, the structure of the metabolites is not dependent on sugar moieties naturally attached to polyphenol but on the structural characteristics of the polyphenol. Protocatechuic acid is the main metabolite detected after anthocyanin consumption [79, 81, 84].

4.5 Considerations Regarding Anthocyanin Bioavailability

Anthocyanins are compounds with a particular chemistry that is responsible for their attractive colors but also for their instability and easy degradation. As previously referred, these compounds are pH sensitive, being more stable at acidic pHs. When the pH rises, chemical transformations of the anthocyanin structure occur and the molecule is no longer a cation (Fig. 79.3), becoming more unstable and losing the red color. The most common methodologies for detection of anthocyanins are based on their color as a flavylium cation form and rely on their ability to convert back into the cationic form after acidification. The fact is that this conversion may not be complete, which could lead to an underestimation of anthocyanins in the analyzed samples. Also, it should be taken into account that at physiologic pH, the main anthocyanin structure is the hemiacetal/chalcone and if these structures are metabolized/biotransformed, it may not be converted to the cationic form, contributing once again to the underestimation of these compounds on biological samples. Besides, the biologic role of these hemiacetal forms or their metabolites is not clear, but it is likely that these structures play a major function on the biologic effects attributed to anthocyanin consumption.

In another perspective, considering that anthocyanin absorption is reduced, perhaps due to its chemical properties, certain biological actions could still occur at the membrane level. As a consequence of a direct interaction with membrane lipids, flavonoids can alter membrane physical properties, modulating enzyme activity, ligand–receptor interactions, ion fluxes, signal transduction, transport, and other membrane-associated functions [87]. These membrane–flavonoid interactions can also affect the absorption of other dietary components, such as macronutrients, vitamins, or even other flavonoids. Flavonoids can also interact with membrane proteins modifying or altering their biological function. This is a point to bear in mind since flavonoids may trigger biological effects that do not depend on their absorption by the cells. Furthermore, interactions with microbiota should be considered, including flavonoid metabolism, as well as flavonoid effects on the microbiota and consequently effects on the balance between a myriad of species that constitute the microbiota. It means that anthocyanin healthy effects could result, at least in part, from these interactions, since microbiota metabolism could markedly interfere with human metabolism.

The scientific community has enriched its knowledge through the widespread use of in vitro techniques. This type of studies has provided valuable biochemical information. However, conclusions, interpretation, and extrapolation should be rigorous and careful in several aspects: (1) regarding the use of cell cultures, one should bear in mind the species from where the cell line is originating: different species may express, for example, different transporters that could have a role in flavonoid absorption; (2) tumor-derived cell lines often have a cellular machinery different from normal cells, thus influencing the measured outcome.

Also, when working with flavonoids, dose is always a concern. Ideally, doses should reflect in vivo physiologic situations, but most of the times, the detection and quantification tools available are not sensible enough for these doses. This leads to the use of higher doses which could compel a particular effect that would not happen or could be less pronounced if lower doses were used. Furthermore, in vitro studies often use the aglycones or native glycosides that, as discussed before, could be biologically irrelevant to the tissue or cell line used in the study; subsequently, the relevance of the conclusions as to their nutritive effects remains speculative.

Nevertheless, the knowledge of the pathways where these compounds may interfere, as well as their affinities to transporters, receptors, or enzymes, is valuable since it allows recognition of new putative therapeutic targets.

On the other hand, in vivo studies have increased the awareness of anthocyanin tissue distribution, have given an insight about anthocyanin biokinetic behavior, and allowed to relate anthocyanin consumption with several beneficial health effects. Even so, these types of studies have some limitations given that, generally, there is not a mechanistic approach about the movement of anthocyanins through the cells or the pathways responsible for the biological effects observed.

All these issues make the study of anthocyanin disposition a difficult task that is not fully understood, regardless the scientific advances that have been made in this field.

5 Conclusion

Overall, anthocyanins found in diverse food sources, with berries, and red wine as main sources, are intestinally absorbed, but mainly reach the colon and are submitted to microbiota metabolization. Content of anthocyanins may vary considerably between food sources and environmental conditions, as a direct sun exposure, cultivars, etc. This fact is often neglected in studies, probably justifying result variability and the, still existing, gap in knowledge.

Anthocyanins seem to be absorbed in the upper GI (stomach and small intestine) mainly in the parent forms. In addition, they, themselves and/or their metabolites seem to be absorbed after a microbial action, and microbiota seems to constitute the main responsible factor for anthocyanin bioavailability.

Healthy known effects associated with consumption of anthocyanin-rich foods should be attributed to: (1) direct effects of the absorbed parent compounds (or their metabolites) and (2) indirect effects mediated by nonabsorbed entities that, probably, induce modifications on microbiota environment and, consequently, on human metabolism.

More studies should be carried out in what concerns anthocyanin transport across biological membranes. There are studies announcing neuroprotective effects of anthocyanin-rich foods, but there is a gap in the knowledge concerning, for example, anthocyanin (and metabolites) transport across blood–brain barrier. On top of this, it is urgent to know dietary factors able to modulate anthocyanin bioavailability, helping health professionals to make dietary recommendations. These recommendations will be relevant for a healthy life but also to alert medical doctors as to possible pharmacological interactions with anthocyanins.

Abstract

Functional foods and nutraceuticals are reported as one of the top trends of the food industry, but because of the different definitions of the terms, it is uneasy to calculate their global market size. With a broad definition, this value is well over

$40 billion, and is showing steady annual increases both in sales and new products launched. However, there are differences according to the ingredients and the claims used.

Several factors are considered crucial for the future market evolution: the degree of acceptance and awareness of functional foods by consumers, the association between manufacturers and academic researchers, and the effects of new regulations for nutrition and health claims. Concretely, the Regulation 1924/2006 will have a great impact on the number of products bearing a claim. We have analyzed European Authority of Food Safety (EFSA) opinions on plant extracts and phytochemicals, including phenolic compounds, since they can provide lessons for the development of functional foods all over the world.

Scientific research is indispensable for the substantiation of the evidence for functional foods. Advances in the characterization of plants ingredients by hyphenated MS and NMR technologies, standardization of human clinical trials, and emerging methodologies like bioinformatics or nutrigenomics can be crucial for the development of new functional products.

1 Introduction

1.1 Definition of Functional Foods, Nutraceuticals, and Related Terms

The advent of functional foods and nutraceuticals on the market has blurred the distinction between pharma and nutrition [1]. Obviously, the concept of foods promoting health is not new. In 400 b.c., Hippocrates already sentenced “Let food be thy medicine and medicine be thy food” [2], and in the countries of the far East, influenced by Chinese culture, foods such as glutinous rice, wheat, sesame, jujube, gingiber, or leek were included in Chinese medicine books for their traditional use for chronic diseases [3]. Nowadays, the development of functional foods is one of the most intensive areas of food product development worldwide, opening multiple challenges for countries with a vast biodiversity and historical use of plant extracts [4].

However, estimating the market size values for functional foods can be difficult, because of the ambiguity of the term “functional food,” the lack of an official or univocally accepted term (in many countries there is no regulatory

Table 80.1 Concepts related to functional foods and nutraceuticals

Functional foods	A food can be regarded as 'functional' if it is satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects in a way that is relevant to either an improved state of health and well-being and/or reduction of risk of disease. Functional foods must remain foods and they must demonstrate their effects in amounts that can normally be expected to be consumed in the diet. They are not pills or capsules, but part of a normal food pattern	[6]
Nutraceuticals	A nutraceutical is a product isolated or purified from foods that is generally sold in medicinal forms not usually associated with food. A nutraceutical is demonstrated to have a physiological benefit or provide protection against chronic disease	[7]
Dietary supplements	A product that contains one or more of the following dietary ingredients: vitamin, mineral, herb, or other botanical, and amino acid (protein). Includes any possible component of the diet as well as concentrates, constituents of extracts or metabolistes of these compounds"	[8]
Food supplements	foodstuffs the purpose of which is to supplement the normal diet and which are concentrated sources of nutrients or other substances with a nutritional or physiological effect, alone or in combination, marketed in dose form, namely forms such as capsules, pastilles, tablets, pills and other similar forms, sachets of powder, ampoules of liquids, drop dispensing bottles, and other similar forms of liquids and powders designed to be taken in measured small unit quantities	[9]
Parnuts	Foodstuffs for particular nutritional uses are foodstuffs suitable for their claimed nutritional purposes and which are marketed in such a way as to indicate such suitability. They can include: – Infant and follow-on formulae – Processed cereal-based foods and baby foods for infants and young children – Food intended for use in energy-restricted diets for weight reduction – Dietary foods for special medical purposes – Foods intended to meet the expenditure of intense muscular effort, especially for sportsmen. – Foods for persons suffering from carbohydrate metabolism disorders (diabetes).	[10]
Herbal medicinal product	Any medicinal product, exclusively containing as active ingredients one or more herbal substances or one or more herbal preparations, or one or more such herbal substances in combination with one or more such herbal preparations	[11]

definition) [5], and the diffused borders between concepts for commercial products also related to health-promoting functions such as "functional foods," "nutraceuticals," "superfoods," "dietary supplements," or "cosmeceutics," many of which respond to marketing criteria. Table 80.1 compiles some of the terminologies currently associated to functional foods and nutraceuticals.

Despite the ancestral knowledge of the link between diet and health, the appearance of specific terms related to foods promoting a health benefit is more recent.

In 1984, the concept of functional food was first promoted in Japan by scientists who were studying the relationships between nutrition, sensory satisfaction, fortification, and modulation of physiological systems [12]. The Japanese Ministry of Health and Welfare then introduced "Foods for Other Specific Health Use" (FOSHU) in 1991, promoting its use as a strategic action to reduce healthcare costs. The success of the initiative (in 2000, the total number of approvals under the FOSHU label reached 174, with an estimated market value of around $2 billion [13], while more than 500 products were labeled as FOSHU in 2005 [5]), united to the success of products with health claims in the USA, paved the way for the development of the functional foods market. However, consensus on a definition or categorization of these foods was established by heterogeneous criteria by manufacturers or scientists, not by regulatory agencies.

In Europe, the International Life Science Institute (ILSI) established an operational definition of functional foods: "a food product can only be considered functional if, together with its basic nutritional impact, it has beneficial effects on one or more functions of the human organism, either improving the general and physical conditions and/or decreasing the risk of evolution of diseases. The amount of intake and form of the functional food should be as it is normally expected for dietary purposes. Therefore, it could not be in the form of pill or capsule but only as a normal food form." This definition would establish a clear separation from nutraceuticals, which can be considered as diet supplements that deliver a concentrated form of a presumed bioactive from a food, presented in a nonfood matrix, and used with the purpose of enhancing health in dosages that exceed those that could be obtained from normal foods [14]. Nutraceuticals are sold in presentations similar to drugs: pills, extracts, tablets, etc. [15]. However, in many cases, the functional food market is referred as the "nutraceutics" market [16], and then, it is difficult to separate the exact values for each. A reason for this interconvertibility of terms is that much of the early development of the nutraceutical concept and products was driven from the USA, where the Dietary Supplement and Health Education Act (DSHEA) allowed considerable flexibility and blurred the boundaries between foods and medicines that can be found in other parts of the world [17]. Anyway, there is no definition for nutraceuticals in neither the UE nor the USA, although both have a definition for supplements, which could be considered equivalent to nutraceuticals.

In opposition, the federal Department of Canada has proposed, via Health Canada, differentiated definitions for nutraceuticals and functional foods. A nutraceutical is a product isolated or purified from foods that is generally sold in medicinal forms not usually associated with food. It is demonstrated to have a physiological benefit or provide protection against chronic disease. A functional food is similar in appearance to, or may be, a conventional food, is consumed as part of a usual diet, and is demonstrated to have physiological benefits and/or reduce the risk of chronic disease beyond basic nutritional functions. In this case, the difference of formulation between both kinds of products is well established [7].

Most functional foods definitions do not intend to exclude natural foods in the functional foods category. However, many manufacturers and the perception of the general public would disagree, since for many of them, the functional food should imply an inherent fortification of the food with a bioactive ingredient. And from the pragmatic point of view of manufacturers concerned about regulation accomplishments, functional foods would be those that bear or intend to bear a nutritional or a health claim.

Another conflictive concept is the one for cosmeceuticals. Neither the FDA nor the EFSA recognizes this term, which is widely used by the cosmetic industry to refer to cosmetic products that have medicinal or drug-like benefits. Like cosmetics, cosmeceuticals are applied topically but differ in that they contain potent ingredients that can influence the biological function of the skin and deliver nutrients to promote healthy skin [18]. Nearly universally around the world, this has become the catchword for the millennium change in cosmetics to retard aging [19].

Other marketing concepts have arisen like "superfoods," which are referred to natural products that have a low glycemic index and provide key nutrients that are lacking in the typical western diets, like beans, dark green leafy vegetables, citrus, sweet potatoes, berries, tomatoes, fish high in omega-3 acids, whole grains, nuts, fat-free milk, and yogurt [20]. A derivative concept, "superfruits," has emerged to design natural fruits (including blueberries, blackberries, cranberries, pomegranate and exotic ones such as açai or goji) that have a high antioxidant capacity. However, neither of those terms has been recognized by the Food and Drug Administration or the European Food Safety Authority.

Finally, other terminologies that used to be popular such as vitafoods, alicaments, or pharmafoods have become obsolete and fallen out of use.

1.2 Socioeconomic Context of Functional Foods and Nutraceuticals

To understand the success in the functional foods and nutraceuticals sector and the reasons behind their expansion in the market as well as the menaces that can compromise their growing, it is necessary to describe the socioeconomic context, which includes many interactions between consumers, scientists, food manufacturers, and legislative bodies.

1.2.1 Functional Foods as a Vector for Health

In the last decades, the social economic development has induced profound changes in consumer behavior, involving, in particular, food consumption dynamics. The elements that have most influenced and still influence consumer eating habits are the lengthening of life expectancy, the progressive ageing of population, the health economic and social costs rising, the widespread desire for a better quality of life, and media and advertising [21].

Major current problem areas for population health include obesity, cardiovascular health, age-related cognitive decline, metabolic syndrome, insulin resistance, and diabetes [22]. All these concerns are expected to grow because of the change of the age pyramid to older societies. People are living longer, and so incidence of specific diseases or conditions of elder people, such as cardiovascular diseases, diabetes type 2, osteoporosis, or neurodegenerative diseases, will increase. The biggest health concern nowadays is obesity and overweight, especially because of the highest increase in developing countries [23]. The WHO estimated in 2003 that over one billion people are obese and over 400 million people are clinically obese [22]. Cardiovascular diseases are also a big concern: They represent 30–50 % of cause of mortality in developed countries. High blood pressure and cholesterol levels have reached pandemic dimensions, and it is predicted that the worldwide incidence of diabetes will exceed 450 million people by 2025 [22]. The prevalence of arthritis and osteoporosis in the aging populations of developed nations is also growing: In 2010, more than 5.5 million people in the seven major markets were forecast to be suffering from rheumatoid arthritis (RA) [24].

Many of the major chronic diseases are caused substantially by poor diets. The consumption of whole grains and better lifestyle choices could represent a reduction of over 100,000 deaths per year in the UK [25]. Since a major issue for public research is targeting prevention of diet-related diseases [26], there is a growing interest about the links between food and health by public health officials [27]. Functional foods have the potential to improve population health in line with the objectives identified by national public health strategies [28], promoting the prevention and risk reduction of disease, and thus reducing mortality rates and medicinal costs associated to therapeutic treatments. For example, it was estimated that in the USA, total direct and indirect costs associated to diabetes and related disorders reached $98 billions in 1997 [22]. In 2005, $466 m were spent on pharmaceutical medication to treat obesity in the seven major markets, and these sales were set to triple to $1.5 billion by 2010. In 2005, $84 billion were spent in the USA and the 5 major European markets on the pharmaceutical treatment of CVD conditions. By 2010, sales were expected to rise to $105 billion. In 2005, it was estimated that around $22.5 billion were spent worldwide on the sale of drugs used to treat rheumatoid arthritis (antirheumatics), osteoporosis (osteoporosis agents), and inflammatory conditions, with $14 billion of this generated from sale of medicines in the top seven countries [24].

In this context, public health organizations and governments share a mutual interest in promoting health through nutrition and adequate lifestyles, thus reducing medical costs. For example, the consumption of whole grains and better lifestyle choices could represent a reduction of over 100,000 deaths per year in the UK [25]. In fact, this was the key reason why the Japanese government introduced the FOSHU system: to keep the aging population healthy through functional foods and to keep the health care costs down. Similar policies are spread all over the world. For example, agriculture, food, and health are significant themes in the European Union's current Seventh Framework Research Programme (FP7) [26].

1.2.2 The Perspective of the Consumer

Consumer acceptance of the concept functional foods, together with a better awareness of its determinants, is widely recognized as key success factor for market orientation, consumer-led product development, and successfully negotiating market opportunities [29]. However, little research has been conducted to analyze the perspective of the consumers [30].

In fact, one of the main reasons of the success of functional foods has been the role of consumers undertaking new trends to a healthier lifestyle. Many objective data show this tendency. For example, between 2006 and 2007, vegetables and fruits were the top 2 products whose use increased in North America, Western Europe, and Nordic Europe, while processed foods, salty snacks, and sugars were some of the products with the biggest decrease in use. In the last 25 years, butter has decreased from around 70 % of the yellow fat market to 25 %, while low fat spreads have captured half this market. In the cooking fat sector, vegetable oils have taken over the animal fats. Skimmed and semi-skimmed milks have copped 2/3 of milk sales, while low calorie soft drinks have increased to 20 % of the soft drink market [31].

Apart from these examples of healthier choices taken from objective market data, several surveys are periodically conducted in developed countries to follow the public attitude toward health. In 2011, according to the International Food Information Council Foundation Food & Health Survey, 59 % of Americans declared that they were attempting to make changes to improve the healthfulness of their diets, in order to ameliorate their overall well-being (65 %), lose weight (56 %), improve their physical health (56 %), because of a specific health condition (32 %), and/or maintain weight (20 %) [32]. Similar tendencies can be found in European countries.

However, these pronouncements have to be considered carefully, because some data have reported lower frequencies of healthy food consumption in American consumers, despite their intention of eating healthily more often [33]. This distance between the consumers' aspirations and the real consumption is a clear menace to the success of the functional foods niche and should be overcome by providing functional products that are attractive to the potential buyer, both in price, and taste and efficacy.

Acceptance of Functional Foods and Willingness to Buy New Products

In the process of developing new functional ingredients or foods, there must be a consumer need or a problem that requires solution, and there must be self-awareness of the problem from the consumer. But it is also crucial that consumers must be willing to spend money to solve the problem or satisfy the need they have identified [23].

The Functional Foods/Foods for Health Consumer's trending survey is being conducted every 2–3 years since 1998 and provides ongoing American consumers insights into their interest and perceptions about food and beverages and the roles they have in promoting health and wellness [34]. This study summarizes some of the points that can explain the reasons for the success of functional foods. A first aspect to be considered is the acceptance by consumers that functional foods can have added health and wellness benefits. Most data from other surveys in other countries show conformity with this topic. According to the 2009 IFIC Functional Foods/Foods for Health Consumer Trending survey, between 68 % and 85 % of Americans agree that foods or beverages can provide specific health benefits such as improving heart health, contributing to healthy grown and development in children, or improving bone health [34]. In Europe, even when consumers had not heard the term “functional foods,” more than 50 % agreed to fortify functional ingredients in specific food products [35]. Japanese consumers have traditionally been aware of the importance of certain foods for the promotion of health.

Obviously, general health orientation varies systematically as a function of age and gender. According to the results obtained from different questionnaires, rational food consumers are the primary potential target of functional food producers. Women tend to be substantially more health-oriented than men, which explains the females’ stronger purchase interest toward functional foods, an observation that has met consensus in different studies. In general, women have shown to be more reflective about food and health issue. Another relevant socio-demographic factor is the presence of children in the family. On the other hand, middle-aged and elderly consumers tend to be substantially more health-oriented than young consumers. In truth, middle-aged and elderly are the largest group who uses functional foods to target a specific health concern. In this case, it is hypothesized that this group is more likely to have confronted relatives’ loss of good health, and this experience with illnesses and associated economic and social consequences increase probability of functional food acceptance [29]. In overall, the hypothesized effects of socio-demographic determinants are that acceptance of functional foods increases with higher age, being female, having young children, and having an ill family member.

At the same time, there are discrepancies about the role of education in the acceptance of functional foods. In Europe, it is biased toward the higher socioeconomic groups, reflecting a higher willingness or ability to pay a premium price; while in the USA, there is a higher acceptation among the lower educated. Another difference between American and European consumers is the far more critical attitude toward new product and technologies, and therefore, it can be hypothesized that European’s acceptance of functional foods is less unconditional [5].

In conclusion, it seems to be a global acceptance of functional foods, but this must not be taken for granted and cannot reflect the perception of concrete functional foods. In this sense, another of the aspects addressed in consumers’ research is the awareness of functional foods.

Concerning the awareness of the terminology of functional foods, different surveys show that consumers are not greatly informed about this concept, although there is a steady tendency to increase these levels of awareness in all the countries. For example, in an Italian quantitative survey conducted in 400 consumers, 24 % were unable to give a definition for functional foods, 20 % confused them with light and dietary products, and 16 % incorrectly associated them with food for those who have specific health problems [36]. In Belgium, 49 % of consumers were familiar with the term “functional food,” but only 30 % in Hungary and 4 % in Poland [37].

Given the positive acceptance showed for functional foods in general, it should come to no surprise that most studies have shown a significant willingness to pay for this kind of products. For example, Mintel Oxygen 2010 reported that more than half of consumers had bought a functional food or beverage in the 3 months previous to the study. More than half of the Americans reported in 2009 the consumption of foods or beverages for overall health and wellness (56 %), heart health benefit (55 %), or to contribute to a healthy body weight [34]. In a recent survey in Europe, 15 % of consumers reported a daily consumption of functional foods, 24 % reported a high-frequency consumption, and 28 % considered themselves occasional buyers. Only 21 % of respondents stated that they had never consumed these products [36].

Again, regardless of the global willingness to pay for healthy products, the acceptance of a specific functional ingredient is linked to the consumers' knowledge of the health effects. Functional ingredients which are in the mind of the consumers for a relatively long period of time (e.g., vitamins, minerals, fiber, low sugars, etc.) achieve considerably higher rates of acceptance than ingredients that are used for a short period of time. This can have a great impact in the context of the economic recession. Although it can be demonstrated that consumers are willing to spend for relevant functional benefits even in times of financial crisis, consumers are less likely to experiment with new functional foods and beverages: In this sense, the credibility of the health effect and the perceived effectiveness of the product, as well as a correct knowledge of the ingredient and a correct association between the ingredient and the health benefit, is crucial. For example, fiber, calcium, iron, and vitamin D are well-known ingredients and consumers are correctly aware of the kind of health benefit they can expect from them. Omega-3, probiotics, and phytosterols were less known, but thanks to the advertising policies communicating their health effects, consumers have a good knowledge of their benefits. In opposite, products like oligosaccharides, lutein, or peptides are less popular. It is of great importance to have well-informed consumers, conscious of the effects of the ingredients, in order to avoid incorrect expectancies that can further lead to deception and lack of trust in future products.

In sum, for those products with limited consumers' knowledge, there are strong needs for specific information and communication activities. Doctors, nutritional advisers, and public entities are the sources in which the consumers have most confidence (42–45 % of trust), while a lesser degree of confidence is given to producers and product labels [13, 36]. The implementation of specific regulations restricting the use of nutrition and health claims to products with a solid scientific evidence will also offer a reinforcement of the trust of consumers in the long term. But in the short term, the withdrawal of many health claims for top products, some of them very popular among consumers, because of insufficient scientific evidence, can have the contrary effect. So, it is advisable to reinforce the transparency on the information to consumers to avoid a bad global perception of the functional foods products.

1.2.3 Association of the Industry and the Scientific Community

It must not be forgotten that because of its innovative component, functional foods have been possible, thanks to the arousal of new knowledge about the relationship between ingredients and health, which has mainly been provided by the advances in the scientific research on the subject.

Innovative concepts in the area may thus emerge from academic researchers, although they often are not aware of how to translate these ideas into final marketable food products [38]. In consequence, most frequently it is the industry that initiates the cycle of development, but working closely with academics (for example, through the formation of scientific advisory boards) to provide a solid ground to design a new functionality/ingredient, as well as to conduct the series of safety, efficacy, and bioavailability tests to prove the applicability of the new designs. This cycle of innovation can lead to breakthrough products, which can be defined as products, which provide a company with greater profits and longer-lasting competitive advantage in the marketplace in comparison to minor product development or line extensions [39], that can be as well a good and easier way to include a health claim in food products. But while the first case would in general be early-movers, in the second case, normally, it would be companies deciding to approach the functional food market in response to its astonishing growth [40]. This difference in the degree of innovation is well recognized in the UE Regulation 1924/2006, which distinguishes innovative products (Article 13.5), while at the same time provides a list (Article 13.1) that already states more usual ingredients-activities relationships.

2 Market Prospect of Functional Foods

2.1 Global Sales: A Steady Progression

Many market studies of global sales of functional foods differ in the data, depending on the criteria used for the inclusion of products in the analysis. For example, under a strict definition, according to Leatherheadfood, the functional food and drinks market had a combined value of $19.4 billion in 2007, whereas with a broader definition, the market raised to $41.9 billion [41]. In 2011, the global market for a strict definition of functional products as those offering specific health claims was estimated at $24.2 billion [42]. BCC research established a Nutraceuticals Global Market for nutraceutical foods, nutraceutical beverages, and nutraceutical supplements of $40 billion each.

Another source of confusion for the precise definition of the market size is that many functional ingredients were initially included in foods for reasons other than their health-promoting values. For example, the use of antioxidants for food preservation purposes was prior to their commercialization as health-enhancing functional additives, and bioactive compounds such as anthocyanins from red berries or lycopene from tomato were more appreciated because of their application as natural colorants rather than because of their biological activity against free radicals. Obviously, the higher added-value obtained because of their healthy properties has meant a faster growing development of these products. In 2007, global sales of antioxidants used in the manufacture of foods amounted to $788 million, representing a constant yearly increase of 3 %. Functional antioxidants in 2007 already accounted for the majority of sales, holding a value share of almost 56 %, with antioxidants used for food preservation purposes making up the remainder [43].

Despite this lack of precision concerning the data, functional foods have undeniably been reported as one of the top trends facing the food industry. They have been especially active since the last decade, when the annual growth rate of the functional foods market ranged from 15 % to 20 % at the end of the 1990s [29]. The global functional food market in 2002 was roughly estimated to be between $10 billion and $40 billion with an annual increase of about 8 % [39]. In 2008, when using a definition of functional foods that comprised all "products bearing a health claim," this group of products had arisen as the fastest-growing sector of the food market, with estimates forecasting an expected annual growth rate of 10 % for functional foods as compared to an average 2–3 % for the food industry as a whole [44]. Although growth rates estimates have decreased over time, the numbers remain impressive compared to growth rates for the food industry as a whole.

Even in the actual situation of economic recession, which should compromise the willingness of consumers to buy more expensive foods, recent estimates remain optimistic. Consumer interest in functional foods remains strong, and the rising costs of healthcare and the needs of an aging population should still encourage the consumers' commitment to health and wellness pursued through the diet. Recent data from 2007 by Pricewaterhouse Coopers [45] predicted that functional foods in the USA could grow by up to 20 % or five times that of the food industry as a whole [46], which is consistent with other reports by Leatherhead [47] that products making specific health claims –not including neither energy and mood drinks, nor food supplements – are predicted to grow at 4–5 % for the next few years [48]. According to market analyst Freedonia, demand for nutraceutical ingredients like botanicals, vitamins, minerals, and omega-3 s will grow 7.2 % annually until at least 2015 to be worth €18.5 billion with newer markets like Mexico and South Korea helping drive growth in the sector [49]. And a report by Global Industrial Analysts projected the global nutraceuticals market projected to exceed US$243 billion by 2015 [50].

Figure 80.1 shows this evolution in the functional foods and beverages market size.

Concerning differences between countries, according to Datamonitor, some of 90 % of total sales occurs in Europe, the USA, and Japan [51]. In Japan, according to a Leatherhead report utilizing tight functional food definitions, global sales in 2010 reached $24.22 billion, which would represent the 38.4 % of the global functional market, followed by the USA with 31.1 % and Europe (28.9 %) [48].

In the USA, with between $20 billion and $30 billion in sales a year, functional foods comprise about 5 % of the entire US food market [52].

In Europe, Germany, France, United Kingdom, and the Netherlands represent the most important countries within the functional foods market, but many other European markets are experiencing high growth rates, such as the Netherlands and Spain.

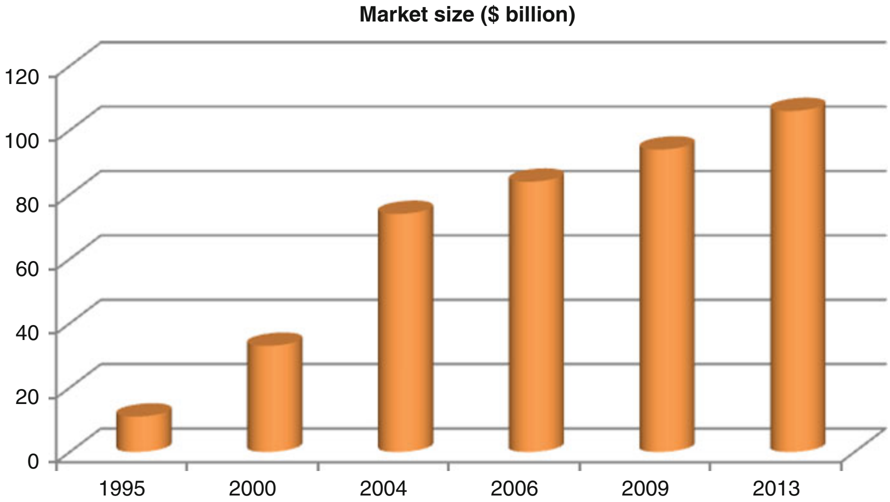

Fig. 80.1 Global market size of functional foods (Sources: New Nutrition Business (1995, 2000) [53]; Euromonitor International (2004, 2006, 2009) [54]; BCC Research (2013) (http://www.bccresearch.com/report/nutraceuticals-processing-markets-fod013c.html))

In addition, newly emerging markets like Hungary, Poland, and Russia are also well positioned [36].

2.2 Situation of Specific Product Launches, Ingredients, and Claims

The growth of the functional food market has been correlated with a steadying increase of the number of functional food products launches. According to Mintel analysts, the global launches of functional products between 2005 and 2009 were more than doubled, from 904 to 1859. Between 2008 and the first half of 2009, USA was the leader in healthy product launches (881 products), followed by Japan (314), Italy (325), UK (237), Germany (235), and France (150) [46].

The main functional foods category correspond to dairy products, that account for the 38 % of the market, followed by bakery and cereals (22.7 %), beverages (12.5 %), meat, fats and oils (8.1 %), fish and eggs (7.4 %), and soy products (5.8 %). In most cases, there has been a significant growth in the market. For example, according to Euromonitor the global market for pre- and probiotic spoonable yogurt had a growth of 128 % between 2004 and 2009, from $3.3 billion to $7.6 billion, while for drinking yogurt, it grew a 44 % to $11.2 billion [55]. Sales of functional spreadable oils and fats grew 54 %.

Classified according to health claims made on the product, digestive health has been the most used claim for new products (Fig. 80.2) [56].

It is relevant to state that food traditions and cultural heritage influence the interest of consumers in functional foods. For example, despite dairy is the biggest

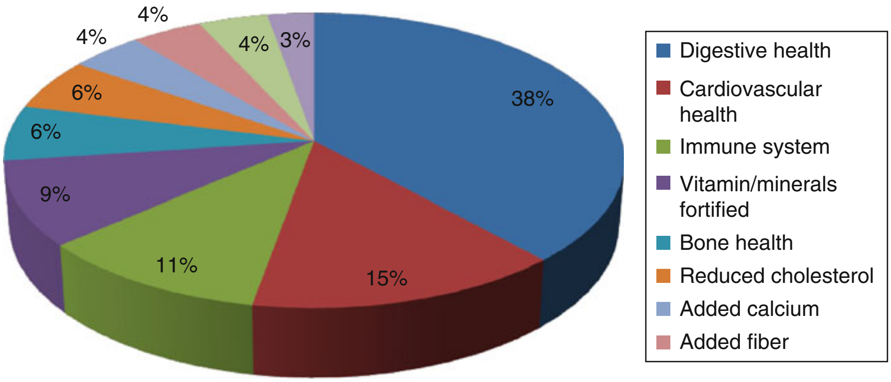

Fig. 80.2 Global distribution of health claims in functional products launches between 2005 and 2009 (Source: Mintel's Global New Products Database)

segment in the global market, in the USA, this predominance is for functional beverages, including energy and mood beverages. According to Leatherhead Food International, functional drinks account for 50 % of the US functional food market, followed by cereal products [48]. Another characteristic of the USA is that consumer expenditures on nutraceuticals are especially active, having reached a reported $20.50 billion in 2004, more than double the amount spent in 2004. Supplementation is also quite popular in Japan, whereas European consumers are less driven to these kinds of products. Another example of regional particularities is the fact that Japan is the world's largest market for green tea sold in leaf, which accounts for nearly 65 % of total leaf tea sales in the domestic market [43].

Concerning claims, digestive health is not the top claim in the USA, this honor belonging to cardiovascular health. On the opposite side, cardiovascular health claims are quite reduced in Japan (less than 10 % of the new functional foods launches). In the UK, cardiovascular health claims have represented a 20 % of the 530 new products between 2005 and 2009 [58].

2.3 New Perspectives

Despite the continuous introduction of new functional food or beverage products to the market, in the last few years, a certain reduction in the number of launches for some of the functional ingredients has been observed. Mintel reported in 2010 a slowdown in the market for energy drinks and fortified waters in the USA [57]. Figure 80.3 shows the reduction on the number of new products with claims related to the polyphenols family, according to Datamonitor. This reduction that can be attributed to different factors such as the development of new legislations such as the recent implementation of the UE 1924/2006 Regulation, that is limiting the use of nutrition and health claims by establishing the need of a strong substantiation of the evidence of the claimed effect. This has led to the dismissal of several health

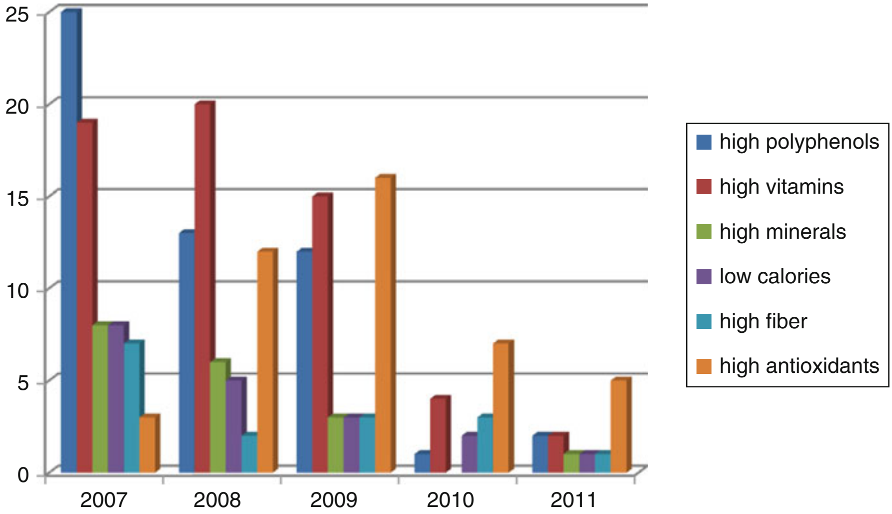

Fig. 80.3 Number of global launches of ingredients with polyphenols associated to different claims (Source: Datamonitor)

claims for many products, especially in areas like natural plant extracts or probiotics. This will mean a reduction on both the number of functional foods as well as their market value, at least according to the definition of functional foods as those wearing a nutrition or health claim. For example, there was an 11 % drop in the number of health claim-bearing launches between 2009 and 2010, even if the transition period for many products was still applied in the UE.

Additionally, in a global economic situation of recession, food companies can find difficulties to assume the costs associated to the development and scientific substantiation of evidence for new products, especially for cases that could imply expensive research.

The difference of the economic impact between products with health claims compared to those without them is uncertain. For example, in the USA in 2000, the market for functional foods with specific health claims achieved a turnover of around $0.5 billion, while functional foods without claims had an annual turnover of at least $15 billion [13].

3 Functional Foods Under Scrutiny: Situation of Natural Products Relating to the Substantiation of Evidence

3.1 Regulation of Functional Foods and Nutraceuticals Market

To ensure that the products are not misleading consumers, governments from various countries have developed regulation systems. Normally there exist associated organizations that take care of the accuracy of the claims used for functional foods and nutraceuticals. Some of these organizations are the European Authority of Food Safety (EFSA) in Europe, the Food and Drug Administration (FDA) in the United States, or the Ministry of Health, Labour and Welfare (MHLW) in Japan. We will discuss the current situation of the USA and Europe in relation to the approval of claims.

3.1.1 USA

In the USA, claims on foods and dietary supplements can belong to three different categories: nutrient content claims, structure/function claims and health claims.

Structure/function claims can be used for dietary supplements, and describe the effect on the structure or function of the body [8, 58].

Nutrient content claims can be considered as "expressed nutrient content claims," which is any direct statement about the level (or range) of a nutrient in the food, or as "implied nutrient content claims," which denotes any claim describing the food or an ingredient therein in a manner that suggests that a nutrient is absent or present in a certain amount or suggests that the food, because of its nutrient content, may be useful in maintaining healthy dietary practices. Annex Table 80.3 shows the nutrient content claims of the USA.

Health claim means any claim (including statements, symbols, vignettes, etc.), made on the label or in labeling of a food or dietary supplement, that characterizes the relationship of any substance to a disease or health-related condition.

In their origin (1990), health claims had to be based on a very high standard of scientific evidence, evaluated by the FDA. However, after the result from a 1999 Court of Appeals Decision, Pearson v. Shalala, the *Qualified Health Claims* were introduced for substance/diseases relationships with lower standards of evidence, that is considered credible but without reaching a significant scientific agreement standard. In the case of Qualified Health Claims, the proposed claim has to include qualifying language that identifies limits to the level of scientific evidence to support the relationship [59].

Table 80.2 compiles the Health Claims and Qualified Health Claims approved by the FDA.

3.1.2 European Union

The EU Regulation 1924/2006 [60] distinguishes two types of claims:

Nutrition claims are claims that state, suggest, or imply that a food has particular beneficial nutritional properties due to the energy it provides or the nutrients it contains [61]. Annex Table 80.4 compiles these claims.

Health claims are any claim that state, suggest, or imply that a relationship exists between a food category, a food, or one of its constituents and health. *Reduction disease risk claims* are health claims that state, suggest, or imply that the consumption of a food category, a food, or one of its constituents significantly reduces a risk factor in the development of a human disease.

The regulation classifies health claims into three main types. Article 13.1 claims pertain to "general function" claims relating to growth, development, and functions

Table 80.2 Health claims and qualified health claims approved by the FDA

Health claims	
Calcium, Vitamin D	Osteoporosis
Dietary lipids (fat)	Cancer
Dietary saturated fat and cholesterol	Risk of coronary heart disease
Dietary non-cariogenic carbohydrate sweeteners	Dental caries
Fiber-containing grain products, fruits and vegetables	Cancer
Folic acid	Neural tube defects
Fruits and vegetables	Cancer
Fruits, vegetables and grain products that contain fiber, particularly soluble fiber,	Risk of coronary heart disease
Sodium	Hypertension
Soluble fiber from certain foods (whole oat, barley, psyllium seed husk)	Risk of coronary heart disease
Soy protein	Risk of coronary heart disease
Oatrim	Risk of coronary heart disease
Stanols/Sterols	Risk of coronary heart disease
Qualified health claims	
Tomatoes and/or tomato sauce	Prostate, ovarian, gastric, and pancreatic cancer risk
Calcium	Colon/Rectal cancer & calcium and recurrent colon/ Rectal polyps risk
Green tea	Cancer risk
Selenium	Cancer risk
Antioxidant vitamins	Cancer risk
Nuts	Heart disease
Walnuts	Heart disease
Omega-3 fatty acids	Coronary heart disease
B vitamins	Vascular disease
Monounsaturated fatty acids from olive oil	Coronary heart disease
Unsaturated fatty acids from canola oil	Coronary heart disease
Corn Oil	Heart disease
Phosphatidylserine	Cognitive dysfunction and dementia
Chromium picolinate	Diabetes
Calcium	Hypertension, pregnancy-induced hypertension, and preeclampsia
0.8 mg folic acid	Neural tube birth defects

of the body. They should be based on generally accepted evidence and could be used by any manufacturers as long as the conditions of use are kept. Article 13.5 claims pertain to general function claims based on new and/or proprietary data. This type of claim is particularly relevant for manufacturers who have invested in innovation and wish to protect their claim and/or underpinning scientific data [62].

Article 14 claims refer to risk reduction claims or claims related to children's health and development.

According to the Regulation, the European Food and Safety Authority (EFSA) is the consulting organization for the analysis of the scientific substantiation of evidence of Health Claims. Its evaluating process, which started after the implementation of the Regulation, will imply a change in the allowed health claims for functional foods in Europe. The Fig. 80.4 compares, for some of the most popular ingredients, the successes and failures on obtaining a positive opinion about the scientific substantiation of evidence for the ingredient's intake and health relationship.

As it can be inferred from EFSA opinions, while there are some ingredients with well-established relationships of cause and effect between their intake and the claimed effects, for many other compounds, this association is much less proven.

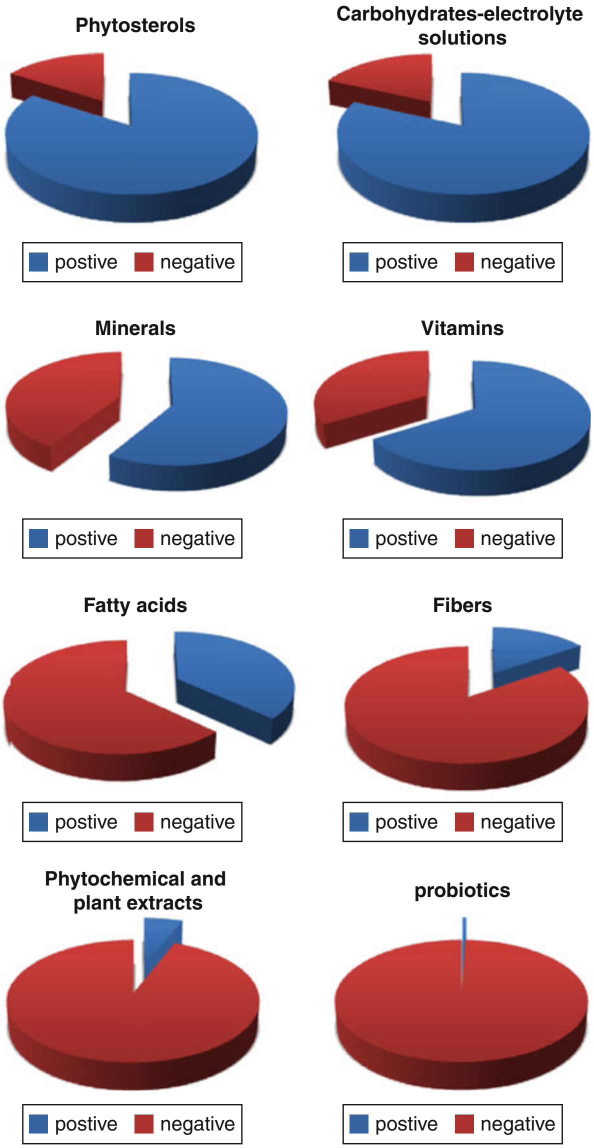
On the positive side, with a high percentage of success, the cholesterol-lowering effect of phytosterols, the role of carbohydrate-electrolyte solutions for the enhancement of water absorption during physical exercise, or the importance of vitamins and minerals toward different processes is well accepted.

In opposition, the cause-effect relationship of probiotics, prebiotic fiber, and phytochemicals (including plant extracts), among other ingredients, has commonly been considered as insufficiently substantiated. For probiotics, an inadequate identification of the probiotic strains, as well as the difficulty to correlate the changes in microflora with a beneficial physiological outcome, can be stated as the main reasons for most of the negative opinions emitted. In the case of phytochemicals, the characterization is also a main reason of rejection, together with the quality of the studies presented and the relevance of biomarkers used to sustain the effect.

Other ingredients show a more equilibrated balance between positive and negative opinions. With reference to fatty acids, positive opinions, for example, in the case of some omega-3 fatty acids like docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA), or linolenic acid and their role in maintenance of triglycerides levels, and for long-chain omega-3 fatty acids maintenance and development of vision and brain function have been published. In contrast, the evidence for conjugated linolenic acids or gamma-linolenic acids has been considered unsatisfactory. Concerning fibers, the importance of distinguishing the effects depending on the concrete fiber has been established. For example, the maintenance of normal blood cholesterol levels is well accepted for beta-glucans, glucomannans, or guar gum, but not for acacia gum or isomalto-oligosaccharides. The role of soluble and insoluble fibers is well known to be different, and in consequence, concrete claims related to non-well characterized fibers usually lack enough scientific evidence. For example, reduction on many claims for various foods related to glycaemic index control has been dismissed because of an inadequate definition of the type or carbohydrates.

It is out of the scope of this chapter to make an exhaustive analysis of the scientific gaps that have been found by the EFSA panel. However, they provide

Fig. 80.4 Percentage of positive and negative opinion for different families of ingredients published by EFSA (Source: EFSA Journal, 2008–July 2012)



valuable lessons for the future development of future functional foods, and will undeniably have an impact on the market as well as on the approach to scientific evidence substantiation studies. In consequence, we will analyze some of the key aspects, focused on the families of plant extracts and phytochemicals, that scientists must take into account in order to assist in these developments.

3.2 EFSA Opinions on Phytochemicals and Plant Extracts

In the case of plant extracts and bioactive compounds deriving from them, the levels of success throughout the process of evaluation of health claims by EFSA have been modest at the best. Concerning phytochemicals, between 2008 and July 2012, very few compounds have obtained a positive opinion:

- Caffeine (from guarana, tea, chocolate, coffee, or as a pure form) and increased attention/alertness, reduction in the perceived effort, and increase in endurance capacity and physical performance during short-term high-intensity exercise.
- Polyphenols in olive and protection of LDL particles from oxidative damage.
- Monacolin K from red yeast rice and maintenance of normal LDL-cholesterol concentrations.
- Beta-carotene and maintenance of the normal function of the immune system.
- Cocoa flavanols and maintenance of normal endothelium-dependent vasodilation.

Other popular compounds such as lycopene, lutein, resveratrol, quercetin, catechins from tea, grapes, or cranberries, or soy isoflavones have not obtained a favorable opinion, except in cases where they were actually associated with other compounds that had already proven to have an effect like vitamin E or C.

Concerning plant extracts, many of them have been kept on hold by the European legislation. Prior to this reschedule, all those evaluated by the provisions of Article 13.1 obtained a negative opinion. But at the same time, stories of success have also arisen. It is an illustrative example the case of the tomato WSC extract, whose effect over platelets aggregation was well established by pertinent and company-proprietary clinical studies and was worth of being the first accepted ingredient via the Article 13.5.

This example illustrates how, although there have been more deceptions than triumphs in the evaluation of scientific evidence provided by plant extracts and phytochemicals, these results, rather than being seen as a disappointment, can be considered an excellent opportunity for manufacturers to invest in scientific research in order to complete standardized quality studies that clearly establish a cause-relation effect between the ingredient intake and the claimed effect, and thus obtaining specific claims according to the article 13.5 of the 1924/2006 Regulation.

3.3 Lessons Learned: Key Scientific Aspects to be Controlled for Obtaining a Health Claim

Following the lessons learned by the EFSA evaluation of health claims, 3 different aspects have to be assessed for obtaining a health claim:

1. Characterization of the ingredients
2. Relevance of the sustained claimed effect
3. Scientific evidence provided by efficacy studies

3.3.1 Characterization

Although many of the functional ingredients (vitamins, minerals, omega-3 fatty acids, etc.) possess reliable methodologies of quantification, this aspect is sometimes incomplete for plant extracts. In some cases, there was no reference to the content of bioactive compounds, the part of the plant used for the preparation, no indication of diary doses, or the extracts were used as multibotanical combinations without specification of the other components.

One of the main reasons for this lack of concretion is the complexity of plant matrices, whose diversified secondary metabolism includes a vast number of different compounds with close structures that can be hard to identify. Some of these families with a well-documented bibliography related to health effects comprise alkaloids, phenolic compounds (including phenolic acids, stilbenes like resveratrol, or flavonoids such as anthocyanins, procyanidins, or isoflavones), terpenoids, carotenoids, sulfur compounds (such as glucosinolates and isothiocyanates), etc. Their presence and amount in the plant source depend on multiple factors including variety, organ of the plant, soil, sun exposure, climate, or even ways of cultivation.

There are several fast tests that estimate the content of these compounds as a whole by spectrophotometric methodologies. However, it is well stated that many of these compounds interact with the metabolic pathways and exert their effect on a structure-dependent manner. So, for understanding the mechanism of action of an extract, and more important, to obtain standardized extracts on the bioactive principles, the development of validated methodologies of identification, analysis, and quantification of individual components should be mandatory.

3.3.2 Relevance of the Claimed Effect

Another aspect that must not be overlooked is the nature of the intended claim. The use of clinical claims should be avoided (these could fall under the scope of the Directive 2004/24/EC for traditional herbal medicinal products, but not for health claims on foods). Claims too vague and unspecific also fall out of the consideration of the Regulation. It would be the case of "energy and vitality," "tonic," or "detoxification," often used in plant extracts submissions.

Finally, it has to be assessed that the claimed effect has significance to human health. In this aspect, it is worthy to make a detailed analysis of the claims related to antioxidants.

"Antioxidant" Claims

More than half of the claimed effects for phytochemicals and plant extracts are related to their protective effect as antioxidants, and many products include this term on their presentations for marketing purposes.

In fact, a first discussion should contemplate the adequateness of the use of the term "antioxidants" as a nutrition claim. There are main differences between UE and US legislations.

In the USA, it has been finally included in the US Food Labeling Part of the Code of Regulations, § 101.54 (f), which states that "a nutrient content claim that characterizes the level of antioxidant nutrients present in a food may be used on the label or in the labeling of that food when: An RDI has been established for each of the nutrients; The nutrients that are the subject of the claim have recognized antioxidant activity; that is, when there exists scientific evidence that, following absorption from the gastrointestinal tract, the substance participates in physiological, biochemical, or cellular processes that inactivate free radicals or prevent free radical-initiated chemical reactions; The level of each nutrient that is the subject of the claim is sufficient to qualify for the claim The names of the nutrients that are the subject of the claim are included as part of the claim (e.g., – high in antioxidant vitamins C and E||)."

In contraposition, the term "antioxidants" as a nutrition claim has not been included in the corresponding Annex for Nutrition Claims of the UE 1924/2006 Regulation or its amendments. In consequence, for submitting an antioxidant claim, it should be submitted as a health claim, and thus, the significance of the effect for human health has to be considered. And, in this case, the terminology used is of importance.

- "Antioxidant activity, antioxidant capacity, antioxidant properties": These claims would refer to the capacity of food/constituents to scavenge free radicals and/or to their reducing capacity, normally in in vitro models. Since there is no evidence that having antioxidant activity/content and/or antioxidant properties is a beneficial physiological effect on human health (factors such as bioavailability would affect the effects in human), it cannot be considered an acceptable claim [63].
- "Protection of DNA, proteins, and lipids from oxidative damage." This wording reflects correctly and effect that is significant for human health, and so it is acceptable.

3.3.3 Providing the Evidence from Science

The important objective for the development of health claims is to ensure that claims for food components and nutraceuticals are properly justified and they are scientifically substantiated [64]. The evidence provided has to be sufficient to establish a cause and effect relationship between the consumption of the ingredient and the claimed effect. For phytochemicals and plant extracts, it is often not the case. One of the main problems is that in many cases, only in vitro or animal studies have been conducted to sustain the evidence of the claim, or the human data consist of epidemiological studies. Information related to the pharmacopeia alone, often used for the plant extracts submissions, is also insufficient.

Substantiation of a claim should be based on human data, primarily from well-designed intervention studies considering target population, appropriate controls, adequate duration of exposure, and follow-up to demonstrate the intended effect [17]. Randomized clinical trials are the standard trials for providing evidence.

The design and quality of the human studies conducted is a key point to obtain a positive opinion about the scientific substantiation of the effect. Common mistakes include an inadequate choice of outcomes measured to assess the effect or the use of nonvalidated biomarkers, recruiting individuals not representative of the target population, or conducting studies with products that differ from the ingredient object of the claim.

The major factors involved in the design, conduct, and reporting of human studies can be adapted from the Consolidated Standards of Reporting Trials (CONSORT) checklist for medical trials [65]. Recently, the ILSI has published their own guidelines for the design, conduct, and reporting of human intervention studies to evaluate the health benefits of foods [66].

4 The Impact of New Methodologies for the Assessment of Functional Foods

4.1 Hyphenated Methods for the Characterization of Ingredients

The role of advances in chromatographic techniques has been a step point in the development of phytochemistry [67]. Because of the complexity of crude herbal extracts, various online hyphenated techniques have been developed for the analysis of the complex mixtures. These techniques include liquid chromatography (LC), mass spectrometry (MS), LC nuclear magnetic resonance (NMR), and LC-NMR-MS [68]. They facilitate the structure determination of unknown constituents in crude extracts. For example, they are of great applicability in the analysis of flavonoids and other phenolic compounds [69, 70].

Regarding MS instruments, time-of-flight detectors provide elevated mass resolution and accuracy over a broad mass of range, and thus help structural elucidation of nontargeted compounds based on accurate mass measurements and isotopic patterns. Triple quadrupole instruments are particularly well suited for targeted analysis and provide excellent sensitive and selectivity by performing tandem MS/MS analysis [71].

Despite the prominence attributed in scientific research to these hyphenated methodologies, other techniques are worth to be considered in the identification of bioactive vegetal compounds. High-performance thin-layer chromatography (HPTLC) is an evolution of thin layer chromatography (TLC) that remains the sole technique in which all the components of the sample are included in the chromatogram and presents the results as an image [67]. In HPLC, irreversible adsorption of some compounds can occur in the stationary phase, which in consequence cannot be eluted or detected, while TLC and HPTLC avoid this problem. Another technique avoiding this irreversible adsorption is countercurrent chromatography, which is an all-liquid separation technique which relies on the partition of a sample between two immiscible solvents [67], and can be used for the fractionation of crude plant extracts (in multigram quantities) or for final purification steps.

4.2 Bioinformatics

In several aspects, the approach toward finding a new functional ingredient is quite similar to the development of new pharmaceuticals. Bioinformatics tools have been largely employed as the first steps for drug design and recently, they are beginning to be used in connection with food or food-related components in several areas of food chemistry [72]. It is widely reported that natural compounds in the diet can improve health conditions and prevent disease by direct interaction with key proteins in metabolic pathways. For example, pure monacolin K (lovastatin) has been shown to be effective in reducing total cholesterol and LDL-cholesterol concentrations in individuals with hypercholesterolemia and is a well-known inhibitor of HMG-CoA reductase.

Studies of molecular similarity, pharmacophore modeling, molecular docking, and quantitative structure-analysis relationships (QSAR), based on in silico calculations, can be good screening methodologies for selecting those ingredients with the best predicted probability to interact with those targets and to predict their activity. At the same time, they can assist in formulating theoretical plausible mechanisms of action for the ingredients.

Molecular similarity searches are based on the hypothesis that similar molecules will have similar properties. In pharmacophore modeling, the chemical features and conformation of the modulating ligands in relation to the target proteins is extracted from 3D structures, and in consequence the response of multiple ingredients can be screened depending on their fitting with this model. Molecular docking actually calculates the best conformation of a molecule to fit into the target-binding pocket. In the case of QSAR models, a prediction of the activity of molecules according to 2D or 3D descriptors is obtained after establishing a model with experimentally measured outcomes.

4.3 Omics Data

One of the biggest challenges in nutrition is the establishment of adequate biomarkers that are able to predict health benefits, as well as early indicators for disease risk [73]. Nowadays, new -omics technologies are used in nutrition research, giving access to holistic discovery of efficacy biomarkers by transcriptomics, proteomics, and metabolomics data. They are considered by the ILSI as emerging technologies for efficacy demonstration [74].

Transcriptomic studies, which analyze gene expression, have improved the understanding of the complex interaction between genetic and environmental factors, such as lifestyle and nutrition. Transcriptomic technologies have arguably achieved the highest level of technical maturity of any of the functional genomics. Production of very high-quality, genome-wide expression profiling data by DNA microarrays is now a routine matter.

Proteomics is a central platform in elucidating the molecular events in nutrition: It can identify and quantify bioactive proteins and peptides and address questions of nutritional bioefficacy. The advances in methods of separation of peptides by microflow and nanoflows or chip detections, as well as mass spectrometry–rooted proteomic techniques like MALDI-TOF for protein identification and quantification have been pivotal in the application of these methodologies to understand nutritional effects of ingredients [75].

Metabolomics is the comprehensive analysis of metabolites and has gained a strong impact on nutritional research [76]. The great asset of these methodologies is the quantitative, noninvasive analysis of easily accessible human body fluids like urine, blood, saliva, and tears. The metabolome is complex, and thus requires multiple highly sophisticated techniques of separation and identification, such as NMR and MS. Additionally, the use of chemometrics for analyzing the complex data obtained is mandatory [73].

5 Conclusions

The functional foods and nutraceuticals market is one of the healthiest sectors in food industry, and is experiencing a continuous growth even in the context of an economic recession. However, to keep being successful, it is mandatory to assure the acceptance and awareness of consumers. The presence of many ingredients whose efficacy can be doubted can first mislead consumers and later compromise the credibility of the whole functional foods concept.

In consequence, manufacturers have to collaborate actively with academic researchers in order to provide the scientific evidence to substantiate health claims. This substantiation has to address three main points: the characterization of the ingredient, the relevance of the claimed effect, and the establishment of a cause and effect relationship between the ingredient’s intake and the claimed effect by efficacy studies on human intervention trials. These trials have to follow strict criteria of quality and design in order to be successful, especially by choosing adequate participants, outcomes, and biomarkers.

At the same time, scientific research is very important for the development of new functional foods. Discoveries provided by holistic techniques like -omics methodologies are allowing a better comprehension of the effects of nutrition and the interaction with the human metabolism. This will allow to define new biomarkers, especially early indicators of disease risk, that will contribute to designing new functional products.

Acknowledgments The authors wish to thank Alberto Pasamontes, Aleksandra Rózek, Maria Pilar Martí, Eva Borràs, and Montse Cabré for their assistance in the analysis of EFSA opinions on health claims.

Annexes

Table 80.3 Nutrient content claims approved In the USA

Nutrient content claims for protein, vitamins, minerals, dietary fiber, antioxidants in relation to the reference intake value or daily reference value	
"High," "Rich in," "Excellent source of"	20 % or more of the Reference Daily Intake (RDI) or the Daily Reference Value (DRV) per reference amount customarily consumed
"Good source," "Contains," "Provides"	10–19 % of the RDI or the DRV per reference amount customarily consumed
"High in fiber," "Good source of fiber," "more fiber"	If the food is not "low" in total fat, then the label shall disclose the level of total fat per labeled serving.
"More," "Fortified," "Enriched," "added," "Extra," "Plus" for Protein, Vitamin, Minerals, Dietary Fiber, Potassium" (Realtive claims)	10 % more of the RDI (Vitamins, minerals) of the RDI or the DRV per reference amount customarily consumed/per 100 g of food than an appropriate food
	10 % more of the DRV (Protein, Dietary fiber, potassium) of the RDI or the DRV per reference amount customarily consumed/per 100 g of food than an appropriate food
"High potency"	Individual vitamins or minerals at 100 % or more of the RDI per reference amount customarily consumed
High/Good source/More "Antioxidant"	An RDI has to be established for antioxidant nutrients
Nutrient content claims for "light" or "lite"	
"Light," "Lite" when the food derives 50 % or more of its calories from fat	Fat content reduced by 50 % or more per reference amount customarily consumed compared to an appropriate reference food
"Light," "Lite" when the food derives less than 50 % of its calories from fat	The number of calories is reduced by at least 33.33 %
	The fat content is reduced by 50 % or more per reference amount customarily consumed compared to an appropriate reference food
"Light," "Lite" for a product whose reference food contains 40 cal or less and 3 g fat or less per reference amount customarily consumed	Sodium content reduced by 50 % or more
"Light in sodium," "Lite in sodium" for a product whose reference food that contains more than 40 cal or more than 3 g fat or less per reference amount customarily consumed	Sodium content reduced by 50 % or more
"lightly salted"	50 % less sodium than which is normally added to the reference food, indicating when the product is "not low in sodium"
Nutrient content claims for the calorie content of foods	
"Calorie free," "Free of calories," "No calories," "Zero calories," "Without calories," "Trivial source of calories," "Negligible source of calories," "Dietarily insignificant source of calories"	The food contains less than 5 cal per reference amount customarily consumed and per labeled serving.

(*continued*)

Table 80.3 (continued)

"Low calorie," "Few calories," "Contains a small amount of calories," "Low source of calories," "Low in calories"	(a) The food has a reference amount customarily consumed greater than 30 gram (g) or greater than 2 tablespoons and does not provide more than 40 cal per reference amount customarily consumed (b) The food has a reference amount customarily consumed of 30 g or less or 2 tablespoons or less and does not provide more than 40 cal per reference amount customarily consumed and per 50 g (except for sugar substitutes) (c) For mails, if the product contains 120 cal or less per 100 g
"Reduced calorie," "Reduced in calories," "Calorie reduced," "Fewer calories," "Lower calorie," "Lower in calories"	The food contains at least 25 % fewer calories per reference amount customarily consumed than appropriate reference food
Sugar content claims	
"Sugar free," "free of sugar," "No sugar," "Zero sugar," "Without sugar," "Sugarless," "Trivial source of sugar," "Negligible source of sugar," "Dietarily insignificant source of sugar"	The food contains less than 0.5 of sugars per reference amount customarily consumed and per labeled serving
"No added sugar"; "Without added sugar"; "No sugar added"	No amounts of sugars, or any other ingredient that contains sugars that functionally substitute for added sugars is added during processing or packaging[. . .] The food that it resembles and for which it substitutes normally contents added sugars[. . .]
"Reduced sugar," "Reduced in sugar," "less sugar," "lower sugar," "Lower in sugar"	The food contains at least 25 % less sugar per reference amount customarily consumed than an appropriate reference food
Nutrient content claims for the sodium content of foods	
"Sodium free"; "Free of sodium," "Zero sodium," "Without sodium," "Trivial source of sodium," "Negligible source of sodium," "Dietary insignificant source of sodium"	The food contains less than 5 mg of sodium per reference amount customarily consumed and per labeled serving
"Very low sodium," "Very low in sodium"	The food has a reference amount customarily consumed greater than 30 g and contains 35 mg or less sodium per reference amount customarily consumed
"Low sodium," "Low in sodium," "little sodium," "contains a small amount of sodium," "low source of sodium"	The food has a reference amount customarily consumed greater than 30 g and contains 140 mg or less sodium per reference amount customarily consumed
"Reduced sodium," "Reduced in sodium," "Sodium reduced," "Less sodium," "Lower sodium," "Lower in sodium"	The food contains at least 25 % less sodium per reference amount customarily consumed than an appropriate reference food
"Salt free"	Only if the food is "sodium free"

(*continued*)

Table 80.3 (continued)

“Without added salt,” “Unsalted,” “No salt,” “No salt added”	No salt is added during processing; the food that it resembles and for which it substitutes is normally processed with salt; and if the food is not sodium free, it includes a statement “not a sodium free food” or “not for control of sodium in the diet”
Nutrient claims for fat, fatty acid, and cholesterol content of foods	
“Fat free,” “Free of fat,” “No fat,” “Zero fat,” “Without fat,” “negligible source of fat,” “Dietarily insignificant source of fat”	The food contains less than 0.5 g of fat per reference amount customarily consumed and per labeled serving or, in the case of a meal product or main dish product, less than 0.5 g of fat per labeled serving; and
	The food contains no added ingredient that is a fat or is generally understood by consumers to contain fat unless the listing of the ingredient in the ingredient statement is followed by an asterisk that refers to the statement below the list of ingredients, which states “adds a trivial amount of fat,” “adds a negligible amount of fat,” or “adds a dietarily insignificant amount of fat;” and
	If the food meets these conditions without the benefit of special processing, alteration, formulation, or reformulation to lower fat content, it is labeled to disclose that fat is not usually present in the food (e.g., “broccoli, a fat-free food”)
“Low fat”; “Low in fat,” “Contains a small amount of fat”; “Low source of fat”; “Little fat”	The food has a reference amount customarily consumed greater than 30 g or greater than 2 tablespoons and contains 3 g or less of fat per reference amount customarily consumed; or
	The food has a reference amount of 30 g or less or 2 tablespoons or less customarily consumed and contains 3 g or less of fat per reference amount customarily consumed and per 50 g of food (for dehydrated foods that must be reconstituted before typical consumption with water or a diluent containing an insignificant amount of all nutrients per reference amount customarily consumed, the per 50-g criterion refers to the “as prepared” form); and
	If the food meets these conditions without the benefit of special processing, alteration, formulation, or reformulation to lower fat content, it is labeled to clearly refer to all foods of its type and not merely to the particular brand to which the label attaches (e.g., “frozen perch, a low fat food”).
“Reduced fat”; “Reduced in fat”; “Fat reduced”; “Less fat”; “Lower fat”; “Lower in fat”	The food contains at least 25 % less fat per reference amount customarily consumed than an appropriate reference
“X % fat free”	The food meets the criteria for “low fat.” A “100 % fat free” claim may be made only on foods that meet the criteria for “fat free,” that contain less than 0.5 g of fat per 100 g, and that contain no added fat

(*continued*)

Table 80.3 (continued)

"Saturated fat free," "free of saturated fat," "no saturated fat," "zero saturated fat," "without saturated fat," "trivial source of saturated fat," "negligible source of saturated fat," or "dietarily insignificant source of saturated fat"	The food contains less than 0.5 g of saturated fat and less than 0.5 g trans fatty acid per reference amount customarily consumed and per labeled serving and
	The food contains no ingredient that is generally understood by consumers to contain saturated fat (unless the listing of the ingredient in the ingredient statement is followed by an asterisk that refers to the statement below the list of ingredients which states, "adds a trivial amount of saturated fat," "adds a negligible amount of saturated fat," or "adds a dietarily insignificant amount of saturated fat," and
	If the food meets these conditions without the benefit of special processing, alteration, formulation, or reformulation to lower saturated fat content, it is labeled to disclose that saturated fat is not usually present in the food.
"Low in saturated fat," "low saturated fat," "contains a small amount of saturated fat," "low source of saturated fat," or "a little saturated fat"	The food contains 1 g or less of saturated fatty acids per reference amount customarily consumed and not more than 15 % of calories from saturated fatty acids.
	If a food meets these conditions without benefit of special processing, alteration, formulation, or reformulation to lower saturated fat content, it is labeled to clearly refer to all foods of its type and not merely to the particular brand to which the label attaches (e.g., "raspberries, a low saturated fat food").
"Reduced saturated fat," "reduced in saturated fat," "saturated fat reduced," "less saturated fat," "lower saturated fat," or "lower in saturated fat"	The food contains at least 25 % less saturated fat per amount customarily consumed than an appropriate reference food
"Cholesterol free," "free of cholesterol," "zero cholesterol," "without cholesterol," "no cholesterol," "trivial source of cholesterol," "negligible source of cholesterol," or "dietarily insignificant source of cholesterol"	The food contains less than 2 mg of cholesterol per reference amount customarily consumed and per labeling serving and
	The food contains no ingredient that is generally understood by consumers to contain cholesterol (unless the listing of the ingredient in the ingredient statement is followed by an asterisk that refers to the statement below the list of ingredients, which states "adds a trivial amount of cholesterol," "adds a negligible amount of cholesterol," or "adds a dietarily insignificant amount of cholesterol") and
	The food contains 2 g or less of saturated fatty acids per reference amount customarily consumed
	If the food contains less than 2 mg of cholesterol per reference amount customarily consumed without the benefit of special processing, alteration, formulation, or reformulation to lower cholesterol content, it is labeled to disclose that cholesterol is not usually present in the food (e.g., "applesauce, a cholesterol-free food").

(*continued*)

Table 80.3 (continued)

"Low in cholesterol," "low cholesterol," "contains a small amount of cholesterol," "low source of cholesterol," or "little cholesterol"	The food contains 20 mg or less of cholesterol per reference amount customarily consumed
	The food contains 2 g or less of saturated fatty acids per reference amount customarily consumed and
	If the food meets these conditions without the benefit of special processing, alteration, formulation, or reformulation to lower cholesterol content, it is labeled to clearly refer to all foods of that type and not merely to the particular brand to which the label attaches (e.g., "low fat cottage cheese, a low cholesterol food").
"Reduced cholesterol," "reduced in cholesterol," "cholesterol reduced," "less cholesterol," "lower cholesterol," or "lower in cholesterol"	The food has been specifically formulated, altered, or processed to reduce its cholesterol by 25 % or more from the reference food it resembles and
	The food contains 2 g or less of saturated fatty acids per reference amount customarily consumed
"Lean" and extra lean claims	
"Lean"	The food is a seafood or game meat product and as packaged contains less than 10 g total fat, 4.5 g or less saturated fat, and less than 95 mg cholesterol per reference amount customarily consumed and per 100 g
"Extra lean"	The food is a discrete seafood or game meat product and as packaged contains less than 5 g total fat, less than 2 g saturated fat, and less than 95 mg cholesterol per reference amount customarily consumed and per 100 g

Table 80.4 Nutrition claims approved in UE

Nutrition claims for energy	
"Low Energy"	The product does not contain more than 40 kcal (170 kJ)/100 g for solids or more than 20 kcal (80 kJ)/100 ml for liquids. For table-top sweeteners the limit of 4 kcal (17 kJ)/portion, with equivalent sweetening properties to 6 g of sucrose (approximately 1 teaspoon of sucrose), applies.
"Energy-reduced"	The energy value is reduced by at least 30 %, with an indication of the characteristic(s) which make(s) the food reduced in its total energy value
"Energy-free"	The product does not contain more than 4 kcal (17 kJ)/100 ml. For table-top sweeteners the limit of 0,4 kcal (1,7 kJ)/portion, with equivalent sweetening properties to 6 g of sucrose (approximately 1 teaspoon of sucrose), applies.
Nutrition claims for fat	
Low fat:	The product contains no more than 3 g of fat per 100 g for solids or 1.5 g of fat per 100 ml for liquids (1.8 g of fat per 100 ml for semi-skimmed milk).
Fat-free:	The product contains no more than 0.5 g of fat per 100 g or 100 ml. However, claims expressed as "X % fat-free" shall be prohibited.
Nutrition claims for saturated fat	
Low saturated-fat:	The sum of saturated fatty acids and trans-fatty acids in the product does not exceed 1.5 g per 100 g for solids or 0.75 g/100 ml for liquids and in either case the sum of saturated fatty acids and trans-fatty acids must not provide more than 10 % of energy.

(*continued*)

Table 80.4 (continued)

Saturated fat-free:	The sum of saturated fat and trans-fatty acids does not exceed 0.1 g of saturated fat per 100 g or 100 ml.
Nutrition claims for omega-3 fatty acids	
Source of:	The product contains at least 0.3 g alpha-linolenic acid per 100 g and per 100 kcal, or at least 40 mg of the sum of eicosapentaenoic acid and docosahexaenoic acid per 100 g and per 100 kcal.
High:	The product contains at least 0.6 g alpha-linolenic acid per 100 g and per 100 kcal, or at least 80 mg of the sum of eicosapentaenoic acid and docosahexaenoic acid per 100 g and per 100 kcal.
Nutrition claims for monounsaturated fat	
High:	At least 45 % of the fatty acids present in the product derive from monounsaturated fat under the condition that monounsaturated fat provides more than 20 % of energy of the product.
Nutrition claims for polyunsaturated fat	
High:	At least 45 % of the fatty acids present in the product derive from polyunsaturated fat under the condition that polyunsaturated fat provides more than 20 % of energy of the product.
Nutrition claims for unsaturated fat	
High:	At least 70 % of the fatty acids present in the product derive from unsaturated fat under the condition that unsaturated fat provides more than 20 % of energy of the product
Nutrition claims for sugar	
Low Sugar:	The product contains no more than 5 g of sugars per 100 g for solids or 2.5 g of sugars per 100 ml for liquids.
Sugars-free:	The product contains no more than 0.5 g of sugars per 100 g or 100 ml.
With no added sugar	The product does not contain any added mono- or disaccharides or any other food used for its sweetening properties. If sugars are naturally present in the food, the following indication should also appear on the label: "CONTAINS NATURALLY OCCURRING SUGARS."
Nutrition claims for sodium/salt	
Low sodium/salt:	The product contains no more than 0.12 g of sodium, or the equivalent value for salt, per 100 g or per 100 ml. For waters, other than natural mineral waters falling within the scope of Directive 80/777/EEC, this value should not exceed 2 mg of sodium per 100 ml.
Very low sodium/salt:	The product contains no more than 0.04 g of sodium, or the equivalent value for salt, per 100 g or per 100 ml. This claim shall not be used for natural mineral waters and other waters.
Sodium-free or salt-free	The product contains no more than 0.005 g of sodium, or the equivalent value for salt, per 100 g.
Nutrition claims for fiber	
Source of fiber:	The product contains at least 3 g of fiber per 100 g or at least 1.5 g of fiber per 100 kcal.
High fiber:	The product contains at least 6 g of fiber per 100 g or at least 3 g of fiber per 100 kcal.
Nutrition claims for protein	
Source of protein:	At least 12 % of the energy value of the food is provided by protein.
High protein:	At least 20 % of the energy value of the food is provided by protein.

(*continued*)

Table 80.4 (continued)

Nutrition claims for vitamins/minerals	
Source of:	The product contains at least a significant amount as defined in the Annex to Directive 90/496/EEC or an amount provided for by derogations granted according to Article 6 of Regulation (EC) No 1925/2006 of the European Parliament and of the Council of 20 December 2006 on the addition of vitamins and minerals and of certain other substances to foods
High:	The product contains at least twice the value of "source of [NAME OF VITAMIN/S] and/or [NAME OF MINERAL/S]."
Nutrition claims for nutrients or other substances	
Contains:	The product complies with all the applicable provisions of this Regulation, and in particular Article 5. For vitamins and minerals, the conditions of the claim "source of" shall apply.
Increased:	The product meets the conditions for the claim "source of" and the increase in content is at least 30 % compared to a similar product.
Reduced:	The reduction in content is at least 30 % compared to a similar product, except for micronutrients, where a 10 % difference in the reference values as set in Directive 90/496/EEC shall be acceptable, and for sodium, or the equivalent value for salt, where a 25 % difference shall be acceptable.
Nutrition claims for omega-3 fatty acids	
Source of:	The product contains at least 0.3 g alpha-linolenic acid per 100 g and per 100 kcal, or at least 40 mg of the sum of eicosapentaenoic acid and docosahexaenoic acid per 100 g and per 100 kcal.
High:	The product contains at least 0.6 g alpha-linolenic acid per 100 g and per 100 kcal, or at least 80 mg of the sum of eicosapentaenoic acid and docosahexaenoic acid per 100 g and per 100 kcal.
Nutrition claims for monounsaturated fat	
High:	At least 45 % of the fatty acids present in the product derive from monounsaturated fat under the condition that monounsaturated fat provides more than 20 % of energy of the product.
Nutrition claims for polyunsaturated fat	
High:	At least 45 % of the fatty acids present in the product derive from polyunsaturated fat under the condition that polyunsaturated fat provides more than 20 % of energy of the product.
Nutrition claims for unsaturated fat	
High:	At least 70 % of the fatty acids present in the product derive from unsaturated fat under the condition that unsaturated fat provides more than 20 % of energy of the product.
Other Nutrition claims	
Light/lite	Shall follow the same conditions as those set for the term 'reduced'; the claim shall also be accompanied by an indication of the characteristic(s) which make(s) the food "light" or "lite."
Naturally/Natural	Where a food naturally meets the condition(s) for the use of a nutritional claim, the term "naturally/natural" may be used as a prefix to the claim.

Abstract

Phenolic compounds are a diverse group of phytochemicals classified into flavonoids, phenolic acids, lignans, coumarins, phenols, phenylpropanoids, quinines, stilbenoids, and xanthones. Flavonoids, which make up the largest cadre among phenolics, are further subdivided into anthocyanins, flavanols including proanthocyanidins, flavonols, dihydroflavonols, flavones, isoflavonoids, flavonones, chalcones, and

dihydrochalcones. Phenolic acids are further subclassified as hydroxybenzoic acids, hydroxycinnamic acids, hydroxyphenylacetic acids, and hydroxyphenylpropanoic acids. Other phenolics include alkylmethoxyphenols, alkylphenols, curcuminoids, furacoumarins, hydroxybenzaldehydes, hydroxybenzoketones, hydroxycinnamaldehydes, hydroxycoumarins, hydroxyphenylpropenes, methoxyphenols, naphthoquinones, phenolic terpenes, and tyrosols. Food databases specifically on phenolic compounds include Phenol-Explorer, USDA-Iowa State University database for isoflavones, USDA database for flavonoids, and USDA database for proanthocyanidins. The phenolic content in foods can be obtained from these accessible databases. The occurrence of phenolics as well as concentration in foods is summarized based on the current literature. Cloves, cocoa powder, dried peppermint, star anise, dried Mexican oregano, celery seed, black chokecherry, dark chocolate, flaxseed meal, and black elderberry are among the top foods abundant in phenolics.

Keywords

Food sources • phenolic compounds • phenolic acids • flavonoids • total phenolic content

Abbreviations

FW	Fresh weight
SIF	Sum of individual flavonoids
SIPA	Sum of individual phenolic acids
TAC	Total anthocyanin content
TPC	Total phenolic content

1 Introduction

Phenolic compounds widely existing in plants and plant-derived foods have been shown to impact human health [1, 2]. Several hundreds of molecules having a polyphenol structure have been found in edible plants [3]. Their abundant presence in our diets coupled with the recognition of their antioxidant properties and purported role in the prevention of various diseases associated with oxidative stress [3] mandates an in-depth understanding of phenolic compounds as constituents of edible plants and foods for researchers and consumers. In addition to numerous literature sources on phenolics, systematic databases such as Phenol-Explorer database on polyphenol content of foods [4], USDA database for flavonoids [5], USDA-Iowa State University database for isoflavones [6], and USDA database for proanthocyanidins [7] exist. The databases are accessible to researchers and consumers providing useful information. Phenolic compounds which are present in food sources are reviewed primarily on the basis of the Phenol-Explorer database. The total phenolic content (TPC, also total polyphenol content), obtained using the Folin assay, is an indirect indication of antioxidant capacity since the method provides a crude estimation of the total antioxidant content [8]. A high TPC is associated with a high antioxidant capacity. Data on TPC, phenolic acids, flavonoids, other phenolic compounds, and total anthocyanin content (TAC) were summarized from the Phenol-Explorer database [4] unless explicitly indicated otherwise. Food sources have been classified into nine groups including nonalcoholic beverages, alcoholic beverages, fruits and fruit products, vegetables, cereals and cereal products, seeds, cocoa, seasonings, and oils for comparison of the levels of their phenolic compounds [9]. All content values are expressed as mg per 100 g fresh weight (FW) for solid foods and as mg per 100 ml for liquid foods according to Phenol-Explorer database [4] unless indicated otherwise. The ten foods most abundant in polyphenols among 452 sources examined were cloves (15,188.0 mg 100 g^{-1}), dried peppermint (11,960.0 mg 100 g^{-1}), star anise (5,460.0 mg 100 g^{-1}), cocoa powder (3,448.0 mg 100 g^{-1}), Mexican oregano, dried (2,319.0 mg 100 g^{-1}), celery seed (2,094.0 mg 100 g^{-1}), black chokeberry (1,756.0 mg 100 g^{-1}), dark chocolate (1,664.0 mg 100 g^{-1}), flaxseed meal (1,528.0 mg 100 g^{-1}), and black elderberry (1,359.0 mg 100 g^{-1}) [8] according to their polyphenol content.

2 Food Sources

2.1 Alcoholic Beverages

Phenolics found in alcoholic beverages include 33 phenolic acids, 75 flavonoids, 7 lignins, 13 stilbenes, and 19 other polyphenols [9]. The major phenolics in alcoholic beverages are summarized in Table 81.1.

2.1.1 TPC

It is evident that TPC has a highly positive relationship with antioxidant capacity [10]; therefore, the antioxidant potential of food sources can be evaluated according to their TPC. Table 81.1 shows TPC in decreasing order according to the maximum values reported in alcoholic beverages [4]. TPC (mg 100 ml^{-1}) in alcoholic beverage ranged from 33 to 70 for ale beer, 7–60 for dark beer, 4–49 for regular beer, 5–23 for alcohol-free beer, 41–42 for antho-beer [11], 13–130 for cider, 24–388 for walnut liquor, 41–83 for black currant wine, 74–418 for red grape wine, 34–130 for rosé grape wine, 10–85 for white grape wine, and 18–20 for champagne. Values of 93 for anthograin liqueur, 7 for Canadian whisky, and 6 for special old rye whisky were recently reported for TPC [12].

2.1.2 Phenolic Acids

The existence of different molecular structures of phenolic acids results in differences in antioxidant activity, for example, protocatechuic acid, chlorogenic acid, caffeic acid, *p*-hydroxybenzoic acid, gentisic acid, ferulic acid, vanillic acid, syringic acid, and *p*-coumaric acid [13]. Such rankings make the information on the composition of phenolic acids in foods imperative. Phenolic acids are divided into hydroxybenzoic, hydroxybenzoic, hydroxycinnamic, hydroxyphenylacetic, and hydroxyphenylpropanoic acids. Phenolic acids exist as three forms in food sources, namely, free phenolic acids, soluble phenolic esters, and insoluble-bound phenolic acids [14]. Since bound phenolic acids are the major forms present in various foods, individual phenolic acids can be released from the bound forms through hydrolysis and then quantified. The sum of

Table 81.1 TPC range (mg/100 ml) and major phenolics in alcoholic beverages

Name	TPC	Major phenolics
Wine [red]	74–418	Malvidin *3-O*-glucoside, (+)-catechin
Walnut, liquor	24–388	Gallic acid, (+)-catechin
Wine [rosé]	34–130	*3*-Caffeoylquinic acid, caffeic acid
Cider	13–130	(−)-Epicatechin
Wine [white]	10–85	(−)-Epicatechin, (+)-catechin
Black currant, wine	41–83	Myricetin, quercetin
Beer [ale]	33–70	(+)-Catechin, ferulic acid
Beer [dark]	7–60	Vanillic acid, isoxanthohumol
Beer [regular]	4–49	*4*-Hydroxybenzoic acid, ferulic acid
Beer [alcohol-free]	5–23	Protocatechuic acid, (+)-catechin
Champagne	18–20	Caffeoyl tartaric acid, *2-S*-glutathionyl caftaric acid

individual phenolic acids (SIPA) indicates the level of phenolic acids in foods given their significant role as contributors to total antioxidant activity of dietary food sources.

Alcoholic beverages with a high maximum SIPA (mg 100 ml^{-1}) were red grape wine (3.0–60.0), walnut liquor (15.1–28.4), white grape wine (2.3–9.0), sherry (6.0–7.2), rosé grape wine (6.0–7.0), and regular beer (0.3–6.6). Others had maximum SIPA of less than 5.0.

The major phenolic acids (mg 100 ml^{-1}) in the above alcoholic beverages with high maximum SIPA (>10 mg 100 ml^{-1}) were identified as caffeoyl tartaric (0.1–17.9) and gallic (0–12.6) acids in red grape wine and gallic (11.2–21.7) and syringic (2.4–3.6) acids in walnut liquor. The SIPA were obtained without performing a hydrolysis step.

After hydrolysis, SIPA of alcoholic beverages were 0.8–11.0 for red grape wine, 4.0 for rosé grape wine, and 1.3–3.8 for regular beer. The major phenolic acids present were *p*-coumaric acid (0.8–11.0) in red grape wine, caffeic (1.8) and *p*-coumaric (0.8) acids in rosé grape wine, and ferulic (0.4–1.7) and gallic (0.3–0.9) acids in regular beer.

2.1.3 Flavonoids

Flavonoids are also important antioxidants in many food sources. Flavonoids are divided into anthocyanins, flavanols/flavans, flavanones, flavones, flavonols, and isoflavones/isoflavonoids [15]. The sum of individual flavonoids (SIF) can be a simple indicator of flavonoid levels in dietary food sources which provides useful information for their potential benefits in human health.

Alcoholic beverages with high maximum SIF (mg 100 ml^{-1}) were red grape wine (21.0–211.9), white grape wine (0.7–15.5), and sherry (8.2) without hydrolysis being conducted on the samples. The maximum SIF was less than 4.0 for the other alcoholic beverages.

The major flavonoids (mg 100 ml^{-1}) in the above alcoholic beverages with a high maximum SIF (>10 mg 100 ml^{-1}) were (+)-catechin (1.4–39.0), malvidin *3-O*-glucoside (0–38.2), (−)-epicatechin (0–16.5), procyanidin dimer B1 (2.2–14.0), procyanidin dimer B3 (0–12.0), procyanidin dimer B4 (0.1–11.3), malvidin

3-*O*-(*6*-acetyl)-glucoside (0.5–11.3), and procyanidin dimer B2 (0.4–9.0) in red grape wine and (−)-epicatechin (0–6.0) and (+)-catechin (0–4.6) in white grape wine.

After hydrolysis, SIF of alcoholic beverages were 0–7.8 for red grape wine, 1.0–3.7 for black currant wine, and 1.5 for black crowberry wine. The major flavonoids identified in the beverages were quercetin (0–3.2), myricetin (0–2.0), and isorhamnetin (0–1.9) in red grape wine; myricetin (0.7–2.3) and quercetin (0.3–1.2) in black currant wine; and quercetin (0.7) and myricetin (0.7) in black crowberry wine.

2.1.4 Other Phenolic Compounds

Other phenolic compounds included proanthocyanins (02–10-mers and >10 polymers), lignins, and stilbenes. The other phenolic compounds (mg 100 ml^{-1}) with high maximum values in alcoholic beverages were tyrosol (0.6–4.5), syringaldehyde (0–4.5), resveratrol *3*-*O*-glucoside (0–4.4), >10 polymers (11.0), 04–06-mers (6.7), 07–10-mers (5.0), and 02-mers (4.0) in red grape wine, resveratrol (1.4–4.4) in red muscadine grape wine, and tyrosol (5.7) in sherry.

2.2 Cereals and Cereal Products

Phenolics reported in cereals and cereal products include 29 phenolic acids, 33 flavonoids, 6 lignans, and 2 other polyphenols [9]. The major phenolics in cereals and cereal products are summarized in Table 81.2.

2.2.1 TPC

Table 81.2 shows TPC in decreasing order according to the maximum values reported in cereals and cereal products [4]. Cereal products had TPC (mg 100 g^{-1} FW) of 131–315 for whole grain flour bread, 111 for purple wheat flour bread [16], 52 for wheat white flour bread [16], 26–156 for purple wheat bran muffin [17], 35–114 for wheat bran muffin [17], 17–277 for infant cereals [18], 77–153 for uncooked whole wheat pasta [19], 72–93 for uncooked regular pasta [19], and 117–271 for whole meal oat breakfast cereals.

TPC of cereals ranged from 2 to 185 for barley whole grain flour, 8–3,300 for buckwheat whole grain flour, 127–783 for thermally treated buckwheat groat, 314–1,096 for common wheat germ, 1–344 for common wheat whole grain flour, 0.1–81 for common wheat refined flour, 171–199 for hard wheat whole grain flour, 25–686 for maize whole grain, 2–390 for oat whole grain flour, 0.8–106 for rye whole grain flour, and 345 (17.8 μmol/g in pearl, sum of soluble, and bound) to 2,214 (114.0 μmol/g in kodo, sum of soluble, and bound) for millet whole grains [20]. Values of 158 for buckwheat refined flour, 56 for hard wheat refined flour, 102 for maize refined flour, 26 for rolled oat, 95 for rice whole grain, 45 for rye refined flour, and 413 for sorghum whole grain were also reported for TPC.

2.2.2 Phenolic Acids

Cereals and cereal products with high maximum SIPA (mg 100 g^{-1} FW) were hard wheat whole grain flour (72.2), oat whole grain flour (9.5–15.1), hard wheat refined flour (14.1), common wheat refined flour (0.1–9.8), oat refined flour (7.5–9.2),

Table 81.2 TPC range (mg/100 g FW) and major phenolics in cereals and cereal products

Name	TPC	Major phenolics
Buckwheat, whole grain flour	8–3,300	Quercetin *3-O*-rutinoside
Common wheat, germ	314–1,096	Ferulic acid, sinapic acid
Buckwheat, thermally treated groats	127–783	Quercetin *3-O*-rutinoside
Maize, whole grain	25–686	Ferulic acid, *o*-coumaric acid
Sorghum, whole grain	413	Polymers (>10 mers), 07–10 mers, 04–06 mers
Oat, whole grain flour	1–390	Ferulic acid, avenanthramide 2c
Common wheat, whole grain flour	1–344	Apigenin galactoside-arabinoside, ferulic acid
Bread, whole grain flour	131–315	*5*-Heneicosylresorcinol, *5*-nonadecylresorcinol
Breakfast cereals, oat, whole meal	117–271	
Hard wheat, whole grain flour	171–199	Ferulic acid, *5*-heneicosylresorcinol
Barley, whole grain flour	2–185	Prodelphinidin dimer B3, procyanidin dimer B3
Buckwheat, refined flour	158	Quercetin *3-O*-rutinoside, *p*-coumaric acid
Rye, whole grain flour	1–106	Ferulic acid, *5*-heptadecylresorcinol
Maize, refined flour	102	Ferulic acid, *5-8′*-dehydrodiferulic acid
Rice, whole grain	95	Ferulic acid
Common wheat, refined flour	50–81	Apigenin galactoside-arabinoside, ferulic acid
Hard wheat, refined flour	56	Ferulic acid
Rye, refined flour	45	Ferulic acid, *5*-nonadecylresorcinol
Oat, rolled	26	Avenanthramide 2c, avenanthramide 2f

sorghum whole grain (0.7–7.9), and rye whole grain flour bread (5.2). Other cereal-based sources had maximum SIPA of less than 3.0. SIPA in whole grain flour is higher than that of the derived refined flour since the bran removed during the milling process contains higher total phenolics than the refined flour [21].

The major phenolic acids (mg 100 g^{-1} FW) in the above cereals and cereal products with high maximum SIPA (>10 mg 100 g^{-1} FW) were ferulic acid in hard wheat whole grain flour (72.2); oat whole grain flour (35.8); hard wheat refined flour (14.1); and avenanthramide 2c (3.8–3.9), avenanthramide 2p (1.4–3.1), avenanthramide 2f (2.6–2.7), and avenanthramide K (1.2–2.7) in oat whole grain flour without conducting a hydrolysis step.

After hydrolysis, cereals and cereal products with high maximum SIPA were maize whole grain (111.0–330.0), maize refined flour (88.6–218.8), hard wheat semolina (1.4–176.6), common wheat germ (164.8–168.9), rye whole grain flour (61.9–167.2), rye whole grain flour bread (120.7), hard wheat whole grain flour (56.7–74.6), common wheat whole grain flour (64.7), oat whole grain flour (35.8), rye refined flour (26.0–35.1), and rice whole grain (29.8). The maximum SIPA was less than 8.0 for other cereal sources. Phenolic acids, which mainly exist as bound forms in cereals such as 80–90 % bound phenolic acids in brown rice [22], need to be released from their bound states through hydrolysis. The SIPA is significantly higher after subjecting cereals to hydrolysis than values obtained without inclusion of a hydrolysis step.

After hydrolysis, the major phenolic acids in cereals and cereal products with high maximum SIPA (>100 mg 100 g^{-1} FW) were identified as ferulic (90.6–255.3), *o*-coumaric (10.9–49.5), and *p*-coumaric (8.4–18.1) acids in maize whole grain; ferulic (62.2–184.9) and *5-8′*-dehydrodiferulic acids (8.3) in maize refined flour; ferulic (0.9–120.0), *8-O-4′*-dehydrodiferulic (0.1–20.8), and *5-8′*-benzofuran dehydrodiferulic (0.1–15.5) acids in hard wheat semolina; ferulic (123.5) and sinapic (27.1–29.6) acids in common wheat germ; ferulic (29.9–105.7), *8-O-4′*-dehydrodiferulic (11.5–18.0), and sinapic (1.6–13.8) acids in rye whole grain flour; and ferulic (109.9) and *p*-coumaric (3.2) acids in rye whole grain flour bread.

2.2.3 Flavonoids

The SIF (mg 100 g^{-1} FW) of cereals and cereal products were 51.5–108.4 for common wheat whole grain flour, 16.4–63.4 for buckwheat whole grain flour, 32.7–39.0 for barley whole grain flour, 13.2–26.3 for common wheat refined flour, 1.7–17.0 for buckwheat refined flour, and 4.0–13.4 for buckwheat thermally treated groats.

The major flavonoids (mg 100 g^{-1} FW) present in the above cereals and cereal products were apigenin arabinoside-glucoside (6.8–50.9) and apigenin galactoside-arabinoside (44.7–57.5) in common wheat whole grain flour; quercetin *3-O*-rutinoside (15.5–62.3) and apigenin *6-C*-glucoside (0.9) in buckwheat whole grain flour; prodelphinidin dimer B3 (22.9–23.4), procyanidin dimer B3 (8.8–14.2), and (+)-catechin (1.0–1.4) in barley whole grain flour; apigenin galactoside-arabinoside (7.2–16.3) and apigenin arabinoside-glucoside (6.0–10.0) in common wheat refined flour; quercetin *3-O*-rutinoside (1.7–16.8) in buckwheat refined flour; and quercetin *3-O*-rutinoside (3.8–13.0) in buckwheat thermally treated groats.

2.2.4 Other Phenolic Compounds

The other phenolic compounds in cereals and cereal products with high maximum values (mg 100 g^{-1} FW) were *5*-heneicosylresorcinol (92.8), *5*-heneicosenylresorcinol (81.5), and *5*-nonadecylresorcinol (43.1–53.5) in bran breakfast cereals; *5*-nonadecylresorcinol (0.4–33.4), *5*-heptadecylresorcinol (0.4–33.1), and *5*-heneicosylresorcinol (0.3–23.9) in rye whole grain flour; *5*-heneicosylresorcinol (9.6–32.6), *5*-nonadecylresorcinol (5.6–24.6), and *5*-heneicosenylresorcinol (9.9–23.7) in common wheat whole grain flour; *5*-nonadecylresorcinol (3.6–34.2), *5*-heneicosylresorcinol (1.9–24.2), and *5*-heptadecylresorcinol (1.3–22.2) in rye whole grain flour bread; and >10 polymers (1307.3–1767.0), 07–10 mers (150.0–325.0), and 04–06 mers (85.1–253) in sorghum whole grain.

2.3 Cocoa

Phenolics found in cocoa include 13 phenolic acids, 25 flavonoids, 2 stilbenes, and 5 other polyphenols [9]. The major phenolics in cocoa are summarized in Table 81.3.

2.3.1 TPC

Table 81.3 shows TPC in decreasing order according to the maximum values reported in cocoa [4]. TPC (mg 100 g^{-1} FW) ranged from 1,173 to 4,437 for dark chocolate, 325–2,439 for milk chocolate, and 1,005–1,204 for cocoa powder.

Table 81.3 TPC range (mg/100 g FW) and major phenolics in cocoa

Name	TPC	Major phenolics
Chocolate, dark	1,173–4,437	04–06-mers, 02-mers, 03-mers, (−)-Epicatechin, cinnamtannin A2, procyanidin dimer B2, (+)-catechin, procyanidin trimer C1
Chocolate, milk	325–2,439	Polymers (>10 mers), 04–06-mers, 07–10-mers, 02-mers, 03-mers, (−)-epicatechin, (+)-catechin
Cocoa, powder	1,005–1,204	Polymers (>10 mers), 04–06-mers, 07–10-mers, 03-mers, 02-mers, protocatechuic acid, (−)-epicatechin, procyanidin dimer B2, (+)-catechin, procyanidin dimer B1, cinnamtannin A2, caffeoyl aspartic acid, procyanidin trimer C1

2.3.2 Phenolic Acids

The SIPA (mg 100 g^{-1} FW) of cocoa powder and dark chocolate were 37.0 and 24.0, respectively. The major phenolic acids (mg 100 g^{-1} FW) were identified as caffeoyl aspartic acid (37.0) in cocoa powder and ferulic acid (24.0) in dark chocolate without performing any hydrolysis. After hydrolysis, SIPA of cocoa powder was 47.8 and its phenolic acid constituents comprised of protocatechuic (40.0), syringic (4.1), and vanillic (3.7) acids.

2.3.3 Flavonoids

The SIF (mg 100 g^{-1} FW) ranged from 256.0 to 1005.0 for cocoa powder, 135.5–392.0 for dark chocolate, and 15.2–36.0 for chocolate milk. The major flavonoids (mg 100 g^{-1} FW) were identified as (−)-epicatechin (63.0–330.0), procyanidin dimer B2 (13.0–262.0), (+)-catechin (61.0–202.0), procyanidin dimer B1 (112.0), cinnamtannin A2 (0–56.0), and procyanidin trimer C1 (5.0–36.0) in cocoa powder; (−)-epicatechin (32.7–125.0), cinnamtannin A2 (29.0–86.0), procyanidin dimer B2 (21.0–54.0), (+)-catechin (10.8–50.0), procyanidin trimer C1(13.0–44.0), and quercetin (25.0) in dark chocolate; and (−)-epicatechin (12.5–24.0) and (+)-catechin (2.7–12.0) in chocolate milk.

2.3.4 Other Phenolic Compounds

The other phenolic compounds with high maximum values (mg 100 g^{-1} FW) in cocoa were 04–06-mers (55.5–1605.0), 02-mers (31.2–1463.0), 03-mers (21.1–1170.0), >10 polymers (68.2–697.0), and 07–10-mers (38.5–295.0) in dark chocolate; >10 polymers (980.0–1685.0), 04–06-mers (736.0–1094.0), 07–10-mers (440.0–745.0), 03-mers (69.0–183.0), and 02-mers (70.0–178.0) in cocoa powder; and >10 polymers (32.8–114.0), 04–06-mers (38.0–68.0), and 07–10-mers (17.0–41.0) in chocolate milk.

2.4 Fruits and Fruit Products

Phenolics reported in fruits and fruit products include 47 phenolic acids, 112 flavonoids, 7 stilbenes, 6 lignans, and 1 other polyphenol [9]. The major phenolics in fruits and fruit products are summarized in Tables 81.4 and 81.5.

Table 81.4 TPC range (mg/100 g FW) and major phenolics in fruits and fruit products

Name	TPC	Major phenolics
Black chokeberry	690–2,556	Cyanidin *3-O*-galactoside, polymers (>10 mers)
Black elderberry	1,950	Cyanidin *3-O*-glucoside, cyanidin 3-O-sambubioside
Skunk currant	1,790	
Black currant	498–1,410	Delphinidin *3-O*-rutinoside, cyanidin *3-O*-rutinoside
Plum, fresh	88–1,400	*3*-Caffeoylquinic acid, cyanidin *3-O*-rutinoside
Black huckleberry	163–1,286	*5*-Caffeoylquinic acid, Quercetin
Plum, prune	1,195	*3*-Caffeoylquinic acid, *5*-caffeoylquinic acid
Evergreen huckleberry	283–1,169	*5*-Caffeoylquinic acid, ferulic acid
Grape, raisin	1,065	Caffeoyl tartaric acid
Blackberry	193–1,056	Cyanidin *3-O*-glucoside, ellagic acid
Ovalleaf huckleberry	261–1,054	Quercetin, myricetin
Black raspberry	980	Ellagic acid, quercetin *3-O*-rutinoside
Rabbiteye blueberry	48–961	Gallic acid, *4*-hydroxybenzoic acid,
Fig, dried	960	
Buffalo berry	958	
Highbush blueberry	20–868	*5*-Caffeoylquinic acid, *5*-caffeoylquinic acid
Lowbush blueberry	295–795	Polymers (>10 mers), malvidin *3-O*-glucoside
Apple [dessert], peeled	16–690	*5*-Caffeoylquinic acid, procyanidin dimer B2
Date, dried	172–667	Ferulic acid, *p*-coumaric acid
Canada blueberry	656	
Lingonberry	652	Cyanidin *3-O*-galactoside, quercetin
Gooseberry	191–630	Polymers (>10 mers), 07–10-mers
Apple [cider], peeled	43–600	*5*-Caffeoylquinic acid, procyanidin dimer B2
Red currant	372–540	Polymers (>10 mers), cyanidin *3-O*-sambubioside
Bilberry	525	Quercetin, *p*-coumaric acid, ferulic acid
Red raspberry	56–517	Ellagic acid, cyanidin *3-O*-sophoroside
Cascade huckleberry	140–491	*5*-Caffeoylquinic acid, caffeic acid
Strawberry	73–443	Pelargonidin *3-O*-glucoside, myricetin
Apple [dessert], whole	66–430	*5*-Caffeoylquinic acid, procyanidin dimer B2
Sour cherry	254–407	Cyanidin *3-O*-glucosyl-rutinoside
Sweet cherry	75–339	Cyanidin *3-O*-rutinoside, 3-*p*-coumaroylquinic acid
Jostaberry	301–338	Caffeoyl glucose, feruloyl glucose
Orange [blond]	9–337	Hesperetin, naringenin
American cranberry	315	Benzoic acid, *p*-coumaric acid
Peach, whole	23–300	*5*-Caffeoylquinic acid, *3*-caffeoylquinic acid
Fig, whole, fresh	49–281	
Date, fresh	2–280	Ferulic acid, caffeic acid
Kiwi	61–278	04–06-mers, 07–10-mers
Mango	48–266	04–06-mers, (+)-catechin
Peach, peeled	25–240	Procyanidin dimer B1, *5*-caffeoylquinic acid

Table 81.5 TPC range (mg/100 g FW) and major phenolics in fruits and fruit products

Name	TPC	Major phenolics
Banana	12–231	(+)-Catechin, 04–06-mers
Red huckleberry	74–228	*4*-Hydroxybenzoic acid, caffeic acid
Pear, peeled	38–220	*5*-Caffeoylquinic acid, (−)-epicatechin
Red raspberry, jam	219	Quercetin *3*-O-glucoside, cyanidin *3*-*O*-glucoside
Grapefruit	14–214	Naringenin, ferulic acid
Grape [black]	175–209	Malvidin *3*-*O*-glucoside
Sour cherry, jam	133–200	Cyanidin *3*-*O*-glucosyl-rutinoside
Half-highbush blueberry	110–199	*5*-Caffeoylquinic acid, caffeic acid
Tangerine	192	
Pear, whole	43–190	*5*-Caffeoylquinic acid, (−)-epicatechin
Pineapple	41–174	Syringaresinol, lariciresinol
Loquat	82–174	*5*-Caffeoylquinic acid, *3*-caffeoylquinic acid
Bog bilberry	151–171	Myricetin, quercetin
Grape [green]	29–145	Caffeoyl tartaric acid, polymers (>10 mers)
Plum, jam	141–144	
European cranberry	135–144	Quercetin, myricetin, *p*-coumaric acid
Star fruit	143	
Apricot	133	*5*-Caffeoylquinic acid, (−)-epicatechin
Guava	126	
Cantaloupe	9–124	
Fig, peeled, fresh	37–101	(+)-Catechin, (−)-epicatechin
Lemon	38–82	(−)-Epicatechin, hesperetin
Nectarine, whole	29–80	Procyanidin dimer B1, (+)-catechin
Nectarine, peeled	27–77	Procyanidin dimer B1, *5*-caffeoylquinic acid
Honeydew melon	6–72	
Watermelon	6–59	Luteolin
Papaya	58	
Passion fruit	57	
Lichee	29	
Longan	15	

2.4.1 TPC

Tables 81.4 and 81.5 show TPC in decreasing order according to the maximum values reported in fruits and fruit products [4].

Dried fruits had TPC (mg 100 g^{-1} FW) of 1,195 for prune plum, 1,065 for raisin grape, 960 for dried fig, and from 172 to 667 for dried date.

Berries had TPC of 690–2,556 for black chokeberry, 1,950 for black elderberry, 1,790 for skunk currant, 498–1,410 for black currant, 163–1,286 for black huckleberry, 283–1,169 for evergreen huckleberry, 193–1,056 for blackberry, 261–1,054 for ovalleaf huckleberry, 980 for black raspberry, 48–961 for rabbiteye blueberry, 958 for buffalo berry, 20–868 for highbush blueberry, 295–795 for lowbush blueberry, 656 for Canada blueberry, 652 for lingonberry, 191–630 for gooseberry, 372–540 for red currant, 525

Fig. 81.1 Saskatoon berry

for bilberry, 57–517 for red raspberry, 140–491 for cascade huckleberry, 73–443 for strawberry, 301–338 for jostaberry, 315 for American cranberry, 74–228 for red huckleberry, 175–209 for black grape, 110–199 for half-highbush blueberry, 151–171 for bog bilberry, 29–145 for green grape, and 135–144 for European cranberry.

Values of 2,283 and 3,791 mg 100 g^{-1} dry weight basis were reported for TPC of sea buckthorn without stone and saskatoon berry (Fig. 81.1), respectively [23].

TPC of citrus ranged from 9 to 337 for blond orange, 14–214 for grapefruit, 192 for tangerine, and 38–82 for lemon.

Drupes had TPC of 88–1,400 for fresh plum, 254–407 for sour cherry, 75–339 for sweet cherry, 23–300 for whole peach, 25–240 for peeled peach, 133 for apricot, 29–80 for whole nectarine, and 27–77 for peeled nectarine.

TPC of gourds ranged from 9 to 124 for cantaloupe, 6–72 for honeydew melon, and 6–59 for watermelon.

Pomes had TPC ranging from 16 to 690 for peeled dessert apple, 43–600 for peeled cider apple, 66–430 for whole dessert apple, 38–220 for peeled pear, and 43–190 for whole pear.

Tropical fruits had TPC of 61–278 for kiwi, 48–266 for mango, 12–231 for banana, 41–174 for pineapple, 82–174 for loquat, 143 for star fruit, 126 for guava, 58 for papaya, 57 for passion fruit, 29 for lichee, and 15 for longan.

The TPC in other fruits ranged from 49 to 281 for fresh whole fig, 2–280 for fresh date, and 37–101 for fresh peeled fig.

The TPC of red raspberry jam was 219 while the content in drupe jams was 133–200 for sour cherry jam and 141–144 for plum jam.

2.4.2 Phenolic Acids

Fruits and fruit products with high maximum SIPA (mg 100 g^{-1} FW) were peeled cider apple (19.0–417.1), sweet cherry (18.3–266.2), fresh plum (5.2–248.7), prune plum (128.8–234.4), black fox grape (227.6), highbush blueberry (68.6–214.1), red raspberry (109.8–161.1), black chokeberry (141.1), loquat (48.0–138.4), lowbush blueberry

(59.0–110.0), blackberry (28.6–90.2), sour cherry (25.0–75.0), dried date (11.5–73.9), American cranberry (51.8–62.0), whole dessert apple (3.1–57.0), whole pear (2.0–52.4), fresh date (5.2–49.6), peeled dessert apple (4.3–47.1), peeled nectarine (3.5–46.0), whole peach (8.1–41.6), black raspberry (38.0), peeled peach (1.6–33.6), peeled quince (0.7–30.0), strawberry (2.5–28.6), apricot (3.5–26.1), cloudberry (25.8), quince jam (1.1–23.0), black currant (11.3–19.3), lingonberry (12.2–16.6), jostaberry (16.2), whole nectarine (5.3–14.8), green grape (0.5–12.6), raisin grape (4.1–11.9), and apricot jam (1.3–10.8). The maximum SIPA was less than 9.0 for the other fruit-based sources.

The major phenolic acids (mg 100 g^{-1} FW) in the above fruits and fruit products high max SIPA (>100 mg 100 g^{-1} FW) were *5*-caffeoylquinic (15.8–400.6) and *4*-*p*-coumaroylquinic (0.1–13.5) acids in peeled cider apple; *3*-*p*-coumaroylquinic (7.2–131.5) and *3*-caffeoylquinic (8.2–128.2) acids in sweet cherry; *3*-caffeoylquinic (2.7–215.4) and *5*-caffeoylquinic (0.9–21.0) acids in fresh plum; caffeoyl tartaric (185.9) and *p*-coumaroyl tartaric (41.8) acids in black fox grape; *5*-caffeoylquinic acid (64.6–207.5) in highbush blueberry; sanguiin H-6 (75.9–89.8), lambertianin C (30.8–44.6), and ellagic acid (0–22.0) in red raspberry; caffeic acid (141.1) in black chokeberry; *5*-caffeoylquinic (32.9–90.7), *3*-caffeoylquinic (9.6–20.7), *5*-feruloylquinic (2.8–14.5), and *4*-hydroxybenzoic (2.2–8.2) acids in loquat; and *5*-caffeoylquinic acid (59.0–110.0) in lowbush blueberry without conducting a hydrolysis step.

After hydrolysis, fruits and fruit products with a high maximum SIPA were American cranberry (568.6), rabbiteye blueberry (0–407.7), highbush blueberry (100.1–203.5), half-highbush blueberry (148.8–176.6), red raspberry (4.5–166.6), red huckleberry (71.2–107.5), strawberry (9.6–71.8), arctic blackberry (0–68.6), evergreen huckleberry (61.0–64.0), cloudberry (0–60.6), dried date (7.5–58.7), blackberry (38.9–49.5), fresh date (2.6–37.2), bog bilberry (0.8–33.2), strawberry jam (19.6–25.4), European cranberry (21.1–25.2), fresh plum (3.1–22.2), cascade huckleberry (12.2–17.8), and black huckleberry (11.9–15.2). Other fruit sources had maximum SIPA of less than 8.0.

After hydrolysis, the major phenolic acids identified in the above fruits and fruit products with high maximum SIPA (>100 mg 100 g^{-1} FW) were benzoic (474.1), *p*-coumaric (25.4), sinapic (21.2), caffeic (15.6), *o*-coumaric (8.9), and ferulic (8.8) acids in American cranberry; gallic (0–258.9), *4*-hydroxybenzoic (0–103.7), ferulic (0–17.0), *p*-coumaric (0–15.8), caffeic (0–6.3), and ellagic (0–6.0) acids in rabbiteye blueberry; *5*-caffeoylquinic (98.1–157.6), caffeic (0–22.3), *p*-coumaric (0–7.2), and ellagic (0–6.7) acids in highbush blueberry; *5*-caffeoylquinic (130.4–152.1), caffeic (13.9–18.6), and ferulic (4.2–5.4) acids in half-highbush blueberry; ellagic (0–160.0) and *4*-hydroxybenzoic (2.6) acids in red raspberry; and *4*-hydroxybenzoic (40.7–68.7), caffeic (14.3–15.5), *p*-coumaric (7.6–11.2), and *5*-caffeoylquinic (5.0–7.7) acids in red huckleberry.

2.4.3 Flavonoids

Fruits and fruit products with high maximum SIF (mg 100 g^{-1} FW) were black elderberry (685.6–2212.7), black chokeberry (394.5–1538.5), black currant (378.6–865.4), sweet cherry (13.3–493.1), lowbush blueberry (55.1–365.4), peeled cider apple (13.4–330.9), blackberry (103.8–315.0), fresh plum (44.4–295.4), highbush blueberry (95.0–264.3), red raspberry (12.5–255.1), black grape (18.0–243.1), strawberry (32.3–151.7), sour cherry (10.2–128.6), peeled peach (8.6–122.8), whole dessert apple (7.2–101.8), peeled dessert apple (4.3–100.7), peeled nectarine (1.3–95.5), lingonberry (91.7), quince jelly (4.4–84.2), American cranberry (78.0), black aestivalis grape (76.6), red currant (24.0–53.3), quince jam (0–35.1), whole nectarine (3.9–31.3), sweet cherry jam (10.2–29.5), custard apple (24.9), lowbush blueberry jam (18.0–21.6), blackberry jam (0.2–21.4), apricot (0.7–20.5), black raspberry (19.0), gooseberry (2.2–15.9), dessert apple puree (15.7), green grape (1.0–12.5), black fox grape (12.2), green currant (11.1), apricot puree (5.8–11.0), and banana (0.1–10.6). The maximum SIF was less than 10.0 for other fruit-based sources.

The major flavonoids (mg 100 g^{-1} FW) in the above fruits and fruit products with a high maximum SIF (>100 mg 100 g^{-1} FW) were identified as cyanidin *3-O*-glucoside (361.0–1266.0), cyanidin *3-O*-sambubioside (269.0–706.4), cyanidin *3-O*-sambubiosyl *5-O*-glucoside (14.0–136.7), quercetin (29.0–60.0), and cyanidin *3,5-O*-diglucoside (5.0–36.0) in black elderberry; cyanidin *3-O*-galactoside (125.6–989.7), cyanidin *3-O*-arabinoside (132.9–372.6), cyanidin *3-O*-xyloside (43.8–48.1), quercetin *3-O*-galactoside (46.5), and quercetin *3-O*-glucoside (42.0) in black chokeberry; delphinidin *3-O*-rutinoside (197.4–409.2), cyanidin *3-O*-rutinoside (93.3–241.1), delphinidin *3-O*-glucoside (54.2–113.2), and cyanidin *3-O*-glucoside (12.5–51.8) in black currant; cyanidin *3-O*-rutinoside (1.6–393.0) and cyanidin *3-O*-glucoside (0–48.0) in sweet cherry; malvidin *3-O*-glucoside (12.6–44.4), malvidin *3-O*-(*6*-acetyl)-glucoside) (0–39.8), malvidin *3-O*-galactoside (1.5–38.6), delphinidin *3-O*-glucoside (5.0–26.0), and delphinidin *3-O*-galactoside (9.5–24.1) in lowbush blueberry; (−)-epicatechin (0–141.0), procyanidin dimer B2 (5.7–87.6), and (+)-catechin (0–58.0) in peeled cider apple; cyanidin *3-O*-glucoside (85.2–190.6) in blackberry; cyanidin *3-O*-rutinoside (0–144.8) and cyanidin *3-O*-glucoside (0–64.1) in fresh plum; delphinidin *3-O*-galactoside (10.7–39.0), petunidin *3-O*-galactoside (5.8–22.9), malvidin *3-O*-galactoside (15.1–19.6), and delphinidin *3-O*-arabinoside (9.1–18.6) in highbush blueberry; cyanidin *3-O*-sophoroside (0–106.2), cyanidin *3-O*-glucosyl-rutinoside (0–30.9), cyanidin *3-O*-glucoside (0–30.5), and cyanidin *3-O*-rutinoside (0–28.4) in red raspberry; malvidin *3-O*-glucoside (0.9–120.3), malvidin *3-O*-(*6-p*-coumaroyl)-glucoside (0–39.0), and peonidin *3-O*-glucoside (2.1–19.3) in black grape; pelargonidin *3-O*-glucoside (20.3–68.3), pelargonidin *3-O*-(*6″*-succinyl)-glucoside (0–31.3), and (+)-catechin (1.6–18.7) in strawberry; cyanidin *3-O*-glucosyl-rutinoside (6.2–109.7) in sour cherry; procyanidin dimer B1 (0.7–68.7), (+)-catechin (0.5–19.7), and (−)-epicatechin (0.7–16.5) in peeled peach; procyanidin dimer B2 (0.9–38.5) and (−)-epicatechin (1.8–19.2) in whole dessert apple; and procyanidin dimer B2 (0–21.3), procyanidin dimer B1 (0–17.3), and (−)-epicatechin (0–19.8) in peeled dessert apple without conducting a hydrolysis step.

After hydrolysis, fruits and fruit products with high maximum SIF were strawberry (0.3–102.0), blackberry (0–67.4), grapefruit (54.5), blond orange (42.0–53.8), lime (46.8), bog bilberry (16.5–40.6), black currant (3.7–39.0), lemon (35.1–38.8), European cranberry (11.4–37.5), American cranberry (12.3–27.9), rabbiteye blueberry (0–22.3), lingonberry (0–21.5), half-highbush blueberry (8.5–17.3), and black crowberry (9.7–10.5). Other fruit sources had maximum SIF of less than 10.0.

The major flavonoids in the above fruits and fruit products with a high maximum SIF (>50 mg 100 g^{-1} FW) were identified as myricetin (0–99.4) in strawberry, myricetin (0–63.6) in blackberry, naringenin (53.0) in grapefruit, and hesperetin (31.0–41.4) and naringenin (11.0–11.9) in blond orange.

Many fruits are rich in anthocyanins which are the major flavonoid compounds present in these fruits that significantly contribute to their total antioxidant activity. The TAC is an indication of anthocyanin levels in fruit. High TAC corresponds to high anthocyanin levels in the fruit. Fruits with high TAC (mg 100 g^{-1} FW) were evergreen huckleberry (336.0–617.0), black raspberry (589.0), rabbiteye blueberry (12.7–515.0), black chokeberry (428.0–460.5), highbush blueberry (35.5–430.0), black currant (128.0–411.0), ovalleaf huckleberry (185.0–400.0), black huckleberry (101.0–360.0), skunk currant (358.0), bilberry (299.0), Canada blueberry (298.0), buffalo berry (273.0), half-highbush blueberry (89.0–265.0), blackberry (67.4–256.0), lowbush blueberry (91.1–208.0), red raspberry (0–206.0), cascade huckleberry (134.0–176.0), bog bilberry (79.0–170.0), jostaberry (43.0–89.0), sour cherry (8.7–67.1), and sweet cherry (0.5–63.4).

2.4.4 Other Phenolic Compounds

The other phenolic compounds in fruits and fruit products with high maximum values (mg 100 g^{-1} FW) were arbutin (0–16.0) in quince jam; >10 polymers (542.6), 07–10-mers (52.9), and 04–06-mers (40.3) in black chokeberry; >10 polymers (260.4), 07–10-mers (27.8), and 04–06-mers (25.7) in lowbush blueberry; >10 polymers (57.3–115.3), 04–06-mers (49.9–64.7), 07–10-mers (33.8–41.2), and 02-mers (16.0–31.5) in fresh plum; >10 polymers (129.0) and 04–06-mers (19.6) in highbush blueberry; >10 polymers (98.7–138.6), 07–10-mers (8.5–10.9), and 04–06-mers (6.7–10.6) in black currant; >10 polymers (75.8), 04–06-mers (28.1), and 07–10-mers (23.9) in strawberry; >10-mers (35.4–113.3) and 07–10-mers (4.49–8.6) in gooseberry; and >10 polymers (27.7–37.6), 04–06-mers (22.8–30.2), and 07–10-mers (19.5–25.4) in whole dessert apple.

2.5 Nonalcoholic Beverages

Phenolics found in nonalcoholic beverages include 49 phenolic acids, 105 flavonoids, 6 stilbenes, 2 lignans, and 12 other polyphenols [9]. The major phenolics in nonalcoholic beverages are summarized in Table 81.6.

2.5.1 TPC

Table 81.6 shows TPC in decreasing order according to the maximum values reported in nonalcoholic beverages [4]. Nonalcoholic beverages had TPC (mg 100 ml^{-1}) of 246–282 for filter coffee beverage and 264–273 for decaffeinated filter coffee beverage. Among the berry juices, a TPC of 68 was recorded for black grape pure juice.

Citrus juices had TPC of 351 for grapefruit juice from concentrate, 180 for lemon juice from concentrate, 122 for lime pure juice, 38–115 for blood orange pure juice, 36–76 for blond orange pure juice, and 54 for grapefruit pure juice.

Table 81.6 TPC range (mg/100 ml) and major phenolics in nonalcoholic beverages

Name	TPC	Major phenolics
Apple [cider], pure juice	52–1,360	5-Caffeoylquinic acid, (−)-epicatechin
Grapefruit, juice from concentrate	351	Naringin, narirutin
Coffee beverage [filter]	246–282	5-Caffeoylquinic acid, 4-caffeoylquinic acid
Coffee beverage [filter], decaffeinated	264–273	5-Caffeoylquinic acid, 3-caffeoylquinic acid
Pomegranate, pure juice	175–257	Punicalagin, cyanidin 3-*O*-glucoside
Lemon, juice from concentrate	180	Hesperidin, eriocitrin
Tea [black], infusion	12–135	(−)-Epigallocatechin 3-*O*-gallate
Lime, pure juice	122	Hesperidin, eriocitrin
Orange [blood], pure juice	38–115	Cyanidin 3-*O*-(6″-malonyl-glucoside)
Tea [green], infusion	29–103	(−)-Epigallocatechin 3-*O*-gallate
Orange [blond], pure juice	36–76	Hesperidin, narirutin
Grape [black], pure juice	68	
Grapefruit, pure juice	54	Naringin, narirutin, phlorin
Common thyme, tea	51	
Pear, pure juice	20–46	5-Caffeoylquinic acid, (−)-epicatechin
Common sage, tea	43	
Pineapple, pure juice	36	
Rosemary, tea	36	
Spearmint, tea	36	
Apple [dessert], pure juice	34	5-Caffeoylquinic acid, procyanidin dimer B2
Peppermint, tea	31	(−)-Epicatechin 3-*O*-gallate
Tarragon, tea	30	
Winter savory, tea	26	
Lemon thyme, tea	25	
Small-leaf linden, tea	23	
Fennel, tea	23	Quercetin 3-*O*-glucuronide, anethole
German camomile, tea	23	(−)-Epigallocatechin 3-*O*-gallate
Roman camomile, tea	18	
Hyssop, tea	17	
Sweet bay, tea	17	
Sweet basil, tea	16	
Coriander, tea	12	
Lovage, tea	11	
Lemongrass, tea	10	
Lemon verbena, tea	8	Verbascoside, luteolin 7-*O*-diglucuronide

TPC of pome juices ranged from 52 to 1,360 for cider apple pure juice, 20–46 for pear pure juice, and 34 for dessert apple pure juice. TPC of tropical fruit juices included 175–257 for pomegranate pure juice and 36 for pineapple pure juice.

TPC was determined in several herbal infusions and values of 51 for common thyme tea, 43 for common sage tea, 36 for rosemary tea, 36 for spearmint tea, 31 for peppermint tea, 30 for tarragon tea, 26 for winter savory tea, 25 for lemon thyme tea, 23 for small-leaf linden tea, 23 for fennel tea, 23 for German camomile tea, 18 for Roman camomile tea, 17 for hyssop tea, 17 for sweet bay tea, 16 for sweet basil tea, 12 for coriander tea, 11 for lovage tea, 10 for lemongrass tea, and 8 for lemon verbena tea were obtained. Tea infusions had TPC ranging from 12 to 135 for black tea infusion and 29–103 for green tea infusion.

2.5.2 Phenolic Acids

Nonalcoholic beverages with a high maximum SIPA (mg 100 ml^{-1}) included decaffeinated filter coffee beverage (32.8–541.9), filter coffee beverage (171.6–256.6), filter robusta coffee beverage (204.6), pomegranate juice from concentrate (168.3), pomegranate pure juice (9.4–147.3), cider apple pure juice (3.3–138.5), filter arabica coffee beverage (87.7), dessert apple pure juice (3.4–83.5), rowanberry pure juice (81.7), green fox grape pure juice (29.9–41.6), plum prune juice from concentrate (41.5), lemon verbena tea (39.4), plum prune pure juice (2.8–37.9), green grape pure juice (3.3–35.2), black tea infusion (6.6–34.0), pear pure juice (7.6–26.2), green tea infusion (11.5–16.5), and cider apple juice from concentrate (1.4–10.2). The other beverages had maximum SIPA of less than 10.0.

The major phenolic acids (mg 100 ml^{-1}) in the above nonalcoholic beverages with high maximum SIPA (>100 mg 100 ml^{-1}) were *5*-caffeoylquinic (11.7–235.6), *3*-caffeoylquinic (7.1–106.1), and *4*-caffeoylquinic (9.9–104.8) acids in decaffeinated filter coffee beverage; *5*-caffeoylquinic (47.9–96.0), *4*-caffeoylquinic (53.0–66.2), and 3-caffeoylquinic (40.0–63.6) acids in filter coffee beverage; *5*-caffeoylquinic (75.8), *4*-caffeoylquinic (36.5), *3*-caffeoylquinic (32.3), and *4*-feruloylquinic (30.1) acids in filter robusta coffee beverage; punicalagin (135.3) and ellagic acid (17.3) in pomegranate juice from concentrate; punicalagin (2.3–126.0) and ellagic acid glucoside (1.8–8.3) in pomegranate pure juice; and *5*-caffeoylquinic (0.7–109.9) and *4-p*-coumaroylquinic (0.5–21.4) acids in cider apple pure juice without conducting a hydrolysis step.

After hydrolysis, SIPA of nonalcoholic beverages were 93.4–207.9 for filter coffee beverage, 5.9–15.9 for blood orange pure juice, 4.6–9.0 for blond orange pure juice, 6.9–8.9 for blood orange juice from concentrate, and 6.2–6.7 for blond orange juice from concentrate. The major phenolic acids identified were caffeic (83.0–96.0), *5*-caffeoylquinic (0–96.0), and ferulic (9.1–14.3) acids in filter coffee beverage; ferulic (3.2–6.4) and *p*-coumaric (1.2–4.5) acids in blood orange pure juice; ferulic (3.0–4.0) and *p*-coumaric (0.7–2.9) acids in blond orange pure juice; ferulic (3.9–4.4) and *p*-coumaric (1.4–2.3) acids in blood orange juice from concentrate; and ferulic (3.5–3.7) and *p*-coumaric (1.6–1.6) acids in blond orange juice from concentrate.

2.5.3 Flavonoids

Nonalcoholic beverages with high maximum SIF (mg 100 ml^{-1}) were green tea infusion (11.5–549.7), soy milk (4.0–376.3), black tea infusion (8.4–359.1), cider apple pure juice (1.3–213.2), oolong tea infusion (0.4–158.8), dessert apple pure juice (21.0–131.9), blond orange pure juice (15.4–111.0), grapefruit pure juice (12.2–101.1), bottled black tea (78.2–94.9), lemon pure juice (10.8–93.5), grapefruit pummelo hybrid pure juice (41.6–92.6), grapefruit juice from concentrate (17.3–86.1), blood orange pure juice (23.1–85.1), blond orange juice from concentrate (57.7–73.9), lemon juice from concentrate (14.7–71.7), tangerine juice from concentrate (15.5–69.7), bottled green tea (8.1–64.3), blood orange juice from concentrate (61.7), plum prune pure juice (10.1–51.0), pomegranate pure juice (0.6–40.9), sea buckthorn berry pure juice (36.5–40.1), chocolate milk beverage (7.9–33.3), red raspberry pure juice (0.1–30.1), bottled oolong tea (13.8–28.0), lime pure juice (16.4–23.9), green grape pure juice (0.5–20.5), plum prune juice from concentrate (17.9), peppermint tea (3.7–16.7), pomegranate juice from concentrate (16.2), pummelo pure juice (3.3–14.4), and lemon verbena tea (10.6). The other beverages had maximum SIF of less than 10.0. The TAC of blood orange pure juice ranged from 9.7 to 103.8 mg 100 ml^{-1}.

The major flavonoids (mg 100 ml^{-1}) in the above nonalcoholic beverages with high maximum SIF (>100 mg 100 ml^{-1}) were identified as (−)-epigallocatechin *3-O*-gallate (0.6–271.4), (−)-epigallocatechin (0.0–100.0), (−)-epicatechin (0–73.9), and (−)-epicatechin *3-O*-gallate (0.1–64.3) in green tea infusion; *6″-O*-malonylgenistin (0.2–87.1), *6″-O*-acetylgenistin (0–82.0), genistin (2.4–71.0), *6″-O*-malonyldaidzin (0.1–69.0), and daidzin (1.3–41.0) in soy milk; (−)-epigallocatechin *3-O*-gallate (0–67.9), (+)-gallocatechin (0–59.2), (−)-epigallocatechin (0–50.9), and (−)-epicatechin *3-O*-gallate (0–31.7) in black tea infusion; (−)-epicatechin (0–82.2), procyanidin dimer B2 (0–55.0), and (+)-catechin (0–40.7) in cider apple pure juice; (−)-epigallocatechin *3-O*-gallate (0.4–85.7) and (−)-epigallocatechin (0–40.0) in oolong tea infusion; procyanidin trimer C1 (19.9–40.0), procyanidin dimer B2 (0.1–22.9), (−)-epicatechin (0.5–22.6), and phloridzin (0.4–19.6) in dessert apple pure juice; hesperidin (4.5–73.0) and narirutin (1.5–15.2) in blond orange pure juice; and naringin (7.3–65.6) and narirutin (2.3–17.9) in grapefruit pure juice without performing a hydrolysis step.

After hydrolysis, nonalcoholic beverages with a high maximum SIF were soy milk (2.5–21.1), blond orange pure juice (9.8–11.2), green tea infusion (0.9–5.1), black tea infusion (0–4.7), and oolong tea infusion (2.7). Other nonalcoholic beverages had maximum SIF of less than 1.0. The major flavonoids in above nonalcoholic beverages with high maximum SIF (>10 mg 100 ml^{-1}) were genistein (1.9–12.2) and daidzein (0.7–8.7) in soy milk and hesperetin (9.0) and quercetin (0–1.3) in blond orange pure juice.

2.5.4 Other Phenolic Compounds

The other phenolic compounds (mg 100 ml^{-1}) with high maximum values in nonalcoholic beverages were phlorin (3.0–10.8) and bergapten (0–1.9) in grapefruit pure juice, phlorin (9.1) in pummelo pure juice, anethole (0–6.7) and *p*-anisaldehyde (0–1.5) in fennel tea, phlorin (4.3) in lemon pure juice, phlorin (1.1–3.7) in blond orange pure juice, and 02 mers (2.2) in chocolate milk beverage.

2.6 Oils

Phenolics found in oils include 28 phenolic acids, 11 flavonoids, 2 stilbenes, 12 lignans, and 22 other polyphenols [9]. The major phenolics in oils are summarized in Table 81.7.

Table 81.7 TPC range (mg/100 g FW) and major phenolics in oils and cereal oils

Name	TPC	Major phenolics
Peanut, butter	536	03-mers, 02-mers
Olive, oil, extra virgin	6–141	*3*,*4*-DHPEA-EDA, *p*-HPEA-EDA
Rapeseed, oil	0–107	*4*-Vinylsyringol, sinapine
Olive, oil, virgin	4–81	*p*-HPEA-EDA, oleuropein-aglycone
Olive, oil, refined	18–20	Oleuropein-aglycone, *3*,*4*-DHPEA-EDA
Sesame seed, oil	2	Sesamin, sesamolin, sesaminol
Soy, oil	0–1	*p*-Coumaric acid, ferulic acid
Sunflower seed, oil	1	

2.6.1 TPC

Table 81.7 shows TPC in decreasing order according to the maximum values reported in oils [4]. Fruit vegetable oils had TPC (mg 100 g^{-1} FW) of 6–141 for extra virgin olive oil, 4–81 for virgin olive oil, and 18–20 for refined olive oil. TPC was 536 for peanut butter among the nut oils. The TPC measured in other seed oils resulted in values of 0–107 for rapeseed oil, 2 for sesame seed oil, 0–2 for soy oil, and 1 for sunflower seed oil.

2.6.2 Phenolic Acids

Oils with high maximum SIPA (mg 100 g^{-1} FW) included maize bran oil (557.0), rapeseed oil (0.8–5.8), and virgin olive oil (0.1–2.6). The maximum SIPA was less than 2.0 in other oils. The major phenolic acids were identified as stigmastanol ferulate (360.0), *24*-methylcholestanol ferulate (100.0), *24*-methylcholesterol ferulate (50.0), and sitosterol ferulate (30.0) in maize bran oil; sinapine (0–2.6) and sinapic acid (0–2.3) in rapeseed oil; and vanillic (0–1.0) and syringic (0–0.4) acids in virgin olive oil.

2.6.3 Flavonoids

Oils with high maximum SIF (mg 100 g^{-1} FW) included extra virgin olive oil (0.1–4.0) and virgin olive oil (0–1.2). Other oils had maximum SIF of less than 1.0. The major flavonoids present were apigenin (0–3.2) and luteolin (0.1–0.8) in extra virgin olive oil and luteolin (0–0.8) and apigenin (0–0.4) in virgin olive oil.

2.6.4 Other Phenolic Compounds

The other phenolic compounds (mg 100 g^{-1} FW) with high maximum values in oils were identified as oleuropein-aglycone dialdehyde (0–163.5), oleuropein-aglycone *mono*-aldehyde (0–60.9), oleuropein-aglycone (0.1–45.9), ligstroside-aglycone dialdehyde (0.1–40.7), ligstroside-aglycone *mono*-aldehyde (0–34.6), hydroxytyrosol acetate (0–24.7), ligstroside-aglycone (0–23.3), and *1*-acetoxypinoresinol (0–11.2) in virgin olive oil; oleuropein-aglycone dialdehyde (0.1–94.2), ligstroside-aglycone dialdehyde (1.2–33.5), and oleuropein-aglycone *mono*-aldehyde (0–25.8) in extra virgin olive oil; *4*-vinylsyringol (0–62.9) in rapeseed oil; sesamin (7.0–1860.0), sesamolin (0–1000.0), sesaminol (6.6–720.0), sesamol (0–337.1), episesamin (192.6), sesamolinol (8.0–124.0), and episesaminol (8.8–81.6) in sesame seed oil; sesamin (13.0–1850.0), sesamolin (34.0–1060.0), sesaminol (16.0–500.0), sesamolinol (0–111.0), and sesamol (0–48.0) in black sesame seed oil; and 03-mers (8.1) in peanut butter.

2.7 Seasonings

Phenolics reported in seasonings include 29 phenolic acids, 62 flavonoids, 1 stilbene, and 25 other polyphenols [9]. The major phenolics in seasonings and herbs are summarized in Tables 81.8 and 81.9.

2.7.1 TPC

Tables 81.8 and 81.9 show TPC in decreasing order according to the maximum values reported in seasonings and herbs [4].

Several herbs have been analyzed to obtain TPC (mg 100 g^{-1} FW) of 1,650–11,500 for dried spearmint, 9,306 for dried pot marjoram, 1,690–8,000 for dried marjoram, 5,452–7,282 for dried wild marjoram oregano, 740–6,550 for dried sweet basil, 1,360–4,767 for common dried sage, 4,512 for dried summer savory, 4,170 for dried sweet bay, 520–4,000 for dried coriander, 2,100–3,196 for dried rosemary, 520–2,726 for dried hyssop, 226–2,580 for fresh peppermint, 2,483 for dried roman camomile, 126–2,253 for fresh lemon balm, 2,250 for dried fenugreek, 960–2,244 for dried parsley, 435–2,221 for fresh wild marjoram oregano, 1,710–1,920 for dried common thyme, 1,880 for dried winter savory, 1,700 for dried lemon balm, 213–1,537 for fresh common thyme, 219–1,377 for fresh rosemary, 850–1,270 for dried German camomile, 1,250 for dried dill, 1,165 for fresh Italian oregano, 854 for fresh marjoram, 155–771 for fresh lemon verbena, 68–701 for fresh fennel leaves, 662 for fresh lemongrass, 570 for fresh tarragon, 402 for fresh sweet bay, 94–400 for fresh spearmint, 350 for dried sorrel, 316 for fresh winter savory, 129–312 for fresh dill, 83–284 for fresh coriander, 263 for fresh lovage, 223–234 for fresh sweet basil, 226 for fresh orange mint, 199–218 for fresh fenugreek, 215 for fresh hyssop, 201 for fresh summer savory, 134–198 for fresh common sage, 180 for dried anise herb, 178 for fresh lemon thyme, 68–152 for fresh parsley, 48–150 for fresh garlic, 131 for fresh pineapple sage, 120 for dried silver linden, 75–105 for fresh chives, and 94 for fresh wild turnip tops.

Spices had TPC ranging from 11,319 to 24,390 for cloves, 7,500–11,900 for Ceylon cinnamon, 230–9,000 for cumin, 610–6,750 for caraway, 3,600 for capers, 148–2,420 for cardamom, 1,610–2,200 for nutmeg, 2,117 for dried turmeric, 1,600–2,020 for star anise, 300–1,700 for black pepper spice, 134–1,250 for coriander seed, 830 for fenugreek seed, 780 for white pepper spice, 317–630 for dried ginger, 380 for green pepper spice, 201–221 for fresh ginger, and 90 for dried horseradish. Curry powder had TPC of 1,075 among spice blends.

2.7.2 Phenolic Acids

Seasonings with high maximum SIPA (mg 100 g^{-1} FW) were dried peppermint (75.9–3860.0), fresh common verbena (840.0–2270.0), dried common sage (277.7–1523.4),

Table 81.8 TPC range (mg/100 g FW) and major phenolics in seasonings and herbs

Name	TPC	Major phenolics
Cloves	11,319–24,390	Rosmarinic acid, *5*-caffeoylquinic acid
Ceylon cinnamon	7,500–11,900	
Spearmint, dried	1,650–11,500	Ferulic acid, caffeic acid, apigenin
Pot marjoram, dried	9,306	Rosmarinic acid, *5*-caffeoylquinic acid
Cumin	230–9,000	Rosmarinic acid, vanillic acid
Marjoram, dried	1,690–8,000	Rosmarinic acid, carnosic acid
Oregano, dried (wild marjoram)	5,452–7,282	
Caraway	610–6,750	
Sweet basil, dried	740–6,550	Quercetin
Common sage, dried	1,360–4,767	Rosmarinic acid, caffeic acid
Summer savory, dried	4,512	Ferulic acid, caffeic acid
Sweet bay, dried	4,170	
Coriander, dried	520–4,000	
Capers	3,600	
Rosemary, dried	2,100–3,196	
Hyssop, dried	520–2,726	Apigenin, bergapten, psoralen
Peppermint, fresh	226–2,580	Apigenin, luteolin
Roman camomile, dried	2,483	Rosmarinic acid, caffeic acid, luteolin
Cardamom	148–2,420	
Lemon balm, fresh	126–2,253	Ferulic acid, caffeic acid
Fenugreek, dried	2,250	Rosmarinic acid, luteolin, hispidulin
Parsley, dried	960–2,244	Carnosic acid, rosmarinic acid, rosmanol
Oregano, fresh (wild marjoram)	435–2,221	*4*-Hydroxybenzoic acid, ferulic acid
Nutmeg	1,610–2,200	Quercetin, vanillic acid
Turmeric, dried	2,117	Rosmarinic acid, hispidulin
Star anise	1,600–2,020	
Common thyme, dried	1,710–1,920	
Winter savory, dried	1,880	*2*-Hydroxybenzoic acid, quercetin
Lemon balm, dried	1,700	
Pepper spice [black]	300–1,700	Kaempferol, quercetin
Common thyme, fresh	213–1,537	
Rosemary, fresh	219–1,377	
German camomile, dried	850–1,270	
Dill, dried	1,250	
Coriander seed	134–1,250	Quercetin, isorhamnetin, kaempferol
Italian oregano, fresh	1,165	Ferulic acid, caffeic acid, gallic acid
Curry, powder	1,075	Quercetin, kaempferol
Marjoram, fresh	854	
Fenugreek seed	830	
Pepper spice [white]	780	Quercetin *3-O*-rutinoside

Table 81.9 TPC range (mg/100 g FW) and major phenolics in seasonings and herbs

Name	TPC	Major phenolics
Lemon verbena, fresh	155–771	
Fennel, fresh leaves	68–701	
Lemongrass, fresh	662	Rosmarinic acid, luteolin
Ginger, dried	317–630	Ferulic acid, gallic acid
Tarragon, fresh	570	
Sweet bay, fresh	402	Apigenin, myricetin, bergapten
Spearmint, fresh	94–400	
Pepper spice [green]	380	
Sorrel, dried	350	*p*-Coumaric acid, vanillic acid
Winter savory, fresh	316	Kaempferol, quercetin, isorhamnetin
Dill, fresh	129–312	Kaempferol, caffeic acid
Coriander, fresh	83–284	Quercetin, luteolin
Lovage, fresh	263	Luteolin *7*-*O*-(*2*-apiosyl-*6*-malonyl)-glucoside
Sweet basil, fresh	223–234	Kaempferol
Orange mint, fresh	226	Verbascoside, luteolin *7*-*O*-diglucuronide
Ginger, fresh	201–221	Caffeic acid, ferulic acid
Fenugreek, fresh	199–218	Jaceosidin, hispidulin
Hyssop, fresh	215	Pinocembrin, naringenin, galangin
Summer savory, fresh	201	Eriocitrin, rosmarinic acid
Common sage, fresh	134–198	
Anise herb, dried	180	Quercetin, kaempferol
Lemon thyme, fresh	178	Caffeic acid, hesperidin
Parsley, fresh	68–152	Genistin, genistein, daidzein
Garlic, fresh	48–150	Tyrosol, (+)-catechin, gallic acid
Pineapple sage, fresh	131	Eugenol, acetyl eugenol, gallic acid
Silver linden, dried	120	Caffeic acid, protocatechuic acid
Chives, fresh	75–105	Kaempferol, caffeic acid, ferulic acid
Wild turnip tops, fresh	94	Caffeic acid, kaempferol
Horseradish, dried	90	Quercetin *3*-*O*-rutinoside

dried spearmint (613.0–1491.0), dried rosemary (918.9–1161.3), dried common thyme (471.4–1075.4), cloves (18.26–802.32), dried wild marjoram oregano (622.0–706.5), dried sweet basil (322.0), fresh rosemary (34.4–219.7), fresh Italian oregano (165.0), fresh common sage (127.5), fresh common thyme (103.5), star anise (52.4), Chinese cinnamon (7.7–35.8), vinegar (0.1–32.3 mg 100 ml^{-1}), Ceylon cinnamon (25.7–29.1), cumin (16.6), caraway (16.4), nutmeg (16.3–16.4), dried ginger (15.5), and dried marjoram (13.0). The other seasonings had maximum SIPA of less than 1.0.

The major phenolic acids (mg 100 g^{-1} FW) in the above seasonings with high maximum SIPA (>100 mg 100 g^{-1} FW) were rosmarinic acid (75.9–3860.0) in dried peppermint; verbascoside (840.0–2270.0) in fresh common verbena; rosmarinic (250.0–1410.0), caffeic (11.0–40.0), and 5-caffeoylquinic (16.7–23.0) acids in dried common sage; rosmarinic (562.0–1430.0), *5*-caffeoylquinic (31.0), and caffeic (20.0–30.0) acids in dried spearmint; rosmarinic (916.0–1100.0) and caffeic (2.9–20.0) acids in dried rosemary; rosmarinic (450.0–1000.0) and caffeic (10.0–30.0) acids in dried common thyme; gallic (17.47–783.5) and *p*-coumaric (0–17.0) acids in cloves; rosmarinic (598.0–600.0), *5*-caffeoylquinic (24.0–33.4), and caffeic (0–21.4) acids in dried wild marjoram oregano; rosmarinic (308.0) and vanillic (14.0) acids in dried sweet basil; rosmarinic (32.8–215.0) and caffeic (1.2–3.0) acids in fresh rosemary; rosmarinic (154.6) and caffeic (10.4) acids in fresh Italian oregano; rosmarinic (117.8) and caffeic (7.4) acids in fresh common sage; and rosmarinic (91.8) and caffeic (11.7) acids in fresh common thyme.

After hydrolysis, seasonings with high maximum SIPA were fennel fresh leaves (142.9), dried lemon balm (66.2), fresh coriander (39.7), fenugreek seed (30.3), fresh tarragon (27.0), dried hyssop (25.1), dried common thyme (16.2), dried marjoram (16.0), dried rosemary (15.8), dried fennel (13.4), dried spearmint (13.2), cumin (11.9), and fresh wild turnip tops (10.3). Others in max SIPA were less than 10.0. The major phenolic acids in the above seasonings high maximum SIPA (>50 mg 100 g^{-1} FW) were *2*-hydroxybenzoic (125.8) and ferulic (7.4) acids in fennel fresh leaves and ferulic (48.0) and caffeic (13.8) acids in dried lemon balm.

2.7.3 Flavonoids

Seasonings with high maximum SIF (mg 100 g^{-1} FW) were dried peppermint (326.9–21763.5), dried Mexican oregano (1,410.5–3,140.1), celery seed (2,094.0), capers (89.0–2,008.0), fresh common verbena (580.0–1,140.0), saffron (318.5–770.5), dried lemon verbena (30.8–215.8), fresh celery leaves (133.4), fresh rosemary (63.1–102.2), fresh common sage (66.4), fresh common thyme (60.3), fresh Italian oregano (52.2), cloves (52.2), cumin (38.6), caraway (16.4), vinegar (0–10.4), and dried marjoram (10.0). Other seasonings had maximum SIF below 6.0.

The major flavonoids (mg 100 g^{-1} FW) in the above seasonings with high maximum SIF (>100 mg 100 g^{-1} FW) were eriocitrin (108.5–14,980.0), luteolin *7-O*-rutinoside (36.5–2,320.0), narirutin (40.0–1,590.0), hesperidin (61.5–1,310.0), isorhoifolin (2.5–500.0), diosmin (30.0–470.0), eriodictyol *7-O*-glucoside (5.5–420.0), and pebrellin (20.9–72.3) in dried peppermint; pinocembrin (53.0–916.0), naringenin (335.0–418.0), galangin (20.0–347.0), luteolin *7-O*-glucoside (256.0–328.0), dihydroquercetin (98.0–149.0), phloridzin (117.0–148.0), hispidulin (85.0–117.5), *6*-hydroxyluteolin (78.1–105.6), sakuranetin (90.0–98.0), eriodictyol (72.0–93.0), cirsimaritin (49.4–83.4), *6*-hydroxyluteolin *7-O*-rhamnoside (23.0–76.0), methylgalangin (0–72.6), and luteolin (51.0–62.0) in dried Mexican oregano; luteolin *7-O*-(*2*-apiosyl-glucoside) (632.0), chrysoeriol *7-O*-apiosyl-glucoside (467.0), luteolin *7-O*-(*2*-apiosyl-*6*-malonyl)-glucoside (427.0), chrysoeriol *7-O*-(*6″*-malonyl-apiosyl-glucoside) (238.0), apigenin *7-O*-apiosyl-glucoside (111.0), luteolin *7-O*-malonyl-glucoside (92.0), and luteolin *7-O*-glucoside (80.0) in celery seed; kaempferol (10.0–280.0), quercetin (3.0–145.0), quercetin *3-O*-rutinoside (76.0–1047.0), kaempferol *3-O*-rutinoside (0–465.0), and kaempferol *3-O*-rhamnosyl-rhamnosyl-glucoside (0–71.0) in capers; luteolin *7-O*-diglucuronide (340.0–700.0) and apigenin *7-O*-diglucuronide (240.0–440.0) in fresh common verbena; kaempferol

3-O-sophoroside *7-O*-glucoside (183.1–321.3), kaempferol *3-O*-sophoroside (60.9–311.5), and kaempferol *3,7,4′-O*-triglucoside (74.5–137.7) in saffron; jaceosidin (9.8–70.2), hispidulin (11.1–52.3), and cirsilineol (3.9–39.0) in dried lemon verbena; luteolin *7-O*-(*2*-apiosyl-*6*-malonyl)-glucoside (35.8), chrysoeriol *7-O*-(*6″*-malonyl-apiosyl-glucoside) (35.6), and apigenin *7-O*-(*6″*-malonyl-apiosyl-glucoside) (31.6) in fresh celery leaves; and naringin (53.1–57.0), cirsimaritin (8.0–24.4), and hispidulin (2.0–19.7) in fresh rosemary without conducting a hydrolysis step.

After hydrolysis, seasonings with high maximum SIF were fresh parsley (0–581.7), fresh lovage (177.0), fresh dill (51.7–163.2), fresh angelica (1.9–138.8), fresh celery leaves (11.1–99.3), fennel fresh leaves (82.5), dried parsley (1.5–63.4), fresh common thyme (56.0), dried common thyme (40.0), dried dill (36.0), fresh chives (6.6–31.7), and fresh tarragon (27.0). Other seasonings had maximum SIF of less than 8.0.

After hydrolysis, major flavonoids in the above high max SIF (>100 mg 100 g^{-1} FW) seasonings were apigenin (0–570.0) and myricetin (0–8.1) in fresh parsley; quercetin (170.0) and kaempferol (7.0) in fresh lovage; quercetin (7.5–79.0), isorhamnetin (43.5), and kaempferol (0–40.0) in fresh dill; and quercetin (1.9–80.9) and luteolin (0–57.9) in fresh angelica.

2.7.4 Other Phenolic Compounds

The other phenolic compounds (mg 100 g^{-1} FW) with high maximum values in seasonings were eugenol (9381.7–14650.0) and acetyl eugenol (2075.1) in cloves; curcumin (580.0–5650.0), demethoxycurcumin (830.0–3360.0), and bisdemethoxycurcumin (420.0–2160.0) in dried turmeric; anethole (5407.9) in star anise; carnosic acid (126.6–1218.0), rosmanol (124.1), and carnosol (53.0) in fresh rosemary; carnosic acid (299.0–716.0) in dried common sage; curcumin (50.0–580.0) in curry powder; *6*-gingerol (187.3) in dried ginger; and coumarin (9.8–43.2) in Chinese cinnamon.

2.8 Seeds

Phenolics found in seeds include 16 phenolic acids, 76 flavonoids, 3 stilbenes, 18 lignins, and 4 other polyphenols [9]. The major phenolics in seeds are summarized in Table 81.10.

2.8.1 TPC

Table 81.10 shows TPC in decreasing order according to the maximum values reported in seeds [4]. TPC (mg 100 g^{-1} FW) measured in nuts included values of 1,580–3,673 for raw chestnut, 1,284–2,016 for pecan nut, 867–1,657 for pistachio, 1,558–1,625 for walnut, 291–835 for hazelnut, 396–420 for peanut, 127–418 for almond, 112–310 for Brazil nut, 137–274 for cashew nut, 46–156 for macadamia nut, 91–114 for dehulled peanut, 0.1–108 for roasted dehulled peanut, 47–71 for dehulled almond, and 32–68 for pines. Common beans had TPC of 55–9,360 for raw whole common bean, 56–4,400 for raw whole black common bean, 42–2,665 for raw dehulled common bean, 62–2,276 for raw dehulled black common bean, 9–490 for raw whole white common bean, and

Table 81.10 TPC range (mg/100 g FW) and major phenolics in seeds

Name	TPC	Major phenolics
Common bean [others], whole, raw	55–9,360	Polymers (>10 mers), 07–10-mers
Adzuki bean, whole, raw	8,970	
Lentils, whole, raw	6,346–6,760	(+)-Catechin *3-O*-glucose
Broad bean seed, whole, raw	55–5,590	(−)-Epicatechin, (−)-epigallocatechin
Common bean [black], whole, raw	56–4,400	Ferulic acid, *p*-coumaric acid
Chestnut, raw	1,580–3,673	Ellagic acid, gallic acid
Common bean [others], dehulled, raw	42–2,665	Ferulic acid, *5*-caffeoylquinic acid
Common bean [black], dehulled, raw	62–2,276	Ferulic acid, *5*-caffeoylquinic acid
Dried pea, whole, raw	2–2,260	
Pecan nut	1,284–2,016	Polymers (>10 mers), 04–06-mers
Pistachio	867–1,657	Polymers (>10 mers), 04–06-mers
Walnut	1,558–1,625	Myricetin, ellagic acid
Pigeon pea, whole, raw	104–1,328	
Hazelnut	291–835	Polymers (>10 mers), 07–10-mers
Common bean [white], whole, raw	9–490	Kaempferol *3-O*-glucoside
Peanut	396–420	Resveratrol, daidzein
Almond	127–418	Polymers (>10 mers), 04–06-mers
Brazil nut	112–310	
Cashew nut	137–274	02-mers, (−)-epicatechin
Macadamia nut	46–156	
Peanut, dehulled	91–114	*p*-Coumaric acid
Climbing bean, whole, raw	109	
Peanut, roasted, dehulled	0.1–108	*p*-Coumaric acid
Almond, dehulled	47–71	
Pines	32–68	
Common bean [white], dehulled, raw	42–53	Ferulic acid, *p*-coumaric acid
Broad bean seed, dehulled, raw	33	*p*-Coumaric acid, ferulic acid
Dried pea, dehulled, raw	16	Ferulic acid, syringic acid

42–53 for raw dehulled white common bean. Other beans had TPC of 8,970 for raw whole adzuki bean, 55–5,590 for raw whole broad bean seed, 109 for raw whole climbing bean, and 33 for raw dehulled broad bean seed. TPC in lentils was 6,346–6,760 for raw whole lentils. Peas had TPC of 2–2,260 for raw whole dried pea, 104–1,328 for raw whole pigeon pea, and 16 for raw dehulled dried pea.

2.8.2 Phenolic Acids

Seeds with high maximum SIPA (mg 100 g^{-1} FW) were raw chestnut (547.0–1959.0), sunflower seed meal (68.5–1265.6), dehulled walnut (21.1–70.9), walnut (25.0–32.0), Japanese walnut (9.0–24.0), and roasted dehulled peanut (2.0–11.7). Other seeds had maximum SIPA of less than 7.0. Major phenolic acids (mg 100 g^{-1} FW) in the above seeds with high max SIPA (>20 mg 100 g^{-1} FW) were ellagic (271.0–1052.0) and gallic (276.0–907.0) acids in raw chestnut, *5*-caffeoylquinic (63.0–1250.0) and caffeic (5.5–15.6) acids in sunflower seed meal, syringic (16.6–57.5) and ellagic (3.3–9.8) acids in dehulled walnut, ellagic acid (25.0–32.0) in walnut, and ellagic acid (9.0–24.0) in Japanese walnut without conducting a hydrolysis step.

After hydrolysis, seeds with high maximum SIPA were flaxseed meal (430.0–820.0), walnut (401.0–497.8), Japanese walnut (191.6–285.3), defatted soy flour (59.9), raw whole white common bean (48.2), raw whole black common bean (24.4–47.2), raw whole other common beans (0–39.3), and raw dehulled cowpea (16.3). The maximum SIPA was less than 10.0 for the other seeds. The major phenolic acids in the above seeds with high maximum SIPA (>50 mg 100 g^{-1} FW) were identified as ferulic acid *4-O*-glucoside (210.0–440.0) and *p*-coumaric acid *4-O*-glucoside (220.0–380.0) in flaxseed meal; ellagic acid (222.0–283.0) and valoneic acid dilactone (179.0–214.8) in walnut; ellagic acid (120.0–167.0) and valoneic acid dilactone (71.6–118.3)in Japanese walnut; and syringic (28.8), ferulic (15.7), and *p*-coumaric (9.4) acids in defatted soy flour.

2.8.3 Flavonoids

Seeds with high maximum values of SIF (mg 100 g^{-1} FW) were soy flour (140.6–887.9), roasted soy nut soybean (136.2–350.4), soy tofu (13.4–324.8), soy tempeh (37.6–298.8), soy paste cheonggukang (245.3–282.1), green soybean edamame (19.1–252.5), soy milk powder (40.0–245.1), soy paste nato (77.1–172.4), soy yogurt (48.8–121.9), raw whole common bean others (54.0–95.5), raw whole white common bean (19.3–82.8), fermented soy tofu sufu (7.5–64.7), raw whole black common bean (54.3), raw whole broad bean seed (49.4), soy pudding (29.1–45.2), soy sausage (19.9–39.4), raw soy burger (0.5–23.8), raw soybean sprout (3.5–17.3), pecan nut (16.7), almond (5.0–14.4), and soy bacon bits (14.4). Other seeds had maximum SIF of less than 9.0.

The major flavonoids (mg 100 g^{-1} FW) identified in the above seeds with high maximum SIF (>100 mg 100 g^{-1} FW) were genistin (1.9–229.0), *6″-O*-malonyldaidzin (26.1–179.3), daidzin (1.3–163.4), *6″-O*-malonylgenistin (102.3–139.5), and *6″-O*-malonylglycitin (5.7–61.1) in soy flour; genistin (55.1–96.8), *6″-O*-acetylgenistin (5.4–74.3), *6″-O*-acetyldaidzin (7.1–68.0), and daidzin (46.0–47.4) in roasted soy nut soybean; *6″-O*-malonylgenistin (4.0–78.8), *6″-O*-malonyldaidzin (1.3–75.3), genistin (4.6–56.2), and daidzin (2.5–45.3) in soy tofu; *6″-O*-malonylgenistin (11.1–75.0), glycitein (0.9–51.8), *6″-O*-malonyldaidzin (6.4–40.4), genistin (6.5–34.6), daidzein (6.9–31.8), genistein (3.1–19.3), and daidzin (0.2–18.2) in soy tempeh; daidzin (79.1–92.6), genistin (86.6–90.8), *6″-O*-acetyldaidzin (34.1), *6″-O*-malonylgenistin (21.8–21.9), and daidzein (3.8–20.4) in soy paste cheonggukang; *6″-O*-malonylgenistin (6.9–85.1), *6″-O*-malonyldaidzin (5.5–51.5), daidzin (1.0–45.1), and genistin (1.3–43.0) in green soybean edamame; genistin (10.3–77.5), daidzin (6.2–52.5), *6″-O*-malonylgenistin (12.8–31.6), and *6″-O*-malonyldaidzin (3.9–26.8) in soy milk powder; genistin (28.3–61.9), daidzin (34.7–56.0), and glycitin (2.3–26.5) in soy paste nato; and genistin (22.9–32.2), *6″-O*-malonylgenistin (5.4–25.1), daidzin (15.7–18.3), and *6″-O*-acetylgenistin (0.7–12.4) in soy yogurt without performing a hydrolysis step.

After hydrolysis, seeds with high maximum values of SIF were walnut (0–456.5), soy bacon bits (6.0–149.8), soy flour (47.3–129.9), raw soybean sprout (0.8–77.0), roasted soybean soy nut (74.7), soy cheese (59.3), soy tofu (3.8–40.9), soy paste miso (4.1–40.1), soy meat (7.4–39.2), green soybean edamame (26.6), raw soy burger (0.3–24.8), soy flakes (21.1), soy tempeh (18.3), soy sausage (0.3–16.7), raw whole common bean others (0.4–15.7), and soy yogurt (10.2). Others in max SIF were less than 8.0. The major flavonoids in the above seeds with high maximum values of SIF (>50 mg 100 g^{-1} FW) were myricetin (0–456.5) in walnut, daidzein (1.0–93.9) and genistein (5.0–45.9) in soy bacon bits, daidzein (30.9–54.1) and genistein (12.4–62.1) in soy flour, genistein (0.5–51.7) and daidzein (0.3–22.5) in raw soybean sprout, genistein (36.3) and daidzein (28.4) in roasted soybean soy nut, and genistein (38.2) and daidzein (21.1) in soy cheese.

2.8.4 Other Phenolic Compounds

The other phenolic compounds (mg 100 g^{-1} FW) with high maximum values in seeds were juglone (6.9–19.2) in dehulled walnut; sesamin (538.1–538.1), sesamolin (133.9), and sesaminol (102.9) in sesame seed meal; >10 polymers (252.9–459.6), 07–10-mers (75.7–135.6), 04–06-mers (80.0–125.9), 02-mers (19.4–32.0), and 03-mers (18.1–29.1) in raw whole common bean others; >10 polymers (322.4), 07–10-mers (74.6), and 04–06-mers (67.7) in hazelnut; >10 polymers (223.0), 04–06-mers (101.4), 07–10 mers (84.2), 02-mers (42.1), and 03-mers (26.0) in pecan nut; >10 polymers (122.5), 04–06-mers (42.2), and 07–10-mers (37.9) in pistachio; >10 polymers (80.3), 04–06-mers (40.0), and 07–10-mers (37.7) in almond; and 04–06-mers (22.1) and >10 polymers (20.0) in walnut.

After hydrolysis, the other phenolic compounds with high maximum values in seeds were secoisolariciresinol (81.7–3236.7), matairesinol (0–52.0), lariciresinol (3.0–36.7), and pinoresinol (3.3–24.6) in flaxseed meal and sesamin (62.72), pinoresinol (29.3–47.1), matairesinol (1.1–39.3), and lariciresinol (9.5–13.1) in sesame seed meal.

2.9 Vegetables

Phenolics found in vegetables include 51 phenolic acids, 92 flavonoids, 6 lignins, and 12 other polyphenols [9]. The major phenolics in vegetables are summarized in Tables 81.11 and 81.12.

2.9.1 TPC

Tables 81.11 and 81.12 show TPC in decreasing order according to the maximum values reported in vegetables [4]. Cabbages had TPC (mg 100 g^{-1} FW) of 254–679 for raw red common cabbage, 91–351 for raw brussels sprouts, 25–337 for raw broccoli, 10–274 for raw cauliflower, 53–224 for raw green common cabbage, 145–206 for raw kale, 183 for raw mustard cabbage, 105–179 for raw savoy cabbage, 109 for raw black cabbage, 108 for raw Italian cabbage, 57–86 for sauerkraut, and 15 for raw white common cabbage. Chinese cabbages had TPC of 119–268 for raw pak choy and 75–158 for raw napa cabbage.

TPC of fruit vegetables included 18–580 for raw green olive, 158–579 for raw red chilli pepper, 114–566 for raw yellow sweet pepper, 101–524 for raw green chilli pepper, 59–424 for raw red sweet pepper, 257–385 for raw yellow chilli pepper, 45–309 for raw green sweet pepper, 21–290 for raw black olive, 24–187 for raw avocado, 24–96 for raw whole tomato, and 57–65 for raw whole purple eggplant.

Table 81.11 TPC range (mg/100 g FW) and major phenolics in vegetables

Name	TPC	Major phenolics
Swiss chard leaves [red], raw	1,320	Kaempferol, quercetin, myricetin
Globe artichoke, heads, raw	731–1,305	*5*-Caffeoylquinic acid, luteolin
Swiss chard leaves [white], raw	830	Syringic acid, ferulic acid
Dandelion, raw	26–745	
Common cabbage [red], raw	254–679	Quercetin, luteolin, apigenin
Olive [green], raw	18–580	Oleuropein, hydroxytyrosol, sinapic acid
Chilli pepper [red], raw	158–579	Quercetin, luteolin
Sweet pepper [yellow], raw	114–566	Luteolin, quercetin
Chilli pepper [green], raw	101–524	Quercetin, luteolin
Spinach, raw	33–484	*5,4′*-Dihydroxy-*3,3′*-dimethoxy-*6*:*7*-methylenedioxyflavone *4′*-*O*-glucuronide
Green bean, raw	5–458	Quercetin *3*-*O*-rutinoside, (−)-epicatechin
Sweet pepper [red], raw	59–424	Luteolin, feruloyl glucose, *p*-coumaroyl glucose
Swiss chard stems [red], raw	410	Syringic acid, ferulic acid, *p*-coumaric acid
Chilli pepper [yellow], raw	257–385	Quercetin, luteolin
Brussels sprouts, raw	91–351	Kaempferol, luteolin, quercetin
Broccoli, raw	25–337	Kaempferol *3*-*O*-sophoroside, *3*-caffeoylquinic acid
Sweet pepper [green], raw	45–309	Quercetin, luteolin, quercetin *3*-*O*-rhamnoside
Swiss chard stems [white], raw	290	Vanillic acid, *p*-coumaric acid, ferulic acid
Olive [black], raw	21–290	Hydroxytyrosol, verbascoside
Cauliflower, raw	10–274	Sinapic acid, quercetin,
Pak choy, raw	119–268	Quercetin, kaempferol, apigenin
Common cabbage [green], raw	53–224	Kaempferol, quercetin
Kale, raw	145–206	Kaempferol, quercetin
Avocado, raw	24–187	04–06-mers, 02-mers, 03-mers
Mustard cabbage, raw	183	
Onion [yellow], raw	17–181	Quercetin *3,4′*-*O*-diglucoside
Savoy cabbage, raw	105–179	Kaempferol, apigenin, quercetin
Kohlrabi, raw	168	Kaempferol, luteolin
Red beetroot, raw	164	Luteolin, quercetin
Potato, raw	17–163	*5*-Caffeoylquinic acid, caffeic acid
Napa cabbage, raw	75–158	Quercetin, kaempferol
Pumpkin, raw	16–157	Syringic acid, *5*-caffeoylquinic acid
Carrot, raw	8–156	*5*-Caffeoylquinic acid, caffeic acid
Burdock root, raw	141	*5*-Caffeoylquinic acid
Asparagus, raw	14–141	Quercetin *3*-*O*-rutinoside, secoisolariciresinol
Arugula, raw	136	
Lettuce [green], raw	4–131	Quercetin *3*-*O*-(6"-malonyl-glucoside), quercetin
Chicory [red], raw	130	*5*-Caffeoylquinic acid, chicoric acid
Onion [red], raw	82–126	Quercetin *3,4′*-*O*-diglucoside, quercetin *4′*-*O*-glucoside

Table 81.12 TPC range (mg/100 g FW) and major phenolics in vegetables

Name	TPC	Major phenolics
Beet greens, raw	37–118	
Shallot [pink], raw	115	
Lettuce [red], raw	114	Quercetin *3-O*-(*6*″-malonyl-glucoside), quercetin
Black cabbage, raw	109	
Italian cabbage, raw	108	
Tomato, whole, raw	24–96	*5*-Caffeoylquinic acid, quercetin
Leek, raw	42–88	Kaempferol, quercetin
Sauerkraut	57–86	Apigenin
Eggplant [purple], whole, raw	57–65	Protocatechuic acid
Radish, raw	29–61	Kaempferol
Celeriac, raw	59	Apigenin, quercetin
Turnip root, raw	55	
Squash, raw	12–51	
Onion [white], raw	46	Quercetin *3,4*′*-O*-diglucoside
Zucchini, raw	26–38	Quercetin *3-O*-rutinoside
Fennel	28	
Cucumber, raw	14–27	Kaempferol, quercetin
Common cabbage [white], raw	15	Quercetin, kaempferol
Celery stalks, raw	13–15	Bergapten, xanthotoxin, isopimpinellin

TPC of 16–157 for raw pumpkin, 12–51 for raw squash, 26–38 for raw zucchini, and 14–27 for raw cucumber were obtained among gourds.

Leafy vegetables had TPC of 1,320 for raw red Swiss chard leaves (Fig. 81.2), 830 for raw white Swiss chard leaves, 26–745 for raw dandelion, 33–484 for raw spinach, 136 for raw arugula, 4–131 for raw green lettuce, 130 for raw red chicory, 37–118 for raw beet greens, and 114 for raw red lettuce.

TPC measured in onion-family vegetables included 17–181 for raw yellow onion, 82–126 for raw red onion, 115 for raw pink shallot, 42–88 for raw leek, and 46 for raw white onion. Among pod vegetables, raw green bean had TPC of 5–458.

Root vegetables had TPC of 168 for raw kohlrabi, 164 for raw red beetroot, 8–156 for raw carrot, 141 for raw burdock root, 30–61 for raw radish, 59 for raw celeriac, and 55 for raw turnip root.

Shoot vegetables had TPC of 731–1,305 for raw globe artichoke heads, 14–141 for raw asparagus, and 28 for fennel.

Stalk vegetables had TPC of 410 for raw red Swiss chard stems, 290 for raw white Swiss chard stems, and 13–15 for raw celery stalks.

TPC of tubers was 17–163 for raw potato.

2.9.2 Phenolic Acids

Vegetables with high maximum values of SIPA (mg 100 g^{-1} FW) were raw red chicory (84.8–555.8), raw black olive (1.4–523.0), raw globe artichoke heads (136.0–305.1), raw green olive (21.3–303.5), raw green chicory (91.1–294.1),

Fig. 81.2 Raw red Swiss chard leaves and stem

raw burdock root (126.8), raw potato (11.1–51.2), raw broccoli (3.2–48.5), and raw carrot (7.0–20.6). Other vegetables had maximum SIPA of less than 10.0.

The major phenolic acids (mg 100 g^{-1} FW) in the above vegetables with maximum SIPA (>100 mg 100 g^{-1} FW) were 5-caffeoylquinic (51.3–432.9), chicoric (14.2–59.7), gallic (8.0–30.9), and protocatechuic (11.2–25.7) acids in raw red chicory; verbascoside (0–320.2), syringic (0–74.4), sinapic (0–40.0), *m*-coumaric (0–25.0), and protocatechuic (0–21.0) acids in raw black olive; 5-caffeoylquinic acid (136.0–305.1) in raw globe artichoke heads; sinapic acid (5.0–83.0), verbascoside (0–66.5), cinnamic (4.0–26.0), and *o*-coumaric (0–20.0) acids in raw green olive; 5-caffeoylquinic (43.2–158.6), chicoric (21.8–61.1), gallic (12.8–38.9), and protocatechuic (13.4–30.2) acids in raw green chicory; and 5-caffeoylquinic acid (126.8) in raw burdock root without performing any hydrolysis step.

After hydrolysis, vegetables with high maximum values of SIPA were raw black olive (151.0–464.0), raw green olive (81.0–360.0), raw red Swiss chard leaves (102.5) (Fig. 81.2), raw white Swiss chard leaves (88.9), raw red Swiss chard stems (27.1) (Fig. 81.2), raw white Swiss chard stems (23.9), and raw carrot (20.7). The maximum SIPA was less than 5.0 for the other vegetables. The major phenolic acids in the above vegetables with maximum SIPA (>50 mg 100 g^{-1} FW) were homovanillic (36.0–111.0), protocatechuic (43.0–74.0), syringic (0–48.0), sinapic (14.0–40.0), *5*-caffeoylquinic (2.0–40.0), vanillic (17.0–32.0), and *m*-coumaric (0–25.0) acids in raw black olive; sinapic (7.0–83.0), *o*-coumaric (31.0–45.0), homovanillic (17.0–43.0), ferulic (4.0–40.0), cinnamic (13.0–29.0), and caffeic (0–28.0) acids in raw green olive; syringic (44.9), caffeic (14.8), and *p*-coumaric (10.4) acids in raw red Swiss chard leaves; and syringic (45.1) and ferulic (10.8) acids in raw white Swiss chard leaves.

2.9.3 Flavonoids

Vegetables with high maximum values of SIF (mg 100 g^{-1} FW) were raw black olive (15.0–552.2), raw red onion (67.2–403.3), raw yellow onion (27.2–290.5), raw spinach (33.6–288.4), raw broad bean pod (169.4–209.7), raw globe artichoke heads (3.2–112.4), raw shallot (112.2), raw curly endive (7.3–40.8), raw red lettuce (12.2–33.1), raw asparagus (0–28.7), raw broccoli (27.8), raw green bean (1.4–25.4), raw escarole endive (18.2), and raw green lettuce (0.1–15.5). Other vegetables had maximum SIF of less than 10.0.

The major flavonoids (mg 100 g^{-1} FW) in the above vegetables with high maximum values of SIF (>100 mg 100 g^{-1} FW) were identified as cyanidin *3-O*-rutinoside (0–320.6), cyanidin *3-O*-glucoside (0–88.2), quercetin *3-O*-rutinoside (11.1–78.7), and luteolin *7-O*-glucoside (0.5–29.2) in raw black olive; quercetin *3,4′-O*-diglucoside (20.2–207.5), quercetin *4′-O*-glucoside (30.0–114.3), and quercetin (0–55.8) in raw red onion; quercetin *3,4′-O*-diglucoside (11.4–135.8), quercetin *4′-O*-glucoside (13.8–83.0), and isorhamnetin (0–53.9) in raw yellow onion; *5,4′*-dihydroxy-*3,3′*-dimethoxy-*6*:*7*-methylenedioxyflavone *4′-O*-glucuronide (6.8–113.1), patuletin *3-O*-glucosyl-(1->6)-[apiosyl(1->2)]-glucoside (7.2–45.0), spinacetin *3-O*-(*2″*-feruloylglucosyl)(1->6)-[apiosyl(1->2)]-glucoside (6.9–26.5), *5,3′,4′*-trihydroxy-*3*-methoxy-*6*:*7*-methylenedioxyflavone *4′-O*-glucuronide (0–22.3), spinacetin *3-O*-glucosyl-(1->6)-glucoside (1.6–22.1), spinacetin *3-O*-glucosyl-(1->6)-[apiosyl(1->2)]-glucoside (5.4–21.9), patuletin *3-O*-(*2″*-feruloyl-glucosyl)(1->6)-[apiosyl(1->2)]-glucoside (4.0–20.2), and jaceidin *4′-O*-glucuronide (1.8–15.4) in raw spinach; (−)-epicatechin (37.6), prodelphinidin dimer B3 (23.5), quercetin *3-O*-galactoside *7-O*-rhamnoside (6.1–22.2), procyanidin dimer B4 (18.5), (−)-epigallocatechin (17.4), (+)-catechin (16.2), procyanidin dimer B2 (12.1), procyanidin dimer B1 (11.3), quercetin *3-O*-(*6″*-acetyl-galactoside) *7-O*-rhamnoside (1.8–10.8), and kaempferol *3-O*-(*6″*-acetyl-galactoside) *7-O*-rhamnoside (2.0–10.0) in raw broad bean pod; luteolin (0–84.2), luteolin *7-O*-glucuronide (0–16.6), and apigenin *7-O*-glucuronide (3.2–11.6) in raw globe artichoke heads; and quercetin *3,4′-O*-diglucoside (74.6) and quercetin *4′-O*-glucoside (35.6) in raw shallot without performing any hydrolysis.

After hydrolysis, vegetables with high maximum values of SIF were raw red lettuce (2.2–91.1), raw spinach (0–88.9), raw yellow chilli pepper (5.8–88.7), raw white onion (0–63.4), raw kale (0.5–59.0), raw red onion (5.6–55.9), raw Pak choy (54.4), raw yellow onion (2.8–52.4), raw green chilli pepper (0–32.8), raw whole cherry tomato (2.1–29.5), raw Swede (0–26.5), raw celery stalks (0–23.1), raw broccoli (4.6–20.9), raw red Swiss chard leave (18.9), raw green lettuce (0–17.0), raw garden cress (14.0), raw whole tomato (0.1–12.9), raw white Swiss chard leaves (11.1), and raw red chilli pepper (0.7–10.0). Other vegetables had maximum SIF of less than 8.0.

After hydrolysis, the major flavonoids in the above vegetables with high maximum values of SIF (>50 mg 100 g^{-1} FW) were identified as quercetin (2.2–91.1) in raw red lettuce, kaempferol (0–55.0) and quercetin (0–27.2) in raw spinach, quercetin (4.2–78.4) and luteolin (1.6–10.4) in raw yellow chilli pepper, quercetin (0–63.4) in raw white onion, kaempferol (0.5–47.0) and quercetin (0–12.0) in raw kale, quercetin (5.6–45.0) and kaempferol (0–4.5) in raw red onion, quercetin (39.0) and kaempferol (9.6) in raw pak choy, and quercetin (2.8–46.3) and myricetin (0–4.1) in raw yellow onion.

2.9.4 Other Phenolic Compounds

The other phenolic compounds (mg 100 g^{-1} FW) with high maximum values in vegetables were hydroxytyrosol (0–413.3), oleuropein (3.6–240.6), oleuropein-aglycone (2.0–199.1), tyrosol (0.9–118.6), demethyloleuropein (1.3–60.0), and oleuropein-aglycone *mono*-aldehyde (1.0–17.0) in raw black olive; oleuropein (0–325.0), hydroxytyrosol (4.3–116.0), oleuropein-aglycone (36.0–81.0), oleuropein-aglycone mono-aldehyde (13.0–22.0), tyrosol (0–21.0), and demethyloleuropein (12.0–14.0) in raw green olive; and 04–06-mers (3.2), 02-mers (1.5), and 03-mers (1.4) in raw avocado.

3 Conclusion

Phenolic compounds are important phytochemicals in foods purported to protect health and prevent diseases. Total phenolic content is a useful tool to predict the antioxidant potential of food sources. To understand the role of dietary sources of plant foods in health, food composition databases of phenolic compounds need to be complete taking into account geographical origin, varietal and environmental factors, and analytical techniques used. Regardless of the challenges, there is a full gamut of dietary foods from plant sources that serve as significant sources of phenolics. Included among the top foods abundant in phenolics are cloves, cocoa powder, dried peppermint, star anise, dried Mexican oregano, celery seed, black chokecherry, dark chocolate, flaxseed meal, and black elderberry.

specific health or medical benefits, in addition to the basic nutritional value found in the food. A significant source for nutraceutical ingredients is bioactive phytochemicals like alkaloids, various terpenoids, and polyphenols (anthocyanins, flavones, flavanols, isoflavones, stilbenes, ellagic acid, etc.). A variety of these phytochemical compounds form an integral part of the nutraceutical market being antioxidants, and they help in the prevention of many degenerative and chronic diseases. In this review, classification of nutraceuticals, phytochemical classes as nutraceutical ingredients, antioxidants as nutraceuticals, and advantages and drawbacks along with nutraceutical market development are discussed.

Keywords

Antioxidants • dietary supplements • functional foods • nutraceuticals • phytochemicals

Abbreviations

CAGR	Compound annual growth rate
FMCG	Fast-moving consumer goods
ROS	Reactive oxygen species

1 Introduction

Nutraceutical, a term coined by combining the words "nutrition" and "pharmaceutical," is defined by Health Canada as "a product isolated or purified from foods that is generally sold in medicinal forms not usually associated with food." A nutraceutical is demonstrated to have a physiological benefit or provide protection against chronic disease [1]. The term nutraceutical was coined in 1989 by Stephen DeFelice, founder and chairman of the Foundation for Innovation in Medicine, an American organization which encourages medical health [2–5]. According to DeFelice, "a nutraceutical is any substance that is a food or a part of food and provides medical or health benefits, including the prevention and treatment of disease." The term nutraceutical is a hybrid term coined from nutrition and pharmaceuticals (Fig. 82.1). Within European Union law, the legal categorization of a nutraceutical is, in general, made on the basis of its accepted effects on the body. Thus, if the substance contributes only to the maintenance of healthy tissues and organs, it may be considered to be a food ingredient. If, however, it can be shown to have a modifying effect on one or more of the body's physiological processes, it is likely to be considered to be a medicinal substance. Within European medicines law, a nutraceutical can be defined as a medicine for two reasons:

1. If it presented for the prevention, treatment, or cure of a condition or disease
2. If it can be administered with a view to restoring, correcting, or modifying physiological functions in human beings. Such products may range from isolated

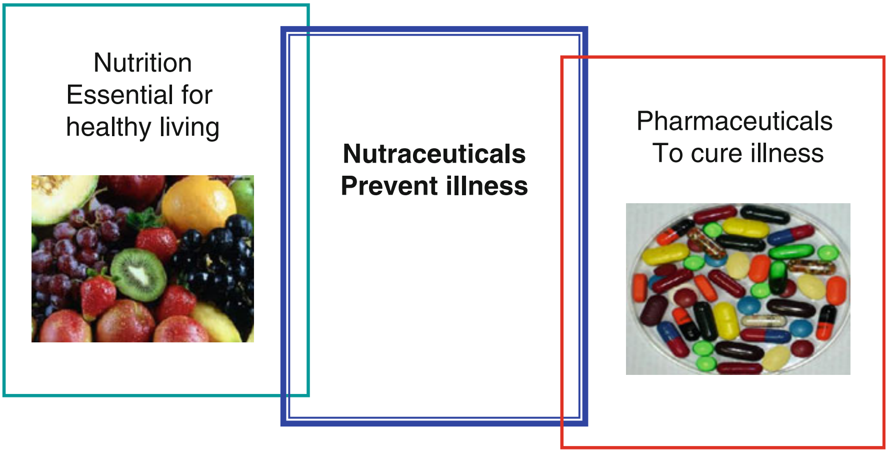

Fig. 82.1 Nutraceutical – term coined from nutrition and pharmaceuticals

nutrients, dietary supplements, and specific diets to genetically engineered designer foods and herbal products [2, 6]. They are natural bioactive, chemical compounds that have health-promoting, disease-preventing, or medicinal properties and found in a mosaic of products. They can be derived from plants (e.g., *Echinacea*, fenugreek), from animals and microorganisms (e.g., essential fatty acids, enzymes), and from marine sources (e.g., glucosamine, chitosan, fish oils). Flaxseed and fish oil are beneficial in cardiovascular diseases. Flaxseeds contain lignans and fiber which are involved in cardiac protection.

The concept of nutraceuticals is not entirely new, although it has evolved considerably over the years. In the early 1900s, food manufacturers in the United States began adding iodine to salt in an effort to prevent goiter (an enlargement of the thyroid gland), representing one of the first attempts at creating a functional component through fortification. Today, researchers have identified hundreds of compounds with functional qualities, and they continue to make new discoveries surrounding the complex benefits of phytochemicals (nonnutritive plant chemicals that have protective or disease-preventive properties) in foods. Table 82.1 represents a sample of available nutraceuticals, their components, their sources, and their potential health benefits. The main attractions of nutraceuticals are their lack of side effects and the possibility that they may be able to affect beneficially the disease course rather than just ameliorating symptoms. They play important role in the treatment of many diseases (Fig. 82.2).

There is a slight difference between the functional foods and nutraceuticals. When food is being cooked or prepared using “scientific intelligence” with or without knowledge of how or why it is being used, the food is called “functional food.” Thus, functional food provides the body with the required amount of vitamins, fats, proteins, carbohydrates, etc., needed for its healthy survival. When

Table 82.1 Functional components of available nutraceuticals, their sources, and their potential health benefits

S. no.	Functional components	Source	Potential health benefits
1.	*Carotenoids*		
	Alpha carotene	Carrots, sweet potatoes, pumpkin, winter squash, broccoli, peas, spinach, turnips, lettuce	Neutralizes free radicals that may cause damage to cells, boosts cellular antioxidant defenses, protects cornea against UV light
	Beta carotene	Carrots, oat, pumpkin, sweet potato	
	Lutein	Green vegetables, corn, egg yolk	Anticancer (colon), reduces risk of macular degeneration
	Zeaxanthine	Eggs, citrus, corn	Maintenance of healthy vision
	Lycopene	Tomatoes, watermelon, guava, papaya	Antioxidant, reduces prostate cancer
2.	*Saponins*	Soybeans, chickpea	Anticancer, lower cholesterol
3.	*Polyphenolic compounds*		
	Flavanones	Citrus fruits	Antioxidant, anticancer
	Flavones	Fruits, vegetables, soybean	Antioxidant, reduce risk of cancer
	Anthocyanins	Blueberries, blackberries, black raspberries	Antioxidant, anticancer, improve visual capacity and brain cognitive performance
	Proanthocyanidins	Fruits (grapes, apples, strawberries), beans, nuts, cocoa	Reduce cardiovascular diseases, improve urinary tract
	Resveratrol	Grapes, raisins, berries, peanuts	Anticancer, reduces cardiovascular diseases and ischemic damage
	Curcumin	Turmeric root	Anticancer, antioxidant, lower blood cholesterol, promotes wound healing, prevents skin wrinkling, inhibits inflammation
	Ellagic acid and ellagitannins	Blackberries, raspberries, strawberries, walnuts, pomegranates	Antiproliferative, antioxidant
	Catechins	Tea, mustard cake, rapeseed some fruits and vegetables and wine	Neutralize free radicals, reduce risk of cancer, protect the skin from UV radiation-induced damage
4.	*Dietary fiber*		
	Soluble fiber (beta glucan)	Oats, barley, peas, beans, apple, psyllium seed husk	Reduce cardiovascular diseases, protects against some cancers, digestive stimulant, lower total cholesterol
	Insoluble fiber	Whole-grain foods, wheat, and corn bran	Reduces the risk of breast or colon cancer, digestive stimulant

(*continued*)

Table 82.1 (continued)

S. no.	Functional components	Source	Potential health benefits
5.	*Fatty acids*		
	Omega-3 fatty acids DHA/EPA	Salmon, flaxseed, olive oil, canola oil	Anti-inflammatory, maintain brain functions, reduce cholesterol deposition.
	Conjugated linoleic acid (CLA)	Milk, cheese, meat products	Improves body composition, reduces cancers
6.	*Phytoestrogens*		
	Isoflavones (genistein, daidzein)	Soybeans, legumes, soy-based food products	Antioxidant, lower LDL cholesterol, reduce menopause symptoms, increase bone strength
	Lignans	Flaxseed, rye, vegetables	Reduce cancer and heart diseases
7.	*Probiotics/prebiotics*		
	Lactobacillus	Yogurt, other dairy products	Improve gastrointestinal health and quality of intestinal microflora
	Fructooligosaccharides	Whole grains, onions, artichokes	
8.	*Glucosinolates*	Cruciferous vegetables	Anticancer, greatest protection against bladder cancer
9.	*Sulfides/thiols*	Garlic and cruciferous vegetables	Improve immune functions
10.	*Tocotrienols*	Grains, palm oil	Inhibit breast cancer cell growth, possess cholesterol-lowering property
11.	*Phytosterols*	Green and yellow vegetables	Anti-inflammatory, block the uptake of cholesterol and facilitate its excretion from the body
12.	*Limonoids*	Citrus fruits	Provide protection to lung tissue
13.	*Nutrients*		
	Vitamins (vitamins A, B, C, E, K)	Food products, fruits, vegetables, milk, eggs, fish	Antioxidant; for growth and development, blood clotting, wound healing, etc.
	Minerals (calcium, selenium, potassium, zinc, copper, cobalt, iodine, iron)	Food products, fruits, vegetables	For growth and development, energy production, etc.
14.	*Sugar alcohols* (xylitol, sorbitol, mannitol, lactitol)	Some chewing gums and other food applications	May reduce risk of dental cavities

functional food aids in the prevention and/or treatment of disease(s) and/or disorder(s) other than anemia, it is called a nutraceutical (Since most of the functional foods act in some way or the other as antianemic, the exception to anemia is considered so as to have a clear distinction between the two terms, functional food and nutraceutical). Examples of nutraceuticals include fortified dairy products (e.g., milk) and citrus fruits (e.g., orange juice) [7].

2 Classification of Nutraceuticals

Nutraceuticals are nonspecific biological therapies used to promote wellness, prevent malignant processes, and control symptoms. It is a broad umbrella term used to describe any product derived from food sources that provides extra health benefits in addition to the basic nutritional value found in foods. The definition of nutraceuticals and related products often depends on the source. Phytochemicals and antioxidants are two specific types of nutraceuticals. It has been proved that phytochemicals found in foods may help to provide protection from diseases such as cancer, diabetes, heart disease, and hypertension, for example, carotenoids found in carrots. Antioxidants may be helpful in avoiding chronic diseases, by preventing oxidative damage in body [8]. There are multiple different types of products that come under the category of nutraceuticals:

1. Dietary supplements
2. Functional foods
3. Medical foods
4. Farmaceuticals

2.1 Dietary Supplements

A dietary supplement, also known as food supplement or nutritional supplement, is a product that contains nutrients derived from food products that are concentrated in liquid or capsule form. The Dietary Supplement Health and Education Act

(DSHEA) of 1994 defined a dietary supplement as “a product taken that contains a ‘dietary ingredient’ intended to supplement the diet and the ‘dietary ingredients’ may include: vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandular, and metabolites.” Dietary supplements do not have to be approved by the US Food and Drug Administration (FDA) before marketing. Dietary supplements are not intended to treat or cure disease [9] whereas nutraceuticals more emphasize the expected results of these products, such as prevention or treatment of diseases [10].

2.2 Functional Foods

Functional foods are designed to allow consumers to eat enriched foods close to their natural state, rather than by taking dietary supplements manufactured in liquid or capsule form. Functional foods are either enriched or fortified by a process called “nutrification.” This practice restores the nutrient content in a food back to similar levels from before the food was processed. For example, Activia® is a probiotic yogurt marketed to help “regulate your digestive system.” It contains a subspecies strain of *Bifidobacterium animalis*, which is marketed as *Bifidus Regularis*®. Other functional foods include red grapes and cranberry juice (for the oligomeric proanthocyanidins, OPCs) and oat bran (for the fiber content), all with health benefits attributed to “non-nutrient” compounds as classified by standard agreement of the term. Cranberry juice cocktail is now marketed as a functional food with a structure/function claim regarding support of urinary tract health. Several companies are marketing breakfast cereals as functional foods when enriched with inulin (an oligosaccharide) or psyllium. Plasma total cholesterol was reduced by 7.9 % and total triglycerides by 21.2 % in young men consuming a 50-g serving of a breakfast cereal fortified with 18 % inulin for 4 weeks [11]. Similarly, breakfast cereal containing 50 g of soluble fiber as psyllium, oat, and barley showed that it significantly reduced total cholesterol and low-density lipoprotein (LDL) concentrations in the blood as compared to a wheat bran cereal for middle-aged mildly hypercholesterolemic men who were already eating a diet low in saturated fat [12]. Plant sterol-enriched margarines, originally projected as dietary supplements but now marketed in the United States as functional foods, were shown to reduce blood cholesterol levels in mildly hypercholesterolemic subjects in a human trial [13]. Functional foods are an emerging field in food science due to their increasing popularity with health-conscious consumers. Like dietary supplements, functional foods are not required to undergo safety and efficacy testing prior to marketing.

2.3 Medical Foods

Medical foods are considered by the FDA as “formulated to be consumed or administered internally under the supervision of a physician, and which is intended for the specific dietary management of a disease or condition for which distinctive nutritional requirements, on the basis of recognized scientific principles, are established by medical evaluation" [14]. Nutraceuticals and supplements are not classified as medical foods as they do not meet these requirements. Medical foods are always designed to meet certain nutritional requirements for people diagnosed with specific illnesses and can be ingested through mouth or tube feeding. They are regulated by the FDA and prescribed/monitored by medical supervision. In order to be considered a medical food, the product must, at a minimum:

1. Be a food for oral ingestion or tube feeding (nasogastric tube)
2. Be labeled for the dietary management of a specific medical disorder, disease, or condition for which there are distinctive nutritional requirements
3. Be intended to be used under medical supervision

Drugs can be found sometimes in foods and can participate in the metabolism. However, these substances are not normally exposed in humans at the dose at which they exert their beneficial effect. Some dietary supplements are drug-like when ingested in amounts that could never be achieved in the diet, even though they are essential nutrients when ingested in smaller quantities, for example, tryptophan is an essential amino acid required for metabolism and incorporation into proteins at low dose in humans. At high dose, it increases 5-hydroxytryptamine levels in brain and thus acts as a drug to treat insomnia.

Unlike dietary supplements, medical foods can be labeled for medical conditions such as Alzheimer disease. Dietary supplements must be labeled for so-called structure and function claims and cannot make claims to treat or prevent disease [9]. For example, ginkgo may be labeled "supports memory function" but not "for treatment of dementia." A drug or medical food could be labeled "for treatment of dementia associated with Alzheimer disease."

2.4 Farmaceuticals

According to a report written for the United States Congress entitled "Agriculture: A Glossary of Terms, Programs, and Laws," farmaceuticals is a melding of the words farm and pharmaceuticals. It refers to medically valuable compounds produced from modified agricultural crops or animals (usually through biotechnology). Proponents believe that using crops and possibly even animals as pharmaceutical factories could be much more cost-effective than conventional methods (i.e., in enclosed manufacturing facilities) and also provide agricultural producers with higher earnings. The term farmaceuticals is more frequently associated, in agricultural circles, with medical applications of genetically engineered crops or animals [15].

3 Phytochemicals as Nutraceuticals

It is well established that plant-derived foods such as wine, fruits, nuts, vegetables, cereals, pulses, and spices exert beneficial effects on human health particularly to conditions related to aging. With increase in average life span, chronic age-related diseases are increasing and correlative with dietary habits such as cardiovascular diseases, neurodegenerative diseases, type II diabetes, and several types of cancer. This has provided a way to look into bioactive molecules present in the diet. These bioactive molecules present in plant-derived foods are not nutrients primarily. These phytochemicals have been shown to exert a wide range of biological activities. Though, they have low potency as compare to a drug molecule, but because of regular intake, they may exert remarkable long-term physiological effects.

Three major classes of secondary metabolites are involved in these phytochemicals, which are alkaloids, terpenes, and phenolics [16]. There are many phytochemicals recognized with health benefits such as sulfur-containing compounds of garlic family, various terpenoids, and polyphenols (anthocyanins, flavones, flavanols, isoflavones, stilbenes, ellagic acid, etc.).

3.1 Alkaloids

Among nitrogen-containing compounds and alkaloids, glucosinolates (present in cruciferous vegetables such as broccoli, cauliflower, and cabbage) and purine alkaloids (present in tea, coffee, etc.) are widely consumed, and their beneficial health-promoting effects are well established [17–19]. Glucosinolates are transformed into isothiocyanates, dithioelthiones, and sulforaphanes. Glucosinolates are released from damaged plant cells and converted by the enzyme myrosinase into isothiocyanates [20]. The current interest in glucosinolates is largely focused on their ability to protect against cancer. There is good evidence from epidemiological studies showing an inverse relationship between consumption of cruciferous vegetables and risk of cancer [21, 22]. These compounds inhibit the neoplastic effects of various carcinogens at a number of organ sites [18].

Caffeine, a purine alkaloid, is mostly ingested in coffee, tea, and cola soft drinks and remains the world’s most widely used pharmacologically active substance. Caffeine is potentially beneficial to human health since it increases extracellular levels of acetylcholine and serotonin (both are neurotransmitter hormones involved in the transmission of nerve impulses) by binding to adenosine receptors in human brain suggesting that caffeine usage can reduce age-related cognitive decline [17].

3.2 Terpenes

Terpenes, present in green foods, soy plants, and cereals, are the largest class of phytonutrients. When terpenes are modified chemically, such as by oxidation or rearrangement of the carbon skeleton, the resulting compounds are generally referred to as terpenoids. Terpenoids are also known as isoprenoids. They are important for plants due to their ability to fix carbon through photosynthetic reactions using photosensitizing pigments like chlorophyll and carotene. These compounds provide protection from certain diseases such as chronic damage and growth dysregulation in animals as these are utilized for hormonal and growth regulatory functions [18]. Tocotrienols and tocopherols are the most studied terpene antioxidants that occur naturally in cereals. Tocotrienols and tocopherols and their derivatives possess antiproliferative and apoptotic effects and help in preventing or reducing the risk of breast cancer in women [23].

Carotenes (tetraterpenes) are a large group of intense red and yellow pigments found in all plants that photosynthesize. Carotenoids (carotenes without oxygen) are fat-soluble pigments widely distributed in plants and animals and possess antioxidant activity. They provide health benefits by decreasing the risk of disease, particularly certain cancers, stroke, heart disease, and eye disease, and strengthen the immune system. Carotene and xanthophylls are two types of molecules that comprise carotenoids. They play an essential nutritional role as they are precursors to vitamin A. Carotenoids from vegetable juices is able to enhance the immune system in those who consume a low-carotenoid diet [24]. The carotenes γ-carotene, lycopene, and lutein protect against uterine, prostate, breast, colorectal, lung, and digestive tract cancers [25, 26]. Limonoids (tetranortriterpenes) are present in the plants belonging to the family Rutaceae (e.g., citrus fruits) and Meliaceae. They possess chemotherapeutic activity [27] and provide protection to lung tissue [28].

Phytosterols are another important terpene subclass. Two sterol molecules that are synthesized by plants are β-sitosterol and its glycoside. In animals, these two molecules exhibit anti-inflammatory, antineoplastic, antipyretic, and immune-modulating activity [29]. Phytosterols were reported to block inflammatory enzymes, for example, by modifying the prostaglandin pathways in a way that protected platelets [30].

3.3 Phenols

In an excellent work, occurrence, structure, and the role of secondary metabolites in human diet have been described [31], which includes phytochemicals present in fruits, vegetables, herbs and spices, nuts, cereals, and beverages [32]. Simple phenols and polyphenolics are widely distributed in the plant kingdom. Phenolics are characterized by having at least one aromatic ring with one or more hydroxyl groups attached [33]. All phenolics can be broadly divided into flavonoids {flavonols (quercetin), flavones (apigenin), flavanols (catechin and its derivatives, proanthocyanidins), anthocyanidins (anthocyanins), flavanones (hesperidin), isoflavones (genistin, diadzin)} and non-flavonoids {stilbenes (resveratrol), phenolic acids (gallic acid, hydroxybenzoic acid, hydroxycinnamic acid)} [31].

Details about structure, biosynthesis, and classification of phenolics are described in the other chapters in this handbook. Plant phenolics have a distinctive ability to form non-covalent, intermolecular complexes with each other and with both large and small molecules. Recognition of the antioxidant activities of many polyphenols has established correlation with the health benefits by such compounds [34]. This leads to the development of commercial products containing free-radical-scavenging phytochemical mixtures, for example, Pycnogenol (procyanidin extracted from *Pinus maritima*). Table 82.2 represents a list of polyphenolic compounds used in nutraceuticals and their biologic effects on human health.

Table 82.2 Polyphenolic compounds used in nutraceuticals and their biologic effects

Active polyphenolic compound	Source	Biologic effect	References
Quercetin	Citrus fruits, apples, onions, parsley, tea, and red wine	Potent antioxidant, anti-inflammatory, antiallergic, anticancer, inhibits mitogen-activated protein (MAP) kinase in human epidermal carcinoma cells, inhibits tumor growth	[35–37]
Ellagic acid	Pomegranate, raspberries, cranberries, *Terminalia chebula* fruit, pecans, and walnuts	Strengthens the immune system, anticancer, induces apoptosis of cancer cells and suppresses angiogenesis, prevents heart disease and liver fibrosis, promotes wound healing, prevents the binding of carcinogens to DNA	[38]
Luteolin	Thyme, peppermint, basil herb, celery, and artichoke	Possesses free-radical scavenging activity, protects human single-cell DNA from oxidative attack	[39]
Curcumin	Turmeric roots	Suppresses the production of cytokines such as IFN-γ, interleukins, and TNF; inhibits the inducible nitric oxide synthase (iNOS)	[40]
Resveratrol	Grapes, raisins, berries, peanuts	Antiaging, anticarcinogenic, anti-inflammatory, and antioxidant properties; improves insulin sensitivity in type 2 diabetic patients	[41]
Apigenin	Parsley, thyme, peppermint, red wine and tomato sauce	Antidepressant, anticancer, antitumor, anti-inflammatory	[42]
Ferulic acid	Rice, wheat, oats, coffee, apple, peanut, orange and pineapple	Provides neuroprotection against oxidative stress-related apoptosis by inhibiting ICAM-1 mRNA expression after cerebral ischemia, hypotension, and hypoglycemia	[43–45]
Caffeic acid	White grapes, white wine, olives, spinach, cabbage, asparagus and, coffee	Exerts antidepressive and anxiolytic-like effects through indirect modulation of the alpha 1A-adrenoceptor system	[46]
Catechins	Tea, chocolate, red wine, apples, and berries	Prevents human plasma oxidation by delaying the consumption of endogenous lipid-soluble antioxidants and inhibiting lipid oxidation	[47]

3.4 Flavonoids

Flavonoids are commonly present in fruits and vegetables, while isoflavones are present in soybean and other pulses. Biological activities of flavonoids include action against free radicals, free-radical-mediated cellular signaling, inflammation, allergies, platelet aggregation, microbes, ulcers, viruses, tumors, and hepatotoxins [18, 21, 48, 49]. Anti-inflammatory and antibacterial activities of flavonoids are well established in case of luteolin and kaempferol, apigenin, and myricetin [18]. Curcumin, a dietary pigmented polyphenol, suppressed tumor promotion in mouse skin possibly through suppression of protein kinase C activity and nuclear oncogene expression [40, 50].

3.5 Catechins and Stilbenes

Major sources of catechins are grapes, berries, cocoa, and green tea. Tea contains considerable amounts of gallic acid esters, such as epicatechin, epicatechin gallate, and epigallocatechin gallate (EGCG). The green tea polyphenol EGCG has beneficial activity in a number of human diseases. It reduces several harmful effects in pathologic conditions (diseases of insulin dysregulation, neurodegenerative diseases, anxiety, memory loss, multiple sclerosis, etc.) in part by altering intracellular signal transduction pathways, by scavenging reactive oxygen and nitrogen species and iron and by affecting cytokine production and expression of neurotransmitters or their receptors [19].

Catechin is one of the major phenolics in grapes and red wines, and it is considered to be responsible for part of the protective effects of red wine against atherosclerotic and cardiovascular diseases [18]. Besides catechin, grapes and red wines contain several other polyphenolics including mainly flavonoids and stilbenes.

Stilbenes constitute large class of compounds, monomers, and oligomers (mainly dimers, trimers, and tetramers), formed by oxidative condensation of the resveratrol monomer. Stilbenes exhibit potent biological activities in vitro on several targets that might be able to influence favorably several physiological and pathological processes, leading to protective effect against cardiovascular diseases and cancer [51]. Epidemiological studies on moderate red wine consumption and reduced risk of cardiovascular diseases are popularly known as “French paradox.”

3.6 Anthocyanins

Anthocyanins impart red-purple color to fruits and flowers due to varying composition of its aglycones such as pelargonidin, cyanidin, peonidin, delphinidin, petunidin, and malvidin. The color of these pigments is influenced by pH and metal ion complexes [52]. A large number of recent reports suggest that anthocyanins and anthocyanin-rich berries or their extracts exhibit a wide range of protective effects with potential benefits for human and animal health [52, 53]. It has been observed that some of these effects may be related to the chemical characteristics and associated antioxidant activity of these compounds. These compounds may also alter gene expression to modulate health benefits [54, 55]. Though, the available data may not be conclusive for beneficial effects of anthocyanins in a particular disease, the increasing number of evidence suggest beneficial effects of anthocyanin-rich berries or their extracts on decrease in oxidative cell damage, increase in levels of reduced glutathione (it protects from reactive oxygen species (ROS)), protection from DNA damage, increased peripheral blood flow, improvement in muscle fatigue, enhanced endogenous oxidant defense system, decreased blood pressure, cardioprotective effects, neuroprotection and inhibition of lung cancer, metastasis, etc. These beneficial effects were concluded on the basis of modulation of disease-related marker measurements [52, 53, 56, 57].

3.7 Flavanones

The most extensively investigated are the aglycones naringenin and hesperetin (glycosidic forms called naringin and hesperidin) present in grapefruits and oranges, respectively. These compounds exhibit a wide range of biological and pharmacological activities, such as antioxidant, hypocholesterolemic, hypoglycemic, prevention of bone losses, and antitumor. These beneficial effects have consequences in protection against diseases like cardiovascular, diabetes, osteoporosis, and cancer [52].

3.8 Isoflavones

Isoflavones are flavonoids commonly called as phytoestrogens and one of the most extensively investigated polyphenols. These are present in soybeans, soybean products, and other pulses, widely consumed in Asian and Southeast Asian countries. Isoflavones have attracted attention mainly due to their role in the amelioration of postmenopausal symptoms such as hot flushes and osteoporosis [52, 58, 59]. The other beneficial and important biological properties have been established which are related to effects on cardiovascular diseases, cognitive functions, and breast and prostate cancers. These conclusions were based on wide-ranging studies and parameters which showed positive effects, for example, reduction of hot flushes, the excretion of bone resorption markers, increase in bone mineral density, the lower LDL and total cholesterol, reduction in colon cancer, and modulation of immune function [60, 61]. Chemical structures of some important molecules of these phytochemical classes are represented in Fig. 82.3.

Phytochemicals, acting as nutraceuticals, play an important role as hormetic compounds and protect from some chronic diseases. Natural environmental stresses stimulate plants to produce specific endogenous chemicals that help protect the plant against the change in conditions that could otherwise be detrimental. These are regarded as “hormetic compounds” [62]. Under stressful conditions, plants produce these specialized chemicals which are transferred to animals while eating

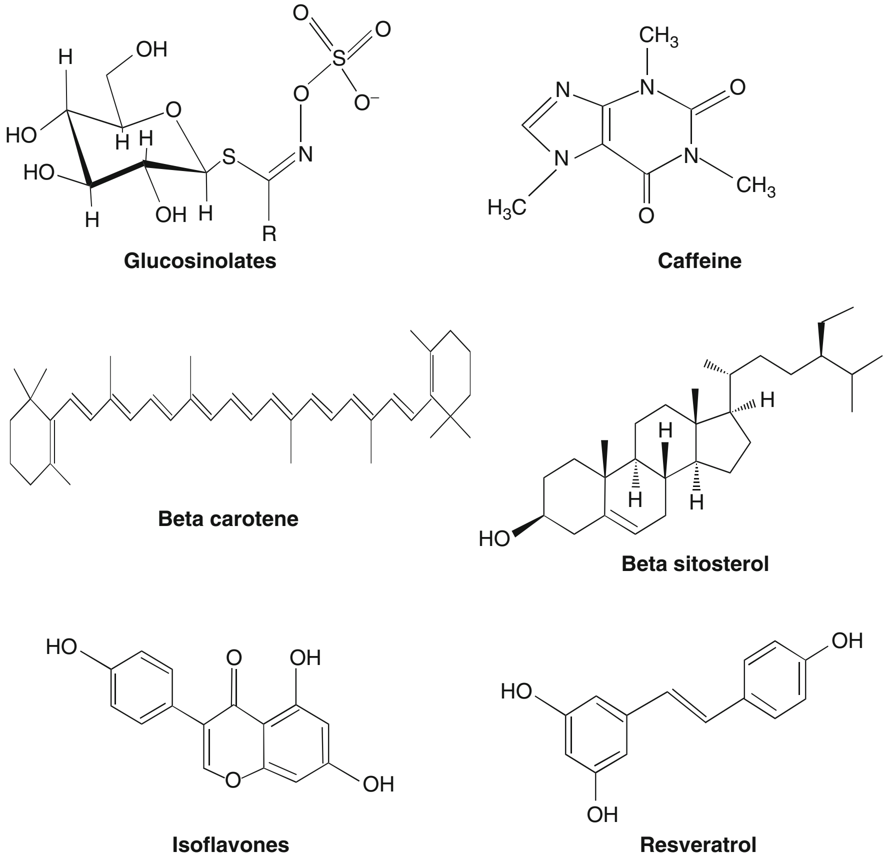

Fig. 82.3 Chemical structures of some important molecules: (**a**) glucosinolates, (**b**) caffeine, (**c**) beta carotene, (**d**) beta sitosterol, (**e**) isoflavones, and (**f**) resveratrol

the plants. Similar protective mechanisms are activated in the cells of the animals as are activated in the cells of the plants. When these plant chemicals act in animals in this way, they are referred as "xenohormetic compounds." The xenohormesis hypothesis [63] proposes that organisms have evolved to respond to stress-signaling molecules (hormetic compounds) produced by dietary plant species where they live, so enabling them to be prepared to resist potentially detrimental effects. Hormetic compounds are present in all vegetables and fruit at different levels. Among the most well known are various berry fruits, broccoli, cocoa, and green tea. One of the most potent hormetic compounds is the polyphenolic compound resveratrol which enhance stress resistance and thus survival pathways in cells via stimulation of sirtuins [64]. The prevention of platelet aggregation by resveratrol involves its selective inactivation of the prostaglandin H2 synthase, cyclooxygenase (Cox)-1, over Cox-2 [65]. Sirtuin or Sir2 proteins are a class of proteins that possess either histone deacetylase or mono-ribosyltransferase activity. Resveratrol, via stimulation of the sirtuin, Sirt1-mediated deacetylation of PGC-1 (peroxisome proliferator-activated receptor-γ coactivator, a crucial regulator of mitochondrial biogenesis and function), improves mitochondrial function and energy balance [66, 67]. Resveratrol also shows dilatation of blood vessels, anti-atherosclerotic effects, lowering of lipid peroxidation, protection of endothelial cells against apoptosis, lowering of blood pressure, oxidative stress, etc. Tea catechins, genistein, quercetin, etc., are other major hormetic compounds.

4 Use of Antioxidants as Nutraceuticals

Antioxidants are substances which retard or prevent the deterioration, damage, or destruction caused by oxidation. Oxidative stress arises by the generation of reactive oxygen species (ROS) and reactive nitrogen species in case of lack of antioxidant defense or by the increase of oxidative processes in the body. Free radicals are a major cause of many degenerative diseases. Many chronic diseases such as cardiovascular diseases, neurodegenerative diseases, and carcinogenic processes are related to free radicals [68]. Antioxidants form an integral part of the nutraceutical market. They are the major part of the most commonly known nutrients. Many compounds possess direct or indirect antioxidant activity. These are quite large in number and diverse in nature and prevent oxidation by neutralizing free radicals at relatively small concentrations. The only official definition of antioxidants is related to "dietary antioxidants" [68]. The definition proposed by the Panel on Dietary Antioxidants and Related Compounds of the Food and Nutrition Board is that "a dietary antioxidant is a substance in food that significantly decreases the adverse effects of ROS, reactive nitrogen species, or both on normal physiological function in human" [69]. Antioxidants prevent the damage at the cellular level by using the following mechanisms: they may reduce the energy of the free radical or suppress radical formation or repair damage and reconstitute membranes. Dietary intake of antioxidants exerts many potential benefits. Ingestion of antioxidants present in fruits and vegetables or administration of synthetic antioxidants decreases certain chronic diseases of aging [8]. For example, high dietary intake of vitamin E may prevent Parkinson's disease [70]. Many vitamins can inhibit low-density lipoproteins (LDL) oxidation, protecting heart against diseases [71]. Terpenes have a unique antioxidant activity as they react with free radicals by partitioning themselves into fatty membranes by virtue their long carbon side chain and help in cure of diseases. Phenols protect plants from oxidative damage. They also act as antioxidant protectant for humans. Phenolic antioxidants such as tocopherols, green tea polyphenols, and phytoestrogens decrease oxidative cell injuries and inflammatory reactions improving brain's health [72, 73]. Scientific focus on the identification of health-protectant components within food and their mechanism(s) of action, such as beta glucan in oat bran, directs attention to the term nutraceuticals rather than to the whole-food concepts implicit in a term such as functional foods [74].

5 Drawbacks of Nutraceuticals

The use of nutraceuticals is increasing due to their easy availability without a prescription from a health-care provider. Natural products are gaining popularity, as in some diseases, standard drugs fail. But, there are some drawbacks in using these products. The lack of quality control is a major area of concern for nutraceuticals [75]. Nutraceuticals are regulated as foods, not as drugs. The plant material quality and manufacturing processes are regulated by food laws, which lack the specificity requirement for botanical drugs. This can have potentially fatal consequences such as contamination with toxins after fungal infection of raw plant material or with other ingredients [76, 77]. Adulterations have been reported in the medical literature because they remain undetected due to a lack of pharmaceutical quality control [78]. Absence of quality control not only increases the risk to the consumer but also results in problems to conduct adequate research that demonstrate the potential health benefit of nutraceuticals or ensures their safety [79].

The purity and dosage requirements of most of the nutraceuticals are not clear. They do not have the scientific basis of dose recommendation [52]. Cost is another main factor in the production of nutraceuticals. The raw materials are often very costly. Most commercially available nutraceuticals contain a mixture of compounds. Often, the non-declared and unhealthy ingredients that are non-herbal in nature and origin are present (e.g., high content of saturated fat in tortilla chips). Thus, an unhealthy food product can be marketed with the implication of a health benefit. Interferences between compounds during uptake are also not known [52, 79].

6 Market Trends of Nutraceuticals

Rapid advances in science and technology, increasing health-care costs, an aging population, and rising interest in attaining wellness through diet are some important factors due to which interest in nutraceuticals is increasing [80]. The 2004 global nutraceuticals market at the retail level is estimated at approximately $106 billion and is poised to grow at a compounded annual growth rate of 6.0 % during 2004–2009 to be around $140 billion in 2009 [80]. Nearly 2/3 of the American population take at least one type of nutraceutical health product. The use of nutraceuticals is increasing as they give desirable therapeutic outcomes with reduced side effects and fit into the today's lifestyle. The nutraceutical industry in the USA is about $ 86 billion. This amount is slightly higher in Europe and in Japan and represents 47 % of the total annual food sales in the Japanese population that consume nutraceuticals [81]. India and China are becoming the fastest-growing markets. One possible explanation for the growth of nutraceuticals in the USA is the aging majority population. As the average age of the citizens continues to rise, the populations increase its focus on health and wellness. Various types of nutraceutical products are currently available in the market which include fortified cereals, vitamins and mineral supplements, energy drinks and tablets, foods to reduce cholesterol levels, and protein powders. [82]. Resveratrol and

Table 82.3 List of some nutraceuticals available in market

S. no.	Brand name	Constituents	Function	Company
1.	Xangold	Lutein esters	Healthy vision	Cognis Nutrition & Health, USA
2.	Cholestaid	Alfalfa saponins extract	Reduce cholesterol	Omni Nutraceuticals, Inc., USA
3.	Green Tea Max™	Active antioxidants such as green tea (leaf) extract, turmeric, red clover, grape seed extract, pine bark extract, ellagic acid	Potent antioxidant; provides nutritional support to heart, brain, and general cellular functions in the body	Nature's Benefit, Inc., USA
4.	Ferradol Food® Powder	Carbohydrate, protein, niacinamide, calcium, iron, zinc, vitamins	Nutritional supplement for children and adults	Pfizer Limited, India
5.	Z Trim	Corn fiber	Zero calorie fat replacer	US Department of Agriculture
6.	IsoExtend-W™	Isoflavones	Women health (menopause)	Physica Pharma, France
7.	Magnum Big C™	Creatine	Increases intracellular energy and endurance; intensifies muscle hardening, strength, and energy	Magnum Nutraceuticals
8.	BeneFlora Probiotic	Lactobacillus, Bifidobacterium and fructooligosaccharides	Improve gastrointestinal health and systematic immunity	Ortis natural herbal supplements, UK
9.	Nutrilite Iron-Folic	Iron and folic acid	Nutritional supplement, energy provider	Amway Corporation, USA
10.	Acai Berry Pure	Antioxidants, vitamins, minerals, amino acids, proteins, and fiber	Reduces free radicals that can cause cancer and other diseases, promotes heart health, and lowers cholesterol	Apex Nutraceuticals, USA

isoflavonoids from soybean are pioneer bioactive molecules put in market in different products ranging from skin improvement products, antioxidant products to antiaging products. Red wine therapy (polyphenolics) includes drinking massage and bath in red wine for the improvement of health [83]. Wine growers associate of Bordeaux, France, not only promote red wine consumption but support research leading to finding out the bioactive molecules involved in French paradox at the Institute of Sciences of Vine and Wine, Villenave-d'Ornon, (at the outskirt of Bordeaux) France [84]. Selected nutraceutical market products are presented in Table 82.3 and Fig. 82.4. The nutraceutical market is becoming more competitive with the entry of pharmaceutical and major food companies into the nutraceutical arena such as Kellogg, Heinz, Quaker Oats, Unilever, Cargill, Hormel, GlaxoSmithKline, Warner-Lambert, Johnson & Johnson, and Wyeth.

Magnum Big C^{TM} Nutrilite Iron-Folic Acai berry pure

Cholestaid Z-trim BeneFlora-Probiotic

Fig. 82.4 Pictures of some commercially available nutraceutical products

Indian nutraceutical market in 2008 is estimated to be US dollar one billion. While the global market has been growing at a compound annual growth rate (CAGR) of 7 %, the Indian market has been growing much faster at a CAGR of 18 % for the last 3 years, driven by functional food and beverages categories. The Indian nutraceutical market is dominated primarily by pharmaceuticals and “fast-moving consumer goods (FMCG)” companies which are very few pure-play nutraceuticals companies. Some major companies marketing nutraceuticals in India are GlaxoSmithKline Consumer Healthcare, Dabur India Ltd., Cadila Healthcare, EID Parry Limited, Zandu Pharmaceuticals, Himalaya Herbal Healthcare, Amway, Sami Labs Limited, Elder Pharmaceuticals Ltd., and Ranbaxy Laboratories Limited.

7 Conclusion

In present system of medicine and healthcare, nutraceuticals play a significant role. These products are extremely active, have profound effect on cell metabolism, and possess little adverse effects. The limitations of nutraceuticals such as lack of quality control and dose recommendation are the major areas of concern. Nutraceutical professionals and regulatory bodies need to play a crucial role for safety maintenance and advances of nutraceuticals. Food fortification is just beginning and has immense scope for the benefit of human population in underdeveloped and developing countries. This can lead to rapid elimination of problems related to malnutrition and associated diseases. Production of such nutraceuticals at industrial level has huge economic consequences and results in development of related technologies.

Abstract

Grape is one of the earliest cultivated plants all around the world. Health-benefiting grape properties have been widely studied in vitro, ex vivo, and in vivo. These properties are mainly attributed to phenolic composition, which

is also responsible for many quality properties. Grape contains anthocyanins, flavonols, flavanols, hydroxycinnamic acid derivatives, hydroxybenzoic acids, and stilbenes. All these show bioactivity and, therefore, antioxidant, cardioprotective, anticarcinogenic, neuroprotective, and other activities are nowadays associated with grape consumption. Clinical studies on the intake of grape or grape derivative products report positive results. For this reason, numerous food products are enriched with different types of grape extracts. Grape extracts are added to meat, fish, dairy products, bread, and beverages so as to increase their nutritional value. The functional product market is an emerging market, and this type of products can be expected to increase in the near future. In this sense, further research is required.

1 Introduction

The Vitaceae family consists of almost 1,000 species, grouped into 17 genera. Grapevines are classified in the *Vitis* genus, and the most widely cultivated *Vitis vinifera* is generally accepted to comprise up to 5,000 true cultivars used in wine, table (fresh fruit), and dried grape manufacture around the world. The *Vitis vinifera* grape is one of the earliest cultivated plants and is thought to have originated in the region between the Mediterranean and the Caspian Seas. Vine cultivars are thought to have slowly spread eastward across southern Asia and westward around the Mediterranean Sea. The Germplasm Resources Information Network (www.ars-grin.gov) of the United States Department of Agriculture describes the genera and 43 species, 5 natural hybrids, and 15 varieties of species in *Vitis*. *V. Vinifera* as the most successfully used grape species, with thousands of wine, table, and raisin grape cultivars grown throughout the world's temperate zones.

The numerous uses of the grapevine fruit, especially for wine and beverages, have made it one of the most important plants worldwide. Grapes are grown in more than 90 countries and are the world's largest fruit crop with a total production of 69 million tons. The countries with the greatest acreage are Spain, France, Italy, Turkey, China, and the United States [1].

Grapes have been praised for thousands of years for their medicinal and nutritional values. Since the ancient age of human civilization, grapes have been considered as a fruit with "healing power." Egyptians loved grapes, and ancient Greek and Roman philosophers and physicians heralded their healing powers, particularly as fermented grape juice or wine. This health character of grapes has been supported scientifically in recent years.

Chronic diseases are the most prevalent cause of death in the world, led by cardiovascular diseases and followed by cancer, chronic lung diseases, and diabetes mellitus. Epidemiological studies indicate that high serum cholesterol might have a strong correlation with increased risk of coronary heart disease (CHD). These findings led to the classical diet – heart hypothesis – which postulated the primary role of saturated fat and cholesterol in the development of atherosclerosis and CHD. In addition, initial studies suggested a direct relationship between high dietary fat intake and increased risk of breast and colon cancer. However, large prospective studies have not only addressed the effects of high dietary fat intake but also indicated the prevention of certain chronic conditions with a vegetable/fruit-rich diet. In recent years, the relationship between the consumption of specific foods and/or overall dietary patterns and the risk of CHD has been examined. Accumulating evidence from epidemiological, case control, and cohort studies suggests that a vegetable/fruit-rich diet may offer protection against chronic diseases. A study published in JAMA in 1999 by Joshipura et al. [2] clearly proved the need for higher fruit and vegetable consumption to reduce the risk of certain diseases such as ischemic stroke. However, no apparent further reduction in risk was observed beyond six servings per day. Another study has shown reduced risk of myocardial infarction in women consuming five fruit and vegetable servings [3]. The abovementioned literature suggests that fruits and vegetables may have an important role in keeping a healthy lifestyle. This observation leads to a million dollar question: which components of fruits and vegetables may be responsible for this protective effect? In this sense, many clinical trials have used different bioactive compounds for chronic disease prevention. Polyphenols are thoroughly researched for their human health-benefiting properties at different stages and have reached clinical studies, which confirm the potency of these bioactive compounds.

This chapter deals with grapevine products as functional foods and sources of nutraceuticals. Complex grape polyphenol chemistry is reviewed, and emphasis is laid on health benefits arising from the consumption of grape products. Finally, functional food from grapes is examined.

2 Chemical Composition

Grape contains (per 100 g): Water (80.5 g), carbohydrates (18.1 g), fat (0.16 g), protein (0.72 g), fiber (0.9 g), potassium (191 mg), sodium (2 mg), phosphorous (20 mg), calcium (10 mg), magnesium (7 mg), iron (0.36 mg), zinc (0.07 mg), vitamin C (10.8 mg), vitamin B1 (0.07 mg), vitamin B6 (0.09 mg), vitamin B2 (0.07 mg), vitamin A (66 IU), and vitamin E (0.19 mg). All above provide around 69 Kcal per 100 g of intake (from USDA Nutrient Database for Standard Reference, Release 24; http://ndb.nal.usda.gov/ndb/foods/list).

Moreover, apart from these main components, grapes contain secondary metabolites such as flavonoid and non-flavonoid phenolic compounds, sesquiterpenes, and melatonin. Most of the grape's medicinal value can be attributed to its seed and skin, which researchers have found to be rich in nutritional value due to the presence of polyphenolic antioxidants. At least 500 different types of antioxidants have been found in various parts of this fruit [4].

2.1 Phenolic Compounds

Grapevine quality, as with most plants, mainly depends on its metabolites. Metabolite production is especially sensitive to external conditions. In particular, the chemical diversity of grapevine is mostly affected by secondary metabolites.

These secondary metabolites consist of a wide array of species-specific chemicals and belong to different phytochemical groups such as alkaloids, terpenes, antibiotics, volatile oils, resins, cardiac glycosides, tannins, sterols, saponins, and phenolics, many of which have proven highly valuable for the pharmaceutical, agrochemical, food, and fragrance industries [5]. In general, secondary metabolites are known to play key physiological functions in plants, including their adaptation to the environment [6], acquired resistance to pests and diseases, pollinator attractant capacity, and the building of symbiotic relations with microorganisms [7]. They are also very often crucial in quality determination in food attributes (color, taste, and aroma) and colors and pigments in ornamental plants [8].

We have focused on phenolics because they are a large and complex group of metabolites that particularly contribute to the (sensorial and bioactivity) features of grapes.

There are a large number of phenolic compound structures and, therefore, a large number of properties as well. Grapevine phenolics may either arise from the fruit (mainly skins and seeds) and vine stems or be products of yeast metabolism. Their schematic biosynthesis is shown in Fig. 83.1. Briefly, the phenylpropanoid pathway generates most phenolic compounds found in nature, including flavonoids and stilbenoids. Biosynthesis of phenylpropanoid compounds is not only developmentally activated in specific tissues and cell types but can also be activated in other tissues in response to environmental stresses such as wounding, pathogen infection, or UV irradiation. Phenylalanine is an end product of the shikimate pathway. The structural diversity of phenylpropanoids derived from phenylalanine and the key phenylpropanoid intermediate *p*-coumarate is due to the action of enzymes and enzyme complexes that bring about region-specific condensation, cyclization, aromatization, hydroxylation, glycosylation, acylation, prenylation, sulfation, and methylation reactions [9].

2.1.1 Anthocyanins

Anthocyanins are the most abundant pigments in red grape skins (Fig. 83.2a). These water-soluble pigments are responsible for blue, red, and purple color in red grape skin and red wine. Anthocyanins of *Vitis* are monoglucosides of five anthocyanidins, namely, delphinidin, cyanidin, petunidin, peonidin, and malvidin. Acylated anthocyanins are esters of the glucose moiety of the free anthocyanins with acetic, *p*-coumaric, or caffeic acids (Fig. 83.2a).

Malvidin 3-glucoside is the main anthocyanin in all the varieties of *Vitis vinifera*. The amount of anthocyanins in grapes, as well as in all phenolics, depends on the grapevine variety and is highly influenced by viticultural and environmental factors such as light, temperature, altitude, soil type, water, nutritional status, pathogenesis, and various developmental processes [10]. Temperature has a great

influence on anthocyanin biosynthesis. Anthocyanin levels in Cabernet Sauvignon grapes are higher when day temperatures remain constant at around 20°C rather than 30°C. Therefore, increased anthocyanin content is associated with grapes grown at higher altitudes. However, this relationship is complicated by the effect of diurnal differences in temperature: lower night temperatures result in greater

accumulation of anthocyanins [11]. The accumulation of anthocyanins starts at the veraison stage with occasional decreases toward the end of ripe stage, especially in hot climates [12]. In fact, reduced grape berry color has been observed in very hot seasons. Whether this decrease occurs through degradation of existing anthocyanins or reduced anthocyanin biosynthesis is not known. Hence, the range of concentration varies from 500 to 5,000 mg/kg fw (Table 83.1).

2.1.2 Flavonols

Flavonols are found in grape only as glycosides of myricetin, quercetin, laricitrin, kaempferol, isorhamnetin, and syringetin (Fig. 83.2b). The corresponding aglycones can be found in wine, together with 3-glycosides. Glucose is the common sugar attached to the C-3 position of kaempferol, quercetin, myricetin, and isorhamnetin, but glucuronic acid has also been found as glycosylation of quercetin, kaempferol, myricetin and isorhamnetin, and laricitrin. Furthermore, quercetin has been found in grapes as 3-galactoside, 3-rhamnosylglucoside (also called rutin), 3-glucosylgalactose, and 3-glucosylxyloside. Kaempferol, laricitrin, and isorhamnetin have been described as galactoside derivatives (Table 83.1).

As described for anthocyanin, climate impacts on the amount of flavonol in grape. In contrast to anthocyanin and tannin synthesis, which are scarcely affected by shading treatments, a positive relationship was observed between sunlight exposure and increased flavonol accumulation [26, 27].

Flavonols are exclusively found in red and white grape skins, and its concentration ranges from traces to 300 mg/kg fw (Table 83.1).

2.1.3 Flavan-3-ol Monomers and Procyanidins

Flavan-3-ols are another large family of polyphenolic compounds comprising mainly catechin, epicatechin, epicatechin 3-*O*-gallate, gallocatechin, epigallocatechin, and epigallocatechin 3-*O*-gallate (Fig. 83.2c). Procyanidins, also known as condensed tannins, are both oligomeric and polymeric compounds arising from polyhydroxy flavan-3-ol and flavan-3,4-diol units and their epimers through C4 → C8 or C4 → C6 bonds. In grape seeds and skin, about 20 procyanidin dimers and trimers have been identified [28], B1, B2, B3, and B4 being the main ones (Fig. 83.2d). In *Vitis,* procyanidins are mainly present in grape seed, skin, and stem tissues. In the grape seed, they represent the major fraction of total polyphenols, characterized by a lower polymerization degree than those in grape skin. However, skin procyanidins are more easily extracted during winemaking, thus conferring organoleptic properties on wine such as astringency and bitterness [29]. Moreover, the grape seed contains procyanidin of catechins, epicatechin, and epicatechin gallate units, while grape skin and wine show procyanidins mostly based on epicatechin and epigallocatechin units [30].

Unlike anthocyanins and flavonols, climatic conditions have little effect on flavan-3-ols, as these compounds mainly occur in the seed. In fact, climate seems to have greater effect on composition than on quantity. Low-vigor vines show grapes with higher procyanidin content, increased proportion of epigallocatechin subunits in procyanidins, and increased polymer size, and, therefore, these compounds show decreased astringency [10]. Besides, considerable differences in types and concentrations have been observed among cultivars [31].

Seed flavanol monomers and polymers ranged from 240 to 730 and from 330 to 790 mg/kg fw, respectively [17, 20]. Skin flavonol monomers and polymers ranged from 10 to 40 and from 40 to 100 mg/kg fw, respectively. The total amount of procyanidins is reported to vary from 1.7 to 4.4 g/kg of berries in skin, 1.1–6.4 g/kg in seeds, and 0.2–1 g/kg in pulp [21] (Table 83.1).

2.1.4 Hydroxycinnamic Acid Derivatives

Hydroxycinnamics are the third most abundant group of phenolic compounds in grapes and mainly comprise caffeic, coumaric, ferulic acids, and their corresponding tartaric esters (Fig. 83.2e). The hydroxycinnamic esters are more concentrated (2- to 100-fold) in grape skin than in pulp. Differences in total amount and proportion have been reported according to grape varieties [32].

These compounds are major phenols in white wine, and their concentration in grape ranges from traces to 50 mg/kg fw (Table 83.1). In addition, these compounds are important constituents of acylated anthocyanins.

2.1.5 Hydroxybenzoic Acids

Hydroxybenzoic acids are a minor group of phenolic compounds in grapes (Fig. 83.2f). The commonest ones are gallic acid, protocatechuic acid, p-hydroxybenzoic acid, vanillic acid, and syringic acid, which are mainly found in free form [33, 34]. Hydroxybenzoic acids are mostly represented by gallic acid, which is found both free and acyl substituent in flavan-3-ols. Two forms of gallic acid (i.e., 3-*O*-b-glucopyranoside and 4-*O*-b-glucopyranoside) have been reported in grape [35]. They are found in grape skin, and their total amount ranges from 2 to 5 mg/kg fw (Table 83.1).

2.1.6 Stilbenes

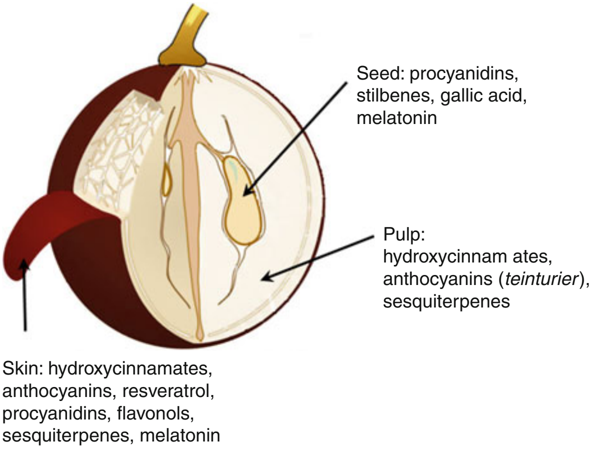
Stilbenes are minor compounds in grapes. However, their importance is due to the fact that grape is the main source of stilbenes in diet. Stilbenes are essentially located in grape skin [36, 37] but have also been reported in grape seeds [38] and grape stem [39] (Fig. 83.2g). The main stilbenes in grape are resveratrol (*trans* and *cis*) and piceid (*trans* and *cis*), but some others have also been described: piceatannol, astringin, pterostilbene, ε-viniferin, and δ-viniferin [40].

As described for the other polyphenols, the amount of resveratrol in grape depends heavily on many factors such as grape variety, geographic region, and agronomic and climatic factors. Furthermore, as resveratrol is a grape-synthesized phytoalexin after grape exposure to biotic or abiotic stress, the presence of resveratrol in grapes depends on the degree of stress exposure.

Total stilbenoid concentration was calculated taking into account just piceids and resveratrol (the major ones) and resulted higher for red than for white grapes [23]. Total stilbenoid concentration can reach 8.5 and 22 mg/kg fw in white and red grapes, respectively (Table 83.1).

2.2 Other Bioactive Compounds in Grape

Sesquiterpenoids are compounds that show woody, spicy, sweet, floral, clove, and fresh-like flavors. More than 40 sesquiterpenoids have been identified in grapes. However, quantification is a difficult task due to the lack of standards. Sesquiterpenoids have been described to contribute to the varietal volatile composition between 56% and 80% [41].



Seed: procyanidins, stilbenes, gallic acid, melatonin
Pulp: hydroxycinnam ates, anthocyanins (*teinturier*), sesquiterpenes
Skin: hydroxycinnamates, anthocyanins, resveratrol, procyanidins, flavonols, sesquiterpenes, melatonin

Fig. 83.3 Tissue localization of phenolic compounds in grape berry

Another bioactive compound described in grape and wine is melatonin. As reported for phenolic compounds, differences in genotypes and agrometeorological conditions contribute to the differing melatonin content reported in grape. Melatonin in grape ranged from traces to 0.9 ng/g fw [42, 43]. Some authors suggest that the synthesis of melatonin in wine is directly related to yeast metabolism [44].

Figure 83.3 shows the distribution/location of all abovementioned compounds in grape seed, skin, and pulp.

3 Biological Activities

From a medical point of view, the bioactive compounds of plant food are not considered pharmaceuticals, though they can improve life quality and expectancy. These compounds are named nutraceuticals, since they act as dietary therapeutic or pharmaconutrients (i.e., compounds that, if regularly included in diet, can prevent, block, or delay the onset of major chronic diseases).

First of all, it is worth mentioning the most remarkable bioactivities and bioavailability by phenolic family compounds separately. Secondly, we shall describe the different bioactivities attributed to the consumption of grape derivatives.

3.1 Bioactivity and Bioavailability of Phenolic Compounds

Anthocyanins have been reported to be strong antioxidants. They inhibit the growth of cancerous cells and inflammation, act as vasoprotectors, and have antiobesity effects [45, 46]. It has been described that delphinidin may preserve endothelium integrity, as endothelium alteration leads to several pathologies, including cardiovascular diseases such as atherosclerosis, and is often associated with cancer [47].

Anthocyanins, as a supplement, have also shown beneficial results on HDL- and LDL-cholesterol concentrations. Increased HDL-cholesterol and decreased LDL-cholesterol were reported in a recent study on dyslipidemic patients who were given 160 mg anthocyanins twice daily throughout a 12-week trial. Furthermore, the anthocyanin supplementation led to decreased mass and activity of plasma cholesteryl ester transfer protein and increased cellular cholesterol efflux to serum [48].

Anthocyanins seem to be absorbed very rapidly but rather inefficiently [49]. However, the bioavailability of anthocyanins may have been underestimated due to either methodological inaccuracy or the different chemical forms that anthocyanins can take depending on pH. This may explain why all anthocyanins' effects are contingent on sufficient bioavailability in terms of exposure at both cell and organism level through the diet [50].

Flavonols comprise some of the most prominent dietary antioxidants. Among the flavonols, quercetin can be singled out, for it presents a wide variety of pharmacological activities that provide protection not only against osteoporosis, certain forms of cancer, and pulmonary and cardiovascular diseases but also against aging [51]. Even more significantly, quercetin plays a pivotal role in reducing blood pressure by reducing oxidative stress in a dose-dependent way [52, 53]. In the 1970s, quercetin was reported to be mutagenic. However, more recent studies in vivo indicate that quercetin is not carcinogenic. In fact, in the USA and Europe, quercetin supplements are commercially available, and their beneficial effects have been reported in clinical trials [54]. With respect to its bioavailability, quercetin is absorbed in humans and can reach high concentrations that are sufficient to increase plasma antioxidant capacity [55]. Moreover, quercetin glucosides, one of the main flavonols present in grape, are among the polyphenols most readily absorbed in humans [49].

Flavan-3-ols with various types of structure act as antioxidants, free radical scavengers, and anticarcinogenic. They have cardiopreventive, antimicrobial, and antiviral properties and may also play a significant role in maintaining neurological health [56]. Relationships have been established between the structure of flavan-3-ols and their strong antioxidant and free radical scavenging properties. Their antioxidant function depends on the ring structure and number of catechol groups [57]. However, some evidence points out that the opposite must also be considered, as flavan-3-ols may behave as antinutrients, procarcinogens, pro-oxidants, hemorrhage inducers, mutagens, or hepatotoxins depending on the source, type, amount, and existence of other dietary factors [58].

Bioavailability of flavan-3-ol monomers is generally good, although it differs markedly among different compounds. Catechin, present in high concentrations in the plasma of Mediterranean diet consumers, is able to reduce the progression of atherosclerosis in vivo [59]. The fact that grape is one of the main sources of catechin in diet supports the finding that grape has anti-atherosclerotic effect [60].

Procyanidins are considered to be among the most effective antioxidants present in grapes. When rabbits were fed with procyanidins from grape seed extract, the compounds were active in preventing lipid oxidation while in the digestive tract [61]. The consumption of proanthocyanidin-rich foods has been shown to (1) increase plasma antioxidant capacity, (2) have positive effects on vascular function, and (3) reduce platelet activity in humans [62]. Unlike flavan-3-ol monomers, procyanidins are less permeable through cell walls and are therefore absorbed less readily. In fact, their polymerization impairs intestinal absorption [49, 56]. However, the health effects of proanthocyanidins may not require efficient absorption through the gut. These compounds may have direct effects on the intestinal mucosa and protect it against oxidative stress and carcinogens. Procyanidins bioactivity is not only due to their activity itself but also to their metabolites bioactivities and also to the modulation of intestinal bacterial population [63].

Hydroxycinnamic acid derivatives have shown antioxidant and anti-inflammatory properties in vivo and in vitro. They contribute to DNA protection and help to prevent Alzheimer's disease [64, 65]. However, data are still too limited for an informed assessment of hydroxycinnamics [49].

Stilbenes in general, and *trans*-resveratrol in particular, have been reported to be responsible for various beneficial effects. Resveratrol's biological properties include antibacterial and antifungal effects, as well as cardioprotective, neuroprotective, and anticancer action [40]. Anticancer resveratrol activity is one of the most promising bioactivities of resveratrol. In 1997, Jang et al. [66] reported the ability of resveratrol to inhibit carcinogenesis at multiple stages (initiation, promotion, and progression). Their finding that topical application of resveratrol reduces the number of skin tumors per mouse by up to 98% triggered research on resveratrol all around the world. Resveratrol could slow down tumor development through multiple complementary mechanisms. It inhibits the enzymatic activity of both forms of cyclooxygenase, which implies a reduction in the risk of developing many cancers. Another mechanism by which resveratrol could combat tumor formation is induction of cell cycle arrest and apoptosis. Its antiproliferative and pro-apoptotic effects in tumor cell lines have been extensively documented in vitro [67] and are supported by down regulation of cell cycle proteins [68] and increased apoptosis [69] in tumor models in vivo. However, in some in vivo experiments, resveratrol failed to impact cancer, which suggests that other factors such as dosage, delivery method, tumor origin, and other diet components could all contribute to the efficacy of resveratrol treatment. Overall, in vivo studies clearly show a promising use of this molecule in cancer treatment. Other remarkable activity of resveratrol is its neuroprotective character. It is able to penetrate the blood-brain barrier and exerts strong neuroprotective effect. Moreover, it has been shown to combat neuronal dysfunction in Huntington's, Alzheimer's, and Parkinson's diseases [70]. Resveratrol also has positive effects on longevity and age-related deterioration [71–73]. Other stilbenes such as piceatannol and viniferins are usually found in grape in lower concentrations than resveratrol, and, as a result, their bioactivity has been studied less than that of resveratrol. Nevertheless, some of their health-benefiting properties have also been researched [40, 74, 75].

Numerous studies on animals and humans have shown resveratrol's low bioavailability. Once it is absorbed, at least 70% of the ingested resveratrol is readily metabolized to form mainly glucuronide and sulfate derivatives. Since the in vivo concentration of individual metabolites from ingested resveratrol can be much higher than that of resveratrol itself, further studies on the activity of its metabolites become necessary.

Resveratrol binds to albumin, and albumin has been suggested a natural polyphenol reservoir in in vivo context, where it might play a pivotal role in the distribution and bioavailability of circulating resveratrol [76]. The accumulation of resveratrol in other organs such as heart, liver, and lung after chronic administration was described for the first time in 1996 [77] and has more recently been confirmed [78, 79] and extended to bile, stomach, and kidneys [80]. It is also worth considering the potential interactions between polyphenols. For example, resveratrol has been shown to synergize with both quercetin and ellagic acid in the induction of apoptosis in human leukemia cells [81], with ethanol in the inhibition of iNOS expression [82], with vitamin E in the prevention of lipid peroxidation [83], with catechin in the protection of PC12 cells from β-amyloid toxicity [84], with nucleoside analogues in the inhibition of HIV1 replication in cultured T lymphocytes [85], and with tyrosol and β-sitoesterol in modulation of LDL oxidative stress and PGE2 synthesis [86].

Sesquiterpenoids have been related with medicinal plants with different health applications, mainly anti-inflammatory [87], anti-HIV [88], antibacterial [89], and antitumor activity [88]. Up to date, no study has covered the biological activity of sesquiterpenoids from *Vitis vinifera L* grapes. Sesquiterpenoids such as farnesol and nerolidol have been reported to have the ability to enhance bacterial permeability and susceptibility to exogenous antimicrobial compounds. These compounds increase the susceptibility of *Staphylococcus aureus* and *Escherichia coli* to antibiotics by disrupting the normal barrier function of the bacterial cell membrane, allowing permeation into the cell of exogenous solutes such as antibiotics [90].

Melatonin (*N*-acetyl-5-methoxytryptamine) is a neurohormone produced in the pineal gland. Its biological properties have been studied in depth, particularly those concerning the circadian rhythm. Melatonin shows antioxidant properties as a direct free radical scavenger and a stimulator of antioxidant enzymes [91–94]. Melatonin's role in neuroprotection is an important issue. Melatonin has been tested in sleep disorders. It generally reduces sleep latency and improves sleep especially in case of disturbed circadian phasing. In this case, melatonin was found particularly effective in patients with neurodegenerative diseases [95]. The European Food Safety Authority (EFSA) accepted the health claims related to melatonin and alleviation of subjective feelings of jet lag. Melatonin dosage must be within 0.5 and 5 mg per day [96]. Numerous research attempts have been made or are currently being developed to mitigate neurodegenerative diseases such as Alzheimer's, Parkinson's, and Huntington's diseases and amyotrophic lateral sclerosis. Melatonin was shown to inhibit Aβ fibrillogenesis [97, 98]. Melatonin

Table 83.2 Antioxidant compounds from grapes and main bioactivity

Family	Most prominent bioactivity against disease	References
Anthocyanins	Decrease cardiovascular and cancer risk	[45–48]
Flavonols	Provide protection against osteoporosis, cancer, pulmonary and cardiovascular diseases	[51–53]
Total flavan-3-ols	Anticarcinogenic, cardiopreventive, antimicrobial, and antiviral properties	[56, 57]
Hydroxycinnamic acid derivatives	DNA protection and help prevent Alzheimer's disease	[64, 65]
Stilbenes (resveratrol)	Cardioprotective, neuroprotective, antiaging, and anticancer actions	[66, 70, 71]
Sesquiterpenes	Anti-inflammatory and antibacterial actions	[87, 89]
Melatonin	Neuroprotection action	[70]

(200 mg/kg) has recently been shown to reduce edema in impacted striatum versus traumatic brain injury [99].

In addition to plasma melatonin levels, urine-excreted melatonin metabolite 6-sulfatoxymelatonin is easy to determine. Indeed, higher melatonin excretion in the first morning urine was 16% higher in women with higher quartile vegetable intake in comparison to those with lower quartile intake [100]. Moreover, nutrition habits and lifestyle have also been correlated with melatonin [101]. A statistically inverse relation was found between age, smoking, and body mass index, on one hand, and urinary 6-sulfatoxymelatonin [102].

The most important bioactivities of these compounds in diseases are summarized in Table 83.2.

Moreover, many of the described health properties may not be attributed to single polyphenols present in grape but rather to synergism among polyphenols themselves and/or between them and other types of bioactive compounds. For instance, some studies on grape or grape juice are detailed next.

3.2 Antioxidant Activities of Grape and Grape Derivative Products

The most widely researched biological activity of polyphenols is their antioxidant capacity, though they also have a plethora of more or less correlated properties such as antimutagenic, anti-inflammatory, antitumoral, antineurodegenerative, antihypertensive, and cardioprotective activities.

Oxidative stress is broadly defined as a perturbation of cellular homeostasis, so that the production rate of reactive oxygen species (ROS) exceeds their neutralization rate. If homeostasis is not reestablished, oxidative stress may progress toward the onset of apoptotic cell death and tissue degeneration [103]. In order to cope with excessive production of free radicals, human bodies have developed sophisticated mechanisms for maintaining redox homeostasis. These protective mechanisms include ROS scavenging or detoxification, ROS production blockage, and sequestration of transition metals, as well as enzymatic and nonenzymatic antioxidant defenses both endogenous (body-produced) and exogenous (diet-supplied). Among them, dietary polyphenols have been widely studied for their strong antioxidant capacities and other properties that regulate cell functions [104].

Flavonoids act as antioxidants by donating electrons and stopping radical chains. This activity is attributed to phenolic hydroxyls, especially in 3′,4′ positions in the B-ring and to the 2,3-double bond in the C-ring, thus increasing with the number of OH groups in A and B rings [105]. In fact, most epidemiological and intervention studies on flavonoids' beneficial effects have been focused on their antioxidant capacity.

The antioxidant capacity of red grapes was evaluated in HepG2 (human hepatocellular liver carcinoma) cells and positively correlated with the total phenolic content and the oxygen radical absorbance capacity (ORAC) values of grape extracts. Results suggest that increasing fruit consumption is a suitable strategy to counteract oxidative stress [106].

A similar conclusion is drawn in a study developed on oxidative stress markers in 32 healthy subjects. Daily consumption of grape juice (10 mL/kg body weight) for 2 weeks resulted in increased resistance of LDL to ex vivo oxidation, comparable to the value obtained after α-tocopherol. Furthermore, decreased protein-carbonyl concentration was observed at the same time [107]. These results agree with those contributed by other authors, who showed that the daily intake of grape juice (125 mL) for 1 week in a group of six men and six women led to significantly reduced LDL oxidation [108]. In a short-term study, the acute intake of a phenolic-rich juice (400 mL), with grapes as a major ingredient, improved the antioxidant status in healthy subjects according to their plasma thiobarbituric levels [109]. In a group of 27 hemodialysis patients, regular ingestion of concentrated red grape juice (100 ml) for 2 weeks reduced inflammatory biomarkers to a greater extent than vitamin E [110].

High daily intakes of grape juice are not feasible in most population. To overcome this difficulty, new derivative products such as power extracts are proposed. The daily supplementation of lyophilized grape powder (36 g) for 4 weeks reduced urinary F2-isoprostanes (in women), which are biomarkers of oxidative stress, in pre- and postmenopausal women [111]. The administration of grape seed extract (600 mg/day) for 4 weeks was reported to have led to significant improvement in insulin resistance and plasma CRP markers in a group of 32 type 2 diabetic patients [112]. The consumption of black grape (1 g/kg body weight) has also been described to exert similar effects to juice and powder: significantly increased antioxidant potential was observed in healthy volunteers 4 h after ingestion [113].

Furthermore, this antioxidant capacity of grape is also able to protect DNA oxidation and therefore mutagenesis-, carcinogenesis-, and aging-related DNA damage. Daily grape juice supplementation (480 mL) for 8 weeks led to reduced DNA strand breaks in peripheral lymphocytes, apart from decreasing the amount of released ROS [114]. Similarly, treatment of human lymphocytes with grape seed extract reduced the frequency of micronuclei by 40% and the production of malonyldialdehyde, a biomarker of lipid peroxidation, by 30%, while it increased the activity of antioxidant enzymes catalase and glutathione S-transferase by 10% and 15%, respectively [115].

3.3 Cardioprotective Activity of Grape and Grape Derivative Products

Vessel injury and thrombus formation are the cause of most ischemic coronary syndromes, and in this setting, activated platelets stimulate platelet recruitment up to the growing thrombus. Hypertension is one of the major risk factors for cardiovascular disease, with an impact on global health. Multiple studies have suggested that various dietary factors are associated with blood pressure and hypertension. However, the effects of fruit and vegetable consumption on plasma lipid levels, diabetes, and body weight have not yet been thoroughly explored [116]. Evidence suggests an inverse relationship between grape product consumption and cardiovascular disease. In studies conducted with grapes and grape juice, clinical trials demonstrated improved endothelial function, reduced platelet aggregation, and a positive influence on biomarkers such as LDL and HDL. In a study on 15 patients with coronary artery disease, the consumption of 8 mL/kg/day of red grape juice for 2 weeks improved the endothelial function and reduced the susceptibility of LDL-cholesterol to oxidation [117]. In fact, Vison et al. found that red grape juice, in contrast with orange juice, enriched LDL and VLDL and reduced their oxidation susceptibility in vitro, ex vivo, and in vivo [118]. Regarding platelet aggregation, many promising results have been reported. Platelet incubation with red grape juice led to inhibited aggregation, enhanced the release of platelet-derived NO, and reduced superoxide production. Oral consumption of standardized grape extract (100 and 200 mg/kg) provided significant cardioprotection by improving postischemic ventricular recovery and reducing myocardial infarction in rats [119].

In other study, 20 healthy subjects were supplemented with grape juice (7 mL/kg) for 14 days. Significantly decreased platelet aggregation, increased platelet-derived NO release, and decreased superoxide production were observed. The suppression of platelet-mediated thrombosis represents a potential mechanism for the beneficial effects of purple grape products in cardiovascular disease [120]. Similarly, proanthocyanidin-rich extract of grape seed (50 and 100 mg/kg for 3 weeks) had cardioprotective effects against reperfusion-induced injury in isolated rat hearts [121]. A lower dose (36 g of lyophilized power grape/day for 4 weeks) was tested in pre- and postmenopausal women. Lipoprotein metabolism, oxidative stress, and inflammatory markers were achieved, and, therefore, CHD risk factors were reduced [122].

Moreover, numerous studies have been developed on CHD patients. The intake of red grape polyphenol extract – which contains epicatechin, catechin, gallic acid, *trans*-resveratrol, ε-viniferin, rutin, quercetin, p-coumaric, and ferulic acid – improved the endothelial function in CHD patients. Similar results have been found for red grape juice [123]. Hypercholesterolemic patients were asked to consume red grape juice (500 mL/day) and red wine (250 mL/day) for 14 days. Results showed increased brachial artery flow-mediated dilation in both cases. However, increased endothelium-independent vasodilation was observed only in red wine-drinking patients [124]. Similar results and the same conclusions were drawn from a similar study on red grape juice. The daily ingestion of moderate amounts of red grape juice improves endothelial function in patients with atherosclerotic vascular disease, has no adverse affects on lipid and glucose metabolism, and reduces LDL susceptibility to oxidation [117, 125]. The consumption of purple grape juice offered protection against the oxidation of LDL-cholesterol, as shown by an in vivo study with dogs, monkeys, and humans from which the flavonoids of purple grape juice and red wine could be inferred to be able to inhibit the initiation of atherosclerosis [126].

3.4 Anticarcinogenic Activity of Grape and Grape Derivative Products

Cancer is a term commonly used for diseases in which abnormal cells divide uncontrollably and invade other tissues. Cancer cells can spread to other parts of the body through the blood and lymph systems. Cancer is not just one disease but many diseases. There are more than 100 different types of cancer, hence, the complexity of cancer treatment. It is the second leading cause of death worldwide after heart disease, and its risk and incidence increase with patient age (www.cancer.gov). In addition to genetic factors, environmental and nutritional factors play a main role in cancer etiology. In westernized countries, breast, prostate, and colon-rectum cancers predominate because diets are usually rich in animal-source foods and refined carbohydrates and deficient in plant foods. Conversely, in developing countries, where diets are largely based on cereal/starchy foods, esophageal, stomach, and liver cancers are more incident [127].

Fruit and vegetable consumption may reduce the risk of oropharynx, esophagus, lung, stomach, and colon-rectum cancers. A recent study has evaluated the potential effect of interventions aimed at increasing the intake of fruits and vegetables up to the recommended level (500 g/day) on future cancer incidence in Europe. Data on cancer incidence and daily intake of fruit and vegetables were collected for France, Germany, the Netherlands, Spain, and Sweden. The results predicted 212,000 fruit- and vegetable-related cancer cases in these countries in 2050, out of which 398 (0.19%) might be prevented if the 500 g/day fruit and vegetable intake was achieved in the aforementioned countries. The largest absolute impact was observed for lung cancer with 257 (out of 136,517) preventable cases if the intervention was successfully implemented. Increasing fruit and vegetable consumption has a small impact on reducing the burden of cancer in Europe. Nevertheless, although health impact is rather limited, it can be used as a tool in chronic disease prevention [128]. In another previous study, quantitative conclusions regarding the contribution of fruit and vegetables intake to the occurrence of oral cancer were drawn from a meta-analysis. Promising results were contributed in this study. The authors conclude that each portion of fruit consumed per day significantly reduces the risk of oral cancer by 49%. Moreover, the multivariable meta-regression showed that the lower risk of oral cancer associated with fruit consumption was significantly influenced by both the type of fruit consumed and the time interval of dietary recall [129].

Many of the studies on the cancer-preventive mechanisms of phenolic compounds have been focused on individual compounds (mainly on resveratrol, procyanidins, and melatonin at too high concentrations to be achieved via dietary consumption). In contrast, few intervention studies have been found in the database. Some of them, related with their antioxidant activity, are cited in Sect. 3.2 in this chapter. Some others are detailed below. The effects of black grape extract, including seeds, on the activity of DNA turnover enzymes in cancerous human colon tissues have been tested. Results showed that the extract inhibited the activity of the enzymes involved in rapid DNA synthesis. Thus, extract intake may have beneficial effects on colon human cancer [130]. In vitro studies on grape seed extract (usually on grape seed extract) also showed promising efficacy against both angiogenesis and metastasis, which are involved in cancer progression in mammary, colon, prostate, and breast carcinoma [131–134]. Skin carcinogenesis in mice was reduced by combining topical and dietary treatment with freeze-dried grape powder [135].

Literature review for this chapter found only one human study that had examined the relationship between grape products and cancer. In an intervention study involving smoking and nonsmoking humans, Park et al. found that supplementation with 480 mL/day of purple grape juice for 8 weeks decreased lymphocyte DNA damage, reduced the release of reactive oxygen species by 15%, and reduced DNA damage to a greater extent in smokers (25% vs. 18% decrease). While these results suggest grape juice's potential anticarcinogenic role, further well-designed studies in humans are needed to corroborate these findings.

3.5 Neuroprotective Activity of Grape and Grape Derivative Products

Neural dysfunction and metabolic imbalances underlie many progressive neurodegenerative conditions such as Alzheimer's, Huntington's, and Parkinson's diseases. As commented before, resveratrol and melatonin can penetrate the blood-brain barrier and exerts strong neuroprotective effects, even at low doses. Several studies support that the onset of the neurodegenerative disease may be delayed or mitigated with the use of dietary chemopreventive agents that provide protection against β-amyloid plate formation and oxidative damage [136, 137].

The effect of grape seed extract, rich in procyanidin, on the stress-induced neuronal cell death model has been studied in vitro using a hippocampal neuron-rich culture. The extract led to increased interleukin-6, which protected neuronal cells from death by oxidative stress [138]. Ono et al. [139] showed that a commercially available grape seed polyphenolic extract (MegaNatural-AZ) significantly attenuated Alzheimer´s disease-type cognitive deterioration and reduced cerebral amyloid deposition. Similarly, Wang et al. [140, 141] found that a naturally derived grape seed polyphenolic extract can significantly inhibit amyloid β-protein aggregation into high-molecular-weight oligomers in vitro.

Regarding in vivo studies, when orally administered to Tg2576 mice, this polyphenolic preparation significantly attenuated Alzheimer's disease-type cognitive deterioration, coincidentally with reduced HMW soluble oligomeric Aβ in the brain. Grape seed-derived polyphenolics were suggested to be useful agents to prevent or treat Alzheimer's disease. Moderate consumption of two unrelated red wines made from different grape species (Cabernet Sauvignon and Muscadine) and characterized by different component composition of polyphenolic compounds significantly attenuated the development of the Alzheimer's disease-type brain pathology and memory deterioration in a transgenic Alzheimer's disease mouse model [142]. Treatment with Cabernet Sauvignon was found to reduce the generation of Alzheimer's disease-type Aβ peptides, while the Muscadine treatment was found to attenuate Aβ neuropathology and Aβ-related cognitive deterioration in Tg2576 mice by interfering with oligomerization of Aβ molecules to soluble HMW Aβ oligomer species, which are responsible for initiating a cascade of cellular events resulting in cognitive decline. These authors suggested the possibility of developing a "combination" of dietary polyphenolic compounds for Alzheimer's disease prevention and/or therapy by modulating multiple Aβ-related mechanisms.

Concord grape juice supplementation has been shown to reduce inflammation, blood pressure, and vascular pathology in patients with cardiovascular disease. Besides, the consumption of such flavonoid-containing foods is associated with reduced risk of dementia. In addition, preliminary animal data have indicated improved memory and motor function with grape juice supplementation, suggesting its potential for cognitive benefits in aging humans. In this initial research on neurocognitive effects, 12 older adults with memory decline but not dementia took part in a randomized, placebo-controlled, double-blind trial with Concord grape juice supplementation for 12 weeks. Significant improvement was observed in verbal learning measurements, as well as nonsignificant enhancement of verbal and spatial memory. The intervention was observed to have no appreciable effect on both depressive symptoms and weight or waist circumference. These preliminary findings suggest that Concord grape juice supplementation may enhance cognitive function in older adults with early memory decline. In addition, they set a basis for further comprehensive research on its potential benefits and assessment of its mechanisms of action.

Prospective cohort studies on flavonoid intake and risk of developing dementia have led to inconsistent results [143–148], since high blood levels of homocysteine may be increased in Alzheimer's disease and hyperhomocysteinemia may contribute to disease pathophysiology by vascular and direct neurotoxic mechanism [149]. The effect of a polyphenol-rich antioxidant beverage on plasma homocysteine levels in Alzheimer patients has been recently evaluated. With this purpose, Morillas-Ruiz et al. performed a multicenter, randomized, double-blind controlled clinical trial with polyphenol supplementation in 100 subjects [150]. Twenty-four patients with initial Alzheimer's disease, 24 patients with moderate AS, and 52 controls were randomly assigned to assume either a polyphenol-rich antioxidant beverage or an identical placebo beverage (200 ml/day) for 8 months. The fasting plasma homocysteine concentration levels measured before and after the ingestion of the beverage showed higher baseline levels in Alzheimer patients than in both mild-Alzheimer and control patients. The antioxidant beverage versus placebo attenuated homocysteine increase in the control and Alzheimer groups, especially in the mild one, yet no other effects were achieved.

4 Functional Food from Grapes

Functional foods were first described by Roberfroid [151] as "Food similar in appearance to conventional food that is intended to be consumed as part of a normal diet, but has been modified to subserve physiological roles beyond the provision of simple nutrient requirements." More simply put, functional foods are foods that may provide health benefits beyond basic nutrition. Functional foods can arise from a desire to provide additional benefits to consumers in the way of enhanced nutrition. They can also be useful in making nutrients more available by providing particular dietary components in foods, thus increasing their usual availability and palatability [152].

Enrichment of foods with phenolics can be a promising strategy to produce functional foods with higher antioxidant activity. A number of products such as "grape seed extract," "grape extract," "red wine powders," "anthocyanin extracts," and even "leaf extracts" are currently being marketed and employed in the formulation of dietary supplements. Among these, grape seed extract (GSE) seems the most widely extended. In addition, plant callus/cell cultures have proven potentially promising for the production of secondary metabolites [153]: mainly anthocyanins and other phenolics in grapes [154–156]. These in vitro cultures involve some advantages over fresh fruit extracts such as the possibility of continuous production of natural compounds, large scale production depending on specific needs, lower cost and opportunity for the manipulation of the direction of the biosynthesis of anthocyanins, or other phenolics [155].

Finally, other grape derivative, phenolic-rich products are by-products: mainly pomace, which is made of solid residues; 80% of grape production is used in winemaking, and therefore millions of tons of grape pomace are produced within a few weeks after harvest. Pomace's phenolic extracts show high antioxidant and antimicrobial properties [157].

The following section contributes a revision of different grape extract-enriched food products.

4.1 Enrichment of Dairy Products

In cheese-making, the curd is generally made by coagulating milk casein with an enzyme, an acid, and either with or without further curd treatments by heat, pressure, salt, and fermentation with selected microorganisms. The retention coefficient is an important parameter in predicting the recuperation rate of value-added functional ingredients such as polyphenols. Indeed, low-molecular-weight soluble compounds are often lost to a great extent in the cheese whey. A high retention coefficient is considered desirable in the cheese-making process, as higher retention coefficients indicate reduced loss of functional ingredients. The retention coefficients of phenolic compounds in cheese are attributable to the interactions between phenolic compounds and proteins. Therefore, there is growing interest in determining the interactions between bioactive ingredients and milk proteins to enhance their recovery in cheese [158]. In this sense, grape extracts including skin, pulp, and seed (among other extracts) were added as functional components to prepared cheese. The nutritional value of cheese product was improved, since the retention coefficient of bioactive compounds and antiradical activity in cheese curd increased 1.5- and 3.5-fold, respectively [158]. However, it affected milk's gel-formatting kinetics, mainly because of pH and curd moisture content, and textural properties were therefore affected too [159]. Further research is needed before applying this technology in the food industry.

In fact, many aspects beyond the functional properties must be considered for the addition of polyphenols to dairy products. Apart from their antioxidant capacity, their sensorial attributes such as bitterness or the astringency of procyanidins can be easily translated into the dairy product [160]. When grape seed extract was added to low-fat ultra-high temperature (UHT) milk, the flavor characteristics of the milk were suppressed. Moreover, astringency and bitterness were also detected in fortified milks. The authors suggest joining this extract to cyclodextrins, thus forming complex polyphenols that result in reduced perception of sensory attributes [160, 161].

Yogurt is another fermented dairy product; beyond its nutritional characteristics and importance for the human diet, yogurt is not currently considered a significant source of phenolic compounds. Therefore, plant-based additives have been used to enhance phenolic content in yogurt [155, 162].

In recent research, high anthocyanin and phenolic levels (as much as 17.7 and 78.46 mg/kg, respectively) were reported in yogurts inoculated with extracts obtained from red grape varieties or grape callus cultures. Thus, high level of free radical scavenging capacity was also observed. Phenolic acids such as gallic acid, caffeic acid, p-coumaric acid, vanillic acid, gentisic acid, vanillin, catechin, epicatechin, *trans*-resveratrol, hesperidin, and quercetin were identified in fortified yogurts. These compounds were concluded the main constituents of the antioxidant power of yogurts enriched with functional ingredients. However, decreased total phenolic content, anthocyanin content, and antioxidant activity were observed in all assayed yogurt samples along time (2 weeks of storage). Finally, the authors state that grape callus/cell cultures can be a valuable alternative for the biomanufacturation of chemopreventive and nutraceutical fortified yogurt [155].

4.2 Enrichment of Meat Products

Grape seed extract (GSE) has proven antioxidant activities both in vivo and in vitro in various meat products [163–167]. In the meat system, GSE proves its antioxidant activity by reducing the amount of primary (e.g., lipid hydroperoxides and hexanal) and secondary (e.g., thiobarbituric acid reactive substances – TBARS) lipid oxidation products [163]. GSE has reduced rancid flavor development and antioxidant activities in various meat products like raw beef, cooked beef, raw and cooked pork patties, turkey, and ground chicken breast and thigh meat [168–173]. The antioxidant activity of GSE is concentration-dependant between 0.02% and 0.1% [168]. Grape seed extract at 0.1% (w/w) is an effective radical scavenger in muscle tissues and has been shown to reduce secondary oxidation products in beef, chicken, and turkey during refrigerated storage [168, 173, 174]. At this level (0.1% w/w), GSE can be used as an effective antioxidant in both raw and cooked meat systems. Addition of GSE ($\geq$1,000 μg/g) results in minor increase ("a" – redness values) in the surface color of raw meat and retention (due to the anthocyanins present in GSE) in cooked meat, which may have a negative impact on consumer preference based on meat product color without affecting meat eating quality [168, 171, 175]. The addition of GSE (6,000 ppm) does not change flavor scores in irradiated and nonirradiated whole chicken breasts [176]. Furthermore, GSE (0.1% w/w) was observed to have no effect on pH, yield, and water activity in ground chicken breast samples [170].

Other authors have researched the usefulness of grape seed flour from grape by-products [177]. Grape seed flour can beat alternative materials used in various food products due to its high antioxidant activity and high dietary fiber content (http://www.vitis-vital.de/). Grape seed flour was incorporated into frankfurters at seven different concentrations (from 0% to 5%), and its effects were observed on the researched products' physical, nutritional, and sensory features. Oxidation in frankfurters was minimized with increasing levels of grape seed flour in their formulation as a result of the strong antioxidant properties of grape seed flour. Moreover, increased levels of grape seed flour led to frankfurters' increased total dietary fiber and water-holding capacity, thus increasing the products' value. However, the products' sensorial properties were significantly modified, and further research therefore becomes necessary to improve product palatability [177].

4.3 Enrichment of Bread

Bakery products, particularly bread, have a significant share in the food guide pyramid for daily food choices recommended by the US Department of Health and Human Services. Therefore, the development of polyphenol-enriched bread is an efficient way to increase polyphenol intake.

In a recent study, different amounts of grape seed extract (300, 600, and 1,000 mg), source of catechin and procyanidin, were added to bread ingredients before the bread-making process. Although thermal processing decreased the antioxidant activity of the extract, fortified bread showed significantly higher antioxidant capacity. Moreover, the antioxidant capacity of the extract contributed to the reduction of N^{ε}-carboxymethyllysine, a potential toxicant in food, in enriched bread. Regarding bread sensory properties, only a favorable change in bread color was observed, with no significant alteration in quality parameters (sweetness, porosity, astringency, and stickiness) [178].

The study evaluated the effect of grape by-products (GP) on the chemical composition, soluble and insoluble dietary fiber, phenolic compounds and antioxidant activity, and organoleptic characteristics of sourdough mixed rye bread. The following samples of sourdough mixed rye bread were prepared: control bread and breads with GP at four different levels, 4%, 6%, 8%, and 10%. The addition of GP significantly improved dietary fraction contents, as bread with 10% added GP accounted for 39% and 37% higher contents of soluble and insoluble dietary fiber than control bread. The assay of radical scavenging activity and reducing ability showed that GP addition greatly enhanced the antioxidant properties of mixed rye breads. The profiles of phenolic compounds of supplemented breads were dominated by procyanidin B1 and B2, catechin, epicatechin, caffeic acid, and myricetin. Increased GP levels led to significantly increased bread hardness and gumminess. Although both control bread and supplemented breads showed common volatile compound profiles, slight differences were observed in the concentration of these components. Sensory evaluation of GP-enhanced breads revealed that a maximum of 6% GP could be added to prepare acceptable products.

4.4 Enrichment of Seafood

Lipid oxidation is still today a problem in the food industry, especially for products that contain marine lipids. The high content of polyunsaturated fatty acids (PUFA), highly beneficial for human health particularly in preventing cardiovascular diseases, in fish oil makes it very attractive to the rising market of functional products. However, at the same time, this high PUFA content makes marine lipids highly susceptible to oxidation, consequently affecting fish oil quality during storage through flavor, odor, color, and texture deterioration and even producing toxic compounds [179].

Antioxidant phenolics are often added to food to inhibit the initiation and propagation of oxidation's radical chain reactions, thus delaying the oxidation process. New antioxidants capable of retarding oxidation in fish oil-enriched foods would be desirable, especially if these new antioxidants had relevant biological properties. In this sense, grape procyanidins and resveratrol derivatives have been examined as inhibitors of oxidation in fresh Atlantic horse mackerel [180, 181]. Procyanidins were added at 50 and 100 ppm (W/W) to minced muscle fish. Procyanidin supplementation stabilized the fish product and maintained its functionality associated with the presence of PUFA and α-tocopherol. Regarding the stability and biological activity of grape procyanidins during chilled storage, their antioxidant activity has been described to remain stable for more than one year at 4 °C [180]. On the other hand, resveratrol, piceid, and some resveratrol derivatives were tested at similar concentration (100 ppm) on minced muscle fish. Resveratrol and piceid showed notable antioxidant activity in fish oil-in-water emulsions.

Neither lipophilization nor glycosylation of resveratrol led to improved antioxidant efficiency [181]. The authors conclude that these biologically relevant phenols could be used as natural antioxidant in this type of food matrix.

4.5 Enrichment of Grape Derivative Beverages

As the fastest growing segment in the food industry, functional beverages represent an attractive alternative to conventional food products for health conscious individuals. Through the incorporation of fortifying agents and antioxidant-eliciting ingredients, ordinary beverages are being transformed into "superfoods" [182, 183]. Functional beverages and plant-based fortified products are especially attractive to consumers [153] and represent new opportunities for beverage producers.

Newly developed foods and beverages have incorporated grape-derived extracts to gain health appeal [184]. A concentrated food ingredient comprising green tea and grape skin and seed extracts has been developed. A mix of green tea extract (3.0 g/L)+grape skin extract (12.0 g/L)+grape seed extract (0.5 g/L)+fungus extract (0.1 g/L)+vitamin C (0.3 g/L) yielded 1,155 mg/L of polyphenol content [185]. Other authors have formulated new grape extracts rich in procyanidins: 15% monomers and 20% of dimers and up to 30% of trimers, tetramers, and pentamers by weight [186]. The product was tested in the treatment of prehypertensive patients and was successful in reducing both systolic and diastolic blood pressure by 8% on a dose of 300 mg/day for 8 weeks.

In 2008, a patent application by Perlman et al. [187] presented an interesting use of the "rich" by-product of the grape juice industry. Based on the fact that grape pomace solids contain at least ten times greater amounts of polyphenols than pressed grape juice, the authors proposed the fortification of such juice with pomace polyphenol extract. The beverage was tested at different extract concentrations for sensorial acceptance and antioxidant activity. Unacceptable astringency was observed together with significantly increased antioxidant activity. As described for other food products, cyclodextrin was proposed for successful reduction of the astringent sensation. Draijer et al. [188] described the invention of a beverage containing 550 mg of red wine polyphenols + 250 mg of red grape polyphenols added to 200 mL of a soy-based drink. Results of daily doses for breakfast suggest a positive impact on blood pressure.

Wine has traditionally been identified as a health-benefiting product due to its effects on coronary heart disease after the so-called French paradox [189] delaying tumor onset [190] and its high antioxidant activity [191]. These benefits have been ascribed to phenolic compounds abundant in red wine. As previously commented, resveratrol is one of the main bioactive compounds found in wine. Wine with higher resveratrol content may therefore be regarded as "functional wine" due to resveratrol's positive health effects. Some research is currently being developed in this sense. Metabolic engineering has been used to obtain transgenic yeasts that enhance resveratrol content in wine [192, 193]. In some cases, the conversion rate was higher than 20-fold [194]. Moreover, as resveratrol is a phytoalexin synthesized by grapes after exposure to biotic or abiotic stress, the presence of resveratrol in grapes depends on the degree of stress exposure. Preharvest chemical treatments such as BTH, chitosan, methyl jasmonate, jasmonic acid, salicylic acid, beta-aminobutyric acid, ozone, aluminum chloride, and UVC can be used to enhance nutraceutical grape properties [40]. Guerrero et al. obtained resveratrol-enriched red wines by using UVC [195], while Gaudette et al. did it by adding resveratrol directly to the wine [183]. Both studies concluded that increased resveratrol content does not alter wine's quality properties. In addition, enriched wines showed significantly higher antioxidant capacity compared to control wines [183].

Market studies suggest that the functional attribute in wine positively and significantly affects the probability of selecting a particular red wine and consumer willingness to pay for this attribute [196]. However, it should be mentioned that the term "functional" cannot be used for beverages with over 1.2% alcohol content in Europe according to the EU Regulation 1924/2007. Remarkably, a winery is already commercializing this type of wines in the Australian market (www.winedoctor.com.au). They extract resveratrol from grape and add it to wine, thus achieving resveratrol wine content up to 100 g/L – an outstanding achievement regarding usual resveratrol content in wine.

5 Conclusion and Perspectives

From an economic viewpoint, grapevine is one of the most important crops in the world and has a deeply rooted significance in human culture. The functional ingredients of grapevine include several flavonoids that have been reported to show different activities including antioxidant, anticancer, and prevention of cardiovascular disease, as well as the treatment of several neurological disorders. Grape seed extract and its active components such as proanthocyanidins, resveratrol, and quercetin seem to be potent antioxidants. The consumption of grapes and grape juice is likely to have positive effects on human health.

In this sense, numerous food products are enriched with grape polyphenols, thus entering the market of functional foods. Functional foods (and nutraceuticals) constitute a promising field to improve health and prevent age-related chronic diseases. There has been a growing interest in researching, developing, and commercializing functional food. Moreover, recent trends have shown consumers' growing interest in many health-promoting food and supplements. The addition of fruit polyphenols to food products is increasing with the currently emerging popularity of functional food (ISI Web of Knowledge; 1,585 entries in the last 11 years). For that reason, further research is needed, since the effectiveness of functional products in vivo is a really complex topic on which there is still too little knowledge. In this way, both synergistic effects among phenolics and the effect of food matrices on bioavailability will be taken into account.

Acknowledgments Authors thank the INIA and FEDER for their financial support (Project RTA2011-00002 and RTA2009-00022-C02).

Abstract

Flavonoids exert a multiplicity of neuroprotective actions within the brain, including a potential to protect neurons against injury induced by neurotoxins, an ability to suppress neuroinflammation, and the potential to promote memory,

learning, and cognitive function. These effects appear to be underpinned by their interaction with critical protein and lipid kinase signaling cascades in the brain leading to an inhibition of apoptosis triggered by neurotoxic species and to a promotion of neuronal survival and synaptic plasticity. Through these mechanisms, the consumption of flavonoid-rich foods throughout life holds the potential to limit neurodegeneration, decrease neuroinflammation, and prevent or reverse age-dependent loses in cognitive performance. The intense interest in the development of drugs capable of enhancing brain function means that flavonoids may represent important precursor molecules in the quest to develop a new generation of brain-enhancing drugs.

Keywords

Flavonoids • memory • neurodegeneration • neuroinflammation • signaling pathways

Abbreviations

AD	Alzheimer’s disease
Arc/Arg3.1	Activity-regulated cytoskeletal-associated protein
ASK1	Apoptosis signal-regulating kinase 1
BBB	Blood-brain barrier
BDNF	Brain-derived neurotrophic factor
CaMKIV	Calcium/calmodulin kinase IV
CREB	Cyclic AMP regulatory-binding protein
EGCG	Epigallocatechin-3-gallate
ERK1/2	Extracellular signal-regulated kinase 1 and 2
GSPE	Grape seed polyphenolic extract
JNK	c-jun N-terminal kinase
LTP	Long-term potentiation
MAPK	Mitogen-activated protein kinase
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
mTOR	The mammalian target of rapamycin
NGF	Nerve growth factor
PD	Parkinson’s disease
PI-3K	Phosphoinositide 3-kinase
PKB	Protein kinase B
PKC	Protein kinase C
ROS	Reactive oxygen species

1 Introduction

Due to significant advances in medical science over the past century, there has been a gradual increase in human life span, with people over the age of 60 expected to double between 2000 and 2050 [1]. Although this is a great achievement, an increase in age-related diseases including neurodegenerative disorders has been observed to parallel the extended life span. This will soon have profound economical and social implications, and it is already becoming a burden for health-care systems. Aging is an important risk factor for neurodegenerative diseases, of which Alzheimer's disease and Parkinson's disease are the most common. Neuronal loss underlies the clinical impairment in these conditions, and this cell death is associated with numerous pathogenic cellular and molecular events [2]. The majority of existing drug treatments for neurodegenerative disorders can afford symptomatic relief but are not disease-modifying, that is, cannot prevent the underlying degeneration of neurons. Therefore, there is an urgent need to develop therapeutic interventions capable of preventing the progressive loss of neurons. Because many of these neurodegenerative diseases have been linked to increases in oxidative stress, strong efforts have been aimed at exploring dietary and therapeutic antioxidant strategies to combat the neuronal damage. Recent attention has focused on the neuroprotective effects of major dietary polyphenols called flavonoids, which have been effective in protecting against both age-related cognitive and motor decline in vivo. While historically research focused on their antioxidant properties [3], recent data support the view that flavonoids, and their in vivo metabolites, do not act as conventional hydrogen-donating antioxidants but may exert modulatory actions in cells through actions at protein kinase and lipid kinase signaling pathways [4]. This chapter will highlight the neuroprotective mechanisms of flavonoids through their ability to interact with neuronal signaling pathways and their potential to modulate neuroinflammation, to counteract neurotoxin-induced neurodegenerative disorders, and to enhance memory, learning, and cognitive performances.

2 Flavonoid Bioavailability and Accessibility to the Brain

Many studies have reported the bioavailability of flavonoids in the systemic circulation [5–8], however, little is known about their uptake within the central nervous system (CNS; brain and spinal cord). In order to understand whether these phenolic compounds affect neurons and glial cells, it is crucial to ascertain their presence within the cerebral tissue. In order for flavonoids to access the brain, they must first cross a tightly regulated, selectively permeable endothelial cell layer which isolates the CNS tissue from the vasculature, the blood-brain barrier (BBB). The BBB is permeable to nutrients and actively excludes many substances from the central nervous system [9]. Using in vitro models, researchers have provided the first information on the capacity of flavonoids to traverse the BBB [10] and demonstrated that less polar *O*-methylated metabolites appear to be capable to greater brain uptake than the more polar flavonoid glucuronides [11]. The degree of entry of flavonoids or their metabolites into the CNS was also observed to depend on their interactions with transporters, such as P-glycoprotein, expressed in the BBB whose function is to export xenobiotics and unwanted metabolites [12].

For example, P-glycoprotein is considered to be responsible for the differences between naringenin and quercetin flux into the brain in situ [10]. Further to in vitro models, animal investigations have also substantiated these findings and indicated that flavanones were able to enter the brain following their intravenous administration [13], while epigallocatechin gallate [14], epicatechin [15], and anthocyanins [16, 17] were found in the brain after their oral administration. Furthermore, several anthocyanins have been identified in different regions of the rat [18, 19] and pig brains [20, 21] of blueberry-fed animals. Altogether, these results indicate that many flavonoids are able to traverse the BBB and localize in the brain, suggesting that they can directly exert neuroprotective and neuromodulatory actions.

3 Flavonoids and Memory, Learning, and Neurocognitive Performance

There is a growing interest in the potential of phytochemicals to improve memory, learning, and general cognitive ability [22, 23]. A recent prospective study aimed at examining flavonoid intake in relation to cognitive function and decline has provided strong evidence that dietary flavonoid intake is associated with better cognitive evolution, that is, the preservation of cognitive performance with aging [24]. In particular, subjects included in the two highest quartiles of flavonoid intake had better cognitive evolution than subjects in the lowest quartile and after 10 years follow-up. Subjects with the lowest flavonoid intake had lost on average 2.1 points on the Mini-Mental State Examination, whereas subjects with the highest quartile had lost 1.2 points. Such data provides a strong indication that regular flavonoid consumption may have a positive effect on neurocognitive performance as we age.

There has been much interest in the neurocognitive effects of soy isoflavones, primarily in postmenopausal women [25, 26]. Isoflavone supplementation has been observed to have a favorable effect on cognitive function [27], particularly verbal memory, in postmenopausal women [28], and a 6- and 12-week supplementation was observed to have a positive effect on frontal lobe function [29]. Furthermore, animal studies have also indicated that isoflavones are capable of improving cognitive function [30, 31]. However, there is still uncertainty regarding their effects as some large intervention trials have reported that isoflavone supplementation does not lead to cognitive improvements [32]. The rationale behind the potential of isoflavones to exert positive effects on cognitive function is believed to lie primarily in their potential to mimic the actions and functions of estrogens in the brain [33]. For example, postmenopausal women who undertake estrogen replacement therapy have a significantly lower risk for the onset of Alzheimer's disease than women who do not [34]. They may also be effective by affecting the synthesis of acetylcholine and neurotrophic factors such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) in hippocampus and frontal cortex [35, 36].

There is also extensive evidence that berries, in particular blueberries, are effective at reversing age-related deficits in motor function and spatial working memory [37–39]. In addition to spatial memory, blueberry supplementation has been shown to improve "object recognition memory" [40] and "inhibitory fear conditioning learning" [41, 42]. Blueberry appears to have a pronounced effect on short-term memory [42] and has also been shown to improve long-term reference memory following 8 weeks of supplementation [38]. Tests using a radial arm maze have supported these findings and have provided further evidence for the efficacy of blueberries [39]. Indeed, these have shown that improvements in spatial memory may emerge within 3 weeks, the equivalent of about 3 years in humans. The beneficial effects of flavonoid-rich foods and beverages on psychomotor activity in older animals have also been reported [37, 43]. In addition to those with berries, animal studies with tea [44] and pomegranate juice [45] or pure flavonols such as quercetin, rutin [46], or fisetin [47] have provided further evidence that dietary flavonoids are beneficial in reversing the course of neuronal and behavioral aging.

The flavonoid-rich plant extract, *Ginkgo biloba*, has also been shown to induce positive effects on memory, learning, and concentration [48, 49]. *Ginkgo biloba* has a prominent effect on brain activity and short-term memory in animals and humans suffering from cognitive impairment [50, 51] and promotes spatial learning in aged rodents [52, 53]. Furthermore, *Ginkgo biloba* promotes inhibitory avoidance conditioning in rats with high-dose intake leading to short-term, but not long-term, passive avoidance learning in senescent mice [54, 55]. However, the pharmacological mechanisms by which *Ginkgo biloba* promotes cognitive effects are unclear, with its ability to elicit a reduction in levels of reactive oxygen species (ROS) [56], to increase cerebral blood flow [57], to modulate membrane fluidity [54], to interact with muscarinic cholinergic receptors [58], and to protect the striatal dopaminergic system [59] all being suggested as possible mechanisms underlying its actions in the CNS.

4 Flavonoids and Neurodegeneration

There are a number of epidemiological studies which suggest that plant-derived flavonoid-rich foods or supplements might delay the initiation and progression of Alzheimer's disease (AD) and related neurodegenerative disorders. With regard to AD, independent prospective cohort studies have associated the consumption of polyphenolic-rich vegetables, fruit juices, and red wine with delayed onset of the disease [60, 61]. This is in accordance with previous studies linking high consumption of flavonoids to improvements in dementia [24, 62], and collectively, these reports lend some support to the underlying hypothesis that dietary intervention with plant-derived flavonoid-rich foods or supplements could impact on the development of AD. Not all prospective studies have reached the same positive conclusions however, and in the Honolulu-Asia aging study, midlife flavonoid intake, as estimated using mean intake of green and black tea, was not associated with altered risk of late-life incident dementia [5]. Despite this, much of the subsequent work in the field has focused on the potential bioactivity of catechins which are abundant in tea. Indeed, the green tea flavanol epigallocatechin-3-gallate (EGCG) is regarded as a lead candidate molecule for use in AD and is part of an ongoing clinical trial where it is being given in combination with donepezil to 50 patients with AD (NCT00951834).

Many of the preclinical studies of the effects of flavonoids in AD have focused on models where there is increased production of beta-amyloid (Aβ). Aβ is a small protein produced by the enzymatic cleavage of amyloid precursor protein (APP). Aβ is aggregation prone and forms oligomeric species which are directly toxic to synapses and can aggregate further to form amyloid plaques, extracellular protein deposits which are a hallmark of Alzheimer's disease pathology [63]. Studies using transgenic mouse models of AD pathology have begun to address the possible mechanisms involved in the apparently beneficial effects of catechin-rich diets. Oral administration of EGCG for 6 months to Tg2576 mice, a strain which overexpresses the Swedish mutation of APP, reduced Aβ pathology and improved cognition [64]. Similarly, long-term green tea catechin administration improved spatial learning and memory in senescence-prone mice [65]. The mechanisms underlying these changes are not clear but might be linked to increased non-amyloidogenic processing of APP, through stimulating the activity of α-secretase, which cleaves APP at a site which prevents the formation Aβ species [66–68], or could be due to disruption of the interaction of amyloid with cAbl/Fe65 which might alter its ability to be processed into toxic species [69]. Alternatively, it is conceivable that EGCG reduces Aβ plaque pathology by inhibiting amyloid aggregation and fibrillization either as a result of metal chelation activity [70–72] or by favoring the formation of nontoxic (off-target) oligomers [73]. Interestingly, in addition to possessing the ability to inhibit the formation of β-sheet rich amyloid fibrils, EGCG also converts large mature Aβ fibrils into smaller nontoxic aggregates [74]. These are significant observations although very serious consideration must be given as to whether dietary EGCG could drive Aβ disaggregation in AD brain as the micromolar concentrations required to exert these effects in vitro will not be easily achievable in vivo. Anti-amyloidogenic activity is not unique to EGCG, and a number of other flavonoids, most notably myricetin, bind to Aβ fibrils and prevent further fibrillization [75–77]. Gallic acid and catechin-rich grape seed polyphenolic extract (GSPE) administered for 5 months to Tg2576 mice also inhibited cognitive deterioration coincident with reduced levels of soluble high molecular weight oligomers of Aβ [78]. Repeated intraperitoneal injection of the polymethoxylated citrus flavone, nobiletin, has similar effects [79]. However, it is worth noting that beneficial effects have been observed with flavonoids in some AD mouse models without obvious alterations in pathology. For example, feeding blueberry to APP + PS1 double transgenic mice prevented deficits in cognitive performance at 12 months but without altering the Aβ burden [80].

Although these are clearly important studies in that they show in principle that chronic exposure to polyphenolics can influence AD pathology and behavior in vivo, it is likely that the optimal flavonoid structures possessing the necessary bioactivity and bioavailability have not yet been identified. Other mechanisms of action are also possible. Interestingly in this regard, certain flavonols and flavones have been reported to inhibit and suppress expression of an enzyme BACE-1, which is required for the production of Aβ from APP [81, 82]. This observation is consistent with some of the observed Aβ lowering effects reported for flavonoid-rich extracts in vivo and in vitro. The identification of those flavonoid structures possessing the greatest potential inhibitory activity at BACE-1 and defining their precise mechanisms of action are needed.

Despite the well-established and compelling link between Aβ and AD, Aβ pathology and cognitive deficits are not well correlated. Consequently, beneficial effects of flavonoids on cognition may be unrelated to changes in Aβ per se but to key downstream changes, for example, in phosphorylation and fibrillization of tau, a protein which, when abnormally phosphorylated, is found in neurofibrillary tangles: another pathological hallmark of AD. Indeed, a number of flavonoids including myricetin and epicatechin 5-gallate have been shown to potently inhibit heparin-induced tau aggregation [83]. Moreover, grape seed polyphenolic extract (GSPE) also inhibits tau fibrillization, promotes the loss of preformed tau aggregates, and disrupts paired helical filaments [84–87]. (−)-Epigallocatechin-3-gallate (EGCG) appears to have broadly similar effects. (−)-Epicatechin and hesperetin hold the potential to inhibit the development of tau pathology through an alternative mechanism relating to their ability to enhance phosphorylation of a key regulatory enzyme, Akt, to inhibit GSK3β-induced hyperphosphorylation of tau [88, 89]. Whatever the mechanisms involved, collectively, this suggests that orally active flavonoids could have utility in AD beyond anti-Aβ actions.

The potential utility of flavonoids in neurodegeneration extends beyond dementia, and there is also considerable interest in their therapeutic potential in Parkinson's disease (PD). The neurodegeneration observed in PD appears to be triggered by multifactorial events including neuroinflammation, glutamatergic excitotoxicity, increases in iron, and/or depletion of endogenous antioxidants. There is a growing body of evidence to suggest that flavonoids may be able to counteract the neuronal injury underlying these disorders and thus slow the progression of the disease [23, 90]. There is good evidence to suggest that the consumption of green tea may have a beneficial effect in reducing the risk of PD [91], as has been extensively reviewed elsewhere [92, 93]. The efficacy of green tea is likely to be mediated by the effects of EGCG, which has been shown to attenuate the selective degeneration of dopamine neurons in animal models of PD induced by toxins including 6-hydroxydopamine [94] and MPTP [95]. The mechanism of protection is not known, but EGCG has been noted to interact with and modulate signaling pathways involved in neuroprotection, notably protein kinase C (PKC) and PI3 kinase, and has been implicated in reducing dopamine neuron damage in the substantia nigra by the chelation of iron: a mechanism which is also relevant to AD pathology. In vitro studies have also indicated that flavonoids might act to prevent PD pathology via their ability to prevent the formation of the endogenous neurotoxin, 5-*S*-cysteinyl-dopamine [96, 97].

EGCG can also reduce hippocampal neuronal injury induced by transient global ischemia [98]. Neuroprotective effects of flavonoids have also been observed in animal models of Huntington's disease, where the flavonol fisetin has been reported to be effective in reducing pathophysiology through its actions on the extracellular signal-regulated kinase (ERK) pathway [99, 100]. Collectively, these studies suggest that flavonoids have the potential to confer benefit in diverse neurodegenerative disorders. Some of the major neuroprotective mechanisms are discussed in more detail below.

On a note of caution, however, there is still insufficient data to support the clinical use of flavonoids in the treatment of neurodegeneration, and there have been a number of disappointing results from human intervention studies for dementia with various dietary polyphenolics and antioxidants such as curcumin and Gingko biloba. The challenge ahead, therefore, is to proceed cautiously until rigorous randomized controlled clinical trials have been undertaken to determine empirically if flavonoids have efficacy in individuals affected by dementia and other neurodegenerative conditions.

5 Flavonoids and Neuroinflammation

Neuroinflammation is an important defense mechanism in the CNS which typically results from cellular damage but may also arise from other stimuli including infection. While it is a beneficial process, sustained neuroinflammatory processes are known to participate in CNS disease states [101]. For example, neuroinflammation contributes to the progressive neuron death observed in Alzheimer's disease [102], Parkinson's disease [103], and also with neuronal cell death and damage associated with cerebral ischemia [104].

Neuroinflammation is a complex process which involves several CNS cell types and is characterized by a strong reaction of glial cells, namely, microglia: cells within the CNS with an immune function, similar to macrophages; and astrocytes: cells which support neuronal function and maintain BBB integrity. During neuroinflammation, proinflammatory chemical mediators can be released from cells resident in the CNS, including neurons themselves, endothelial cells of the vasculature, and glial cells [101]. If the BBB is impaired, the neuroinflammatory stimulus may involve infiltrating T and B lymphocytes and macrophages which interact with cells resident in the CNS (neurons, microglia, astrocytes) through a complex series of interactions which are not completely understood [105]. In either case, the neuroinflammatory state is characterized by a marked activation of microglia and astrocytes. This response is typically associated with a coordinated cellular response which includes activation of intracellular pathways dependent on the proinflammatory transcription factor NF-κB (nuclear factor kappa-light-chain-enhancer of activated B cells). During neuroinflammation, activated microglia and astrocytes can release a number of factors which are toxic to neurons; these include inflammatory cytokines such as interleukin-1 beta (IL1β), tumor necrosis factor alpha (TNFα), nitric oxide (NO), and glutamate [101, 106, 107].

The best example of a CNS disease state with a major neuroinflammatory component is multiple sclerosis (MS), a chronic debilitating disease which is characterized by demyelination, progressive irreversible axonal damage, and inflammation [105]. The most effective therapies to date act by reducing inflammation and activation of the immune system [108], showing that suppression of neuroinflammation has a positive effect in the disease. Dietary modification to improve multiple sclerosis symptoms and progression is an attractive proposition. Many patients with MS already use special diets, for example, gluten-free and milk-free or dietary supplementation with polyunsaturated fatty acids, vitamins, antioxidants, and/or herbal supplements (e.g., *Gingko biloba*). However, so far, a truly beneficial supplement or protective factor with a sound scientific base has not been elucidated. In part, this is attributed to poor design of the clinical trials [109] but also reflects the fact that the most potent interventions have not been found or, indeed, searched for systematically. Although to date there is no correlation between dietary intake of fruit and vegetables and incidence of MS [110, 111], flavonoids have the potential to be clinically useful in abrogating MS pathology. The studies to date have not excluded links between fruit and vegetable consumption and lowered MS incidence [112]. Dietary supplementation with flavonoid compounds has not been tested in man.

There is data which show encouraging positive effects of flavonoids in animal and in vitro models relevant to MS. A flavanol, (−)-epigallocatechin-3-*O*-gallate (EGCG), delivered orally reduces symptom severity in the autoimmune encephalomyelitis model of relapsing-remitting MS by reducing inflammation and increasing neuroprotection [113]. The flavonol quercetin has also been reported to be effective in the Experimental Autoimmune Encephalomyelitis (EAE) mouse model and reduces T cell proliferation in vitro at concentrations exceeding 10 μM [114]. Two Dutch groups independently identified a number of promising flavonoids using in vitro assays. Hendriks et al. [115] tested six flavonoids and found that one, luteolin, was the most effective at suppressing myelin phagocytosis by the macrophage cell line RAW 264.7 (IC_{50} of 20 μM). Several other flavonoids (quercetin, fisetin, and apigenin) were also effective in this assay but with potencies an order of magnitude lower. In the rat EAE model, luteolin (but not quercetin) showed clinical protection [116]. A separate group tested six flavonoids for their ability to alter T cell proliferation [117]. They showed that micromolar concentrations of luteolin, apigenin, fisetin, and quercetin (but not morin or hesperetin) suppress the production of the cytokine interferon-gamma (IFNγ) from lymph node-derived T cells but, paradoxically, worsen clinical severity in the EAE model. There is strong evidence that the flavone wogonin and a related compound baicalein can inhibit inflammatory responses in macrophages in vitro and in vivo [118, 119]. Thus, the studies to date show promising proof of concept of beneficial effects of flavonoids in suppressing immune and inflammatory responses in models of MS.

During activation of glial cells in neuroinflammatory states, various transcription factors including NF-κB, activator protein-1 (AP-1), and the signal transducer and activator of transcription-1 (STAT-1) have been shown to be involved in proinflammatory responses in astrocytes and microglia [120–124] which can contribute to neuronal death. Of these transcription factors, the NF-κB system is the most studied system in the context of neuroinflammation. Suppression of this pathway can be neuroprotective [125]. Its activation is seen in a number of neurodegenerative states, for example, in postmortem Alzheimer's disease patients, cells in the vicinity of β-amyloid plaques show increased NF-κB immunoreactivity. Numerous flavonoids have been shown to have the ability to inhibit NF-κB in different cell types. The flavonol quercetin (50 μM) reduces phosphorylation of NF-κB subunits in human peripheral blood mononuclear cells [126] and suppresses NF-κB in a microglial cell line [127]. The flavanone oroxylin A (80 μM) reduces LPS-induced NO production and NF-κB activity in RAW 246.7 macrophages [128]. The flavone apigenin (5–15 μM) blocks LPS stimulation of the NF-κB pathway in RAW 246.7 macrophages and reduces κB-transcriptional activity [129]. The flavanol EGCG (5–15 μM) reduces LPS-induced NFκB-activity in peritoneal macrophages [130] and reduces T cell proliferation accompanied by inhibition of NF-κ B [113]. Catechin (0.13–2 mM) has been reported to increase mouse microglial cell survival following exposure to the oxidative agent *tert*-butyl hydroperoxide (tBHP) by suppressing NF-κB activation [131]. The flavone luteolin (20 μM) reduced LPS-induced NF-κB transcriptional activity in fibroblasts [132]. The flavone wogonin (50 μM) was shown to reduce NF-κB activation in C6 glioma cells and prevent microglial activation [133], and baicalein is reported to inhibit $NO^\bullet$ production and NF-κB activity in microglia [134, 135]. The isoflavone genistein has been shown to reduce expression of iNOS in astrocytes, through inhibition of NF-κB activation [136]. While the data gives proof of principle that NF-κB is a potential target of flavonoids, the concentrations required for positive effects of those particular compounds in vitro are high, in the micromolar range, that is, at concentrations which cannot be obtained through the diet. It is likely that, for most of those studies, the antioxidant effects of the flavonoids used account for the positive effects on suppressing NF-κB activation. We have tested dietary-relevant concentrations of flavonoids and shown them to be bioactive in suppressing certain responses in primary astrocytes mediated by transcription via the antioxidant response element [137]. However, at this concentration range (0.1–1 μM), we find flavonoids of different classes are unable to suppress NF-κB signaling pathways in primary astrocytes [169]. Therefore, while flavonoids may be effective agents at suppressing neuroinflammation in vivo, at this time, we do not regard the NF-κB signaling system as the primary signaling system responsible for the effects of flavonoids in vivo.

6 Mechanisms Underpinning the Beneficial Effects of Flavonoids

Historically, the biological actions of flavonoids have been attributed to their antioxidant properties, either through their reducing capacities per se or through their possible influences on intracellular redox status. However, their classical hydrogen-donating antioxidant activity is unlikely to be the sole explanation for the bioactivity of flavonoids in vivo, as during absorption they are extensively metabolized to glucuronides, sulfates, and *O*-methylated forms which are reduced in their antioxidant potential [4]. Rather, it has become evident that flavonoids are more likely to exert their neuroprotective actions by the modulation of intracellular signaling cascades, of particular interest in this context are those protein kinases which are central to pro-survival or pro-death pathways in neurons.

After ingestion, flavonoids are thought to reach sufficiently high concentrations in the CNS, that is, in the high nanomolar range, to exert pharmacological activity by binding to specific protein targets. Numerous studies now show important effects of flavonoids at sub-micromolar concentrations where antioxidant effects are unlikely to be relevant. The effects of flavonoids on neuronal signaling pathways are highly concentration dependent and are likely to be related to their ability to exert high-affinity receptor agonist-like actions at low concentrations (low to mid nanomolar) and direct enzyme inhibition at higher concentrations (high nanomolar to micromolar) [138, 139].

The precise site for the first point of interaction of flavonoids with neurons is still unclear in most cases. Potential flavonoid-binding sites on neurons include adenosine [140], $\mathrm{GABA_A}$ [141, 142], and testosterone receptors [143], and a specific plasma membrane binding site for polyphenols in CNS tissue has been proposed [144]. Evidence indicates that they are capable of regulating signaling pathways, particularly protein kinases, in a number of ways which include: (1) binding to enzymes or receptors which control kinase activation, (2) by modulating the activity of kinases directly, (3) by affecting the function of important phosphatases, which act in opposition to kinases, and (4) by modulating signaling cascades lying downstream of kinases, that is, transcription factor activation to selectively control gene expression [23, 145]. It is beyond the scope of this chapter to list all the pathways which have been shown to be regulated by flavonoids, so we focus on a few key signaling pathways which are intimately associated with neuron survival and plasticity.

There is much evidence to support the actions of nanomolar concentrations of flavonoids, in particular flavanols and flavanones, on the ERK pathway [89, 146], which are, in general, calcium dependent and mediated by interactions with upstream kinases MEK1 and MEK2 and potentially membrane receptors [147]. ERK activation often leads to the activation of the cAMP response element-binding protein (CREB), a transcription factor. CREB is considered to be critical in the induction of long-lasting changes in synaptic plasticity and memory [148, 149]. CREB activation regulates the expression of a number of important genes, including brain-derived neurotrophic factor (BDNF), thus has a pivotal role in controlling neuronal survival and synaptic function in the adult central nervous system [150, 151]. Regulation of BDNF is of particular interest as it is linked with the control of synaptic plasticity and long-term memory [152]. Decreases in BDNF and pro-BDNF have been reported in Alzheimer's disease [153], and a polymorphism that replaces valine for methionine at position 66 of the prodomain of BDNF is associated with memory defects and abnormal hippocampal function in humans [154].

Recent studies have shown that spatial memory performance in rats supplemented with blueberry correlates well with the activation of (CREB) and with increases of BDNF in the hippocampus [42]. Blueberry flavonoid-induced activation of CREB and BDNF expression has also been shown to lead to the activation of the PI3 kinase/Akt signaling pathway [42], via the binding of BDNF to pre- or postsynaptic TrkB receptors. Fisetin, a flavonoid found in strawberries, has been shown to improve long-term potentiation and to enhance object recognition in mice by a mechanism dependent on the activation of ERK and CREB [155].

In general, in vitro studies show that many flavonoids, at submicromar concentrations, activate ERK, as determined by measuring increased phosphorylation of this enzyme. In cortical neurons, the flavanol (−)-epicatechin (0.1 and 0.3 μM) induces both ERK1/2 and CREB activation [47], while nanomolar concentrations of quercetin are effective at enhancing CREB activation [156]. Other flavonoids have also been found to influence the ERK pathway, with the citrus flavanone, hesperetin, capable to activating ERK1/2 signaling in cortical neurons at nanomolar concentrations [157], and flavanols such as EGCC restoring ERK1/2 activities in 6-hydroxydopamine-treated or serum-deprived neurons [94]. This ability to activate the ERK pathway is not restricted to neurons and has also been observed in fibroblasts exposed to nanomolar concentrations of epicatechin [158].

As well as effecting the ERK/CREB/BDNF axis, flavonoids are known to modulate the activity of an enzyme system associated with neuroprotection, Akt (also known as PKB). One of the major enzymes which controls Akt/PKB activity is the lipid kinase, PI3K. In cortical neurons, flavonoids such as the citrus flavanone hesperetin (0.1 and 0.3 μM) cause the activation of Akt/PKB and the consequent inhibition of proteins associated with cell death such as apoptosis signal-regulating kinase 1 (ASK1), Bad, caspase-9, and caspase-3 [89]. The activation of Akt by flavonoids in hippocampal neurons has been shown to trigger the increased translation of specific mRNA subpopulations [159], including the activity-regulated cytoskeletal-associated protein (Arc/Arg3.1) [42]. Arc is also under the regulatory control of both BDNF [160] and ERK signaling [161]. Increased Arc expression may facilitate changes in synaptic strength and the induction of morphological changes in dendritic spines [162]. In support of this, studies have indicated that changes in neuronal morphology occur in response to flavonoid supplementation [163] and that certain flavonoids can influence neuronal dendrite outgrowth in vitro [164] (Fig. 84.1).

As well as pro-survival effects, some flavonoids may inhibit important protective enzymes. Flavonoids can inhibit PI3K via direct interactions with its ATP binding site [165]. The structure of flavonoids determines whether or not they act as potent inhibitors of PI3K [166]. One of the most selective PI3K inhibitors available, LY294002, was modeled on the structure of quercetin [167, 168]. Quercetin and some of its in vivo metabolites have been shown to be neurotoxic in vitro, by inhibiting pro-survival Akt/PKB signaling pathways by a mechanism of action consistent with quercetin and its metabolites acting at and inhibiting PI3K activity [156]. In addition, some flavonoids may be capable of interacting directly with ERK kinases, such as MEK-1 to cause ERK inhibition: the flavone backbone (2-phenyl-1,4-benzopyrone) has close structural homology to a specific MEK-1 inhibitor, PD98059 (2′-amino-3′-methoxyflavone). This data suggests that flavonoid supplementation must be treated with caution; while many compounds are likely to enhance neuroprotective signaling, others may produce unwanted inhibition of key enzymes important for cell survival.

Fig. 84.1 *The interaction of flavonoids with cellular signaling pathways involved in neurodegeneration, neuroinflammation, and learning and memory*. Flavonoid-induced activation and/or inhibition of MAP kinase and PI3 kinase signaling leads to the activation of transcription factors which drive gene expression. For example, activation of ERK/Akt and the downstream transcription factor CREB by flavonoids may promote changes in neuronal viability and synaptic plasticity, which ultimately influence neurodegenerative processes. Flavonoid-induced inhibition of the JNK, ASK1, and p38 pathways leads to an inhibition of both apoptosis in neurons and a reduction of neuroinflammatory reactions in microglia (reduction in iNOS expression and NO$^{\bullet}$ release). Alternatively, their interaction with signaling may lead to direct activation of proteins such as eNOS, which controls nitric oxide release in the vasculature and thus may influence cerebral blood flow

7 Summary

The neuroprotective actions of dietary flavonoids involve a number of effects within the brain, including a potential to protect neurons against injury induced by neurotoxins, an ability to suppress neuroinflammation, and the potential to promote memory, learning, and cognitive function. This multiplicity of effects appears to be underpinned by their capacity to interact with important neuronal signaling cascades in the brain leading to an inhibition of apoptosis triggered by neurotoxic species and to a promotion of neuronal survival and differentiation. Although the consumption of flavonoid-rich foods throughout life may hold a potential to limit neurodegeneration and prevent or reverse age-dependent deteriorations in cognitive performance, at present, the precise temporal nature of the effects of flavonoids on these events is unclear. For example, when one needs to begin consuming flavonoids in order to obtain maximum benefits is not yet known. There are a vast number of flavonoids available, and while many have similar beneficial effects on neuroprotection in animal models, those flavonoids which are the most effective are not yet known. Due to the intense interest in the development of drugs capable of enhancing brain function, flavonoids may represent important precursor molecules in the quest to develop a new generation of brain-enhancing drugs.

Abstract

Consumers and producers have recently shown an increasing interest in health-promoting properties of plant fresh foods, which are currently considered "functional foods." They contain phytochemicals playing a key role in promoting human health by reducing oxidative damages, modulating detoxifying enzymes, stimulating the immune system, and showing chemopreventive actions. Recent findings revealed that the content and composition of phytochemicals in fresh fruit and vegetables is greatly affected by plant genotype, harvest season, soil quality, and agronomic and environmental factors, including mycorrhizal symbioses established by arbuscular mycorrhizal fungi (AMF) with most crop plants. AMF promote plant growth and health and reduce the need of chemical fertilizers and pesticides, leading to less environmental damage and to improved

food quality and health. They also enhance the biosynthesis of plant secondary metabolites with health-promoting activities, such as polyphenols, carotenoids, flavonoids, phytoestrogens, and activity of several antioxidant enzymes. Recent studies reported a higher nutraceutical value in mycorrhizal globe artichoke and tomato, two plant species largely cultivated for human consumption, suggesting that AMF inoculation may represent a suitable biotechnological tool to be implemented in agri-food chains aimed at producing safe and healthy food.

1 Introduction

Consumers and producers have recently shown an increasing interest in health-promoting properties of plant foods, which represent an important societal issue. Fresh fruits and vegetables are currently evaluated not only for their size, weight, appearance, and flavor but also for their nutritional and nutraceutical value, that is, their content in vitamins, mineral nutrients, dietary fibers, and secondary metabolites. Plant fresh foods are considered “functional foods,” “nutraceutical foods,” or “pharmafoods,” since many epidemiological studies have reported that their consumption may play a key role in promoting human health by preventing chronic diseases and decreasing the risk of mortality from cancer and cardiovascular diseases [1–6]. Though, in most cases, it was not investigated whether the biological activity was linked to a specific plant molecule or to additive and synergistic combinations of phytochemicals [7].

Phytochemicals, represented by thousands of secondary metabolites produced by plants belonging to many different families, genera, and species, are dietary plant molecules which, consumed daily, can beneficially modulate human metabolism [8]. In particular, they represent a rich source of natural antioxidant compounds able to reduce or prevent oxidative damages to different biological molecules, such as lipids, proteins, and nucleic acids [9], damages caused by the action of reactive oxygen species (ROS) deriving from cell aerobic respiration [10–12]. Beyond their antioxidant activity, phytochemicals play a beneficial and functional role in human health by modulating detoxifying enzymes [13] and hormone metabolism [14, 15] and by stimulating the immune system [16], showing also antibacterial and antiviral activity [17].

The most important phytochemicals are represented by polyphenols, widespread compounds functioning as scavengers of free radicals and quenchers of single oxygen formation [18]. Polyphenols are widely distributed in plants and are generally considered beneficial, since they affect different processes in mammalian cells, suggesting an anticarcinogenic and antiatherogenic role [19, 20]. Flavonoids, represented by more than 5,000 bioactive compounds, many of which can be found in food and beverages – such as quercetin in tea, kaempferol in cabbages, and myricetin in blackberry and red vine – have been reported to reduce the risk of cardiovascular diseases, to exert a chemoprotective action, and to have a phytoestrogenic activity [21]. Glucosinolates, phytochemical compounds including more than 130 different molecules mainly occurring in Brassicaceae [22], are considered "plant food protection agents" since a clear correlation has been shown between cruciferous plant consumption and cancer risk reduction [6, 23–25]. Other epidemiological data reported that isoflavones have different health-promoting effects, protecting from cardiovascular diseases [26].

Different phytochemical molecules have shown a chemopreventive action [27]: for example, the synthetic oleanane triterpenoid, CDDO-methyl ester, is a potent antiangiogenic agent [28]; epigallocatechin-3-gallate from green tea inhibits tumor angiogenesis and vascular tumor growth [29]; polyphenol curcumin prevents hematogenous breast cancer metastases in immunodeficient mice [30]; polyphenol xanthohumol from hop shows antileukemia effects in Bcr/Abl-transformed cells [31]; hyperforin from *Hypericum perforatum* blocks neutrophil activation of matrix metalloproteinase-9 and restrains inflammation-triggered angiogenesis [32]; lycopene from tomato is active in inflammation and in chemoprevention of prostate cancer [27]; polyphenolic compounds contained in red wine are able to inhibit vascular endothelial growth factor expression in vascular smooth muscle cells [33].

Nevertheless, it is important to note that any health-promoting activity of plant food depends on its bioavailability and bioefficacy, which are often related to individual variables, such as microbiome structure and composition, digestive processes, and absorption in the intestine [34–36].

Some phytochemicals, such as isoflavones and other flavonoids, as well as lignans, coumestans, and stilbenes, display estrogenic (and antiestrogenic) activity and are generally called phytoestrogens, notwithstanding the fact that they do not show any structural similarity to naturally occurring estrogens [37]. For example, lignans contained in seeds, sprouts, fruits, vegetables, and whole grains are active in cancer prevention, similarly to isoflavones [38]. These compounds have been studied for their putative preventive role in osteoporosis, menopausal symptoms, arteriosclerosis, heart disease, and cancer, and some were considered alternative to synthetic compounds for therapeutic purposes in humans [39, 40]. They have a complex mode of action via interaction with the nuclear estrogen receptor isoforms ERa and ERb, exhibiting either estrogen-agonist or estrogen-antagonist effects [41]. In particular, antiestrogenic compounds can antagonize estrogen-dependent processes in their target tissues, counteracting the growth of estrogen-related cancers. Moreover, other polyphenols and lycopene have been considered promising pharmacological agents in cancer prevention, as a result of their antiproliferative effects and their inhibitory action on the human estrogen receptors [42–44].

2 Health-Promoting Phytochemicals as Affected by Agronomic Management

Phytochemicals play a major role in ecological interactions between plants and the surrounding environment, being active against pathogens and viruses, in allelopathic interactions, in insect chemoattraction, and in defense mechanisms against biotic and abiotic stresses. As plant secondary metabolites, they can be constitutively expressed but can also be induced by diverse factors, including attack by fungal and bacterial pathogens and herbivores [45]. Recent findings revealed that the content and composition of phytochemicals in fresh fruit and vegetables (FAVs) is greatly affected by other variables, that is, plant genotype, harvest season, cultivation site and techniques, and soil quality, and by agronomic practices, such as quantity and quality of available nutrients and light, irrigation, use of pesticides and chemical fertilizers, and conventional/organic management [46–48]. Such results increased interest in nutraceutical and functional foods, which stimulated scientists to boost research on beneficial plant secondary metabolites and on the best genetic and agronomic approaches to increase their concentration in FAVs [49, 50].

A key reference paper provided a comprehensive database (collected as part of the USDA National Food and Nutrient Analysis Program) of the total phenolic content and antioxidant capacity in over 100 different foods, including fruits, vegetables, nuts, dried fruits, spices, and cereals [51]. Other investigations reported thorough lists of nutraceutical properties of FAVs, depending on different genetic and agronomic variables. Plant genotype was one of the main factors assessed: the antioxidative activity of 92 plant phenolic extracts was found to vary with plant species, which showed highly variable total phenolic content, calculated as gallic acid equivalents (GAE), ranging from >20 mg g^{-1} GAE in berries to <12.1 mg g^{-1} GAE in apples [11]. Two different cultivars of tomato contained 1.0 and 10 mg kg^{-1} of lycopene, whose content ranged from 10 to 100 mg kg^{-1} in the same tomato variety analyzed at two different ripening stages – turning and red – respectively [52]. Plant genotype affected the production of different metabolites, such as ascorbic acid, whose concentrations ranged from 20 to 300 mg kg^{-1} in apple, from 300 to 500 mg kg^{-1} in orange, and from 290 to 800 mg kg^{-1} in kiwi, depending on the cultivar type [53, 54] and glucosinolates in broccoli, which showed huge variability among 50 screened cultivars [55]. In fruit plants, rootstock type affected the nutritional and nutraceutical quality of peel and flesh of peach fruits, which showed the highest antioxidant capacity associated to a high level of carotenoids and phenols in the rootstocks Mr. S 2/5 and Barrier 1, compared with Ishtara and GF 677 [56, 57].

Several conventional breeding programs in different countries, boosted with the aim of obtaining cultivars with enhanced concentrations of phytochemicals, were successful: for example, improvements were registered in tomato lines with 10–25 times increased concentration in β-carotene, compared with conventional varieties [58, 59] and in new peach and plum genotypes rich in phenolic compounds and antioxidant capacities [60, 61]. Such promising and important results allow us to foresee that in the years to come, new breeding programs will lead to the selection of cultivars with enhanced concentrations in phytochemicals.

Beyond plant genotype, agronomic and environmental factors may play a major role in increasing phytochemical content of FAVs, and it is tempting to speculate on the possibility of selecting the best performing growth conditions and techniques to enhance health-promoting properties of crops.

The production of phytochemicals, such as ascorbic acid, phenolic compounds, carotenoids, and glucosinolates, as a result of plant exposure to low temperatures and high light intensity during the growth period, was much variable in quantity and composition in diverse FAVs. However, high light exposure or intensity generally produced positive effects in the concentration of ascorbate, phenolic compounds, carotenoids, and glucosinolates of FAVs, probably due either to enhanced photo-oxidative stress or to increased photosynthesis [50]. The same variable trend was shown by treatments with specific wavelength irradiation, such as red light, blue light, and UV-B on carotenoids concentration in tomato, suggesting that light influences carotenoid metabolism in a very complex way [62, 63].

Other agronomic factors, such as drought and high salinity, are still under investigation for their putative positive effects on phytochemical concentration in diverse FAVs. Interesting responses to water availability were found in grapevine and field-grown olive trees: deficit irrigation regimes increased the concentration of phenolic compounds, improving the quality of grape and virgin olive oil [64, 65]. Other findings suggested that irrigation with saline water may improve carotenoids content and antioxidant activity of tomatoes [66, 67].

It is important to highlight that the extremely high increases in some phytochemicals obtained through genetic selection, conventional breeding, and metabolic engineering – reaching up to 10–25-fold in carotenoids, 20-fold in glucosinolates, and 36-fold in kaempferol-rutoside – raised concerns on their safety [50], since some compounds, such as polyphenols, generally considered beneficial for their anticarcinogenic and antiatherogenic role [19], have proved to be genotoxic at high concentrations [68, 69]. On the contrary, the increases in phytochemical concentration produced by environmental and agronomic factors – ca. twofold – were claimed to "*represent arguably a good balance between effectiveness and safety*" [50].

Such interesting suggestion gives further support to projects aiming at continuing and extending research on the best agronomic techniques and managements to enhance the production of beneficial phytochemicals in crop plants, cereals, fruits, and vegetables in the years to come. One of the most promising agronomic factors affecting plant secondary metabolic pathway is represented by arbuscular mycorrhizal fungi, belonging to Glomeromycota, an important ecological and economical group of beneficial soil microorganisms that establish mutualistic symbioses with the roots of the vast majority of plant species.

3 Plant Beneficial Symbionts: Arbuscular Mycorrhizal Fungi

Mycorrhizal symbioses are beneficial associations between plant roots and soil-borne fungi, occurring in about 90 % of land plants and involving 240,000 plant species and 6,000 fungal species. Depending on host plants and fungal symbionts, many different mycorrhizal types have been observed in nature; nevertheless, their effects on host plants are similar: a larger growth due to a better nutritional status, a higher tolerance to biotic and abiotic stresses, and a general higher fitness, compared with non-mycorrhizal plants [70]. The most widespread type of mycorrhizal symbiosis is the arbuscular mycorrhiza, which is distributed from arctic to subantarctic regions, in temperate and tropical grassland and forests, scrub and desert ecosystems, from sand dunes to alpine sites [71]. Arbuscular mycorrhizal (AM) symbioses occur within all phyla of land plants, in most plant families, except genera and species belonging to Brassicaceae, Chenopodiaceae, and Cyperaceae, and plants which are exclusively hosts of other mycorrhizal fungi.

The most important agricultural fodder and grain crops form AM symbioses: from cereals, including rice, corn, barley, and wheat, to legumes and fruit trees including citrus, peach, grapevine, and olive and from vegetables like onion, strawberry, tomato, and potato to economically important species, such as sunflower, cassava, cotton, sugarcane, tobacco, coffee, tea, cocoa, rubber, oil palm, and banana [71]. AM fungi (AMF) show low host specificity and are obligate biotrophs, that is, they cannot be cultivated on synthetic media in the absence of the host. Such inability represents the major constraint to their large biotechnological application. Their life cycle starts with spore germination, originating a short-lived asymbiotic mycelium, which is able to recognize host roots and to differentiate infection structures, the appressoria, on the root surface. Hyphae developed from appressoria grow within the root cortex, intercellularly along the longitudinal root axis, and then penetrate within cortex cells, forming haustoria-like branched structures, the arbuscules, originating from the dichotomous branching of intracellular hyphae which progressively reduce their diameter. Arbuscules are the key structure of the mutualistic symbiosis, representing the site where nutrient exchanges between plant and fungus occur. After establishing the symbiosis, plant-derived carbon is transferred to AM symbionts, reaching up to 20 % of total photosynthate, and then transformed into trehalose and other fungal polyols [72]. Such carbon is essential for the extraradical growth of AMF, which produce large mycelial networks exploring the surrounding environment and efficiently absorbing mineral nutrients from the soil, as a result of the high surface-to-volume ratio of the hyphae [73, 74]. Eventually the fungus is able to complete its life cycle by the formation of new spores.

A large body of investigations showed that AMF have important beneficial effects on plant growth, increasing the transfer of soil mineral nutrients, such as phosphorus (P), nitrogen (N), sulfur (S), potassium (K), calcium (Ca), iron (Fe), copper (Cu), and zinc (Zn), and improving plant tolerance to root pathogens and drought [70]. Differential increases in P and N supply to host plants after inoculation of diverse AMF have been ascribed to phenotypic and functional properties of the extraradical mycorrhizal mycelium [75–79], depending also on the occurrence and differential expression of P transporter and N assimilation fungal genes [80–82].

The mechanism involved in the improved P nutrition of mycorrhizal plants is represented by the efficient soil exploration by fungal hyphae extending beyond the depletion zone caused by the fast absorption of P from the soil solution, which cannot be rapidly replenished, given the poor mobility of P in the soil [83]. Electron microscope studies and chemical analyses revealed that hyphal P translocation is operated through the accumulation of polyphosphate granules within hyphal vacuoles, which are transferred from soil-based to root-based hyphae [84–88]. P is then released to the host cells in the arbuscules by means of polyphosphatases and alkaline phosphatases [89–95]. As AMF are coenocytic organisms, that is, they do not possess cross walls, the high flow rates of protoplasm occurring within their hyphae can explain the rapid mobilization and transfer of P and the other soil nutrients.

Indeed, the inflow rates of P in extraradical hyphae may range from 2 to 20 × 10^{-6} mol m^{-2} s^{-1} [96–99], while bidirectional protoplasmic flow rate, measured on the basis of cellular particles movement (presumably vacuoles, nuclei, fat droplets, organelles, granules), ranges from 2.98 to 4.27 μm s^{-1} [100, 101]. However, it is important to underline that the most important factor affecting the transfer of nutrients from soil to root-based hyphae is represented by the flux of mineral nutrients through appressoria, which for P is 3.8 × 10^{-8} mol cm^{-2} s^{-1} [102].

A great diversity has been reported among plant species in the extent to which they depend on AMF. For example, some plant species such as *Citrus* spp. are totally dependent on mycorrhizal inoculation during the seedling stage [103], showing no response to P addition, while other species, such as grasses, show a low mycorrhizal dependency [104]. However, the different degrees of mycorrhizal dependency vary with plant species and cultivars, soil P content, root colonization, and efficiency of the inoculated fungal isolate [105].

Moreover, AMF may represent underground communication ways [106], also activating defense pathways before the pathogen attacks. For example, tomato plants colonized by the same AM symbiont showed increased expression of defense-related genes and higher levels of disease resistance enzymes in healthy "receiver" plants after inoculation of "donor" plants with a pathogen [107].

In conclusion, AMF represent fundamental key factors promoting plant growth and health by processes such as the acquisition of nutrients and water, the modulation of plant hormonal balance, the protection from pathogens, and the abiotic stress protection. Thus, AMF play a major role in organic production of food by reducing the need of chemical fertilizers and pesticides, leading not only to less environmental damage but also to improved food quality and health. Contemporary trends toward low-input, sustainable agriculture consider mycorrhizal inoculation with efficient AM fungal species a promising biofertilization strategy in order to enhance plant growth, yield, and quality.

Recently, AM fungal symbioses have been shown to modify several aspects of host plant metabolism and have been proposed as an environmentally friendly and efficient strategy to enhance plant biosynthesis of secondary metabolites with health-promoting activities.

4 Nutraceutical Value of Mycorrhizal Plants

Many evidences indicate that AM fungal symbiosis may induce changes in primary and secondary metabolism of host plants, for example, increasing the production of secondary compounds – including polyphenols – in the roots of mycorrhizal plants [108–113]. Indeed, the colonization of root cortical cells by AMF causes diverse cytological and metabolic changes: a marked proliferation of plastids, the activation of Krebs cycle, and the modification of plastid biosynthetic pathways during intracellular arbuscule development leading to increased metabolic activity and to higher production of fatty acids, apocarotenoids, and amino acids, such as tyrosine, which, together with phenylalanine, is the main precursor of plant polyphenols in the phenylpropanoid metabolism [114–117]. Interestingly, in *Trifolium repens* plants, accumulation of some flavonoids – quercetin, acacetin, and rhamnetin – was exclusively detected in roots of plants inoculated with *Glomus intraradices* [118].

Several studies investigated also the influence of AM fungal symbiosis on plant shoot metabolic activities. Some authors suggested that accumulation of secondary compounds in the shoots of mycorrhizal plants may represent the main factor conferring resistance to fungal pathogens [119–122]. For example, higher contents of phenolic compounds in mycorrhizal plants were correlated with a reduced severity of diseases caused by *Phytophthora nicotianae* and *Botrytis fabae* in tomato and *Vicia faba*, respectively [123, 124], and with a decrease of *Ralstonia solanacearum* population in tomato [125].

AM fungal inoculation, besides inducing larger plant photosynthetic rates [126, 127], may produce other important biochemical changes, for example, in the non-mevalonate methylerythritol phosphate pathway of isoprenoid biosynthesis, correlated with apocarotenoid accumulation [128], and in physiological mechanisms leading to the accumulation of secondary metabolites, such as phenolic acids, carotenoids, and polyphenols, both in roots and in shoots [129–132]. Moreover, AMF induced also alterations in the activity of superoxide dismutase (SOD) in roots and shoots of different plant species [133–137] and of several antioxidant enzymes in roots of *Phaseolus vulgaris* [138] and in shoots of lavender, rice, and three Mediterranean shrubs [127, 139, 140], suggesting that the induction of plant protective mechanisms could alleviate oxidative damages caused by drought, salt, and other environmental stresses, leading to plant increments in shoot biomass. Accordingly, higher levels of enzymes active in the removal of reactive oxygen species (ROS) in mycorrhizal roots suggested that colonized plants may respond to oxidative stresses by the accumulation of antioxidative enzymes and carotenoids [141–144].

The inoculation of the AM fungal species *Glomus mosseae* and *Glomus versiforme* triggered transient enhancement of the levels of transcripts encoding phenylalanine ammonia-lyase in *Oryza sativa* and *Medicago truncatula* roots, respectively [141, 145], while increased chalcone synthase (CHS) transcript accumulation was found in *M. truncatula* roots colonized by *G. versiforme* [141] and *G. intraradices* [146]. Other effects of AM fungal symbiosis on secondary metabolism, such as phytohormone dynamics, were also reported [147–149].

A recent study found that mycorrhizal red clover showed impaired levels of isoflavones with estrogenic activity, such as biochanin A, formononetin, genistein, or daidzein [150], and natural plant metabolites called “phytoestrogens,” which are believed to play an important preventive role in osteoporosis, menopausal symptoms, arteriosclerosis, heart diseases, and cancer [39, 151] and are investigated as alternative to synthetic compounds for therapeutic purpose in humans [37]. In the species *Arnica montana*, which contains several groups of active secondary compounds, AM fungal inoculation induced sesquiterpene lactones accumulation both in roots and in shoots [131].

Several studies investigated AM fungal effects on the production of phytochemicals in medicinal and aromatic plants. Higher accumulation of antioxidant compounds (rosmarinic acid and caffeic acid) and essential oils was reported in shoots of *Ocimum basilicum* (sweet basil) inoculated with different *Glomus* species [130, 152, 153]. Essential oil concentration increased in fruits of *Coriandrum sativum*, *Anethum graveolens*, and *Trachyspermum ammi* (+43 %, +90 %, and +72 %, respectively, compared with controls) inoculated with *Glomus macrocarpum* and *Glomus fasciculatum* [154, 155], with differences between the two species of fungal symbionts. The concentration of essential oil showed about 62.5 % increase in *Foeniculum vulgare* seeds produced by plants inoculated with *G. fasciculatum*, compared with non-mycorrhizal controls. Moreover, chemical characterization of the essential oil extracted from seeds produced by mycorrhizal plants revealed an enrichment in anethol concentration [156].

Interestingly, essential oil accumulation may be partly due to a non-nutritional effect of AMF, since mycorrhizal *Origanum* sp. plants produced higher oil concentrations compared with those obtained from non-mycorrhizal plants showing equivalent P content [157].

Root concentration of the alkaloid forskolin, a potent cardioactive and hypotensive diterpenoid compound, was consistently higher in *Coleus forskohlii* plants inoculated with different AM fungal species, compared with non-mycorrhizal controls, with the largest increase (+147 %) when the symbiont *Glomus bagyarajii* was used [158]. Phytochemicals with therapeutic value produced by *Echinacea purpurea* (pigments, caffeic acid derivatives, alkylamides, and terpenes) increased their concentration up to 30 times after inoculation with the AM fungal species *G. intraradices* and *Gigaspora margarita* and the entomopathogenic endophyte *Beauveria bassiana* [159].

An increase in thymol derivatives production was observed in roots of *Inula ensifolia* plants inoculated with *G. intraradices* and *Glomus clarum*: the highest concentration of all the analyzed compounds was found in roots colonized by *G. clarum* [160]. Enhanced concentrations of anthraquinone derivatives (hypericin and pseudohypericin) were reported in *H. perforatum* shoots after inoculation with *G. intraradices* and with a mixed AM fungal inoculum [161].

Interestingly, a positive correlation between AM fungal root colonization of the medicinal plant *Castanospermum australe* and the content of castanospermine – an alkaloid of the indolizidine type – was found both in seeds and leaves, under field and greenhouse conditions, respectively [162].

So far a few studies investigated the relationship between plants, AM fungal colonization, and phytochemicals concentration in plants used for human nutrition. In the greenhouse, anthocyanins, carotenoids, and, to a lesser extent, phenolics occurred in higher concentration in the leaves of mycorrhizal lettuce plants than in non-mycorrhizal controls [163], while AM fungal inoculation of *Allium cepa* plants in pots significantly enhanced the total antioxidant capacity of bulb biomass [164]. In a greenhouse experiment, fruits of tomato plants, inoculated with a microbial mix of AMF and different bacteria, showed higher glucose, fructose, malate, and nitrate contents, while β-carotene, lycopene, and lutein contents increased when the substrate was amended with the microbial mix and green compost [165].

A 2-year field study and a multidisciplinary research reported higher nutraceutical value in mycorrhizal globe artichoke and tomato, plants largely cultivated for human consumption.

4.1 Case Study 1: Globe Artichoke

Globe artichoke, *Cynara cardunculus* var. *scolymus* (L.) Fiori, is an ancient perennial plant species (Asteraceae) native to the Mediterranean Basin, probably domesticated by Romans and diffused by the Arabs in the Southern Mediterranean area during the Middle Ages [166]. Globe artichoke, cultivated for its immature flower heads and for its high contents of phytochemicals, including polyphenols and inulin [167, 168], is considered a functional food, according to the definition of the European Commission on Functional Food Science in Europe (FuFoSE) [169, 170]. Artichoke leaves, rich in polyphenols, are utilized by the pharmaceutical industry for the production of commercial extracts for their choleretic, hypocholesterolemic, and antioxidant bioactivities, as a result of high contents in chlorogenic acid, cynarine, and luteolin [171–173]. Artichoke flower heads are among the richest sources of dietary phenolic antioxidants [174], whose levels depend on cultivar genetic diversity, harvest time, and climatic conditions during plant growth [175, 176].

A recent study reported, for the first time, large increases in total polyphenolic content (TPC) and antioxidant activity, expressed as antiradical power (ARP) in both leaves and flower heads of mycorrhizal globe artichoke plants assessed in microcosm and in the field [177]. Artichoke plants were inoculated in microcosm with the AM fungal species *G. mosseae* and *G. intraradices* and with a mixture of them, then transplanted and grown for 2 years in the field, where plants treated with the inoculum mixture showed large increases of main flower head fresh weight, not only in the first (92.8 %), but also in second year (70.6 %). Such mycorrhizal inoculation responses, persisting for 2 years after field transplant, stimulated further molecular studies, aimed at assessing the persistence of inoculated AMF in the field. ITS rDNA sequences clustering with those of *G. mosseae* and *G. intraradices* were retrieved only from inoculated plant roots.

Leaves of mycorrhizal artichoke grown in microcosm showed enhanced phenolic complement, depending on the inoculum composition. TPC and ARP were significantly higher (50 % and 33 %, respectively) in plants inoculated with the *Glomus* mixture, compared with control plants (Fig. 85.1). In the field, inoculated plants showed higher phenolics content in the edible parts (flower heads), compared with controls, with the highest values detected in plants inoculated with the

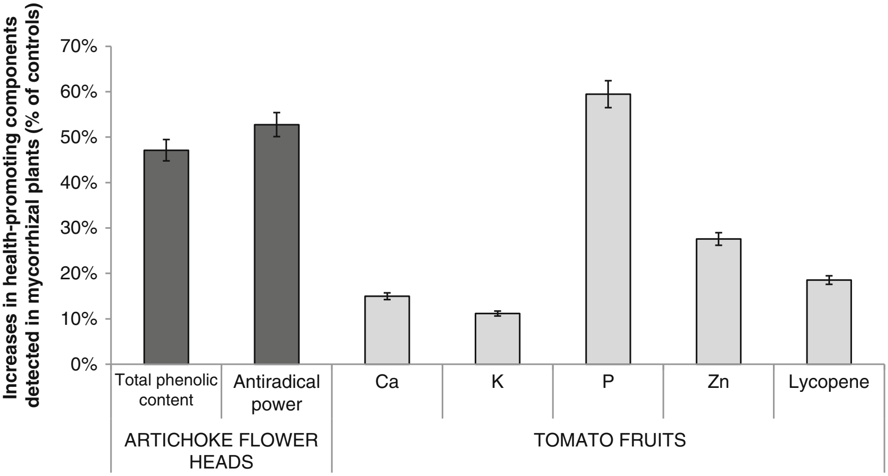

Fig. 85.1 Increases in health-promoting compounds detected in artichoke flower heads and in tomato fruits produced by mycorrhizal plants, compared with non-mycorrhizal controls. Increases are statistically significant ($P< 0.01$)

combination of the two AM fungal species. Higher TPC values were found in secondary flower heads (second year of field cultivation) compared with main flower heads (first year of field cultivation). Antioxidant activity of flower heads followed the same pattern of phenolics accumulation: ARP increases (52 % and 32 % in the first and second year in the field, respectively) were higher in plants inoculated with the mixed AM fungal inoculum. As mycorrhizal inoculation has been proved to induce changes in host plant secondary metabolism, including the phenylpropanoid biosynthesis, further studies should investigate the role of mycorrhizal symbiosis in the activity of two hydroxycinnamoyltransferases, recently isolated and functionally characterized in globe artichoke [178, 179].

4.2 Case Study 2: Tomato

Tomato (*Solanum lycopersicum* L.) is extensively cultivated worldwide, and its fruits have assumed the status of "functional foods" as a result of epidemiological evidence of reduced risks of certain types of cancers and cardiovascular diseases [180, 181]. They are a reservoir of diverse antioxidant molecules, such as lycopene, ascorbic acid, vitamin E, carotenoids, flavonoids, and phenolics, and may provide a significant part of the total intake of beneficial phytochemicals, as a result of their high consumption rates. Among carotenoids, lycopene has a strong antioxidant activity and is able to induce cell-to-cell communications and modulate hormones, immune systems, and other metabolic pathways [182].

The levels of lycopene and other beneficial phytochemicals in fresh tomato fruits may be affected by many agronomic factors, such as cultivars [58], cultural practices and ripening stage [183], and also by cultivation conditions, such as the establishment of mycorrhizal symbioses in plant roots. Recent works reported that mycorrhizal inoculation improved tomato growth and the production of fruits, which contained significantly higher quantities of ascorbic acid and total soluble solids [184].

A recent multidisciplinary work for the first time investigated the nutraceutical value and safety of mycorrhizal tomato fruits produced by mycorrhizal plants inoculated with the AM fungal species *G. intraradices*, by assessing the antioxidant, estrogenic/antiestrogenic, and genotoxic activity of tomato fruits [185]. The data obtained showed that mycorrhizal inoculation positively affected the growth and mineral nutrient content of tomato fruits, with enhanced uptake of soil mineral nutrients, that is, Ca, K, P, and Zn, whose concentrations in tomato fruits produced by inoculated plants were higher than in the controls. Interestingly, fruit P and Zn contents were 60 % and 28 % higher than those of controls, suggesting an important role of the symbiosis in improving the nutritional value of tomatoes, in particular for Zn, which is considered a key human mineral nutrient [186].

Lycopene content of tomato fruits from mycorrhizal plants was 18.5 % higher than that of controls (Fig. 85.1). Such an evidence of plant secondary metabolism modification was not linked with the production of putative unsafe compounds, such as mutagenic ones, since tomato extracts induced no in vitro genotoxic effects. Indeed, the two genotoxicity tests used, that is, the Ames *Salmonella*/microsome mutagenicity assay (the “first line” for detection of gene mutation) and the human lymphocyte MN test (a “first line” for detecting chromosome aberrations), excluded the presence of any putative phytochemical with DNA-damaging activity. Given the chemoprotective/chemopreventive effects of lycopene, it is tempting to suggest that the higher lycopene content detected in mycorrhizal tomato fruits could represent an important factor in neutralizing the DNA-damaging activity of any possible mutagenic compound occurring not only in tomato fruits but also in other foods consumed together with tomatoes.

Moreover, tomato fruit extracts – both hydrophilic and lipophilic fractions, originating from mycorrhizal plants – strongly inhibited 17-β-estradiol-human estrogen receptor binding, showing significantly higher antiestrogenic power, compared with controls. As lycopene represents a promising pharmacological agent in cancer prevention on account of its antiproliferative effects and inhibitory action on the human estrogen receptors [42, 43], the data obtained allow us to suggest that tomato fruits and those produced by mycorrhizal plants at a higher rate could antagonize the estrogen-like activity elicited by several environmental-industrial xenobiotics to which humans are exposed through the food chain [185].

5 Conclusion

Many epidemiological studies have reported that the consumption of FAVs may play a fundamental role in promoting human health by preventing chronic diseases and decreasing the risk of mortality from cancer and cardiovascular diseases. Thus, plant fresh foods are considered “functional foods,” not only because of their nutritional properties but also for their content in phytochemicals, which may vary depending on environmental and agronomic conditions, including plant mycorrhizal status. AM symbionts are ecologically and economically important beneficial fungi playing a major role in sustainable food production systems: they determine higher plant growth rates, increase resistance to biotic and abiotic stresses, and reduce the need of chemical fertilizers and pesticides, allowing a safe production of high-quality food. As they enhance the biosynthesis of many different compounds with nutraceutical value in leaves, roots, and fruits of plants used for human nutrition, the inoculation of selected AM fungal species and isolates may represent a suitable and environmentally friendly biotechnological tool to be implemented in agri-food chains aimed at producing safe and healthy food. Further studies are needed to answer questions as to whether different AM fungal species and isolates may differentially modulate plant secondary metabolism and the production of phytochemicals; whether inoculation time, technique, and protocols may change fungal performance affecting healthy compounds accumulation; and whether agronomic managements and practices may influence the persistence of AMF in the field and their efficacy in inducing favorable changes in the biosynthesis of secondary metabolites with health-promoting activity.

Abstract

Terpenoids are naturally occurring hydrocarbons produced by a wide variety of plants and animals. They are classified based on five-carbon (isoprene) units as their building blocks, numbering more than 55,000 molecules having been discovered till date. Different terpenes include hemiterpenes (C5), monoterpenes (C10), sesquiterpenes (C15), diterpenes (C20), sesterterpenes (C25), triterpenes (C30), and polyterpenes (>C30). Diverse functional roles of terpenoids have been critically studied and well-accepted now. Some of them include natural flavor additives for food or fragrances in perfumery and in traditional and alternate medicines as aromatherapy. Biosynthetically, terpenoids are formed via two major synthetic pathways: mevalonic acid (MVA) pathway and 2*C*-methyl-D-erythritol-4-phosphate (MEP) pathway. Biologically active terpenoids span various orders of magnitude. Most comprehensively studied of which is the effect of terpenes in prevention and treatment of cancer. Illustratively, Taxol derivative (paclitaxel and docetaxel) are among the widely used drugs in cancer chemotherapy. Other important therapeutic uses of terpenoids include antimicrobial, antifungal, antiviral, antihyperglycemic, anti-inflammatory, antioxidants, antiparasitic, immunomodulatory, and as skin permeation enhancer. Since many of these molecules are only found in very low levels in nature, their massive harvesting to obtain sufficient amounts of the drug including synthetic biology and metabolic engineering provides innovative approaches to increase the production of terpenoids.

1 Introduction

Secondary metabolites are small molecule organic compounds that are not essential to the growth and development of the producing organism and are not classified by structure [1]. It is estimated that well over 300,000 secondary metabolites exist, and it's thought that their primary function is to increase the likelihood of an organism's survival by attracting or repelling other organisms. Lack of secondary metabolites does not result in severe complications such as death, but generally, long-term impairment of the organism's survivability or fertility is seen. Natural products often play a key role in plant defense against herbivory and other interspecies defenses [2]. Often, plant secondary metabolites may be referred to as plant natural products, in which case they illicit effects on other organisms.

Most of the secondary metabolites of interest fit into categories which classify them based on their biosynthetic origin. Secondary metabolites are chemicals produced chiefly by plants for which no role has yet been found in photosynthesis, growth, or reproduction. Secondary metabolites are diverse; many thousands have been identified in several major classes. Each plant family, genus, and species produces a characteristic mixture of these secondary metabolites. These chemicals are also used as taxonomic characters in classifying plants. Humans use these natural products as medicines, flavorings, and recreational drugs.

Secondary metabolites can be classified on the basis of their chemical structure (e.g., cyclic and acyclic, containing a sugar moiety), composition (presence or absence of elements, e.g., nitrogen), and aqueous solubility, or based on the pathway by which they are synthesized (e.g., phenylpropanoid, which produces tannins). A simple classification includes three main groups: *terpenes* (made from mevalonic acid, composed almost entirely of carbon and hydrogen), *phenolics* (made from simple sugars, containing benzene rings, oxygen, and hydrogen), and *nitrogen-containing compounds* (extremely diverse). However, there is no strict scheme for classifying natural products: their extreme diversity in structure, function, and biosynthesis allows them to fit neatly into a few simple categories. In practice, however, scientists often speak of five main classes of natural products: terpenoids and steroids, fatty acid–derived substances and polyketides, nonribosomal polypeptides, alkaloids, and enzyme cofactors. Natural products are medicinally of great importance. Most pharmaceuticals are based on plant chemical structures, and secondary metabolites are widely used for recreation and stimulation (the alkaloids nicotine and cocaine, the terpene cannabinol). The study of such plant use is called "*ethnopharmacology*."

2 Terpenes: General Overview

The term “terpene” was given to the compounds isolated from “turpentine” (Latin *balsamum terebinthinae*), a volatile liquid isolated from pine trees. Turpentine contains the “resin acids” and some hydrocarbons, which were referred to as terpenes. The term “terpene” was originally coined to describe a mixture of isomeric plant hydrocarbons of the molecular formula $C_{10}H_{16}$ occurring in the essential oils.

Terpenoids, sometimes called as isoprenoids, are a subclass of the prenyllipids (terpenes, prenylquinones, and sterols). They represent the oldest group of small molecular products synthesized by plants and are one of the most widespread groups of natural products. Terpenoids can be described as modified terpenes, where methyl groups are replaced or removed, oxygen atoms removed or added (hydrogenated/dehydrogenated), or the carbon skeleton is modified by oxidation or rearrangement. Thus, many authors use the term “terpenes” more broadly, to include the terpenoids. Terpenes are the most numerous and structurally diverse secondary metabolites among various natural products (Fig. 86.1) [3].

Historically, terpenes are one of the most ancient natural products having diverse applications. As they are chiefly found in essential oils, they were used in the Ancient Egypt for various religious reasons. Camphor was introduced in Europe from the East by the Arabs in the eleventh century. The process of obtaining plant essential oils by fatty extraction was known by the early Middle Ages. In the twelfth century, Villanosa described distillation of oils from sage and rosemary. He made an *oleum mirabile* from oils of turpentine and rosemary. Analyses of oils of turpentine were made in 1818 by Houston, and it was in 1866 when Dumas proposed the name “terpene,” derived from turpentine, instead of camphor for crystalline oxygenated substances extracted from essential oils. In 1887, Wallach proposed that one isoprenic unit of five carbon atoms (C_5H_8) is always present in the molecule of terpenes [4]. The structures of camphor, pinene, citral, and β-carotene were established by Bredt (1893), Wagner (1894), Tiemann (1895), and Wackenrodder (1837), respectively. It was due to the discovery of chromatographic and spectroscopic techniques that the period since 1945 has seen an extensive explosion in natural product chemistry. Ruzicka (1953) discovered the isoprene unit based on the concept of the “isoprenic rule” [5] which was later completed by Lynen [6] and Bloch [7]. In 1956, mevalonic acid was shown to be a biosynthetic precursor of cholesterol [8], and later, its incorporation into a number of terpenes has been shown.

More than 55,000 terpenes have been isolated, and this number has almost doubled each decade [9, 10]. The diverse functional roles of many terpenoids have been characterized. Eucalyptus, conifer wood, balm trees, cinnamon, cloves, citrus fruits, coriander, ginger, lavender, lemongrass, lilies, carnation, caraway, peppermint species, roses, rosemary, sage, thyme, violet, and many other plants or parts of those (stems, leaves, blossoms, roots, rhizomes, fruits, seed) are well known to smell pleasantly, to taste spicy, or to exhibit specific pharmacological activities which chiefly are attributed to the presence of terpenes. Also, terpenes have shown to be useful as hormones (gibberellins), photosynthetic pigments (phytol, carotenoids),

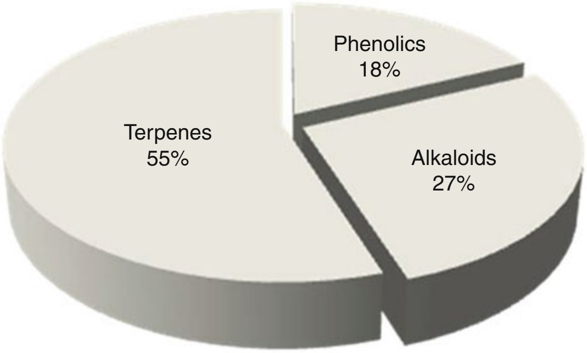

Fig. 86.1 Population of different plant secondary metabolites in nature

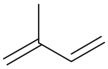
electron carriers (ubiquinone, plastoquinone), and mediators of polysaccharide assembly, as well as communication and defense mechanisms [11].

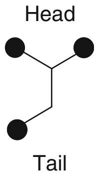
3 Classifications of Terpenes

Thermal decomposition of terpenoids gives isoprene as one of the product. As mentioned previously, Wallach pointed out that terpenoids can be built up of isoprene unit. *Isoprene rule (C5 rule)* states that the terpenoid molecules are constructed from two or more isoprene units.



Isoprene unit

Further, Ingold suggested that isoprene units are joined in the terpenoid via “head-to-tail” fashion. *Special isoprene rule* states that the terpenoid molecules are constructed of two or more isoprene units joined in a “head-to-tail” fashion.



However, exceptions exist to this rule. For example, carotenoids are joined tail to tail at their central, and there are also some terpenoids whose carbon content is not a multiple of 5.

Most natural terpenoid hydrocarbon have the general formula (C_5H_8)n. They can be classified on the basis of value of n or number of carbon atoms present in the structure. As with any class of compounds, not all terpenes contain even numbers of

Table 86.1 Classification of terpenes

Terpenes	Isoprene units	Carbon atoms
Hemiterpenes	1	5
Monoterpenes	2	10
Sesquiterpenes	3	15
Diterpenes	4	20
Sesterpenes	5	25
Triterpenes	6	30
Carotenoids	8	40
Rubber	>100	>500

intact isoprene units, with a few being degraded isoprene moieties with missing carbons such as C_{19} diterpenoids. The simplest of all is hemiterpene, consisting of a single five-carbon isoprene unit (C_5H_8). Their biological significance is not much established.

Mono-, sesqui-, di-, and sesterpenes contain the isoprene units linked in a head-to-tail fashion. The triterpenes and carotenoids (tetraterpenes) contain two C_{15} and C_{20} units, respectively, linked head to head. Many terpenes are hydrocarbons, but oxygen-containing compounds such as alcohols, aldehydes, or ketones are also found to fall in the class of terpenes. These derivatives are more frequently named as terpenoids.

A rational classification of the terpenes has been established based upon the number of isoprene (or isopentane) units incorporated in the basic molecular skeleton (Table 86.1). Some illustrative examples are depicted in Fig. 86.2.

Monoterpenoids are composed of two isoprene units ($C_{10}H_{16}$) that can be found in various states of oxidation in acyclic, monocyclic, and bicyclic forms. Monoterpenoids can be further classified based on their cyclic carbon systems, with a number of them being pharmacologically active. Sesquiterpenoids compounds ($C_{15}H_{24}$) contain three isoprene units, occurring in simple to complex mono- and polycyclic rings. Triterpenoids are C_{30} compounds ($C_{30}H_{48}$) which have wide distribution from more than 40 different carbon skeletons. Carotenes are examples of tetraterpenoids ($C_{40}H_{64}$). Natural rubber is an example of polyterpenoid which contains many cis-isoprene units.

Mono- and sesquiterpenes are the main constituents of the essential oils, while the other terpenes are constituents of balsams, resins, waxes, and rubber. Oleoresin is a roughly equal mixture of turpentine (85 % C_{10}-monoterpenes and 15 % C_{15}- sesquiterpenes) and rosin (C_{20}-diterpene) that acts in many conifer species as a toxic material to invading insects and their pathogenic fungi [12]. A number of angiosperm species have inducible terpenoid defensive compounds (phytoalexins) [13]. These include both sesquiterpenoid and diterpenoid types. Isoprenoid units are also found within the framework of other natural molecules. Thus, indole alkaloids, several quinones (vitamin K), alcohols (vitamin E, vitamin A formed from β-carotene), phenols, and isoprenoid alcohols (also known as terpenols or polyprenols) also contain terpenoid fragments. molecular regulation, and function of plant terpenoids have been the subject of a review [14]. According to literature, there are more than 1,000 monoterpenes, 7,000 sesquiterpenes, and 3,000 diterpenes, and the number is still increasing [15].

4 Biosynthesis of Terpenes

Terpenes are found in each living organism which is derived from the branched C5 carbon skeleton of isoprene. Each isoprenoid is constructed using a different number of isoprene unit repeats, cyclizations, rearrangements, and further oxidation of the carbon skeletons [16, 17]. Biosynthetically, the majority of terpenoids are formed by the well-known mevalonic acid (MVA) pathway (Fig. 86.3), but they may also be formed through triose phosphate utilizing nonmevalonate pathway [18, 19]. The nonmevalonate pathway is also called the 2*C*-methyl-D-erythritol-4-phosphate (MEP) or the 1-deoxy-D-xylulose-5-phosphate (DXP) pathway. In all eukaryotes (all mammals, the cytosol and mitochondria of plants, and fungi), terpenes are synthesized by the mevalonate pathway [20]. The nonmevalonate pathway is present mainly in eubacteria and cyanobacteria, green algae, apicomplexan parasites, and in higher plants [18]. Details on the progress of the elucidation of the biosynthetic pathways have been the subject of many reviews [21–24].

Fig. 86.3 Illustrative biosynthetic pathway of terpenes in eukaryotes (mevalonate pathway)

Although, terpenoids show enormous chemical and structural diversity, their backbones are synthesized from only two universal precursors: isopentenyl pyrophosphate (IPP) and its highly electrophilic allylic isomer dimethylallyl pyrophosphate (DMAPP) [25]. IPP is isomerized to DMAPP by the enzyme isopentenyl pyrophosphate isomerase. The mevalonate pathway for the biosynthesis of terpenoids has been illustrated in Fig. 86.3. To summarize, the active isoprene unit (IPP) is repetitively added to DMAPP or a prenyl diphosphate in sequential head-to-tail condensations catalyzed by the prenyl transferases. In the biosynthesis of mono- and higher terpenoids, the starting molecule is DMAPP, which condenses with an IPP unit to for geranyl pyrophosphate (GPP), which leads to synthesis of monoterpenoids. Sequential condensation of IPP with GPP leads to formation of farnesyl pyrophosphate (FPP) which is the precursor of sesquiterpenoids. Condensation of IPP with FPP forms geranylgeranyl pyrophosphate (GGPP), the precursor of diterpenoids. GGPP and IPP condense to form squalene, which is the precursor of triterpenes, lipids, and steroids. Finally, condensation of appropriate intermediate precursor and/or IPP units leads to synthesis of tetra- and polyterpenoids. Terpenoid synthases or cyclases are the group of enzymes which catalyze the reactions where the primary terpene skeletons are formed from the earlier substrates. The parent skeletal type of mono-, sesqui-, and diterpenes is usually further modified by the activity of an array of different catalyzing enzymes (e.g., hydroxylases, dehydrogenases, reductases and glycosyl, methyl and acyl transferases) which together generate thousands of different terpenoid structures [26].

5 Terpenes: Therapeutic Applications

Of the approximately 55,000 terpene structures known, very few have been investigated from the perspective therapeutic applications. For much of the last century, terpenes were depicted in as products of detoxification or overflow metabolism. However, starting in the late 1960s, various terpenes were shown to be toxins, repellents, or attractants to other organisms, which led to the belief that they have a potential role as prevention and cure of various ailments [11]. Thus, it has been proven time and again that aside from their immense commercial value, terpene products have important biological functions in plants. In the following section, we have described most of the important pharmacological actions of plant terpenes and their plausible role in diverse therapeutic categories.

5.1 Anticancer Activity

Spectrum of activity of terpenoids as anticancer agents is doubtlessly the most explored area since last few decades. Many studies have shown that many dietary monoterpenes are helpful in the prevention and therapy of different cancers [27–30]. Some representative terpenes which possess anticancer activity are shown in Fig. 86.4.

Epidemiological studies demonstrate that dietary monoterpenes may be effective in the prevention and treatment of cancer [31]. Monocyclic monoterpenes D-limonene (Fig. 86.2) and perillyl alcohol (Fig. 86.4) are shown to inhibit the development of liver, skin, mammary, colon, lung, prostate, forestomach, and pancreatic carcinomas in a dose-dependent manner [29, 31–35]. Moreover, the metabolites of D-limonene such as perillic acid, dihydroperillic acid,

limonene-1,2-diol, and the oxygenated molecule of D-limonene, carvone (Fig. 86.2), have also been shown to have potent antitumor activities [28, 32–37].

Paclitaxel (Fig. 86.4), originally known as Taxol, a complex diterpenoid from the bark of specific yew tree, is a potent and one of the most widely used anticancer agents. Paclitaxel has shown excellent activity against breast and ovarian cancers [38], as well as AIDS-related Kaposi's sarcoma [39]. Docetaxel, also used clinically, is a semisynthetic analogue of paclitaxel. Taxanes enhance stability of microtubules, preventing the separation of chromosomes during anaphase [40]. 3-Ingenyl angelate (referred to as PEP005, Fig. 86.4), a hydrophobic diterpene ester isolated from the plant *Euphorbia peplus*, is another anticancer agent used principally for the treatment of skin cancer. 3-Ingenyl angelate is a modest inhibitor of protein kinase C family and causes rapid mitochondrial disruption and cell death by primary necrosis, resulting in a favorable cosmetic gloss of the skin [41]. Efficacy and toxicity of PEP005 has been the subject of an interesting review [42]. Sarcodictyin (sarcodictyin A, R = CH_3; sarcodictyin B, R = C_2H_5; Fig. 86.4) and contignasterol (Fig. 86.4) derivatives belong to the class of marine terpenoids and are demonstrated to be active against cancer in preclinical or clinical studies [43]. Squalamine (Fig. 86.4) is another terpenoid currently evaluated in phase II trials for the treatment of lung and ovarian cancer [44, 45].

Farnesol and geraniol (Fig. 86.2) have also been demonstrated to have anticancer activities against pancreatic cancers [46, 47]. Monoterpenes such as carveol, uroterpenol, and sobrerol (Fig. 86.4) have shown activity against human mammary carcinomas. Carvone (Fig. 86.2) has also been shown to reduce pulmonary adenoma and forestomach tumor formation [48, 49]. In an in vitro antitumor study, betulinic acid (Fig. 86.4) has been shown to induce apoptosis of several human tumor cells, whereas ursolic acid and oleanolic acid reduced leukemia cell growth and inhibited the proliferation of several transplantable tumors in animals [50]. In a recent study, a new class of monoterpenes designated as miliusanes was isolated from *Miliusa sinensis*. A number of the miliusanes such a smiliusol, miliusate, and miliusane-1 demonstrated potent cytotoxic activity against a panel of cancer cell lines [51]. In animal models and at cellular level, a number of dietary monoterpenes prevent the initiation and progression of cancer and along with regression of existing malignant tumors. Monoterpenes administered as a pure chemical or in orange peel oil inhibited the development of chemically induced rodent mammary, kidney, skin, lung, and forestomach cancers in different animal models [31, 33, 52–56]. Many sesquiterpene lactones have also been reported as potential anticancer agents [57]. Retinoids, which belong to the class of dipterenoids, have been shown to play an important role in regulating the growth and differentiation of different cell types, viz., normal, premalignant, and malignant [58]. In animal models, a significant suppression of development of different tumor types (skin, breast, oral cavity, lung, prostate, bladder, liver, and pancreas) was observed [59, 60]. Certain retinoids have also shown efficacy in inhibiting the development of primary cancers of the skin, cell lung cancer, and breast cancer [61, 62]. Several saponins have been reported as potent cytotoxic agents [63–65]. The biologically active constituents in *Eleutherococcus senticosis* are a complex mixture of triterpene saponins known as ginsenosides. In a cell-based assay, anti-proliferative effect of ginsenosides on human prostate cancer LNCaP cell lines has been reported [66]. Epidemiological and intervention studies indicate that carotenoids are potential agents for the chemical prevention of carcinogenesis [67, 68]. It is believed that the effects of carotenoids on colon and prostate cancers are mainly attributed to lutein and lycopene, respectively [69, 70]. Halomin, a halogenated acyclic monoterpene derivative isolated from the red alga *Portieria hornemnnii* is an effective anticancer agent against renal, brain, colon, and non–small cell lung cancer cell lines [71].

Gossypol (Fig. 86.4) is a sesquiterpene dimer found in cotton. Gossypol occurs as a mixture of two enantiomers because of restricted rotation around the central binaphthyl bond. The ratio of (+)- to (−)-gossypol varies widely among cotton cultivars, and each enantiomer has different biological activities. (−)-Gossypol inhibits the growth of cancer cells more than the (+) enantiomer [72] and inhibits male fertility in humans [73]. In China, gossypol has been used to treat infertility in males, and studies have shown an increase in sperm production.

A recent review describes the role of terpenoids present in cruciferous vegetables in the prevention and inhibition of cancers of different types. The review also illustrates different mechanisms by which these terpenoids act as anticancer agents [74]. Two new pentacyclic triterpene esters, uncarinic acids A and B, were discovered by cytotoxic activity of *Uncaria rhynchophylla* which was determined by bioactivity-guided fractionations. These compounds showed inhibition of phospholipase Cγ1 (PLCγ1) (IC_{50} = 35.66 and 44.55 μM, respectively), an enzyme which induces proliferation in human cancer cells [75]. Thus, terpenes represent a promising new class of agents which may be approved as supplementary drugs in contemporary oncology. Chemical and structural diversity in some anticancer terpenoids is exemplified in Fig. 86.4.

5.2 Antibacterial Activity

Squalamine, apart from its known anticancer activity [45], has also been shown to be a potent antibacterial, antifungal, and antiprotozoic agent [44]. Various diterpenes extracted from *Salvia* species exhibited antibacterial activities against a variety of organisms such as *E. faecalis, B. subtilis, S. aureus, S. epidermis, E. coli*,and *P. mirabilis* [76]. Mixtures of different monoterpenes like terpinen-4-ol, *R*-terpineol, 1,8-cineole, and linalool have been shown to possess antibacterial activity against Gram-positive and Gram-negative bacteria isolated from the oral cavity, skin, and respiratory tract [77]. Various studies have reported antibacterial activity of the monoterpene (+)-menthol including those against *S. aureus* and *E. coli* [78, 79]. Diterpenoid ferruginol, a few sesquiterpenes, and their lactone derivatives have also shown potent antimycobacterial activity [80]. Terpenes also display antifungal activity. One illustrative example is the optical isomers of carvone, which are found to be active toward many pathogenic fungi [37]. Cinnamon oil has shown broad-spectrum activity against *Pseudomonas aeruginosa* [81]. John et al. found plant oils from *Neolitsea foliosa*, which also showed some antibacterial properties and included sesquiterpenes such as β-caryophyllene but lacked monoterpenes [82]. Sesquiterpene drimanes have shown potent antibacterial and antifungal activity [83, 84]. The acyclic monoterpenes citronellol, geraniol, and nerol have also been shown to be active against *M. tuberculosis* [85]. Sesquiterpene lactones of the germacranolide, guaianolide, and eudesmanolide types have been shown to be active against *M. tuberculosis* with minimum inhibitory concentration (MIC) values as low as 2 μg/mL [86]. Axisonitrile-3, a marine sesquiterpene isolated from the sponge *Acanthella klethra*, demonstrated potent antimycobacterial activity with MIC of 1.56 μg/mL (50). Puuphenone, a sesquiterpene derivative isolated also from a marine sponge, also showed remarkable 99 % inhibition of *M. tuberculosis* (H3Rv) growth with MIC value of 12.6 μg/mL [87]. (E)-phytol, a diterpene isolated from *Lucas volkensii*, exhibited significant antituberculosis activity with MIC of 2 μg/mL [85]. Carvone and perillaldehyde inhibited the transformation of *Candida albicans* from the coccal to the filamentous form, which is responsible for the pathogenicity of the fungus [37].

5.3 Antiviral Activity

The unusual kaurane-type diterpene neotripterifordin was isolated by Lee and coworkers from the roots of *Tripterygium wilfordii* [88]. This natural product was found to be a potent inhibitor of human immunodeficiency virus (HIV) replication in H9 human lymphocyte cells with an EC50 of 25 nM. Glycyrrhizin, a well-known triterpenoid glycoside isolated from *Glycyrrhiza glabra*, was tested in vitro against RNA viruses like the chandripura virus, measles virus, polio vaccine viruses, polio wild-type viruses, and DNA viruses like the herpes type 1 and 2 viruses. Glycyrrhizin inhibited the DNA virus plaque formation at lower concentrations (0.608 mM), while the RNA viruses were inhibited at higher concentrations (1.216 mM) [89]. Betulinic acid, a triterpenoid isolated from *Syzygium claviflorum*, has been found to contain anti–HIV activity in lymphocytes [90]. Avarol and avarone, a marine sesquiterpenoids isolated from the red sea sponge *Dysidea cinerea*, showed inhibition of HIV reverse transcriptase with respect to its natural substrate (dNTP) [91]. Ilimaquinone, another sesquiterpene derivative isolated from the red sea sponge *Smenospongia* sp., also inhibited HIV reverse transcriptase [92]. Isoborneol demonstrated potent anti–herpes simplex virus-1 (anti-HSV-1) activity by inhibition of virus replication and the glycosylation of viral proteins. As a result, HSV-1 loses its infectivity [36]. Monoterpene derivatives cineol and borneol have also been shown to be potent anti-HSV-1 agents. It has been shown that putranjivain A, isolated from *Euphorbia jolkini* (*Euphorbiaceae*), may affect late stages of HSV-2 replication by inhibiting viral attachment and cell penetration [93]. The terpenoid constituents of *Ganoderma pfeifferi* oil lucialdehyde D and ganoderon A and C were also shown to be potent inhibitors of HSV [94]. Spongiadiol, a tetracyclic furanoditerpene isolated from *Spongia* sp., showed modest inhibition of inhibit HSV1 [95]. Solenolide A, a diterpene lactone isolated from *Solenopodium* sp., also inhibited of rhinovirus ($IC_{50} = 0.39$ μg/mL) along with inhibition of poliovirus III and herpes virus [96].

5.4 Activity Against CNS Disorders

Gb 761, a standardized extract of the leaves of *Ginkgo biloba*, contains 5–7 % ginkgolides and bilobalide (BB) collectively called terpene trilactones [97]. Among various effects shown by EGb 761 in the central nervous system, those related to AD [98], dementia, and memory [99–101] have received most of the attention. EGb 761 is among the most prescribed medications in Germany and France for treatment of dementia [99]. In one of several studies, the water-ethanol extract from roots of *Rhaponticum carthamoides* (which contain several sesquiterpene lactones) injected as a saline solution at 500 mg/kg doses increased the locomotor activity, along with improvement in the learning and memory indices in rats [102]. Also, the root ethanol extract showed a significant improvement in learning and memory ability. Using the maze-training method of active avoidance with punitive reinforcement in experiments in rats, it eliminated the scopolamine-induced memory impairment completely [103]. One study suggests that aqueous extract of *Cecropia glazioui*, which chiefly contains terpenes and flavonoids as its active constituents, promotes an anxiolytic-like effect in mice [104].

5.5 Activity Against CVS Disorders

Petkov et al. demonstrated that the dried residue of ethanol (40%) extract of *Rhaponticum carthamoides* in chloralose-anesthetized male cats at a dose of 200 mg/kg exerted a significant decrease in blood pressure (25–30%) as compared to control group of animals [102]. In a study by Hall et al., some naturally occurring pseudoguaianolides and germacranolides as well as synthetic related compounds were evaluated for their antihyperlipidemic potential where the compounds at a dosage of 20 mg/kg/day resulted in lowering of serum cholesterol by ~30% and of serum triglycerides by ~25% [105]. A recent study reported the first evidence that ginkgolide B protects against cerebral ischemic injury by inhibiting excitotoxicity by modulating the imbalance of excitatory amino acids versus inhibitory amino acids, which may support the traditional use of *Ginkgo biloba* leaves for the treatment of stroke [106]. In a study, administration of ethanolic extract of seeds of *Eugenia jambolana* (which contains a mixture of terpenoids and flavonoids) to alloxan-induced diabetic rats caused a significant hypolipidemic effect with positive alternation in all lipid levels and a decrease in the activity of HMG-CoA reductase [107].

5.6 Antihyperglycemic Activity

Stevioside, a diterpene steviol glycoside extracted from leaves of the plant *Stevia* rebaudiana, has been shown to possess insulinotropic, glucagonostatic, and antihyperglycemic effects. Stevioside and the aglucon steviol have also been shown to potentiate insulin secretion from isolated mouse islets in a dose- and glucose-dependent way [108]. Rebaudioside A, another diterpene glycoside found in *Stevia* leaves, possesses insulinotropic effects, but unlike stevioside, it does not stimulate insulin release at near-normal glucose levels [109]. The four new and four known sesquiterpenoid derivatives were isolated from the roots of *Ferula mongolica* as α-glucosidase inhibitors at the IC_{50} range of 10–100 μM [110]. Centellasapogenol A (an olean-13-ene-type triterpene) and its oligoglycoside, centellasaponin A, were isolated from the methanolic extract of *Centella asiatica* as rat lens aldose reductase inhibitors where methanolic extract of the plant inhibited aldose reductase with an IC_{50} value of 0.80 μg/mL [111–113]. Corosolic acid, isolated from the leaves of *Lagerstroemia speciosa*, displayed a significant glucose transport-stimulating activity at a concentration of 1 μM [114].

5.7 Anti-inflammatory Activity

There is a pool of terpenoids which have demonstrated good anti-inflammatory pharmacological profile [115]. Monoterpenes like linalyl acetate, 1,8-cineole, (−)-linalool, and its esters have shown good anti-inflammatory activity [116, 117]. In particular, 1,8-cineole was found to be useful in bronchitis, sinusitis and steroid-dependent asthma, or in the prevention of returning respiratory infections [118]. Several seco-pseudopterosins and newer pseudopterosins (diterpene glycosides originally isolated from *Pseudopterogorgia elisabethae* [119]) have been demonstrated to possess anti-inflammatory activity and are used for promoting wound healing [115, 120]. Methopterosin (OAS100), a semisynthetic analog of pseudopterosin, also has been reported as potent anti-inflammatory agent [121]. Several plant-derived triterpenoids such as lupane, oleane, ursane, and their natural and synthetic derivatives have also shown good anti-inflammatory profile [122]. *R*-amarin (a pentacyclic terpene) is another example of clinically proven anti-inflammatory terpenoid [123]. Studies have shown that the methanol extract of *Nelumbo nucifera* rhizome as well as its constituent betulinic acid (a steroidal triterpenoid) possessed significant anti-inflammatory activity which was found to be comparable to that of phenylbutazone and dexamethasone [124]. Manolide is the first representative class of marine sesterterpene phospholipase-2 (PLA2) inhibitors possessing potent anti-inflammatory and analgesic activities. However, it was discontinued from phase I trials from further development [121]. Scalaranes, sesterterpenes isolated from *Cacospongia mollior*, are other illustrative examples of PLA2 inhibitors [125, 126]. The sesquiterpene-monoterpene lactone artemisolide, isolated from *Artemisia asiatica*, has been shown to be a potent anti-inflammatory agent acting through inhibition of nuclear factor (NF)-κB. In an in vitro study, artemisolide decreased lipopolysaccharide-induced production of PGE2 and NO in macrophages [127]. Similarly, these and other pro-inflammatory substances (PGE2, TNF-α, and IL1β) were also suppressed by terpinen-4-ol, the main component of the oil of *Melaleuca alternifolia*, and cineole derivatives [128, 129]. Cucurbitacin R has been shown to reduce inducible nitric oxide synthetase (iNOS), cyclooxygenase-2 (COX-2), tumor necrosis factor (TNF)-α, and PGE2 in paw homogenates of rats with adjuvant-induced arthritis [130]. Naturally occurring diterpene pepluanone, isolated from *Euphorbia peplus*, has also been shown to reduce NO, PGE2, and TNF-α production by inhibiting COX-2 and iNOS activity and downregulating NF-κB [131]. A recent study showed that *Ganoderma applanatum* terpenes significantly inhibited inflammation by pressing the expression of interleukin (IL)-1β and COX-2 and inhibiting NF-κB translocation in the liver of BaP-treated mice which indicates applicability of these terpenes in renewing the activities of antioxidant enzymes and suppressing inflammatory response [132]. In a phytochemical study of *Cryptomeria japonica* wood, hexane extract purified by bioactivity-guided fractionation exhibited significant activities on inhibition of nitric oxide production and inducible nitric oxide synthase expression. It also showed upregulation of heme oxygenase-1 expression in lipopolysaccharide-stimulated macrophages along with inhibition of cyclooxygenase-2 enzymatic activity ($IC_{50} = 5$ μg/mL) [133].

5.8 Antiparasitic Activity

Many terpenoids have been shown to act as antiparasitic agents in the literature with high efficacy and selectivity [134, 135]. The block-buster drug artemisinin, which is the most widely used parasitic drug in the world, is a sesquiterpene lactone derivative. Biological source of artemisinin is *Artemisia annua*, an herb, which is native to China [136]. It has been used for malaria therapy in China for over 1,000 years for antimalarial chemotherapy. Many other sesquiterpene peroxides, such as yingzhaosu A and yingzhaosu C, also have shown antiparasitic activity, especially against *Plasmodium berghei* [137]. Diterpenes and their lactones, e.g., dehydroabietinol isolated from *Hyptis suaveolens*, demonstrated potent antimalarial activity [138]. Moreover, diterpenes with a nor-abietane skeleton were found to possess leishmanicidal and antiplasmodial action [139]. Espintanol and piquerol A (which belong to the class of monoterpenes) have been reported as antiprotozoal agents. Similarly, monoterpene phenol derivative of cymene, thymol, and their structural derivatives also have been found to have an antileishmanial activity [140]. Menthol derivatives have also been described to possess trypanocidal activity [141]. The well-known steroidal triterpenoic betulinic acid has also been described to have antimalarial activity [142]. Axisonitrile-3, an unusual and irregular terpene with an isonitrile group, isolated from marine sponge *A. klethra*, was found to have antiplasmodial activity [143]. Diisocyanoadociane is an example of another marine sponge diterpene, which has similar antiplasmodial activity to that of axisonitrile-3. Diisocyanoadociane, a tetracyclic diterpene, isolated from the sponge *Cymbastela hooperi*, demonstrated potent in vitro antimalarial activity against *P. falciparum* [144]. Pyrethrins, a group of six closely related monoterpene esters isolated from pyrethrum flowers, have been shown to act as antiparasitic agents against skin parasites such as head lice by blocking sodium channel repolarization of the arthropod neuron, leading to paralysis and death of the parasite [86]. Halorosellinic acid, a sesterterpene derivative isolated from the marine fungus *Halorosellinia oceanica*, has been shown to be a potent antimalarial agent ($IC_{50} = 13$ μg/mL) [145].

5.9 Antioxidant Activity

Many diterpenes are shown to act as primary antioxidants. Inside the body, some diterpenoids act as primary or synergistic antioxidants [146]. Carotenoids are well known as antioxidant agents and act along two different main pathways: physical and chemical radical quenching [147, 148]. Ertas et al. evaluated the antioxidant activity of petroleum ether, methanolic and acetone extracts, and some isolated ent-kaurane diterpenoids from the aerial parts of *Sideritis arguta* by β-carotene bleaching, free-radical scavenging, and superoxide-anion scavenging activity methods [149]. While both methanol and acetone extracts exhibited similar antioxidant activity in all assays, the active diterpenoid, 7-epi-candicandiol, inhibited lipid peroxidation at IC_{50} of 43.1 μg/mL. The extracts of various parts of *Piper umbellatum* (which contains several mono- and sesquiterpenoids) and several isolated compounds have shown interesting antioxidant activities [150].

5.10 Immunomodulatory Activity

There are also large group of monoterpenes, which possess immunomodulatory properties. It was shown that monoterpenes from *Plantago* species increased the activity of human lymphocyte proliferation and secretion of interferon gamma [151]. Carvone, limonene, and perillic acid were found to increase the total white blood cells (WBC) count in mice [49]. Administration of terpenoids to mice increased the total antibody production, antibody producing cells in spleen, bone marrow cellularity, and alpha-esterase positive cells significantly compared to the normal animals. There has been substantial interest in carotenoids as immunomodulatory agents [152–154]. β-Carotene was able to enhance the cell-mediated immune responses, especially in the elderly. In particular, supplementation leads to enhanced activity of natural killer cells and antigen-presenting monocytes. Especially in patients with HIV infection, the plasma status of β-carotene is low, thus increasing the free-radical-induced peroxidation in these patients. The immunomodulatory effect of carotenoids extracted from carrot was also assessed in rats by the analysis of immune parameters in the blood [155]. Significant increases in monocyte neutrophils, percentage lymphocytes, and platelet count were detected in the group that received carotenoid complex in comparison with the control group, which suggests that carotenoids have clear immunomodulatory effects.

5.11 Skin Penetration–Enhancing Activity

In addition to the above-mentioned therapeutic roles, terpenoids are also useful as skin penetration–enhancing agents (for improving transdermal drug delivery). The activity of terpenes as transdermal enhancers is due to a reversible disturbance of the lipid arrangement in the intercellular region of the stratum corneum, which is the thin, outermost layer of the skin, which generally limits the amount of different agents [156]. Reports suggest that terpenes may increase the permeability of the stratum corneum through intercellular lipid disruption, interaction with proteins, or improved access of agents into the stratum corneum [157]. Thus, such enhancement by terpenes facilitates the diffusion of drugs through the skin, thereby increasing their therapeutic value. Apart from these, advantages of terpenes remain that along with their good penetration-enhancing abilities, they have low skin irritation effects and low systemic toxicity [80]. The best penetration improvement activity has been accounted for monoterpenoid cyclic ether 1,8-cineol, as compared to hydrocarbon or even alcohol or ketone functionalized terpenes [158]. Hydrocarbon terpenes like D-limonene have already been approved as an active enhancer for drugs like steroids. Terpenes have also showed their effectiveness to enhance skin permeability for both the lipophilic molecules like indomethacin and for hydrophilic diazepam and propranolol [159]. Moreover, linalool, carvone, and thymol have been shown to enhance the permeability of model drugs such as 5-fluorouracil through skin and mucous membranes. Nerolidol (a hydrophilic sesquiterpene) and 1,8-cineole (monoterpenoid cyclic ether) improved permeability 20-fold and 95-fold over D-limonene, respectively [160]. A study on the effect of four different terpenes (fenchone, thymol, D-limonene, and nerolidol) on the increase of percutaneous permeation of different drugs (nicardipine, hydrocortisone, carbamazepine, and tamoxifen) was reported. Results showed significant increase in the flux of evaluated model drugs. The flux of nicardipine hydrochloride increased by approximately 135-fold, hydrocortisone by 33-fold, carbamazepine 8-fold, and tamoxifen 2-fold [161].

5.12 Miscellaneous Activity

Since centuries, terpenoids are used as flavors and fragrances in foods and cosmetics (e.g., menthol, nootkatone, linalool, and sclareol) [9]. One more upcoming and promising industrial use of monoterpenes is as substitutes for ozone-depleting chlorofluorocarbons [162]. Similarly, terpenes have also been suggested as substitutes for chlorinated solvents in applications such as cleaning electronic components and cables, degreasing metal, and cleaning aircraft parts [163]. One of the best known and most widely used monoterpenes is menthol, which has been used as a topical antipruritic, a counterirritant in external analgesic preparations and as antiseptics. Arbortristoside A and C, derived from the alcoholic extract of the seeds of *Nyctanthus arbortristis* [164]; two diterpenes, andrographolide and neoandrographolide, isolated from *Andrographis paniculata* [165]; and himachalol, a sesquiterpene alcohol, derived from the hexane soluble extract of the wood of *Cedrus deodara* [166], possess significant antiallergic activity comparable to disodium cromoglycate when tested in the experimental models. In a recent study, it was found that limonene directly binds to the adenosine A2A receptor, which may induce sedative effects. Results from an in vitro radioligand binding assay showed that limonene exhibits selective affinity to A2A receptors. Limonene also increased cytosolic calcium concentration, which can be achieved by the activation of adenosine A2A receptors. These findings suggest that limonene can act as a ligand and an agonist for adenosine A2A receptors [167]. It is shown in a recent study that *Phyllanthus emblica* fruit extract (which contains various terpenes and sesquiterpenoids) possesses antidiarrheal and spasmolytic activities, mediated possibly through dual blockade of muscarinic receptors and Ca^{2+} channels, thus explaining its medicinal use in diarrhea [168]. Uchiyama et al. isolated several new and known terpenoids from *Dracocephalum komarovi*. Among the isolated terpenes, komaroviquinone showed the most potent in vitro trypanocidal activity against epimastigotes of *Trypanosoma cruzi*, the causative agent of Chagas' disease, with minimum lethal concentration of 0.4 mM [169].

5.13 Side-Effects of Terpenes

Most of the therapeutically used terpenes are local irritants and, thus, are capable of causing GI signs and symptoms. CNS manifestations are rare but may range from an altered mental status to seizures to coma. Terpenes are well absorbed from the oral cavity as evidenced by the early onset of toxicity in significant ingestions. Terpenes are metabolized by the family of cytochrome P450 enzymes and are excreted as glucuronide conjugates by the kidney. According to the 2009 Annual Report of the American Association of Poison Control National Poison Data System, 3,362 single exposures to disinfectants containing pine oil, 10,714 single exposures to camphor, and 422 single exposures to turpentine were reported [170]. Exposure to pine oil resulted in two deaths, and exposure to turpentine resulted in one death. No deaths resulted from exposure to camphor [170]. As seen from the numbers, despite the some mild toxicity of these agents, morbidity is extremely low which indicates that terpenes are relatively safe compounds.

6 Conclusion

All living organisms produce terpenes for some essential physiological functions including some defense mechanisms for many plants. The enormous number and diversity of structures of terpenoids exist which is attributed to the fact that there are many ways in which the basic C5 units can be combined together and there are different pathways which the organism follows. Although history of terpenes spans since the Egyptians, it was until last few decades that terpene synthetic pathways are being understood in enough detail. Moreover, the use of bioinformatics and molecular databases has helped greatly in analyzing the chemical and molecular mechanisms behind terpene synthesis. Also, recent developments in analytical chemistry have helped in functional studies by providing a much more detailed view of the spectrum of terpenes present in and around different living organisms than was previously available. In the field of medicine and drug discovery, natural product–based therapeutics have seen a resurgence in interest and discovery of interesting compounds, and not surprisingly, terpenoids also has been explored in great detail for their vast variety of pharmacological actions and therapeutic potential. The wide array of structures and functionalities that have been evolved in natural terpenoids provide an excellent pool of molecules for use in human therapeutics. Terpenoids are successfully used for the treatment of cancer, inflammation, and various infectious diseases of microbial and parasitic origin, and many terpenoids are in the discovery pipeline in various other categories. Apart from these, they can also be used as supplementary agents in topical dermal preparations, cosmetics, and toiletries, which further broaden the applications of terpenes in other areas of human healthcare and medicine. Finally, the better understanding of the functions of genes in terpene production could lead to discovering novel pathways of terpene production or even new terpene compounds, which might explore new door for future therapeutic intervention employing terpenoids.

Abstract

Terpenes form the largest and structurally one of the most intriguing classes of natural products. When looking at their structures, it becomes clear that the evolution of terpene biosynthesis must have been one of the biggest challenges

for Mother Nature, but her solutions are – as often – surprisingly simple. As will be discussed in this chapter, all terpenes are made up from only two five-carbon monomers that have an intrinsic reactivity for the formation of oligomeric linear chains. Virtually the same reactivity is used in cyclization reactions that convert the linear precursors into (poly)cyclic products, not only with introduction of usually several stereogenic centers but also via cationic intermediates in an aqueous environment. How this works – you will find it here.

TIM	Triosephosphate isomerase
TPP	Thiamine diphosphate
UPP	Undecaprenyl diphosphate

1 Introduction

Today, more than 55,000 terpenoids are known, making up the structurally most complex and largest class of natural products [1]. The members of this class can be isolated from almost every single organism, and they play important roles in all processes of life (Fig. 87.1). This is exemplified by the ubiquinones (**1**), ubiquitously found terpenoid molecules that serve in the mitochondrial ATP synthesis as electron carriers in the electron transport chain [2]. The same function in the photosynthetic electron transport is fulfilled by the structurally related plastoquinones (**2**) in the chloroplasts of plants and other photosynthetic organisms. Also of terpenoid origin are the vitamins E (**3**), a group of lipophilic compounds known as tocopherols that are exclusively synthesized by photosynthetically active organisms and must be taken up with their plant diet by all other species [3]. As antioxidant membrane constituents, they preserve oxidative membrane destruction. The retinoids, also termed class A vitamins (**4**), arise from carotenoids by oxidative cleavage and fulfill important roles in the process of vision [4]. Other highly active terpenoid molecules are the steroids that exhibit various regulatory functions. One example is the vitamin D family (**5**) that is involved in processes such as immune suppression, hormone secretion, and intestinal calcium absorption [5]. Finally, the chlorophylls (**6**) are green pigments for the absorption of light energy in photosynthetic organisms. Their porphyrin core structures are decorated with terpenoid side chains.

The structural diversity in terpene secondary metabolites is even higher, and they not only make up the larger portion of the known terpenoid molecules, but they also show a diverse array of bioactivities. In their function as aroma constituents, antibiotics, pheromones, or toxins, they confer a benefit on the producing organism in its particular ecological context. Most importantly, humans can adopt these molecular traits for their own purposes, e.g., in the treatment of infectious diseases or cancer as is exemplified by the clinical use of the antimalaria agent artemisinin (**8**) from *Artemisia annua* or the cytostatic taxol (**9**) from *Taxus brevifolia* that are two of the most promising terpenoid drugs [6, 7].

To understand and control the biosynthesis of terpenes is one of the biggest challenges of natural products chemists. The accumulated knowledge and today’s level of understanding the complex biosynthetic transformations toward terpenes are not only of academic interest but also provide the fundament for the industrial production of pharmacologically useful terpenes by biotechnological processes. The state of the art including the chemistry of the transformed metabolites, the enzymology, and aspects of structural biology in terpene biosynthesis will be presented in this chapter.

2 Biosynthesis of the Isoprenoid Monomers IPP and DMAPP

As was already manifested by the groundbreaking work of Otto Wallach and Leopold Ruzicka who were both awarded the Nobel Prize in chemistry

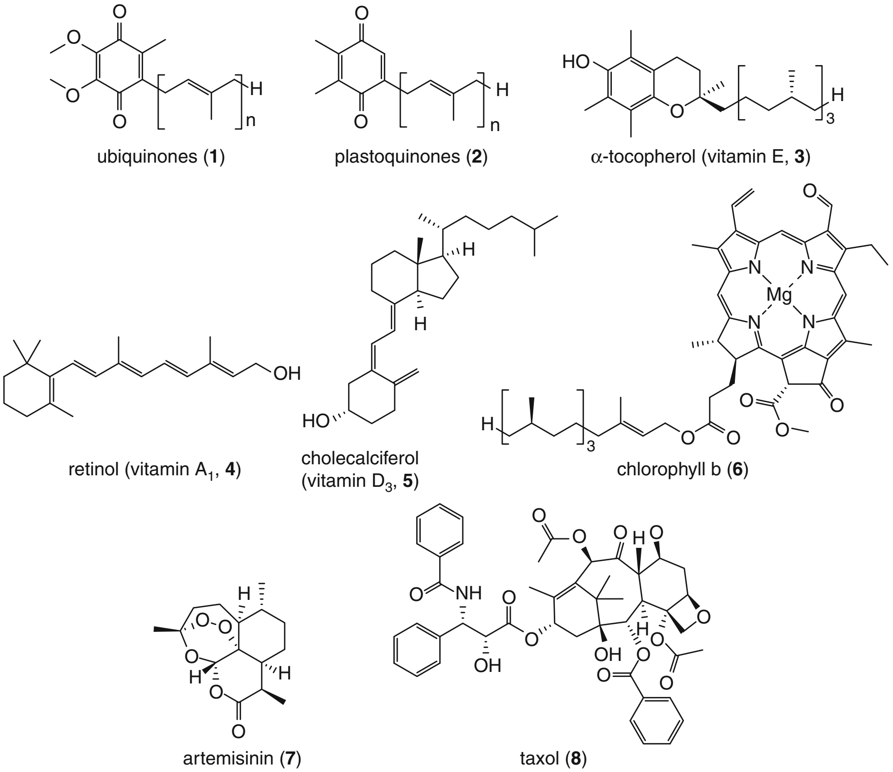

Fig. 87.1 Terpenes with important biological activities

(Wallach 1910; Ruzicka 1939), the usual terpene hydrocarbons are formally oligomers of isoprene [8]. This finding later resulted in Ruzicka's rule [9, 10] that generalized the structures of regular terpenes, exemplified by the cadalanes or cedranes, as constitutional head-to-tail fusions of the isoprene monomers. Structural motifs formally resembling head-to-head or tail-to-tail connections as present, e.g., in the abietanes, were regarded as being irregular (Fig. 87.2, however, such molecules can arise from head-to-tail fused linear polyisoprenoid diphosphates by rearrangements during terpene cyclization, cf. Sect. 5). The biosynthesis of terpenes does not proceed via isoprene itself but relies on two activated molecules that structurally exhibit the same carbon backbone as isoprene: the isoprenoid monomers isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP). These functional entities serve as precursors to all terpenoid structures and are made via two different pathways. The mevalonate pathway was established by Lynen, Bloch, and Cornforth in the 1950s and is known to take place in animals, fungi, the cytosol of plants, archaea, and a few bacteria, while the deoxyxylulose phosphate pathway has been discovered in the late 1990s and early 2000s with main contributions of Lichtenthaler, Rohmer, Arigoni, and Seto and exclusively occurs in the plastids of plants and green algae and in most bacteria. It is intriguing to see that

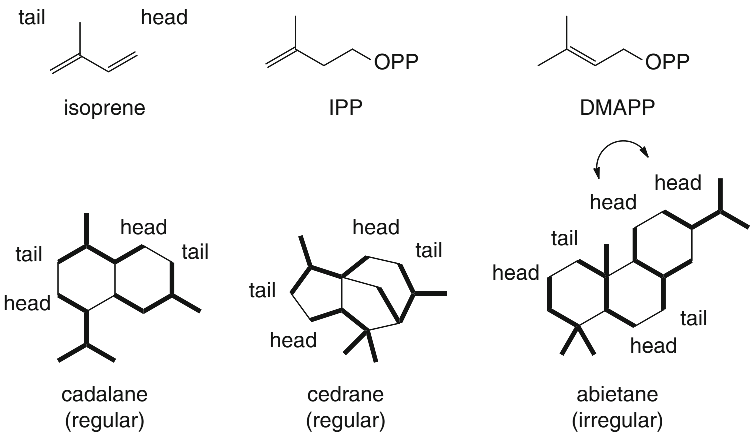

Fig. 87.2 Ruzicka's isoprene rule: regular and irregular terpene skeletons. The irregular head-to-head fusion in the abietanes is highlighted by the *double-headed arrow*

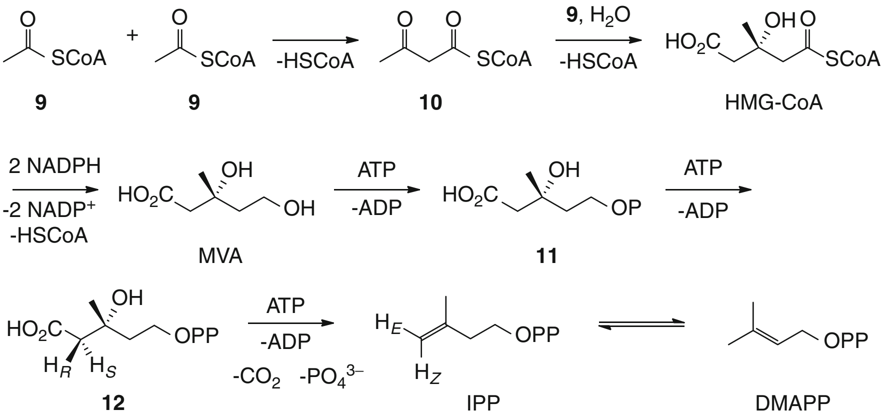
both pathways deliver the same activated isoprenes, IPP and DMAPP, in multiple steps starting from diverse primary metabolites and via completely different intermediates.

2.1 Terpenes from Acid: The Mevalonate Pathway

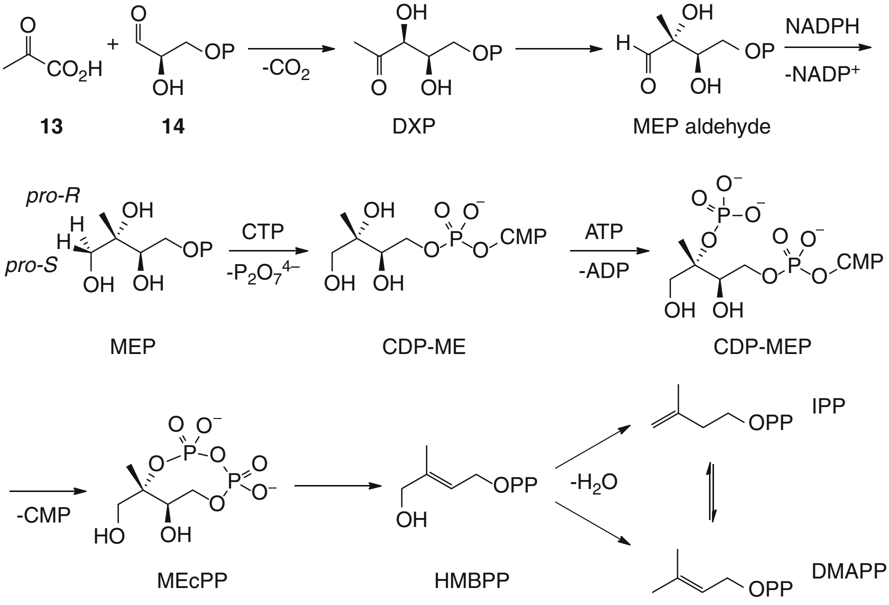
The well-known mevalonate pathway starts with two molecules acetyl-CoA (**9**), the activated form of acetic acid (Scheme 87.1) [11]. In a first step, acetoacetyl-CoA (**10**) is formed via a biological Claisen condensation mediated by the acetoacetyl-CoA acetyltransferase. A biological aldol reaction with a third equivalent of **9** affords (*S*)-3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) catalyzed by the HMG-CoA synthase [12–14]. During this step, the coenzyme A thioester of the newly introduced acetyl-CoA is hydrolyzed to the corresponding free acid. The subsequent action of the HMG-CoA reductase requires two equivalents of NADPH to reduce HMG-CoA to the eponymous intermediate (*R*)-mevalonic acid (MVA) [15–17]. Twofold phosphorylation with ATP gives first 5-phosphomevalonic acid (**11**) by the mevalonate kinase and then 5-diphosphomevalonic acid (**12**) by the 5-phosphomevalonate kinase [18–21]. In the last step, IPP is furnished by the concomittant dehydration-decarboxylation of **12** in a reaction that is mediated by the 5-diphosphomevalonate decarboxylase under consumption of one equivalent ATP [20, 22, 23]. Stereochemically, in this *anti* elimination, the 4-*pro*-*R* proton of **12** is turned into the (4*Z*)-proton of IPP, and the 4-*pro*-*S* proton converts into the (4*E*)-proton, respectively [24, 25]. As will be discussed in more detail in Sect. 3, the primary product IPP can be transformed into its isomer DMAPP by an isopentenyl diphosphate isomerase (IDI), a reaction that is essential in organisms that solely rely on the mevalonate pathway.



Scheme 87.1 The mevalonate pathway

2.2 Terpenes from Sugar: The Deoxyxylulose Phosphate Pathway

After the discovery and full elucidation of the mevalonate pathway, it was initially believed that this pathway is the only one for the biosynthesis of all isoprenoids. From today's point of view, seemingly slavish adherence to this misleading prospect on terpene biogenesis is sometimes referred to as the mevalonate dogma. However, during the years of further research on terpene biosynthesis, more and more data accumulated, mainly from feeding experiments with isotopically labeled glucose [26–28], that were in disagreement with the mevalonate pathway and raised the question whether the mevalonate dogma holds true. Finally, the ambiguities were refined into a newly discovered pathway starting from a phosphorylated deoxysugar, 1-deoxy-D-xylulose 5-phosphate (DXP) [29]. This second pathway for the biogenesis of IPP and DMAPP is known as the deoxyxylulose phosphate pathway (also referred to as non-mevalonate or methylerythritol pathway). The synthesis of DXP itself requires the two glycolysis products pyruvate (**13**) and glyceraldehyde 3-phosphate (**14**) (Scheme 87.2) [30]. Pyruvate is activated by the thiamine diphosphate (TPP) cofactor and after decarboxylation condensed with **14** to form DXP by the DXP synthase [31–34]. The isomerization to 2-*C*-methyl-D-erythrose 4-phosphate (MEP aldehyde) and subsequent reduction with NADPH to 2-*C*-methyl-D-erythritol 4-phosphate (MEP) are catalyzed by a single enzyme termed DXP reductoisomerase (IspC) [35–37]. During this conversion, the C3 proton of DXP is transferred via the aldehyde position in MEP aldehyde to become the 1-*pro-S* proton in MEP, whereas the 1-*pro-R* proton originates from NADPH [38, 39]. The IspD-mediated activation with cytidine triphosphate (CTP) to 4-diphosphocytidyl-2-*C*-methyl-D-erythritol (CDP-ME) and subsequent phosphorylation with ATP by IspE affords 4-diphosphocytidyl-2-*C*-methyl-D-erythritol 2-phosphate (CDP-MEP) [40–43]. The enzyme IspF cyclizes CDP-MEP to 2-*C*-methyl-D-erythritol 2,4-cyclodiphosphate (MEcPP) via elimination of cytidine



Scheme 87.2 The deoxyxylulose phosphate pathway

monophosphate (CMP) after which (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate (HMBPP) is furnished by reduction with IspG [44–47]. In the terminal step HMBPP is transformed to the isoprene equivalents IPP or DMAPP in a fix ratio of about 5:1 by the oxidoreductase IspH [48, 49]. For fine-tuning of the actual building block requirements for terpene biosynthesis, an isomerase can mediate between IPP and DMAPP, but since both products are made simultaneously, an IDI activity is not essential for organisms that use the DXP pathway [50].

Three enzymes of the DXP pathway are mechanistically particularly interesting, and their enzyme mechanisms have been investigated in various approaches. These are the enzymes IspC, IspG, and IspH that will be discussed in more detail in the following sections.

As outlined above, the reductoisomerase IspC has isomerase and dehydrogenase (reductase) activity. Dehydrogenases can be divided into two distinct classes, types A and B, depending on whether they transfer the hydride ion that is abstracted from their substrate to the *Re* face (type A) or the *Si* face (type B) of the NAD(P)$^+$ cofactor. In case of the reverse reaction, class A enzymes reduce their substrates by transfer of the *pro*-*R*-hydrogen, while class B enzymes transfer the *pro*-*S*-hydrogen of NAD(P)H [51]. The DXP reductoisomerase IspC is a class B dehydrogenase and catalyzes the reductive isomerization of DXP to MEP [39, 39]. The first crystal structure was obtained from the *Escherichia coli* enzyme that crystallizes in a homodimeric fashion (Fig. 87.3a) [53, 54]. Each monomer subunit has a V-shaped topology (Fig. 87.3b) and contains the N-terminal NADPH-binding domain, a C-terminal four-helix bundle, and a middle domain

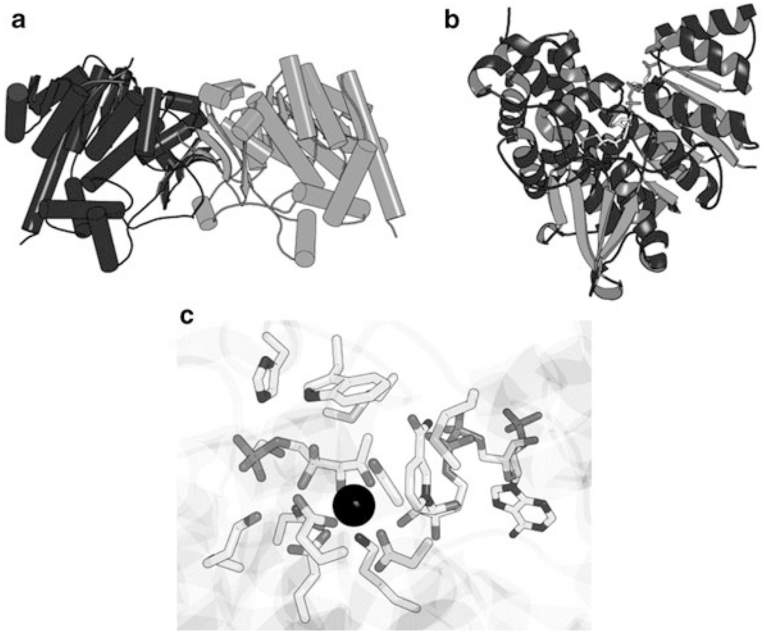


Fig. 87.3 IspC from *E. coli* (1Q0Q) [52]. (**a**) Dimeric structure, (**b**) enzyme complex with NADPH and DXP, and (**c**) close-up on the active site (Mn^{2+} is superimposed from the IspC-Mn^{2+} complex from *Mycobacterium tuberculosis* (4AIC))

that facilitates dimerization. Herein located are conserved aspartate, glutamate, and lysine amino acid residues that bind a divalent metal ion (Mn^{2+}) for catalytic activity (Fig. 87.3c) [53–55].

Although MEP aldehyde has never been observed directly, its intermediacy en route from DXP to MEP seems plausible, as recombinant IspC catalyzes the NADPH-dependent reduction of MEP aldehyde to MEP [56]. For its enzymatic formation from DXP, two possible mechanisms, a retroaldol-aldol mechanism or an α-ketol rearrangement, have been suggested (Scheme 87.3) [56]. The retroaldol-aldol mechanism was supported by kinetic studies and proceeds via the intermediates glycoaldehyde phosphate (**15**) and the (*Z*)-configured enzyme-stabilized enol of hydroxyacetone (**16**) [57–59]. However, no fragment exchange of the putative intermediates could be observed in NMR studies of incubation experiments with IspC and different ^{13}C-labeled substrate isotopologues. This result better fits to the α-ketol-rearrangement mechanism via the transition state **17** or at least points to a very strict fragment containment during the retroaldol-aldol conversion [60]. In contrast, the observed partial epimerization of DXP to 1-deoxy-L-ribulose 5-phosphate (**18**) in the ternary complex of IspC, NADPH, and the substrate was implicated as an evidence for a stepwise mechanism that would allow for rotation of fragment **15** followed by its reaction with **16** to the epimer of DXP, **18** (Scheme 87.3c) [61, 62].

Scheme 87.3 Suggested mechanisms for the IspC reaction. (**a**) Stepwise retroaldol-aldol mechanism, (**b**) concerted α-ketol-rearrangement mechanism, and (**c**) postulated mechanism for the enzymatic formation of the DXP epimer **18**

The enzyme IspG is mechanistically possibly the biggest challenge of all enzymes within the DXP pathway. The homodimeric IspG proteins from *Aquifex aeolicus* and *Thermus thermophilus* have been structurally characterized [63, 64] and show an N-terminal TIM barrel-shaped domain (Fig. 87.4). TIM barrels are named after the triosephosphate isomerase in which this structural motif was first identified and are protein folds made up from eight pairs of alternating α-helices and parallel β-sheets. A smaller C-terminal domain contains a 4Fe-4S cluster [63, 64]. In the first step of the IspG reaction, MEcPP is bound to the TIM barrel and ring-opened to the cationic intermediate **19** (Scheme 87.4). This may cause a switch in the overall enzyme structure into a closed conformation in which the C-terminal domain of one monomer subunit moves toward the TIM barrel of the other subunit and traps the substrate in between [63, 64]. Thereby, the subsequent reduction with involvement of the 4Fe-4S cluster is enabled, and the product HMBPP is released.

Different mechanistic proposals are discussed for the IspG-catalyzed reduction of MEcPP to HMBPP. As an alternative to the initial ring opening of the substrate's cyclodiphosphate to **19**, the formation of an HMBPP epoxide intermediate was proposed (Scheme 87.4) [48, 65, 66]. In support of this intermediate is the finding that HMBPP epoxide is accepted by IspG and reduced to HMBPP [67, 68]. However, semiempirical model calculations disfavor this intermediate that has also never experimentally been observed. A possible explanation is that HMBPP

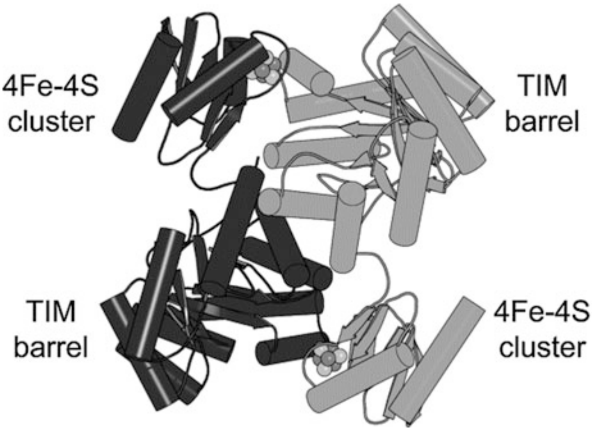

Fig. 87.4 IspG from *A. aeolicus* (3NOY). The enzyme has a homodimeric structure, and each subunit is composed of an N-terminal TIM barrel domain and a C-terminal domain containing the 4Fe-4S cluster

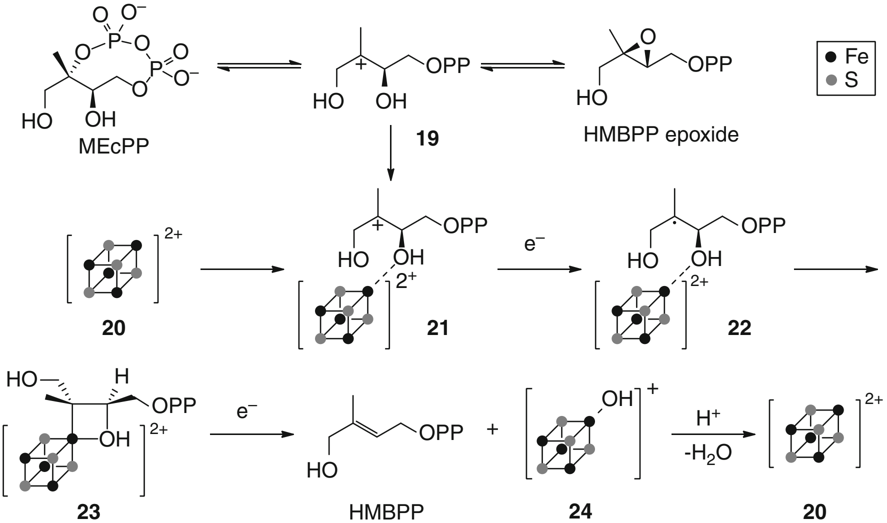

Scheme 87.4 Hypothetical mechanism of the IspG reaction

epoxide, like the native substrate HMBPP, is transformed into cation **19** followed by its reduction. This idea is corroborated by the conversion of HMBPP epoxide into MEcPP by IspG under nonreductive conditions [69]. The reversibility of the C–O bond cleavage at C2 of MEcPP was also demonstrated by incubation of recombinant IspG with ^{18}O-labeled MEcPP [70]. For the reduction of **19** by the 4Fe-4S cluster (**20**), a cascade of substrate binding to **21** followed by one-electron transfer to the radical **22**, protonation and elimination of water to a radical cation (not shown), and a final one-electron transfer to HMBPP were suggested [65, 66]. Semiempirical calculations were in favor of a reverse order of the events, i.e., first

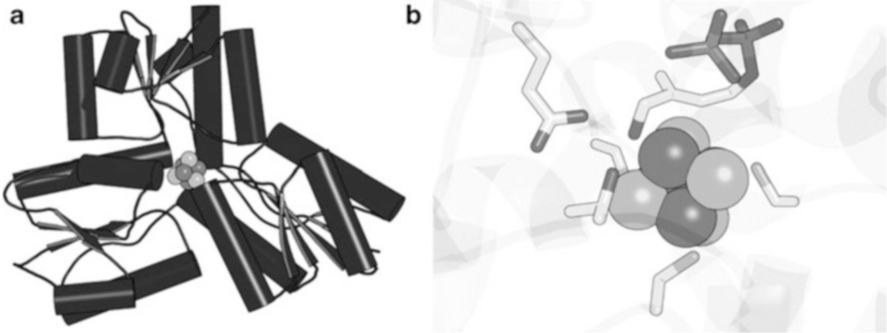

Fig. 87.5 (**a**) IspH from *E. coli* in closed conformation (3KE8) and (**b**) close-up on the active site

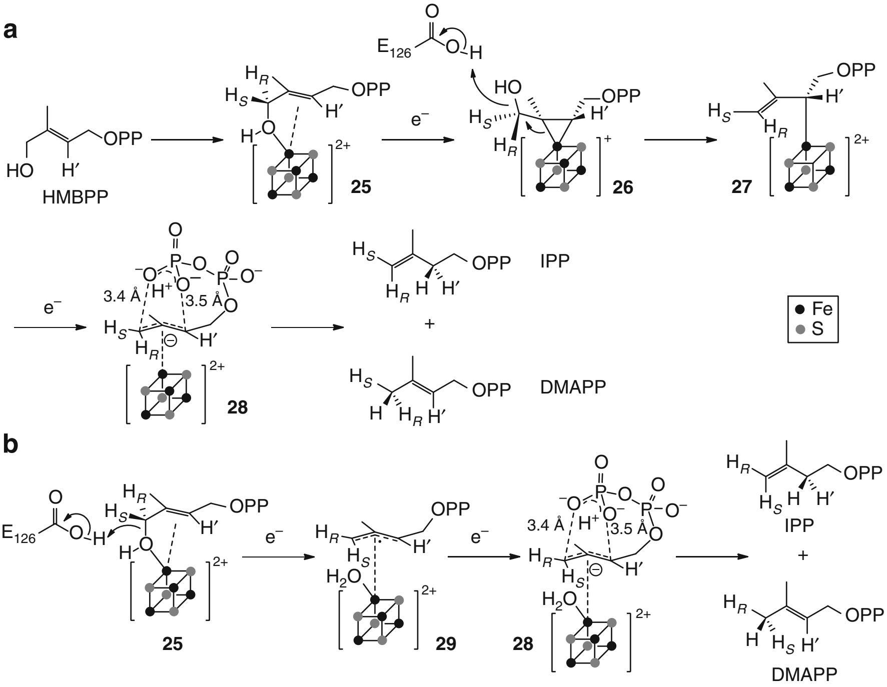
a reduction of **22** to an intermediate tertiary anion species (not shown) followed by protonation and elimination of water to yield HMBPP [67]. Recently, upon incubation of reduced IspG with MEcPP or HMBPP epoxide, a paramagnetic species was detected by different EPR techniques. This finding resulted in the suggestion of a ferraoxetane (**23**) intermediate that could directly be formed from **22** [71–73]. Subsequent reduction and *syn* elimination would give HMBPP and the hydroxy complex **24** from which the 4Fe-4S cluster is restored by protonation and hydrolysis [72].

The mechanism of the IspH reaction was also subject to debate for several years. The first IspH crystal structures were reported from *A. aeolicus* and *E. coli* with a 3Fe-4S cluster surrounded by three structurally homologous domains, albeit without any distinct sequence similarity [74, 75]. This cloverleaf structure can therefore be described as pseudo C_3 symmetric (Fig. 87.5a). Three highly conserved cysteine residues, one from each of the surrounding domains, participate in binding of the central 3Fe-4S cluster [74, 75]. In contrast to these findings, EPR measurements indicated the presence of a 4Fe-4S cluster [76, 77]. Since the fourth Fe is not stabilized by a cysteine residue in the active site, an explanation for the initial detection of the 3Fe-4S cluster is given by the eventual loss of the fourth labile iron center. Instead of a cysteine, a conserved threonine residue was found in close proximity to this Fe, and Mössbauer spectroscopy indicated its involvement in binding of the labile Fe atom [78]. Recently, the fourth Fe atom was also crystallographically observed (Fig. 87.5b) [79].

In the first step of the IspH reaction, an alkoxide complex (**25**) is formed between HMBPP and the fourth labile iron atom of the 4Fe-4S cluster (Scheme 87.5) [74, 75, 79]. Two different mechanisms were proposed for the follow-up steps. The mechanism shown in Scheme 87.5a involves the one-electron reduction of **25** to the metallacyclopropane species **26** that was tentatively identified by EPR spectroscopic methods in the unreactive E126A mutant [80]. Alternatively, **26** could be described as a π-complex. Its protonation/dehydration is likely accomplished by the conserved glutamate E126 and may proceed with preliminary rotation of the hydroxymethyl group into a conformation with the hydroxyl group pointing away



Scheme 87.5 Hypothetical mechanisms of the IspH reaction. (**a**) Metallacyclopropane mechanism and (**b**) Birch reduction mechanism

from the 4Fe-4S cluster. This reaction results in the η^1-allyl complex **27** from which the η^3-allyl anion **28** is generated by a second one-electron transfer. The mechanism shown in Scheme 87.5b is essentially a Birch reduction that starts with a protonation/dehydration of **25** and subsequent one-electron reduction to yield the allyl radical **29**. A modification of this mechanims merges these first two steps to convert **25** directly into the allyl radical **29**. A second one-electron transfer leads to the η^3-allyl anion **28** [48, 81–83]. The last step in both mechanisms A and B includes the protonation of **28** from the *Si* face at C3 to yield IPP [84]. The alternative protonation at C1 to DMAPP proceeds most likely from the same side of the molecule, in other words from the *Re* face. Due to its close proximity within a distance of 3.4–3.5 Å to C1 and C3, respectively, the involvement of the substrate's terminal phosphate group in this last step is discussed and may control the observed ~1:5 product ratio of DMAPP and IPP [79, 85].

The two suggested mechanisms could recently be distinguished due to their different stereochemical implications. Mechanism B implies a stereochemical course in which the 1-*pro-S* hydrogen (H_S) of HMBPP transforms into H_Z of IPP, whereas the 1-*pro-R* hydrogen (H_R) must end up as H_E in IPP. However, feeding experiments with deuterated 1-deoxy-D-xylulose isotopologues showed the contrary result. This finding can only be harmonized with the metallacyclopropane mechanism if the conversion of **26** into **27** indeed proceeds out of the conformation of **26** with the rotated hydroxymethyl group [86]. Further support for this idea was given by quantum chemical calculations [80] and recently reported crystallographic data obtained with IspH mutants for which this rotation of the hydroxymethyl group could directly be observed [87].

3 Isopentenyl Diphosphate-Dimethylallyl Diphosphate Isomerases (IDI)

A central role in the biosynthesis of isoprenoids is filled by the isopentenyl diphosphate-dimethylallyl diphosphate isomerase (IDI) that catalyzes the interconversion of IPP and DMAPP. The necessity for such an enzyme was suggested in the 1950s when only IPP was known as a monomeric isoprenoid precursor, but an allylic diphosphate such as DMAPP was assumed to have the higher intrinsic reactivity for polyisoprenoid synthesis [22, 88, 89]. The first enzymatic isomerization of IPP to DMAPP was observed in 1959 from a cell-free extract of baker's yeast [90, 91]. Two types of IDI with essentially no amino acid sequence or structural similarities are able to catalyze this interconversion by completely different enzyme mechanisms. The well-known IDI-I have been identified in animals, plants, fungi, and bacteria, whereas the IDI-II can be found mainly in archaea but also in some bacteria [92, 93].

3.1 Type I IDI

Type I IDI (IDI-I) are Zn^{2+}-dependent metalloproteins which require a second divalent metal ion (Mg^{2+}) for IPP binding via its diphosphate moiety (Fig. 87.6b, c) [94, 95]. The crystal structure of human IDI-I revealed a homodimeric structure (Fig. 87.6a) with a six-coordinate metal ion binding pocket comprised of three histidine and two glutamate residues. These were initially suggested to bind Mn^{2+} [96, 97], but later on, the metal binding pocket was reassigned to have a much higher affinity for Zn^{2+}. Other divalent metal ions (Cd^{2+}, Co^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+}) are suitable substitutes and can, in some cases, even increase IDI-I activity [98, 99]. A participation of the metal cation in the enzymatic reaction was delineated from X-ray analyses of enzyme-inhibitor complexes [94].

The mechanism of the IPP isomerization is a stereoselective antarafacial 1,3-allylic rearrangement in which a protonation at C4 of IPP from the *Re* side is followed by a stereospecific removal of the 2-*pro-R* proton (Scheme 87.6) [24, 100–102]. In the reverse reaction, DMAPP is protonated at C2 from the *Re* side, while a proton of its (*E*)-methyl group is removed. For yeast IDI-I, a slight lack of fidelity was observed resulting in the partial equalization of the (*E*)- and (*Z*)-methyl groups with a rate of about 2% and a removal of the 2-*pro-S* hydrogen of IPP with a rate of 0.5% [103]. The first of these findings supports a stepwise mechanism rather than a concerted process since the tertiary cation intermediate **30** allows for an exchange

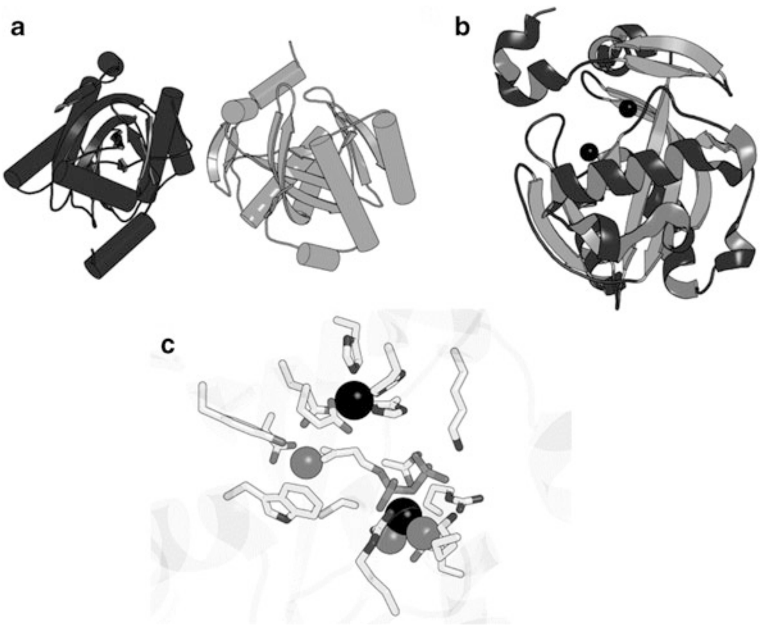


Fig. 87.6 Structure of human IDI-I (2I6K). (**a**) Dimeric structure, (**b**) monomer with Mg^{2+} and Mn^{2+} cofactors, and (**c**) close-up on the active site (DMAPP superimposed from 2ICK)

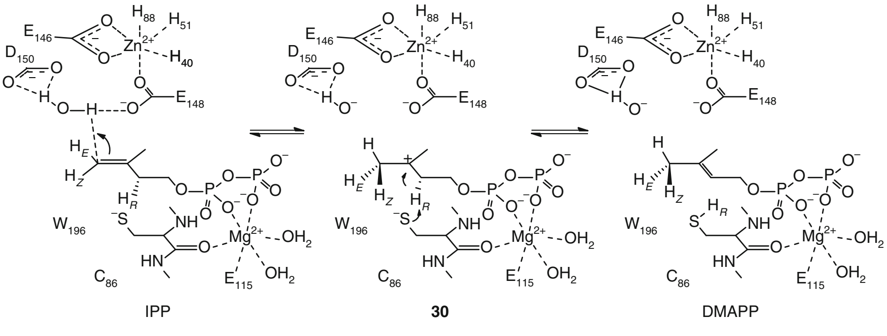

Scheme 87.6 The IDI-I reaction

of the (*E*)- and (*Z*)-methyl groups by rotation around the C2–C3 single bond. This intermediate **30** is likely stabilized by cation-π-interactions with a tryptophane residue in the active site [96].

The amino acid residues E148 and Y136 have been discussed as proton sources for the initial protonation of IPP. However, E148 is likely unprotonated under physiological conditions due to its coordination to Zn^{2+}. Furthermore, site-directed mutagenesis of the conserved tyrosine in *E. coli* IDI-I results in a 1% residual activity, indicating a structural rather than a direct functional role [104, 105].

Water could act as proton donor, but the crystal structure of *E. coli* IDI-I does not contain a water molecule in the active center. In contrast, the crystal structure of human IDI-I exhibits a water molecule that is stabilized by D150 within the active site [95, 106]. This aspartate residue is conserved in eukaryotic IDI-I which coincides with the ca. 20-fold higher activity of the eukaryotic enzyme as compared to *E. coli* IDI-I [50]. A cystein residue has been suggested as proton acceptor for the deprotonation of **30** [91, 107, 108]. Site-directed mutagenesis of this cystein in yeast IDI-I confirmed its critical role for catalytic activity [109].

3.2 Type II IDI

Type II IDI are flavoenzymes that require a reduced flavin mononucleotide (FMN) and a divalent metal ion (Mg^{2+} or Mn^{2+}) for their action [110–114]. The first enzyme of this class has been discovered in 2001 in *Streptomyces* sp. CL190 [111]. The crystal of IDI-II from the archaeon *Sulfolobus shibatae* shows a tetrameric quarternary structure (Fig. 87.7), whereas the *Bacillus subtilis* enzyme is an octamer [115, 116]. The monomers exhibit a TIM barrel domain as it is typical for flavoproteins. The enzyme's requirement of a redox cofactor is surprising since the overall reaction catalyzed by IDI-II is a simple olefinic double bond isomerization without a net change of the redox state of its substrate. Site-directed mutagenesis experiments demonstrated that the reduced flavin cofactor is only acting as a general acid-base catalyst without being involved in any redox chemistry. Herein, a non-redox functionality of a flavin cofactor was established for the first time [115].

For the IDI-II mechanism, a stepwise proton addition/elimination rather than a concerted process was suggested, as olefinic hydrogen exchange without isomerization was observed for an IPP analogue [117]. In the first step, IPP is protonated at C4 to give the intermediate tertiary cation **30** followed by stereoselective removal of the 2-*pro*-*R*-proton [84, 118]. The reverse reaction follows essentially the same stereochemical course in which the protonation of DMAPP at C2 from the *Re* side is succeeded by a selective deprotonation of the (*E*)-methyl group [84, 119]. In theory, the intermediate **30** would allow for a rotation around the C2–C3-bond, but the reaction has a high fidelity with no observable equalization of the (*E*)- and (*Z*)-methyl groups pointing to a tight binding of the substrate to the FMN cofactor [115]. The suprafacial proton transfer catalyzed by IDI-II was suggested from crystallographic observations in an enzyme-substrate complex, experimentally demonstrated in isotopic labeling experiments, and stands in clear contrast to the established antarafacial process in the IDI-I reaction [115, 120]. The structural data together with the observed stereochemistry of the IDI-II reaction were refined into two alternative mechanisms. Either the N5 and N1 nitrogens of FMN in cooperation (Scheme 87.7a) or the N5 nitrogen alone was implicated to mediate the proton transfer (Scheme 87.7b), whereas a participation of conserved amino acid residues as general acid-base catalysts was experimentally ruled out [115, 120]. In mechanism A, the FMN cofactor has a different protonation state after one

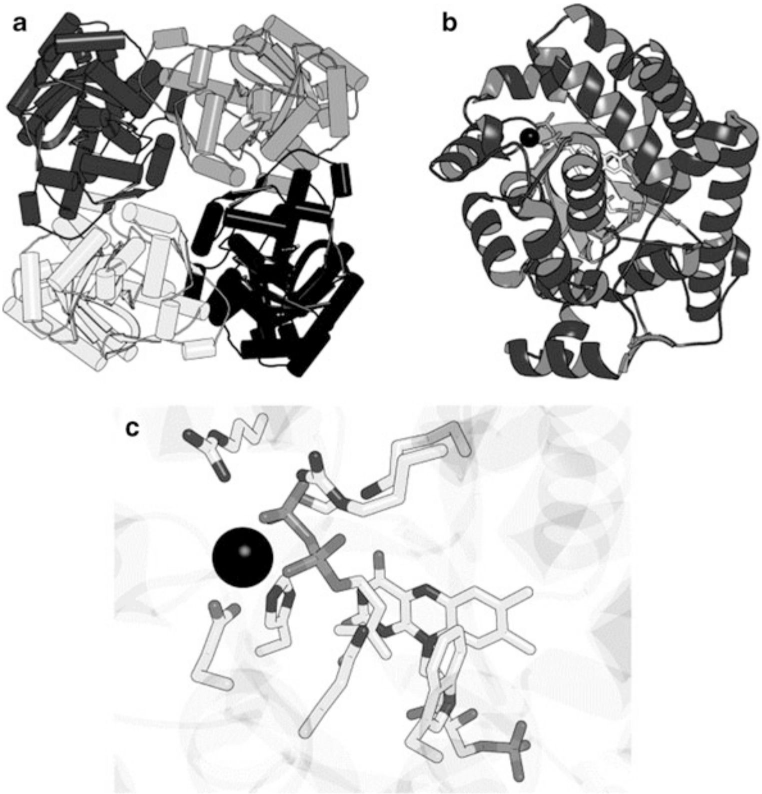

Fig. 87.7 IDI-II from *S. shibatae* (2ZRW). (**a**) Tetrameric structure, (**b**) monomer with FMN cofactor, and (**c**) cocrystallization with Mg^{2+}, FMN, and IPP

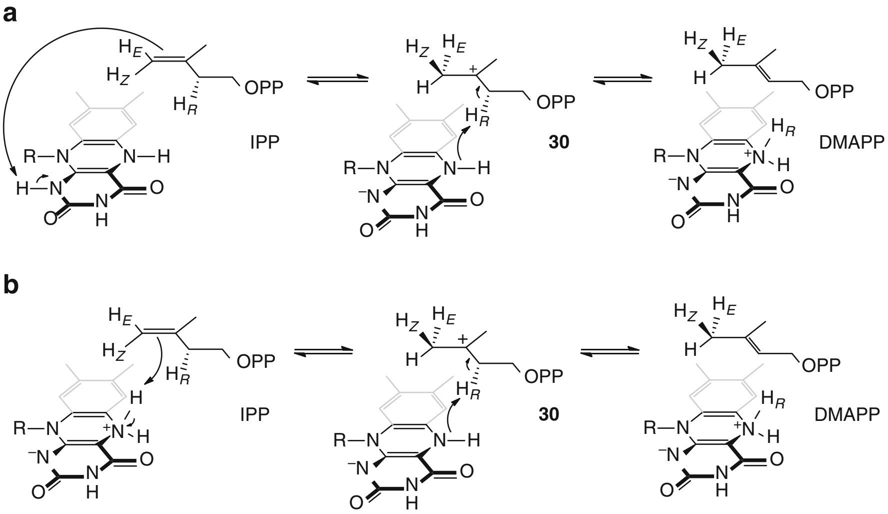
turnover and must be restored by a deprotonation/reprotonation event likely with participation of appropriate amino acid residues prior to its next usage. No such net change of the cofactor occurs in mechanism B during one catalytic turnover.

4 Biosynthesis of Linear Polyisoprenoids

The biosynthesis of linear polyprenyl diphosphates is carried out by prenyltransferases. DMAPP and IPP can be fused under catalysis of the geranyl diphosphate synthase to geranyl diphosphate (GPP). Farnesyl diphosphate (FPP) and geranylgeranyl diphosphate (GGPP) are constructed analogously by repeated addition of IPP under catalysis of the FPP synthase and the GGPP synthase. Only a few examples for the biosynthesis of farnesylgeranyl diphosphate are known from archaea [121]. According to Ogura and Koyama, prenyltransferases can be classified into four groups including the homomeric short-chain prenyl diphosphate synthases (class I, C_{10}–C_{25}), the heteromeric medium-chain prenyl diphosphate



Scheme 87.7 The IDI-II reaction. (**a**) Suggested mechanism with involvement of N5 and N1 of the reduced FMN cofactor and (**b**) mechanism with participation only of N5 of FMN

synthases (class II, C_{30}–C_{35}), the homomeric long-chain prenyl diphosphate synthases (class III, C_{40}–C_{50}), and the (*Z*)-polyprenyl diphosphate synthases (class IV) [122].

Recently, a very useful structural classification for proteins involved in terpene biosynthesis has been proposed by Oldfield and Lin [123]. Following this classification, six enzyme domain structures (α, β, γ, δ, ε, and ζ) can be distinguished that occur in different combinations in enzymes for terpene biosynthesis to fulfill various functions. While terpene cyclases are constructed from α-, β-, and γ-domains (Sect. 5) [124], prenyltransferases are made up from α-, δ-, ε-, and ζ-modules. The (*E*)-selective prenyltransferases fall into two classes that either have a homomeric (αα-type or $(\alpha\alpha)_3$-type) [125] or heterotetrameric ($\alpha_2\delta_2$-type) structure, whereas the (*Z*)-selective prenyltransferases constitute a third distinct group with a completely different enzymology (ζ-type) [126]. In contrast to these head-to-tail connecting prenyltransferases, the specialized ε-type prenyltransferases generate the linear precursors squalene and phytoene by a head-to-head linkage of FPP and GGPP, respectively.

4.1 Homomeric (*E*)-Selective Prenyltransferases

The (*E*)-selective homomeric prenyltransferases are responsible for the formation of polyprenyl diphosphates with product chain lengths from GPP (C_{10}) up to decaprenyl diphosphate (DecPP, C_{50}). At least one (*E*)-selective prenyltransferase is essential for every organism as short-chain (*all-E*)-configured polyisoprenoids are the precursors for the pivotal steroids and carotenoids. These α-helical enzymes

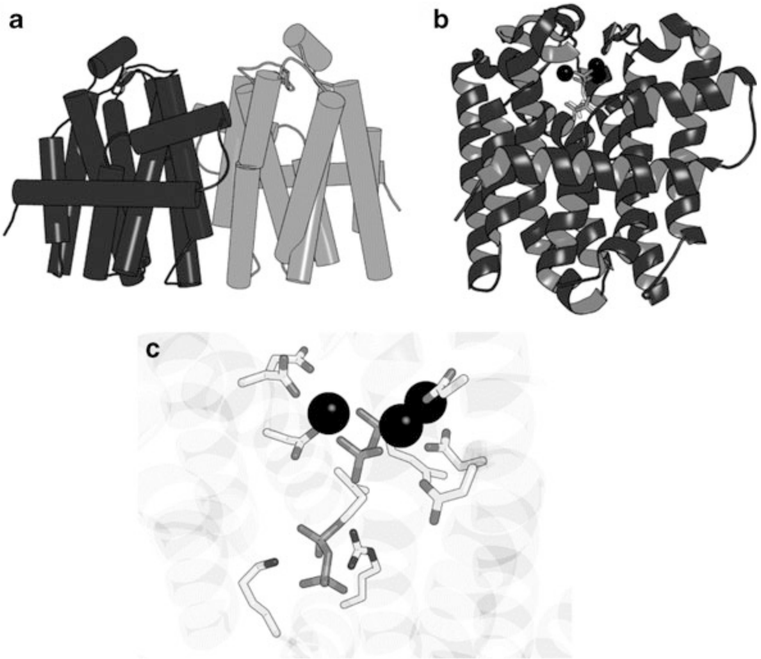


Fig. 87.8 *E. coli* FPP synthase (1RQI). (**a**) Homodimeric structure (αα-type), (**b**) monomer with trinuclear Mg^{2+} cluster, and (**c**) close-up on the active site in complex with Mg^{2+}, IPP, and DMASPP

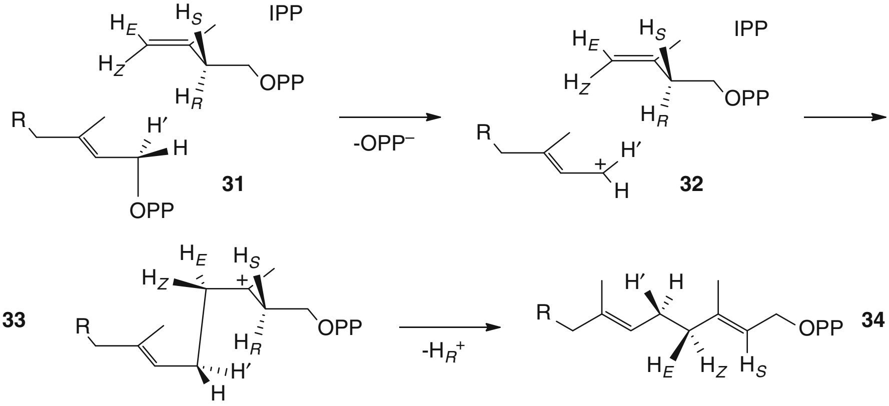
can appear as homodimers (αα-type) exemplified by *E. coli* FPP synthase (Fig. 87.8a) [127] or as hexameric assemblies ($(\alpha\alpha)_3$-type) like in the human GGPP synthase or the solanyldiphosphate (SPP) synthase from *Arabidopsis thaliana* [128, 129]. The αα-type prenyltransferases require divalent metal ions (usually Mg^{2+} or in some cases Mn^{2+}) as a cofactor. Each α-subunit contains two highly conserved aspartate-rich motifs on opposite sides of the active site with a consensus sequence of DDXXD (Fig. 87.8b). These aspartate residues are responsible for the binding of three divalent metal ions via salt bridges (Fig. 87.8c). The resulting trinuclear magnesium cluster coordinates to the diphosphate oxygen atoms of the allylic diphosphate. The elongation unit IPP is bound with its diphosphate moiety to conserved cationic residues in the homoallylic binding site via electrostatic interactions [127].

In the first step of the chain elongation reaction, diphosphate abstraction from DMAPP is initiated by the Lewis-acidic trinuclear magnesium cluster to generate the allyl cation **32**. This enables attack of IPP at C1 of DMAPP with inversion of the configuration resulting in the tertiary cation **33** [100]. Stereoselective removal of the IPP 2-*pro*-*R* proton finishes the assembly of GPP [100, 130]. As the attack of IPP proceeds at its C4 from the *Si* side [24], H_E of IPP ends up as the 4-*pro*-*S*-hydrogen and H_Z as the 4-*pro*-*R*-hydrogen of the newly formed



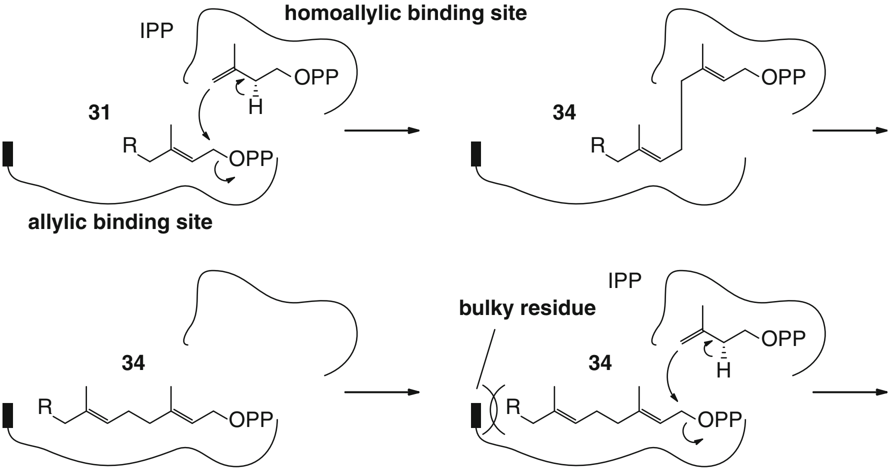
Scheme 87.8 Stereochemical course and intermediates of the polyisoprenoid biosynthesis by (*E*)-selective prenyltransferases

polyisoprenoid **34** (Scheme 87.8). Higher homologues are accessed by ionization of GPP and (*E*,*E*)-FPP that are elongated by IPP addition to yield (*E*,*E*)-FPP and (*all*-*E*)-GGPP, respectively. The stepwise rather than concerted process of the prenyltransferase reaction via the intermediates **32** and **33** was established by incubation of FPP and a less reactive IPP analogue (3-bromobut-3-enyl diphosphate) with the octaprenyl diphosphate (OctPP) synthase resulting in the capture of the farnesyl cation as farnesol [131].

The crystal structures of αα-homodimeric prenyltransferases exhibit a homoallylic binding site for IPP and an allylic binding site for the allylic diphosphate substrate that together constitute a hydrophobic pocket (Scheme 87.9). The individual product chain length of a prenyltransferase is determined by the size of this hydrophobic cleft, i.e., bulky substituents limit the size of the allylic diphosphate substrate and thereby control the maximum chain length of the polyisoprenoid product. Important insights into this control mechanism were obtained by site-directed mutagenesis experiments with avian FPPS, in which such bulky substituents were replaced by smaller ones, thus shifting the product scope to higher homologues of the native FPP product [132]. This idea of chain length control is also supported by a good correlation between the sizes of the hydrophobic clefts and the maximum product chain lengths as revealed by a structural comparison of several enzymes [129, 133, 134].

4.2 Heteromeric (*E*)-Selective Prenyltransferases

The αδ-type prenyltransferases are comprised of two proteins, each of these being inactive on its own, that form an active $\alpha_2\delta_2$-heterotetramer. The first prenyltransferase of this class was described from *Micrococcus luteus* and biochemically characterized as hexaprenyl diphosphate (HexPP) synthase [135].



Scheme 87.9 Product chain length is controlled by the size of the hydrophobic clefts in prenyltransferases

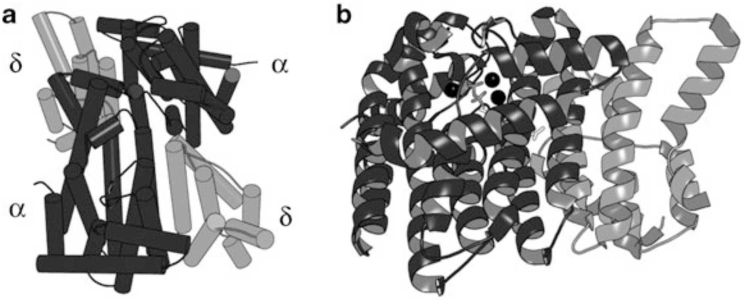


Fig. 87.9 Structure of HexPP synthase from *M. luteus* (3AQC). (**a**) Heterotetramer and (**b**) heterodimer in complex with Mg^{2+} and a less reactive FPP analogue (7,11-dimethyl-2,6,10-dodecatrien-1-yl diphosphate)

GPP synthase from *Mentha* × *piperita* constitutes the first example for which an X-ray structure was obtained [136], followed 1 year later by the crystal structure of HexPP synthase from *M. luteus* [137]. The heterotetramers are made up from two large α- and two small δ-subunits (Fig. 87.9). The α-subunits contain the conserved DDXXD motifs and are structurally related to the α-domains of homomeric prenyltransferases, while the δ-subunits lack the DDXXD motif for catalysis but determine chain length specificity and stabilize the enzyme structure by hydrophobic interactions [137]. The structural similarities between the δ-subunits and the α-domains suggest a close common evolutionary origin. Interestingly, the prenyltransferase from *M.* × *piperita* produces not only GPP but also GGPP without significant amounts of FPP upon prolonged incubation [136].

4.3 The (*Z*)-Selective ζ-Type Prenyltransferases

The (*Z*)-selective prenyltransferases are structurally different to all other prenyltransferases and are made up from so-called ζ-domains. They catalyze the head-to-tail addition of IPP to a growing isoprenoid chain with introduction of a (*Z*)-configured olefinic double bond. Their product chain lengths vary from neryl diphosphate (C_{10}) to undecaprenyl diphosphate (UPP, C_{55}), the latter one being a particularly important molecule for bacterial cell wall biosynthesis [138]. Typically, the long-chain ζ-prenyltransferases including the UPP synthases from *M. luteus* and *E. coli* use (*E*,*E*)-FPP as starter [139–141], while the short-chain enzymes such as the neryl diphosphate synthase from *Solanum lycopersium* and the (*Z*,*Z*)-FPP synthase from *Solanum habrochaites* start the elongation process from DMAPP [142, 143]. An interesting interaction of two ζ-prenyltransferases is known from *M. tuberculosis* where the product of the (*E*,*Z*)-FPP synthase is used by another ζ-prenyltransferase for its further (*Z*)-selective elongation to DecPP [144]. Very long chains up to C_{120} are built by the dehydrodolichyl diphosphate synthase, and polymers composed of more than 10,000 isoprene units are made by the rubber synthases [145–147].

The UPP synthase crystallizes as homodimer, and each monomer exhibits six parallel β-sheets that are surrounded by seven α-helices (Fig. 87.10a) [126, 148, 149]. In agreement with their unique structures, the ζ-prenyltransferases show no sequence homology to (*E*)-selective prenyltransferases and also lack the typical DDXXD motif [139, 140]. However, like the (*E*)-selective enzymes, they require a divalent metal ion for activity [150]. Two highly conserved motifs DGN(G,R)R and, ca. 40 amino acid residues downstream, FSXENXXR are present, and site-directed mutagenesis revealed that the aspartate residue in the first motif is crucial for enzyme activity [151]. Structural analysis confirmed its involvement in Mg^{2+} binding (Fig. 87.10b) that in turn binds the IPP elongation unit [152], while FPP binding proceeds through electrostatic interactions with several cationic residues (Fig. 87.10c) [152–155]. A hydrophobic cavity for binding of the polyprenyl side chain is located adjacent to the active site [148].

The stereochemistry of the (*Z*)-selective prenyl transfer was first investigated for the rubber biosynthesis by the Brazilian rubber tree (*Hevea brasiliensis*) in 1966 by Cornforth and coworkers. Feeding experiments with tritium-labeled MVA were consistent with the specific loss of the 2-*pro*-*S* hydrogen of IPP during chain elongation [156]. Cornforth et al. furthermore observed the specific removal of the 2-*pro*-*R* hydrogen from IPP in the biosynthesis of (*E*,*E*)-FPP (Sect. 4.1) [100]. These and similar observations [157, 158] resulted in the postulate of a strict correlation of the (*E*)-configuration in the product with a specific removal of the 2-*pro*-*R* hydrogen from IPP and vice versa. Later experiments on the (*Z*)-configured malloprenols demonstrated the abstraction of the 2-*pro*-*R* hydrogen from IPP during polyisoprenoid assembly [159–161], a result that contradicted the previously framed rule.

More recently, the complete stereochemical course of rubber biosynthesis in *H. brasiliensis* and *Parthenium argentatum* was investigated in detail. Diphosphate

Scheme 87.10 Stereochemical course of rubber biosynthesis

displacement at the growing chain occurs with inversion of the configuration at C1, IPP attacks the allylic diphosphate **31** from the *Si* face, and the 2-*pro*-*S* proton from IPP is removed (Scheme 87.10) [162]. This stereochemical course is in agreement with the reaction of UPP synthase that also proceeds with attack of IPP from the *Si* face and removal of the 2-*pro*-*S* proton [157, 163]. In contrast to the experiment with (*E*)-selective OctPP synthase (Sect. 4.1), incubation of FPP and 3-bromobut-3-enyl diphosphate with UPP synthase did not result in the capture of farnesol, suggesting that the first step of the reaction catalyzed by (*Z*)-selective prenyltransferases is a concerted DMAPP diphosphate cleavage/IPP attack to **33** without generation of an intermediate allyl cation [131].

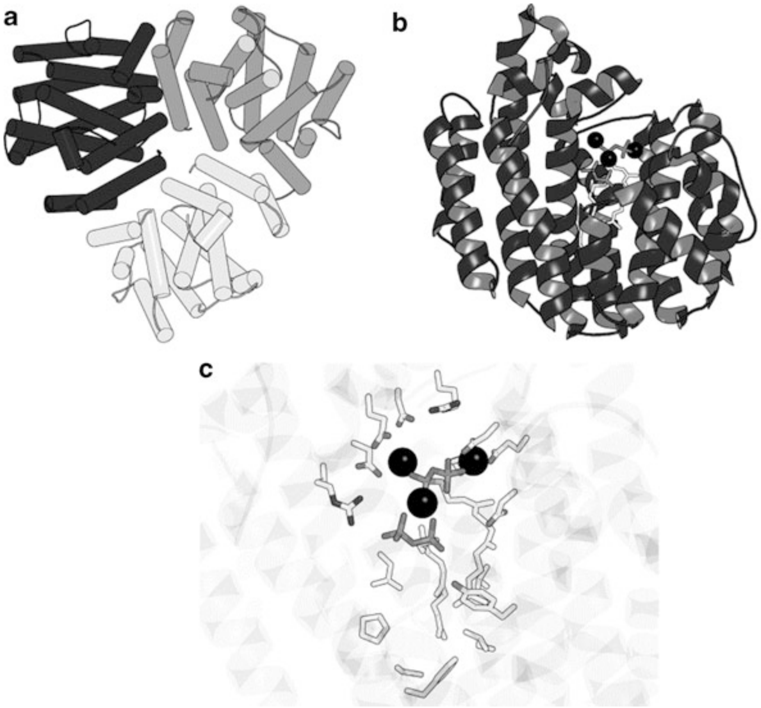

Fig. 87.11 Human squalene synthase (1EZF). (**a**) Homotrimeric structure, (**b**) monomer (Mg^{2+} and FPP superimposed from 2ZCP), and (**c**) close-up on the active site

4.4 Biosynthesis of Squalene and Phytoene

In contrast to the head-to-tail connected polyisoprenoids, squalene (C_{30}) and phytoene (C_{40}) arise from a head-to-head condensation of two molecules FPP or GGPP, respectively. The squalene synthase requires divalent metal ions (Mg^{2+}, Mn^{2+}) as well as an NADPH cofactor. Superimposition of the crystal structure of human squalene synthase with avian FPP synthase reveals a close structural homology, although the sequence identity in the superimposed parts is low [164]. Due to their distinct functionality, the highly α-helical squalene synthases (Fig. 87.11) have been designated an own type of head-to-head prenyltransferases termed ε-class. The highly conserved DDXXD motifs in α-prenyltransferases are altered to DTLED and DYLED motifs in the human squalene synthase.

Two molecules of FPP, one acting as prenyl donor and one as prenyl acceptor, are the direct precursors for squalene [165]. The squalene synthase catalyzes the reductive dimerization of FPP under consumption of one equivalent NADPH via the stable intermediate presqualene diphosphate (**36a**, Scheme 87.11) [166–168]. Its relative and absolute configurations were established by degradation studies and total synthesis [169–172]. The formation of presqualene diphosphate (**36a**) proceeds with inversion of configuration at C1 of the prenyl donor and with attack of

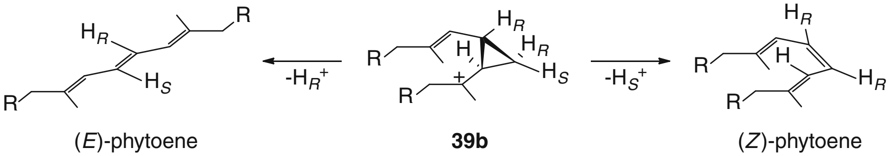
the olefinic double bond of the prenyl acceptor from the *Re* face to form the tertiary cationic intermediate **35a** [173]. The original 1-*pro-S* proton of the prenyl donor is subsequently removed in order to build the cyclopropyl ring of **36a** [174]. An active site for this first half-reaction was tentatively identified in the crystal structure of the human squalene synthase [164]. The prenyl acceptor and the prenyl donor bind each with two conserved aspartate residues of the DDXXD analogous motifs, in both cases via magnesium salt bridges. The prenyl chains of both FPP molecules fit into an adjacent hydrophobic cavity. A neighboring tyrosine together with a glutamate residue presumably acts as a general base, and two arginine residues located next to the binding site of the prenyl donor could stabilize the diphosphate leaving group [164]. The critical role of several of these residues was confirmed by site-directed mutagenesis [175].

The second step in the squalene biosynthesis is the reductive rearrangement of presqualene diphosphate (**36a**) to squalene. Initial diphosphate abstraction formally gives a primary cyclopropylcarbinyl cation **37a** that rearranges via a secondary cyclobutylium intermediate **38a** to the tertiary cyclopropylcarbinyl cation **39a** (Scheme 87.12) [176–178]. Hydride attack from NADPH at C3 terminates the squalene biosynthesis. Evidence for the existence of the tertiary



Scheme 87.13 Formation of (*E*)-phytoene and (*Z*)-phytoene (R = farnesyl)

cyclopropylcarbinyl cation intermediate was provided by isolation of its water adduct rillingol from incubation experiments of recombinant squalene synthase with FPP and NADPH [169, 179]. No such products derived by water attack to **37a** or **38a** have ever been detected, suggesting that the cyclopropylcarbinyl-cyclopropylcarbinyl rearrangement from presqualene diphosphate (**36**) to the tertiary cation **39a** is a rapid and concerted process rather than a stepwise mechanism [179]. This is also corroborated by the strict inversion of configuration at C1 of the original prenyl acceptor en route to squalene [100, 180]. The mechanism of enzyme catalysis in the second half-reaction is not well understood. A common TSRSF motif and additional highly conserved amino acids build a hydrophobic pocket that shields the intermediate carbocations effectively from capture with water [164]. In particular, the phenylalanine within this motif is crucial for activity by stabilization of the intermediate cationic species via cation-π-interactions [175].

The closely related phytoene synthase, also an ε-type enzyme, catalyzes the head-to-head condensation of two units GGPP to phytoene [181]. Its activity depends on divalent metal ions (Mg^{2+} or Mn^{2+}) and is in vitro strongly stimulated by addition of detergents that remove the water-insoluble product from the active site [181, 182]. Similar to the mechanism of squalene formation, the biosynthesis of phytoene proceeds via the intermediate prephytoene diphosphate (**36b**, Scheme 87.11) [173, 183]. Ionization by diphosphate abstraction to **37b** is followed by cyclopropylcarbinyl-cyclopropylcarbinyl rearrangement to the tertiary cationic intermediate **39b**. Its deprotonation can either proceed with specific abstraction of the 1-*pro-R* proton from the original prenyl acceptor to generate (*E*)-phytoene as in *Mycobacterium* sp., or with abstraction of the corresponding 1-*pro-S* hydrogen to establish (*Z*)-phytoene as in *Phycomyces blakesleeanus* (Scheme 87.13) [184].

5 Terpene Cyclases

Terpene synthases constitute a large class of enzymes that are able to convert just a handful of linear isoprenoid precursors, made from IPP and DMAPP by prenyltransferases, into a large diversity of thousands of terpenoids. As most of the enzyme products are of (poly)cyclic nature, these enzymes are often called terpene cyclases. Two types of terpene synthases can be mechanistically distinguished by their formation of a reactive carbocationic species. Class I terpene synthases contain a highly conserved DDXXD motif as also found in α-type prenyltransferases and perform substrate ionization via metal-triggered abstraction

Fig. 87.12 Products of structurally characterized terpene synthases

of a diphosphate group, whereas class II enzymes exhibit a highly conserved DXDD motif that induces reactivity by protonation of a carbon-carbon double bond or an epoxide function. The class I enzymes are typically involved in the biosynthesis of hemi-, mono-, and sesquiterpenes. In case of the linear triterpene precursors squalene or squalene epoxide that lack a diphosphate moiety, initiation of cyclization strictly requires a protonation step by a type II terpene cyclase. Both mechanisms can merge in bifunctional diterpene cyclases such as the abietadiene synthase from *Abies grandis* [185]. Several monofunctional type I terpene cyclases from all kinds of organisms [186–197] and a few type II enzymes such as the human lanosterol synthase (oxidosqualene cyclase, OSC) [198] and squalene/hopene cyclase (SHC) from *Alicyclobacillus acidocaldarius* [199] have been structurally characterized (Fig. 87.12), but the diterpene cyclases have eluded from structural characterization for a long time. Only recently the X-ray structures of the taxadiene synthase from *T. brevifolia* (type I) [200], the *ent*-copalyl diphosphate synthase

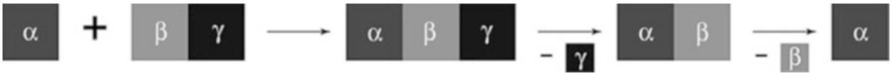

Fig. 87.13 Evolutionary model for terpene cyclases

from *A. thaliana* (type II) [201], and the abietadiene synthase from *A. grandis* [202] have been obtained. These structural information gave important insights into the mechanisms and evolutionary origin of the different classes of terpene synthases.

The structural data together with functional aspects investigated by site-directed mutageneses revealed that terpene cyclases are generally made up from three types of domains in various combinations. This includes α-domains as present in (*E*)-selective prenyltransferases as well as β- and γ-domains. Based on these findings, an evolutionary model has been proposed suggesting that the ancestral βγ-domain proteins such as SHC may have fused to an α-domain prenyltransferase to result in the early αβγ-proteins today seen in the plant diterpene synthases (Fig. 87.13) [124]. Loss of the γ-domain may have resulted in the αβ-domain species as found in plant hemi-, mono-, and sesquiterpene cyclases. The corresponding bacterial and fungal terpene cyclases only contain an α-domain and likely arose by β-domain loss from the plant enzymes.

5.1 Type I Terpene Synthases

Class I terpene synthases are highly α-helical proteins containing conserved aspartate-rich motifs. These motifs bind divalent metal ions (Mg^{2+}) via salt bridges to form a trinuclear metal cluster that complexes the polyisoprenoid for diphosphate abstraction. Like (*E*)-selective prenyltransferases, type I terpene synthases exhibit one conserved aspartate-rich DDXX(D,E) motif, but instead of a second DDXXD on the opposite side of the active center, a consensus sequence of (N,D)D(L,I,V)X (S,T)XXXE (also termed NSE/DTE triad) is found here. One exception is the (+)-δ-cadinene synthase from *Gossypium arboreum* that like prenyltransferases contains two DDXXE motifs [195].

This α-domain is common to all class I terpene synthases and is the only domain in bacterial and fungal class I enzymes such as the pentalenene synthase from *Streptomyces exfoliatus* or the trichodiene synthase from *Fusarium sporotrichioides* (Fig. 87.14a) [191, 194]. Plant hemi-, mono-, and sesquiterpene synthases exhibit a second helical β-domain that resembles a barrel structure. An example of this class is given by the (+)-δ-cadinene synthase from *G. arboreum* (Fig. 87.14b) [195]. In plant diterpene cyclases and in the exceptional case of the (*E*)-α-bisabolene synthase from *A. grandis* (Fig. 87.14c), a third helical γ-domain with a barrel-like structure is present [197, 200, 202]. The β- and γ-domains in the plant enzymes are nonfunctional but are required for correct enzyme folding.

The initial carbocation formation bears the potential for various reactions including intramolecular attack of an olefinic double bond, hydride migrations, or Wagner-Meerwein rearrangements. The transformation of a linear polyisoprenoid

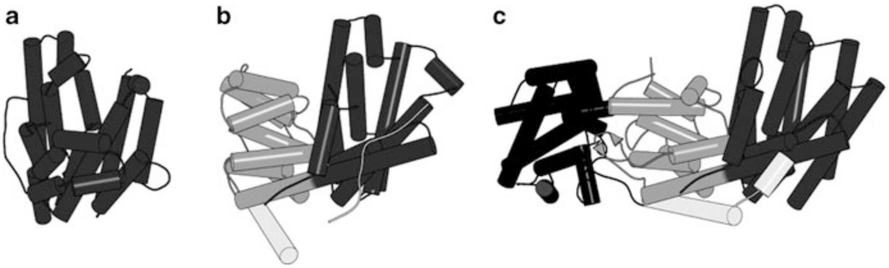

Fig. 87.14 Three different structure types for class I terpene synthases. (**a**) The α-type pentalenene synthase from *S. exfoliatus* (1PS1), (**b**) αβ-type (+)-δ-cadinene synthase from *G. arboreum* (3G4D), and (**c**) αβγ-type (*E*)-α-bisabolene synthase from *A. grandis* (3SAE)

precursor by a terpene cyclase usually involves a multistep cascade of such elementary reactions to assemble a distinct terpenoid. The shape and electrostatic environment within the enzyme's active site determine a certain constitutional fold of the prenyl diphosphate substrate in which the structure of the cyclic product is prearranged [203]. Functionally important in terpene cyclizations are aromatic residues that stabilize the cationic intermediates through cation-π-interactions [204, 205]. Generally, the active site is constructed by hydrophobic rests to exclude water that otherwise may capture the intermediate cations en route to the target terpene. Termination mechanisms include deprotonations or the attack of nucleophiles, in most cases water.

Only about 25 naturally occurring hemiterpenoids are known reflecting the low structural variability within only one isoprenoid unit. Nevertheless, it is estimated that isoprene is released by plants with an annual rate of 500–750 Tg, making it one of the most abundant natural products [206]. The biosynthesis of isoprene is possibly the simplest biosynthetic transformation of any terpene synthase and performed just by ionization of DMAPP to the prenyl cation and proton elimination (Scheme 87.14a). The structure of the isoprene synthase from *Populus* × *canescens* in complex with a DMAPP analogue implicates a substrate-assisted deprotonation of the prenyl cation by the initially removed diphosphate moiety [186]. On the contrary, over 900 monoterpenoids have been described as the structure of GPP gives a lot more opportunities for product diversification. This is already reflected by the larger diversity of linear hydrocarbon products similarly arising by ionization of GPP to the geranyl cation followed by loss of a proton. These two steps potentially yield three alternative hydrocarbons: β-myrcene, (*E*)-β-ocimene, or (*Z*)-β-ocimene (Scheme 87.14b).

Besides a simple ionization-deprotonation process to the acyclic monoterpenes, GPP can also undergo cyclization reactions. The direct Markovnikov-type 1,6-cyclization of the (*E*)-configured geranyl cation by attack of the C6–C7 double bond at the cationic center is impossible since this would give a hypothetical (*E*)-cyclohexene product. Therefore, the isomerization of GPP via the geranyl cation to linalyl diphosphate (LPP) prior to cyclization is required (Scheme 87.15). The possible free rotation of the vinyl group into a *cisoid* conformation privileges

LPP to undergo the 1,6-ring closure to the (*S*)- or (*R*)-α-terpinyl cation (**40**). A hypothetic *anti*-Markovnikov 1,7-cyclization has never been reported as it would imply the formation of a less stable secondary cycloheptenyl cation.

These cyclization reactions open up the possibility for the biosynthesis of a large diversity of (poly)cyclic terpenes. The α-terpinyl cation (**40**) is the key intermediate to a large variety of monoterpenes (Scheme 87.16). Simple deprotonation yields limonene, while 2- and 3-carene can arise by deprotonation with simultaneous construction of a cyclopropyl ring. A 1,2-hydride shift gives the homoterpinyl cation (**41**) as precursor for thujene, terpinolene, α-terpinene, and γ-terpinene. A second 1,2-hydride migration affords the allylic phellandryl cation (**42**), also directly accessable by a 1,3-hydride shift from **40**, that can be deprotonated to α-terpinene, 2-carene, α- and β-phellandrene. The 6,4-ring closure of **41** gives **43**, the precursor for thujene and sabinene, while 7,2-cyclization of **40** to the pinyl cation (**44**) results in the formation of α- and β-pinene after loss of a proton. The secondary bornyl cation (**45**) can be formed by a 7,3-ring closure of **40** or by Wagner-Meerwein rearrangement of **44** and is the precursor for bornene and

tricyclene. Its rearrangement to the camphyl cation (**46**) yields camphene or tricyclene by deprotonation. α-Fenchene can arise from **45** by sequential 1,2-methyl migration to **47**, 1,2-hydride shift to **48**, and deprotonation. All reactions are shown starting from the (*S*)-enantiomer of **40** but are also possible from its optical antipode (*R*)-**40** to yield the respective enantiomeric terpene hydrocarbons. Only terpinolene, α-, and γ-terpinene are achiral and may arise from either of the two enantiomers of **40**.

In the last step of terpene biosynthesis, the carbocationic intermediates are in most cases deprotonated to form a terpene hydrocarbon. Alternative termination mechanisms include the attack of nucleophiles to yield a neutral product. The attack of water results in terpenoid alcohols as is exemplified by the reaction of **40** to α-terpineol (Scheme 87.17). Its subsequent reprotonation to a tertiary cation and intramolecular attack of the hydroxy group facilitates the formation of the achiral

monoterpene 1,8-cineol that is the main product of the cineol synthase from *Salvia fruticosa* [189]. Reattachment of the initially abstracted diphosphate moiety to **45** is a known termination mechanism of the bornyl diphosphate synthase from *Salvia officinalis* [207].

Cyclization modes are even more diverse for the sesquiterpenes than for the discussed hemi- and monoterpenes (Scheme 87.18). *Transoid* sesquiterpene synthases catalyze the ionization of FPP to the farnesyl cation that can cyclize by attack of the C10–C11 double bond. A 1,10-ring closure affords the tertiary (*E*,*E*)-germacradienyl cation in a Markovnikov fashion. Alternatively, the less stable secondary (*E*,*E*)-humulyl cation can be furnished via an *anti*-Markovnikov 1,11-ring closure that is, in contrast to the 1,7-cyclization of the linalyl cation, a well-known reaction. *Cisoid* synthases encourage the reattack of the diphosphate at C3 of the farnesyl cation to give (*R*)- or (*S*)-nerolidyl diphosphate (NPP). As in LPP this allows for rotation of the newly formed vinyl group into a *cisoid* conformation.

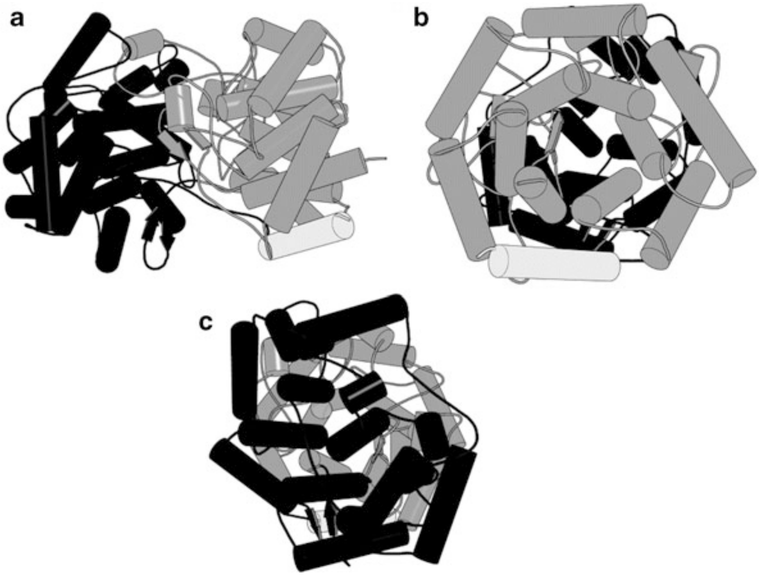

Fig. 87.15 Squalene/hopene cyclase from *A. acidocaldarius* (3SQC). (**a**) βγ-Modular structure, (**b**) top view on the β-domain showing its highly ordered α_6-α_6 barrel structure, and (**c**) top view on the irregular barrel structure of the γ-domain

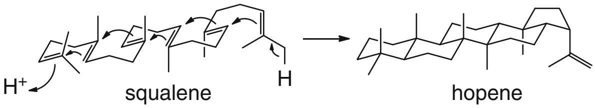
Subsequent ionization yields the nerolidyl cation that can undergo a 1,6-ring closure to the bisabolyl cation or a 1,10-cyclization to the (*E*,*Z*)-germacradienyl cation, both in a Markovnikov fashion. *Anti*-Markovnikov additions may construct the cycloheptenyl cation via 1,7-cyclization or the (*E*,*Z*)-humulyl cation in a 1,11-ring closure. The 1,11-cyclizations do not generate a chiral center, whereas in all other processes, either of two enantiomeric cations may be formed. Similar as described for the monoterpene cyclases, but with much higher structural variability of the preceding steps, these primary cyclizations can be followed by further ring closures, Wagner-Meerwein rearrangements, and hydride migrations. The last cationic intermediate finally collapses to the neutral terpene product by deprotonation or attack of a nucleophile.

5.2 Type II Terpene Cyclases

Class II terpene cyclases are known for the cyclization of di-, sester-, and triterpenoids. Prominent examples of triterpene cyclases are the human lanosterol synthase (oxidosqualene cyclase, OSC) and the squalene/hopene cyclase (SHC) from *A. acidocaldarius* [1]. Both enzymes have a βγ-domain architecture (Fig. 87.15a). The β-domain exhibits a highly regular α_6-α_6 barrel structure with six inner and six outer helices surrounding a central cavity (Fig. 87.15b) [198, 199, 208]. The γ-domains may have originated from the β-domains by gene duplication



Scheme 87.19 Reaction of the squalene/hopene cyclase

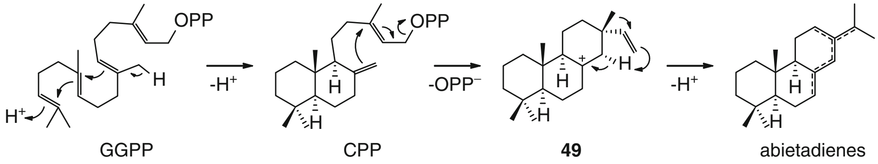
events as the γ-domain fold is similar to a β-domain structure, albeit less regular (Fig. 87.15c) [209]. This ancestral βγ-type of class II terpene cyclases shows multiple characteristic QW motifs with a consensus sequence of (K,R)(G,A)X_{2-3}(F,Y,W)(L,I,V)X_3QX_{2-5}GXW [210, 211]. The glutamine (Q) and tryptophane (W) residues within these motifs facilitate a stacked conformation at the intersection between two α-helices [212] and are implicated to stabilize the overall protein fold against thermal denaturation which is necessary because of the highly exergonic cyclization reactions (~200 kJ/mol) [199, 208]. Site-directed exchange of the tryptophane residues confirmed the stabilizing role for three of the eight QW motifs present in SHC [213].

Monofunctional type II diterpene synthases from plants such as the *ent*-copalyl diphosphate synthase from *A. thaliana* exhibit an αβγ-modular structure [201]. In this type of enzymes, the β-domain contains the conserved DXDD motif, but no DDXXD motif is present within the α-domain which coincides with the lack of type I activity.

The cyclization mechanism of type II terpene cyclases is exemplified by the reaction of the SHC (Scheme 87.19). Important insights into the reaction mechanisms have been obtained from structural data [199, 208]. One of the inner helices of the β-domain of SHC contains a conserved DxD(D,E) motif that is located in the central cavity at the interface between the β- and γ-domains. Its central aspartate residue D376 is polarized via hydrogen bonding to an adjacent histidine residue and protonates the double bond of the squalene substrate to initiate the reaction cascade. Conserved aromatic residues stabilize the intermediate cations by cation-π-interactions. A water molecule is a candidate to act as catalytic base, and this water may also account for the formation of the by-product hopanol. Another bridging water molecule connects D376 to a tyrosine residue and can restore the active site after catalysis by reprotonation of D376.

5.3 Bifunctional Type I and Type II Terpene Cyclases

The bifunctional terpene cyclases with type I and type II activity are restricted to fungal and plant diterpene cyclases. These enzymes like the monofunctional type I or type II plant enzymes exhibit the αβγ-domain architecture, but in contrast to the monofunctional terpene cyclases, both the α-domain and the β-domain contain the highly conserved DDXXD and DXDD motifs, respectively, thus establishing the catalytic activities for type I and type II cyclizations within one enzyme. A model system is the recently structurally characterized abietadiene synthase from *A. grandis* [202] that catalyzes first the class II conversion of



Scheme 87.20 Reaction of the abietadiene synthase

GGPP to copalyl diphosphate (CPP), followed by its transformation into abietadiene via **49** in a class I reaction (Scheme 87.20). Notably, the bifunctional plant terpene synthases are generally involved in the biosynthesis of a large superfamily of terpenes, the labdane-related diterpenoids [214].

6 Conclusions

As presented in this chapter, today, much is known about the process of terpene biosynthesis. The accumulated knowledge includes a detailed picture about the biosynthesis of the terpenoid monomers IPP and DMAPP either via the mevalonate or the DXP route and their interconversion by isomerases. Also, the stereochemical courses and enzyme mechanisms of all transformations have been largely elucidated. Especially the recently obtained structural data of prenyltransferases and various kinds of terpene synthases resulted in an evolutionary model that involves six domains (α, β, γ, δ, ε, and ζ) for the biosynthesis of linear polyisoprenoids from IPP and DMAPP and their subsequent transformation into (poly)cyclic terpenes. All these insights may open up new chances in controlling terpene biosynthesis, e.g., by directed evolution of terpene cyclases or domain swaps in multi-domain enzymes for the production of new terpenes, reconstitution of terpene biosynthetic pathways in heterologous hosts for production optimization, or targeted inhibition of pathways in pathogens for disease control.

Abstract

Terpenoids, the largest family of natural products with more than 40,000 structures, refer to a large class of oxygen-containing terpene analogues that can be found in all classes of living things. Similar to terpenes, they are all derived from five-carbon isoprene units assembled and modified in different ways. Steroids, derived from terpenoid building block isopentenyl pyrophosphate, are a subclass of terpenoids that contain a characteristic arrangement of four cycloalkane rings joined to each other. The terpenoids in plant are widely recognized, conceptually and/or empirically, for their aromatic qualities

and important roles in traditional herbal remedies, also in biomaterials and biofuels. The steroid hormones in animals are often drugs that not only increase protein synthesis in vivo but also control androgenic and virilizing properties. In this chapter, we will describe their properties and classes and functions, biosynthesis and biotransformation and degradation, as well as corresponding enzymes and genes.

Keywords

Terpenoid • terpenoid biosynthesis • terpenoidogenesis • steroid • steroidogenesis • steroid biotransformation and degradation

Abbreviations

CYP11A	Cytochrome P450, family 11, subfamily A
DHEA	Dehydroepiandrosterone
DMAPP	Dimethylallyl pyrophosphate
DOXP	1-Deoxy-D-xylulose 5-phosphate
EDCs	Endocrine-disrupting compounds
FPP	Farnesyl diphosphate
GGPP	Geranylgeranlyl diphosphate
GPP	Geranyl diphosphate
HMBDP	1-Hydroxy-2-methyl-2-(E)-butenyl 4-diphosphate
IPP	Isopentenyl pyrophosphate
MAD	Mevalonate-dependent
MEP	2-C-Methyl-D-erythritol-4-phosphate
MVA	Mevalonate
OCs	Oral contraceptives
RI	Refractive index
SREBP	Sterol regulatory element-binding proteins 1 and 2

1 Introduction

Over 40,000 different identified structures of terpenoids, or isoprenoids, constitute the largest family of natural products [1]. Terpeneoids can be widely found in plants, which are responsible for the scents, flavors, and even colors in many plants [2]. Well-known terpenoids include camphor, menthol, citral, cannabinoids, and so on.

Chemically speaking, terpenoids refer to oxygen-containing terpene analogues. Similar to terpenes, they are derived biosynthetically from isoprene units, $(C_5H_8)_n$. For the terpenoid building block synthesis, there are two biosynthetic pathways, the mevalonate pathway and the non-mevalonate pathway (the MEP/DOXP pathway). The non-mevalonate in the plastids gives rise to the formation of essential oil monoterpenes and linalyl acetate, some sesquiterpenes, diterpenes, and carotenoids and phytol. The mevalonate pathway in the cytosol is responsible for the formation of diverse terpenes, including triterpenes (steroids) and most sesquiterpenes. The biosynthesis of paclitaxel is one of the most important terpenoid synthetical pathways.

Steroids are a class of organic compounds that contain a characteristic arrangement of four cycloalkane rings joined to each other. All steroids are synthesized inside cells either from the sterols lanosterol (in animals and microorganisms) or from cycloartenol (in plants). Both lanosterol and cycloartenol are derived from the cyclization of the triterpene squalene (six isoprene units, 30C) [3–5]. In other words, squalene is the biochemical precursor to the whole family of steroids. Among all of the steroid biosynthesis, steroid hormone biosynthesis is the most concerned.

Hundreds of distinct steroids have been found in plants, animals, and microorganisms, respectively, for example, phytosterols and brassinosteroids in plant, ecdysteroids in insect, cholesterol, sex steroids, corticosteroids and anabolic steroids in vertebrate, and ergosterols in microorganism. Up to now, more than 40 steroid drugs have been marketed since the research and development to steroid drugs was triggered in 1950s [6, 7].

2 Properties, Classes and Functions of Terpenoids

Terpenes are hydrocarbon compounds through the condensation of several isoprene units. Terpenoids, in fact, are modified terpenes, wherein some methyl groups have been removed or replaced, often oxygen atoms added. Most of them are multicyclic structures which differ from one another not only in their basic carbon skeletons but also in functional groups. The structural unit of terpenoid building blocks is isopentenyl pyrophosphate (IPP).

Most terpenoids are optically active and have a bigger refractive index (RI) because of asymmetric carbon atoms in their molecules. Terpenoids commonly are hydrophobic, but their solubility can be improved through the addition of polar groups.

According to the number of isoprene units involved, terpenoids can be classified into [8] (1) hemiterpenoids, one isoprene unit (five carbon atoms) (Fig. 88.1a); (2) monoterpenoids, two isoprene units (10C) (Fig. 88.1b); (3) sesquiterpenoids, three isoprene units (15C) (Fig. 88.1c); (4) diterpenoids, four isoprene units (20C) (Fig. 88.1d); (5) sesterterpenoids, five isoprene units (25C) (Fig. 88.1e); (6) triterpenoids, six isoprene units (30C) (Fig. 88.1f); (7) tetraterpenoids, eight isoprene units (40C) (Fig. 88.1g); and (8) other terpenoids (5nC), isoprene unit condensation compounds (Fig. 88.1h).

Monoterpenoids (derived from geranyl diphosphate, GPP) are a subgroup of terpenoids consisting of two isoprene units (10C). Monoterpenoids may be acyclic or contain rings in their structures. Monoterpenoids usually exist as an oily liquid with distinctive aromas and flavors, such as essential oils, turpentine, and oleoresins of coniferous plants. Important examples of this class include menthol used as topical pain reliever, borneol as disinfectant or deodorant, and camphor as counterirritant, anesthetic, expectorant, antipruritic, etc.

Zeatin / $C_{10}H_{13}N_5O$

Fig. 88.1 The chemical structure of representative terpenoids

Sesquiterpenoids (derived from farnesyl diphosphate, FPP) are a subclass of terpenoids consisting of three isoprene units (15C). Sesquiterpenes are often found in an oily liquid in plants, fungi, marine organisms, and *Streptomyces* species. Sesquiterpenoids usually have antiallergen and anti-inflammatory and allow plants to cope with various types of environmental stress. Artemisinin, isolated from traditional Chinese herb *Artemisia annua*, is the most known sesquiterpenoid for its strong antimalarial activity.

Diterpenoids refer to those compounds having a two consecutive terpenoid structure (20C), usually in crystal state. They can be classified into two subgroups: acyclic and cyclic diterpenoids, for example, phytol (a naturally linear diterpenoid used in preparation of vitamin E and K1) and vitamin A (monocyclo-diterpenoid rich in fish oil). The most important diterpenoids in terms of bioactivities are dicyclo- and tricycle-diterpenoids, such as paclitaxel (Taxol) (details please see in Sect. 4.3 of this chapter below) and its analog docetaxel (Taxotere) for various cancer treatment, and ginkgolides against the aggregation of platelet.

Sesterterpenoids refers to those terpenoids having 25C skeleton compounds. Up to now, only about 40 species are isolated and indentified from several species of plants, marine organisms, and insects. Phytotoxin ophiobolin A, a natural product inhibitor of calmodulin, is an example of sesterterpenoids.

Triterpenoids are essentially derived from the coupling of two sesquiterpene precursors (30C) and known as cancer chemopreventive, antiulcer, and antidiabetic agents; inhibitors of angiogenesis and eukaryotic DNA polymerase, and so on. For example, bruceantin is used as an antineoplastic agent.

Tetraterpenoids contain 40 carbon atoms, derived essentially from the coupling of two diterpene precursors. Tetraterpenoids easily dissolve in nonpolar organic solvents. Often, they are called as tetraterpenoid pigments because of their conjugated polyene chromophores. The well-known tetraterpenoids are carotenoids (α-, β-, γ-carotene) that are naturally occurring in the chloroplasts and chromoplasts of plants as well as some other photosynthetic organisms like algae and some types of bacteria and fungi. Usually, animals cannot manufacture carotenoids, but can obtain carotenoids through their diets and employ them in various ways in metabolism.

Ubiquinones (UQ), often called coenzyme Q_{10}, are electron carriers in oxidative phosphorylation and photosynthesis, respectively. Ubiquinones consist of quinoid nucleus (derived from the shikimate pathway), 4-hydroxybenzoate (derived from chorismate or tyrosine), and terpenoid moiety. Zeatin, a phytohormone, is a member of the cytokinin family involved in various processes of growth and development in plants. Most cytokinins are adenine-type, where the hydrogen of amino group at C_6 position of adenine is replaced with an isoprenoid.

Note that meroterpenes refer to any organic compounds that have a partial terpenoid structure, such as neoaustin and preaustinoid A produced by *Penicillium* sp.

3 Properties, Classes and Functions of Steroids

Structurally speaking, steroids (note that gonane or steroid nucleus is the simplest steroid without any alkyl side chains) are terpenoid lipids characterized by a distinct carbon skeleton with four basal rings (A, B, C, and D), commonly arranged in

Fig. 88.2 The chemical structure of representative steroids (*red colors* indicating the distinctive sites)

a 6-6-6-5 fashion, a methyl group(s) at the carbons C_{10} and C_{13}, and an alkyl side chain at carbon C_{17} (Fig. 88.2a). Further, they are individualized by changing the number of carbon atom, the configuration of the side chain and the functional groups attached to the rings.

Although many conventional names (e.g., cholesterol, cortisol, testosterone, etc.) are used in steroid molecules, the use of systematic names (based on IUPAC rules) is recommended. According to the nomenclature, a complete description of a steroid molecule should include the name of their parent compound (e.g., pregnane-21C, androstane-19C, or estrane-18C series) and the name, number, position, and orientation (α or β) of all functional groups.

According to their chemical structure and origin, the wide array of steroids may be classified into the following groups: (1) sterols (Fig. 88.2b), (2) brassinosteroids (Fig. 88.2c), (3) bufadienolides (Fig. 88.2d), (4) cardenolides (Fig. 88.2e), (5) cucurbitacins (Fig. 88.2f), (6) ecdysteroids (Fig. 88.2g), (7) sapogenins (Fig. 88.2h), (8) steroid alkaloids (Fig. 88.2i), (9) withasteroids (Fig. 88.2j), and (10) bile acids (Fig. 88.2k) [9].

Steroids are derived from the same squalene precursor and have an oxygen-dependent biosynthetic pathway beginning with the formation of the first intermediate, 2,3-oxidosqualene (for details, see Sect. 5.1). Sterols, also known as steroid alcohols, are a subclass of steroids and may be found either as free sterols, acylated, alkylated, sulfated, or linked to a glycoside moiety which can be itself acylated. Sterol biosynthesis is nearly ubiquitous among eukaryotes but almost completely absent in prokaryotes. As a result, the presence of diverse steranes (saturated four-cycle skeleton) in ancient rocks has been considered as evidence for over 2.7 billion years of eukaryotic evolution. Cholesterol is the most well-known sterol found in animal cell membranes (for establishing proper membrane permeability and fluidity) and red blood cells.

Brassinosteroids (derivatives of cholestane) are a subgroup of steroids with two vicinal diols (C_2, C_3 and C_{22}, C_{23}) and a six-keto group. Many of them may be considered as sterols. They are plant growth regulators with structural similarity to animal steroid hormones. Up to now, the highest biological activity of the known brassinosteroids is still brassinolide (a plant hormone promoting stem elongation and cell division) that was first isolated from *Brassica napus* pollen [10].

Bufadienolides are polyhydroxy 24C steroids with a pentadienolide ring at C_{17}. More than 250 compounds have been isolated and identified from plants and animals mostly in glycosides. They are important for their cardiotonic activity, insecticidal, and antimicrobial properties. Hellebrigenin is a cardiac steroid first isolated from the European toad in 1955.

Cardenolide structure is closely related to bufadienolides, but these 23C steroids possess a butenolide ring located at C_{17}. As potent cardiotonics, they are widely distributed in plants mostly as glycosides. Digitoxigenin is a typical example of cardenolides. Besides, they are either toxins or insect deterrents.

Cucurbitacins are the most oxygenated 30C triterpenoids with a dimethyl group at C_4 and three methyl groups at C_9, C_{13}, and C_{14}, respectively. About 50 species have been isolated and identified mainly from *Cucurbitaceae* species commonly in glycosides. Some of them are the most bitter substances known. Unlike common steroids, they are not methylated at C-10. Cucurbitacin D, a typical example of cucurbitacins, is a potential new therapeutic drug for treatment of T-cell leukemia.

Ecdysteroids have a common 7-en-6-one chromophore, sometimes a methyl group at C_{24} and several hydroxyl groups increasing their polarity. About 400 ecdysteroids have been isolated and identified from animals (arthropods) and plants. The most common ecdysteroid in plants is ecdysone that was isolated as an insect-molting hormone in 1954.

Sapogenins are oxygenated 27C steroids with a hydroxyl group in C_3. They are widely distributed in plants (occurring in over 90 plant families). They are important in that they can mimic or regulate steroid hormones. Diosgenin (for details, see Sect. 5.4) is the most important sapogenin that has been widely used as precursor to produce diverse steroid drugs.

Steroid alkaloids are a large group of molecules in which a nitrogen atom is integrated into a ring or as a substituent. Steroid alkaloids are only distributed in *Solanaceae*. Solasodine, the most common species in *Solanum*, is a poisonous glycoalkaloid chemical compound; however, their toxic properties can disappear through structural transformation during ripening. Solasodine, as a precursor, can be used for the production of contraceptive pills.

Withasteroids are 28C ergostane-type steroids with a 22,26-lactone and have a number of oxygenated functional groups (hydroxyl, ketone, especially 1-oxo-group, etc.). Over 200 species are isolated and identified predominantly from *Solanaceae*, some of them as glycosides. Withanolides have important pharmacological properties, such as antitumor, immunosuppressive, antimicrobial, ecdysteroid receptor antagonist functions, etc. Withaferin A is the first member of the withanolides first isolated from winter cherry (*Withania somnifera*), which has significant anticancer activity.

Bile acids, synthesized in the liver in mammals, are 24C steroids with a carboxyl group at C_{24} and up to three hydroxyl groups on the steroid nucleus, one being at C_3. Bile acids are important since they are essential in dietary lipid absorption and cholesterol catabolism. The most abundant bile acids in human bile are chenodeoxycholic acid (45%) and cholic acid (31%).

According to the origin of them, steroids can also be divided into (1) animal steroids, (2) plant steroids, and (3) microbial steroids.

The well-known group, animal steroids/vertebrate hormonal steroids, can further be divided into three subgroups, based on their physiological function or their tissue origin: (1) sexual hormones (andostenedione, 17β-estradiol, progesterone, testosterone, etc.), (2) corticosteroids (cortisol, aldosterone, etc.), and (3) neurosteroids (pregnenolone, allopregnanolone, dehydroepiandrosterone/DHEA, etc.).

Steroids, considered as modified triterpenes, are hydrophobic, or lipophilic, readily dissolved by liposoluble solvents. However, the solubility of steroids can be improved through the addition of polar groups.

Note that in popular language, the term "steroids" commonly refers to anabolic steroids that interact with androgen receptors to increase muscle and bone synthesis.

4 Terpenoid Metabolic Pathway

Terpenoid metabolism includes terpenoid biosynthesis (from simpler precursor acetyl-CoA to IPP), terpenoidogenesis (the biosynthesis of terpenoids from IPP and the metabolic interconversion among diverse terpenoids), and terpenoid degradation (β-oxidation pathway).

4.1 IPP Biosynthesis

There are two biosynthetic pathways, (1) the mevalonate pathway and (2) the MEP/DOXP pathway, responsible for the production of the terpenoid building blocks: isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP), which serve as the basis for the biosynthesis of molecules used in processes as diverse as terpenoid/steroid/hormone synthesis, protein prenylation, protein anchoring, cell membrane maintenance, and N-glycosylation.

4.1.1 Mevalonate Pathway

The mevalonate (MVA) pathway or mevalonic acid pathway, sometimes called HMG-CoA reductase pathway or mevalonate-dependent (MAD) route or isoprenoid pathway, is an important cellular metabolic pathway occurring in the cytosol in all higher eukaryotes and many bacteria.

In this pathway (Fig. 88.3), acetyl-CoA (from TCA cycle) first undergoes condensation with another acetyl-CoA subunit via acetyl-CoA C-acetyltransferase to form acetoacetyl-CoA. Acetoacetyl-CoA then condenses with another acetyl-CoA to form 3-hydroxy-3-methylglutaryl-CoA, which is reduced to mevalonate by NADPH in the cytosol (the rate-limiting step in cholesterol synthesis and a target of statins). Successively, mevalonate is converted to 5-phosphomevalonate, 5-diphosphomevalonate by kinases, and finally to IPP by pyrophosphomevalonate decarboxylase [11].

Several key enzymes in this pathway can be activated through DNA transcriptional regulation of SREBP (sterol regulatory element-binding proteins 1 and 2) [12]. Also, the regulation of this pathway can be achieved by controlling the rate of translation of the mRNA, as well as the level of reductase and kinase (degradation of reductase and phosphorylation).

The mevalonate pathway in cytosol is responsible for the formation of diverse terpenes, also including triterpenes, sterols, and most sesquiterpenes. A number of drugs target the mevalonate pathway, for example, statins used to decrease cholesterol levels and bisphosphonates used to treat various bone-degenerative diseases.

4.1.2 MEP/DOXP Pathway

The MEP/DOXP pathway or non-mevalonate pathway of isoprenoid biosynthesis operating in the plastids is an alternative metabolic pathway that leads to the formation of IPP and its isomer dimethylallyl pyrophosphate (DMAPP) [13]. Unlike the classical mevalonate pathway that is present in higher animals and fungi, the non-mevalonate pathway is often found in plants (note that in green plants, the MEP/DOXP and mevalonate pathways coexist in separate cellular compartments), apicomplexan protozoa and most bacteria.

In this pathway (Fig. 88.4), D-glyceraldehyde-3-phosphate initially condenses with pyruvate to yield 1-deoxy-D-xylulose-5-phosphate (DOXP) through

Finally, 1-hydroxy-2-methyl-2-butenyl-4-diphosphate is converted by 4-hydroxy-3-methylbut-2-enyl diphosphate reductase into a 5–6:1 ratio of IPP and DMAPP, and further adjusted to 7:3 by isopentenyl diphosphate isomerase for polyisoprenoid biosynthesis.

Usually, the MEP/DOXP pathway in plastids is responsible for the production of essential oil monoterpenes and linalyl acetate, some sesquiterpenes, diterpenes, and carotenoids and phytol. A number of drugs target the mevalonate pathway, for example, fosmidomycin specifically inhibits DOXP reductoisomerase, a committed enzyme in the non-mevalonate pathway. In addition, the intermediate 1-hydroxy-2-methyl-2-(E)-butenyl 4-diphosphate (HMBDP) is the natural activator for human $V\gamma9/V\delta2$ T cells, the major $\gamma\delta$ T-cell population in peripheral blood.

4.2 IPP and Terpenoidogenesis

IPP is an important product in both the mevalonate pathway and the DEP/DOXP pathway and the core precursor inside living organisms for the biosynthesis of diverse terpenoids and other products (Fig. 88.5). IPP can be converted further into DMAPP by the enzyme isopentenyl pyrophosphate *delta*-isomerase, GPP by farnesyl diphosphate synthase, geranylgeranlyl diphosphate (GGPP) by geranylgeranlyl diphosphate synthase, and FPP by farnesyl diphosphate synthase. From them, living organisms can generate diverse terpenoids including monoterpenoids, sesquiterpenoids, diterpenoids, triterpenoids, carotenoids (C40), zeatins (C10), and other compounds.

For more details about the monoterpenoid, sesquiterpenoid, diterpenoid, triterpenoid, tetraterpenoid, and ubiquinone, zeatin, and other terpenoid-quinone biosynthesis, please log in at http://www.genome.jp/kegg/pathway/map/map00902.html, http://www.genome.jp/kegg/pathway/map/map00909.html, http://www.genome.jp/kegg/pathway/map/map00904.html, http://www.genome.jp/kegg/pathway/map/map00906.html, and http://www.genome.jp/kegg/pathway/map/map00900.html, respectively.

Almost all of terpenoids can be easily assimilated or digested by organisms via β-oxidation pathway similar to those found in fatty acid metabolism after ring cleavage of their structures, if any.

4.3 Paclitaxel Biosynthesis

Paclitaxel, commonly known as Taxol (the registered trademark), is a powerful diterpenoid anticancer drug with an annual market value of several billion dollars [15]. Taxol was first isolated and identified from the bark of Pacific yew, a slow-growing tree that is adapted to a forest shade environment in the Pacific Northwest of North America. Pathway of the biosynthesis of Taxol in *Taxus* has been primarily deciphered as in Fig. 88.6.

Fig. 88.5 IPP and terpenoidogenesis

The biosynthesis of Taxol starts with GGPP as precursor, followed by a series of 19 predicted pathway-specific enzymatic steps. Formation of the first pathway-specific intermediate taxa-4(5),11(12)-diene is catalyzed by a diterpene taxa-4(5),11(12)-diene synthase (EC 4.2.3.17). Then taxa-4(5),11(12)-diene is hydroxylated by several P450 enzymes and further functionalized by a group of acyl and aroyl transferases to yield a putative intermediate with seven alcohol or ester groups, followed by oxidation to introduce a ketone group and form the characteristic oxetane ring of baccatin III. Phenylalanine aminomutase, baccatin III C13-phenylpropanoyl CoA-transferase, and N-benzoyl transferase are involved in the following steps to form the aromatic side chain of Taxol.

5 Steroidal Metabolic Pathway

Despite their relative simplicity in chemical structure, steroid metabolism is important for the regulation of their cellular and physiological actions. Steroid metabolism involves in three main levels: (1) steroid biosynthesis (from simpler precursors to steroids lanosterol and cycloartenol), (2) steroidogenesis (the metabolic interconversion among diverse steroids), and (3) steroid degradation.

5.1 Lanosterol and Cycloartenol Biosynthesis

Lanosterol and cycloartenol are two tetracyclic triterpenoids found in animals and plants, respectively, from which all steroids are derived. Triterpenoid squalene is the first precursor in the biosynthesis of phytostanols and phytosterols in plants and

photosynthetic organisms. The identity and distribution of phytostanols and phytosterols is characteristic of a plant species. The biosynthesis of steroids lanosterol and cycloartenol is represented in Fig. 88.7.

In the biosynthesis of steroids lanosterol and cycloartenol, the building blocks DMAPP and IPP are first joined through farnesyl diphosphate synthase to form geranyl pyrophosphate (GPP) and then to form FPP, presqualene pyrophosphate, squalene, and (S)-squalene-2,3-epoxide by corresponding enzymes, sequentially. The product (S)-squalene-2,3-epoxide is used to synthesize the sterols lanosterol (in animals) and cycloartenol (in plants) by lanosterol synthase and cycloartenol synthase, respectively [3]. Further, lanosterol and cycloartenol are converted into other steroids through steroidogenesis.

5.2 Steroidogenesis

Steroidogenesis refers to the biological process by which steroids are generated from one steroid to another, often from cholesterol in animals. The pathways of steroidogenesis are often different in different species. The representative pathways of steroidogenesis in animals and plants are shown in Fig. 88.8.

For more details about the bile acid (sterol), brassinosteroid, and steroid hormone biosynthesis, please log in at http://www.genome.jp/kegg-bin/show_pathway?map00120, http://www.genome.jp/kegg-bin/show_pathway?map00905 and http://www.genome.jp/kegg/pathway/map/map00140.html, respectively.

5.3 Steroid Hormone Biosynthesis

Steroid hormones refer to are a class of biologically active compounds that are commonly derived from cholesterol in vertebrates. In this biosynthesis, the cholesterol side-chain cleavage enzyme cytochrome P450, family 11, subfamily A (CYP11A) catalyzes oxidation of cholesterol (27C) to form the first 21C steroid pregnenolone, which is then converted by a bifunctional enzyme complex 3*beta*-hydroxy-*delta*5-steroid dehydrogenase/steroid *delta*-isomerase [EC:1.1.1.145/5.3.3.1] to the gestagen hormone, progesterone. Pregnenolone and progesterone are the starting compounds for the three groups of steroid hormones: 21C steroids of glucocorticoids and mineralocorticoids, 19C steroids of androgens, and 18C steroids of estrogens.

As shown in Fig. 88.9, (1) progesterone can be converted by hydroxylations at C_{21} and C_{11} to corticosterone, which is further modified by hydroxylation and redox reaction at C_{18} to produce aldosterone (a mineralocorticoid). Cortisol, the main glucocorticoid, is produced from pregnenolone with 17*alpha*-hydroxypregnenolone, 17*alpha*-hydroxyprogesterone, and 11-deoxycortisol as intermediates. (2) Male hormone testosterone can be produced from 17*alpha*-hydroxypregnenolone with dehydroepiandrosterone and androstenedione as intermediates. (3) Female hormones estradiol can be produced from testosterone by oxidative removal of the C_{19} methyl group and subsequent aromatization of ring A.

5.4 Steroid Microbial Transformation and Degradation

Diosgenin is the primary precursor for the commercial production of cortisone, oral contraceptives (OCs), and many other steroid drugs. Unluckily, both natural and synthetic steroid drugs are powerful endocrine-disrupting compounds (EDCs) which can cause reproductive toxicity and affect cellular development in mammals and are generally regarded as a serious contributor to water pollution. Hence, research interests of many scientists focus on the biotransformation and degradation of steroid compounds.

5.4.1 Steroid Microbial Transformation

Many microbial transformations of steroids have been reported since 1950s, including steroid dehydrogenation/reduction, hydroxylation, esterification, halogenation, methoxylation, isomerization, and acylation at all carbon atoms of the steroid nucleus but C_{10} and C_{13} [6]. The microbial hydroxylation and dehydrogenation have become the most successful examples of large-scale industrial processes with such advantages as higher specificity, higher conversion rate, more moderate reaction conditions, and lower chemical pollution over the chemical synthesis in the production of steroid drugs (Fig. 88.10) [16, 17].

To further find new steroid microbial reactions for steroid drug production, *Streptomyces virginiae* IBL-14, a powerful degradation strain for steroid compounds including estrone, cholesterol, progesterone, isotestosterone, dihydrotestosterone, and hydrocortisone, was isolated by utilizing diosgenin as the sole carbon source [18]. Two new microbial transformations of diosgenin (6-methoxylation and 25-hydroxylation) were found. Also, nine new compounds, including isonuatigenone, 1-dehydroisonuatigenone, nuatigenone, 1-dehydronuatigenone, 26-acetyl-nuatigenone, 6-methoxy-6-dehydrodiosgenone, 6-methoxy-6-dehydroisonuatigenone, 6-methoxy-6-dehydronuatigenone, and 6-dimethoxy-7α-hydroxyldiosgenone were isolated and identified (Fig. 88.11).

5.4.2 Steroid Microbial Degradation

The degradation of steroidal compounds was first presented by Talalay in 1952 [19]. And the best-studied pathway is the metacleavage pathway from the A-ring of testosterone by *Comamonas testosteroni* TA441, a common bacterial degradation

"*ND*" not detected in TA441, "–" not sequenced or sequence incomplete

pathway for aromatic compounds (note that a ketone group at C_3 position and double bonds at Δ1 and Δ4 are indispensable for the aromatization of the A-ring) [20].

The proposed metacleavage pathway (Fig. 88.12) begins with aromatization of the A-ring, followed by a metacleavage accompanying with the production of 2-hydroxyhexa-2,4-dienoate and 9, 17-dioxo-1,2,3,4,10,19-hexanorandrostan-5-oate. The former is further converted to 4-hydroxy-2-oxohexanoate, which is then broken down to pyruvate and propanal. Further, all metabolites may be broken down via *beta*-oxidation pathway.

Note that the investigation of the details of the degradation pathway of C-, D-rings of 9,17-dioxo-1,2,3,4,10,19-hexanorandrostan-5-oate and other side chains of steroid compounds (E-, F-rings of diosgenin) are still in progress [18].

5.4.3 Steroid Degradation Enzymes and Genes in *Comamonas testosteroni*

Investigation of steroid degradation enzymes and genes in *C. testosteroni* started with the discovery of testosterone degradation by *C. testosteroni* in 1950s [19].

In the metacleavage pathway, the enzymes and genes involved in the A-ring degradation show significant homology to the corresponding genes in bacterial aromatic compound degradation. The enzymes for the degradation reactions are exclusively induced only when bacteria are incubated with steroid compounds [20, 21].

Genes of *C. testosteroni* for the degradation of steroidal backbone structure constitute two main steroid degradation gene clusters, one (named *tes*G-ORF18 in strain TA441) mainly involved in aromatization and cleavage of the A-ring and the other (named *ste*A to *tes*R in strain TA441) involved in β-oxidation of the B-, C-, and D-rings. Further study demonstrates that the two degradation gene clusters are on the same DNA strand several dozens of kilo bases apart, and the 3*alpha*-dehydrogenase gene and the adjacent 5,3*delta*-ketosteroid isomerase gene are located in the DNA region between these clusters (Table 88.1) [20].

6 Conclusions and Perspectives

Current knowledge about terpenoids is primarily based on research in specialized plant chemistry and biochemistry. Modern "omics" techniques are accelerating the discovery of genes and enzymes for biotransformation and regulation of terpenoids. The number of terpenoid-biosynthesis genes found in the plant species that their whole genome sequencing projects have been completed suggests a much wider range of structural diversity and distribution of terpenoids than previously expected. The results of comparative and functional genomics study have also provided new insights into the evolutionary events of repeated gene duplication and subsequent neo-functionalization, as well as the role of allelic variations in new terpenoid biosynthesis [15]. The goal to understand the biotransformation of terpenoids is mainly to fully capture their economic value via metabolic engineering of plant and microbial systems, especially exploring terpenoids as a renewable resource for the production of specialized chemicals and possibly biofuels, as well as for the improving flavor and color of foodstuffs.

Research on steroid chemical and biochemistry has resulted in the discovery of large numbers of steroid compounds; however, efforts are continuously being made for the further applications of steroid compounds, especially in the steroid drug development and their biotransformation and degradation. Genetic manipulation associated with synthetic biology can lead to produce constitutive biocatalysts with high activity and specificity, rather than inducible ones, further to create a large number of new steroid compounds. The exploration of the genetic reservoir of the total microbiota found in nature (metagenome), and the rational designs of enzymes, fermentation, and bioconversion media may lead to the implementation of robust, highly effective biotransformation processes. New biological techniques, particularly highly efficient solid-phase library approaches and high-throughput screening (HTS), associated with combinatorial chemistry, will allow faster and wider screening of new steroidal compounds, to ultimately generate libraries of therapeutically relevant compounds [6, 22].

Besides, the advancements in integrated biotechnology based on integrative strategy, rather than conventional reductionistic approach, will be expected to exert a greater impact on terpenoid and steroid development and utilization.

Abstract

Among the three main groups of secondary metabolites that can be found in plants, terpenes are by far the largest and most diverse. They play an important role in plants in both primary and secondary metabolism and constitute a source of phytochemicals for human health. Plant biotechnology, based on in vitro culture and genetic engineering techniques, has proved to be a promising tool to increase the production of these bioactive compounds. This chapter describes the plant cell and organ culture techniques used in plant biotechnology, the biotechnological production of the different groups of terpenes using empirical approaches and some examples of genetic and metabolic engineering techniques applied to improve the production of these valuable plant secondary metabolites in plant cell and organ cultures.

1 Introduction

Terpenes or isoprenoids are the largest and most diverse group of natural compounds. Although all living organisms are able to synthesize terpenes, it is in the plant kingdom where these compounds display the greatest diversity of chemical structures. Terpenes are derived from the five-carbon precursor isopentenyl diphosphate (IPP), produced via the classical mevalonate pathway, or in plants also by the novel MEP (non-mevalonate or Rohmer) pathway [1]. Plant terpenes play important roles in the organism, for example, phytols, the acyclic side chain of chlorophyll; carotenoids, also involved in photosynthetic process; and phytosterols with functions at the membrane level. Plant growth regulators such as gibberellins, abscisic acid, and brassinosteroids also have terpene structures. All these compounds have primary functions in plants and are widely distributed in the plant kingdom, but most terpenes have functions related with plant defense situations or are involved in the relation of the plant with other organisms. These terpenes have a wide distribution in plants and are considered to be secondary compounds [2].

Terpenes are made up of units of five carbons, C5, C10, C15, C20, C25, C30, C40, and so on (Fig. 89.1), and although generally free, they may be modified or derivatized as esters and glycosides or attached to proteins. Mono- and sesquiterpenes are derived from geranyl diphosphate and farnesyl diphosphate, respectively, and are widespread compounds in plants [3]. These lipophilic and volatile compounds normally accumulate in specialized plant structures called essential oil glands (Fig. 89.2). Mono- and sesquiterpenes include aliphatic acyclic, monocyclic, and polycyclic compounds with isolated double bonds, which are substituted with oxygen groups such as aldehydes, ketones or acids (Fig. 89.2), and abscisic acid, a growth regulator involved in plant stress signals. Diterpenes derived from geranylgeranyl OPP are usually components of plant resins. The most commonly encountered diterpenes are polycyclic and nonvolatile acids from conifers and legumes [2], but this group also includes the plant hormone gibberellins. The progenitor of C30 compounds is squalene arising from dimerization of two molecules of farnesyl OPP (Fig. 89.1). Triterpenes constitute a significant portion of the lipid substances of all plants and are precursors to steroids in both plants and animals. Steroids are components of membranes in plants, and brassinosteroids have hormonal functions. Both triterpenes and steroids occur free, as glycosides or in combined forms. Carotenoids derived from the C40 compound phytoene are probably the most widely distributed of all natural pigments, and they are involved in fundamental processes such as photosynthesis. Chemically, carotenoids are polyunsaturated lipid acyclics or have chains that terminate with one or two six-membered rings. These polyolefinic metabolites serve also as vegetative, floral, and fruit pigments (Fig. 89.2).

In all groups of terpenes, it is possible to find compounds with bioactive functions, and for this reason, they have been used since ancient times for their pharmacological properties. Terpenes also give plants their characteristic tastes and flavors and have been used as food additives or cosmeceuticals, and more recently, properties such as the antioxidant activity of carotenoids have given these

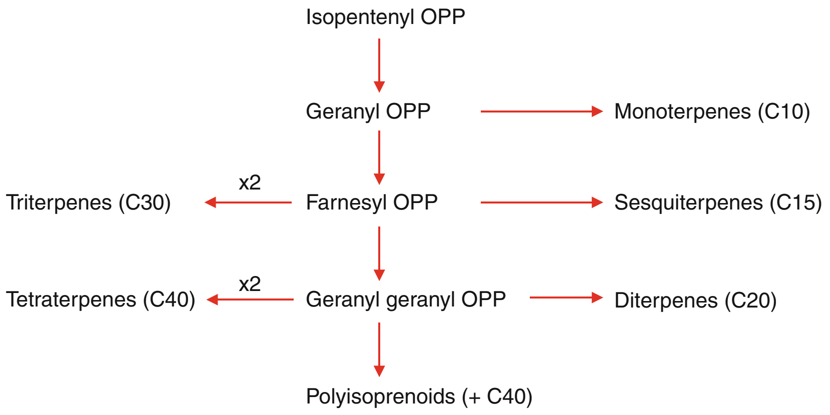

Fig. 89.1 Schematic classification of terpenes

compounds the role of nutraceuticals (Fig. 89.2). The biological activities of some important terpenes are discussed in more detail in other sections, but essential oil components have been used for their antibiotic, expectorant, rubefacient, and carminative properties. In particular, the sesquiterpene artemisinin is widely considered to be the best treatment for uncomplicated malaria when used as a combination therapy [1]. Resins rich in diterpenes are used as feedstocks for products such as insecticides, incense, varnishes, rosin, and adhesives, and as components of drugs and polishes. Triterpenes and steroids also have a wide variety of biological properties. For example, *Panax* saponins have been used as adaptogens and dietary supplements; *Centella* saponins are applied in the cosmetic industry; cardenolides function as cardiovascular drugs; and glycyrrhizin, a triterpenoid glucuronide, is used as a sweetener. However, the most important application of steroidal saponins, such as diosgenin, is as a source of human hormones. Carotenoids have often been used for coloring food products, and their antioxidant properties confer carotenoid-rich nutraceutical properties [4].

Many plants containing high-value terpenes are difficult to cultivate or are becoming endangered because of over-harvesting. Furthermore, the chemical synthesis of some of these compounds, such as the diterpene alkaloid Taxol or steroidal nucleus, is often economically unfeasible due to their highly complex structures and their specific stereochemical requirements [5]. The biotechnological production of high added value terpenes in plant cell or organ cultures is an attractive alternative to the extraction of whole plant material. However, the use of plant cell or organ cultures has had only limited commercial success so far. In this chapter, we describe the main biotechnological systems developed for producing plant secondary metabolism, giving some specific examples of the production of valuable terpenes in plant in vitro cultures. Finally, we discuss the use of a new biotechnological set of tools for improving terpene production in plant cell and organ cultures.

[a] Produced by chemical synthesis

In bold: terpenoid compounds

them plant secondary metabolites, which includes several terpenoid compounds. Although some of them can be synthesized chemically, most are extracted from the plant due to their highly complex structures [4].

This is the case of the diterpene alkaloid Taxol, an important compound for the pharmaceutical industry for its anticancer activity. This compound, like many others synthesized by plants, is found in very small quantities. Extracted from the inner bark of *Taxus* spp., it accumulates at a very low concentration (about 0.02% of dry weight) and its extraction cost is extremely high. Since it is necessary to take 10,000 kg of *Taxus* bark or 3,000 yew trees to produce only 1 kg of the drug, a cancer patient needs approximately 2.5–3 g of Taxol [6]. When the accumulation of the target compound in plants is so low and it is synthesized by an endangered species, it is necessary to look for alternative production techniques, such as processes of chemical synthesis or cultivation. In the case of Taxol, chemical synthesis is not cost-effective, and to produce it in conventional crops, it is necessary to wait many years before obtaining a harvest [7]. In such cases, biotechnological systems based on cell and organ cultures are recommended for the production of the target compounds (Fig. 89.3). In this context, shikonin, berberine, triterpene saponins of *Panax ginseng*, taxanes, and polysaccharides of *Polianthes tuberosa* are all produced commercially by biotechnological systems based on in vitro plant cultures [8].

Although biotechnological processes are expensive and these systems can only be used when the product has a high price in the market, if the specific process is more productive than the plant, it is easy to recover the product from the system, the production is stable, and alternative processes of chemical synthesis do not exist.

In general, not all plant cells are able to develop secondary biosynthetic pathways. These processes are related to cell differentiation and the development of specific tissues and organs [9]. Secondary metabolism depends on precursors

provided by primary metabolism, and the biosynthetic routes do not function throughout the life of the plant (Fig. 89.4). They depend on the plant's development and are restricted to certain moments of the plant ontogeny. However, all plant cells with a functional nucleus are totipotent, which means it is possible to control their gene expression and develop plant secondary metabolism even in undifferentiated cells by modifying external factors, such as plant growth regulators, nutritional requirements, light, temperature, etc. [10] (Fig. 89.4). This opens the way to the use of biotechnological systems based on undifferentiated plant cultures, such as calli and cell suspensions, for the production of plant secondary metabolites with biological activities. The most important biotechnological systems based on plant cell and organ cultures are cell suspensions or immobilized cells and the culture of roots and shoots.

2.1 Plant Cell Cultures

2.1.1 Obtaining Cell Cultures

A preliminary step in obtaining plant cell suspensions is to develop callus cultures. Calli are naturally formed from wounds by the infection of microorganisms due to stimulation by endogenous growth hormones, the auxins and cytokinins. It is possible to develop calli artificially by using tissue culture techniques. Auxins are added to the culture medium for callus induction, their type and quantity depending on the nature and source of the explant and its genotype, in addition to other factors. Callus cultures can be maintained for prolonged periods by repeated sub-culturing. The calli need to be friable, and the cell suspension is prepared by transferring a fragment of callus to the liquid medium where it is aseptically shaken to free the cells (Fig. 89.5). Fine cell suspensions are obtained by filtering through a filter of more than 100 μm pore size in order to eliminate the clusters and obtain the isolated cells. They are then cultured by batch or continuous cultures. As the medium is liquid in nature, the callus pieces remain submerged, which creates anaerobic conditions. To overcome this problem, the suspension cultures are shaken by a rotary shaker (100 rpm), which disperses the cells and exposes them to air (Fig. 89.5).

The advantages of cell suspensions over callus culture are the following: (a) they are less heterogeneous, and cell differentiation is less pronounced; (b) they can be cultured in volumes of more than 1,500 L; (c) they can be subjected to more stringent environmental controls; and (d) manipulations for the production of natural products by feeding precursors are possible [12].

Batch cultures are initiated as single cells in 100–250 mL flasks and are propagated by regularly transferring small aliquots of suspension to a fresh medium (Fig. 89.5). Finally, they are scaled up to bioreactor conditions for the production of phytochemicals. Continuous cultures are maintained in a steady state for a long period by draining out the used medium and adding fresh medium. Cell suspensions are also used for (a) induction of somatic embryos/shoots, (b) in vitro mutagenesis and mutant selection, and (c) genetic transformation.

The first compound to be produced commercially in a biotechnological system was shikonin by Mitsui Petrochemical Industries. Shikonin is a red dye used in cosmetics. Currently, several pharmaceutical companies around the world produce plant secondary terpenoids in biotechnological systems, one of the most

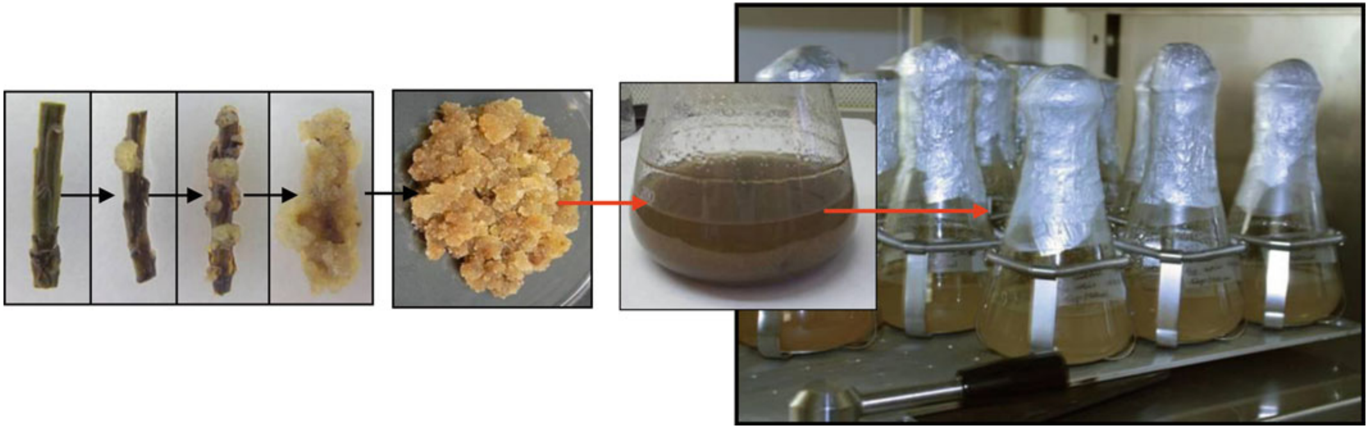

Fig. 89.5 Obtaining a cell suspension culture of *Taxus baccata* for the production of the diterpene alkaloid Taxol. Calli are induced from sterilized segments of the young branches of *T. baccata* trees. When developed from branch segments, callus pieces are isolated and cultured in solid MS (Murashige and Skoog medium). Friable calli are transferred to liquid medium and cultured in a shaker at 110 rpm in the dark at 25 °C. For details of experimental conditions, see the reference [11]

important being Phyton Biotech, which produces the diterpene alkaloid Taxol and other taxanes in *Taxus baccata* cell cultures, or Nitto Denko Co., which manufactures *Panax ginseng* cell mass as a source of triterpene saponins [13]. According to Ramachandra Rao and Ravishankar [10], plant cell cultures have the following advantages over crop plants in the field for producing phytochemicals:

(a) The desired product can be harvested anywhere in the world with strict control of production and quality.
(b) Harmful herbicides and pesticides are avoided.
(c) Climate or ecological problems are not factors.
(d) Growth cycles are of weeks rather than years as in the whole plant.

Nevertheless, not all plant secondary compounds with biological activity can be produced by biotechnological systems. As mentioned above, it is necessary that the production cost is lower than in the whole plant, the product has a high added value in the market (more than 500$ kg^{-1}), and the yield of the process should be over 1–2 mg L^{-1}day^{-1}. To achieve this kind of production, the biotechnological process normally requires optimization.

2.1.2 Optimization of the Production Conditions

Due to the low production of phytochemicals by plant cell cultures, it is frequently necessary to optimize the conditions for producing plant secondary compounds in order to perform a cost-effective bioprocess. The most important steps in production optimization are:

Selection of highly productive cell lines. In vitro techniques promote somaclonal variation, and after callus induction and disaggregation of the callus to obtain cell suspensions, not all the cell lines have the same capacity for the production of phytochemicals [12]. It is therefore necessary to select the most productive cell lines.

Optimization of the growth and production medium. In most cases, phytochemical production is not related with biomass formation, and some culture media and external conditions that promote the latter inhibit the biosynthesis of plant secondary compounds. For this reason, it is necessary to find the best conditions for biomass production as well as for the production of the target compounds.

Addition of biosynthetic precursors. In some biotechnological processes, when the biosynthetic pathway of the bioactive compounds is known, it is possible to add precursors to the culture medium in order to increase the productivity of the system. However, for this, it is necessary that the precursors have a lower market price than the final product of the biosynthetic pathway.

Addition of elicitors. Elicitors are physical or chemical agents that activate secondary metabolism and increase the productivity of the bioprocess. Organic compounds such as methyl jasmonate and salicylic acid are currently used with this aim. Elicitors are used in most biotechnological processes.

Stimulating the release of the target compound to the culture medium. Cell cultures frequently accumulate the bioactive compounds inside the cells or in vacuoles, so it is necessary to harvest the biomass of the culture in order to extract

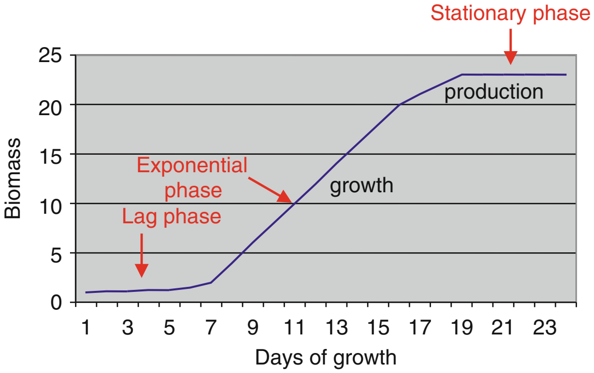

Fig. 89.6 Typical time course of biomass production in a plant cell suspension

the bioactive compounds. Extraction from dry plant matter is a difficult process due to its high quantity of waxes and pigments. Permeabilizing agents can release the phytochemicals caught in the cells to the culture medium, thus facilitating the downstream processing.

The capacity of a plant cell suspension to produce biomass during the culture period shows a sigmoid course with three different phases (Fig. 89.6).

In the first lag phase, the cells do not increase the biomass, while inside the cells, some biochemical processes begin to develop, such as DNA duplication, RNA and protein synthesis, etc. During this phase, cells are preparing all the machinery to initiate the processes of cell division that will start in the second exponential growth phase. During the phase of exponential growth, cells are dividing continuously by mitosis, involving DNA duplication and RNA and protein synthesis [14]. All these processes are included in primary metabolism and use up all the energy and reduced carbon from the cells. In these conditions, secondary metabolism leading to the biosynthesis of plant secondary compounds is inhibited. Finally, in the stationary phase, the biomass of the system remains constant, and the number of cells that divide by mitosis is almost equal to the number of dying cells. It is in these conditions that the cells can accumulate precursors for the biosynthesis of phytochemicals and the machinery of plant secondary metabolism is ready to work.

In most cases, primary and secondary metabolism are antagonistic because they share the same precursors (Fig. 89.7), and, as mentioned, to develop a highly productive bioprocess, it is first necessary to optimize the conditions for biomass production, and when enough biomass has developed, the culture has to be transferred to other conditions in order to boost the secondary metabolism of the cells and achieve the production of phytochemicals.

Based on these facts, the two-stage cultures have been established (Fig. 89.8). In the first stage, all the culture parameters, such as nutrients, PGRs, light, temperature, etc., have to be optimized to produce the maximum quantity of biomass, and then the culture is transferred to other conditions to improve the production of the

target compounds. This requires the optimization of nutritional and environmental conditions, but other factors also play an important role, including feeding with precursors and elicitor treatments. Among the biotic elicitors, the most used are jasmonates, for example, methyl jasmonate, which are plant compounds involved in the response mechanism of the plants to stress conditions. Other elicitors like salicylic acid, chitosan, or coronatine are also successfully applied. Physical factors can also be used, for example, UV treatment, high pH, osmotic stress, injuries like shear stress, or heavy metals are commonly applied to increase the production of biotechnological systems. Similarly, permeabilizing agents such as organic solvents and cyclodextrins, and physical agents such as ultrasounds or electrical treatment, not only provoke the release of the bioactive compounds to the culture medium, simplifying the extraction process, but can also increase phytochemical production.

2.1.3 Immobilization

Plant cells are very sensitive to shaking stress, and changing the growth medium for production medium is difficult to perform in cell suspensions [12]. In order to facilitate the changes of the culture medium and to protect cells from shear stress, cell immobilization protocols have been developed. Plant cells can be easily immobilized in by microencapsulation in sugar polymers or by adhesion to inert matrices [15]. The most utilized inner matrices are polyurethane foam or hollow glass fiber, and alginate has been commonly used as a gelling agent. Alginate (1–2%) forms beads in the presence of ion calcium (0.2–0.3 M), entrapping the plant cells inside (Fig. 89.9).

Compared to cell suspensions, immobilized cells have several advantages: the process can develop continuously, while the product is released from the cells and separated from the culture medium; the culture medium can be changed, allowing several compounds to be added and removed easily and quickly; the biomass can be rejuvenated in situ by perfusion of the growth medium to the cells at different time intervals; and relatively low amounts of biomass can be used efficiently [16, 17].

Shikonin	*Lithospermum*	Bactericide, dye
Thiophenes	*Bidens, Coreopsis, Tagetes*	Solvents

2.2 Organ Cultures

2.2.1 Hairy Root Cultures

Plant roots have a very active metabolism and can biosynthesize a high number of secondary compounds in an exclusive way (Table 89.2). Some of these compounds, including shikonin or triterpenoid saponins of *Panax ginseng* (ginsenosides), can also be biosynthesized in undifferentiated systems such as cell cultures, but in some cases, cell differentiation and organ formation is necessary for producing the bioactive compounds, which is the case of tropane alkaloids, bornyl esters, ajmalicine, and other compounds.

Thus, in the middle of the last century, plant biotechnologists began to work in root cultures. The problem with this type of culture was the low growth rate, and in some cases, adding IAA to improve growth caused a significant decrease in the production of bioactive compounds. Then several years ago, a plant syndrome was discovered: the hairy root syndrome. This condition is provoked by a pathogenic bacterium of plants, *Agrobacterium rhizogenes*, and is characterized by an abundant profusion of roots in the sites of bacterial infection.

A. rhizogenes, as well as *A. tumefaciens*, is able to transfer a section of its plasmid pRi to the plant genome, and the transformed cells begin a process of cell division and cell differentiation to form the so-called hairy roots (Fig. 89.10).

There are several reports indicating that the T-DNA (the DNA fragment from *Agrobacterium* transferred into the plant genome) of *A. rhizogenes* carrying the *rol* genes is responsible for root development. Among the *rol* genes, the most important are the *rol*A gene, which among other actions probably increases the sensitivity of the transformed cells to auxin; the *rol*B gene, which hydrolyzes the inactive conjugates of auxin (auxin + sugar); and *rol*C gene, which hydrolyzes the conjugates of cytokinins. However, most of the effects of these *rol* genes remain unknown [18].

When excised from the plant, hairy roots show a high capacity to grow in culture media without plant growth regulators (Fig. 89.11) and can biosynthesize the same plant secondary compounds as the root of the mother plant. Hairy roots are

currently used for the production of phytochemicals, including several terpenoid compounds whose biosynthesis requires a level of differentiation corresponding to the plant root [19].

The main stages for developing and optimizing a hairy root culture are (Fig. 89.11) (a) establishment of the hairy root culture (by infection of the explants with a virulent strain of *A. rhizogenes*), (b) selection and culture of highly productive root clones, (c) optimization of the production conditions (by improving external conditions, culture medium, elicitor and permeabilizing agent treatments, etc.), and (d) scaling up to bioreactors (by adaptation of the bioreactor to the growth of the roots).

Table 89.3 Plant secondary metabolites with biological activity synthesized in plant shoots

Compounds synthesized in shoots	Genus	Pharmacological activity
Vindoline	*Catharanthus*	Antileukemic
Artemisinin	*Artemisia*	Antimalarial
Camptothecin	*Ophiorrhiza, Camptotheca*	Anticancer activity
Atropine	*Atropa*	Anticholinergic
Vinblastine	*Cinchona*	Antileukemic
Quinine	*Cinchona*	Antimalarial
Withanolides	*Withania*	Antitumor, neuroprotective
Indirubin	*Polygonum*	Antileukemic

Compared to biotechnological systems based on undifferentiated cultures, the advantages of hairy root cultures are:

- Fast growth in culture media without PGRs
- Reproducible and predictable levels of the chemically unaltered product
- Genetic stability over long culture periods
- Large-scale cultivation without loss of biosynthetic capacity

2.2.2 Shoot Cultures

Since secondary metabolite production is generally higher in differentiated tissues, as well as root cultures, the cultivation of shoot cultures for the production of medicinally important compounds has been attempted [20]. Undifferentiated cultures often accumulate secondary metabolites to a lesser extent, or sometimes not at all. For example, a potent antimalarial compound, artemisinin, produced by *Artemisia annua* has not been observed to accumulate in undifferentiated cultures, while trace amounts have been detected in shoot cultures [21]. In addition, the development of adventitious shoots in liquid cultures has been shown to provide a highly proliferative and rapid growing system amenable to automated inoculation, mechanical separation, control of the medium components, and efficient delivery to the final stage for plant growth and development [13]. There are a number of medicinal plants whose shoot cultures have been studied for their secondary metabolites (Table 89.3).

2.3 Scaling up to Bioreactor Level

The last step of a bioprocess based on plant cells or organ cultures is the scale-up to bioreactor level. In these processes, it is possible to monitor and control several parameters, including:

Stirring: Normally up to 100 rpm.

Aeration: Measured by partial pressure of oxygen controlled at 50% of the dissolved oxygen.

Temperature: Normally 25 °C.

Foam: It is possible to add antifoam if necessary, but normally cell cultures do not produce high quantities of foam.

pH: Normally controlled to 5.8.

Table 89.4 Comparative study of the main differential traits of microbial and plant cell cultures (Modified from Chattopadhyay et al. [12])

Main traits of the culture	Microbial	Plant cells
Size	Small (2–10 μm)	Big (50–100 μm)
Single cells/clusters	Single cells and clusters	Clusters and single cells
Growth rate	Fast	Slow
Doubling time	Hours	Days
Sensitivity to shaking	Low	High
Product accumulation	Often extracellular	Often intracellular
Culture medium	Simple	Complex[a]
Inoculum density	Low	High (5–10% fresh weight)
Temperature	26–36 °C	25 °C
Aeration rate	High	Low
Foam	Frequently	Rarely
Culture period	Days	Weeks

[a] Including mineral salts, sugars, amino acids, and plant growth regulators

Table 89.4 shows the most important traits of plant cell cultures compared to microbial cultures, which require the reactor, initially designed for the culture of microorganisms, to be adapted to plant cell and organ cultures.

2.3.1 Adaptation of the Bioreactor Design to Plant Cell and Organ Cultures

Due to their different traits, the bioreactors initially designed for microbial cultures have to be adapted to plant cell cultures. As plant cells are very sensitive to shear stress, the first type of modification in the stirred tanks was to change the shape and disposition of the blades of the bioreactor. Big blades present in bioreactors for bacterial and yeast cultures are removed and replaced by a marine propeller, which is less harmful for plant cells. It is also possible to change the big blade at the bottom of the bioreactor for small blades lined up along the entire axis of the stirred system. Similarly, in the paddle system, the large lower blades of the classical bioreactors are replaced by a completely perforated central blade, which moves the culture medium by the peripheral side, or the helix system where the blades are replaced by an axis shaped like a corkscrew (Fig. 89.12).

In bubble columns, sterile air enters through the bottom of the bioreactor and pushes the culture medium and cells by preventing cell sedimentation and causing the diffusion of nutrients and oxygen in the culture medium. The problem is when the bioreactor tank is very big, in which case the air enters too quickly and forcefully in the tank of the bioreactor, and the air bubbles break cells by crashing into them. One modification of the bubble column is the airlift bioreactor (Fig. 89.12). In this case, inside the tank, there is another tube, the draft tube,

A: Bubble column. B and C: Airlift

Fig. 89.12 Adaptations of the bioreactor design to plant cell cultures. Unfortunately, despite the efforts to minimize shaking stress, it is not possible to eliminate it completely in all stirred tanks, which can be substituted by air-impelled bioreactors such as bubble columns and airlift

which creates an outer chamber where the air bubbles rise without crashing directly into the plant cells inside the draft tube.

A new bioreactor model, the wave-bioreactor, has been recently designed, in which the plant cells are introduced in a disposable plastic bag provided with all the probes (oxygen, pH, etc.) [22]. In this system, the disposable bag is placed over a rocker that moves the cells and the culture medium with wave-like motion, thus preventing the settling of the cells and creating a large turbulent surface for correct oxygen transfer (Fig. 89.13d).

Hairy root cultures are even more difficult to scale up than cell cultures because bioreactors are designed for the culture of microorganisms and not plant organs. Roots need two specific requirements: an anchoring system, since it is known that roots moving inside the bioreactor tank cannot grow, although the bioreactor can only begin to work when the roots are immobilized [23], and are protected from the blades of the stirred system. For both reasons, traditional stirred or airlift bioreactors are equipped with a stainless steel mesh that fixes the roots and protects them from the stirring (Fig. 89.13a, b). These problems have led to the design of new devices for optimizing the growth and production of hairy root cultures, such as the spay-bioreactor (Fig. 89.13c). Unlike other bioreactors, the roots in the spray-bioreactor do not grow immersed in the culture medium but are periodically sprayed with culture medium from the top of

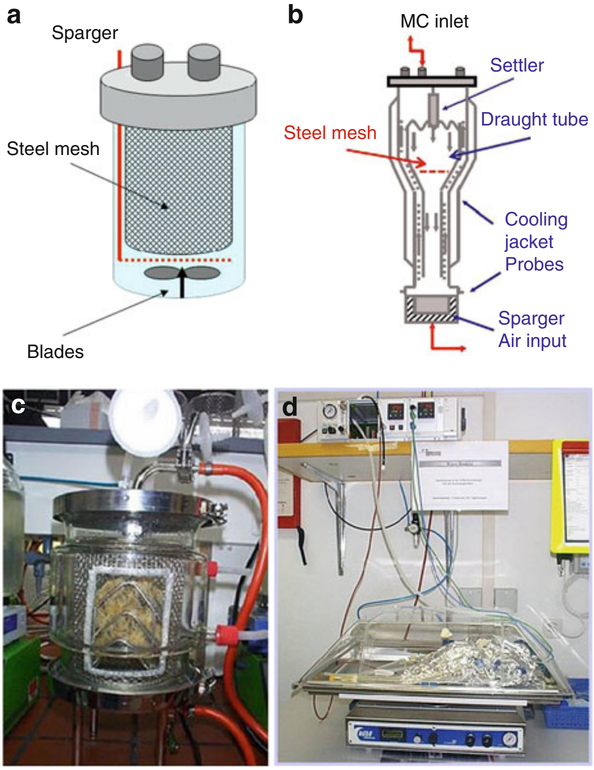

Fig. 89.13 Modifications of the bioreactor design for adaptation to hairy root cultures

the tank. It is as if the roots periodically receive a shower that keeps them moist and fed. The wave-bioreactor is also a good option for root cultures (Fig. 89.13d), and this system has been adopted by ROOTec bioactives Ltd., a company specialized in the production of phytochemicals in hairy root cultures. Also, CBN Biotech from Korea is currently producing and commercializing ginseng extracts from adventitious root cultures from *Panax ginseng* in bioreactors [24].

2.3.2 Industrial Production Systems

For the industrial production of phytochemicals, it is possible to use two kinds of procedures. When the target compound accumulates inside the cells, it is necessary to work in batch cultures (Fig. 89.14). After the growth and production period, the final biomass is harvested from the tank of the bioreactor and normally dried, and then the target compound is extracted from the cells or tissues. On the contrary, when the product is released from the plant cells, it is necessary to work in continuous cultures, in which after the production period, part of the culture

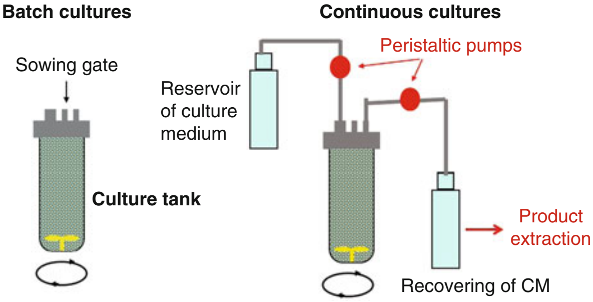

Fig. 89.14 Depictions of industrial process based on plant cell and organ cultures

medium is removed from the tank and replaced by fresh medium in order to rejuvenate the cell biomass (Fig. 89.14). In this system, the product is isolated from the culture medium by a simple procedure.

3 Biotechnological Production of Monoterpenes, Sesquiterpenes, Diterpenes, Triterpenes, and Tetraterpenes

3.1 Monoterpenes

Monoterpenes, the C_{10} class of isoprenoids, are an important class of commercially interesting terpenoids containing colorless lipophilic and volatile compounds. These are mostly found as constituents of essential oils and impart characteristic aromas or fragrances to flowers and flavors to fruits in many plant species. They are also used as herbicides, pesticides, antimicrobial agents, and dietary anticarcinogens. Due to various biological properties, monoterpenes have found extensive industrial applications and have been widely used as flavoring agents in foods and cosmetics, topical medicines, perfumes, and insecticides [25, 26].

Members of the genus *Mentha* are well known for their production of an economically important monoterpene, menthol, which is used as an essential oil throughout the world. Mints have been used and valued as aromatic herbs for thousands of years [27]. There are several examples of menthol production from cell cultures [28–31]. Chang et al. [30] optimized the concentration of chitosan to enhance menthol production in *Mentha piperita* cells and observed that 200 mg L^{-1} gave 166 mg menthol L^{-1} after 12 days of culture. They reported that elicitation with chitosan leads to conversion of pulegone to menthol. Kim et al. [29] studied the effect of a two-phase culture system on cell growth and essential oil formation in *M. piperita*. Their results indicated that the addition of solid second phases (XAD-4, XAD-7, LiChroprep RP-8) affected *M. piperita* cell growth depending on the type and concentrations employed. Cell growth rate was better in the medium containing RP-8 than XAD-4 or XAD-7. Additionally, RP-8 enhanced the peppermint oil formation by 32%. In control cultures (without RP-8), oil content was 89 μg L^{-1}, which was enhanced to 118 μg L^{-1} by a two-phase culture system using RP-8. It is speculated that RP-8 adsorbs the inhibitors of secondary metabolism promoting essential oil biosynthesis. Different strategies like precursor feeding, elicitation, and in situ product removal have been employed, and their synergistic effect has been studied to stimulate menthol production in *M. piperita* [31]. Menthol yield was found to increase by up to 92 and 110 mg L^{-1} in comparison with 77 mg L^{-1} of the control culture upon addition of 60 μM γ-cyclodextrin and 35 μM menthone. Treatment of cells with the fungal elicitor *Aspergillus niger* enhanced the production level up to 140.8 mg L^{-1} in comparison with the control. The synergistic effect of menthone feeding and γ-cyclodextrin treatment followed *by* in situ adsorption with RP-8 has shown a potential way of stimulating menthol production in *M. piperita* cell cultures. The maximum amount of 148 mg L^{-1} menthol has been reported as a result of synergistic effect of these treatments [31].

β-Thujaplicin (also known as hinokitiol), found mostly in trees of the Cupressaceae family, is a novel tropolone responsible for the durability of heartwood [32]. It has also been used clinically and as an ingredient in cosmetics and in toiletry products due to its broad antimicrobial, antifungal, and many other biological activities [33]. Plant cell culture is considered to be an alternative and reasonable approach for the commercial production of monoterpenes as well as tropolone compounds like β-thujaplicin [34–36]. For in vitro production of β-thujaplicin, callus and cell suspension cultures of *Cupressus lusitanica* have been studied and culture conditions were optimized [37, 38]. The concentration of major nutrients, mineral nutrient salts, Fe (II), and vitamins played a role in optimum cell growth and production of β-thujaplicin in cell suspension cultures of *C. lusitanica* [37]. It has been generally found that cell growth is inversely related to secondary product formation. The growth of *C. lusitanica* cells required a sufficient supply of nutrients, but Fe (II) had an inhibitory effect, while insufficient inorganic nutrients and excess Fe were effective for β-thujaplicin production. The type and concentration of the carbohydrate source has also been found to be responsible for monoterpene production. Among the different mono- and disaccharide carbon sources, glucose at a 20 g L^{-1} concentration was found to be the most effective form for β-thujaplicin production in cell suspension cultures of *C. lusitanica* [37]. Sugars are known as a source of carbon as well as acting as an osmotic pressure regulator. Glucose, sorbitol, and mannitol were studied for β-thujaplicin production in the same plant species. A mixture of sugar alcohols (i.e., glucose and sorbitol at 15 g L^{-1}) and small amounts of glucose (5 g L^{-1}) significantly increased the level of β-thujaplicin in the cell culture. Yamada et al. [39] tested the initial cell density for β-thujaplicin production in cell suspension cultures of the same plant species. They found that initial cell density of cultures did not affect β-thujaplicin levels, but the initial addition of β-thujaplicin suppressed its de novo production. They proved that β-thujaplicin synthesis was regulated by a feedback mechanism and that excess accumulation of β-thujaplicin is relieved by its conversion to its methyl ether. Treatment of *C. lusitanica* cells with chemical as well as fungal elicitors can improve the mass production of β-thujaplicin from callus and cell suspension cultures [38, 40]. It has been shown that elicitor treatment with yeast extract induces many novel kinds of terpenes in addition to a significant amount of β-thujaplicin [36].

3.2 Sesquiterpenes

Ambrosia maritima, a perennial herb belonging to the Compositae family, is a source of sesquiterpene lactones. It is used as a molluscicide for the treatment of sites infected with aquatic snails and intermediate hosts of tropical disease. Cell culture systems for these plants have been established for the in vitro production of sesquiterpene lactones [41]. It has been demonstrated that cultured plant cells are able to produce certain secondary metabolites in response to biotic or abiotic stress. Fungal (mycotoxins) and toxic algal extracts (phytoalexins) are the elicitors that act as a biotic stress causing a remarkable increase in active secondary metabolites. It has been reported that toxic algal crude extracts (phytoalexins) promote the production of sesquiterpene lactones (damsin and ambrosin) [41]. To study the effect of a fungal elicitor on sesquiterpene lactone accumulation in this plant species, cell suspension cultures were treated with different concentrations of *Aspergillus niger* [42]. The maximum yield of sesquiterpene lactones was recorded in a culture medium containing 60% fungal extract. HPLC analysis showed that the level of four major sesquiterpene lactones, that is, ambrosin, damsin, neoambrosin, and hymenin, was two times greater than their levels in control cultures. It was concluded from these results that a biotic elicitor with algal and fungal extracts may interact at the enzyme level or with isolated cell components or at the level of tissues, leading to deviations in the metabolic processes of intact plants, tissue culture, or cell suspension culture, versus the biosynthesis and accumulation of secondary metabolites [43].

In the Solanaceae family, bicyclic sesquiterpenoids (rishitin, capsidiol, lubimin, phytuberin, and phytuberol) have been isolated from different plant species including potato, pepper, and tobacco, and they are correlated with the defensive response of plants to invading pathogens [44]. Depending on the plant species, accumulation of the specific sesquiterpenoids occurs when the plant cells are treated with elicitors [45–48]. Chappell and Nable [49] observed an accumulation of large amounts of the sesquiterpenoid capsidiol in tobacco cell suspension cultures upon the addition of an elicitor prepared from fungal hyphae of *Phytophthora megasperma*. They showed the importance of induced HMGR activity, which was responsible for capsidiol production in elicitor-treated tobacco cell suspension cultures.

3.3 Diterpenes

Tanshinones (like tanshinone I, tanshinone IIA, IIB, cryptotanshinone, ferruginol), mainly found in roots and rhizomes of *Salvia miltiorrhiza*, are abietanoid diterpenes with common ortho- or para-naphthoquinone chromophore. They are major bioactive constituents of *S. miltiorrhiza* (Tanshen) with significant pharmacological activities. Tanshen is one of the important herbs used for the treatment of cardiovascular diseases. Other bioactivities include antioxidant, antitumor, and protective effects on the kidney and liver [50, 51]. According to Wang and Wu [52], in vitro cultures are good alternatives for the mass production of tanshinones and other bioactive compounds in *Salvia miltiorrhiza*.

Callus cultures using different explants have been established in *S. miltiorrhiza* by employing Murashige and Skoog medium supplemented with different combinations and concentrations of PGRs [52–54]. Hu et al. [55] studied the tanshinone contents in calli derived from different explants and found only trace amounts of tanshinones in leaf- and petiole-derived calli and a relatively high tanshinone content in calli induced from roots. Calli growth was observed to be faster in light than in the dark. Cell suspension cultures were initiated from calli, and six cell lines were obtained by subculturing the callus cells successively in a liquid MS medium [56]. Ferruginol production in cell suspension cultures was mainly found during the lag phase. Only one cell line was observed to produce cryptotanshinone as well as ferruginol. Medium composition such as the concentration of sucrose, nitrogen source, thiamine, and phosphate had a profound effect on the production of cryptotanshinone and ferruginol in the cell culture [57]. Different strategies like media optimization, elicitor stimulation, immobilization, nutrient feeding, and physical factors (light and dark conditions) have been employed to obtained an enhanced and stable production of tanshinones in *S. miltiorrhiza* in vitro cultures. A two-stage culture method, that is, normal medium for cell growth and then cell transfer to a medium without Fe-EDTA, has been established for a more efficient production of ferruginol from cell culture by Miyasaka et al. [58]. This media was also found to be suitable for cryptotanshinone production in cultured cells. Immobilization of cells from *S. miltiorrhiza* cell suspension cultures was reported to produce 39% and 61% of cryptotanshinone and ferruginol, respectively [59]. Abiotic and biotic elicitors have been applied to stimulate tanshinonene accumulation in *S. miltiorrhiza* cells [60]. Four classes of elicitors, viz., heavy metal ions (Co^{2+}, Ag^{+}·, Cd^{2+}), polysaccharides (yeast extract, chitosan), plant response signaling compounds (salicylic acid, methyl jasmonate), and hyperosmotic stress (sorbitol), were studied for their effects on tanshinone production in cell cultures [60]. Silver nitrate (25 μM), cadmium chloride (25 μM), and yeast extract (100 mg L^{-1}) were found to be the potent elicitors that stimulated the total tanshinone content by more than tenfold (2.3 mg g^{-1} vs. 0.2 mg g^{-1} in control) in *S. miltiorrhiza* cell cultures. Tanshinone biosynthesis in *S. miltiorrhiza* in vitro cultures has been reviewed recently by Wang and Wu [52].

Paclitaxel (Taxol, NSC-125973), obtained from *Taxus* species, is a diterpene with intense antitumoral activity because of its unique mode of action on the microtubular cell system. It is one of the most successful anticancer drugs developed in the past 50 years. Due to several difficulties associated with obtaining Taxol and related taxoids from plants growing in nature, plant cell cultures are considered to be the most favorable and environmentally sustainable approach for its production of at an industrial level. Some pharmaceutical companies, such as the consortium of Bristol-Myers Squibb with Phyton, have developed and commercialized plant cell culture processes for the production of Taxol. Currently, Phyton Biotech is the largest producer of paclitaxel via plant tissue culture, employing a large-scale fermentor with a capacity of up to 75,000 L. Another company, Korean Samyang Genex, uses *Taxus* plant cell cultures to produce paclitaxel with the brand name of Genexol® [6]. The most successful treatments to enhance the Taxol production in different species of *Taxus* involve supplementation of the culture medium with methyl jasmonate. To increase the production of paclitaxel and related taxanes in cell cultures, the effect of methyl jasmonate on free and immobilized cells of *T. baccata* growing in a selected product formation culture medium was investigated by Bonfill et al. [61]. The greatest amounts of paclitaxel (13.20 mg dm^{-3}) and baccatin III (4.62 mg dm^{-3}) were reported upon addition of methyl jasmonate (100 μM) to the culture medium of cells entrapped using a 1.5% and 2.5% alginate solution. Production of paclitaxel and baccatin III has been shown to be affected when *T. baccata* cell lines with different paclitaxel-producing capacities are mixed and cultured in a selected production medium, with and without methyl jasmonate [62]. Through mixing low-, medial-, and high-producing cell lines, paclitaxel productivity in the resulting mixed lines was found to be higher than the mean productivity of the individual lines before mixing, suggesting that the culture components generated by high-producing individual lines within the population might induce paclitaxel production. To study the relationship between the expression of genes from the Taxol biosynthetic pathway and the taxane profile, Onrubia et al. [63] studied the effect of two elicitors, methyl jasmonate and vanadyl sulfate, on the taxane pattern and transcript profile of two key genes (*txs* and *bapt*) involved in Taxol biosynthesis pathway in a selected *T. baccata* cell culture. Methyl jasmonate was found to increase the expression of both *txs* and *bapt* genes as well as significantly activate the production of both Taxol (4-fold) and baccatin III (3.6-fold). However, the presence of vanadyl sulfate in the medium only increased *bapt* gene expression and hence Taxol production (4-fold). These results suggest that analyzing elicitation conditions is a good strategy to improve Taxol production and that the elicitors have different mechanisms of action in Taxol biosynthesis.

3.4 Triterpenes

Triterpenes constitute a very important group of C_{30} terpenes arising from dimerization of two farnesyl pyrophosphate units that produce the intermediate compound, squalene. Among the triterpenes, there are compounds with a primary role in the plant metabolism such as the phytosterols which are involved in the cell membrane formation, whereas others are considered as typical secondary compounds. Some of these secondary compounds, which play a crucial role in the defense and adaptation system of the plant, also show important pharmacological properties and consequently are products of high interest for the chemical-pharmaceutical industry.

Standing out among the bioactive triterpene compounds are the ginsenosides, which are tetracyclic triterpenoid saponins derived from the dammarane skeleton. Ginsenosides are the principal pharmacologically active components of *Panax* spp. roots. The ginseng (*Panax ginseng* Meyer) root has been used for over 2,000 years as a panacea and to promote longevity. Recently, there has been a renewed interest in investigating ginseng pharmacology using biochemical and molecular biological techniques. Pharmacological effects of ginseng have been demonstrated in the CNS and in cardiovascular, endocrine, and immune systems. In addition, ginseng and its constituents have been ascribed antineoplastic, anti-stress, and antioxidant activity. Consequently, ginseng is an herb with many active components, and its beneficial effects are supported by evidence from numerous studies [64].

Ginsenosides are divided into three groups on the basis of their structure: the Rb group (protopanaxadiol including Rb_1, Rb_2, Rc and Rd, and others), Rg group (protopanaxatriols including Rg_1, Rg_2, Re, Rf, and others), and Ro group (oleanolic acid). So far, more than 32 ginsenosides have been identified. It has been shown that the ginsenosides of groups Rb and Rg have different pharmacological properties, some of them being antagonistic, so it is very important to know the exact composition of ginseng material to determine its medicinal activity [65].

Typical ginseng drugs are crude, not well-defined extracts from the roots of 6-year-old plants. The *Panax ginseng* plant is not only widely used as a dietary supplement, but the active ginsenosides are also found in different pharmaceutical forms. In the USA alone, the annual retail sale has reached US $120 million, and the global market is more than US $19.5 billion [66].

Since ginsenosides are accumulated in the root of the plant, mainly after 6 years of growth, their agricultural production is very expensive. Therefore, ginsenoside production by means of biotechnological alternatives has been extensively studied by a number of researchers, using different plant-derived systems such as callus tissues, cell suspensions, and transformed and adventitious root cultures.

The production of ginsenosides in callus cultures started at the beginning of the 1980s. Furuya et al. [67] reported that *Panax ginseng* calli produced considerable amounts of the same kinds of saponins as intact plants and the saponin content was significantly lower in habituated calli than in normal calli. An important European team that studied the ginsenoside production was the Björk group [68], who obtained 33.7 mg g^{-1} DW of total ginsenosides in callus cultures after optimizing the culture conditions. Bonfill et al. [65] achieved total ginsenoside levels of 50 mg g^{-1} DW in root-forming calli, showing that the proportion of Rb group and Rg group ginsenosides depends on the auxin added to the culture.

Panax cell cultures have also been used as a source of ginsenosides since the 1970s. Yasuda et al. [69] started with scaling-up cell cultures to volumes of 600 L. The Japanese company Nitto Denko Corp. established cell cultures at the 20,000–25,000 L bioreactor level, achieving a biomass production of 20 g DW L^{-1} in 4 weeks and also showing that the pharmacological effects of the active ingredients were the same or even higher than the effects caused by the same compounds extracted from the plant roots. Other companies involved in the ginsenoside production by means of cell suspensions are the All-Union Biotechnological Institute from Moscow and PhytoLife in Israel. The effect of the addition of precursors and/or elicitor supplementation on ginsenoside production and pattern in cell cultures has also been assayed. Yue and Zhong [70] have reported that the addition of phenobarbital (1 mM) to the culture medium enhanced the production of ginsenosides belonging to the Rg group but not those of the Rb group. In their studies, they achieved an Rg ginsenoside production of 5.7 mg day^{-1} L^{-1}. Other elicitors such as methyl jasmonate and salicylic acid have also been assayed with good results.

Hairy root cultures have proven to be a good system for ginsenoside production. Mallol et al. [71] obtained *P. ginseng* hairy root cultures producing higher levels of total ginsenosides (5.5 mg g^{-1} DW) than the plant roots (approx. 4.5 mg g^{-1} DW). The same author increased the total ginsenoside production when scaling up the culture from shake flasks to a 2 L wave bioreactor. In fed-batch conditions, the roots produced 2.6 mg ginsenosides L^{-1} day when maintained for 56 days in the bioreactor. Additionally, different reports confirm that ginseng adventitious roots constitute an excellent starting material for ginsenoside production without the problems associated with the presence of foreign genes in the plant genome. Sivakumar et al. [24] showed, after optimizing the culture conditions, that the culture of ginseng adventitious roots in a 10,000 L balloon bioreactor is a good alternative for the production of ginsenosides at an industrial level.

The withanolides are a group of naturally occurring C28-steroidal lactones bearing an ergostane skeleton which are found in species of *Withania*. *W. somnifera* is an important medicinal plant used in Ayurvedic medicine for over 3,000 years. Withanolides are compounds that have shown pharmacological properties such as anti-inflammatory, antitumor, anti-stress, antioxidant, immunomodulatory, hemopoietic, and cardio-protective activities. Recently, Mirjalili et al. [72] have shown that significant levels of withanolide A and withaferin A accumulate in *W. coagulans* transformed roots, suggesting that these roots have considerable capacity to produce withanolides in a scaled-up bioreactor system.

Traditional Mexican medicine has long used *Galphimia glauca* to treat central nervous system disorders. This plant produces nor-seco-galphimines as the main active compounds, which present different pharmacological properties. Osuna et al. [73] reported that free and immobilized cells of this species were able to produce galphimine-B (the most active galphimine compound, with sedative, anticonvulsive, and anxiolytic properties) when cultured on a small scale and in bioreactors. The advantages of immobilized cells include high cell concentration per unit volume of culture, better cell-cell contact, and more favorable conditions for cell differentiation, all promoting cell differentiation and consequently increasing the secondary metabolite production. These authors achieved a 1,381 mg L^{-1} galphimine-B production with immobilized cells growing for 24 days in a stirred bioreactor, with the advantage that all the product of interest, formed inside the cells, was excreted to the medium in its entirety, thus facilitating its recovery.

3.5 Tetraterpenes

Tetraterpenes or carotenoids consist of eight isoprene units derived from isopentenyl diphosphate. Carotenoids are found predominantly in nature as the orange, red, and yellow pigments synthesized by photosynthetic plants, bacteria, and fungi. Chemically divided into xanthophylls and carotenes, carotenoids can serve as precursors to phytohormones and aroma compounds in plants, and they have a multitude of roles in nature [74]. Tomatoes contain a mixture of carotenoids, including carotenoid lycopene, γ-carotene, phytoene, neurosporene, phytofluene, ζ-carotene, β-carotene, and lutein [75]. Campbell et al. [76] used a plant cell culture approach to biosynthesize and radiolabel phytoene and phytofluene for prostate cancer cell culture studies. To induce the biosynthesis and accumulation of the lycopene precursors, phytoene and phytofluene, the herbicide norflurazon was added to established cell suspension cultures of tomato (*Lycopersicon esculentum* cv. VFNT cherry). Norflurazon concentrations, solvent carrier type and concentration, and duration of culture exposure to norflurazon were studied to optimize phytoene and phytofluene synthesis. The maximum yields of both phytoene and phytofluene were observed after 7 days of treatment with 0.03 mg norflurazon/40 mL fresh medium, provided in a 0.07% solvent carrier. Introduction of 14C-sucrose to the tomato cell culture medium enabled the production of 14C-labeled phytoene for subsequent prostate tumor cell uptake studies. In an attempt to increase the carotenoid production in cell cultures of *L. esculentum*, two bleaching herbicides, 2-(4-chlorophenyl-thio)-triethylamine (CPTA) and norflurazon, separately or in combination, were administered during the culture incubation to produce varying ratios of carotenoid lycopene, phytoene, and phytofluene [77]. Norflurazon inhibits phytoene desaturase, leading to the accumulation of phytoene and phytofluene, while CPTA inhibits lycopene cyclase, leading to an increase in carotenoid lycopene accumulation. It has been found that treatment with both herbicides results in an optimal production of all three carotenoids. Screening and selection of high carotenoid-producing in vitro tomato cell culture lines for isotopically labeled [(13)C]-carotenoid production in tomato cell cultures were first achieved by [77]. Different *Solanum lycopersicum* allelic variants for high lycopene production and varying herbicide treatments were compared for carotenoid accumulation in calli as well as cell suspension cultures.

Tomato ripening involves many processes, such as flavor development, color formation, and softening. Regulation of ripening initiation and its progress has been attributed to the influence of many chemical substances. These substances include ethylene, auxins, cytokinins, calcium, copper, ammonia, abscisic acid, polyamines, and oligosaccharides [78]. Lycopene, the red pigment which is involved in ripening of tomato fruits is another example of tetraterpene. Cell suspension cultures of tomato have been used to observe the enhancement of lycopene in tomato cells using auxins (2-(4-chlorophenylthio)-triethylamine (CPTA) and picloram) to confirm the role of CPTA as an enhancer of protein synthesis [79] and as a stimulator of the disappearance of chloroplasts and the accumulation of chromoplasts [80]. Robertson et al. [78] reported the use of cell culture methods for the in vitro observation of in vivo lycopene formation. They reported the use of growth regulators, sucrose, and temperature to regulate lycopene accumulation and found that the native auxin indole-3-acetic acid (IAA) was substantially more effective than 2,4-dichlorophenoxyacetic acid (2,4-D) in promoting lycopene formation, sucrose-inhibited lycopene formation (cell basis), and an optimum temperature of 18–26 °C produced a pattern similar to that observed in the field. Chilling injury of tomato plants is a cellular phenomenon, so cell cultures are a useful model system to study this mechanism. To observe the effect of chilling temperature, tomato cell cultures were kept at temperatures below 10 °C [81]. It was shown that chilling temperatures quickly inhibited the growth of tomato cells but did not kill them.

4 Metabolic Engineering of Terpenes in Plant Cells and Roots

The biosynthetic production levels of many secondary compounds have been increased by the application of metabolic engineering techniques. The stable transfer and integration of genes involved in flux-limiting steps of a biosynthetic route could enhance the endogenous production of the resulting compounds. So it is necessary to understand the relevant biosynthetic pathway(s) and know which enzymes catalyze the sequence of reactions, particularly the slow steps, and which genes encode these enzymes.

Some applications of metabolic engineering to improve terpene production in plant cells and roots are presented here.

4.1 Artemisinin Production in Engineered Hairy Roots

Artemisia annua is an annual herb that produces the antimalarial drug artemisinin, a *sesquiterpene* lactone present mainly in the aerial parts.

As artemisinin has a terpenic structure, its biosynthesis starts in the formation of isopentenyl diphosphate (IPP), as in all the natural terpenoids. In plants, IPP is synthesized either via the mevalonate pathway in the cytosol or via the 2-C-methyl-D-erythritol 4-phosphate (MEP) pathway in the plastid. The IPP derived from the mevalonate pathway is generally used in the biosynthesis of sesquiterpenes (such as artemisinin), phytosterols, and triterpenes, and the IPP derived from the non-mevalonate pathway is employed in the biosynthesis of monoterpenes, diterpenes, and tetraterpenes (Fig. 89.15).

Farnesyl diphosphate (FPP) is the starting molecule for the committed step in sesquiterpene biosynthesis, so artemisinin is synthesized from FPP via the mevalonate pathway in the cytosol (Fig. 89.15). A rational approach has enhanced artemisinin yields by the overexpression of farnesyl diphosphate synthase

(FPS, EC2.5.1.1/EC2.5.1.10), the enzyme that catalyzes two consecutive condensations of isopentenyl diphosphate with dimethylallyl diphosphate to form FPP. The cDNA encoding FPS placed under a 35S CaMV promoter was transferred into *Artemisia annua* using *Agrobacterium rhizogenes* to obtain hairy roots with the *fps* transgene. This study has shown that engineered hairy roots can produce 2–3 mg g^{-1} DW artemisinin, a quantity three to four times greater than achieved in the controls [82].

4.2 Taxol and Taxane Production in Engineered Plant Cells

Taxol is a *diterpene* alkaloid with notable antineoplastic properties due to its unique mode of action on the microtubular cell system. The difficulty of obtaining Taxol from its natural source and costly synthetic processes place it among the compounds with highest added value. Taxol can also be produced semisynthetically from more abundant taxoids, but extracting the precursors is also difficult and expensive. Although Taxol is currently being produced in *Taxus* cell cultures on a bioreactor scale, the amount obtained is still insufficient to meet growing world demand. Metabolic engineering of *Taxus* with rate-influencing genes is a potentially successful approach to increasing Taxol production in cell cultures.

As Taxol has a diterpenic structure, its biosynthesis starts in the formation of isopentenyl diphosphate (IPP) via the 2-C-methyl-D-erythritol 4-phosphate (MEP)

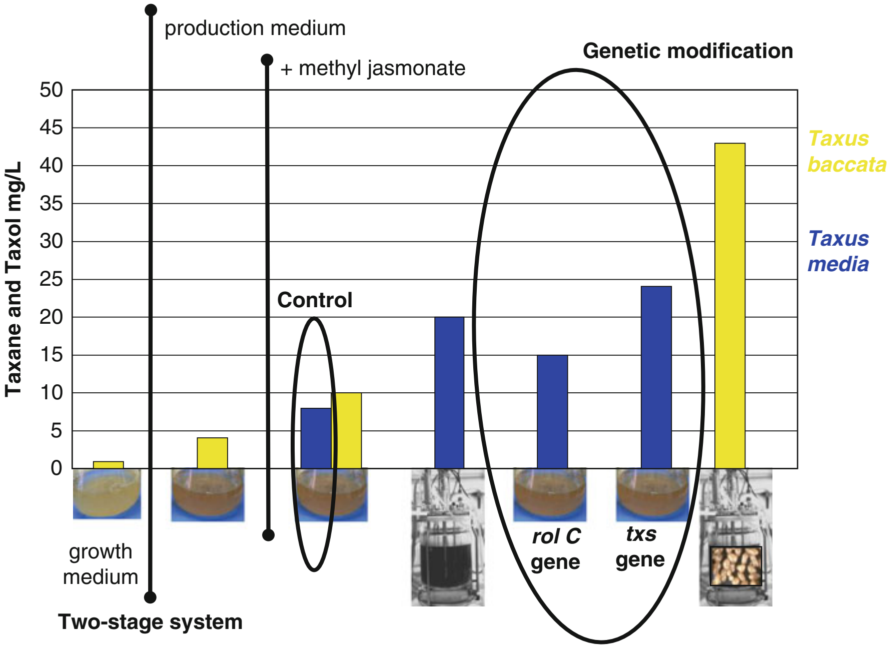

Fig. 89.16 Different approaches to taxane production

pathway in the plastid. Metabolic engineering techniques were applied to establish *Taxus media* transformed cultures harboring the taxadiene synthase (*txs*) gene, which is known to encode taxadiene synthase (TXS, EC 4.2.3.17), the enzyme that controls the first step in the taxane skeleton formation (Fig. 89.15). The stable transfer and integration of this gene could enhance the endogenous production of Taxol.

After direct inoculation of *T. media* seedlings with *Agrobacterium*, two transformed cell lines were studied: RolC, carrying the T-DNA of *A. rhizogenes* 9402 and TXS, carrying both the T-DNA of *A. rhizogenes* and the *txs* transgene of *T. baccata* under the control of the 35S CaMV promoter. The transformed cell lines were cultured in a production medium supplemented with the elicitor methyl jasmonate, and their production was compared with an untransformed *T. media* cell line cultured in the same conditions. The highest taxane production was observed in the TXS cell line when cultured in the optimized production medium with methyl jasmonate, being 265% greater than in the untransformed control and 170% greater than in the RolC cell line [83].

Figure 89.16 compares the different approaches to taxane production using untransformed *T. baccata* cells (yellow) and untransformed and transformed *T. media* cells (blue) under different conditions. An empirical approach to these cultures involved the use of a growth medium, a production medium, and a production medium supplemented with the elicitor methyl jasmonate.

The rational approach involved the genetically modified *T. media* lines (RolC and TXS). These transformed lines showed a higher taxane production than the non transformed line under the same culture conditions. The next step to further increase taxane production could be to culture immobilized cells of these transformed lines in a stirred bioreactor.

4.3 Withanolide Production in Engineered Hairy Roots

The genus *Withania* (*Solanaceae*) includes two medicinally important species, *W. somnifera* and *W. coagulans*, whose antitumor and neuropharmacological properties have been attributed to *triterpenic* steroidal lactones named withanolides. The biosynthetic pathway of withanolides is not fully known, but since they probably derive from cholesterol, they likely follow the mevalonate pathway in the cytosol like all the triterpenes. Among the genes involved in this pathway, the squalene synthase gene (*ss*) is particularly interesting because it encodes squalene synthase (SS, EC2.5.1.21), the enzyme that dimerizes two molecules of farnesyl diphosphate to synthesize squalene, a shared precursor in steroid and triterpenoid biosynthesis in plants (Fig. 89.15). The *ss1* gene from *Arabidopsis thaliana* was introduced in *W. coagulans* under the control of the 35S CaMV promoter together with the T-DNA of *Agrobacterium rhizogenes* A4. The obtained engineered roots carrying the *ss1* gene (SS lines) increased the production of withanolides 2.5-fold in relation to the control roots harboring only the T-DNA from pRiA4 [84].

5 Conclusion

Biotechnology offers an opportunity to sustainably exploit plant cells, tissues, organs, and the entire plant organism, using in vitro cultures and genetic manipulation, for the production of plant secondary metabolites, including important terpene compounds that are beneficial for human health and nutrition. Cultivable land and endangered species would benefit from this alternative practice. As described in this chapter, empirical approaches have been employed for the development and optimization of plant cell-based bioprocesses for terpene production. An empirical approach typically optimizes the plant cell culture system regarding its input factors (cell line, medium, culture parameters, bioreactors, process operations, etc.) and output factors (cell growth, nutrient uptake, productivity, yield, etc.), but what occurs at the cellular and molecular levels remains largely unexplored [85]. In contrast, a rational approach aims to gain knowledge about what is happening in the cells when production increases, but this requires the characterization of genes and proteins involved in secondary pathways, as well as an understanding of their respective regulatory function and role, before finally the biosynthetic pathways can be manipulated for a given application via metabolic engineering. Powerful new tools are currently available, such as those used in studies of functional genomics (transcriptomics, proteomics, and metabolomics).

This has led to an acceleration in the last decade in secondary metabolism research and generated a wealth of new knowledge related with terpene metabolism and other plant secondary pathways [5].

Metabolic engineering in plants, involving the modification of endogenous pathways, has three basic goals: to increase the production of a desired compound, to decrease the production of unwanted compounds, and to produce novel compounds. Strategies for achieving these goals include the engineering of single steps in a pathway to increase or decrease metabolic flux to the target compound, blocking competitive pathways or introducing shortcuts that divert metabolic flux in a particular way. However, this approach has only limited value, and targeting multiple steps in the same pathway could help to control metabolic flux in a more predictable maner. In this context, the use of regulatory genes to establish multiple control over one or more pathways in the cells can constitute an effective strategy [86]. The ability to switch on an entire metabolic pathway in engineered cell cultures by ectopic expression of transcription factors or other regulatory peptides opens new possibilities for secondary metabolic pathways [87], especially those that are not fully elucidated, as is the case of several secondary terpene compounds. This system probably constitutes one of the most promising strategies to develop biotechnological processes for producing high-value terpenoids at an industrial level.

Abstract

Paclitaxel (Taxol®), a diterpenoid natural product, has emerged as a widely used anticancer drug with its unique mode of action and efficacy against multiple forms of cancers. The fast growing demand in basic research and clinic chemotherapy requires to increase the global supply. Current industrial production of the drug with semisynthesis with the extraction of Taxol precursors from the yew trees cannot meet the market requirement. Thus, alternative techniques have been intensively explored. One of the promising strategies is the use of fungal

fermentation for Taxol production. This chapter summarizes the recent advances on the study of Taxol-producing fungi, including its taxonomical diversity of the identified strains, the methods for characterization of fungal Taxol, and the molecular basis and heterogenous biosynthesis of Taxol. Current problems delaying fungal production of Taxol in industry were also discussed.

1 Introduction

As one of the most successful antitumor drugs, paclitaxel (Taxol®), a diterpenoid natural product, was originally isolated in the bark of the Pacific yew tree *Taxus* *brevifolia* in the mid-1960s [1]. The structure by X-ray crystallography was reported by Wall, Wani, and MacPhail in 1971 [2]. In the later years, an antimicrotubular action of paclitaxel was revealed, i.e., to inhibit disassembly of microtubule and arrest cell cycle at the stage of G2-M phase, thereby causing cell death via apoptosis [3–7]. In addition, Taxol has also been shown to repress angiogenesis by altering cytoskeletal structures and inhibiting endothelial cell migration in vitro and in vivo [7, 8]. Taxanes, a family of natural compounds with the same tricyclic diterpene nucleus that paclitaxel carries, have been increasingly found ever since. Many of them are shown to have a strong antitumor activity and may serve as excellent lead molecules for new drug development [1]. Approximately 10 more taxanes are in either Phase I or Phase II clinical trials, and another 23 taxanes are in preclinical development in PHRMA [9].

Since its approval for treatment of refractory ovarian cancer by FDA in 1992, Taxol has achieved great success in treatment due to its effectiveness and less side effects than other drugs. It has been the best selling drug of its kind in the market. As a broad-spectrum cancer killer, Taxol is currently used in the therapy against ovarian, breast, melanoma, pancreatic, lung, gastric, head and neck carcinomas, and the AIDS-related Kaposi's sarcoma [7, 10]. Besides, new applications of Taxol keep forthcoming, for instance, Taxol protects primary cortical neurons from beta amyloid (Aβ)-induced cell death; thus, it may be used for the purpose of slowing the development of neurofibrillary that leads to the loss of neuronal integrity in Alzheimer's disease [11–13]. Comparing to classic bare-metal stents, paclitaxel-eluting stents (PES) have superb safety and can markedly decrease angiographic and clinical restenosis following percutaneous coronary intervention [14]. The PES system, TAXUS™ Express2™, was granted an approval for clinical application by FDA to Boston Scientific Corporation in March 2004.

Development of novel variant treatments utilizing Taxol has boosted the consumption of Taxol, and as a consequence the demand of Taxol supply in the market keeps growing. Major obstacles for best therapeutic results with Taxol are its poor solubility and consequently difficulties in delivery [15]. Researchers have made attempts to improve the Taxol efficiency by combination with other drugs or modified to develop Taxol analogues [16]. Docetaxel (Taxotere), a modified derivative of Taxol, is easier to formulate and administer due to its greater aqueous solubility. A novel C-seco taxane analogue, IDN 5390, is active against all human tumor xenografts investigated, including the PTX-resistant ones [17, 18]. The anti-vascular endothelial growth factor receptor antibody bevacizumab and sunitinib in combination with Taxol exhibits a better outcome than taxane alone in the treatment of metastatic breast cancer (MBC) [19, 20]. Vorinostat enhances the efficacy of carboplatin and paclitaxel in patients with advanced non-small-cell lung cancer cell lines [21]. The anionic and amide introduction strategy may allow for delivery of Taxol into the central nervous system (CNS) [22].

With more pharmacological applications, the demand for Taxol in the market keeps increasing annually by an estimate of 5–8%. Short global supply exists as a major drawback for the use of the drug as the affordability is concerned.

This chapter focuses on the study of Taxol-producing fungi that promise an alternative way of paclitaxel manufacturing and virtually change the situation of the drug supply in the market.

2 Current Methods for Taxol Production

2.1 Extraction of Taxol from Yew Tree Materials

In the early years after marketed, Taxol was largely extracted from wild yew trees, its bark and other parts. Leading pharmaceutical companies soon started large-scale farming of yew trees. By now, extract of this chemical from raw tree materials is still playing a part in Taxol industry. Unfortunately, Taxol makes up only a small proportion of the total taxoids in *Taxus* trees [23]. Its natural concentration is approximately 0.01% of a dry weight basis in Pacific yew [24]. The taxane contents varied among and within *Taxus* spp. [25–27]. Even in *T. media* Hicksii, a hybrid variety of yew with a highest content of Taxol known so far, Taxol content is between 109 and 112 mg/kg of the dried needles [25]. The problem with this extraction strategy is that Taxol content is significantly influenced by the geographical location, altitude, age, and sex of the trees [23]. The season to harvest and the way to handle the tree materials also have effects on the yield of Taxol [28, 29]. Due to slow growth of yew trees and the low-yield extraction techniques [30], global production of Taxol with this strategy is limited and cannot meet the growing market.

2.2 Taxol from Plant Tissue Culture and Cell Suspensions

Plant cell, tissue cultures, or cell suspension culture of *Taxus* spp. is considered as a comparably fast way to obtain sufficient amount of tree biomass [31–33]. *Taxus* cell cultures have been extensively investigated to increase the content of Taxol via different methods, including screening for the high-taxol-producing genotypes and hybrids [34], nutrients, chemical elicitors (methyl jasmonate, silver thiosulfate), plant growth regulators [35–38], the heat shock [39], mechanical stimulating, two-phase culture [40], and others. The production of Taxol was remarkably improved by these processes. Plant cell fermentation (PCF) technology developed by the German and Canadian biotechnology company Phyton Biotech, Inc., is used for Taxol production (http://www.phytonbiotech.com/news_031215.htm). However, low and unstable Taxol yield, high production cost, and by-product contamination are the main bottleneck for large-scale commercial application of this technology [32]. The overall cost of Taxol production via cell culture or cell suspension remains still high.

2.3 Total Chemical Synthesis of Taxol

Several different synthesis routes of paclitaxel have been published. The total synthesis has been first achieved independently by two teams in 1994, the Holton's and the Nicolaou's [41–43]. The third synthetic route was accomplished by Danishefsky's group in 1996 [44]. Total synthesis of Taxol is a complex task for chemists given the fact that the molecule consists of four complicated rings (A, B, C rings and the oxetane ring) and has 11 chiral centers. The synthesis processed more than 20 steps, and only 0.07% and 2.7% production rates for the Holton's and Nicolaou's routes were obtained, respectively [41, 42]. Mukaiyama et al. have proposed an improved method for the asymmetric total synthesis of Taxol by a different way [45]. An automated synthesizer with a 36-step synthesis sequences for intermediate of Taxol was developed by Doi et al. (2006) [46]. Due to the complexity of Taxol structure, the expensive chemical reagents, and the strict requirement for reaction, the process of the total synthesis of Taxol is multiple-step, costly, and commercially unfeasible for industrial application for Taxol manufacture.

2.4 Semisynthesis of Taxol

Starting with 10-deacetylbaccatin III (10-DAB III), a precursor of Taxol biosynthesis in yew with higher content, several coupling strategies of a phenylisoserine moiety with protected 10-DAB III have been reported by several groups [47–51]. 10-DAB III can be isolated from the needles of *T. media* and *T. baccata* with relatively higher yield [52–55]. The development of Taxol synthesized from baccatin III and C-13 Taxol side chain represents a breakthrough of Taxol industrial production and has become a major source of Taxol and taxotere in industry [47–51]. This semisynthesis has significantly improved the production and global supply of the drug and makes the drug more affordable to patients. However, an unsolved issue of this widely used method is its dependence on the supply of yew tree materials.

3 Taxol-Producing Fungi: A Prospective New Source for Taxol Making

In 1993, Stierle, et al. [56] reported a fungus from the bark of a Pacific yew tree (*T. brevifolia*) that was able to produce Taxol, even when the fungus was grown as a pure culture. This finding stirred up interest of scientists in searching for Taxol-producing fungi all over the world that promises a different approach to produce the compound. Fungal fermentation has been widely used in agriculture, pharmaceutical, and food industries for a long history. It is certainly a good practice for Taxol production at the industrial scale. Advantages of growing fungi over plant cell culture include the medium is simple and inexpensive, the period of fermentation is short, and fungi are convenient for genetic manipulation which is a benefit for breeding to improve the yield of Taxol. Still more, since large-scale fermentation will provide sufficient biomass for Taxol preparation, consumption of yew trees will eventually be eliminated.

3.1 Biodiversity of Taxol-Producing Fungi

Over the past decades, more than 50 Taxol-producing fungal isolates were described by groups from all over the world [57–61]. Most of these strains were isolated from various *Taxus* spp. as endophytes. Yet Taxol-producing fungi were also isolated from bald cypress [62], Wollemi pine [63], *Torreya grandifolia* [64], *Ginkgo biloba* [65], *Podocarpus* [66], *Terminalia arjuna* [67], *Hibiscus rosa-sinensis* [68], and other non-*Taxus* plants. A few epiphytic or saprophytic fungi were also found to make the compound [69]. Noh et al. [70] obtained a Taxol producer, *Pestalotia heterocornis*, from the soil collected in yew forest. Recently, our group isolated a Taxol-producing fungus NK101 from plant debris in the soil as well [71].

Several studies claimed traditional Asian medicinal plants may provide a fertile source for drug discovery. Gangadevi and Muthumary isolated a series of Taxol-producing fungi from medicinal plants [72–75]. Pandi et al. [76] found Taxol in the fermentation broth of an endophytic fungus, *Lasiodiplodia theobromae*, which was isolated from the leaves of *Morinda citrifolia*, a medicinal plant.

By far, identified Taxol-producing fungal strains are distributed to 36 genera: *Achaetomium*, *Alternaria*, *Aspergillus*, *Bartalinia*, *Beauveria*, *Bionectria*, *Botryodiplodia*, *Botrytis*, *Chaetomium*, *Cheatomella*, *Cladosporium*, *Colletotrichum*, *Ectostroma*, *Epicoccum*, *Fusarium*, *Gelasinospora*, *Geotrichum*, *Metarhizium*, *Monochaetia*, *Mucor*, *Ozonium* [57–61], *Papulaspora*, *Penicillium*, *Periconia*, *Pestalotia*, *Pestalotiopsis*, *Phoma*, *Phomopsis*, *Phyllosticta*, *Pithomyces*, *Sporormia*, *Taxomyces*, *Trichothecium*, *Tubercularia*, and *Xylaria*. Some strains remain to be classified [58]. The species in genus *Pestalotiopsis* are the most encountered Taxol producers.

3.2 Methods for Screening Taxol-Producing Fungi

A lack of high throughput screening methods is a drag for identification of fungal Taxol producers. Conventional screening steps include the isolation of fungal strains from collected samples, the culture of fungal isolates, and the extraction of the cultures with organic solvents. The organic phase needs to be concentrated to small volume of 0.5 mL. The residue was subjected to biochemical analysis including chromatography, ultraviolet absorption and mass spectrometry, nuclear magnetic resonance (NMR), and anticancer tests. This is a tedious and time-intensive procedure [71].

A few groups reported the development of Taxol-specific monoclonal antibodies (TSMA) and the enzyme-linked immunosorbent (ELISA) assay for Taxol screening. Jaziri et al. reported the use of TSMA for the detection and the semi-quantification of Taxol in a concentration ranging from 1 to 100 ng [77]. Grothaus developed an indirect competitive inhibition enzyme immunoassay (CIEIA) method in the detection of Taxol and cephalomannine in a concentration as low as 0.3 ng mL^{-1} [78]. Unfortunately, Taxol is a poor antigen, and sophisticated antibody is few in the market. Screening methods based on ELISA are not widely found in literature.

A couple of reports used molecular approaches for the purpose of screening Taxol-producing fungi. For instance, PCR screening procedure was used to amplify fungal genes putatively coding for the Taxol biosynthetic enzymes, such as taxadiene synthase (TS), 10-deacetylbaccatin III-10-O-acetyl transferase (DBAT), and C-13 phenylpropanoid side chain-CoA acyltransferase (BAPT), which are demonstrated to be involved in Taxol biosynthesis in yew trees [79, 80]. Foland constructed a paclitaxel-sensitive budding yeast strain *Saccharomyces cerevisiae* strain AD1-8-tax by introducing a mutated β-tubulin yeast gene that conferred the yeast a sensitivity to Taxol [81]. AD1-8-tax can be used as a convenient tool as a tester in a high throughput screening for Taxol produced in fungal culture. Based on our experience, the low sensitivity of AD1-8-tax strain is a limit of this method as for the time being Taxol concentration in fungal culture is still low.

4 Molecular Study on Taxol Biosynthesis

4.1 The Biosynthesis Pathway in Yew Tree

The biosynthesis of Taxol in *Taxus* spp. has been extensively investigated and basically elucidated due to tremendous efforts by Croteau and coworkers [82, 83]. Based on Taxol structure, it is believed that 19 enzymatic steps are required from the ubiquitous diterpenoid precursor geranylgeranyl diphosphate (GGPP), which is derived from deoxyxylulose-5-phosphate pathway and the mevalonate pathway. GGPP is cyclized by taxadiene synthase to form taxa-4(5),11(12)-diene which is regarded as the first committed step in Taxol biosynthesis. Following stages involve eight steps of cytochrome P450-mediated oxygenations, an array of acylations, oxetane ring formation, and several steps of side chain assembly, resulting ultimately in the synthesis of Taxol. Most of the genes encoding key enzymes involved in this pathway have been cloned and characterized, e.g., geranylgeranyl diphosphate synthase (GGPPS), taxadiene synthase (TS), taxane 5α-hydroxylase (THY5α), taxa-4(20), 11(12)-dien-5α-ol-O-acetyltransferase(TAT), taxane 10β-hydroxylase (DBAT), taxane 13α-hydroxylase (THY13α), taxane 2α-O-benzoyltransferase (TBT), 10-deacetylbaccatin III-10-O-acetyltransferase(10-DABT), phenylalanine aminomutase (PAM), baccatin III:3-amino-3-phenylpropanoyltransferase (BAPT),

and 3′-N-debenzoyl-2′-deoxytaxol N-benzoyltransferase (DBTNBT) [32, 83–87]. Although effective transformation methods have been successfully established in *Taxus* species [88–90], the roles of the genes in Taxol biosynthesis have not been directly demonstrated by genetic manipulation such as gene deletion.

4.2 The Biosynthesis of Taxol in Fungi Remains a Puzzle

The biosynthesis pathway and regulation mechanism of Taxol in fungi are utterly unknown. An intriguing question is whether the pathway is conserved among fungi and plants. Several recent studies suggested using counterpart genes in Taxol biosynthesis in yew trees as molecular markers in the screening for Taxol-producing fungi [79, 80, 91]. A putative taxadiene synthase encoding gene and a 10-deacetylbaccatin III-10-O-acetyltransferase encoding gene have been amplified from Taxol-producing fungi and possessed a high homology to the equivalent genes in *Taxus* spp. [92–94]. However, all reports did not show any direct evidence on the roles of these genes in Taxol biosynthesis in fungi. At least, a targeted knockout mutant of the genes is needed to demonstrate their exact roles in Taxol biosynthesis. Thus, at this stage, genes or pathways related to fungal Taxol biosynthesis are still at large.

4.3 Genetic Engineering for Taxol Production

To construct Taxol biosynthetic pathway in organisms that originally do not produce the chemical has been attempted [95, 96]. Takahashi et al. engineered the baker's yeast *S. cerevisiae* by enhancing the carbon flux to the mevalonate pathway (MEP) and co-expressed terpene synthase genes to accumulate high levels of farnesyl diphosphate (FPP) [96]. Genes in the five sequential steps in early isoprenoid biosynthetic pathway to the intermediate taxadien-5a-acetoxy-10b-ol were expressed in yeast, although the engineered host only yielded a trace level of taxadien-5a-ol [95]. Huang et al. successfully synthesized a precursor of Taxol, taxadiene (1.3 mg L^{-1}), in *E. coli* by expressing genes encoding deoxyxylulose-5-phosphate synthase, isopentenyl diphosphate isomerase, geranylgeranyl diphosphate synthase, and taxadiene synthase [97]. Engels et al. reported an efficient system for the synthesis of taxadiene (8.7 ± 0.85 mg L^{-1}) in yeast [98]. Lately, Ajikumar et al. dramatically increased the titers of taxadiene to approximately 1 g/l (15,000-fold) in an engineered *E. coli* strain by a multivariate-modular approach [99]. These successful cases in taxadiene production suggest that genetic engineering of Taxol biosynthesis pathway in *E. coli* or *S. cerevisiae* may be a shortcut to realize the production of Taxol in microorganisms. The remaining route is still long, however, considering that taxadiene is only the first step toward the final product Taxol in the pathway.

5 Problems and Perspective

A couple of issues delay the application of fungal production of the drug after the first report in 1993. The yield of Taxol in fungal strains is still low for the commercial purpose. The level of Taxol in fungi ranges from a few nanograms to several hundred micrograms per liter of liquid culture. Even worse, a trouble encountered by many groups is the capability of Taxol biosynthesis is unsustainable in the fungal strains after cultured for generations. Several groups provided solid evidence showing that fungal isolates produced genuine Taxol and later the compound disappeared in the same strain. The cause behind this phenomenon may be complicated and is still unclear. Successive transfers of a Taxol-producing fungus *Periconia* sp. resulted in fading Taxol biosynthesis even though fungal growth was little unaffected [64]. A recheck of the first isolate *T. andreanae* by Staniek et al. did not find Taxol in the culture even in scaled up cultures [100]. Wang and his colleagues have observed the same phenomenon in Taxol-producing entophyte *Tubercularia* sp. TF5 [101]. The strain lost the capability of producing Taxol after long-term laboratory culture. The team tried to reactivate the production of Taxol by protoplast mutagenesis and genome shuffling approaches. Nevertheless, Taxol has not been detected again in any mutants.

Many factors may contribute to the instability of Taxol in the culture. Numerous hydrolyzable ester groups and chiral centers on Taxol molecule may undergo hydrolysis or epimerization. Treatment of Taxol with hydrogen peroxide generates 10-deacetylpaclitaxel only. Exposure of Taxol to high-intensity light results in a number of degradants [102]. Tian and Stella studied in detail the degradation kinetics of Taxol as function of temperature, pH 1–12, and buffer components. They found that the compound was stable under acid pH conditions with the optimal stability at pH 4–5 [103–105]. We observed in a culture broth for a Taxol-producing strain that pH value starting with pH 6.0 kept increasing to pH 9.5 at the end of the culture. Under such a condition, Taxol may undergo conversion or degradation.

Loss of the capability to produce Taxol may occur at the genetic level. For example, an aging strain may lose its genetic materials. Transposons may mute genes for Taxol biosynthesis once the chemical is no longer a benefit for competition under laboratory condition. Latest advance in the field of fungal secondary metabolism (SM) revealed that the majority of genes involved in SM stay silenced until an elicitor appears. A similar case was found for an inducible terpenoid defense system in conifers [106]. Stierie and Strobel [107] found that addition of yew needle extract into fungi medium resulted in 100-fold increase in Taxol production. Li and coworkers found that coculture of the cell suspension of *T. chinensis var. mairei* and its endophytic fungus, *Fusarium mairei*, successfully increased the yield of Taxol by 38-fold [108]. Taxol exhibits a strong inhibitory activity against oomycetes including *Pythium*, *Phytophthora*, and *Aphanomyces* [109], implying that Taxol might be originally produced as a protective, antifungal compound against competitors in nature. Environmental elements may play critical roles in activating Taxol biosynthetic genes [100].

It seems evident that fungal fermentation has advantages over the current techniques that are currently used in industrial production of Taxol. Despite the fact that numerous hurdles need to be overcome, application of fungal production of this important antitumor drug is a significant research theme. Studies in this field have generated fruitful results. A great number of Taxol-producing fungi have been found from all over the world. Screening for more fungal isolates from diverse natural niches may facilitate to identify better start strains with higher yield of the compound. On the other hand, to illustrate the genetic basis of the biosynthesis of Taxol in fungi should be put on the top of the working list. Revelation of Taxol genetics will help to find out the mechanism of regulation of Taxol biosynthesis and the exact reasons for its instability in the culture. Hopefully, bioinformatics tools and new genome sequencing techniques will certainly expedite the study toward the solution of existing difficulties.

high interest for humans. Here, we present the current knowledge on isoprenoid metabolism before describing the strategies that have been used for isoprenoid metabolic engineering. We discuss the advantages and drawbacks of using micro-organisms and plants as cell platform for the production of isoprenoids of interest.

SqS	Squalene synthase
TPS	Terpene synthase
VOCS	Volatile organic compounds.

1 Introduction

Isoprenoids, also called terpenoids, constitute a large class of natural compounds with highly diverse structures and functions. They have been identified in many different organisms including microorganisms and animals but are the most diverse in plants with tens of thousands compounds identified so far [1]. Indeed some terpenoids are essential compounds in plants such as sterols necessary for membrane fluidity, phytols chains and carotenoids involved in photosynthesis and photo-protection, respectively, or hormones, for example, gibberellins and abscisic acid, necessary for plant growth and plant response to non-biotic stresses. However, most isoprenoids are not essential for plant development, but play important functions in the relationship between plants and their environment. Among them, volatile isoprenoids contribute to protective effect under thermic or oxidative stress [2], insect attraction for pollination [3], or the defense against pathogen and herbivore attack [4]. Volatile terpenoids may also serve as signal molecules in plant-to-plant communication [5] and together with fatty acids, amino acids, benzene derivatives, and phenylpropanoids are part of the volatile organic compounds (VOCs) released into the atmosphere by plants in response to biotic and non-biotic stresses [6].

In addition to their role in plants, terpenoids have been the focus of numerous studies as they meet human needs in many different fields, including food industry as colorants (lycopene, β-carotene [7]), "cosmetics and perfumes" industry, production of antimicrobial compounds (reviewed in [8]), and of medicines like the antimalarial compounds artemisinin (dihydroartemisinic acid, [9]) or anticancer drugs [10], for example, taxol [11].

Given the wide range of isoprenoid applications, engineering of this metabolite pathway has attracted a lot of interest. Furthermore in some cases, natural sources of highly valuable terpenoids are limited. As an example, taxol is produced by yew tree in very low amounts (0.02% of dry weight) with an extraction process leading to the death of the tree. Extensive extraction of this molecule in the 1990s has endangered this plant species, making it necessary to find alternative source of taxol [12]. So far, many studies have focused on microorganisms as heterologous system for isoprenoid production (for a recent review [13]). Indeed bacteria have proven to be efficient platforms for carotenoid synthesis [14] yet are limited by several factors including substrate availability, and limited storage for end products which impair their use for industrial production [15]. Aside from carotenoids, other isoprenoids could be produced in bacteria and several ongoing works aim at promoting bacteria as a general platform for isoprenoids production. Despite several improvements, industrial production is not yet affordable using bacteria. Moreover, the huge diversity of isoprenoids of interest is far above the number of plant genes of this pathway actually known, therefore limiting the engineering in heterologous hosts (reviewed in [16]). Yeast [17], algae [18], plant cell culture (reviewed in [19]), and hairy root culture transformed with *Agrobacterium rhizogenes* (reviewed in [20]) offer additional ways for the production of secondary compounds. So far industrial production of carotenoids can be achieved using the microscopic green alga *Xanthophyllomices dendrorhous* for asthaxantin and *Dunaliella salina* for β-carotene production (reviewed in [21]).

Metabolic engineering of higher plants also provides an alternative system to produce high value isoprenoids which may help overcoming the limitations of microorganism-based cell platforms. At the present time, isoprenoid engineering in plants has been successfully performed with the aim to improve plant resistance

Fig. 91.1 Overview of terpenoids synthesis. Colored frames indicate the cellular localisation of the different pools of metabolites: *green* frames for a plastidial localisation, *blue* frames for a cytosolic localisation, *grey* frames for a mitochondrial localisation. *Black vertical arrow* stands for GPS activity, *doted vertical arrow* for FPS, *red vertical arrow* for GGPS and *green vertical arrow* for long chain prenyl transferase. Cell compartimentalization has been shown according to

to herbivores [22], to modify the fragrance of flowers from ornamental plants or the aroma in plant products (reviewed in [23]), to modulate the content of metabolites having an impact on human health (e.g., carotenoids, reviewed by [24, 25]), or to produce compounds of pharmaceutical interest [26].

In this chapter, we will present various strategies that have been developed for isoprenoid engineering. It is of course beyond the scope of this chapter to present a detailed analysis of isoprenoid biosynthesis. Yet, metabolic engineering of isoprenoid pathways in plants necessitate not only to have access to the genes encoding the proteins that control isoprenoid synthesis but also to acquire a precise understanding of the plant organs and tissues accumulating these molecules as well as of the mechanisms that regulate their accumulation. For these reasons, the first part of this chapter will focus on a general description of isoprenoid pathways. In the second part, different strategies aimed at modifying isoprenoid synthesis in microorganisms and plants will be presented. For extensive analysis of metabolic engineering on specific isoprenoid classes, readers are directed to recent reviews focusing specifically on volatile terpenes [27, 28], triterpenes [29], carotenoids [24], and specific molecules of high health value such as arthemisinin [9] and taxol [30].

2 Biosynthesis and Accumulation of Isoprenoids in Plants

The diversity of terpenoids derives from the complexity of the metabolic pathways governing the synthesis of this group of metabolites. Yet, all terpenes are produced from the C5 basic unit isopentenyl pyrophosphate (IPP) and its isomer dimethylallyl diphosphate (DMAPP). IPP and DMAPP are condensed to form geranyl diphosphate (GPP, C10), farnesyl diphosphate (FPP, C15), and geranyl geranyl diphosphate (GGPP, C20) precursors of monoterpenes, sesquiterpenes, and diterpenes, respectively. Higher order terpenoids are formed following the condensation of two FPP molecules (triterpenes, C30) or two GGPP molecules (tetraterpenes, C40), and polyterpenes (C45 and more) synthesis occurs by sequential addition of IPP to allylic diphosphates (Fig. 91.1). In a general way, terpenoid synthesis proceeds through three sequential steps: (1) synthesis of the IPP-DMAPP precursors, (2) production of linear Cn carbon backbones, (3) generation of the tremendous diversity of isoprenoid molecules following specific secondary enzymatic modifications (cyclization, methylation, oxidation,

Multi-enzymatic steps are indicated by multiple *arrows*. Each *grey cube* represents a 5-carbon building block constituting the different classes of isoprenoid. *MEP* methyl-D-erythritol 4-phosphate, *MVA* acetate/mevalonate, *DXP* 1-deoxy-D-xylulose 5-phosphate, *HMG* 3-hydroxyl-3-methylglutaryl, *DMAPP* dimethylallyl diphosphate, *IPP* isopentenyl diphosphate, *GPP* geranyl diphosphate, *NPP* neryl diphosphate, *FPP* farnesyl diphosphate, *GPPP* geranylgeranyl diphosphate, *TPS* terpene synthase, *SqS* squalene synthase, *Psy* phytoene synthase, *IS* isoprene synthase, *GPS* geranyl pyrophosphate synthase, *FPS* farnesyl pyrophosphate synthase, *GGPS* geranyl geranyl pyrophosphate synthase epoxidation, etc.). Additional complexity arises from cellular compartmentalization, tissue specialization, and complex regulation of isoprenoid biosynthesis.

2.1 Isoprenoid Biosynthetic Pathways

2.1.1 IPP Synthesis Occurs Following Two Independent Pathways

It has been thought over almost half a century that IPP was only produced from the cytoplasmic mevalonate (MVA) pathway. The discovery that bacteria produced IPP following a totally different pathway, the 2-*C*-methyl-D-erythritol 4-phosphate (MEP) pathway, has brought a totally new view on the regulation of isoprenoid biosynthesis [31]. The MVA pathway, which operates in archaebacteria and most eukaryotes, relies on acetyl-CoA supply and is generally considered to provide the precursors for the production of sesquiterpenes (artemisinin, gossypol, etc.), triterpenes (sterols) as well as for protein farnesylation. The MVA pathway has long been described as cytosolic but different data suggest a peroxisomal localization for the full set of enzymes both in mammals [32, 33] and in plants [34]. The MEP pathway is found in most eubacteria [35] and in plants where it is restricted to the plastids [36]. It initiates with the condensation of D-glyceraldehyde-3-phosphate and pyruvate (Fig. 91.1). In plants, where both the MVA and MEP pathways coexist, the MEP pathway typically provides the precursors required for the synthesis of plastidic isoprenoids including isoprene, monoterpenes, diterpenes, and tetraterpenes. However, recent studies suggest that the origin of IPP/DMAPP used for terpene synthesis may depend on the species, tissue, and physiological state of the plant (for a recent review, see [37]). Both cytosolic and plastidic IPP pools have been suggested to contribute to artemisinin synthesis [38], to sesquiterpene synthesis in peppermint [39], in snapdragon [40] and in wild and cultivated tomato species [41, 42]. Thus the subcellular channeling of the isoprenoid pathways might not be as strict as initially thought, although the exact flux of terpenoid precursors between cytosol, plastids, and, in some cases, mitochondria compartments remains to be determined (for a review, see [37]).

2.1.2 Prenyltransferases Catalyze the Production of Isoprenoid Linear Carbon Skeletons

Prenyltransferases (EC 2.5.1.1, PTS) (also called isoprenyl diphosphate synthases, IDSs) catalyze sequential 1′-4 (head-to-tail) associations between IPP and an allylic diphosphate primer substrate (reviewed in [43]). This process requires the initial condensation of IPP with its isomer DMAPP. DMAPP is directly produced through the MEP pathway or obtained from IPP by the enzymatic activity of the IPP isomerase (EC 5.3.3.2). IDSs have been classified as *trans*-prenyltransferases and *cis*-prenyltransferases based on the stereochemistry of the newly formed double bonds (Fig. 91.2) (reviewed in [44, 45]). Hence, IDS form two families of structurally unrelated enzymes that use different mechanisms [46].

In each family, IDS are further separated according to the length of the end product they form. *Cis*-prenyltransferases were initially shown to generate

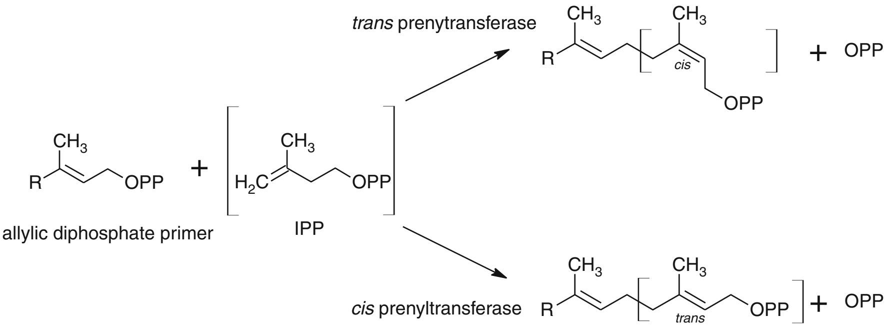

Fig. 91.2 Schematic representation of the reactions catalyzed by *trans*-prenyltransferases and *cis*-prenyltransferases showing the stereochemistry of the double bond formed in the enzyme product. *IPP* isopentenyl diphosphate, *OPP* diphosphate ester

isoprenoid chains longer than C50 (10 isoprene units) by using all-*trans* short chain prenyl diphosphates as allylic primer substrates. *Cis*-PTSs are involved in dolichol [47] and rubber synthesis [48, 49]. Recently, short chain *cis*-prenyltransferases have also been characterized such as the (Z,Z)-FPP synthase [42], and the neryl diphosphate synthase [50] from wild tomato, suggesting that the function of *cis*-PTS in terpene metabolism should be reevaluated [51].

The three central precursors for isoprenoid synthesis, that is, GPP, FPP, GGPP, are essentially produced by IDSs belonging to the *trans*-prenyltransferases group. These enzymes, namely, geranyl pyrophosphate synthase (EC 2.5.1.1, GPS), farnesyl pyrophosphate synthase (EC 2.5.1.10, FPS), and geranyl geranyl pyrophosphate synthase (EC 2.5.1.29, GGPS), play major roles in isoprenoid synthesis. Other *trans*-PTS catalyze the formation of products of more than 20 carbon atoms required for the synthesis of ubiquinone and plastoquinone isoprenoid chains and also specific terpenoids such as chicle (a C500 polymer) [44].

Both *trans*-PTS and *cis*-PTS are poorly conserved at the amino acid level, which makes the prediction of PTS specificity based on sequence analysis difficult [43, 45, 52–55]. Indeed the specificity of PTS appears to be mainly governed by one or two amino acids at the bottom of the enzyme active sites (reviewed in [54]). Yet, some PTS are characterized by enzymatic plasticity that results in the synthesis of more than one compound with different chain lengths [56–58]. For example, the *A. thaliana* solanesyl diphosphate synthase has been shown to accept GPP, FPP, and GGP as substrates, which leads to producing multiple medium/long chain isoprenoids (C25 to C45 in vitro and C35 to C45 in recombinant systems) [59, 60].

Therefore, substrate availability may influence the enzymatic reaction catalyzed by given PTS. In the context of isoprenoid engineering, the choice of the subcellular location for the production of recombinant PTS is an important issue. Indeed, native PTS are present in different cell compartments, that is, plastids, cytosol, mitochondria, and endoplasmic reticulum, depending on their function in cell metabolism.

2.1.3 Several Enzymes Contribute to the Diversity of Isoprenoids

Terpene synthases (TPSs) are responsible for the formation of all isoprenoids using DMAPP, GPP, FPP, or GGPP as substrate. They include isoprene, monoterpene, sesquiterpene, diterpene, triterpene, and tetraterpene synthases which catalyze the first committed step to the biosynthesis of each class of terpenes. Different TPS classifications have been proposed based on their reaction mechanism and products formed (see, e.g., [61, 62]). Among them, squalene synthase and phytoene synthase which catalyze the first committed step, respectively, toward sterol (C30) and carotenoid (C40) synthesis, are structurally distinct from other TPSs [61]. They catalyze the "head-to-head" condensation of FPP and GGPP to form squalene (C30) and phytoene (C40), respectively, with the elimination of both pyrophosphate groups. Other TPSs are evolutionary related to each other [61] and it is not usually possible to predict their product profile on the basis of their primary structure alone.

Most of TPSs catalyze the formation of carbocation intermediates with multiple possible rearrangements of the carbon backbone, eventually leading to multiple products from a single substrate (for a recent review, see [63]). In Norway spruce (*Picea abies*), the diterpene synthase, levopimaradiene/abietadiene synthase, has been shown to produce a mixture of four diterpenes (i.e., abietadiene, levopimaradiene, neobetadiene, and palustradiene). Strikingly, another diterpene synthase from the same species, the isopimaradiene synthase, shares 91% amino acid identity with the former enzyme but products a single-product, isopimaradiene [64, 65]. This example illustrates the high evolutionary plasticity of TPS (for a review, see [62]).

At the time being, genomic and expressed sequence tag (EST) data sets have boosted our knowledge of *TPS* gene families in model plants such as *Arabidopsis* [66], tomato [67], *Medicago* [68], or *Picea* [64, 69]. At one extreme, the genome of the moss *Physcomitrella patens* contains a single functional *TPS* gene encoding a bifunctional copalyl diphosphate synthase/kaurene synthase (CPS/KS; [70]). *TPS* gene families in plant genomes examined so far range in size from 19 to 152 [62]. These arise from cycles of gene duplication, multiple mutations, and functional divergence [61, 62]. To date, the *TPS* gene family has been extensively studied in *A. thaliana*. However, among the 32 potential proteins encoded by the *A. thaliana* TPS genes [66], only 14 have been assigned a biochemical function and classified as monoterpene, sesquiterpene, or diterpene synthase [71–78]. It should be noted that product specificity might also depend on the terpene precursor available. Thus, some sesquiterpene synthases may produce monoterpenes when provided with GPP as starting substrate, and inversely, providing monoterpene synthases with FPP may lead to sesquiterpene synthesis [79]. Therefore, as already discussed in the case of IDS, the subcellular targeting of TPS by determining substrate availability contributes to specifying terpene production [80].

The huge diversity of primary terpene skeletons formed by TPSs can be further modified by the action of various other enzyme classes, such as cytochrome P450 hydroxylases (EC 1.14.14.1), dehydrogenases (EC 1.1; alcohol and aldehyde oxidoreductases), reductases, glycosyl transferases (EC 2.4), and methyl transferases (EC 2.1.1). Among these enzymes, cytochrome P450 hydroxylases play a major role since many terpenes undergo final oxidation steps [81, 82]. Cytochrome P450 monooxygenases, which catalyze substrate-, regio- and stereo-specific oxidation steps, form one of the largest families of enzyme proteins in plants. For example, plant genome sequencing projects revealed 71 full-length P450 genes in the moss *Physcomitrella patens* [83], and 216 in *A. thaliana* [84]. However, according to the most recent survey, the function of more than 70% of the P450s found in the *A. thaliana* genome is still unknown or poorly understood [84]. Deciphering the function of specific cytochromes P450 may be however valuable since the manipulation of cytochrome P450 hydroxylase abundance can be used to modify the proportion of the different terpenoids produced from a common precursor in complex mixture of terpenoids, such as peppermint oil [85, 86]. For example, by reducing the expression of cytochrome P450 menthofuran synthase in peppermint, it has been possible to produce essential oils with a significant reduction in menthofuran content, an undesirable monoterpene oil component [85].

As a conclusion, isoprenoid biosynthesis involves multiple intricate metabolic pathways, operating in parallel in different cell compartments. Indeed most of the isoprenoid biosynthetic enzymes exist as multiple forms with various subcellular localizations and different expression profiles, as revealed by a detailed analysis using *A. thaliana* [51]. Hence, identification of the different genes involved in a specific isoprenoid biosynthesis, which appear necessary for bioengineering experiments, may be quite challenging. Recent reports [60, 80, 87] show that integrated approaches, including combined transcriptomic analysis and biochemical characterization of recombinant enzymes, are highly helpful to associate a function to a gene. Moreover, many enzymes involved in terpenoids synthesis, including some prenyltransferases and terpene synthases, accept more than one substrate and depending on the substrate availability, the product formed may differ [79]. This demonstrates that the substrate availability will ultimately determine the specificity of terpene produced in vivo. As a consequence, for bioengineering experiments, the cellular localization and metabolism context of transgene expression must be carefully taken into account.

2.2 Distribution of Isoprenoids in Plants

The complexity of isoprenoid metabolic pathways relies in part on the diversity of enzymes that participate in this metabolic pathway and on their subcellular localization. Another layer of complexity is brought about by the tight regulation of their synthesis and by their sequestration in various specialized structures. Such specialized structures are essential to consider for metabolic engineering of isoprenoid pathways as they allow high level of terppenoid accumulation. However, it should be noted that some terpenoids do not accumulate in plants. For instance, the simplest terpenoid, the hydrocarbon isoprene (C5H8), is a volatile gas emitted during photosynthesis in large quantities by leaves of many tree species, contributing to VOCs released into the atmosphere [88]. Similarly, a lack of connection between monoterpene synthesis and secretory structures has been reported and plants such as corn and *Phaseolus lunatus*, which are not usually considered as monoterpene essential oil producers, can emit several monoterpenoids when attacked by phytophagous insects ([89], for a review, see [22]).

2.2.1 Isoprenoids are Stored in Plant Tissues

Oleoresin are Produced in Resin Ducts

Volatile terpenes are constituents of the essential oils, floral scents, and resins of aromatic plants, to which they impart their characteristic aromas and flavors [90–92]. Oleoresin, for example, is a viscous and odoriferous liquid found in conifers that contains approximately equal amounts of monoterpenes and diterpenes and smaller amounts of sesquiterpenes [93]. Pine tree resin is one of the best characterized oleoresin and contains large quantities of monoterpenoids, including limonene, pinene, and myrcene, which give the organic solvent turpentine its characteristic sharp odor. However, the ratio of these terpenoid classes and thus the physical and chemical properties of oleoresin can vary with stresses such as air pollution [94], fertilizer application [95], drought stress [96], herbivory [97, 98], and fungal inoculation [99]. Constitutive oleoresin biosynthesis and accumulation in conifers is restricted to various types of resin ducts or blisters (Fig. 91.3a) composed of several layers of epithelial cells with a central storage cavity [100, 101]. Inducing a local terpenoid response by mechanical damage or herbivory leads to the formation of specialized traumatic resin ducts in the stem xylem [98, 102–104].

Various Structures Accumulate Essential Oils

Similarly, essential oils, which can be produced in many plant organs, accumulate in specialized structures. Essential oils are extracted from various aromatic plants belonging to 60 families and mainly localized in temperate to warm areas like Mediterranean and tropical countries where they represent an important part of the traditional pharmacopoeia. Indeed, essential oils are essentially composed of terpenes, mainly mono- and sesquiterpenoids with low quantities of di- and triterpenoids, but also contain aromatic and aliphatic compounds [105]. In most cases, they are characterized by a high concentration of two to three major volatile terpenes whereas secondary molecules are found in trace amounts (reviewed in [8]).

Essential oils can be synthesized by all plant organs (buds, flowers, leaves, stems, seeds, fruits, and sometimes roots, wood, or bark) and are stored and released to the environment by a variety of specialized structures, which include oil cells, cavities, canals, scent glands of flowers, secretory glands (eucalyptus), glandular hairs, or trichomes (labiates) (for a review, see [106]). Besides epidermal hairs, essential oil terpenes may also be accumulated in specialized mesophyll glands, as observed in patchouli (*Pogostemon cablin*) [107].

The simplest secretory system is probably represented by oil cells (Fig. 91.3b) that accumulate essential oils in the vacuole as reported by Lewinsohn et al. [108] on lemongrass leaves. Glandular trichomes represent a more sophisticated system which consists of a stalk composed of one to three cells that supports the head. The number of cells constituting the head has been the basis of glandular trichome

classification that are separated in two main types [109]: the capitate type with a single head cell, and the peltate type that is characterized by a multicellular head as in peppermint [110, 111]. Oils may then simply accumulate within the central vacuole of the secretory cells, or between the cell wall and cuticle (Fig. 91.3c)

[112]. As example, in the peppermint trichomes, monoterpene biosynthesis occurs in the secretory cells and essential oil is stored in the subcuticular storage cavity ([112–114], Fig. 91.3d). Although the early works on glandular trichomes have been conducted on Lamiaceae species, tomato trichomes are now extensively studied and characterized, and Solanaceae could become the reference in terms of trichome biology. Glandular trichomes of *Solanum* range in seven subgroups that differ between species ([115] and references therein). Subgroups distinction is based on the stalk length, cell number of the secretory head as well as on the metabolite content of the trichomes. However, recent extensive transcriptomic and metabolic analyses of *Solanum* trichomes demonstrate quantitative rather than qualitative metabolite differences. Several genes involved in terpenoid synthesis are highly expressed in *Solanum* trichomes and their relative abundance varies between species [80, 116]. Interestingly, genes involved in photosynthesis and carbon fixation are also expressed in *Solanum* trichome, suggesting a possible link between carbon metabolism and requirement of carbon skeleton for terpenoids and probably other secondary compounds synthesis [116].

Finally, oil glands, observed on petals or in the peels of oranges, lemons, and other citrus fruits, represent a clearly distinct class of secretory structure. Oil glands initiate when a small set of cells start producing oil and progressively recruit neighboring cells that in turn start synthesizing terpenoids and so on. In holocrine type of glands, oil cells break down when mature, therefore creating a central lumen. The gland grows larger as more cells become converted to oil-producing cells. Such glands may grow either symmetrically or only on one side, giving either spherical or tube-like structure structures, respectively ([117], Fig. 91.3e).

Laticifers

Another class of terpenoids that accumulate in specialized cells are polyterpenes, such as rubber. Natural rubber is a *cis*-1,4-polyisoprene polymer made from isopentyl pyrophosphate monomers with a C15 *trans* tail derived from the original initiating allylic pyrophosphate. It is one of the most important industrial raw materials in the world, and its sole commercial source is currently the para rubber tree *Hevea brasiliensis* [118]. The biosynthesis of natural rubber takes place in the latex of laticifers, long multinucleate pipes formed from anatomized cells, where it is stored in 0.08–2-μm rubber particles and may reach 40% of the latex dry content [119].

Isoprenoid Intracellular Storage

Many isoprenoids are synthesized by cytosolic pathway; they may then accumulate in the cytosol as cytokinin, or rubber, although the cytosol is deeply modified in this latter case to form latex, or may be incorporated into membranes as sterols [119]. Isoprenoids may also be stored in vacuoles, as observed in the case of essential oils, independantly of the subcellular compartment where constituents are synthesized: in the cytosol (as sesquiterpenes) or in plastids (most of the monoterpenes and diterpenes) [112].

By contrast, carotenoids are synthesized and accumulate in plastids: chromoplasts for fruits, flowers, roots and chloroplasts in photosynthetic tissues.

In chloroplasts, carotenoids (mainly lutein, β-carotene, violaxanthin, neoxanthin, and zeaxanthin) are located in the thylakoid membranes. Their amount and type are relatively conserved across most plant species. In contrast, carotenoid content of nongreen plant plastids may vary considerably [120]: from low (as in white flower petals) to high amounts (as in the dark orange petals of certain marigold varieties). Chromoplast pigments may be those found in the chloroplasts (e.g., lutein of marigold flower petals), be derived from carotenoids (e.g., capsanthin and capsorubin of red pepper fruits, synthesized from violaxanthin), and may be pathway intermediates (e.g., lycopene in red tomato fruits). In those plastids, significant amounts of carotenoids may be stored in membranes, oil bodies, or other crystalline structures within the stroma [120, 121]. Chromoplasts accumulate massive amounts of carotenoids by generating carotenoid-lipoprotein substructures, known as carotenoid-sequestering structures [122, 123] which serve as sinks to sequester excess carotenoids [124, 125].

Hence, the complexity and the compartmentalization of isoprenoid metabolic pathway lead to various terpenoids' localization at the organism and cellular levels. Yet the synthesis and accumulation of isoprenoids is under precise regulatory mechanisms (reviewed in [126]).

2.2.2 Isoprenoid Production is Tightly Regulated in Plants

It has long been described that oil accumulation is tightly correlated with leaf development in many aromatic plants and with the abundance of glandular trichomes [127–130]. Ontogeny also affects oil quality as in *C. martini* characterized by an increase in geraniol content from 65% to 81% until flowering stage at the expense of geranyl acetate [106]. Several reports suggest that the primary control of volatile isoprenoid synthesis during plant development occurs at the transcriptional level. Consistent with this view, a clear correlation has been established between TPS gene expression and the accumulation of the corresponding compounds in leaves and flowers of various plants (see, e.g., [76, 131–134]) that was confirmed by the recent analysis of the tomato TPS gene family [67]. In addition, regulation of isoprenoid synthesis by circadian clock and phytochrome has been reported by many authors and the emission of volatile terpenes, for example, has been shown to follow a diurnal rhythm [126].

Besides being regulated in a development-specific way, essential oil production may be modulated through environmental regulations [135]. In nature, essential oils play an important role in the defense against pathogen and herbivore attack; therefore, they may be produced constitutively and in response to a stimulus (reviewed in [136]). For example, thyme basil (*Acinos suaveolens*) growing in an area regularly grazed by herbivores contains twice the amount of monoterpenoids (15.61 vs. 8.18 mg/g dry matter) as compared to plants growing in inaccessible areas. Moreover *Acinos suaveolens* produces two monoterpenoids (menthone and R-(+)-pulegone) with different toxicities. The more toxic R-(+)-pulegone shows an increase in relative abundance (66.3% vs. 47.5%) in plants exposed to browsing [137]. Yet Opitz et al. [138] showed that terpenoid levels in cotton foliage increased after mechanical damage, herbivory, and jasmonic acid treatments, with a 15-fold increase in E-β-ocimene (monoterpene) amount, for example. These higher levels of terpenoids were achieved by two mechanisms: increased filling of existing glands with terpenoids and production of additional glands. Part of the terpenoids emitted following herbivore attacks attracts predators of these herbivores, therefore contributing to the indirect defense of plants [139]. It should also be noted that volatile isoprenoids are essential components of the plant cellular response to non-biotic stresses being involved in the protection against thermic and oxidative stresses that trigger emission of isoprene and monoterpenes (reviewed in [2]).

Similarly, the levels of carotenoids and their profiles are influenced by many factors, including the developmental stage, environment, and stress: For example exposure of plants to high light intensities leads to an accumulation of zeaxanthin, which has essential photoprotective roles [140]. On the other hand, there are many reports describing changes in carotenoid gene transcript abundance during fruit ripening, flower development, or stress, which coincide with changes in carotenoid content [141]. However, other studies clearly showed that the formation of carotenoid-sequestering structures plays also an important role in regulating carotenoid accumulation (for review, see [142]). Thus, control of the formation of a metabolic sink can offer a novel approach to mediate carotenoid accumulation in food crops. Direct evidence comes from works of Li et al. [143] and Lu et al. [144] on the *Or* gene. *Or* gene expression into wild type cauliflower induces the formation of chromoplasts in the curd cells of transformants whose tissues are colored due to an increased level of β-carotene [144]. Expression of the *Or* transgene in potato tubers leads to increased carotenoid levels as well [144, 145], demonstrating that the *Or* gene controls chromoplast differentiation and could serve as a novel genetic tool to enrich carotenoid content of plants.

As a conclusion, isoprenoids accumulate in structures of various complexities, from sequestration substructures in plastids to specialized cells as laticifers or multicellular structures such as glandular trichomes. Obviously such specialized cells and/or tissues are efficient cell factories that aim at producing and accumulating terpenoids and as such should be considered as essential target for isoprenoid metabolic engineering. On the other hand, knowledge of regulation and genes encoding proteins that control isoprenoid accumulation such as *Or* is also a prerequisite before considering the different strategies that can be developed for isoprenoid metabolic engineering.

3 Isoprenoid Metabolic Engineering

3.1 Aims and Strategy

Metabolic engineering refers to genetic manipulation of cells with the aim to enhance yield and rate of selected metabolite production by remodeling or deregulating metabolic networks [146]. Initial strategies were based on the engineering of single enzyme that was thought to be rate limiting. Today's metabolic engineering allows the transfer of all or part of biosynthetic pathway to selected cell systems [147]. Yet, the main question remains unchanged: to identify key enzymatic steps that impact directly or indirectly metabolite yield. To address this point, stoichiometric modeling of the selected pathway has to be carried out in order to identify key proteins that can enhance product synthesis. Stated another way, metabolic engineering emphasizes metabolic pathway integration and relies on metabolic fluxes as determinants of cell physiology and measures of metabolic control. Metabolic flux control can be pursued in the framework of metabolic control analysis (MCA) developed in the 1970s for the quantitative representation of the degree of flux control exercised by specific enzymes, metabolites, and effectors in the pathway [148] or directly by metabolic flux analysis [149].

An alternative to modeling approaches when pathways are under complex kinetic and/or regulatory interaction lies in the combination of genetic alterations with high-throughput screening [150]. Considering the variety of terpenoids [4], the diversity of enzymes involved in this metabolic network, and the limited knowledge of pathway regulation, engineering isoprenoid metabolism has always been challenging. However, since terpenoids present health-related beneficial properties, many efforts have been undertaken in microorganisms but also in plants to produce specific terpenoids, for example, artemisinin [151] and paclitaxel or to improve the yield and/or composition in terpenoids mixtures such as essential oils or carotenoids [152].

At the present time, an outstanding amount of information concerning biosynthetic genes, enzyme functions, and regulation of isoprenoid biosynthetic pathway is available in bacteria, yeast, and plants [37]. Plant web resources have recently been developed such as the public online databases AraCyc (http://www.arabidopsis.org/biocyc) and KEGG (http://www.genome.jp/kegg) and more recently AtIPD (http://www.atipd.ethz.ch, [153]). These tools provide necessary knowledge for the integrative analysis of isoprenoid metabolism including gene, metabolite, and protein information as well as the subcellular organization of the pathway. All these efforts have contributed to give a boost to research on the engineering of isoprenoid pathways with the aim to industrializing their production via microbial fermentations [154] or plant cell and organ cultures [155]. Transgenic plants or organs [15, 156, 157] with modified terpenoid metabolism have also been developed either with plant model systems such as *Arabidopsis*, rice, and maize or plants that already produce isoprenoids of high added value [10, 24, 30, 158, 159]. So far, different strategies to improve isoprenoid production in microorganism and plant systems have been used with various success: (a) optimization of the available isoprenoid precursor pool, (b) manipulation of pathway by introducing single or combination of genes, or (c) increase storage capabilities for lipophilic isoprenoids, (4) remodeling of the pathway for subcellular organization, and (5) manipulation of regulatory genes.

3.2 Microorganisms as Isoprenoid-Producing Platforms

3.2.1 Advantages of Microorganisms as Cell Factories

Microorganisms are currently considered as cell factories for the synthesis of highly valuable terpenoids [15]. Indeed, they present several advantages over other isoprenoid-producing systems among which the use of low cost carbon sources, the possibility of large-scale fermentation processes, the uncoupling between production phase and growth, and the reduced culture times open the way to industrial production. In addition, some microorganisms are characterized by poor competing metabolic fluxes and co-extraction compound problems as they have limited isoprenoid secondary metabolism [160]. This is the case for *Escherichia coli* and *Saccharomyces cerevisiae*. They have often been used in pathway engineering for isoprenoid biosynthesis as they are well characterized and thoroughly susceptible to genetic manipulation. In these hosts, extended engineering is necessary to build up operational biosynthetic pathways as they barely present isoprenoid synthesis except for central metabolites like quinones or sterols. However, the fair handling of these microorganisms offers a serious advantage over the engineering of poorly characterized native strains since their genome, transcriptome, and metabolome elucidation is nearly completed, supporting deeper engineering investigation [161].

3.2.2 Isoprenoid Engineering in Microorganism and Limitations

Although initially limited by low yield and high costs for large-scale synthesis, engineering of isoprenoid pathway in microorganisms stressed on several breakthroughs during the past 15 years. Of course, the initial cloning and expression of diverse heterologous genes in the downstream isoprenoid biosynthesis pathways led to the first *E. coli* producing plant sesquiterpenes. However, product yield was very poor probably due to low prenyldiphosphate availability which highlighted the limitation of unmodified *E. coli* strains as cell factories for isoprenoid production [162]. This was solved by introducing part or all of the MVA in *E. coli*, leading – as far as lycopene production was concerned – to a tenfold increase in yield compared to the wild type strain counterpart [163]. Introduction of the *S. cerevisiae* MVA pathway in *E. coli* allowed improved isoprenoid precursor production, although this was described to be toxic for the host. The toxicity issue was further resolved by introducing a truncated HMGR, not susceptible to degradation [164]. Alternative strategies to improve precursor supply were based on the engineering of the MEP pathway. Overexpression of DXS and IDI led to an increase in IPP and DMAPP syntheses and as a consequence in the carotenoid yield [165]. More recently, the combination between precursor pathway engineering with the use of improved enzyme variants turned out to be a successful approach to overproduce levopimaradiene in *E. coli* [166]. Such a strategy looks highly promising for the production of other terpenoids of high added value for humans.

Prenyl diphosphate synthesis is also directly depending on the carbon flux diverted from the central metabolic network. Creating new metabolic sinks, that is, uncontrolled isoprenoid biosynthetic pathways, may therefore result in metabolic imbalance and low final product yield. To address this point, *E. coli* strains that control lycopene synthesis in response to carbon availability have been developed making use of the *glnAP2* promoter [14]. This promoter is stimulated by excess glycolytic flux through sensing of acetyl phosphate. This approach led to a significant increase in lycopene synthesis by *E. coli*. Other strategies to enhance the availability of central carbon metabolism precursors for isoprenoid pathway consist in the inactivation of competing pathways at the level of pyruvate and acetyl-CoA. This resulted in an increased carbon flux to IPP and therefore to lycopene with a production which was 45% higher [167]. In yeast, rerouting of the carbon flux into the targeted isoprenoid compound, that is, minimizing competing pathways, also appeared as a workable solution. A fivefold increase in amorphadiene production was reached by downregulating the squalene synthase expression, therefore limiting the sterol branch [168]. Several high-throughput approaches were also used to determine events not predicted by the knowledge base prediction pathway, for example, randomly genetic variations unrelated to terpenoid pathway but modifying it [169].

Additional limitations of metabolic engineering are linked to natural control points in organisms that balance supply and metabolite synthesis. Metabolic engineering struggles to refine these bottlenecks by adjusting the expression level of native/heterologous genes. A striking example of that approach is the case of paclitaxel, the successful anticancer drug, also named taxol. The engineered pathway in *E. coli* consists of its native MEP pathway plus a heterologous isoprenoid downstream pathway. This led to limited yield around 10 mg/L taxadiene [170]. This classical engineering ignores bottleneck effects or intermediate compounds' toxicity. Combinatorial approaches provide solutions to such issues. In this strategy, the complete pathway is split into two modules. Various gene copy numbers and promoters with different strengths drive expression levels of these two modules. *E. coli* strains with various combinations of these two modules were constructed and tested for taxadiene content. The best yield reached 1 g/L, almost 100-fold higher than yields obtained by classical engineering [154]. This example also demonstrates the potential of combinatorial approaches over classical engineering.

3.2.3 Challenges

As discussed in Sect. 2.1, the diversity of isoprenoid relies on the wide range of enzymes that are involved in these metabolic pathways (see Sect. 2.1.1). The sequence information concerning terpene synthase as well as the wide range of additional enzymes, for example, cytochrome P450 hydroxylases, dehydrogenases reductases, glycosyl transferases, etc., which contribute to diversify isoprenoids, is now available [62]. However, one important problem of isoprenoid engineering in microorganism hosts is managing functional expression of heterologous proteins. As an example, *E. coli* cannot functionally express the P450s enzymes that are extensively taking part in the isoprenoid biosynthetic pathway. Plant P450s are mainly membrane bound and they require a reductase partner for their function [13]. However, P450s coming from bacteria can be used. For instance, P450 from *Bacillus megaterium* is a fusion enzyme made of a P450 part and a eukaryote-like reductase domain [171].

Although microorganisms engineering offers many advantages over plant hosts for isoprenoid biosynthesis, many plant isoprenoid biosynthetic pathways are not yet completely known and are therefore not transposable into microbial strains.

3.3 Isoprenoid Metabolic Engineering in Plants: Current Achievements and Limitations

Plants present an interesting alternative to microorganisms since as natural terpenoid producers they possess all requirements for isoprenoid biosynthesis including the complex subcellular organization of this metabolic pathway and storage capacity both at the subcellular and tissue levels (See Sect. 2). In addition, plants have almost unlimited carbon resources insured by photosynthesis which makes them a good alternative to industrial incubator for microorganism production of isoprenoids. Obviously, one important objective of isoprenoid metabolic engineering in plants is to produce compounds of high added value that cannot be extracted in sufficient amount and at low price using natural resources [30, 151] such as the antimalarial compound, artemisinin a sesquiterpene extracted from *Artemisa annua* [9]. In addition, engineering of isoprenoid metabolism in plants is a rapidly expanding research field and there have been many attempts to manipulate monoterpene, sesquiterpene, diterpene, triterpene, or carotenoid syntheses over the last 15 years [24, 27–29].

3.3.1 Constitutive Expression of Selected Genes: A General Strategy to Manipulate Isoprenoid Profiles for Plant Trait Modification

Initial attempts to engineer isoprenoid metabolism in plants relied mainly on the constitutive overexpression of one selected enzyme with the aim to enhance the carbon flux for isoprenoid precursor synthesis or to modify isoprenoid profiles. Indeed, many successful manipulations were reported. As recent examples, the constitutive expression in tomato fruit of a citrus lycopene β-cyclase, which catalyzes the conversion of lycopene to β-carotene, led to a 30% increase in total carotenoid content and a fourfold increase in β-carotene [172], similar to previous attempts using the tomato *Lcyb* gene [173, 174]. Other works focusing on the overexpression of the *PSY1* gene in tomato [175] and in kumquat [176] led to an enhanced accumulation of phytoene, lycopene, and β-carotene. Constitutive expression of PSY1 in tomato was shown to cause competition for precursor availability with other isoprenoid pathways that require GGPP as a starting point. This resulted in abnormal plant phenotypes such as dwarfism due to depletion in gibberellins [175]. Similarly, the ectopic expression during tomato fruit ripening of the lemon basil α-zingiberene led to both mono- and sesquiterpene accumulation while lycopene accumulation was reduced, indicating a competition for plastidic DMAPP and IPP pools [177].

Yet, competition between pathways has been successfully used to redirect carbon flux toward the synthesis of selected isoprenoids by means of the constitutive overexpression of specific monoterpene and/or sesquiterpene synthases. Indeed, modification of monoterpene profiles has been successfully reported, demonstrating that part of the GPP pool could be efficiently redirected to the synthesis of limonene, γ-terpinene, or β-pinene in a series of plants including lavender, eucalyptus, or tobacco [178–180]. The absence of reported effect on plant development as well as the high emission level of the engineered monoterpenes reported is consistent with GPP being not limiting in these studies. In a similar way, constitutive overexpression of the maize *TPS10* gene in *Arabidopsis* plants led to a high level of the sesquiterpenes (E)-β-farnesene and (E)-α-bergamotene emission without detectable effects on sterol or other triterpene accumulation [181], indicative of sufficient FPP availability. This contrasts with other reports clearly indicating a limitation in GPP or FPP availability. Linalool emission in carnation constitutively expressing the *C. breweri* limonene synthase gene did not exceed 6% of total emitted volatiles [182] and minute amount of limonene was produced by tobacco plants expressing the *Perilla frutescens* limonene synthase gene under the control of the strong and constitutive promoter *E2I* [183]. Similarly, tobacco plants constitutively overexpressing a trichodiene synthase, the amorpha-4,11-diene synthase, or even (E)-ß-farnesene synthase only produced trace amounts of the targeted sesquiterpenes, probably due to limited FPP availability [184–186].

Similar strategies were developed to enhance artemisinin production, making use of *Agrobacterium*-mediated transformation of *A. annua* that was reported more than 15 years ago and optimized since that time [187, 188]. Overexpression of single gene, that is, the *IPT* gene from *A. tumefaciens*, the *FPS* gene from *Gossypium arboretum*, or even the gene encoding the enzyme amorpha-4,11-diene synthase (ADS) which catalyzes the first committed step to artemisinin, led to a limited increase in this compound accumulation. This raise ranged between 30% and 100% as compared to control without major differences between the engineered genes [188–191]. Metabolic analysis of the transgenic *A. annua* indicates that there are several bottlenecks that limit the deregulation of this metabolic pathway. These include limitation in the availability of IPP and DMAPP precursors that appear to be furnished by both the MVA and MEP pathways [192, 193]. This issue could be partly solved with the co-transformation of both HMGR and ADS that allowed the coordinate stimulation of precursor synthesis via the MVA pathway and of artemisinin synthesis. Yet the overall efficiency of this approach remained limited due to epigenetic effects, leading to transgene silencing [194].

Indeed, GPP, FPP, and other precursor availabilities may differ between plants, organs, and developmental stages and therefore explain the variability observed between independent experiments performed on tobacco, *Arabidopsis*, maize, and other plants. Consistent with this interpretation, the ectopic expression of enzymes of the MVA or of the MEP pathway led to increased level of MVA-derived isoprenoids (sterols, sesquiterpenoids [195–197]), and MEP-derived isoprenoids (monoterpenoids, chlorophylls, and carotenoids), respectively [86, 198]. Rerouting of GGPP was also possible in the *r* tomato mutant that lacks the fruit-specific phytoene synthase protein and therefore cannot accumulate carotenoid during fruit ripening. In this case, the expression of a taxadiene synthase in the yellow tomato fruits allowed the extraction of 160 mg/kg DW of taxadiene [199]. These plants were often parthenocarpic, produced less fruits and few viable seeds.

Hence, constitutive ectopic expression of selected proteins demonstrates the feasibility of terpene engineering in plants but also highlights several limitations. Among them competition between pathways for precursor availability may lead to unwanted secondary effects on plant development or may result in low product yield. Other limitation not discussed here includes further modifications of the selected product, (e.g., hydroxylation, glycosylation [79, 200]), as well as epigenetic effects (e.g., cosuppression [175]). In addition, constitutive TPS overexpression may lead to inhibitory effects on plant development due to product toxicity. As a conclusion, isoprenoid engineering using strong and constitutive expression of enzymes gives variable results, depending on terpenoid classes, organs, and plants. This demonstrates the requirement of more sophisticated strategies. Such strategies should consider the subcellular localization of the pathway, the necessity to reconstruct part or all pathways to take into account precursor limitation and competition as well as the tissue-specific expression of targeted gene and storage capacity of the products synthesized.

3.3.2 Plant as Cell Platform for the Production of Specific Terpenoids: Reconstructing the Isoprenoid Pathways in Chosen Subcellular Compartment

Terpenoids are mainly produced in the cytosol or in plastids (see Sect. 2). Relocating terpenoid synthesis to a nonnative cell compartment was shown to result in significant yield improvement in yeast [201], suggesting that it could also be successful for other cell producing platform including plants. Following the recent cloning of genes of the artemisinin pathway [202], *Nicotiana* species were used as heterologous hosts both with transient and stable transformation systems [26, 151, 203]. Transient assays using agro-infiltration allowed demonstrating that *Nicotiana benthamiana* could be used as a production platform for the artemisinin precursors, artemisinic and dihydroartemisinic acids, despite a limited accumulation due to internal glycolysation and insufficient oxidation toward the acids. However a real breakthrough was reached following the stable co-expression of up to five plant- and yeast-derived genes involved in the mevalonate and artemisinin pathways in tobacco plants, which led to low levels of artemisinin synthesis in this heterologous system [151]. Indeed, this could be achieved following a combination of favorable factors including the use of a multigene transfer system within a single vector to stably integrate five genes controlled by various promoters, the carbon flux enhancement through the MVA pathway by expressing a truncated form of the HMGR (tHMGR) enzyme that was shown to allow a tenfold increase in sterol biosynthesis [204], and the use of appropriate plant culture conditions. In addition, a major breakthrough was the targeting of amorphadiene synthase (ADS) to mitochondria which led to approximately five- to tenfold increase in artemisinin content as compared to plants with cytosolic ADS. The final yield remained however much lower than in *A. annua*. Further improvement may rely on providing sufficient precursors within the targeted subcellular compartment (i.e., mitochondria in the case presented here).

Consistent with this view, the targeting of FaNES1 to mitochondria only led to the synthesis of traces amount of nerolidol derivatives [139] due to a limited availability of FPP in *Arabidopsis* mitochondria. Inversely, the coordinate targeting to the chloroplast of an avian FPS and a sesquiterpene synthase, the patchoulol synthase (PTS) normally localized in the cytosol, led to a high level of patchoulol synthesis in tobacco leaves which accumulated up to 5–30 μg/g FW [205], above 100 times higher than when addressed to the native cellular compartment. This highlights that precursor availability is indeed a critical issue when redirecting the isoprenoid pathway in a new compartment that may require the co-introduction of several genes for a complete pathway reconstruction.

Multigene transfer (MGT) using *Agrobacterium*-based transformation has been described and a few reports describing this approach for isoprenoid metabolic engineering are available (for a recent review [147]). The best known example, "golden rice," was developed more than 20 years ago by introducing genes encoding the *PSY1* and *LYCB* gene from daffodil together with the bacterial *CRTI* gene which allows the synthesis of β-carotene from GGPP [206]. This strategy led to a limited accumulation of β-carotene (1.6 μg/gDW) that was increased to 37 μg/gDW when the daffodil PSY1 protein was replaced by the corn one which presents a higher activity [207]. More recently, similar approaches were successfully developed in canola [150, 208] or potato [209]. Yet MGT remains a challenging task that requires either to perform co-transformations without possible prediction on the output, retransformation of already transformed lines, or sexual crossing between transgenic lines. For this reason, MGT has often been limited to two to three genes and only few reports described the successful transformation with up to nine genes [150, 208, 210]. A recent technical breakthrough that allows the co-transformation of multigene arrays may provide tools for a routine multienzyme engineering of metabolic pathways in plants [211].

As far as expression in plastids is concerned, the recent development of transformation methods that allow the stable integration of up to six to seven genes in the plastidic genome opens a new alternative for multigene isoprenoid engineering in this cellular compartment. It is not the scope of this chapter to present a detailed analysis of transplastomic, which has been recently reviewed [212]. This approach presents many advantages including limitation of transgene flow and absence of epigenetic effects that may lead to gene silencing. Additionally stacking genes in operon allows the coordinated expression of series of proteins from polycistronic RNA. At the present time, transplastomic has been successfully used to introduce single gene for β-carotene synthesis in tomato [213] and for DXR overexpression in tobacco leaves [214]. More recently, the remodeling of the complete isoprenoid pathway in *N. tabacum* was achieved following the introduction of six genes of the MVA pathway into the chloroplast genome and their coordinated expression [215]. In these plants, both cytosolic and plastidic isoprenoid synthesis was impacted, further supporting the idea of cross talk between both compartments.

3.3.3 Control of Metabolic Pathways: From Promoters to Regulatory Proteins

Although successful in some cases, the use of strong and constitutive promoters for terpenoid engineering may lead to deleterious effects on plants due to competition between the new and endogenous pathways. A pioneering work performed on tomato more than 15 years ago clearly illustrates this point. Constitutive overexpression of the *PSY*1 gene, which encodes a functional phytoene synthase in tomato plants, resulted in an enhanced carotenoid synthesis in most plant organs. However, this also led to dwarfism following the competition created between PSY1 and the ent-kaurene synthase, which catalyzes the first committed step to GA synthesis [175]. This could be easily solved by using a fruit-specific promoter [216]. Indeed many works aiming at modifying the carotenoid profile in plants made use of organ- and/or tissue-specific promoters to limit potential secondary effects. These include the albumen-specific promoters used in rice and corn [150, 206, 207], tuber-specific promoters in potato [209, 217], seed-specific promoters in *Arabidopsis* and *Brassica napus* [208, 218], and promoters specific for tomato fruit ripening [216]. This targeted expression allowed modifying carotenoid profile in specific tissues without impacting other plant traits.

The use of regulatory proteins and mechanisms provides alternative approaches to modulate isoprenoid accumulation. At that time, the general knowledge of the regulatory network that governs isoprenoid accumulation has remained poor. Indeed it is known that both environmental and developmental factors may impact the synthesis of these molecules, depending on their physiological function (see Sect. 2.2), but very few regulatory proteins have been identified so far. The AaWRKY1 transcription factor which appears to be involved in the regulation of artemisinin biosynthetic genes, including the ADS gene, is one rare example of a TF that could be used to manipulate a terpenoid pathway [189]. Identification of transcription factors shall however provide essential tools to modulate all pathways, including steps that were not initially identified as essential for the accumulation of the targeted product. For example, the ORCA3 transcription factor that has been shown to regulate genes involved in terpenoid indole alkaloid synthesis also activates genes initially not anticipated (reviewed in [219]). Interestingly, the phytochrome interacting factors that repress photomorphogenesis are negative regulators of the *PSY* gene and provide an alternative approach to enhance the synthesis of this class of isoprenoid [220]. Light signaling mechanisms have been the recent focus of a tomato TILLING collection screen in order to identify regulatory proteins that impact carotenoid regulation during fruit development and ripening [221].

Other regulatory mechanisms affecting the transcriptional status of genes concern epigenetic mechanisms, that is, histone posttranslational modifications and DNA methylation directed by small RNA [222]. Such mechanisms have been recently shown to impact carotenoid biosynthesis in plants. Recent works demonstrate that carotenoid isomerase (CRTISO) regulation requires the SET DOMAIN GROUP 8 (SDG8) protein which is a chromatin-modifying histone methyltransferase [223]. Moreover, DE-ETIOLATED 1 (DET1), a negative regulator of light signal transduction pathway, affects carotenoid pathway [224, 225] and binds H2B histone in vivo, suggesting that DET1 may affect chromatin condensation states [226]. Furthermore, studies indicate that the abundance of ABA, a carotenoid-derived phytohormone, is in part controlled by HISTONE MONOUBIQUITINATION 1 (HUB1) that mono-ubiquitinates the histone H2B [227], and on the other hand, by DNA methylation mediated by a microRNA (miR402) under abiotic stress conditions [228]. LeSPL-CNR was identified as an epimutant that impacts carotenoid accumulation during tomato fruit ripening together with many other aspects of fruit maturation [229]. Indeed the manipulation of some of these regulatory proteins including DET1 and cryptochrome 2 (CRY2), a blue light receptor, in tomato led to an increased accumulation of fruit carotenoids [225, 230, 231]. Similarly, the repression of DET1 and the overexpression of the microRNA miR 156b resulted in higher accumulation of carotenoids in seeds [232, 233]. These results point out the potential of these approaches to modulate isoprenoid biosynthesis in plants.

Indeed tissue- and stage-specific promoters and regulatory proteins are well suited for modifying plant nutritional traits, for example, carotenoid profile and/or amount. The use of plant cells as platforms for the production of specific isoprenoid remains a more challenging task that requires the precise manipulation of cells capable not only to produce but also to accumulate high level of specific isoprenoids without any effect on cell viability. Plant glandular trichomes present these properties and, as such, are relevant targets for isoprenoid metabolism engineering. Such "green factories" may limit major drawbacks linked to the production of volatile terpenes and diterpenes in plants, that is, cytotoxicity of molecules [8], conversion to conjugated forms that limit the accumulation of the desired product [79, 200], or low accumulation levels due to evaporation of small terpenes. Indeed modifying oils' production in mint glandular trichomes has been achieved with constitutive promoters controlling the expression of the *DXR* gene to enhance IPP synthesis, as well as an antisense metofurane synthase gene to reduce the abundance of the corresponding compound [85, 86]. Similarly, an antisense construct driven by the P35S promoter was sufficient to reduce diterpenoid production in tobacco trichomes [234]. Much better results were however obtained with an RNAi construct using the cembratrienol synthase promoter specifically expressed in tobacco trichomes [235]. So far, the number of available trichome-specific promoters is limited [235, 236] which makes difficult the engineering of series of genes in this cell type.

4 Conclusion

Over the last 15 years, considerable progress has been made in the understanding and engineering of isoprenoid metabolism in both microorganisms and plants. Isoprenoid metabolic engineering pursues two main objectives: (1) the production of highly valuable compounds that can be achieved either using microorganisms or plants and (2) the modification of isoprenoid profiles in plants with the aim to modify agricultural or nutritional properties. In both cases, a general need of pathway knowledge including enzyme functions and regulatory mechanisms is fundamental. However, producing molecules of interest often necessitates a complete knowledge of all enzymatic steps to achieve sufficient yield and easy extraction process, which is not an absolute requirement when agricultural or nutritional traits are targeted.

In this context, genome sequencing programs as well as the public availability of EST resources from a wide range of plant species have boosted the current knowledge of genes encoding enzymes of this pathway. Of particular interest with respect to isoprenoid metabolic engineering, recent works have analyzed the genome wide distribution of enzymes encoding TPS genes using gene model in fully sequenced plant genomes [67], as they contribute to the huge diversity of isoprenoids. Most relevant experiments done are EST sequence analyses and RNA-seq approaches on plant tissues and cells known to accumulate high amounts of terpenoids (see, e.g., [69, 80, 116, 237–239]. Yet, many proteins that are identified as potential TPS have no attributed function. An important challenge will therefore be to develop high-throughput screening methods in order to determine TPS product specificity, which so far has mainly relied on the functional expression of proteins in *E. coli*. In some cases, the correlative analysis of selected gene expression and terpene emission provides information about TPS specificity (e.g., [132, 133, 240]. Indeed, at a larger scale, integration of transcriptomic data together with metabolic profiling of isoprenoids in various plant tissues may provide an efficient way to attribute functions to unknown TPS. Gene network reconstruction provides an alternative approach toward this goal and was recently used to determine the function of a transprenyl diphosphate synthase involved in the synthesis of the solanesyl part of ubiquinone 9 [60]. Function identification of proteins involved in the synthesis of the huge diversity of isoprenoids known so far – still increasing – will be an important research area for this pathway engineering in microorganisms as well as in plants.

A general limitation in isoprenoid production when it is aimed at producing and purifying molecules of interest is due to the low yield of targeted products. Although significant progress has been done in both microorganisms and plant-based systems, in many cases, the final amount of product reached does not allow industrial production. Each isoprenoid is produced via a specific set of reactions that necessitate being identified and transferred to selected hosts before optimizing yield and productivity. Indeed, combinatorial approaches used in *E. coli* have led to encouraging results for taxadiene production [154] and the use of protein engineering, with targeted or random mutations, combined with metabolic engineering was shown to be a relevant approach to achieve high production levels of isoprenoids in bacteria [166]. Successful production of isoprenoids has also been achieved in yeast and although initial experiments were almost exclusively performed in *E. coli*, mostly for the production of carotenoids there have been an increasing number of publications using yeast as a heterologous expression system for the production of functional isoprenoids [200]. Yeast cells present a cellular organization closer to plant cells than do bacteria. Furthermore, the functional expression of P450 enzymes, which is a critical issue for the production of isoprenoids in bacteria turned out to be easier in yeast [13]. This has led to major breakthrough using this cell system by redesigning part of the endogenous isoprenoid pathway with the aim of boosting acetyl-CoA flux toward the mevalonate pathway [241], enhancing IPP synthesis by means of a truncated HMGR [242], and overexpressing FPP and GGPP synthases for increase sesqui-, di-, and polyterpene syntheses [243]. The coordinate use of different intracellular compartments, for example, mitochondria and cytosol [201], allows the scaling up of the targeted isoprenoid production; this in turn opens new possibilities for the metabolic engineering in yeast but also in plants [151]. This highlights the interest of combining complementary approaches with various cell systems.

Indeed, plant-based systems are an appropriate alternative to heterologous system as they naturally produce many different types of isoprenoids and have unlimited carbon resources. Nonetheless, the efficiency of terpenoid metabolic engineering in plant is variable, depending on pursued objectives and isoprenoid classes. In a general sense, the success of a strategy will depend on the ability to redirect carbon flux toward the synthesis of the selected compounds. Hence, precursor availability is a main point that needs to be solved. Of course, in the case of monoterpenes, many successful attempts indicate that GPP might not be limiting although this may vary between organs and developmental stages. Inversely, low sesquiterpene yield suggests that the availability of FPP is often limited, as might be GGPP. Various strategies have been used to circumvent this issue, including overexpression of enzymes of the MVA or of the MEP pathway, the use of a deregulated HMGR enzyme, the spatial and temporal control of isoprenoid biosynthesis gene expression, and recently the retargeting of part of all precursor pathways in a nonnative compartment that may relieve the normal control of carbon flux within this new pathway. At this stage it should be noted that very little work has been focusing on the interface between isoprenoid synthesis and carbon primary metabolism. Yet, both the MVA pathway and the MEP pathway directly depend on the carbon flux provided by the TCA cycle and by the glycolysis, respectively. In this context, it is particularly relevant that genes involved in photosynthesis and carbon fixation are expressed in *Solanum* trichomes that accumulate high terpenoid levels [116]. Furthermore, depletion of sucrose availability in tomato fruit pericarp has been shown to dramatically limit lycopene accumulation, indicating a direct link between carotenoid synthesis and carbon availability [244]. This is consistent with the recent demonstration that impairing PRL1 (PLEIOTROPIC REGULATORY LOCUS 1), which results in sugar accumulation in *Arabidopsis* seedling, enhances isoprenoid accumulation [245]. These results indicate that system biology approaches with the integration of isoprenoid metabolism together with carbon primary metabolism should be developed with the aim to identify important control points involved in the control of terpenoid accumulation. Coordinate regulation of isoprenoid and precursor pathways might also occur at the transcriptional level. Indeed, it is well established that in many cases, isoprenoid accumulation is primarily controlled at the gene expression level although there is no transcription factors identified that control genes of the isoprenoid pathway. Therefore, identifying relevant TFs might provide alternative strategies to deregulated isoprenoid accumulation in plants. Similarly, unraveling the relevance of epigenetic type of regulation in relation with environmental constraints or development cues might also provide new tools to fine-tune isoprenoid production in relation to chromatin remodeling mechanisms.

Efficient terpenoid engineering is also dependent on the storage capacity of end products. This was elegantly illustrated following the characterization of the cauliflower *or* mutant which creates a metabolic sink by enabling chromoplast differentiation, therefore carotenoid accumulation [144]. End product storage is also a critical issue when volatile or diterpenes need to be produced and purified. Indeed reprogramming flower scent or terpene emission as a response to pathogens may not require high storage capability, contrary to the production of molecules of interest such as artemisinin, normally produced in glandular trichome of *A. annua* [202]. Glandular trichomes have been the focus of intense research over the last few years using combined transcriptomic and metabolic profiling approaches [115] and evidence indicates a close relationship between the control of the MEP pathway, volatile terpene synthesis, and trichome density in tomato [246]. No doubt that such approach will allow unraveling the specific metabolism of these cells and provide tools to efficiently use them as "green factories" for the production of highly valuable terpenes.

Acknowledgments We wish to thank Dr Sophie Colombié for critical reading of this manuscript. Dr Anne Pribat was in receipt of a grant from the French National Research Agency (ANR) in the frame of the "Polyterp" project.

Abstract

There is a rising concern about the nutritional and functional properties of food and its use to promote human health and prevent diseases. Considering the high level of consumption of tomato, this vegetable has become an ideal source of health promoting compounds. Among the terpenes, carotenoids have received most part of the attention. The terpenes lycopene and β-carotene have been related to decreased levels of certain heart diseases as well as certain types of cancer. Consequently, a high interest has been placed in the selection of lines with increased levels of these terpenes. The main difficulties in this process have relied on the necessity to separate genotypic effects on the trait from

environmental or interaction effects. On the other hand, the availability of rapid and efficient methods to determine the content in these compounds has also limited progress in the area. Mutants identified in the cultivated species and wild relatives enable an improved accumulation of total carotenoids or a different distribution among them. Some of these mutants have been used in the development of new cultivars, but usually involve a decrease in yield. The modification of the biosynthetic pathway via genetic engineering has contributed to the dissection of these allelic variants, and to provide new approaches for the development of high carotenoid lines.

Keywords

β-carotene • Breeding • Genetic engineering • Lycopene

Abbreviations

ABA	Abscisic acid
CRTISO	Carotene isomerase
CRTR-B	β-ring hydroxylase
CRTR-E	ε-ring hydroxylase
CYC-B	Chromoplast-specific lycopene-β-cyclase
DXS	1-deoxy-D-xylulose-5-phosphate synthase
EMS	Ethyl methanesulphonate
GGPP	Geranylgeranyl pyrophosphate
IPP	Methylerythritol-4-phosphate
LCY-B	Lycopene-β-cyclase
LCY-E	Lycopene-ε-cyclase
MEP	Methylerythritol-4-phosphate
MVA	Mevalonic acid
NXS	Neoxanthin synthase
PDS	Phytoene desaturase
PSY	Phytoene synthase
ZDS	ζ-carotene desaturase
ZE	Zeaxanthin epoxidase

1 Introduction

The concept of quality for tomato, as well as for other vegetables, has evolved during the last decades. In previous years, the demands of wholesalers and retailers prevailed in the development of new varieties and quality was based on the external appearance of the fruit. Consequently, varieties with high uniformity, deep red color, without green shoulders or cracking scars, and with a long shelf-life were demanded. The focus in breeding programs was set in the external appearance together with high yields and disease resistance, neglecting other aspects such as flavor. As a result, this last trait degenerated progressively and consumers' complaints on tomato flavor became generalized [1]. Ever since, organoleptic quality started to receive more attention by the seed industry.

Following this shift of the quality concept from the external appearance to internal attributes, the health benefits of whole food consumption started to be valued [2]. Accordingly, the nutritional value and functional value of tomato varieties gained importance as breeding objectives. In this area, among the complex family of tomato terpenes, carotenoids and especially lycopene and β-carotene represent the maximum potential for improved internal quality and they have been thoroughly studied during the last two decades. Their antioxidant characteristics have been related to the prevention of degenerative diseases, and thus, they have become a major component of the functional value of tomato.

In this context, a high content in these phytochemicals has gained importance in the tomato marketing. Nevertheless, it is difficult to tell whether consumer interests in healthy products have conditioned the marketing of produces based on health functionality or vice versa [3]. In fact, the correlation between food and health is still open to debate, though it seems that diet plays a major role in the development of different cancers [4]. In a review of more than 200 studies, Block et al. [5] concluded that persons with low fruit and vegetable intake experience twice the risk of cancer compared to those with high intake.

In the case of carotenoids, it has been observed certain inverse relation between their intake in the diet, mainly lycopene and β-carotene, and the development of certain types of cancer [6–8], and a reduced incidence of heart disease [9–11].

In a recent review performed by the U.S. Food and Drug Administration including several studies relating tomato consumption and reduced cancer risk, it was concluded that evidences supporting this correlation were very limited [12]. In the same line, the association of fruits and vegetables intake and the occurrence of coronary heart disease has been questioned [13].

Nonetheless, it should also be considered that it is difficult to prove that a certain component of a complex diet is specifically directly responsible for reduced risk of suffering a disease with a prolonged evolution or a heart disease. The fact that the risk of suffering both types of diseases is determined by a complex mix of different factors combined in different ways in different individuals also adds complexity to the analysis of epidemiological studies and clinical trials.

In fact, recent publications show that carotenoid derivatives would participate in the modulation of transcription systems important in cancer and inflammatory processes [14]. And new large-populations studies again confirm the existence of a relationship between carotenoid intake and the probability of suffering certain cancers. For example, in the case of breast cancer, carotenoid intake would have an inverse relationship with cancer in premenopausal women (especially for smokers), but not in postmenopausal [15].

Despite the absence of clear evidence for a role in prevention of diseases, carotenoids continue to play a role in the diet of consumers and continue to be debated in the light of recent dietary trends [16]. Thus, the research on the effects of carotenoids on health should go on, as well as the efforts to provide new varieties with higher amounts on these terpenes. Here we review the progress made during the last years in the development of high carotenoid lines following conventional and genetic engineering strategies, as well as the limitations found by breeders in the process.

2 Occurrence

Carotenoids include many of yellow, orange, and red pigments present in nature, providing colors to different organs. In the case of tomato, carotenoids are synthesized in leaf tissues, flowers, and fruits. In leaves, β-carotene, lutein, violaxanthin, and neoxanthin are accumulated, with lutein representing the higher concentrations (Table 92.1). In these tissues, carotenoids play an important role in the performance of the plant light-harvesting complex as photoprotectors [19]. In the flowers, the typical yellow color of tomato petals is due to the accumulation of the xanthophylls violaxanthin and neoxanthin [18]. Finally, in the ripe fruits, lycopene is the most abundant carotenoid followed by β-carotene (Table 92.1).

It should be considered though, that the distribution of major carotenoids in the ripe fruit is irregular, with more than twofold amounts of lycopene in the pericarp than in the locules and fourfold higher amounts of β-carotene in the locules than in the pericarp [17].

Carotenoids are synthesized in plastids: in chloroplasts in green tissues, and in chromoplasts in ripening fruits and flowers. During the ripening process, chloroplasts are converted to chromoplasts. The thylakoid structures disassemble, chlorophylls are degraded, and plastoglobules accumulate. Plastoglobules represent the site for accumulation of high amounts of carotenoids [20].

At the mature green stage, all the plastids in the fruit are chloroplasts; at the breaker stage, intermediate chloro-chromoplasts can be identified with both chlorophylls and carotenoids; and at the red ripe stage, only fully developed chromoplasts are found [21]. Recent studies [22] show that following the ripening process, lycopene starts to be found in tomatoes at the breaker stage in tissues of the locular cavities, under the outer pericarp, and it increases in concentration as the process continues (Fig. 92.1). Consequently, the external color changes generally lag behind the internal composition changes.

3 Biosynthetic Pathway

The analysis of tomato color mutants found in *Solanum lycopersicum* or in crosses with related wild species, as well as genetic engineering studies have clarified enormously the biosynthetic pathway of carotenoids. Carotenoids, as other plastid isoprenoids, derive from isopentenyl diphosphate (IPP). IPP used in the synthesis of these compounds may arise at some developmental stages partly from the mevalonic (MVA) pathway [23], but it is mainly synthesized through the methylerythritol-4-phosphate (MEP) pathway [24]. The first enzyme of this pathway,

1-deoxy-D-xylulose-5-phosphate synthase (DXS), has shown a strong correlation with carotenoid synthesis during fruit development and has been proved to catalyze the first regulatory step in carotenoid biosynthesis [25].

The initiation of the carotenoid biosynthesis pathway requires four IPP units that will be joined progressively including isomerization and condensation reactions to form geranylgeranyl pyrophosphate (GGPP), which is the immediate precursor of carotenoids (Scheme 92.1). Two units of GGPP would then be condensed to form 15-*cis*-phytoene. This reaction is catalyzed by the enzyme phytoene synthase (PSY).

In tomato two PSY encoding genes have been identified: *Psy-1* and *Psy-2*. *Psy-1* encodes the fruit-ripening-specific isoform, which has been proved to be the key enzyme in the control of carotenoid biosynthesis [28]. *Psy-2* encoded enzyme predominates in green tissues (including mature green fruit) and petals and has no role in carotenoid synthesis in ripening fruit [29, 26]. As an example of the role of this enzyme in carotenoid biosynthesis, a null mutation in *Psy-1* in the yellow-flesh (*r*) mutant arrests carotenoid synthesis [30]. In this mutant, the accumulation of the flavonoid rutin in the fruit skin would lead to the development of yellowish fruits.

Continuing the pathway, 15-*cis*-phytoene would suffer then two desaturations carried out by phytoene desaturase, PDS [31], forming phytofluene and ζ-carotene. Two subsequent desaturations are then performed by ζ-carotene desaturase (ZDS) forming neurosporene and finally tetra-*cis*-lycopene (prolycopene).

The analysis of the tangerine (*t*) mutation with orange fruit phenotype due to the accumulation of prolycopene enabled the identification of a carotene isomerase, CRTISO, which is responsible for the conversion of prolycopene to all-*trans*-lycopene [32]. The accumulation of all-*trans*-lycopene as the primary carotenoid in ripe tomato fruits enables the development of red color starting from the colorless precursor phytoene.

Carotenoid pathway continues with the cyclization of lycopene, involving the formation of 6C cyclic end groups. Two major enzymes participate at this point: lycopene-β-cyclase (LCY-B) and lycopene-ε-cyclase (LCY-E). Unusually, tomato contains two lycopene β-cyclases, LCY-B [33] as described above, and also CYC-B, a chromoplast-specific cyclase that would play a major role in carotenoid accumulation in fruits [34]. Lycopene β-cyclase forms initially γ-carotene which only accumulates to traces in ripe fruits as a second β-ring is added by the same enzyme to yield β-carotene.

In red ripe tomatoes, the activity of lycopene β-cyclases is low. In fact, LCY-B transcription level decreases at the breaker stage [33]. On the contrary, in mutants such as Beta (*B*), with orange fruits, CYC-B transcription is dramatically increased, reducing lycopene fruit content and increasing β-carotene accumulation. In fact, the major differences between the wild allele (*b*) and that responsible for the beta phenotype (*B*) exist in the promoter region [34]. Other two alleles of the same gene, the *old-gold* (*og*) and old-gold-crimson (og^c) mutants, represent null alleles arising from two different frameshift mutations. These alleles result in increased lycopene content, as β-carotene synthesis becomes restricted. Another gene linked to *Beta*,

Scheme 92.1 Carotenoid biosynthesis pathway in tomato (Adapted from [18], [25], [26] and [27]). Mutants for each enzyme are identified in *square brackets*. Genes involved in external regulation represented in the *squares*

Beta modifier (*mo*$_B$) modifies the expression of *Beta*. In *BB mo*$_B$ *mo*$_B$ genotypes 90 % of the carotenoid content is present as β-carotene and the fruits are orange. On the other hand, in *BB mo*$_B{}^+$ *mo*$_B{}^+$ 50 % of the carotenoids are present as β-carotene and lycopene accumulates up to less than 50 % of total carotenoids, resulting in red-orange fruits [35].

Following an alternative sub-pathway LCY-E using lycopene as substrate introduces an ε-ring forming δ-carotene. Interestingly, LCY-B may also play a role in this sub-pathway introducing an additional β-ring in the other end of the molecule and yielding α-carotene from δ-carotene. In common red fruit cultivars, the transcript level of LCY-E decreases at the breaker stage to undetectable levels in the ripe fruit. In the delta tomato mutant (*Del*), characterized by an orange fruit color due to δ-carotene accumulation, the transcript level of LCY-E is increased 30-fold during fruit ripening [36].

Xanthophylls are formed by the hydroxylation of carotenes. Specific hydroxylases perform its function on β-rings (CRTR-B) or ε-rings (CRTR-E). Regarding β-ring hydroxylases, CRTR-B1 and CRTR-B2 hydroxylases have been described in tomato. The homolog gene encoding CRTR-B1 is present in all tissues, though the highest expression levels are detected in leaves, while CRTR-B2 would be expressed in chromoplasts of flowers and fruits [18].

The action of CRTR-B would yield zeaxanthin from β-carotene following two hydroxylations with beta-cryptoxanthin as intermediate. On the second sub-pathway, it was initially proposed that the joint action of CRTR-E and CRTB2 would produce lutein from α-carotene with α-cryptoxanthin as intermediate [37]. But recent works [26] show that the β-ring hydroxylase CYP97A29 (also CRTR-B1 and CRTR-B2) would produce zeinoxanthin that would be converted to lutein by the ε-ring hydroxylase CYP97C11. Only when β-hydroxylases are impaired or downregulated, α-carotene would be hydroxylated by CYP97C11 yielding α-cryptoxanthin. As β-ring hydroxylases would not be able to hydroxylate the β-ring of α-cryptoxanthin efficiently, no lutein would be produced.

Epoxidation of zeaxanthin by zeaxanthin epoxidase (ZE) would result in the production of violaxanthin via antheraxanthin. From that substrate, the enzyme neoxanthin synthase (NXS) would yield neoxanthin opening the cyclohexenyl 5–6 epoxide ring in violaxanthin [38]. Neoxanthin would be the last product of carotenoid biosynthesis in green parts of the plant, and it would derive in the abscisic acid (ABA) synthesis pathway. The accumulation of neoxanthin and violaxanthin in flowers results in wildtype yellow petals. A defective mutation in the gene encoding CRTR-B2 prevents formation of these xanthophylls, resulting in the white-flower phenotype [18].

Defective ZE mutants may result in an arrest of the ABA biosynthetic pathway that starts from the neoxanthin produced with zeaxanthin [39]. Consequently these mutants may result in wilty phenotypes. In the case of the mutant *high pigment-3* (*hp-3*), coding a defective ZE, it seems that ABA deficiency would increase plastid division, enabling higher biosynthesis and accumulation of carotenoids [40].

The carotenoid biosynthetic pathway described can be regulated at different levels. Some regulations would result in a global increase or decrease of carotenoids, while others would change the natural accumulation profile of carotenoids rather than the global amount.

It must be considered that the development of chromoplasts and plastoglobules is necessary step in the accumulation of carotenoids. The primary growth regulator of the fruit ripening process also plays a major role in the control of the carotenoid synthesis pathway. The key enzyme phytoene synthase (PSY) is under strong positive control of ethylene, and lycopene β-cyclase (LCY-B) is repressed by ethylene resulting in a primary accumulation of lycopene [20]. In fact, during the ripening process, the regulation of the pathway involves an increase in the mRNA levels for the lycopene-producing enzymes phytoene synthase (PSY) and phytoene desaturase (PDS), while the mRNA levels of the genes for the lycopene β- and ε-cyclases, which convert lycopene to either β- or δ-carotene, respectively, decline and completely disappear. Consequently, mutations affecting ethylene synthesis or perception, such as *rin*, *nor*, *alç*, etc., apart from affecting the normal ripening process also result in altered carotenoid content.

Apart from the light-independent component of the carotenogenesis regulation, there is also a light-dependent component. In fact, fruit-localized phytochromes also regulate the extent of carotenoid accumulation [41]. In this context, the mutation *high pigment-1* (*hp-1*), and the allelic *hp-1*^{w}, represents a mutation in a tomato UV-damaged DNA Binding Protein (DDB1) homolog [42]. As a result, the plant would act as perceiving a continuous perception of light. The mutation *high pigment-2* (*hp-2*), and the allelic *hp-2*^{j} and *hp-2*^{dg} [43], affects the photomorphogenesis regulatory gene TDET1 [44], and also affects the light signal-transduction machinery and results in enhanced global carotenoid content. Another mutant, *Intense pigment* (*Ip*) is implicated in a promotion of phytochrome signal amplification [45] and results in 34–38 % more soluble solids and 62.6 % more total carotenoids [46]. Therefore, the modification of light perception may also have a role in the strategies followed in breeding efforts for carotenoid content improvement.

Regarding other modifications that may result in global carotenoid increase, as stated before, an alteration in the ABA pathway, such as in the case of the *high pigment-3* (*hp-3*) mutant, may result in increased carotenoid content, but it may be related with increased plastid division [40].

Instead of a global increase or decrease in total carotenoid content, changes in the enzymes of the biosynthetic pathway may result in a different carotenoid profile. As explained before, the *r* mutant affecting PSY results in an arrest of carotenoid biosynthesis and yellow fruits and the *t* mutant affecting CRTISO accumulates prolycopene and produces orange fruits. After the synthesis of all-*trans* lycopene, the *Del* mutant affecting LCY-E results in δ-carotene accumulation at the expense of lycopene and orange fruits. On the other branch of the pathway, the mutants *B*, *og*, and *og*^{c} affect LCY-B and result in increased β-carotene content at the expense of lycopene (*B*) or increased lycopene at the expense of β-carotene (*og* and *og*^{c}). Finally, the mutant *hp-3*, apart from its side effects related with the ABA pathway, results in decreased content of violaxanthin and neoxanthin.

4 Breeding Strategies

A breeding program for improved carotenoid content in tomato requires, in general, three phases: (a) identification of genotypes with high potential for the accumulation of carotenoids, (b) transfer of the genes controlling the trait into breeding lines, and (c) the evaluation of the expression of the introgressed genes in the new genetic background and selection of elite genotypes with good agronomic performance.

At the moment two main strategies are followed in order to transfer desired genes into breeding lines. The first one involves the exploitation of natural diversity present in the genus. Donor parents are selected among genetic resources of the cultivated species and related wild species, once their carotenoid profile has been evaluated. The genetic control of the trait may be ascertained after the analysis of family progenies. If the genetic control is simple, the efficiency of the breeding program would be higher, though it is not mandatory. Once the donor resources have been identified, the genes responsible for the trait can be introgressed into breeding lines following different hybridization strategies and selection generations. In the process, both carotenoid content and agronomic performance are considered in the selection of appropriate genotypes. Technical advances in genetic engineering have promoted a second strategy during the last decades. Several of the genes controlling high carotenoid content in the genus or in other species and even kingdoms have been cloned and introgressed directly, causing minor alterations of the genetic background of breeding lines. The introgressed genes may alter the biosynthetic pathways and result in increased or decreased contents of compounds related to nutritional or functional value.

Independent of the strategy followed, during breeding programs, two major limitations arise. The first one involves the difficulty of developing a rapid, wide, and precise evaluation of carotenoid contents in breeding lines during the different generations of a breeding program. The second is related to the important environmental influence in the accumulation of carotenoids in tomato [17] that interferes with the identification of the genetic potential of the plants being evaluated. Both factors make extremely difficult an efficient evaluation and selection of elite genotypes and hinder the development of new cultivars with improved carotenoid content.

4.1 Conventional Breeding

The breeding objectives concerning terpenes content and nutritional or functional value have been centered on the development of cultivars with high contents in lycopene and/or β-carotene. These objectives have been pursued for more than 70 years, developing studies targeted to the identification of sources of variability that could be used as donor parents in breeding programs. In this sense, wild species of the genus *Solanum Lycopersicum* related to the cultivated tomato have provided a valuable range of diversity that was lost during the domestication process in the cultivated species.

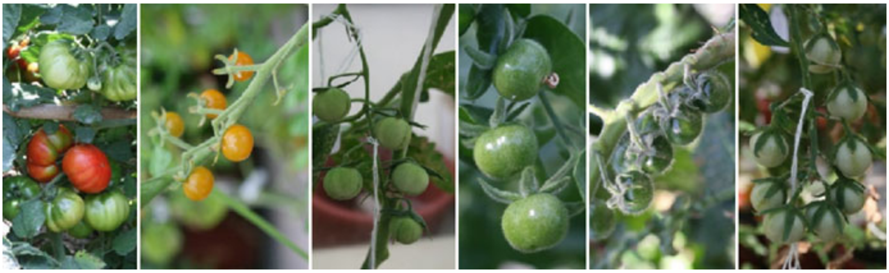

Fig. 92.2 Genetic resources used for the identification of genes modifying carotenoid contents or profile. From *left* to *right*: *Solanum lycopersicum, Solanum chesmaniae, Solanum chmielewskii, Solanum pennellii, Solanum habrochaites, and Solanum chilense* (Photo courtesy of J.V. Valcárcel, COMAV)

Initially, one of the breeding strategies that received great efforts was targeted to the identification of useful variability in the wild species of the section with green fruits (Fig. 92.2), mainly *Solanum habrochaites, Solanum chmielewski, Solanum neorickii, and Solanum pennellii* [48] (Classification following Peralta and Spooner [47] which corresponds to *L. hirsutum, L. chmielewskii, L. parviflorum*, and *L. pennellii*, respectively.). Considering that the lycopene content in these species with green fruits is practically null and the content in β-carotene is low and that in tomato normal contents average 30 mg kg^{-1} [49, 50] and β-carotene 4 mg kg^{-1} [49], it may seem that these sources of diversity would not be the most appropriate. Nevertheless, after several backcrossing generations toward the cultivates species, followed by several selfing generations, an incredible variability was revealed for the accumulation of different carotenoids including the sought lycopene and β-carotene, as well as, phytoene, phytofluene, δ-, α-, and γ-carotene, among others [51, 52]. This new diversity and especially the transgressive segregation of some part of it (especially for lycopene) enabled the selection of genotypes with high carotenoid contents in advanced generations.

This wide range of variability in carotenoid contents relies on considerable differences in the carotenoid biosynthesis pathway between parent species. Therefore, it has been difficult to select in the different progenies genotypes with high carotenoid content. Only after several backcrossing generations, the biosynthesis pathway has been normalized and new phenotypes have been revealed. In fact, this procedure enabled the identification of the mutant phenotypes and genes *B*, mo_B, and *Del* involved in high accumulation of β-carotene and δ-carotene as a result of lycopene cyclization (Table 92.2).

For commercial breeding purposes, the gene *Del* has limited interest, as δ-carotene has no activity as provitamin A. Other mutants such as the mutant *apricot* (*at*) identified in a Mexican population of *S. lycopersicum* conferring an apricot color due to β-carotene accumulation in the absence of lycopene [58] have received little attention. Therefore, most interest has been placed in the selection of genotypes carrying the *B* gene with its modifier mo_B. The most important fresh

Table 92.2 Mutant genes that alter the normal carotene biosynthesis in tomato fruits [30, 34–36, 40, 42, 44, 45, 53–57]

Genes[a]	Species of origin[b]	Gene action	Phenotypic characteristics
t	*S. lycopersicum*	Determinates the poly-*cis* structure of the polyene chain of carotenoid molecules (in opposition to the common all-*trans* carotene structure). Codes a defective CRTISO.	Orange colored fruits due to tetra-*cis*-lycopene accumulation.
at	*S. lycopersicum*	Inhibition of lycopene accumulation without effects on β-carotene synthesis. Probably related to carotenogenesis regulation.	Apricot-like colored fruits.
[B,og, og^c], mo$_B$	*S. chmielewskii (B, mo$_B$), S. habrochaites (B, mo$_B$), S. pennellii (B, mo$_B$), S. neorickii (B, mo$_B$), S. cheesmanii (B), S. galapagoense (B), S. lycopersicum (og, og^c)*	*B* gene increases the β-carotene content at the expense of lycopene by cyclization of lycopene into β-carotene; *og* and *og^c* are null mutants in the locus *B* that block cyclization of lycopene; mo$_B$ is a gene modifier for the *B* gene. *B* encodes CYC-B with altered promoter; *og* and *og^c* encode defective CYC-B	*B* gene induces fruits orange or orange-red in color whereas *og* genes produce dark-red color of fruits even in the early stages of ripening.
Del	*S. chmielewskii, S. chilense, S. pennellii*	Increases the cyclization of lycopene into δ-carotene (increases δ-carotene at the expense of lycopene). Encodes LCY-E.	Orange-red colored fruits due to accumulation of δ -carotene
[hp-1, hp-1^w] *[hp-2, hp-2^j, hp-2^{dg}]*	*S. lycopersicum*	High total carotene content via light regulation.	Higher pigmentation in leafs and fruits. The *hp* genes introduce certain unfavorable traits: slow seed germination and sprout growth, low survival percentage, and breaking plants
Ip	*S. chmielewskii*	High total carotene content via light regulation.	Similar phenotype to *hp* mutants but with lower deleterious effects

(*continued*)

Table 92.2 (continued)

Genes[a]	Species of origin[b]	Gene action	Phenotypic characteristics
r	*S. lycopersicum*	Low total carotene content. Encodes a defective PSY	Yellow pigmentation in fruits by accumulation of the flavonoid rutin.
hp-3	EMS-induced mutant in *S. lycopersicum*	Encodes a defective ZE, blocking the ABA biosynthesis pathway and resulting in increased plastid division	Higher carotenoid accumulation and deep red colored fruits

[a]Genes into brackets have allelic relationships. Genes notated with uppercase are dominant and with lowercase are recessive. *Del* gene is partially dominant.

[b]Classification following Peralta and Spooner [47] (information obtained using with previous classification was actualized).

tomato cultivars developed introgressing these genes have been Caro Red [59] and Caro Rich [60]. These cultivars show orange fruits with β-carotene contents up 50 mg kg^{-1} (roughly tenfold the normal content in standard red cultivars).

In accessions with orangish fruits of the species *Solanum galapagoense, S. cheesmanii*, and *S. pimpinellifolium* (Classification following Peralta and Spooner [47] which corresponds to *L. chesmaniae* (the two first) and *L. pimpinellifolium* respectively.) with high contents in β-carotene, the mutations for the genes *B* and *mo*$_B$ have also been identified [51, 61–65]. But in this case, the carotenoid biosynthesis pathway is similar to the one in cultivated tomato except for the lycopene cyclization mediated by the gene *B*. In these accessions the content in β-carotene is about 60 mg kg^{-1} and lycopene content is very low.

The introgression of these mutations from these species into *S. lycopersicum* is very simple and efficient, as these species have good crossability with cultivated tomato, and it is easier and faster to identify genotypes with interesting pigmentation characteristics.

This approached has been used in the development of the processing tomato cultivar Caro beta (30–40 mg kg^{-1} β-carotene) from a cross between *S. lycopersicum* and *S. galapagoense* [66]. Several indeterminate lines have also been developed with β-carotene contents ranging 60–80 mg kg^{-1} [67]. One accession of *S. lycopersicum* (former var. *cerasiforme*) with orangish fruits has also shown similar β-carotene contents to Caro beta but with standard lycopene contents [68] and shows an additive genetic control [69]. This accession constitutes an alternative and interesting source of variation yet to be exploited.

Unfortunately, the cultivars developed with orange fruits and high β-carotene content have not been commercially successful, as consumers seem to prefer red tomato varieties. Consequently, these nongreen wild relatives, specifically the former var. *cerasiforme* of *S. lycopersicum*, *S. pimpinellifolium*, and *S. cheesmanii*, have been used as sources of variability for high lycopene red-fruited cultivars.

In the former var. *cerasiforme* of *S. lycopersicum* and *in S. pimpinellifolium*, accessions with five- to ninefold lycopene content and three- to fourfold β-carotene content compared to standard cultivars have been identified [52, 70–72]. These materials have great interest in the development of red cultivars with high contents of both compounds [52, 70–72].

The mutants old-gold (*og*) and especially old-gold-crimson (*og*^{c}) identified in *S. lycopersicum* offer another approach increasing specifically lycopene content. These mutants are allelic to the gene *B* [34] and inhibit the cyclization of lycopene to yield β-carotene and result in increases of 30 % in lycopene and a reduction of 40 % in the accumulation of β-carotene [27]. Several cultivars of the crimson type have been developed using these mutants, and despite their lower β-carotene content, they have succeeded commercially due to their intense red pigmentation even when the fruits are not completely ripe, thus satisfying consumer preference regarding external appearance.

Nonetheless, the best results in the development of high carotenoid content cultivars have been obtained using accessions carrying the mutants for the genes *hp-1*, *hp-2*, and *hp-2*^{dg}. These genes improve total carotenoid content over two- and threefold [73–77] without affecting significantly the carotenoid partition of standard cultivars. Cultivars carrying both crimson and high pigment produce fruits with lycopene content up to three- to fourfold that of the standard varieties [78]. Despite the efficiency of these mutants, cultivars with the *hp* genes have associated undesirable pleiotropic effects such as slow seed germination, increased seedling mortality, brittle stems, premature defoliation, and reduced yields. These deleterious effects have limited the success of these varieties, as a yield reduction compensates the benefits of higher carotenoid content.

The mutant *Intense Pigment* (*Ip*) introgressed into *S. lycopersicum* from *S. chmielewski* [79] has effects on carotenoid accumulation similar to those of the genes *hp*, but in this case, the *Ip* gene is dominant, and thus, it is more interesting for the development of hybrid cultivars, avoiding the introgression of the other recessive genes in both parent lines. Additionally, this mutant shows less deleterious effects on seed germination and plant vigor.

The monogenic mutants described have great effects on fruit pigmentation. In fact, several of them have been cloned and sequenced. Therefore, marker-assisted selection is feasible in breeding programs to introgress these mutant genes in parent lines of hybrid cultivars. But despite the advances in the knowledge of these sources of variation, their contributions in the development of new cultivars have been limited. Another alternative to the use of monogenic mutants follows the trends for other quantitative traits with an expression relying in complex metabolic processes. In this context, in addition to phenotypic selection, a great effort is being placed on the identification of quantitative trait loci (QTL) linked to variation in fruit pigmentation. This procedure emulates the approach applied to the selection of cultivars for improved fruit firmness or soluble solid contents. Numerous QTLs introgressed from *S. pimpinellifolium* [80, 81], *S. habrochaites* [82–84], *S. pennellii* [85], *S. peruvianum* [84, 86], and *S. neorickii* [87] or detected in *S. lycopersicum* [88, 89] have been reported.

Nevertheless, it is still necessary to continue in this direction, as the use of QTL-assisted selection may boost the exploitation of the variability present in related species, especially in *S. pimpinellifolium*. The use of markers is a priceless tool to enable selection in early stages of development, avoiding late and costly determinations in ripe fruits.

4.2 Genetic Engineering

A considerable advance has been made during the last decade in the knowledge of the biosynthesis of carotenoids, the metabolic pathway, its precursors, and its regulation. Following this advance, numerous works have been published reporting high carotenoid tomato lines obtained by manipulating the genes controlling several steps via genetic engineering. Most of this works try to emulate the results of the mutants identified using conventional approaches, and some even try to avoid undesirable side effects.

Regarding the manipulation of isoprenoid precursors pathway, it has been attempted to increase the levels of IPP required for the formation of geranylgeranyl diphosphate, the first step in the carotenoid pathway. This has been achieved by intervening in the mevalonic (MVA) pathway expressing constitutively the gene 3-hydroxymethylglutaryl CoA (*hmgr-1*) from *Arabidopsis thaliana* and in the methylerythritol-4-phosphate (MEP) pathway using the gene 1-deoxy-ᴅ-xylulose-5-phosphate synthase (*dxs*) from *Escherichia coli* [90].

The use of *hmgr-1* resulted in elevated levels of phytosterols (up to 2.4-fold), but IPP-derived isoprenoids in the plastid were unaltered. Transgenic lines containing the bacterial *dxs* targeted to the plastid with the tomato *dxs* transit sequence resulted in an increased carotenoid content (1.6-fold), with phytoene and β-carotene exhibiting the highest increases (2.4- and 2.2-fold, respectively). This result emphasizes the idea that IPP used for the carotenoid pathway is mostly obtained from the MEP pathway [24].

In a second approach, several works have been targeted to alter the enzymes that directly participate in the carotenoid biosynthesis pathway. Among these, phytoene synthase, phytoene desaturase, and lycopene cyclases have received most part of the attention.

Fray et al. [91] expressed constitutively a tomato phytoene synthase (PSY1) in tomato, but in this case, high expressers showed reduced height. It was proposed that dwarfism was caused as a consequence of overproduction of phytoene synthase which converts geranylgeranyl diphosphate into phytoene, thus diverting that intermediate away from the gibberellin and phytol biosynthetic pathways. This kind of results stressed the need to utilize promoters, restricting the overexpression or repression of genes to the fruits and during the ripening process.

Fraser et al. [92] also overexpressed the phytoene synthase (CRTR-B) gene, in this case from *Erwinia uredovora*, in tomato under the control of the tomato polygalacturonase promoter, resulting in 2.4-, 1.8-, and 2.2-fold higher contents of lycopene, β-carotene, and lutein, respectively, than the controls. In this case, avoiding constitutive expression, the transgenic plants showed a similar growth and development compared to the wild type.

Following with the next enzyme in the pathway, Romer et al. [93] introduced the gene *crtI* encoding a bacterial (*Erwinia uredovora*) phytoene desaturase, which converts phytoene to lycopene. Although levels of carotenoids were not increased in the transformed lines, β-carotene contents increased threefold without further effects on growth and development. This result was due to an upregulation of carotenoid genes, except phytoene synthase that was downregulated.

The next step in the pathway being modified following different approaches has been the one corresponding to lycopene cyclases. Their importance relies on the role of this step in the regulation of the whole pathway and its role in the partition of the main carotenoids lycopene and β-carotene. The gene silencing of CYC-B using a reverse construct of a fragment of the gene constitutively expressed resulted in flowers with orangish color typical of the *og* mutation with increased lycopene content at the expense of β-β-xanthophyll and deeper red color in fruits due to higher accumulation of lycopene at the expense of β-carotene [34].

Following the opposite approach, plants overexpressing lycopene β-cyclase (LCY-B) cDNA resulted in high contents of beta-carotene at the expense of lycopene, which was almost completely cyclized [94]. The plants did not show collateral effects, instead showed an increased productivity. Total carotenoid content was also increased in some progenies and beta-carotene content was twofold that of the beta mutant.

β-cyclases from other species have also been introgressed via genetic engineering in tomato. Rosati et al. [95] introduced the *A. thaliana* lycopene cyclase gene (*LcyB*) under the control of tomato phytoene desaturase (*psd*) promoter. Apel and Bock [96] introduced the lycopene beta cyclase genes from *Erwinia herbicola* and *Narcissus pseudonarcissus*. The first did not have much effect on β-carotene content, while the second increased the level of beta-carotene in fruits and almost increased total carotenoid content in 50 %, enhancing the flux through the pathway. In green leaves, it increased the levels of the beta branch xanthophylls. Guo et al. [97] constitutively expressed citrus beta cyclase gene (*Lycb-1*) and increased fourfold the content in β-carotene and 30 % total carotenoid content. The alpha branch was repressed until ripening stage, when high contents of α-carotene were obtained. The constitutive expression of this gene altered several different pathways including the synthesis of fatty acids, flavonoids, and phenylpropanoids, among others.

Following a new approach, Ma et al. [98] selectively repressed LCY-B and LCY-E enzymes by reducing mRNA following an RNAi approach. In lines with reduced LCY-E, β-carotene increased while lutein decreased and total carotenoids increased 1.7-fold. In LCY-B reduced RNA lines, β-carotene, lutein, and total carotenoid content decreased. In both lines, an increase of lycopene content up to 4.2-fold was observed.

The metabolic engineering of xanthophyll contents in tomato has also been tried. The overexpression of lycopene β-cyclase (LCY-B) and a *Capsicum* β-carotene hydroxylase (B-CHY) using the fruit-specific *pds* promoter resulted in increased contents of β-carotene (9.2–12.6-fold), β-cryptoxanthin, up to 11 μg/g, and zeaxanthin, up to 13 μg/g [99].

Allelic variants of genes participating in the biosynthesis pathway have also been identified following a TILLING strategy. For example, in the case of phytoene synthase (PSY-1) gene, two mutants with an early stop codon and an amino acid substitution resulted respectively in yellow fruits with similar phenotype to the *r* mutant and yellow fruits until 3 days post-breaker but eventually turning red [100]. These results contribute to the identification of strategies regulating enzyme activity in the fruits.

During recent years, the study of the biosynthetic pathway of carotenoids in tomato has not only been targeted to the study of cDNAs of the genes encoding the responsible enzymes, but also in the study of the corresponding promoters. Though this area of study is still underdeveloped, the tomato PDS promoter has been characterized [101], as well as *S. habrochaites* lycopene β-cyclase (CYC-B) promoter [102]. Other promoters from different species have also been tested in tomato. This would be the case of the zeaxanthin epoxidase (GlZEP) promoter from *Gentiana lutea* [103]. At the same time, an important progress has been made in the identification and characterization of fruit-specific promoters such as ethylene response genes *E8* and *E4m* polygalacturonase and lipoxygenase, mainly acting in the late-ripening stage or the *LA22CD07* and *LesAffx.6852.1.Sl* in green- and red-ripening fruits [104].

Although most part of the effort in the identification and cloning of genes and their genetic engineering has been placed in the carotenoid synthesis pathway, other alternatives have also been considered. As Dellapenna et al. [105] stated, one strategy to obtain more general increases in several metabolites could be to modulate regulatory genes whose products control flux through several biosynthetic pathways.

One of the strategies used in this sense has been to analyze the light-dependent regulation of carotenogenesis. Following this approach, Liu et al. [42] demonstrated that *hp-1* alleles present in the *high pigment 1* mutant represent mutations in a tomato UV-damaged DNA Binding Protein (DDB1) homolog. Trying to emulate this action, the authors proved that repression of LeCOP1LIKE expression resulted in plants with exaggerated photomorphogenesis, dark leaves, and elevated fruit carotenoid content. On the other hand, downregulated LeHY5 plants showed defects in light responses including reduced carotenoid accumulation. Long et al. [106] showed that *hp-1* and *hp-1/og*^{c} lines showed increased levels of carotenoids including phytoene, lycopene, β-carotene, and lutein as well as flavonoids in pericarp and skin tissues. The combination of *hp-1* and *og*^{c} as in the LA3771 mutant would show higher carotenoid contents; thus, it would appear that manipulation of environmental sensing mechanisms are the most effective means of creating high carotenoid/flavonoid fruit [106].

Also dealing with genes encoding components of the light signal-transduction machinery, Davaluri et al. [107] attempted to increase nutritional value in tomato suppressing photomorphogenesis regulatory gene *TDET1* using fruit-specific promoters combined with an RNA interference approach based on inverted repeat constructs. It had been proved previously that *TDET1* is the gene responsible for the phenotype of the mutant *hp2* [44]. This mutant is characterized by an excessive photoreaction involving high flavonoid and carotenoid content but with collateral effects such as causing reduced plant statures, bushiness, and dwarfing that have hindered its exploitation in commercial varieties. Precisely, the targeted suppression in fruits tried to avoid vegetative collateral effects. As DET1 transcripts were specifically degraded in the fruit, carotenoids, phenylpropanoids, and flavonoids content increased significantly (to similar or greater levels than with *hp2*). The increase in the content of two unrelated beneficial groups of plant antioxidants is of great interest in the development of new varieties with enhanced functional or nutritional quality, especially as the analysis of mutants altered in structural genes for carotenoid biosynthesis shows no significant alteration of phenolic or flavonoid contents [106]. Though in this case, minor reductions in fruit weight and Brix were observed, apparently, the collateral effects were much reduced from those observed in the natural mutant *hp-2*.

Giliberto et al. [108] also intervened in the control of photomorphogenesis overexpressing and silencing (virus mediated silencing) the tomato cryptochrome 2 (*CRY2*) gene. Overexpressing plants showed short hypocotyls and internodes, flowering delay, and axillary branches outgrowth but also overproduced chlorophylls and anthocyanins in leaves and flavonoids, carotenoids, and xanthophylls in fruits. Specifically, lycopene, β-carotene, and lutein increased 1.7- 1.3-, and 1.5-fold respectively. The increase in the carotenoid pathway compounds was accompanied by a decrease in the expression of lycopene β-cyclase genes. Virus-induced gene silencing caused minor internode elongation, though Potato virus X infection complicated the interpretation of results.

Other regulatory approaches consisted in the downregulation of abscisic acid (ABA) in tomato during ripening using an RNAi construct of the SINCED1 gene encoding 9-*cis*-epoxycarotenoid dioxygenase driven by the fruit-specific promoter *E8* [109, 110]. This approach caused a reduction in 20–50 % of ABA concentration during ripening. As a result, upstream compounds in the ABA synthesis pathway, such as lycopene and β-carotene, increased their accumulation. This strategy also resulted in an increase of ethylene production. This result may be related to the effects of the *high pigment-3* mutant. In this case, the mutation present in the *hp-3* allele results in a defective zeaxanthin epoxidase that results in ABA deficiency that would cause an enlargement of plastids (twofold larger), probably due to increased plastid division [40].

In addition to the mentioned approaches, some unexpected increase in carotenoid content has been obtained when trying to modify other biosynthetic routes. This was the case of the expression of the yeast *S*-adenosylmethionine decarboxylase gene (ySAMdc;*Spe2*) with the *E8* promoter in tomato plants targeted to increase the levels of the polyamines spermine and spermidine in tomato fruit during ripening [111]. In this case, the increased level of these polyamines was accompanied by higher lycopene concentrations (two- to threefold), prolonged vine life, and enhanced precipitated weight ration and serum viscosity. Recently, the constitutive overexpression of the apple spermidine synthase cDNA in tomato, a key enzyme of the polyamine biosynthesis pathway, also resulted in increased carotenoid concentration, especially in lycopene (1.3–2.2-fold). In this case, the genes encoding the enzymes upstream lycopene formation DXS, PSY, PDS were upregulated while the genes encoding the enzymes downstream LCY-B and LCY-E were downregulated in tomato ripe fruits compared to the wild type. Therefore, authors suggested that a high level of polyamines regulates the steady-state level of transcription of genes responsible for the lycopene metabolic pathway [112].

As it has been stated, genetic engineering can offer an alternative to improve carotenoid content or its profile in tomato. In some cases, this has been achieved with minor or null side effects in the vegetative development. Nonetheless, it should be considered that most part of the evaluations have been made in glasshouse experimental conditions. In fact, in several of the mentioned studies, the results on production of the controls are far from the yields typical of commercial growing conditions. Therefore, it is still necessary to check if these strategies really improve carotenoid content without negative effects of the commercial agronomical performance of the lines.

Additionally, despite the progress being made improving the functional value using genetic engineering approaches, it should be considered that public skepticism on transgenic crops makes rather unlikely that the developed materials could have a commercial use in the near future [3].

4.3 Limitations and Drawbacks Associated with Analysis and Environment

The quantification of lycopene and β-carotene in tomato fruits was initially based on spectrophotometric methods accounting for the relationship between absorbance at certain wavelengths and concentrations of these compounds in organic solvents [85, 113]. Despite the low precision of these non-separation methods compared to chromatography, they have been widely used considering their simplicity and their low operational and capital costs. But at the moment, high-performance liquid chromatography (HPLC) is the most frequently technique used for the analysis of carotenoids in fruit and vegetable extracts [114, 115]. Reversed-phase columns packed with several C_{18} stationary phases still are the preferred chromatographic supports for measuring total carotenoids [116, 117]. However, these chromatographic methods have several shortcomings including the time-consuming conditioning of the columns, the large consumption of solvents, and the high price of the column. In the last years, capillary electrochromatography (CEC) has received much attention as emerging separation technique [118, 119] with high selectivity (as in HPLC) and high efficiency. Nowadays, there are CEC methods available for fast determination of prominent carotenoids in tomato fruits by capillary electrochromatography using methacrylate-ester-based monolithic columns [120] that can be useful in germplasm evaluation.

Nevertheless, during selection processes in breeding programs, it is complex to use these analytical methods, as the sample homogenization, carotenoid extraction

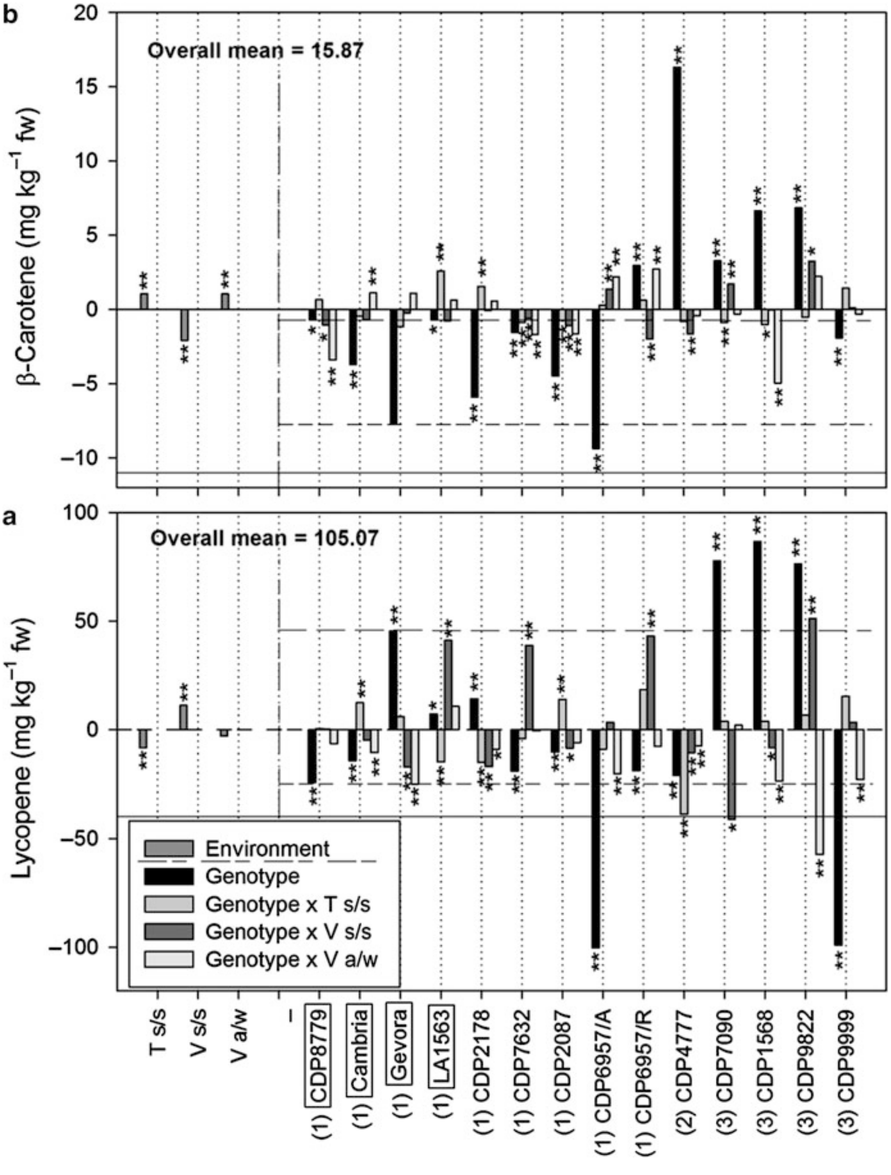

Fig. 92.3 Predicted genotypic, environmental, and interaction effects for lycopene and β-carotene content of the tomato accessions evaluated in three growing environments (Adapted from Journal of the Science of Food and Agricultre, Vol. 91, Roselló S, Adalid AM, Cebolla-Cornejo J, Nuez F, Evaluation of the genotype, environment and their interaction on carotenoid and ascorbic acid accumulation in tomato germplasm, pp. 1014–1021, Copyright (2011) with kind permission of John Wiley and Sons). The growing environments of trial in Spain were: T s/s = Turis, open field, spring-summer cycle; V s/s = Valencia, glasshouse, spring-summer cycle; V a/w = Valencia, glasshouse, autumn-winter cycle. Estimated value significantly different from zero (*t*-test) at P = 0.1, 0.05, and 0.01 level respectively. Controls in X axis are inside a *box*. In *parentheses*:

with organic solvents, and sample preparation, which are common for any of the mentioned analysis, are time consuming. Thus, when hundreds of samples are to be analyzed in a very short time to select the interesting individuals, these approaches offer low efficiency, and the analysis becomes a limiting factor. Consequently, indirect determination using nondestructive methods has been pursued.

D'souza [121] and Hyman et al. [122] proposed colorimetric determination of whole fruits and the use of simple functions such as $(a^*/b^*)^2$ or $(a^*/b^*)^{2.5}$ to determine the contents of lycopene and β-carotene, obtaining determination coefficients of 0.75–0.90 and 0.55, respectively. Nonetheless, the goodness of fit of indirect methods using colorimetric measurements is highly dependent on the genotypes being evaluated. With this methodology, only the external color of the fruit is measured, but as commented in the previous sections, carotenoid content is not limited to the external area of the fruit, and its distribution may vary between genotypes. Therefore, better results are obtained when a specific function is obtained for the specific materials under use [123]. This approach requires the development of complex specific calibration models before analyzing the materials in field. Again this limits the practicability of the methodology.

During the last years, nondestructive methodologies based on VIS-NIR spectroscopy have being developed [124] and they seem quite promising for breeding programs. These methods offer a possibly more reliable prediction, as the measure is not restricted to the surface of the fruit as in the colorimetric approach. In fact, these methods involve prediction errors averaging 3 mg kg^{-1}, but they can be used in nondestructive fast determinations in the field, thus offering a rough but rapid screening of the materials. More precise but time-consuming HPLC or CEC methods may be used in later phases to check the advances achieved and detect minor differences between materials.

Another important matter to consider in carotenoid breeding programs with tomatoes is the influence of the environment on the expression of the character. The content of carotenoids in tomato fruits depends not only on the genotypic potential, but also on the environmental effect and on the interaction between genotype and environment. This environmental influence determines the character heritability and highly influences the success of selections in breeding programs.

It has been reported that the lycopene accumulation depends on temperature and seems to take place at a range of average day temperature between 12 °C and 32 °C [125] or 35 °C [126], with the optimal conditions around 22–26 °C [127]. For β-carotene accumulation, the range of average day temperature is wider than for lycopene. Its biosynthesis is poorly affected by temperatures lower than 12 °C [128] and with temperatures higher than 35 °C; when the lycopene accumulation is

Fig. 92.3 (continued) 1 = *Solanum lycopersicum*; 2 = *S. lycopersicum* (former var. c*erasiforme*); 3 = *S. pimpinellifolium*. Scaling in Y axis is overall mean centered. Reference lines: genotypic *upper* control (*long dashed line*), genotypic *lower* control (*short dashed line*), reported phenotypic average content (*continuous line*). The reported average content considered is: 65, 3.9, and 200 mg kg^{-1} for lycopene [130] and β-carotene [49] respectively inhibited, the conversion of lycopene into β-carotene is stimulated [126]. Nevertheless, the optimal temperature for β-carotene accumulation seems to be around 30 °C [126]. At favorable temperatures, the lycopene and β-carotene biosynthesis increases with the sunlight intensity, probably [127, 129] due to increases in photosynthetic rates. In the case of lycopene, when a harmful direct radiation level occurs (650 Wm^{-2} for 1.5–4 h), its biosynthesis is inhibited.

It is more difficult to assess the effect of genotype-environment interaction (G × E). But this interaction will condition the stability of the expression of the genotypic potential for the trait and, thus, the potential environments recommended for the future cultivar. Therefore, the genetic merit of the accessions tested must be evaluated considering both genotype main effect and G × E interaction, being compared with the genetic merit of the controls for reference (Fig. 92.3). One of the decisions for the breeder would be if it is preferable to develop "high functional value" cultivars with high environmental stability or if it is preferable to develop specific cultivars for specific target environments. This kind of studies requiring multi-environmental evaluation is usually performed in the last phases of the breeding program as they are expensive and time consuming. Nonetheless, it is important to perform them in the early phases of identification of promising sources of variation before deciding to start even more expensive breeding programs to introgress the trait.

In general, the high genetic component responsible for the accumulation of lycopene and β-carotene makes possible the selection of elite genotypes with high content of both carotenoids in tomato breeding programs. The high ratio of genotypic to environmental variance decomposition seems to indicate that high accumulation cultivars with wide adaptation might be successful despite the important environmental effects on carotenoid biosynthesis. Although there is a high genotypic correlation between the carotenoids studied, to perform a joint selection for both carotenoids, it is mandatory to conduct multi-environment trials due to the existence of considerably high negative environmental correlations that may hinder joint selection in a single environment [68].

5 Conclusion

There is an increasing demand in the development of functional food targeted to prevent certain degenerative diseases. Under these premises, antioxidant compounds found in fruits and vegetables have been linked to reduced risks of cancer and cardiovascular diseases. Consequently, seed industry has stressed the need to develop new varieties with high concentrations of these compounds. Among the terpenes present in tomato fruits, carotenoids represent an interesting antioxidant activity. Consequently, numerous efforts have been targeted to improve the content of total carotenoids or of the carotenoid profile of tomato.

Breeders trying to fulfill this objective have encountered two main limitations in their way. The first one relates to the difficulty of determining the carotenoid content in large number of samples typical of breeding programs. Very precise techniques are available, but they require a rather tedious process of carotenoid extraction and are rather expensive. Alternatives for indirect determination via colorimetric measures or VIS-NIR radiation require continuous calibrations which are specific for different materials, and cannot be considered fully reliable for breeding programs. The second limitation arises from the important impact of environment on the accumulation of carotenoids. Consequently, it becomes really difficult to decompose the actual carotenoid content into its genotypic, environmental, and interaction components. In plant breeding, this fact is especially important, as selecting one individual by its measured carotenoid content would not imply that it really has a true genotypic potential.

Despite these important limitations, considerable advances have been made in the selection of high carotenoid lines. In conventional breeding, an important part of this success relies on the use of color mutants identified in the cultivated species, as well as in related wild species. These mutants have altered either enzymes in the carotenoid biosynthetic pathway or in related regulatory systems and result either in increased total carotenoid content or in increases either in lycopene or β-carotene at the expense of the other. Although mutations such as the *high pigments* have been introgressed in commercial varieties offering increased lycopene content, a considerable decrease in yield appears as a side effect.

Advances in the genetic engineering have been obtained following the advances in the knowledge of the biosynthetic pathway and in the genetic analysis of the color mutants. In fact, an important progress has been made using alleles responsible for color mutations combined with promoters specific for fruit tissues and ripening stages. Therefore, side effects arising from the expression of those alleles in vegetative tissues can be prevented. Most part of the results in the area of genetic engineering have been obtained in controlled conditions with very limited productions, and it is still necessary to check if the same results would apply to commercial conditions.

Abstract

Volatile oils of algae contain a variety of compounds. The main group, terpenes, contains acyclic: linalool, geraniol, citronellol; monocyclic: limonene, 1-8-cineol, *p*-cymene; bicyclic: *α*- and *β*-pinene, cadinene, aromatic eugenol, and isoeugenol. The others are benzaldehyde, phenol, *p*-cresol, various acids, alcohols, aldehydes, amines, ketones, sulfur containing and halogenated compounds. When volatile oil components of algae and terrestrial plants are compared, the algae were found to be relatively poor. Importantly, halogenated compounds occur only in algae, but not in terrestrial plants. In this chapter, we present briefly but comprehensively the occurrence of various volatile compounds in different classes of algae.

Abbreviations

A	Amines
AC	Acids
ACE	Acetic acid
ACR	Acrylic acid
AD	Amides
AL	Aldehydes
ALC	Alcohols
AM	Amine
ATL	Acetaldehyde
BC	Bromocresol
BE	Benzaldehyde
BH	Bromo-4-hydroxybenzaldehyde
BP	Bromophenol

BU	Butyric acid
BZ	Benzoic acid
BZT	Benzothiazole
CA	Caproic acid
CAP	Caprylic acid
CAR	Carvone
CI	Cineol
CIT	Citronellal
CR	Cresol
CTN	Citronellol
CY	*p*-Cymene
DBA	Dibromoanisole
DBC	Dibromocresol
DBH	Dibromo-4-hydroxybenzaldehyde
DBP	Dibromophenol
DCM	Dichloromethane
DMA	Dimethylamine
DMS	Dimethyl disulfide
EA	Ethylamine
EU	Eugenol
FO	Formic acid
FU	Furfural
FUR	Furfuryl alcohol
GE	Geraniol
HALC	Halogenated alcohol
HC	Halogenated compounds
HDC	Hydrocarbon
IAA	Isoamylamine
IBA	Isobutylamine
IEU	Isoeugenol
IVA	Isovaleric acid
KE	Ketones
LI	Linalool
LIM	Limonene
MA	Methylamine
MFU	Methylfurfural
MMPA	2-Methyl-mercapto-propylamine
PA	Propylamine
PEA	2-Phenylethylamine
PH	Phenols
PI	Pinene
PR	Propionic acid
Pro	Propional
S	Sulfur compounds

TA	Terpenyl acetate
TBA	Tribromoanisole
TBP	Tribromophenol
TE	Terpinolene
TERP	Terpenes
TMA	Trimethylamine
TOL	Terpineol
VA	Valeraldehyde

1 Introduction

Volatile oils comprise all the substances which pass through steam distillation process. The origin of volatile oil is traditional of German work Aetherischen Oele in the first time described by Gildemeister and Hoffmann in 1899 [1]. It is the Quinta essentia (quintessence) which represents the efficient part of every drug. The current name "essential" oil recalls the Paracelsian concept [2]. The quintessential oil originates from the Aristotelian idea that matter is composed of four elements, namely, fire, air, earth, and water. The fifth element, or quintessence, was then considered to be spirit or life force [3]. The term "essential oils" is also used for volatile oils.

History: In the past, volatile oils of terrestrial plants were used in Chinese [4], Assyrian [5], Sumerian [6], Babylonian [7], and Egyptian civilizations [7–9]. Volatile oil was first isolated from marine algae, Fucus, by Heilbron et al. [10] and later in a series of research by Katayama in 1951–1961 [11].

Volatile oil is a mixture of numerous components such as terpenes, amines, sulfur, halogenated compounds, nonterpenic hydrocarbons, and others (acids, alcohols, aldehydes, phenols, etc.) [12].

Some exogenous volatile compounds were found in marine algae, whereas endogenous aliphatic hydrocarbons are originally found in algae [13].

In this chapter, volatile oils have been listed in systematic classification and the compounds in alphabetical order as acids, alcohols, aldehydes, amines, halogenated compounds, hydrocarbons, phenols, sulfurs, terpenoids.

2 Rhodophyta

2.1 Bangiales

2.1.1 Bangiaceae

Porphyra columbina

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Porphyra tenera (Pyropia tenera)

Volatile constituents (dry weight): 0.053 % [11].

AC: FO; ACE; PR; BU; IVA; *n*-CA; CAP [11]; nonanoic; decanoic [15].

AL: PRO; FU; MFU; *n*-VA; BE [11]; ATL; IVA; isobutylaldehyde; tiglic aldehyde; 2-methyl-2-pentanal [16]; (2*E*,4*E*)-octadienal; (2*E*,6*Z*)-nonadienal; (2*E*,4*Z*)-decadienal; (2*E*,4*E*)-decadienal; tridecanal; tetradecanal; pentadecanal; (7Z,10Z)-hexadecadienal; (7Z)-hexadecenal; (8Z,11Z)-heptadecadienal; (8Z)-heptadecenal [15].

ALC: Benzyl alcohol [15].

KE: α-Ionone; *β*-Ionone; 6,10,14-trimethylpentadecan-2-one [15].

Lactone: Dihydroactinidiolide [15].

PH: *p*-Cr [11].

S: Methanethiol [11]; BZT [15].

TERP: LI; GE; 1,8-CI; *p*-CY [11, 17]; α-TOL; α-Cadinol; Cubenol [15]; TE; LIM; α-PI; CAR [17].

2.2 Nemaliales

2.2.1 Galaxauraceae

Galaxaura marginata

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Galaxaura obtusata

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.3 Ahnfeltiales

2.3.1 Ahnfeltiaceae

Ahnfeltia plicata

A: MA; TMA [18].

2.4 Gelidiales

2.4.1 Gelidiaceae

***Gelidium* sp.**

Volatile constituents (dry weight): 0.130 % [11].

TERP: LI; GE; 1,8-CI [19].

PH: *p*-CR [19].

Gelidium amansii

Volatile constituents (dry weight): 0.130 % [11].

Gelidium crinale
A: PEA [20–22].

2.4.2 Pterocladiaceae

Pterocladiella capillacea
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Pterocladia capillacea (Gelidium capillaceum)
Volatile constituents (dry weight): 0.28 % [23].
AC: Isobutyric acid [23].
ALC: Nonanol [23, 24]; 3,4-dihydroxybenzyl alcohol; 4-hydroxybenzyl alcohol [25].
TERP: GE; GE formate; GE acetate; TE; CIT; 1,8-CI; α- and β-PI; EU [23].

Pterocladia lucida
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.5 Gracilariales

2.5.1 Gracilariaceae

***Gracilaria* sp.**
Volatile constituents (dry weight): 0.094 % [11].

Gracilaria bursa-pastoris
A: PEA [22].

Gracilaria edulis
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Gracilaria secundata
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.6 Bonnemaisoniales

2.6.1 Bonnemaisoniaceae

Asparagopsis armata
HC: $CHBr_2Cl$; $CHBr_3$; CBr_4; $CHBr_2I$; CH_2BrCHO; $CHBr_2CHO$; CH_3I; CH_2ClI; $CHCl_3$; CCl_4; $CHBrCl_2$ [26]; eight haloacetones [27–31].

Asparagopsis taxiformis
HC: $CHBr_3$; $CHClBr_2$; CHClBrI; $CHBr_2I$; $CHBrI_2$; CHI_3; CBr_4; four tetrahalopropenes; four polyhalobut-3-en-2-ones, MeCOCH2R (R = Br, I); Br_2C:CHCHO [28]; two haloacetones; eight halobutenoles [27–31] carbonyldiiodide (COI_2);

ICH_2CH_2OH; $BrCH_2CH_2I$; twenty halogenated isopropanols; two halogenatad 2-acetoxy-propanes; $CHBrOCHCHBr_2$; four 1,1,3,3,-tetrahalopropenes; dibromoacrolein; four haloacetamides; eight polyhaloacetone derivatives; seven haloacetic acid derivatives; five haloacrylic acid derivatives [27–30]; 1-octen-3-ones [31].

Bonnemaisonia nootkana

HC: trans-1,3,3,-Tribromo-1-hepteneoxide [32].
ALC: Tetrabromo-2-heptanol; tetrabromo-2-nonanol [32].
KE: 1,1,3,3-Tetrabromo-2-nonanone [32].
AC: Z-3-Bromo-2-heptenoic acid; *Z*-3-bromo-2-nonenoic acid; 3,3-dibromo-*n*-butylacrylic acid; 3,3-dibromo-*n*-hexylacrylic acid [32].

Bonnemaisonia asparagopsis

KE: 5 Chlorinated and brominated 1-octene-3-ones: 1-bromo-2-chloro (1-octene-3-ones); 1-bromo-2,3-dichloro(1-octene-3-ones); 1,2-dibromo-3-chloro(1-octene-3-ones); 1,2,3-tribromo(1-octene-3-ones); 2,3-dibromo-1-chloro (1-octene-3-ones) [33].

Bonnemaisonia hamifera

KE: 1,3-Dibromo-2-heptanone; 1,3,3-tribromo-2-heptanone; 3,3-dibromo-1-iodo-2-heptanone [34].

Delisea pulchra

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Falkenbergia rufolanosa

HC: $CHBr_3$ [27].

2.7 Corallinales

2.7.1 Corallinaceae

Amphiroa anceps

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Cheilosporum sagittatum

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Corallina berteri

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Corallina officinalis

A: MA; TMA; IAA [35].
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

***Corallina rubens* (*Jania rubens*)**
TERP: GE; TE; 1,8-CI [36].

Haliptilon roseum
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.8 Gigartinales

2.8.1 Areschougiaceae

Callophycus tridentifer
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.8.2 Cystocloniaceae

Cystoclonium purpureum
A: MA; TMA; EA; PA; IBA; IAA; PEA; MMPA [35].

2.8.3 Dumontiaceae

***Dumontia incrassata* (*Dumontia contorta*)**
A: MA; TMA; EA; PA; IBA; IAA; PEA; MMPA [35].

2.8.4 Gigartinaceae

Chondrus crispus
A: MA; TMA; IAA [35].

Gigartina stellata
HC: Polybromomethanes [37].

2.8.5 Phyllophoraceae

***Phyllophora nervosa* (*Phyllophora crispa*)**
Volatile constituents (dry weight): 0.04 % [38].
A: PEA [21].
TERP: GE; 1,8-CI [38].

2.8.6 Polyidaceae

Polyides rotundus
A: MA; DMA; TMA; EA; PA; IBA; IAA; PEA; MMPA [35].

2.8.7 Solieriaceae

Solieria robusta
KE: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.8.8 Sphaerococcaceae

Sphaerococcus coronopifolius
Volatile constituents (dry weight): 0.21 % [39].

2.9 Rhodymeniales

2.9.1 Rhodymeniaceae

Lomentaria catenata

KE: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.9.2 Halymeniaceae

Halymenia floresii

A: PEA [21].

KE: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

2.10 Plocamiales

2.10.1 Plocamiaceae

Plocamium angustatum

KE: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

***Plocamium vulgare* (*Plocamium cartilagineum*)**

A: MA; TMA; IAA [35].

2.11 Ceramiales

2.11.1 Ceramiaceae

Ceramium rubrum

A: MA; TMA; EA; PA; IBA; IAA; PEA; MMPA [35].

2.11.2 Delesseriaceae

Delesseria sanguinea

A: MA; TMA; EA; IBA; IAA; PEA; MMPA [35].

2.11.3 Rhodomelaceae

Bostrychia calliptera

AL: (*E*)-2-Octenal; nonanal; (*E,Z*)-2,6-nonadienal; (*E*)-2-nonenal; decanal; (*E*)-2-decenal; (*E,Z*)-2,4-decadienal; undecanal; (*E,E*)-2,4-decadienal; dodecanal; tetradecanal; pentadecanal; hexadecanal [40].

ALC: 1-Octen-3-ol; (*E*)-2-octenol; 3,4-dimethylcyclohexanol; 1-nonanol; 1-decanol; undecanol; tridecanol; tetradecanol; pentadecanol; Hexadecanol [40].

HDC: Tetradecene; pentadecene; hexadecane; 1-heptadecene; heptadecane [40].

KE: 2-Decanone; α-ionone; β-ionone; 6,10,14-trimethyl-2-pentadecanone [40].

PH: 2,4-Di-*tert*-butylphenol [40].

TERP: 2,3-Dihydrocitral; β-cyclocitral; β-cyclohomocitral; (*E*)-geranylacetone [40].

Bostrychia radicans

AC: Nonanoic [40].

AL: BE; (*E*)-2-Octenal; nonanal; (*E,Z*)-2,6-nonadienal; (*E*)-2-nonenal; decanal; (*E*)-2-decenal; (*E,Z*)-2,4-decadienal; undecanal; (*E,E*)-2,4-decadienal; dodecanal; tridecanal; tetradecanal; pentadecanal [40].

ALC: 1-Octen-3-ol; (*E*)-2-octenol; 1-octanol; 3,4-dimethylcyclohexanol; 1-nonanol; tridecanol; tetradecanol; pentadecanol; hexadecanol [40].

HDC: 1,3,5-Octatriene; tetradecene; tetradecane; pentadecene; pentadecane; hexadecane; 8-heptadecene; 1-heptadecene; heptadecane [40].

KE: 2-Decanone; α-ionone; β-Ionone; 6,10,14-trimethyl-2-pentadecanone [40].

TERP: 2,3-Dihydrocitral; β-cyclocitral; β-cyclohomocitral; (*E*)-geranylacetone [40].

Bostrychia tenella

AL: BE; (*E*)-2-octenal; nonanal; (*E*)-2-nonenal; decanal; (*E*)-2-decenal; (*E,Z*)-2,4-decadienal; undecanal; (*E,E*)-2,4-decadienal; dodecanal; tridecanal; tetradecanal; pentadecanal; hexadecanal [40].

ALC: 1-Octen-3-ol; (*E*)-2Octenol; 3,4-dimethylcyclohexanol; undecanol; dodecanol; tridecanol; tetradecanol; pentadecanol; hexadecanol [40].

KE: 2-Decanone; α-ionone; β-ionone; 6,10,14-trimethyl-2-pentadecanone [40].

TERP: β-Cyclocitral; β-cyclohomocitral; (*E*)-geranylacetone [40].

HDC: Tridecene; tetradecene; tetradecane; pentadecene; pentadecane; hexadecane; 8-heptadecene; 1-heptadecene; heptadecane; Octadecane [40].

PH: 2,4-Di-*tert*-butylphenol [40].

Chondria crassicaulis

Volatile constituents (dry weight): 0.12 % [39].

Chondria succulenta

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Digenea simplex

Volatile constituents (dry weight): 0.008 % [11].

A: FO; ACE; PR; BU; IVA; *n*-CA; CAP [11].

AL: FUR; MFU; *n*-VA; BE [11].

PH: *p*-CR [11].

S: Methanethiol [11].

TERP: LI; GE; 1,8-CI; *p*-CY [11].

Halopithys incurva

Volatile constituents (dry weight): 0.05 % [41].

TERP: p-CY; EU; IEU; α- and β-PI [41].

Laurencia caespitosa (*Osmundea hybrida*)

TERP: 6-Hydroxycaespitol; caespitane [42].

ALC: Caespitol, Isocaespitol [42].

Laurencia dendroidea

TERP: (1*R**,2*S**,3*R**,5*S**,8*S**,9*R**)-2,3,5,9-tetramethyltricyclo[6.3.0.0^{1,5}] undecan-2-ol; (1*S**,2*S**,3*S**,5*S**,8*S**,9*S**)-2,3,5,9-tetramethyltricyclo-[6.3.0.0^{1,5}] undecan-2-ol [43].

Laurencia nipponica

Volatile constituents (dry weight): 0.82 % [39].

Laurencia glandulifera

Volatile constituents (dry weight): 0.075 % [44].

TERP: Cadelene; azulene [44].

Polysiphonia lanosa

AC: ACR [45].

S: DMS [45].

Polysiphonia morrowii

A: PEA [22].

Polysiphonia tripinnata

A: PEA [22].

***Polysiphonia sphaerocarpa* (*Neosiphonia sphaerocarpa*)**

ALC: CR [46].

HC: $CHBr_3$; CH_3Cl; CH_3Br; CH_3I [47]; 2,4-DBA; 2,4,6-TBA; 3-BH; 3-BC; 3,5-DBC [46].

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [45].

AL: 3,5-DBH; brominated anisole; 3,5-dibromo-4-hydroxybenzaldehyde; brominated 3,4-dihydroxybenzaldehyde [46].

ALC: 3,4-Dihydroxybenzyl; 4-hydroxybenzyl; lanosol [46].

***Polysiphonia urceolata* (*Polysiphonia stricta*)**

A: MA; TMA; EA; PA; IBA; IAA; PEA; MMPA [35].

Rhodomela confervoides

A: MA; TMA; EA; IBA; IAA [35].

3 Ochrophyta

3.1 Desmarestiales

3.1.1 Desmarestiaceae

Desmarestia aculeata

A: MA; DMA; TMA; EA; PA; IBA; IAA; PEA; MMPA [35].

HC: CH_3I; CH_2ClI; $CH_3CH_2CH_2I$; CH_3CHICH_3; CH_2I_2; $CHBrCl_2$; $CHBr_2Cl$; CH_2Br_2; $CHBr_3$ [48].

Desmarestia anceps

HC: CH_3Br; CH_2Br_2; $CHBr_2Cl$; $CHBrCl_2$, CH_2I_2; CH_2ClI; $CH_3CH_2Br_2$ [49].

Desmarestia menziesii

HC: CH_3Br; CH_2Br_2; $CHBr_2Cl$; $CHBrCl_2$; CH_2I_2; CH_2ClI; $CH_3CH_2Br_2$ [49].

Desmarestia viridis

A: MA; DMA; TMA; IBA; IAA; PEA; MMPA [35].

3.2 Dictyotales

3.2.1 Dictyotaceae

Dictyopteris australis

TERP: Dictyopterene A [49–51]; dictyopterene B; dictyopterene C′; dictyopterene D′ [49].

Dictyopteris divaricata

Volatile constituents (dry weight): 3.28 % [39].

HDC: Volatile odoriferous hydrocarbons C_{11} were found as cyclic group: Dictyopterene A′, B, C′, D′; acyclic undecapolyenes as three 1,3,5-undecatrienes, four 2,4,6-undecatrienes, two 1,3,5,8-undecatetraenes.

TERP: Cadiene; 1-cadinol [52]; *β*-elemene; germacrene; cubenol [53].

Dictyopteris latiscula

TERP: Dictyopterene B; dictyopterene C′; dictyopterene D′ [54].

***Dictyopteris membranacea* (*Dictyopteris polypodioides*)**

AC: Dodecanoic; tetradecanoic; hexadecanoic [55].

AL: 2-Heptenal [55].

HDC: 3-Butyl-4-vinylcyclopentene; 3-(1-hexenyl)cyclopentene; 6-(1-butenyl)-cyclohepta-1,4-diene; 6-butylcyclo-1,4-heptadiene; 1,3,5-undecatriene; 2,4,6-undecatriene; heptadecane; 5-octadecene; eicosa-5,8,11,14-tetramethylenoate; eicosa-5,8,11,14,17-pentamethylenoate [55].

KE: 1-Undecen-3-one; 3-undecanone; 1,4-undecadien-3-one; 3-hexyl-4,5-dithiacycloheptanone [55].

S: 3-Oxo-un-4-decenyl [55].

TERP: Dictyoprolene [55].

Dictyopteris plagiogramma

TERP: Dictyopterene A [49–51]; dictyopterene B; dictyopterene C′; dictyopterene D′ [49].

Dictyopteris prolifera

AL: Dictyoprolenol [54].

HDC: *cis*-3-Butyl-4-vinylcyclopentene; *trans*-1-[(1*Z*)-hexenyl]-2-vinylcyclopropane, 4-[(1*E*)-hexenyl]-cyclopentene, 6-[(1*E*)-butenyl]-cyclohepta-1,4-diene [53].

TERP: Dictyopterene A [51]; dictyopterene B; dictyopterene C′; dictyopterene D′ [54]; cubenol [53]; neodictyoprolenol [54].

Dictyopteris undulata

HDC: 4-[(1*E*)-Hexenyl]-cyclopentene; 6-[(1*E*)-butenyl]-cyclohepta-1,4-diene; *cis*-3-butyl-4-vinylcyclopentene; *trans*-1-[(1*Z*)-hexenyl]-2-vinylcyclopropane [53].

TERP: Dictyopterene A [51]; dictyopterene B; C′; D′; neodictyoprolenol; dictyoprolenol; neodictyoprolenol [54].

Dictyopteris zonarioides

TERP: Cadinene [56].

Dictyota dichotoma

Volatile constituents (dry weight): 0.39 % [39].

TERP: Dictyol C; dictyol D [57].

Dictyota dentata (Dictyota mertensii)

Terp: Dictyol C; dictyol H; pachydictyol A [58].

Dictyota dichotoma var. implexa (*Dictyota implexa*)

TERP: Piperitone [59].

Dictyota cervicornis (Canistrocarpus cervicornis)

TERP: Dolastane [60, 61].

Dictyota divaricata (*Dictyota implexa*)

Volatile constituents (dry weight): 3.28 % [39].

TERP: Dictyopterene A [51]; cadinene [53].

Homoeostrichus sinclairii

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Lobophora variegata

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Taonia atomaria

TERP: 4-Cadainene; Cadinane-4; (-)-germacrene D; (-)-cubenol; 4-epi-cubebol [60].

HDC: 5-Diene [62].

3.3 Ectocarpales

3.3.1 Chordariaceae

***Sphaerotrichia japonica* (*Sphaerotrichia divaricata*)**

Volatile constituents (dry weight): 0.21 % [39].

3.4 Fucales

3.4.1 Cystoseiraceae

Cystoseira barbata

AD: Dimethylformamide [63].
HALC: $CH_2Cl.CHBrOH$ [63].
HC: $CH_2Cl.CH_2Br$; $CHCl_2.CH_2Cl$; $CHCl_2$. $CHCl_2$; hexachlorobutadiene [63].
TERP: 1,8-CI; TOL; GE; α-PI [64].

Cystoseira crinita

ALC: 2,3-Butanediol [65]
AC: Chloroacetic; Chloroacetic acid ethyl ester [65].
S: DMS [65].
TERP: Crinitol [57, 66–68]; geranylgeraniol [67].

Cystoseira stricta var. amentacea

ALC: Hexanol; Octanol [69].
TERP: Cubenol [69].

***Cystoseira stricta var. spicata* (*Cystoseira amentacea var. spicata*)**

HC: 2-[(2′*E*,6′*E*,14′*E*)-10′,11′-Dihydoxy-3′,7′,11′,15′-tetramethylhexadeca-2′,6′,14′-trien]-1,4-dihydroxy-6-methylbenzene [70].

KE: Quinone [70].

***Cystoseira trinodis* (*Sirophysalis trinodis*)**

PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

3.4.2 Fucaceae

Ascophyllum nodosum

HC: Polybromomethanes [37].

Fucus distichus

HC: CH_3I; CH_2ClI; $CH_3CH_2CH_2I$; CH_3CHICH_3; CH_2I_2; $CHBrCl_2$; $CHBr_2Cl$; CH_2Br_2; $CHBr_3$ [46].

Fucus serratus

A: MA; TMA [35].

Fucus spiralis
A: MA; TMA [35].

Fucus vesiculosus
A: MA; TMA [34].
HC: CH_3CH_2I; $CHBr_3$; CH_2Br_2; CH_2Br_2Cl; CH_2I_2; C_2H_5I; C_3H_7I (1-, 2-); C_4H_9I [71]; polybromomethanes [37].

3.4.3 Hormosiraceae

Hormosira banksii
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

3.4.4 Sargassaceae

Cystophora intermedia
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

***Cystophora moniliformis* (Esper) Womersley & Nizamuddin**
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

Halidrys siliquosa
A: MA; TMA [35].

***Hizikia fusiformis* (*Sargassum fusiforme*)**
Volatile constituents (dry weight): 0.053 % [11].

Hormophysa cuneiformis
HDC: 2-octene [54].

Sargassum sp.
Volatile constituents (dry weight): 0.062 % [11].

Codium lucasii
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

4.6 Caulerpales

4.6.1 Caulerpaceae

Caulerpa cactoides
PH: 2-BP; 4-BP; 2,4-DBP; 2,6-DBP; 2,4,6-TBP [14].

5 Discussion

The origin of volatile oils in algae was discussed by various authors [83, 87, 92–96]. The pleasant-odorous compounds of marine algae are terpenes and unpleasant components are especially aldehydes, amines, halogenated, sulfurous, and other compounds.

Many aliphatic acids, such as FO, AC, PRO, BUT, VAL, and rare-aromatic acids, such as BZ, were found in marine algae. The origin of these acids has not been reported. The origin of acrylic acid was shown to result from hydrolysis of dimethyl-β-propiothetin [82]. Nonvolatile fatty acid amounts in algae were previously published [97].

Short- and middle-chain aliphatic aldehydes and aromatic aldehydes were found in algae. Volatile long chain aldehydes (C_{15}-C_{17}) in *Ulva pertusa* are formed from the fatty acid through the formation of the corresponding 2-hydroperoxy acids [88, 98]. Long chain aldehydes in green algae are formed by decomposition of acids [96]. Some of them are metabolites and some are biosynthesis products. Long chain aldehydes, such as tetradecanal, pentadecanal, (8*Z*,11*Z*)-heptadecadienal, and (8*Z*)-heptadecenal, were shown to be formed enzymatically in the filament of the algae [15].

Marine algal amines were first investigated by Steiner and Hartmann [18] and reviewed [20, 21]. Amine compounds such as MA; TMA; DMA; EA; PA; IBA; IAA; PEA were found in algae [35]. Volatile amines in algae occur from decarboxylation of amino acids [99]. TMA and TMA oxides were also found in marine algae [100]. PEA was found in red algae *Ceramium rubrum, Cystoclonium purpureum, Desmarestia aculeate, Dumontias incrassate* [20]; it was also detected in only 6 of 17 algae species of red algae G*elidium crinale, Polysiphonia morrowii, P. tripinnata, Gracilaria bursa-pastoris, Halymenia floresii* (Clemente) C. Agardh*, Phyllophora crispa* but PEA was not found in brown and green algae [22].

There are numerous halogenated compounds in algae. Only volatile halogenated compounds have been included in this chapter. Many volatile biogenic halogenated compounds were synthesized by algae and emitted into atmosphere and can produce halogen by photo degradation, then destroy ozone. Therefore, these compounds are important for atmospheric chemistry [101, 102]. The highest release of brominated compounds was caused by *Laminaria saccharina* [46].

Bromophenols as 2-and 4-BP, 2,4-and 2,6-DBP, and 2,4,6-TBP were found in 87 samples of red, brown, and green marine algae. 2,4,6-TBP was found in all samples [14]. Bromo peroxidases are capable of brominating organic substances in the presence of bromide and hydrogen peroxide in the biosynthesis of bromophenols in marine algae [103]. It was assumed that CBr_2Cl_2 and $CHBrCl_2$ are possibly formed by macroalgae [104]. The biosynthesis of all the bromo compounds was not clearly explained.

Iodinated compounds (CH_2I_2) were reported in *Laminaria saccharina* and *Fucus distichus* and for $CHBr_3$ in *Laminaria saccharina* and *Desmerestia aculeata*. The richness of halogenated compounds CH_2I_2 in *Laminaria saccharina* and *Fucus distichus; and* $CHBr_3$ in *Laminaria saccharina* and *Desmerestia aculeata* is noticeable.

The main difference between volatile oils of terrestrial plants and algae is halogenated compound content.

Marine algae can synthesize hydrocarbons and some aliphatic hydrocarbons [13]. On the other hand, marine algae can take up hydrocarbons from seawater contaminants such as petroleum derivatives [13, 105–108], phthalates [109], and pesticide [110]. Recently, volatile compounds like 86 aliphatic, 56 cyclic oil components have been identified in algae [104]. These exogenous compounds found in algae led to erroneous results. The problem in this field is the differentiation of autochthonous and exogenous hydrocarbons in algae. For example, some of the substances reported in the literature are 2,4,5-trimethyl-1,3-dioxolane; 1,3-dioxan-5-ol; 2-ethoxybutane; 2-ethylhexanol; 1-methyl-3-(1-methylethyl)-benzene; 2-phenoxy-ethanol; benzothiazole, etc. The origins of these and other suspicious compounds should be proven as autochthonous or exogenous [105–107, 111].

Some of the volatile odorous components of algae, such as dimethyl sulfide, are unpleasant and are mainly distributed in Chlorophyta and also in some Rhodophyta [112]. Dimethyl sulfide and acrylic acid have resulted from the enzymatic cleavage products of dimethyl-β-propiothetin (dimethyl-2-carboxyethylsulfonium hydroxide), from *Enteromorpha intestinalis* and *Acrosiphonia centralis* [113], which is a metabolite of methionine [45] released into the sea water [112].

The important pleasant odorous constituents of volatile oil in algae are terpenes which are isoprene units, hooked together. The precursor, isoprene (3-metyhl-1.3-butadien), is not found in a free form in plants. Terpenes are classified according to the number of isoprene units. In volatile group terpenes, mainly acyclic, mono-, and dicyclic groups are present. Many nonvolatile group terpenes were found in algae, but only volatile oil terpenes are included in this chapter. In acyclic group of the terpene constituents contains generally most pleasant odorous compounds. The important compounds for perfumery found in algae are in acyclic group: linalool, citral, geraniol, terpinolene; in cyclic group: 1,8-cineol; in bicyclic group: α-pinene and β-pinene, and aromatic group eugenol and isoeugenol. As can be seen, only a small number of terpene compounds were reported in algae. Since there is no sufficient number of reports, we cannot estimate which algae contain the highest levels and distributional differentiation of these terpene compounds. Terpenes acyclic series are labile compounds and rapidly transformed in free form by various factors such as light, temperature, air, and microorganisms but oxidation and reduction products of terpenes were not found in algae. A number of literatures have been published on the transformation of terpene compounds. By these factors, macrobiological and fungal conversion of citral and geraniol to geranic acid was reported [114]. To prevent the biotransformation of terpenes, it is necessary to work with fresh algae.

5.1 Pharmacological Activities of Volatile Oils

The general activities of volatile oils are antiseptic, antiflogistic, expectorant, sedative, and spasmolytic [115]. Anisole showed spasmolytic activity [115]. 1,8-Cineol showed acetylcholine esterase inhibitor activity [115].

Many reports have been published on antibacterial effects of volatile oils from algae. However, antibacterial activity of the active constituent of the volatile oil has not been reported. We used only the first publication on antibacterial activity of volatile oils in algae and excluded the subsequent ones. Various fractions obtained from *Enteromorpha* showed antibacterial activity, and inhibited *Escherichia coli* and *Staphylococcus aureus*. Antibacterial action of this alga was at least partially attributed to its volatile components [17, 80]. Essential oil of *Pterocladia capillacea* was found to be active against bacteria and fungus [24].

Acrylic acid showed a broad spectrum of antibacterial activity and inhibited both Gram-positive and Gram-negative bacteria at similar concentrations. Acrylic acid feed levels between 0.01 % and 1.0 % caused an apparent increase in the growth rate of chicks, whereas 10 % levels caused anorexia and death [116].

Two sesquiterpenes (1*R**,2*S**,3*R**,5*S**,8*S**,9*R**)-2,3,5,9-tetramethyltricyclo [6.3.0.0^{1,5}] -undecan-2-ol; (1*S**,2*S**,3*S**,5*S**,8*S**,9*S**)-2,3,5,9-tetramethyltricyclo-[6.3.0.0^{1,5}]undecan-2-ol isolated from *Laurencia dendroidea* were not active against eight bacteria strains and the yeast *Candida albicans*, but showed some antioxidant activity [43].

Volatile compounds of *Laminaria japonica, Kjellmania crassifolia, Gracilaria verrucosa* and *Ulva pertusa* showed antimicrobial activities [117].

Aroma profiles of fresh *Ulva pertusa* were examined and it was found that 7-heptadecene, hexanal, (*E*)-2-octenal, (*E*)-2-nonenal, (*Z,E*)-2,6-nonadienal, (*E,E*)-2,4-decadienal, (*Z,Z*)-8,11-heptadecadienal, (*Z,Z,Z*)-8,11,14-heptadecatrienal, and (*Z*)-8-heptadecenal were responsible for the sensory characteristic aroma of the Ulvales [83].

Volatile fractions obtained from *Ulva pertusa* were tested for anthelmintic activity using santonine solution as the control. Dimethylsulfide fraction was the most powerful against the earthworms which were killed at 1,000, 2,000, and 4,000 times dilutions as compared to santonine, terpene, and carbonyl fractions [118]. The effects of volatile constituents of marine algae (*Ulva pertusa*, *Enteromorpha*, *Codium*, and *Sargassum*) on muscle contraction of earthworms were also investigated. Middle segment of a test worm was dissected, fixed on a hook, and dipped in Ringer solution. Carbonyl and terpene fractions at 0.001 % dilutions had strong contractive effect, while the muscle did not seem to react to dimethylsulfide and fatty acids. Furfural, present in carbonyl fraction, caused muscle contraction at 0.1 % concentration [119]. The active principle in the terpene fraction was unknown.

Volatile oil of *Ulva pertusa* showed feeding attractants activity [120].

6 Conclusion

Volatile oils of algae contain a variety of compounds. The main group, terpenes, contains acyclic: linalool, geraniol, citronellol; monocyclic: limonene, 1-8-cineol, *p*-cymene; bicyclic: α- and β- pinene, cadinene, aromatic eugenol, and isoeugenol. The others are benzaldehyde, phenol, *p*-cresol, various acids, alcohols, aldehydes, amines, ketones, sulfur-containing compounds, and halogenated compounds. These compounds except halogenated ones were also found in terrestrial plants. The volatile oil components of algae did not show noteworthy pharmacological activity.

Abstract

Terpenoids comprise the largest and most structurally diverse class of organic compounds. Terpenoids have a multitude of ecological functions, which might be perturbed under changing environmental conditions. The best-known functions of terpenoids in-, and volatilized from, plant tissues are related to adaptation to abiotic stresses and biotic stressors, such as herbivores and pathogens. However, the high volatility and reactivity of some terpenoids may also affect the atmosphere composition. Volatility of terpenoids provides, for sessile plants, a tool for communication with other organisms such as neighboring plants, pollinators and foes of herbivores, via air-borne infochemicals. We review the main properties of biogenic terpenoids, from various scales, including the plant cell, leaf surface and canopy. We also explore links to ecological functions and atmospheric behavior, including the chemical transformations of terpenoids. The functionality of the terpenoids could be strongly influenced by the predicted changes of climatic conditions upon proceeding global climate change. On the other hand, volatile terpenoids released by large forested areas continues to have a significant effect on local climatic conditions e.g., by formation of light-scattering blue haze which is composed of terpenoid-derived secondary aerosol particles. Such processes might also be altered by climatic changes.

Keywords

Climate • defense • herbivory • pollination • pollutants • resins • secondary aerosols • storage • terpenes • volatiles

Abbreviations

BVOC	Biogenic volatile organic compound
CBSC	Carbon-based secondary compound
DMADP	Dimethylallyl diphosphate
DMNT	(E)-4,8-dimethyl-1,3,7-nonatriene
IDP	Isopentenyl diphosphate
MBO	Methyl butenol or 2-methyl-3-butene-2-ol
MEP	2-C-methyl-D-erythritol-4-phosphate pathway
MT	Monoterpene
MVA	Mevalonic acid pathway

NO_x	Oxides of nitrogen
O_3	Ozone
SQT	Sesquiterpene
TMTT	(E,E)-4,8,12-trimethyltrideca-1,3,7,11-tetraene
VOC	Volatile organic compound

1 Introduction

Terpenoid compounds comprise a major group of secondary compounds and are the most diverse among those synthesized by organisms, with 30,000 members [1]. All terpenoids are derived from the five carbon unit (C_5) skeleton of isoprene, and therefore terpenoids can referred to as isoprenoids. Terpenoid classification is dependent upon the number of five-carbon units present in each compound. For example, isoprene is a hemiterpenoid; ten-carbon terpenoids with two C_5 units are called monoterpenoids. Other compound groups are sesquiterpenoids (C_{15}), diterpenoids (C_{20}), triterpenoids (C_{30}), tetraterpenoids (C_{40}) and polyterpenoids ($C_{[n>40]}$). If terpenoids are pure hydrocarbons formed from isoprene units, without removal or addition of methyl groups or addition of oxygen atoms, they are called terpenes. Irregular homoterpenes, C_{11}-homoterpene DMNT and C_{16}-analog TMTT are common floral odor constituents and herbivore-induced compounds in vegetative parts of plants.

The importance of terpenoids to life is highlighted by the fact that two separate pathways have been found to produce the terpenoid precursor C_5 units isopentenyl diphosphate (IDP) and dimethylallyl diphosphate (DMADP). The mevalonic acid (MVA) pathway is functional in archae, animals and fungi, 2-C-methyl-D-erythritol-4-phosphate (MEP) pathway is found in green algae, and terpenoids are produced by both pathways in bacteria and plants [2]. In plants the MVA pathway is active in the cytosol and it provides C_5 units for sesquiterpene, triterpene and polyterpene biosynthesis whereas the MEP pathway occurs in plastids and produces C_5 units for isoprene, monoterpenes, diterpenes and carotenoids [1]. Recent reports have indicated metabolic crosstalk between biosynthesis pathways and e.g., the homoterpene DMNT may originate from both pathways.

Terpenoids can be found in various plant organs. Concentrations of terpenoids in plant tissues are controlled by the availability of substrate and the activity and type of biosynthesis enzymes. Emission rates of volatile terpenoids from plant leaves are controlled by their synthesis rates and compound-specific physicochemical characteristics, mainly their solubility, volatility and diffusivity. These are affected by physicochemical constraints caused by temperature, stomatal conductance and leaf structure. Storage of terpenoids could be isolated from other plant tissues with specialized structures such as secretory cavities, resin canals (Fig. 94.1), latex canals (lactifers), and glandular trichomes.

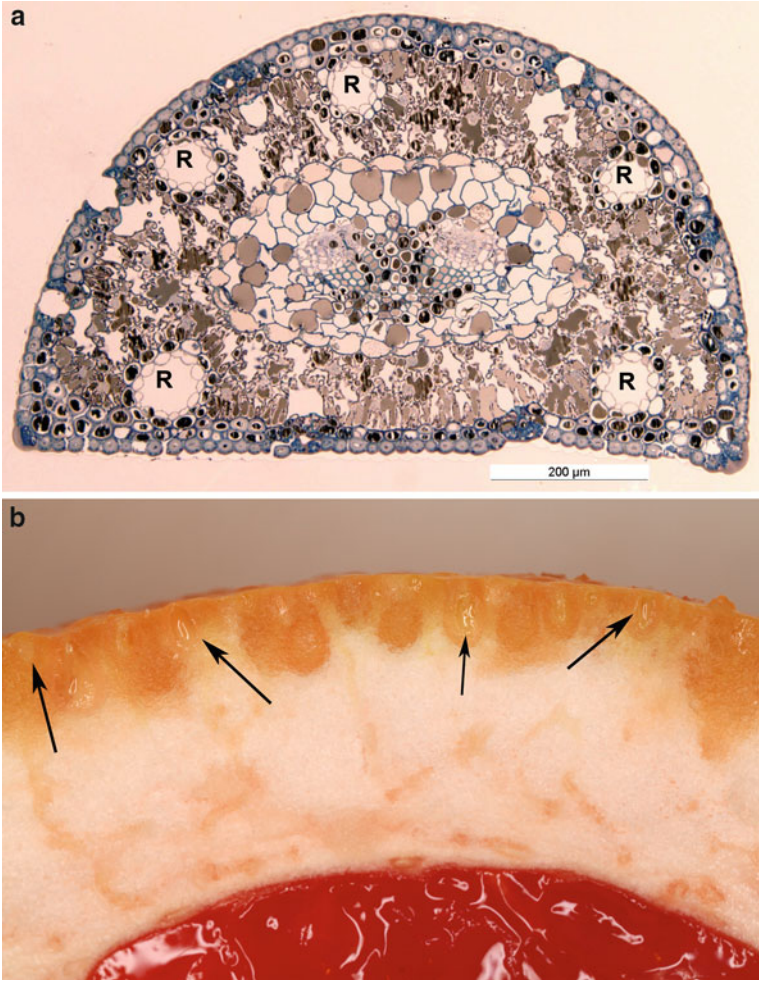

Fig. 94.1 Examples of terpenoid storage structures embedded in plant tissues. (**a**) Cross-section of (*Pinus halepensis*) needle showing four resin canals (*R*) in the needle mesophyll layer (micrograph provided by Dr. Minna Kivimäenpää). (**b**) Secretory cavities of red grapefruit (*Citrus paradisii*) peel for storage of monoterpenes, mostly limonene

Highly volatile terpenoids have a small storage pool and their emission rates are directly responsive to light- and temperature-dependent synthesis rates. Less volatile terpenoids have a large storage pool and total plant emission rate is a combination of emissions from direct synthesis and temperature-dependent evaporation from storage pools.

2 Ecological Functions of Major Groups of Terpenoids

Enormous diversity of terpenoids found in nature suggests that they are important compounds in plant evolution and ecology. The chemical properties of terpenoids and their derivates are manifold. The same chemical compound may have different ecological functions when appearing in solid, liquid or gaseous phase.

2.1 Hemiterpenoids

The most important C_5 hemiterpenoid is the highly volatile isoprene, which is not stored, but emitted from plant chloroplasts in a temperature- and light-dependent manner. Total global isoprene emissions from vegetation are estimated to be 412–601 $\times$ 10^{12} g C annually [3]. Occasionally isoprene-bound carbon emission can represent up to 5% of the photosynthetic net carbon uptake in an individual plant. In the plant kingdom, species of the same genus can represent a wholly different strategy in their capacity to synthesize and emit isoprene; a certain species might not emit isoprene whereas in a closely-related species isoprene can be the dominant VOC emitted. Other biogenic sources of isoprene emissions are breath of humans and animals.

A multitude of functions for isoprene are proposed to explain why plants invest in costly isoprene production to then release such a large amount of recently fixed carbon back into the atmosphere. Improved thermotolerance and enhanced tolerance against ozone and other reactive oxygen species (ROS) are the most often associated responses with the enhanced isoprene production in plants [4]. In contrast, as isoprene emission also consumes metabolites, it has been proposed that plants use isoprene emission as a "safety valve" to get rid of unwanted metabolites. Isoprene is not generally known to affect herbivory, but some evidence indicates that transgenic isoprene emitting plant species, which normally do not emit isoprene, are able to deter caterpillars from feeding and also repel parasitic wasps [5]. Isoprene oxidation products, methacrolein and methyl vinyl ketone are common constituents of the atmosphere above isoprene-emitting trees.

Another common hemiterpenoid in conifer forest atmospheres is methylbutenol (MBO), a five-carbon alcohol produced and emitted only by species of pines (*Pinus* spp.) native to western North America and northern Europe. MBO is biochemically synthesized in chloroplasts by MBO synthase from same precursors as isoprene. Ecophysiological and ecological functions of MBO are poorly understood as this compound has been detected only from pines.

Other hemiterpenoids are e.g., hemiterpenoid glucosides which are found to accumulate in plant roots under nutrient deprivation and carbon flux overflow.

2.2 Monoterpenoids

Monoterpenoids with C_{10} skeleton is not the most diverse group of terpenoids, but they can be considered to be the most important because of their abundance and frequent appearance in nature. Most common monoterpenes e.g., α-pinene can be detected from nearly every green plant since chloroplasts produce monoterpenes, even by those species which do not synthesize isoprene. Plastids of other cells such as epithelial cells of resin duct in conifers produce α-pinene and other monoterpenoids in storage structures. Resin of conifers is a mixture of monoterpenes and diterpenes. The word "terpene" is derived from the word "turpentine," which is mostly an essential oil containing α-pinene distilled from tree resins, originally from "turpentine tree" *Pistacia terebinthus*.

Molecular structures of monoterpenoids are present as three major types: acyclic, monocyclic and bicyclic. Oxygenated derivatives of *acyclic monoterpenes* are more widespread in nature than acyclic monoterpenes themselves. Such derivatives are the monoterpene alcohols citronellol and geraniol, or the monoterpene aldehydes citronellal and geranial. *Mononocyclic monoterpene hydrocarbons* are exemplified by limonene, which is a major component of orange and lemon peel oils, and β-phellandrene, which is emitted by conifer trees under biotic stress. These compounds are relatively common in nature. *Bicyclic monoterpenes* are represented by the aforementioned α-pinene, one of the most abundant and important monoterpenes.

High volatility of monoterpenes has been recognized for a long time and humans have used steam distillation to separate monoterpene-rich essential oils from plants for perfume and flavoring purposes. Monoterpene-rich spicy plants have monoterpenes stored in glandular trichomes on leaf surface (Fig. 94.2). Humans have used spice plants to flavor food, because warm food releases monoterpenoids from plant storage. Songbirds use a similar strategy by adding fresh spicy plants such as *Lavandula stoechas* in their nest [6]. Warmth of nestlings increases monoterpene emissions from plants, reduce bacteria growth in nest and repel bird ectoparasites from nestlings. Perhaps this avian use of monoterpenoids also mark nests and play a role in behavioral ecology.

Monoterpenes produced in chloroplasts have similar functions as isoprene to control thermotolerance and ozone tolerance of plants. Owing to their lower volatility, monoterpenes can be adsorbed on plant membranes or even taken up by neighboring non-emitting plants for temporary storage when temperature is below +20 °C. Plants that do not store monoterpenes emit these compounds mostly in a light–dependent manner while species storing monoterpenes can emit them in darkness if temperature is sufficiently high.

There are a multitude of ecological functions of monoterpenoids. The best known functions are as signal molecules in flower scent to attract pollinators, and as defense-related roles against herbivores and plant pathogens. Very important here is indirect defense signaling to attract natural enemies of herbivores and allelopathic effects between higher plants to improve plant performance in plant communities. Although monoterpenes are repellent or feeding deterrents for many

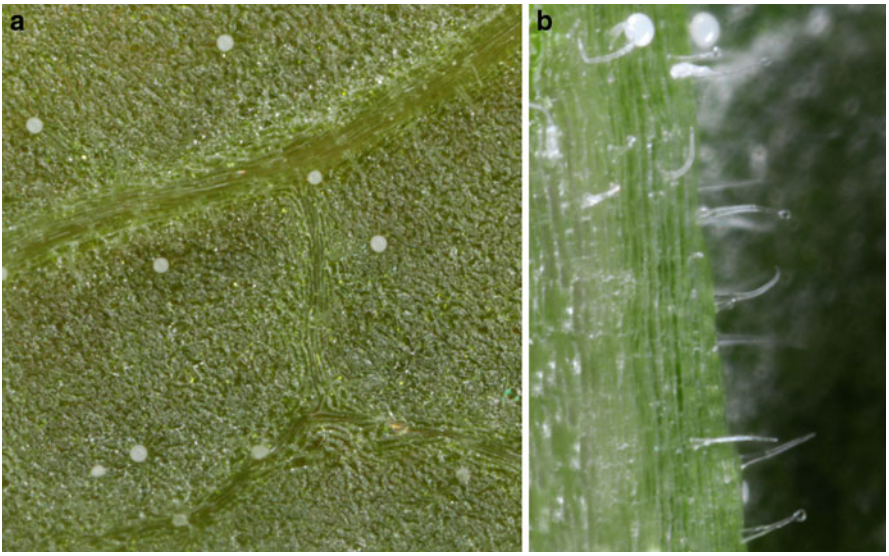

Fig. 94.2 Glandular trichomes of sage (*Salvia officinalis*) store essential oil composed of monoterpenes. (**a**) Peltate glandular trichomes forming oil glands on lower leaf surface of sage. (**b**) Peltate glandular trichomes, capitate glandular trichomes and non-glandular trichomes on leaf veins of sage

herbivore species, insects as well as mammals, there are many animal species that are particularly adapted to feed on monoterpene-rich plant species. The ratio of specific monoterpenes or their enantiomers can often act as the cue for herbivores to identify the most suitable plant species and individuals for food. Herb species in the family Apiacea differ in their relative concentration of the same common monoterpenes and the host selection of species specific psyllids (Homoptera: Psyllidae) are associated to monoterpene composition of Apiacea host species. Several Australian marsupial species feed on *Eucalyptus* leaves almost exclusively. In the boreal conifer forests vole species and moose consume the monoterpene-rich Scots pine. Also humans consume fruits, vegetables and spicy leaves rich in monoterpenes, which indicate the low toxicity of many common monoterpenoids to mammals, and perhaps a metabolic benefit to consumers.

Conifer resin, which is a mixture of monoterpenes and diterpenes is an important protective compound against bark beetles and other conifer herbivores. The volatile monoterpenes emanating from a specific tree is often the cue for bark beetles to find a tree where the tree defenses could be compromised from abiotic or biotic stresses. The synchronized mass attack is the strategy bark beetles use to reduce the effects of resin-based defenses in conifers. Aggregation hormones released by bark beetles are oxidized monoterpenoids such as ipsdienol, ipsenol and verbenol. It is believed that these compounds can be oxidation products of host plant monoterpenes such as myrcene. Recently it has been observed that most of the monoterpenoid aggregation pheromone components are biosynthesized *de novo* in bark beetles [7].

Plant feeding insects are able to store host plant monoterpenes and use the compounds in their own defense. Pine sawfly larvae store mono- and diterpenes of host plant resin for defensive purposes (see diterpenes). Larvae of Chrysomelid leaf beetles feeding on *Salix* and *Populus* are able to store and sequester precursors of iridoids (cyclopentane monoterpenoids) derived from host plant. In addition to this sequestration iridoids may even have a dual origin as larvae of *Plagiodera versicolora* and *Phratora laticollis* have the potential to de novo produce iridoids from the precursors in their food [8].

Flower scent is extremely variable between plant species, but often monoterpenes are the dominating group of compounds in floral odor bouquet. Flowers of one plant species can emit more than 100 scent compounds. Linalool, β-ocimene and β-myrcene are monoterpenes that have been most-oft reported from flowers. Proportion of monoterpenes of the total scent is variable depending on the age of flowers and the part of the flower analyzed, but their proportion in many cases exceeds 50% of the total flower emission. The ratio of different compounds in flower scent affects the composition of pollinating insect communities. Wasps, flies, beetles and butterflies have a different odor preference in addition to preferences of visible flower colors. Specialized pollinator species use the combination of visual and olfactometric cues of flowers to detect their specific host species.

2.3 Sesquiterpenoids

Sesquiterpenoids are the largest and most diverse class of terpenoids having more than 6,500 described compounds [1]. The structure is based on the union of three C_5 groups leading to C_{15} substances and their derivates. Most of the sesquiterpenes are semivolatile liquids and often comprise plant essential oils together with monoterpenes. Molecular structures may be acyclic or contain rings, like the monoterpenes. Farnesene is an example of common *acyclic* sesquiterpenes, which with oxidation can become a sesquiterpenoid such as sesquiterpene alcohol farnesol. Example of a *monocyclic* sesquiterpenes is humulene which is common in the essential oil of hops (*Humulus lupulus*). *Bicyclic* sesquiterpene β-caryophyllene, with an additional cyclobutane ring, is a sesquiterpene found in flowers of many species and it has a significant function as an alarm pheromone in aphids. Alarm pheromones are released by attacked aphids to encourage other members of the aphid colony to escape from their enemies. *Tricyclic* sesquiterpenes, such as longifolene from longleaf pine, have a third ring in their structure.

Oxygenated tricyclic sesquiterpene alcohols ledol and palustrol are sticky semivolatiles produced high amounts e.g., by circumpolar *Rhododendron tomentosum* (formerly *Ledum palustre*) known also as wild rosemary or northern Labrador tea. These sesquiterpene alcohols are toxic to humans in high concentrations but act as effective repellents against blood-feeding insects and ticks. Recently these semivolatile compounds have been found in condensate on the leaf surfaces of neighboring plants in their natural growth habitats during nighttime and reemitted to the atmosphere during warm daytime conditions. These properties are associated to repellency of herbivorous insect from neighboring plants suggesting an “extended chemical defense” by these sesquiterpenoids on plant community level [9].

Derivatives of sesquiterpenes have an important role in plant-herbivore interactions. Drimane-type dialdehyde sesquiterpenes such as polygodial and warburganal are known feeding deterrents for several herbivorous insect species and human perceive these as hot tasting [10]. Sesquiterpene lactones are characterized by a lactone ring and many representatives are toxic to herbivores from several insect orders. These compounds are frequently found from glandular trichomes or latex ducts of members of the Compositae family. Gossypol in cotton is a phenolic sesquiterpene dimer produced by the pigment glands of cotton. Gossypol is toxic to several herbivorous insects and acts as a feeding deterrent to a variety of important defoliators of cotton.

2.4 Diterpenoids

Diterpenoids are C_{20} compound formed of four C_5 units. Basic diterpenes are mostly non-volatile compounds found from plant resins (e.g., in the Coniferae) and latex (e.g., in the Euphorbiaceae). In conifer resin abietic acid and other diterpene carboxylic acids are solids mixed with essential oils when formed in resin ducts. The viscosity and flow of resin is controlled by the proportion of essential oils, which are composed of monoterpenes and sesquiterpenes. When these oily substances evaporate, resin acids crystallize and form a solid protective layer on the damage site. Bark beetle attack induces resin flow on conifer bark (Fig. 94.3).

Resin acids in conifer are important feeding deterrents for many polyphagous herbivores. However, specialist herbivores of conifer trees are adapted to detoxify diterpenes and other terpenoids of resin or store these substances for defense against their own natural enemies. Pine sawfly larvae are serious defoliators which store diterpene and monoterpene mixtures in special storages connected to foregut. When attacked by predators sawfly larvae discharge a droplet of resin towards the enemy with a rapid backward movement (Fig. 94.4). After smeared with a sticky resin the predator often abandons pursuit of sawfly larvae.

2.5 Triterpenoids

Triterpenoids, C_{30} compounds with basic skeleton composed of six isoprene units, is a large and diverse group of compounds which have several ecological functions. Triterpenoids produced by plants can appear in plants mixed in resins, latex, corks or in leaf waxes. They often act as feeding deterrent for herbivores (including humans), and may interfere with insect growth and development. Major groups of ecologically significant triterpenoids produced by plants are cucurbitacins, limonoids, saponins and cardenolides (cardiac glycosides) [10].

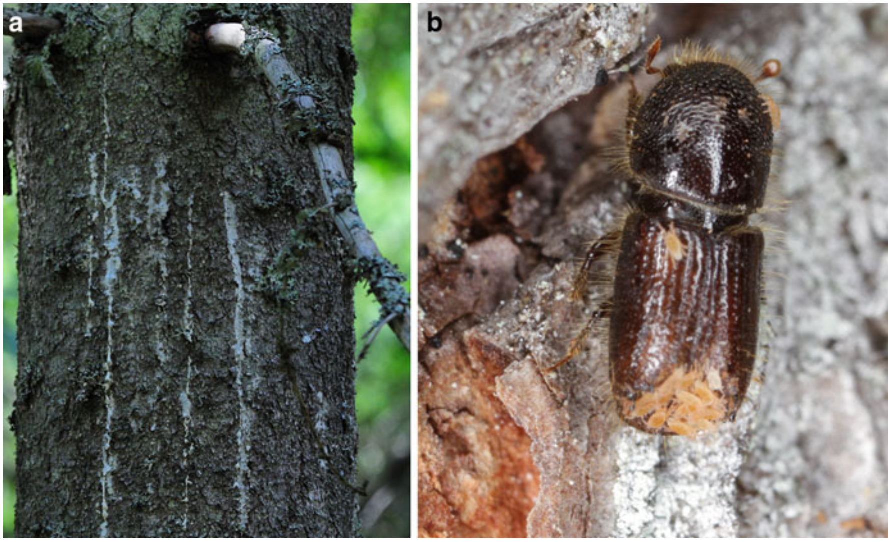

Fig. 94.3 Conifer tree defense against bark beetles with induced resin production. (**a**) Resin flow on Norway Spruce (*Picea abies*) bark after attack by bark beetles. (**b**) The European spruce bark beetle (*Ips typographus*), the most serious bark beetle pest of Norway spruce, attacking spruce bark with phoretic mites, which are probably involved in the transmission of fungal tree pathogens

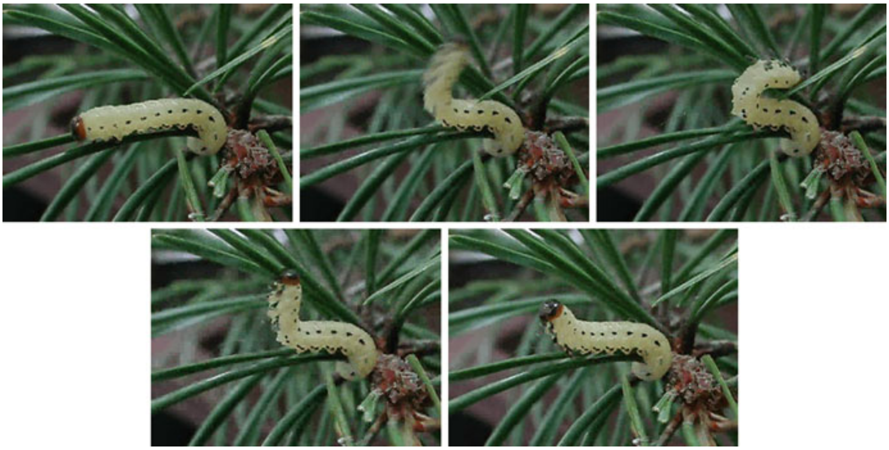

Fig. 94.4 When disturbed, e.g., by birds or other predators, the pine sawfly *Diprion pini* larva shows a rapid defense movement and discharges a droplet of resin which is chemically identical mixture of mono- and diterpenes as resin produced by the pine host *Pinus sylvestris*

Cucurtbitacins are tetracyclic compounds produced by plants of Cucurbitaceae family and humans sense their taste as bitter. Some specialized cucumber leaf beetles of can efficiently detoxify these compounds. Limonoids are a large group of oxygenated triterpenoids produced by plants in Rutaceae and Meliaceae families.

Limonoid azadirachting is produced by the neem tree and China berry and is very strong feeding deterrent for several insect species and acts as a natural insecticide that is effective against the desert locust. Saponins are a group of triterpenoid glycosides with soap-like properties. This is because of the presence of hydrophobic triterpene and hydrophilic sugar group in one molecule will give saponins detergent-like properties. Cardenolides are steroidal glycosides, triterpene derivatives that are referred to as cardiac glycosides because of their heart-arresting properties. Many of these compounds are bitter-tasting and lethal to mammals in high concentrations. Often cardenolides induce vomiting in mammals, which reduce the risk of fatal poisoning. Specialist herbivorous insect species adapted to feed on milkweeds (*Asclepias*) such as the Monarch butterfly, are often bright colored and they are able to sequester host plant cardenolides for defensive purposes [11].

Other ecologically important triterpenes are the phytoecdysteroids, which are plant derived ecdysteroids, triterpene analogues to insect molting hormone ecdysone. Many ferns and gymnosperms contain these compounds in high concentration and they are expected to give protection against insect herbivores. Papyriferic acid is a triterpene in the resin of birch (*Betula*) species that protects bark against winter browsing by mammals.

3 Distribution of Terpenes Within Plants and in Environment

3.1 Localization in Cells and Organs

Concentrations of terpenes in plants are enormously variable among individuals and even organs within populations. Genetic control of terpene synthesis affects the composition of terpenes in each individual. Environmental and temporal variation in each organ could be very high e.g., some specific compounds in young leaves can be replaced with other compounds in older foliage. This variation is also affected by abiotic or biotic factor inducibility.

One terpene localization strategy by plants is production in specialized structures such as resin and latex ducts, secretory cavities and glandular trichomes. In these structures terpenoids are synthesized by secretory cells and stored in very high concentrations, which could be autotoxic to other plant tissues. Ecological interactions are influenced by locale and type of structures in plant organs. For example organs such as leaves face threats against different herbivores than in wood. Conifer needles produce monoterpenes and diterpenes protect against totally different insect herbivore or fungal pathogen species than in woody stem phloem.

Terpenes volatilization can be sensed by herbivores as they approach a potential host plant with implications for the defense strategies of plants. Volatile compounds can repel most potential generalist herbivores at some distance from the plant, but the same emitted VOCs have an opposite function in attracting host plant-specific herbivores. Terpenes secreted on plant surfaces as waxes or resins or deposited in glandular hairs may give direct protection against many small insect and mite herbivores and inhibit the germination of fungal spores and growth of pathogenic fungal hyphae. Latex and resins ducts located in leaf or needle mesophyll layer are efficient upon herbivore wounding of tissues feeding. Defense compounds are rapidly released from pressurized and damaged ducts. Sticky compounds can physically or chemically halt feeding.

3.2 Volatile Compounds in the Atmosphere

Isoprene, monoterpene and sesquiterpenes are volatile terpenes which have several functions after release from plants. Monoterpenes and sesquiterpenes are important part of flower scents to attract pollinator species. Different flower parts such as sepals, pets, anthers and pollen have different scent profiles of volatile compounds. Pollinators can use this volatile profile to detect the optimal availability of pollen. With pollen several less-volatile terpenoid compound can spread over long distances from the original host plant.

Vegetative isoprene and monoterpene emissions have strong light- and temperature-dependence because of large amounts of biosynthesis in chloroplasts. Changes in temperature and photosynthetically active radiation (PAR) affect emission rates of these volatiles. Emission from species having monoterpenes emitted from storage, and emissions of sesquiterpenes are more strongly related to changes in temperature than light. Also other abiotic factors influence emission rates, but the most distinctive changes are caused by biotic factors which induce the production of volatile terpenoids. Herbivore-induced terpenoid emissions affect defense responses of neighboring plants and behavior of other herbivores, but more importantly they affect the efficiency of natural enemy search for herbivore hosts. Homoterpene emissions are particularly typical for herbivore-damaged plants.

Different mono- and sesquiterpenes have variable lifetimes in the atmosphere depending the other reactive compounds in the atmosphere. In atmospheres rich of oxides of nitrogen (NO_x) volatile terpenes participate in the formation of ozone (O_3). If the concentrations of NO_x are low, monoterpenes and sesquiterpenes react with O_3 leading to lower concentration of phytotoxic O_3. The reaction products can be liquid or amorphic solid nano-scale particles which later aggregate into larger aerosol particles [12]. Reaction products of VOCs are called secondary organic aerosol particles (SOA), because they are formed in the atmosphere from gases and fumes.

3.3 Accumulation and Functions in Soil

In the rhyzosphere terpenoids can affect seeds and roots of competing plants, soil microbes and animals. Terpenoids spread through volatilization from plant rhizosphere, leaching from above-group parts of plants, or by decomposition of plant debris. When terpenoids accumulate in soil in high concentrations from terpene-rich plant species, plant species sensitive to phytotoxic terpenes will gradually disappear in ecological time, leading to changes in plant community composition. Understory vegetation of conifer forest is adapted to monoterpene and dipterpene-rich needle litter which may release degradation products several years after needle cast. Monoterpenes of plant essential oil, sesquiterpenes, particularly sesquiterpene lactones have been reported to have biological effects on soil fauna and microbes.

Plant communication via volatile sesquiterpenes at the third trophic level, natural enemies of herbivores, has been shown in soil ecosystems. Root beetle damages on maize root system will induce production and emissions of (*E*)-β-caryophyllene, also known as an aphid alarm pheromone. This compound spreads through soil pores where it attracts entomopathogenic nematodes that, in turn, control root beetle larvae [13].

Monoterpenes in the coniferous soil atmosphere have been shown to affect microbial activities and net nitrogen mineralization and nitrification in nitrogen poor soils. These observations suggest that terpenes together with condensed tannins in soil, may have a crucial role in microbial processes related to soil C and N cycling. One of the proposed mechanisms is binding of proteins and certain other organic N-containing compounds [14].

3.4 Aquatic and Marine Environments

Photosynthesizing vegetation in terrestrial ecosystems is known to be important source of isoprene and monoterpenes released into the atmosphere. Globally the average net primary production expressed as a dry mass produced per area unit per year (g m^{-2} $year^{-1}$) is even higher in marine algal beds and reefs than in tropical rainforests. Therefore, it is astonishing that only very recently it has been observed that algae in an active phytoplankton bloom of the ocean can be a significant source of monoterpene emissions into the atmosphere [15]. In low chlorophyll regions of oceans, monoterpenes over the sea surface are mostly below detection limits. In laboratory conditions cyanobacteria produce isoprene in a significantly higher emission rate than diatoms and the isoprene emission rates are related to the actual cell volume.

Less volatile terpenes have been described from macroalgae. Recently it has been shown that macroalgae are able to damage corals using hydrophobic allelochemicals present on their surfaces. The monoterpene lactone, loliolide, in red algae and diterpene derivates from the green alga *Chlorodesmis fastigiata* have been described as potent allelochemicals that induce damage in corals in site-specific spots of algal contact. Corals in global decline, such as *Acropora*, are most severely affected [16]. Several marine invertebrates cover their bodies with species of seaweeds, polyps, sponges, or bacteria that contain diterpene alcohols. These "clothing" species give protection against the predatory fishes. Fish- repellant properties of the diterpene alcohols produced by the companion organisms are the chemical mediators of this mutualistic behavior [17]. The advantage for the "covering" mutualist species is that the mobile invertebrate host will improve their food availability when searching for its own food sources.

4 Terpenoids and Plant Adaptation to Climate Change-Related Abiotic Stresses

4.1 Temperature Changes

Temperature is a major driving factor for the formation of ecosystems and biomes. Geographical distribution of species largely depends on their adaptation to a local temperature range. Warming or cooling of local climate will lead to changes in the distribution of biotic organisms. Distribution changes occur more rapidly for mobile animals than in sessile plants. Therefore, plant adaptation to changing climatal temperatures is predicted to be slower than that of animals. Herbaceous plant species with a massive production of plumed seeds for long-range wind-dispersion exemplifies one strategy for coping with rapid changes in local climate; guerilla adaptation. At the other extreme of adaptation capability to climate warming are trees with very long life cycles with local seed dispersal; phalanx adaptation. Guerilla adaptation is more suited for annual invaders whereas phalanx adaptation is seen more in climax species.

Global climate warming is a result of extensive use of fossil energy which has resulted in continuously increasing concentrations CO_2 and other greenhouse gases in the atmosphere. In the greenhouse effect, solar infrared radiation warms the lower atmosphere and surface of the earth efficiently owing to absorption of warming infrared radiation by higher concentration of greenhouse gases. Climate warming also affects annual precipitation in large areas and together these factors have a strong impact on the survival of plant and animals in ecosystems.

The biosynthesis of secondary metabolites in various organisms is directly dependent on temperature. Rapid changes in the physiological status e.g., stomatal function and allocation of resources (i.e., substrate availability) at high temperatures could have dramatic changes in production of terpenes by plants. Volatile terpenes also have higher volatility at higher temperatures, which affects emission rates, but also affects concentrations in tissues. At higher temperatures isoprene and monoterpene emission have consistently increased reported emission rates in monitoring studies [18]. This is a result from more active synthesis in leaves and needles, but partly higher release rate from storage, which may lead to lower concentrations in the tissues, even though emission rates are higher.

In deciduous trees even elevated night temperatures have resulted in higher daytime emissions rates of isoprene, monoterpenes, sesquiterpenes and a homoterpene on a leaf-area basis. This increased emission per leaf area unit was associated with substantial increase of total leaf area of tree saplings. The strong correlation of plant growth rate and terpenoid emission rates from plants with temperature indicates that there are likely increased terpenoid emissions under warmer climate conditions. For plant species which defend against herbivores with semivolatile compounds adsorbed on their leaf surfaces, higher night temperatures coupled with a loss of defensive cover could mean increased susceptibility to herbivores.

There is less knowledge of the responses of diterpenes to changing temperature. However, the evidence of resin acid concentrations of conifer needles and bark at elevated temperature suggests slight increase in concentrations, but the situation is not as clear as for monoterpene response. The production of triterpenes of tropical plants did not follow the significant temperature dependence of tannin in some plant species. It is possible that the terpenes with higher number of isoprene units are not as responsive to temperature changes as other plant secondary metabolites, because plant allocate substrates to less costly isoprene and monoterpene synthesis.

4.2 Drought and Flooding

Drought stress is a typical seasonal situation in many geographical; particularly affecting agriculture. Some plants go dormant and some are structurally adapted to low water availability. During climate warming the timing of rainy and dry seasons have changed in large areas such as the horn of Africa in the eastern part of the continent, where long drought periods in recent years have resulted in serious yield losses and famine. Often changed climatic conditions will lead to more frequent heavy rains and flooding in the geographical areas where the vegetation has not adapted to such high precipitation. Of course, precipitation timing also affects plant growth and development.

Long dry periods lead often to accumulation of salts in soil and create an additional stress for plant roots. Drought and salt-induced stress in root systems also results in leaf stomata closure, and thus creates biochemical limitations of photosynthesis. Both the reduction of photosynthesis and the stomatal closure are expected to negatively affect carbon supply into the MEP pathway and reduce terpenoid biosynthesis. Against this hypothesis, experimental evidence has shown that isoprene is not reduced by increasing drought stress until the stress becomes heavy and almost completely inhibits photosynthesis. Carbon labeling experiments have shown that under stress isoprene synthesis in plants continue by using alternative sources of carbon earlier fixed and carbon stores are possibly related to starch breakdown. This change of isoprene precursor is temporal and rewatering of plants leads to isoprene emission bursts when photosynthesis-dependent isoprene production is reactivated [4].

In Scots pine and Norway spruce saplings episodes of severe drought has resulted in the increased concentrations of several individual monoterpenes and diterpene resin acids in the xylem storage vesicles. Elevated monoterpene concentrations have been detected from the needles of Norway spruce. Emission analysis of inducible volatile terpenes of maize after simulated moth damage showed variable responses of individual mono-, sesqui- and homoterpenes to decreasing soil water availability. During drought conditions, the emissions of monoterpene linalool and sesquiterpenes β-caryophyllene and (*E*)-nerolidol and homoterpene TMTT were decreased whereas emissions of sesquiterpenes α-farnesene and β-bisabolene showed the opposite trend.

In California chaparral and Mediterranean bush vegetation, monoterpenes produced by above and below-ground plant parts accumulate in soil. Sequestration to soil is related to plant allelopathy, which improves root competitive ability to the host.

Dry and hot periods promote monoterpene volatilization from soil and may also increase flammability. As a result, recurrent dry periods may lead to more frequent and more rapidly spreading bushfires when monoterpene-rich soil supports the spread of fire, again removing competitors.

Flood-simulating root water-logging does not affect needle monoterpene concentrations of Norway spruce. Root anoxia as a result of flooding results in increased emission of many stress marker volatile compounds such as ethanol, acetaldehyde and nitric oxide (NO), but less is known about the influence of flooding on monoterpene and isoprene emission of plants.

4.3 Changing Atmospheric CO_2

Climate warming is a result of increased greenhouse gas concentrations in the atmosphere. Carbon dioxide is crucial for plant photosynthesis and therefore changes in atmospheric CO_2 concentration have direct effects for plant physiology and concentration of carbon-based compounds. The average atmospheric CO_2 concentration was approximately 320 ppm in the mid-1960s and reached the level of 393 ppm in early 2012 at the Mauna Loa Observatory, Hawaii. Three-quarters of the increase was likely the result of greater fossil fuel use and the remainder of increase from changes in land-use such as increased deforestation.

Increased atmospheric CO_2 concentrations with more carbon available for photosynthesis increases plant productivity and indirectly increases capacity of vegetation to produce terpene per area unit. One typical characteristic for plants grown at elevated CO_2 concentration atmospheres is thicker leaves. Emission of volatile terpenoids per leaf area unit could therefore be higher at elevated- than ambient CO_2 concentration. However, current observations from elevated CO_2 exposure experiments have reported the opposite [18]. In particular isoprene emission has decreased at elevated CO_2 and monoterpene emissions have responded in a variable manner depending on the individual monoterpene compound being monitored. Reduced isoprene and monoterpene emissions at high CO_2 environments might suggest the uncoupling of isoprene synthesis from photosynthesis, similarly to that under drought stress, leading to consequent inhibition of isoprene emission at the leaf level.

Evidence from terpenoid analyses of plant tissues support the observations of the effects of elevated atmospheric CO_2 concentrations on volatile terpenoid emissions. Responses of stored monoterpenes and diterpenes in the needles of Scots pine and Norway spruce sapling to elevated CO_2 were opposite when compared to temperature effect; significantly reduced concentrations of many compounds have been detected [19]. Elevated CO_2 had less influence on the concentrations of the stored monoterpenes and diterpenes in the stem bark, phloem and xylem. In Scots pines grown at elevated CO_2 and elevated temperature environments in large closed-top-chambers, elevated CO_2 resulted in consistently reduced total monoterpene concentration while temperature effects were more variable [20].

4.4 Eutrophication and Nutrient Availability

Eutrophication of coastal areas results in an increase of phytoplankton aquatic ecosystems and the potential of rapidly increased emissions of isoprene and monoterpenes from the algae and cyanobacteria in the bloom. Eutrophication, therefore, could be a result of higher density and biomass of phytoplankton per area unit, but unfortunately studies of terpenoid production of single species under the excess nutrients have not been performed.

In terrestrial plants the allocation of carbon to carbon-based secondary metabolites, particularly phenolic compounds, is often attenuated when higher amount of nitrogen and other nutrients are available for plant growth. Terpenoids, such as diterpenes and monoterpenes found in resin, sequestered in special storage structures, normally responds variably. When compared to nutrient deficient plants, fertilized plants grown faster and develop larger organs. It has been observed that under improved nitrogen availability pine needles grow larger and they form increased number of resin canals. This means higher resin concentration in well-developed needles and may result in higher emissions rates of monoterpenes by diffusion from the storage.

4.5 Ozone and Oxidative Stress

In the troposphere, the lowest layer of atmosphere, volatile terpenes perform a dual action, depending on the presence of anthropogenic pollutants such as oxides of nitrogen (NOx). When NOx concentrations are low, volatile terpenes react with ozone to reduce the atmospheric concentration of this phytotoxic gas. When air is contaminated with NO_x formed e.g., by combustion, volatile terpenes participate in reactions which results in formation of tropospheric ozone.

There is very wide variation in the reactivity and the atmospheric lifetime of volatile terpenes with ozone in standardized conditions at an average ambient O_3 concentration of 30 ppb. Among the shortest lifetimes of phytogenic terpenes are 1 min for the monoterpene α-terpinene and 2 min for the sesquiterpene β-caryophyllene. The longest lifetimes are more than 235 days for the monoterpenoid camphor, more than 110 days for the monoterpene monoterpene 1,8-cineole and more than 33 days for the sesquiterpene longifolene. In similar conditions isoprene has a lifetime of 1.3 days and the monoterpene α-pinene, for 4.6 h [21].

It has been suggested that volatile terpenes play a similar dual action inside the leaves and participate in ozone quenching in the intercellular spaces before they are released into the atmosphere. In plants exposed to ozone either a reduction or an increase of isoprene and monoterpene emission is observed. Particularly high ozone concentrations induce the terpene emission often as a result of cellular damage. There is evidence that volatile terpenes are able to reduce ozone damage and to quench ozone and reactive oxygen species (ROS). Furthermore, it has been demonstrated in tropical forests a large fraction of total plant sesquiterpene emissions undergo within-canopy ozonolysis, which may benefit plants by reducing ozone uptake and oxidative damage to the foliage.

Exposure of terpene-storing conifers to moderately elevated ozone concentration does not lead to substantial changes in monoterpene or diterpene concentrations in needles.

4.6 UV-B Radiation

Solar UV-B radiation has been increased in the areas of stratospheric ozone hole in the polar area. Some observations of isoprene emission from vegetation experimentally exposed to supplemental UV-B simulated 20–30% depletion of stratospheric ozone, which suggests increased emission of isoprene under elevated UV-B radiation conditions.

4.7 Multiple Abiotic Stresses

Most scenarios of future climate change includes several abiotic factors affecting plant growth changing at the same time relative to current conditions. Very few studies have attempted to investigate volatile terpene emissions under multiple abiotic stresses, either in the laboratory or field. In one of these, [19] terpenoid concentration and emission studies were performed on trees in chamber and open field experiments. In these experiments exposures to elevated temperature and CO_2 concentration, to elevated ozone and elevated CO_2 concentration and to elevated ozone concentration and elevated temperature were combined. It is expected e.g., that combination of warmer growth temperature and doubled ambient CO_2 concentration could improve plant capacity to produce costly terpenoids for defense and other essential functions. However, monoterpene content of needles of Scots pine trees grown at elevated CO_2 and elevated temperature environments and their combinations in large closed-top-chambers was lowest in the combination treatment. Interestingly, analysis of monoterpene emission from the same combined CO_2 and temperature treatment indicated significantly increased monoterpene emissions compared to ambient conditions [19]. This observation suggests that increased monoterpene emission rates from conifer needles may indicate reduced storage in needles.

European aspen grown in field site in Finland with combined doubled atmospheric ozone levels and increased average temperature of +1 °C had a differential response in isoprene and monoterpene α-pinene emissions depending on genotype [22]. Isoprene emission was decreased at elevated temperature in one clone, but ozone exposure compensated for this decrease. Both clones had slightly reduced α-pinene emission rates at elevated ozone, but elevated temperature treatment compensated for the ozone effect.

A long-term large field exposure of North American deciduous trees to doubled atmospheric ozone and CO_2 in Wisconsin was studied relative to terpenoid responses. Elevated ozone reduced the gene expression coding the isoprene synthase activity and the amount of this enzyme in American aspen. Combining elevated ozone and elevated CO_2 treatments demonstrated that elevated CO_2 cannot compensate for this effect [23]. Both treatments combined or singly reduced isoprene emission from the ozone sensitive clone.

5 Ecological Functions of Terpenoids under Abiotic Stresses

5.1 Plant–Animal Communication

Plant-animal communication that occurs between the primary producers (plants), primary consumers (herbivorous animals) and secondary consumers (carnivorous animals) is one of the most intriguing and sensitive processes in ecosystems. In particular volatile terpenoids play an important role as chemical cues in these interactions below- and above ground and changes in the abiotic environment may disturb this interplay in different phases (Table 94.1, [24]).

5.1.1 Types of Cues and Signals and Signal Perception

Herbivores can typically sense suitable host plants using olfactory cues from long distance. Many volatile terpenoids bear the essential information in their molecular structure. Different stereo isomers of the same compound may result in different response when sensed by insect antennae or the olfactory sensors in the nose of vertebrate animals. Another important factor affecting signal perception and behavioral response in herbivore is the relative proportion of different volatile compounds, terpenoids or other volatiles, in the odor plume released by a plant. Combination of certain monoterpenes and sesquiterpenes are very distinctive in certain plant families. Specialist herbivore species can separate these combinations from similar monoterpenes released by other plants, because of their strict ratio in the host species.

Table 94.1 Types of chemical plant defenses against herbivorous animals, and the type of functions and advantages for the plant. Terpenes are functional in all type of defenses

Type of defense	Functionality	Advantages for the plant
Constitutive defense	Continuous production of defense compounds	Cost effective, if plant is continuously under herbivore attack
Inducible defense	Production of defense compounds is activated after herbivore damage	Cost effective, if there is not a great herbivore load
Direct defense	Defense compounds directly affect the damaging herbivore by reducing feeding (also termed bottom-up effects)	Direct defense can be constitutive or inducible
Indirect defense	Chemical compounds attract natural enemies of an herbivore to locate a suitable prey after attack (also termed top-down effects or multitrophic interactions)	Indirect defense is normally inducible and thus cost effective under a low herbivore environment. Effective only if natural enemies are within the range of spreading signals

If communication is based on the combination of extremely reactive and less reactive volatile compounds, the original ratio of compounds could soon be corrupted under environmental disturbances that affect reactivity of volatile terpenes. A signal could still be reliable for short distances, but in longer distance communication, the original proportion of individual compounds and the information they transmit may be lost.

5.1.2 Direct Herbivore Defense

Volatile terpenoids released by a plant can act as a repellent for herbivorous species which do not prefer the odor. To keep herbivore away before probing is a strategy to avoid occasional biting and induced damage, but repellents also give protection against plant virus diseases transmitted by many sucking insects. In many cases short stylet probing is sufficient for virus transmission from an insect to plant. The weakness of this strategy is that the same volatiles that repel most of the polyphagous species could signal the presence of the plant to certain potential specialist herbivores.

Orientation of herbivorous insects could be disturbed if environmental factors reduce synthesis and emission of repellent compounds or destroy the molecules soon after their release into the atmosphere. This will affect the efficiency of repellent compound to prevent herbivorous insect recognition of the plant for attack. Weakness of the volatile signals may reduce their repelling efficiency against generalist herbivore species. On the other hand, the pressure from specialist herbivore species could be reduced when their detection rate of suitable host plants is reduced.

Terpenoids sequestered on plant surfaces, such as glandular trichomes, resins on stem and bark and compounds bound in the epidermal waxes have the potential to prevent herbivory or other exploits. In particular, females of many fly and butterfly species walk on the surface of a herbaceous plant to taste the quality of plant to decide if it is a suitable host. These insects have contact chemoreceptor hairs in the tarsal segments of their legs for tasting. Insects making test bites for tasting can be deterred from feeding with high concentration of bad-tasting terpenoids in plant tissues.

Changes in environmental conditions affect nutrient availability and uptake by plants. Variability of nutrient availability and particularly nitrogen influences plant physiology and growth affecting available plant biomass for herbivores. An extensive meta-analysis [25] of resource availability effects on carbon-based secondary metabolites (CBSCs) in plant foliage demonstrated that concentrations of most CBSCs were reduced when nitrogen availability improved. Terpenoids did not follow this rule. Improved nitrogen availability increased concentration of monoterpenes and diterpenes in conifers. In general, CBSCs were not influenced by phosphorous availability from soil. Performance of herbivores is affected more by the nitrogen-carbon (N/C) ratio in the foliar tissue than by the actual concentration of terpenes and other CBSCs in the foliage, making the assessment of terpenoid effects on herbivores under nutrition deficiency condition difficult.

Elevating atmospheric CO_2 concentrations affect plant N/C ratio conversely to that of nitrogen fertilization, but in the same direction as nitrogen deficiency. Plants grown in enriched CO_2 atmosphere have "nitrogen dilution effect" leading to lower foliar nitrogen content than in plants grown in similar condition in the current ambient CO_2 concentration (ca. 390 ppm). This have frequently resulted in higher consumption rate and food intake by insect herbivores, their lower growth rate and often delayed developmental time and reduced pupal weight. Increased food uptake by herbivores also result in their increased exposure to CBSCs, including terpenoids, although terpenoid concentrations in green tissues could be decreased. In conifers increased resin flow in mature pine trees growing under elevated CO_2 and moderate soil fertility have been detected [26] This result suggests that under elevated CO_2 atmospheres conifers trees could become better protected against bark beetles, because excessive resin flow is a major defense system in conifers against bark beetles.

Elevated temperature is related to increased atmospheric CO_2. A meta-analysis of the combined effect of elevated CO_2 and temperature [27] on plant-herbivore interaction revealed that plant terpenoids are not significantly affected by CO_2, but increase of temperature or temperature in combination with CO_2 resulted in increased terpenoid concentration. In woody plants the woody tissues are more responsive than green tissues. Insect herbivore performance has been reduced at elevated CO_2 and improved at elevated temperature, but the combination of these treatments has mostly canceled these effects.

Phytotoxic ozone (O_3) has a similar increasing trend as CO_2 in atmosphere, but it is more variable spatially and appears in much lower concentrations (e.g., in range of 30 ppb–80 ppb). Impact of elevated O_3 on plant terpenoids and herbivore performance has not been studied as extensively as CO_2. A meta-analysis [28] of recent literature of combined O_3 and CO_2 effects on plants indicated that O_3 alone did not affect primary metabolites, but concentrations of terpenoids were significantly increased by 8% and combination with elevated CO_2 intensified O_3 impact. Although terpenoids were increased, elevated O_3 improved some indices of insect performance such as higher pupal mass and shorter larval development time, but these effects were counteracted by elevated CO_2.

As O_3 is a strong oxidant and it will affect terpenoid compounds found on the cuticular wax layer of plant leaves, even at the concentrations that do not penetrate in plant mesophyll through stomata. Waxes and their terpenoid content affect plant resistance against larval stages of some moth species, including the most globally-distributed pest of cultivated plants, diamondback moth (*Plutella xylostella*). Changes in triterpene composition of cuticular waxes have been found as a result of elevated O_3 exposures. In general, the combined effects of climate change factors on plant defense chemistry and ecology of herbivores could be very complex and generalizations are therefore difficult to make with any confidence.

5.1.3 Indirect Herbivore Defense

Volatile compound spectrum induced in plants by herbivore feeding is most often dominated by terpenoids. Among other common induced compounds are fatty acid-derived C_6 green leaf volatiles (GLVs) and their derivatives, phenylpropanoid aromatic compounds (such as methyl salicylate (MeSA) and indole), and certain alkanes, alkenes, alcohols, esters, aldehydes and ketones. These induced compounds emitted by plants are responsible for the attraction of natural enemies of herbivores. This "cry for help" with herbivore-induced VOCs is called indirect plant defense against herbivores [1]. The composition of volatile bouquet released by plants differs between inducing herbivore species and particularly between insects with different feeding habits. The emission profile after feeding by chewing insects could have more terpenoids than other compounds. Aphid feeding on the same plant species may result in methyl salicylate-dominated emissions.

Herbivore-induced volatile terpenoids have more functions in plant physiology, defense and modifiers of atmospheric properties beyond being carnivore attractants. The same compounds shown to be functional with only few plant–herbivore–carnivore combinations may have several other functions in the species interactions in natural communities; e.g., controlling growth of fungal pathogens or the behavior of hyperparasitoids attack on first order carnivores. Therefore, these compounds should be taken in the context of an infochemical web that overlays food webs of a community [29]. Volatile compounds known as herbivore-induced compounds can be induced also by fungal attackers, although the ratio of terpenoids and other compounds such as methyl salicylate could be different than for those induced by herbivores.

The mechanism of how climate change-related abiotic factors affect the efficiency of indirect defenses in plants is still poorly understood. The role of volatile emissions for indirect defense is crucial in terrestrial ecosystems. Currently, the research activity on plant volatile compounds and response to climate change factors is extensive. The research is driven to better understand the possible role of VOCs in global climate change. Abiotic factors related global climate change on volatile terpenoids and type of growth and physiological responses of plants on these stresses is summarized in Table 94.2.

There are very few reports of cases when indirect defense function of volatile terpenes has changed under climate change factors. Elevating temperature may increase the volatility of herbivore-induced terpenes, but not necessary their synthesis. If carbon is allocated more to terpenoids and isoprenes to mitigate temperature stress, their overproduction could negatively affect induction of sesquiterpenes and homoterpenes, and even result in reduced indirect defense.

Moth-damaged cabbage plants grown at elevated CO_2 (720 μmol mol^{-1}) had only minor reduction in the emission of homoterpene DMNT and sesquiterpene (*E,E*)-α-farnesene when compared to plants grown at ambient CO_2. However, this decrease was sufficient to disturb volatile signaling to the third trophic level. A generalist, the predatory pentatomid bug, and a specialist Braconid parasitoid of the moth were not able to discriminate between the odors of intact and moth-larvae damaged plants when both types of plants were grown at elevated CO_2. The same species preferred volatiles from damaged plants when plants were grown at ambient CO_2. [31]. On the contrary, when grown at elevated CO_2 oilseed rape

Table 94.2 Reported effects of abiotic factors on volatile, non-stored volatile terpenoids.

Abiotic factor	Plant physiological response	Terpenoid emission response
Elevated temperature (moderate)	Enhanced growth and metabolism, higher photosynthesis	Mostly increased, but no effect or decrease also reported
Short-term high temperature	Stomatal closure, inhibition of photosynthesis, heat shock protein formation	Increased
Elevated CO_2	Enhanced growth, stomatal response, decreased leaf area	Mostly decreased, but no effect or increased also reported
Elevated O_3	Oxidative stress, lesion formation and cell death, retarded growth, flower abortion	Increased emission upon induction and decreased atmospheric concentrations due to high reactivity
Long-term drought	Retardation of growth, decreased leaf area, enhanced stomatal closure, enhanced root growth, earlier abscission	Variable, depending on plant species
General nutrient deficiency	Reduced growth	Decreased to no effect
Nitrogen deficiency	Reduced growth	Increased to no effect
Salt stress	Stomatal response, osmotic effects	Decreased or increased
UV-B radiation	Impaired photosynthesis, reduced growth	Increased to no effect

References: [18, 24, 30]

plants increased their induced terpenoid emissions. Parasitoid wasps were able to orientate to host-damaged plants independent of plant type or CO_2 concentration.

Elevated O_3 reduces the concentration and shortens lifetime of herbivore-induced volatile terpenes in the atmosphere. This effect has influenced the behavior parasitoid wasps on genetically engineered oilseed rape plants for Bt toxin overexpression. Under elevated O_3, moth-damaged non-Bt plants attracted 75% of the parasitoids, but only 36.8% of parasitoids orientated to moth-damaged Bt plants compared with controls [32].

5.1.4 Pollination Biology

The attraction of floral colors for pollinating insects has long been known. Also floral scent from volatile compounds, including terpenoids, is an important cues for attracting pollinators. Pollinators sense flowers from long distance by odorants, whereas they use both visual and scent cues at closer distances from the target flower (Fig. 94.5). Both generalist and specialist pollinators use volatile cues [33]. Bees (*Apis* sp.) are especially adept at recognizing specific volatile bouquets [34], while moths rely more on longer range location strategies [35].

In addition to aromatic phenolic compounds and sesquiterpenes, the common monoterpenes linalool, β-myrcene and β-ocimene in flower scent have high signaling value for pollinators. Recently it has been calculated that as the result of their reactivity with ozone, these monoterpenes have had their signaling distance to bees

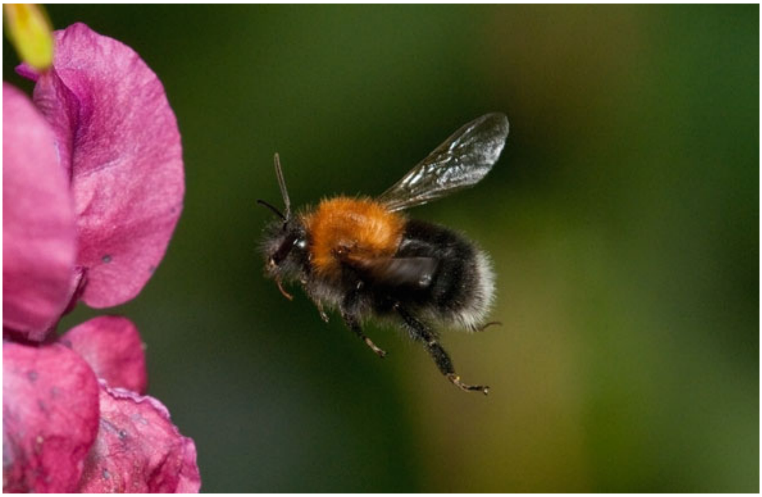

Fig. 94.5 Bees, bumblebees, butterflies and other pollinators use volatile terpenoids as cues when they orientate their flight towards flowering plants. Tree bumblebees (*Bombus hypnorum*) keep their antennae stretched out when approaching a flower to collect odorants

and other pollinators reduced from several kilometers in pre-industrial times to less than 200 m in the more ozone-polluted environments today [36]. Pollution causes them to lose their way en route to flowers, their food.

5.2 Plant–Plant Interactions

Plants are able to send warning signals of herbivore attack to their neighbors with herbivore-induce volatiles. Intact receiver plants can activate their defenses when exposed to these signals and thus be better prepared if herbivores will damage them. Recently [37] it has been shown that at elevated O_3 concentration of 80 ppb at an ozone-rich atmosphere can significantly degrade monoterpene β-ocimene and homoterpenes DMNT and TMTT released by spider mite-damaged lima bean plants. The decreased concentration of these terpene compounds in O_3-rich atmosphere reduced the distance over which signaling occurred between herbivore-damaged and intact plants. The measure of signaling response in receiver plants was induced production of extra floral nectar which is an arrestant and alternative food source for predatory mites.

5.3 Plant–Fungi Interactions

Various fungal species are able to synthesize and emit mono- and sesquiterpenes [38]. These can be detected from hyphae and fruiting bodies such as mushrooms.

Terpene production in fungi may be related to inhibition of growth of other microbes, but also for attraction of animals to spread the fungal spores. On the other hand, growth of hyphae and germination of spores of many plant pathogenic fungi is inhibited by high concentrations of volatile monoterpenes produced by host plant [39]. For the growth of most plant pathogenic fungi sufficient humidity is needed. Under hot and dry conditions fungal growth is inhibited by low humidity. Elevated temperature will increase volatility of plant monoterpenes and sesquiterpenes and may intensify growth inhibitory effects of the volatile plant terpenoids against fungal pathogens. In many plant species fungal infection induce similar bouquet of inducible volatiles compounds as herbivore feeding. Due to their microbial induction and antimicrobial effects the compounds induced by fungi and bacteria can be called phytoalexins. There is evidence the some inducible VOC could stimulate the sporulation of fungi that could be pathogenic to e.g., herbivorous spider mites. This tritrophic communication could be disturbed by VOC degrading effects of elevated O_3 concentrations.

5.4 Terpenes and Ecosystem Function

It has been shown that plant volatiles distributed in the environment have several functions in ecosystems. Many of the plant-emitted volatile terpenes have been reported to shape ecological interactions occurring among species within single or between multiple trophic levels. Recently reported adsorption of semivolatile sesquiterpenoids by birch foliage from a neighboring shrub species [9] indicated that up to 25% of the compounds emitted by an individual plant in the morning could be volatiles originally synthesized by other plant species in the same community. Because these compounds have a potential to give protection against herbivores by an associative way the results suggest that semivolatile terpenoids will have important role to affect plant species distribution and community level dynamics.

Plants are able to control oxidative capacity of atmosphere by the emissions of reactive volatile terpenes. The capability to control tropospheric ozone formation and degradation by reactive volatile emissions makes the major monoterpene emitters such as conifer trees, ecosystem engineers that can affect the atmospheric quality. If boreal conifer forests adapt to global warming by substantial increases in reactive monoterpene emissions they may have potential to add secondary organic aerosol formation in the forested areas. Higher aerosol density has been shown to increase light diffusion, promote cloud formation and increase cloud albedo and an overall cooling impact on climate. Increased diffusion of solar radiation has been shown to improve light penetration into conifer tree canopies. Finally, enhanced photosynthesis will improve CO_2 uptake within a conifer canopy and result in ameliorated carbon sequestration and higher net primary production of the ecosystem.

6 Conclusions and Future Prospects

Based upon the current knowledge of plant terpenoids reviewed here, we can be reasonably sure that factors related to global climate change will have an impact on terpenoid synthesis in plants and the dispersal of terpenoids in the atmosphere and soil. The ecological functions of terpenoids could be severely disturbed e.g., when atmospheric ozone degrades the important volatile information compounds such as monoterpenes and sesquiterpenes.

The efforts for more efficient food production to feed the increasing human population require new and efficient, environmentally sustainable and pollinator-friendly pest control strategies in crop plant protection. Terpenoids produced by crop plants or their companion plants could be one important tool to advance to that direction. Applications that minimize the harm for the environment and risk of development of resistant pest populations are needed. The principles of terpenoid-based natural indirect herbivore defense should be assessed more thoroughly to steer plant breeding to better include these properties in future cultivars.

Abstract

A fantastic source of natural products encompassing the vast group of the terpenes, alkaloids, and phenolic compounds is provided by the plants. About 25,000 of these secondary metabolites hold a strong potential in a large domain of industrial and pharmaceutical applications. Plant families, such as *Lamiaceae, Asteraceae, and Taxaceae*, synthesize several terpenoid classes with a great economic value. Hairy roots, resulting from *Agrobacterium rhizogenes*–mediated transformation of plant cells, can be harnessed for terpenoid production on a large scale. *A. rhizogenes* over other transformation systems makes possible an

easy regeneration of transgenic plants. Based on the deletion of *rol* genes located on the wild-type Ri-T-DNA, disarmed versions are created in order to overcome abnormalities of Ri-plants. Terpenoid accumulation from hairy roots can be optimized by elicitation treatment with jasmonates. Ri-T-DNA activation tagging system and transcriptome analyses are powerful tools to isolate new function genes involved in the terpenoid biosynthesis. Such genes encoding enzymes involved in the secondary metabolism can be inserted between the T-DNA borders. Lastly, some pharmacological properties of these plant terpenes/terpenoids involved in the therapy of more or less severe pathologies are reported.

1 Introduction

Plants represent most structurally vast and varied source of natural products, although less than half of the estimated 200,000+ secondary metabolites have been identified at the present time [1]. In nature, a plethora of phytochemicals have specialized functions in ecological interactions and are frequently produced in response to pathogen or abiotic stresses [2]. These natural secondary compounds can play a beneficial or deleterious role in the plant-insect, plant-pathogen, and plant-plant relations [3]. Owing to their large number and great diversity, the secondary metabolites hold an immense potential in industrial and/or medicinal application fields [4], notably as cosmetics, food additives, perfumes, and biopharmaceuticals for the human and animal healthcare [5]. Based on their biosynthetic origins, these secondary products can be divided into three major groups including the alkaloids (±12,000 types), phenolic compounds (±8,000 types), and terpenes (±25,000 types) which do not seem to be all directly involved in the development and growth of plants [4, 6]. The terpenes that are hydrocarbons exclusively composed of carbon and hydrogen and the terpene-derived terpenoids (or isoprenoids) by oxidation or some alteration of the carbon skeleton encompass more than 40,000 structures and constitute the largest and mostly diverse class of all known natural molecules [7]. Among them, a great chemical diversity is composed of primary metabolites (chlorophylls, carotenoids, cytokinins, gibberellins) and more than 25,000 secondary or specialized metabolites have harmful or beneficial effects on other organisms [3, 6]. Specialized terpenes/terpenoids have a myriad of important industrial applications notably, as flavoring agents, perfumes, insecticides, and biopharmaceuticals [8]. Higher plants biosynthesize commonly terpenes via two IPP (isopentenyl pyrophosphate) sources generated from two independent pathways: acetate-mevalonate (Ac-MEV) (in the cytosol) and 2-C-methyl-D-erythritol 4-phosphate (MEP) or deoxyxylulose 5-phosphate (DXP) (in the plastids) pathways (Fig. 95.1), present in vegetative tissues, flowers, and more occasionally in roots [9]. The early steps of terpene/terpenoid biosynthesis in the plants start by the formation and assembly of C5 isoprene units (1 isoprene unit = a monomer form) that result from two separate pathways. Polymerization of C5 isoprene units leads, for example, to monoterpenes C_{10} (2 isoprene units), sesquiterpenes C_{15} (3 isoprene units), and diterpenes C_{20} (4 isoprene units) [9] (Fig. 95.1). Indeed, terpene biosynthesis occurs, in the cytosol or the plastids, through the condensation of the five-carbon precursor isopentenyl pyrophosphate (IPP) (active isoprene unit) and its allylic isomer dimethylallyl pyrophosphate (DMAPP). The sequential head-to-tail addition of IPP units to DMAPP leads to the prenyl diphosphate geranyl pyrophosphate (GPP), farnesyl pyrophosphate (FPP), and geranylgeranyl pyrophosphate (GGPP). These three previous components serve respectively as precursors for sesquiterpenes, triterpenes (in the cytosol) and monoterpenes, diterpenes and tetraterpenes (in the plastids) (Fig. 95.1). Several terpenoids of a great industrial/medicinal interest are accumulated in the plant roots [10].

In the past three decades, hairy root cultures have been extensively investigated in vitro as a fascinating and alternative research tool for producing secondary metabolites at levels comparable to those found in the wild roots [11–20] and/or for revealing novel biomolecules [21, 22]. Hairy roots offer many advantages over cellular suspension cultures, notably their high growth rate, genetic stability, and hormonal independence [23]. Compared with transformed roots, undifferentiated cell cultures show most often a permanent instability responsible for low levels of secondary products and/or a rapid loss of the accumulation potential [24–27].

This chapter focuses on the terpenoid production from plant species, hairy root cultures, and Ri-plants; the terpenoid increase by hairy root elicitation; and recent strategies as T-DNA activation tagging/transcriptome analyses for isolating novel genes and hairy root engineering in order to improve terpene metabolism pathways. Lastly, therapeutic properties of some plant-derived terpenoids are reported.

Fig. 95.1 *Terpene biosynthesis pathways and their subcellular localization in the plants*. Different classes of terpenes are respectively formed in the cytosol or the plastid by two independent pathways in the plants, that is, acetate-mevalonate pathway (MEV) (cytosol) and methylerythritol 4-phosphate (MEP) or deoxyxylulose 5-phosphate pathway (DXP) (plastid). Monoterpenes, diterpenes, and tetraterpenes are derived from IPP and DMAPP from the plastidial MEP or DXP pathway. Sesquiterpenes and triterpenes are biosynthesized from IPP and DMAPP from the cytosol pathway. *Black square* with a white question mark suggests a possible transport of IPP (isopentenylpyrophosphate) from the plastid to the cytosol. Other metabolites involved in the different steps are *DMAPP* dimethylallylpyrophosphate, *FPP* farnesylpyrophosphate, *GA3P* D- glyceraldehyde- 3-phosphate, *GPP* geranylpyrophosphate, *GGPP* geranylgeranylpyrophosphate. TPSs in the *circle* correspond to terpene synthases. *Broken arrows* show several enzymatic steps (Adapted from Aharoni et al. [8] and Sallaud et al. [154])

2 Terpenoid Biosynthesis in Plants

Plant species are capable of manufacturing different types of secondary products which can be harnessed by humans for their beneficial properties in a large domain of industrial or medicinal applications [4]. World Health Organization (WHO) estimates that up to 80% of people rely mainly on traditional herbs as remedies for their medicines [28, 29]. Extracted from entire plants, secondary products are used by food and pharmaceutical industries, although most often numerous natural plant-derived molecules remain undiscovered or unexplored for their pharmacological properties [1]. Nowadays, the distribution of terpenes/terpenoids in the nature is extensively studding [30] and numerous terpenoids, presenting tremendous industrial and therapeutic properties, have already been identified in perennial herbs or woody plant species (Table 95.1). A large number of highly efficient terpenes, including

monoterpenes and sesquiterpenes, play a significant role in the interactions of plants with other environmental organisms [8]; notably terpene volatiles, carrying out important information, permit the pollinators to locate flowers and protect reproductive tissues against diverse attacks [31]. Monoterpenoids, sesquiterpenes, and norisoprenoids of low molecular weights, which have commonly been identified as volatile compounds or volatile oils emitted from flowers, fruits, and leaves of numerous plants, possess important values, such as flavor, fragrance, and aroma compounds. Likewise, other terpenoid volatiles, mainly monoterpene alcohols, for example, linalool, geraniol, nerol, and terpineol, have been considered as flavor and aroma products of grapevine berries and vine [32]. The composition of floral volatiles, for example, pollen volatiles from several grapevine varieties serve as attractants for pollinators, but also may function to deter herbivore attacks and defend the flowers against the pathogen, desiccation, or UV-light damages. Likewise, sesquiterpene volatiles at the highest levels were detected in this floral organ of *Vitis vinifera* L. cv. Cabernet Sauvignon immediately before bloom and at bloom [31]. Aromatic herbs, such as *Ocimum basilicum* L. (sweet basil), *Thymus vulgaris* L., and *Ocimum gratissimum* L., of the family Lamiaceae are largely utilized because of multiple properties as distinctive aroma additives to food or as medicinal herbs [9, 33–35]. These aromatic oils, stored in the leaves, are composed of aroma monoterpenes (eugenol, thymol, carvacrol, and linalool) and exhibit potent antioxidant properties [36]. Essential oils, that is, green pesticides are an excellent alternative to synthetic pesticides in order to reduce negative impacts to human health and environment [37].

Plant species, belonging to different genera and synthesizing several under classes or types of terpenes/terpenoids, are succinctly described below (Table 95.1). The first genus *Salvia*, the largest genus of the family Lamiaceae (or Labiatae), distributed throughout the world, offers a great and cosmopolitan group of about 236 genera and 900–1,000 species [38] and is phytochemically characterized by their diterpene contents [39, 40]. *Salvia* species that are of widespread interest owing to their large spectrum of medicinal activities can be cultivated in several countries of Europe [41]. Turkey is one of the major centers of diversity for genus *Salvia*, with 93 species of which 54 % are endemic [38]. Two subgenera *Salvia* and *Sclarea* possess abietane diterpenes, whereas *Calosphace* has clerodane diterpenes and *Leonia*, abietane and clerodane diterpenes. Considered as compounds specific to this species the diterpenoid tanshinones of *Salvia miltiorrhiza* (Chinese sage), contained in the rhizomes, have received more attention [41]. The aerial parts of *Salvia sclarea* contain mostly monoterpenoids and sesquiterpenoids, whereas twelve diterpenoids and two triterpenoids have been identified in the roots of this species. Most of the diterpenoids, abietane or arranged abietane-type, show various biological activities [40]. Genus *Aesculus* belonging to Hippocastanaceae or Horse-chesnut family regroups 100 species or varieties. *Aesculus* sp. are deciduous trees and shrubs among which several species, such as *Aesculus hippocastanum, Aesculus chinensis, Abronia turbinata, and Acalypha indica*, have been cultured as pharmaceutical crops for providing Standardized Therapeutic Extracts (STEs) [42]. More than 210 biomolecules have been isolated from the genus *Aesculus* and identified as belonging to different terpenoid classes, triterpenoids, triterpenoid glycosides (saponins), and tetraterpenoids (carotenoids) [42, 43] (Table 95.1). Two Eurasian species, of which aescin and individual compounds have been identified and other *Aesculus* sp. exhibit potent antitumor, antiviral, antioxidative, anti-inflammatory effects. The root of *Panax ginseng* CA Meyer is largely used as traditional medicine since ancient time due to its stimulating and tonic properties [44]. Genus *Panax* (Araliaceae family), regrouping about 11 slow-growing species, that is, perennial plants with strong roots, has been used for therapeutic aspects for centuries. Among them *Panax japonicus* (Japanese ginseng), *Panax quinquefolius* (American ginseng), and *Panax ginseng* (Korea or Asia ginseng) [45, 46] are cultured in Japan, China, Korea, but also in the United States and Canada [47]. *P. ginseng* is the most required species for its restorative properties [48], and its roots contain active principles detected as ginseng triterpenoid saponins and ginsenosides (Rx), that is, saponin glycosides, the most prominent constituents of ginseng [49]. The chemical compounds of different *Panax* species are relatively similar and approximately 38 types of ginsenosides have been identified with variable levels according to the *Panax* species [46]. *Panax ginseng* is close to *Gynostemma pentaphyllum* because of the secondary metabolite production and pharmacological properties that its chemical entities confer on this plant species. *Gynostemma pentaphyllum* Thunb. or jiaogulan (Chinese name), a member of the family Cucurbitaceae and genus *Gynostemma*, is an oriental medicinal herb biosynthesizing numerous Dammarane-type saponin glycosides, and about 90 compounds known as gypenosides that have been isolated and considered as responsible for the pharmacological properties recently attributed to this species [50, 51] (Table 95.1).

Lastly, two other important genera regroup precious species biosynthesizing phytochemicals involved in the treatment of mortal pathologies. In first, the genus *Artemisia* is one of the largest of the family Asteraceae with more than 500 species and includes a large number of aromatic plants. Genus *Artemisia* is mostly composed of perennial plants and distributed worldwide, mainly across the temperate zones of the Northern Hemisphere, but a few species can also be observed on the Southern Hemisphere [52]. Overall *Artemisia* species are considered as herbs (*Artemisia annua* L., *Artemisia vulgaris* L.), subshrubs (*A. changaica* Krasch, *A. crithmifolia* L.), or shrubs (*A. tridentate* Nutt.) with strong aroma [52, 53]. Artemisinin, a sesquiterpene lactone with an endoperoxide bridge [42, 54], has been isolated from species *Artemisia annua* L., a model plant owing to its small genome, which is widely used to treat the malaria disorders [42] (Table 95.1).

Another important genus *Taxus*, composed of small coniferous trees and shrubs, belongs to the family Taxaceae including many species, such as *Taxus baccata*, *Taxus brevifolia*, *Taxus chinensis*, *Taxus Canadensis* or *Taxus cuspidata* or still *Taxus media*. These coniferous trees, relatively slow-growing, can reach between 1 and 40 m in length and produce red berry-like fruits. Known commonly as yews, these species are poisonous because most of the trees produce taxol. Taxol or Paclitaxel (its generic name) that was isolated in 1971 [55] from the bark of the yew tree (*Taxus brevifolia* Nutt) is a complex diterpenoid (diterpene alkaloid) possessing very strong antineoplastic efficiency due to its unique mode of action on the cell microtubules [56–58]. Considered as an alternative product to taxol, taxotere or its generic name "docetaxel" is a chemical entity, semi-synthetically via the conversion of non-cytotoxic molecules: baccatin III and 10-deacetylbaccatin III precursors of taxol extracted from the needles of *Taxus baccata* L., the European yew [59] which has provided an interesting and renewable source of taxanes with the similar action mode for treating the same variety of cancer pathologies.

In the last decades, numerous biotechnological investigations have made possible the establishment of hairy root cultures from the plant species, previously described, in order to produce terpene/terpenoids of pharmaceutically great interest.

3 *Agrobacterium rhizogenes:* A Natural Engineer of Genetic Transformation

Phytopathogen gram-negative soil bacterium, *Agrobacterium rhizogenes*, is able to infect wounded plant cells [60] for inducing a tumorous pathology, referred to as "hairy root syndrome" [61, 62] and revealed by the emergence of adventitious roots at or near to the inoculation site of the agrobacteria [63] (Fig. 95.2). Pathogenicity of *Agrobacterium tumefaciens* or *Agrobacterium rhizogenes* depends respectively on a large and extrachromosomal Ti- (for tumor inducing) or Ri- (for root-inducing) plasmid carrying a DNA region termed Ti-T-DNA or Ri-T-DNA respectively, [64] that can be horizontally transferred and stably integrated into the nuclear genome of higher plants [62], as dicotyledon, gymnosperm, and some monocotyledon host species [65]. Ri-T-DNA harbors between its specific border sequences ($T_{R\ (R=\text{right border})}$ and $T_{L\ (L=\text{left border})}$) of 25-bp repeats, notably the T_L-DNA region carrying the root loci (*rol*) genes responsible for the hairy root phenotype. Ri plasmids, such as *pRi*A4 or *pRi*1855, belonging to the hypervirulent agropine-type *Agrobacterium rhizogenes* strains, possess a T-DNA formed of two independent regions [66] termed T_R-DNA and TL-DNA. The T_R-DNA region carries the aux1-2 genes that encode enzymes involved in auxin synthesis and play an ancillary role in the transgenic root formation [67]. Eighteen open reading frames (*Orfs*) have been identified from the TL-DNA region, among them the 10, 11, 12, and 15 *Orfs* correspond respectively to the *A, B, C*, and *D rol* genes [68]. Other genes, termed *ops* genes, are equally located in the T_R-DNA and code for opine synthesis, that is, particular amino acid derivatives serving for specific food to the bacteria [69–72]. Ginkgo biloba, required the use of hypervirulent agropine-type strains [73]. On the contrary some Ri plasmids, as *Ri*8196 or *pRi*2659, have a simple T_L-DNA capable of initiating hairy roots and producing different opine types (mannopine, mikimopine, or cucumopine) according to the *A. rhizogenes* strain [74]. Fundamental studies have improved our understanding of the different molecular events resulting in the T-DNA transfer through the host cytoplasm up to nuclear plant genome. Nevertheless, the final steps of T-DNA insertion into the plant genome, involving host factors, are still unknown. The Ti/Ri plasmids possess *vir* genes (*vir* for virulence) that encode Vir proteins responsible for the plant-bacterium attachment, formation, and protection of the simple and mobile copy of the T-DNA for its translocation from bacterium to the host nucleus [75–77]. Most *vir* genes, carried by the Ti/Ri plasmids and involved in the T-DNA secretion system, are similar. However, the Ri plasmid possesses GALL genes coding for two full-length GALLS (-FL and -CT) proteins, instead of the *vir*E2/*vir*E1 genes present in *A. tumefaciens* [78, 79].

4 Emergence and Development of Hairy Roots

In the previous decades, the strong power of *A. rhizogenes* to transform various plants and induce hairy roots has been largely demonstrated [71]. About 200 species of higher plants (at least 30 families), mostly dicotyledonous species, could be genetically transformed with *A. rhizogenes* and led to the development of adventitious roots [80]. This efficient mode of bacterial transformation is depending on several parameters, including the strain type, bacterial concentration, co-culture time of the bacterium/explant, temperature, light/darkness, as well as the plant species and explant type [81]. Different surface-sterilized explant types (i.e., leaf discs, leaves, stem segments, petioles, roots, embryos, or plantlets) are wounded and then inoculated with *Agrobacteria*. After 2–4 weeks primary adventitious roots, coming from the differentiation of one single plant cell transformed by one bacterium [62], appear at, or near, wound site of plant cells infected by *A. rhizogenes* [82] (Fig. 95.2). Roots, reaching about 1–1.5 cm in length, are excised and placed separately on solid or semi-solid hormone-free medium for initiating a true clone. Hairy root phenotype is characterized by a fast hormone-free growth, an unusual ageotropism, a profusion of root hairs with abundant lateral branching [83–85] (Fig. 95.2). Hairy root cultures can present more and less than root thickness, root length, number of root hairs and root branching, according to plant species and *A. rhizogenes* strain used for hairy root induction [86]. Sometimes, Ri-roots can become brown and stop their growth in liquid medium, because the most crucial step results from the transit of the hairy root clones into agitated liquid medium [87] (Fig. 95.2). But the morphology of *A. rhizogenes*–induced hairy roots is similar in structure to wild-type roots with a few notable exceptions [66]. A recent paper underlined that the A. *rhizogenes*–mediated transformation has made possible the establishment of hairy root cultures from 116 plant species [88].

5 Ri-Plants Taken as Bioreactors

A. rhizogenes–mediated transformation can be exploited for producing terpenoids using plants as bioreactors. Advantages of transformation with *A. rhizogenes* over other methods encompass adventitious organs/roots and rapid shoot regeneration reducing the risk of somaclonal variation [89]. Moreover, this transformation is that it enables the remarkable development of Ri-plants via a marker-free selection through the observation of the hairy root morphology, as the primary indicator of genetic transfer [90]. Lastly, another fundamental advantage from the wild-type *A. rhizogenes strains*, compared with the *A. tumefaciens* ones, is that the hairy root creation can naturally lead to the plantlets. Thereby such plants are free from the legal controls of GMOs in Japan [91]. One pioneered plant regeneration, performed successfully from *Brassica napus* hairy roots, displayed that fertile Ri-plants could sexually transmit the hairy root phenotype to their progenies [83]. Such a heredity of Mendelian type has recently been confirmed by Crane et al. [92] from Ri-plants of *Medicago truncatula*, an interesting legume, that emits a large spectrum of volatile terpenoids, including monoterpenes, sesquiterpenes, and tetranor-terpenoids, induced by herbivore attacks [93]. Studies reported that transgenic plants were regenerated from hairy roots of 62 different taxa, representing 53 plant species from 24 families [89] or still up to 79 plant species [94].

Besides, Ri-plants potentially can equally offer promising horticultural/floricultural applications. Classical breeding in floriculture serves to create new plant varieties, although the available gene pool for introducing novel agronomic or aesthetic features is genetically limited to the parental background [95]. Appeared after the *rol* gene insertion into the plant genome, cytological abnormalities make possible the creation of the novel floricultural varieties with exciting characteristics. For instance, Ri-regenerants of *Kalanchoe blossfeldiana*, an economically important plant in Europe, exhibited a dwarf and compact growth habit compared to an elongated growth habit, commercially disadvantageous, of the control plants [90].

An overview of the literature reveals that plant regeneration from hairy root segments can take, spontaneously, directly or indirectly (after a callusing phase before shoot regeneration) several developmental ways. Thereby, buds were initiated from adventitious Ri-root parts with or without exogenous growth regulators [66], for example in *Aesculus hippocastanum*, a plant species producing triterpenic glycosides [43], buds emerged from hairy roots placed on the solid medium devoid of exogenous hormones [96]. Nevertheless, the number of *A. hippocastanum* buds was found superior when the Ri-roots were placed on the medium supplemented with BAP. Rooting of these shoots was initiated more rapidly with IBA (in 80% of explants) than IAA (in 40% of explants) [96]. Another regeneration model was reported from genus *Solanum* which is one of the largest *genus* of family Solanaceae comprising about 84 genera and 3,000 species and producing numerous flavonoids and terpenoids, such as sesquiterpenoids in *Solanum tuberosum* [97] (Table 95.1). *Solanum nigrum* hairy roots, maintained on a hormone-free medium, developed spontaneously plantlets capable of producing in vitro flowers and fruits, whereas control plantlets remained in the vegetative state [89]. *Pelargonium graveolens* hairy roots, coming from Ri-T-DNA-mediated transformation of leaves and internodal segments, expressed their shoot regenerative capacity from both explant types [98]. *Centaurium erythraea* Rafn (*Gentianaceae*) is a traditional medicinal plant of Croatia that accumulates monoterpenoids in the aerial parts [99] (Table 95.1). *C. erythraea* hairy roots, placed in the medium added with IAA and BAP, formed shoots which were rooted at 68–97% without any hormonal supplement [100]. The Ri-plants regeneration could be associated to the formation of embryogenic calli [100]. *Panax ginseng* CA Meyer possesses numerous pharmacological activities, mostly attributed to one type of its constituents, namely, ginsenosides belonging to triterpenoid saponins [46] (Table 95.1). Placed on the medium without any growth regulator and in the dark, shoots and yellow calli in *Panax ginseng* appeared simultaneously from hairy root clones. Embryogenic calli, transferred to light, gave rise to somatic embryos leading to shoots/plantlets [101]. Transformed callus-derived embryogenic cell lines of *Panax ginseng* have been able to develop embryos and plantlets arising from only *A. rhizogenes rol* C-gene expression [102]. Root segment-derived hairy root lines of *Aralia elata*, a wood shrub producing pharmaceutically important metabolites as triterpenoids (*Aralia* saponins V) [103], and cultured on nutritive medium supplemented with 2, 4-D could generate embryogenic calli able to develop somatic embryos up to the cotyledonary stage without any phytohormone. Embryo germination led to plantlets and 100% of them were successfully acclimatized under greenhouse conditions [103]. Embryogenic calli, cotyledonary embryos and plantlets were developed from hairy root segments of *Codonopsis lanceolata* (Campanulaceae family) cultured in medium supplemented with 2, 4-D and accumulated, in the stems, higher contents of three major triterpenoids (lancemaside A, foetidissimoside A, and aster saponin Hb) than wild-type plants [104].

The third organogenesis type requires an intermediate callus phase before the formation of shoots and plantlets. Thereby, hairy root–derived calluses of *Mentha piperita* proliferated abundantly in the presence of 1 μM NAA, 10 μM CPPU and 10% coconut powder in the culture medium. Placed onto solid hormone-free medium *M. piperita* calli gave rise to shoots and roots [105].

6 Transgenic Plant Devoid of Hairy-Root Phenotype

Ri-Regenerants, arising from genetic transformation by the T-DNA insertion, exhibit frequently typical abnormalities due to the *rol* gene expression as wrinkled leaves, short internodes, dwarfness, numerous lateral shoots, flowers, and plagiotropic roots with an extensive branching [94, 106, 107]. Nevertheless, normal morphology of the leaves, a good stem elongation, and an extensive root system could be observed from Ri-regenerants of *Alhagi pseudoalhagi*, and similarly of *Hypericum perforatum* [108]. In contrast, transgenic somatic embryo-derived plantlets of *Aralia elata* exhibited an aberrant hairy-root phenotype compared to the mother plants [103]. This particular aspect of Ri-plants can be discouraging for initiating certain programs of applied research, notably, in the agronomy fields. Easy protocols have been established to overcome undesirable abnormalities of the Ri-plants by creating disarmed versions, as it has been achieved with *A. tumefaciens* [66]. The abnormal hairy-root phenotype can be suppressed after deletion of the oncogenes, that is, *rol* genes, located on the wild-type Ri-T-DNA and responsible for these morphological singularities. This deletion is performed without any consequence for the T-DNA insertion, since with exception of the right and left borders none of the other T-DNA regions are indispensable to the horizontal transfer of foreign genes into the host genome [109]. Therefore, the *Rol* genes carried by the wild-type Ri-T-DNA may be replaced by additional genes overexpressing secondary metabolites/recombinant proteins or encoding the resistance to herbicides, insects, and various pathogens [110]. Two vector types, co-integrative and binary vectors, can be used as genetic transformation systems [111]. A binary vector system contains, for example, the Ti plasmid carrying only virulence genes, whereas its T-DNA has been removed [112] and the second plasmid carries the foreign gene inserted between the border sequences of the Ri-T-DNA with or without deleting the *rol* genes [113]. Plants coming from leaf explants of *Centaurium erythraea* Raf co-cultured with the *A. rhizogenes* strain LBA 9402, carrying a binary vector, were reported by Piatczak et al. [100]. Using binary vectors, deleted oncogenes, the problem of the surprising hairy root phenotype may be bypassed.

7 Novel Genes Revealed by Ri-T-DNA Activation Tagging and Transcriptome Analysis

Hairy roots, coming from the genetic horizontal transfer of the wild or recombined Ri-T-DNA vectors in the host plant genome, represent an ideal engineering platform for exploiting new biotechnology tools (Fig. 95.2). DNA activation tagging [114] and RNA silencing processes followed by transcriptome analyses are recent powerful tools capable of revealing novel genes, notably those involved in the secondary metabolism, but also, of identifying gene function [114]. Activation tagging process permits to generate gain-of-function mutations, whereas gene silencing leads to loss-of-function approaches [115]. RNA silencing corresponds to a natural mechanism of genetic control taking place in virus resistance, genome maintenance, and developmental control in plants [116]. The classical loss-of-function process can be limiting because of the absence of visible phenotypes which restrict the identification of mutants [16]. Thus, one of the most frequently applied approaches is DNA-activation tagging insertional mutagenesis [117] which can circumvent many disadvantages of loss of function [44]. The *Agrobacterium* spp. T-DNA vector, carrier of multimerized transcriptional enhancers of the cauliflower mosaic virus (CaMV) 35 S promoter, is considered as a powerful mutagen [44] capable of discovering novel dominant or semi-dominant mutations observed in primary transformants [117]. Activation tagging system leads to a random genomic insertion, in the plant genome, of Ri-T-DNA constructs harboring constitutive enhancer sequences positioned next to the right- or left-hand T-DNA border, which are able to cause transcriptional activation of flanking genes [22, 117, 118]. For example, Choi et al. [44] generated activation tagged *P. ginseng* hairy root lines in order to dissect, isolate genes responsible for ginsenoside and triterpene lactone biosynthesis and evaluate the ginsenoside profile of these hairy root lines [119].

Another recent approach based upon the methyl jasmonate inducible system that was applied to hairy root cultures of *Panax ginseng* made possible the identification of new genes through the analysis of 3,134 expressed sequence tags (ESTs) [120]. From the isolated transcripts several would correspond to the genes encoding enzymes as Cytochrome P450, glycosyltransferases, and oxidosqualene cyclase (OSC) involved in the ginsenoside (i.e., triterpene glycosides) biosynthesis [120]. G*inseng* (or other plant species) ESTs data set can provide important information on genes involved in the regulation and biosynthesis of secondary metabolites, only, when their accumulation can be induced by MeJA treatment [120]. Besides, Jian et al. [121] emphasized the fundamental role of the *A. rhizogenes*–mediated transformation system coupling, at once, genetic transformation and regeneration for gene function testing in *Lotus corniculatus*.

8 Engineering of Terpene Metabolism Pathways

The fortification of numerous steps by overexpression of multiple biosynthesis genes or transcription factors for controlling the expression of genes is a fascinating strategy to alter the accumulation of secondary metabolites [122]. Metabolic engineering of terpenoids biosynthesized in plants can be directed toward two major objectives: to increase the plant resistance to predators and diseases or still to increase the production of medicinal or industrial compounds and to make possible a better knowledge of genes encoding enzymes involved in the terpenoid metabolism pathways or its regulation [8]. Understanding the function of genes involved in terpene production can lead to discovery of novel compounds or metabolic pathways, which might reveal favorable properties for human applications [4]. Thereby *Nicotiana tabacum* plants displayed an increase of terpene emission from leaves after insertion of monoterpene synthase genes [4]. The red pigment present in *Salvia militiorrhiza* (*Lamiaceae*) roots is composed of many diterpenoid tanshinones. In this plant, diterpenes are synthesized through the MEP pathway in the plastids (Fig. 95.1) and DXR (DXP (1-deoxy-D-xylulose 5-phosphate) reductoisomerase) is an enzyme catalyzing the first step of this pathway. Wu et al. have cloned and sequenced the gene coding for the DXR protein [41]. Functional expression of the *dxr* gene was controlled by genetic complementation with the lethal *dxr*-deficient *E. coli* mutant strain. Besides, the RNA-blot analysis, from hairy root cultures of *S. militiorrhiza*, elicited with a hyperosmotic stress and/or yeast extract, showed a strong induction of the *dxr* gene transcription that was correlated with the diterpenoid tanshinone increase in these cultures. The same authors concluded that the *dxr* gene involved in the MEP pathway may be a target for the metabolic engineering of diterpenoid tanshinone biosynthesis [41]. The regulation of terpenoid metabolism and, particularly, the regulation of factors controlling genes encoding enzymes of the secondary metabolism require subsequent investigations [123]. *S. militiorrhiza*, taken as a model plant owing to its small genome, made possible the identification of 40 terpenoid biosynthesis-related genes, of which 27 are novel. It was reported that 20 of the 40 genes could be involved in the tanshinone biosynthesis [124].

9 Hairy Roots: Fascinating Routes to Produce Terpenoids

Secondary metabolites of low molecular weights are widely biosynthesized throughout the plant Kingdom [122] and a large biological diversity of them is accumulated in the roots [85]. In the past few years, a great interest for the natural products led private companies to consider the progresses of the biotechnologies as an alternative strategy for producing biomolecules of high added value. Numerous plant species, genetically transformed with the natural vector *Agrobacterium rhizogenes*, are good candidates to accumulate terpene/terpenoids in organ culture systems [23, 40]. Important research investigations that use differentiated cultures, instead of cell suspension cultures, have been focused on transformed (hairy) roots [23] which offer a flexible and versatile system for a large-scale production of phytochemicals [125]. Hairy roots, because of their high differentiation, allow a stable and extensive production of secondary compounds [126]. Moreover, owing to their culture mode in a sterile, confined, and controlled environment avoiding the transgene dissemination, hairy roots present serious advantages compared with entire plants cultured in the open field [18, 22]. The transformed root cultures can be propagated indefinitely in liquid medium and conserve, at once, a morphological integrity and biochemical stability [86, 115]. Besides, the *rol* genes are now known to possess a stimulating effect on the secondary metabolism with a durable stability, over long-term culture [127]. After its insertion in the plant genome, the T-DNA appears to be a remarkable element in the gene regulation [128]. As described below, some hairy root cultures have shown their capacity to accumulate terpenes/terpenoids in vitro. Thereby, chemical analysis displayed that the contents of three major triterpenoids in hairy roots of *Codonopsis lanceolata* Trautv were similar to those found in wild roots harvested from soil [104]. Sterile 4-week-old shoots of *Salvia sclarea* transformed with the *A. rhizogenes* strain, LBA 9402, led to hairy root cultures from which four diterpenoids (ferruginol, salvipisone, aethiopinone, and 1-oxoaethiopinone) and two ursine-type triterpenoids were isolated [40]. The light enhanced significantly the abietane diterpenoid levels and affected slightly the triterpenoid spectrum in transgenic cultures. Kuzma et al. [40] concluded that *S. sclarea* hairy roots, accumulating terpenoids at higher levels than the roots of field-grown plants, could significantly provide a commercial source of diterpenoids. Hairy roots of *Artemisia dubia* and *Artemisia indica* arising from sterile plantlet-derived stems were transformed with both *A. rhizogenes* strains, LBA 9402 and 8196. Artemisinin levels and fresh root biomass were significantly enhanced in the Ri-roots compared with the control roots and according to the *A. rhizogenes* strain and *Artemisia* species used. Higher levels (0.603 % and 0.753 %) of this natural sesquiterpene lactone were detected in *A. dubia* hairy roots when the stems have been respectively inoculated either with LBA 9402 or 8196 *A. rhizogenes* strains [129].

Despite numerous positive results, some transformed root systems accumulated less secondary metabolites than plant tissues in vivo. The *A. hippocastanum* zygotic embryos are known to be the major site of aescin, a group of chemically related triterpenic glycosides (saponins) involved in the treatment of peripheral vascular disorders as venous insufficiency [43, 96]. Androgenic embryos of *Aesculus hippocastanum* (horse-chestnut), induced from anthers and inoculated with the *A. rhizogenes* strain A4GUS, led to hairy root clones [43]. The substantial percentages (3.50 % and 4.1 %) of aescin, detected in two hairy root clones, remained inferior to those found in the cotyledonary embryos placed on the hormone-free medium [43]. These authors concluded that the androgenic embryos of *A. hippocastanum* cultured with 2, 4-D is a better strategy for the aescin production on a large scale. Besides, Zdravkovic et al. [96] reported that the hairy root clones of horse chestnut were subsequently able to regenerate transformed plants which may be useful in horticulture for the bonsai establishment. Another tremendous advantage of hairy roots results from the feasibility of regenerating transgenic plants, whereas the regeneration of tissues transformed with *A. tumefaciens* is proved to be often more problematic. Overall secondary metabolites are biosynthesized and accumulated in the roots/hairy roots; nevertheless, some of them can be produced and/or stored in the aerial parts of the plant. Thereby, the total spectrum of secoiridoids that were detected in the non-transformed plants could be provided in vitro at eightfold superior levels in the roots and aerial parts of *Centaurium erythraea* Ri-plants [100]. Likewise, essential oils were mostly detected in the leaves and stems of *Mentha*, but the highest oil levels of *M. piperita* are found in the leaves of Ri-plants compared with those of the wild-type plants [130]. Moreover, the dwarf regenerants of *Mentha* species displayed the hairy root phenotype abnormalities, which does not present any negative impact on the essential oil production [105]. Most hairy root–derived rose-scented geranium plants (*Pelargonium* species) provided a large panel of monoterpenoids (essential oils) similar to those of the wild-mother plant, at the exception of two Ri-plants that biosynthesized two volatile monoterpenoids possessing better olfactory value offering an improvement from a commercial point of view [98]. Green hairy roots can accumulate some secondary products that are normally synthesized in green aerial parts of the plant [130].

10 Elicitation Treatment: A Booster System of Secondary Products

Plants are capable of producing and releasing active allelochemicals targeted in defense against pathogen attacks and stress conditions [2, 131]. Allelochemicals are accumulated under the impact of stress molecules, called elicitors, and then released by the plants into the environment by root exudation, volatile emissions from leaves and other aerial parts [132]. Several natural elicitors have been observed as efficient inducers for boosting the production and secretion of secondary metabolites in cultures in vitro, notably, when they are added to the hairy root cultures [115]. Thereby, the secondary plant messenger methyl jasmonate (MeJA), and its relatives, from the oxylipin family, is a stress hormone able to induce the improvement or optimization of secondary product contents [10, 18, 97]. In 1962, MeJA was discovered as a sweet-smelling biomolecule present in *Jasminum* *grandiflorum* L. flower extracts [133, 134] and described as “hormone” because of the cellular responses of elicitation, at low levels, distant from its site of biosynthesis. The jasmonate elicitors are synthesized via the octadecanoid pathways, beginning at linolenic acid and ending at (+) – 7- epi-JA and its conjugates and isomers [134]. There are some examples of elicitation processes for stimulating the secondary metabolite accumulation. Gossypol (sesquiterpenoid) is a toxic phytoalexin biosynthesized in *Gossypium barbadense* (a cotton plant) that possesses anticancer, antiviral, antimicrobial, and antiparasitic properties and is routinely isolated from cottonseed or from cotton roots. This terpene aldehyde interacts with various anticancer agents for increasing the efficiency of their pro-apoptic proteins, detoxification enzymes, and signaling kinases. Only MeJA was found to able to stimulate the contents of gossypol and methylated forms in cotton hairy root cultures. Moreover, the distribution of enantiomers was not found to be similar in elicited or control transformed roots of *G. barbadense* [135].

Taxol or Paclitaxel (generic name), a complex diterpenoid, is one of today’s better known antineoplastic drugs [56] and acts as a strong antitumor agent owing to its unique mode of action on the cellular microtubules. Its extraction from its natural source and costly synthetic process make it one of the products with the highest added value [58]. Taxotere or Docetaxel (generic name) is a chemical entity semi-synthetically performed via the conversion of non-cytotoxic molecules: baccatin III and 10-deacetylbaccatin III precursors of taxol extracted from the needles of *Taxus baccata* L., the European yew. Paclitaxel can equally be semi-synthesized from its natural precursor, 10-deacetyl baccatin III. As a promising alternative, cell suspension cultures of various *Taxus* species have been harnessed for the efficient production of taxol and its related taxane compounds [57]. The impact of explant source and growth regulators was tested in order to optimize the induction and selection of fast growing callus lines of *Taxus baccata* (European yew tree) [136]. In *Taxus baccata* L. (European yew tree), Ashrafi et al. [136] tested different combinations of growth regulators and various explants (stems, needles, and base of needle) for callus production. Taxol and baccatin III were respectively increased by 3.1- and 5-fold in the callus-derived cell suspensions cultured in medium added with 2, 4-D + Kin, at different concentrations according to both expected secondary metabolites [136]. *Taxus media* cell lines, transformed with *A. rhizogenes* and termed “TXS” and “Rol C” (*txs* corresponding to the transgene encoding enzyme taxadiene synthase of *T. baccata*), were treated with MeJA for optimizing taxane production. The highest taxane level was observed in the “TXS” cell line and resulted from the activity of enzyme taxadiene synthase and MeJA [58]. To date, the most favorable proceeding for a sustainable production of taxol and related taxoids at industrial level is provided by plant cell cultures [58]. Although production has been scaled-up, a serious drawback of the cell suspension cultures is their instability and unpredictability of the expected secondary products [137]. Due to their great genetic stability and potentially unlimited propagation in vitro, hairy roots as well-differentiated organs, are able to accumulate of important taxanes. For example, three strains of *A. rhizogenes* (R1000, A4 and 15834) were compared for the initiation of *Taxus cuspidata* hairy root lines. As regards its growth capacities, a selected line was treated with MeJA and produced a total paclitaxel content of 52, 5 mg/l over 2 weeks of incubation and at 20-L culture scale. These taxol levels produced after MeJA addition were similar to those detected in the cell suspension cultures of *Taxus* [57]. As another example, taxol and 10-deacetylbaccatin III (10-DAB III) were increased in hairy root cultures of *Taxus* x *media* var. Hicksii Rehd in presence of the BABA precursor, used alone or in combination with MeJA [137]. To date, only two reports have been published for the production of paclitaxel and its related compounds by hairy root cultures [137].

Other molecules, biotic or abiotic, can act as elicitors for successfully boosting the accumulation and/or secretion of secondary products. A non-protein amino acid, that is, β-aminobutyric acid (BABA), used against pathogen attacks and added separately or in combination with the yeast elicitor for enhancing the tanshinone production in *Salvia miltiorrhiza* hairy roots, showed that BABA could strongly potentiate elicitor-induced secondary metabolism in plant organ cultures [138]. From another experimental work, Ge and Wu [139] studied the separate and combined action of biotic (yeast=YE) and abiotic (Ag+) elicitors on the secondary metabolism activities of *Salvia miltiorrhiza* hairy roots. These authors showed that the YE-induced tanshinone production seemed to be mainly derived from a non-MVA pathway encompassing DXS (1-deoxy-D-xylulose 5-phosphate synthase) since YE did not stimulate HMGR (3-hydroxy-3-methylglutaryl CoA reductase). In contrast, Ag+-induced tanshinone production seemed to be dependent on both pathways (MVA and non-MVA pathways), because it was suppressed by the inhibitors of both pathways [139]. Elicitation, but, also cell permeabilization and trapping processes have been investigated to increase the secretion of secondary products in the culture media [18].

11 Hairy Root Cultures on a Large Scale: A True Challenge

Hairy root offers a flexible and versatile culture system that is a promising biotechnology for the large-scale production of valuable phytochemicals [125]. The transfer in bioreactors is the key step toward a commercial production of terpenes/terpenoids by hairy root cultures. Bioreactors offer several advantages for the mass culture of plant cells or organs, for example, a constant regulation of conditions at various stages of the culture [28]. To scale up hairy root cultures, several operational factors, including inoculum size, medium, growth rate, secondary product recovery (intracellular/extracellular), and reproducibility of results, must be overpowered before the technology is ready for commercialization [23]. Thereby a perfect sterility, maintenance of the homogenization of roots as well as biomass measurement, agitation, oxygenation, and nutrition availability are the major goals to reach for scaling-up hairy root cultures [23, 130, 140]. In fact, growth of transgenic roots in liquid medium results in dense and packed root biomass, leading to the formation of stagnation which slows down the fluid nutrient circulation and limits oxygen availability [86]. Mechanical agitation generates wounding of hairy roots and callus formation [130]. To overcome these limiting hurdles, hairy roots can predominantly be grown in spray or droplet bioreactors and mist bioreactors in which the roots are immobilized on mesh support and exposed to humidified air or a gas mixture and nutrients [86]. Recent bioreactors with their different advantages/drawbacks for producing hairy roots, on a large scale, have been detailed and classified by Srivastava and Srivastava [23] as liquid-gas, gas-phase, or hybrid reactors, for example, airlift bioreactors, bubble column reactors, and nutrient mist bioreactors. Conductivity measurements between small- and large-scale reactor cultures of hairy roots were compared [141]. Scaling studies showed that at 1 L *Artemisia annua* and *Arachis hypogaea* hairy roots had better growth in the mist reactor than shake flasks. The mass production of *Panax ginseng* hairy root cultures has been established in bioreactors [142] and the ginsenoside accumulation from transformed root cultures through large-scale reactor system was assessed to 1–10 t [28, 143]. Roots cultured in bioreactors have been shown to release therapeutically active compounds into the liquid medium of the bioreactor, for example, the antineoplastic drug isolated from various *Taxus* species [29].

12 Therapeutic Merits of Plant Terpene/Terpenoids

Numerous terpenoids, such as taxol, ginkgolides, digoxin, gossypol, and artemisinin, have been found efficient in the prevention and therapy of severe pathologies encompassing cancer and other severe diseases. Nevertheless, a vast proportion of higher plants have not still been screened for medicinal activities. Drug discovery from plant species remains an essential strategy in the search for future medicines [144]. From pharmaceutical point of view, terpenoids achieve a rich pool for harnessing new drugs and leading products. Cancer, after cardiovascular pathologies, is the second cause of death [145]. In fact, numerous terpenoids exhibit cytotoxicity against a wide variety of tumor cells as well as anticancer efficacy in preclinical animal models [146]. Terpenoids, a large class of mevalonate-derived phytochemicals, suppress the multiplication of neoplastic cells and the growth of implanted tumors; for example, geraniol, a volatile isoprenoid, is an acyclic dietary monoterpene which exerts an antineoplastic activity against different cancer cells both in vitro and in vivo. This antineoplastic property has successfully been assessed on TC-118 human tumors transplanted into Swiss nu/nu mice [145]. Likewise, it has been exemplified by diterpenoid drug taxol relating to the cancer [123]. Indeed, taxane biomolecules coming from genus Taxus represent one of the most powerful types of compounds among all the chemotherapeutic drugs efficient to treat a variety of cancers (encompassing ovarian, breast, lung, head and neck carcinomas, and the AIDS-related Karposi's carcinoma) [56, 57]. The antitumor property results of the binding of drug to the human β-tubulin, such a chemical interaction leads to inhibit the depolymerization of the microtubules [147]. Docetaxel (taxotere) and Paclitaxel (taxol) offer some different characteristics in their molecular pharmacology, which are potentially responsible for their clinical activity and toxicity profiles [136, 148]. Taxotere displays the greater affinity to β-tubulin, targeting centrosome organization and acting on cells in three phases of the cellular cycle (S, G2, M), whereas Taxol causes cell damage by altering the mitotic spindle at the beginning of the mitosis [57, 136]. Artemisinin (a sesquiterpene lactone) isolated from *Artemisia* sp. is an antimalarial drug efficient against multidrug-resistant strains of the malaria parasites: *Plasmodium* sp. [42], notably, *Plasmodium falciparum* that is the responsible agent for one of the world's most severe pathologies causing at least 500 million cases globally each year and resulting in more than one million deaths [149].

Pharmaceutical properties of several plant species can be due to the association of terpene/terpenoids with other active molecules. That will explain the large spectrum of therapeutic activity of these plant species. *Gynostemma pentaphyllum* (Thunb.) or jiaogulan (Chinese name), a member of the family Cucurbitaceae and genus *Gynostemma*, is an oriental medicinal herb characterized by a large spectrum of pharmacological activities, of which antitumor, antioxidant, cholesterol-lowering, immunopotentiating, and hypoglycemic effects could be observed [50]. Genus *Aesculus* (Horse chesnut) encompasses more than 210 compounds from which different classes have been isolated, in particular triterpenoids, triterpenoid glycosides (saponins), flavonoids, and long fatty chain molecules [42]. Standardized therapeutic extracts (HCSE: Horse chesnut seed extract) and aescin (a saponin mixture) of *Aesculus* sp. are considered as the main source of triterpenic glycosides, a group known as aescin and traditionally used against rheumatism, skin, and peripheral vascular disorders [43]. In Europe, the bark, leaves, HCSE, and aescin have been used in the treatment of chronic venous insufficiency, hemorrhoids, and postoperative edema [42]. Several other medicinal properties have been ascribed to saponins, such as immunostimulant, hypocholesterolaemic, and anticarcinogenic effects [150]. But, one of the most interesting properties is the antitumor action of some novel saponins found recently from the *Aesculus pavia* species [42]. The *Aesculus indica* extract, used against the MCF-7 breast cancer cell line, displayed a significant antiproliferative activity, and dose-dependent effect ranging from 34.2 % (at 10 μ-g/ml) to 94 % (at 500 μ-g/ml) could be observed [151]. Inflammation is a natural response of the mammalian body to a variety of pathologies or hostile agents. Rheumatoid arthritis is one of the challenging diseases associated with inflammatory manifestations. In order to treat similar disorders, various molecules have been isolated as, for example, a potent anti-inflammatory analgesic molecule termed "Aspirin" which was harnessed from bark of *Salix alba* L. Recent findings of several species such as *Achillea millefolium* (Asteraceae) or *Aspilia Africana* C.D. Adams (Asteraceae) and *Bacopa monnieri* (Scrophulariaceae) showed an anti-inflammatory activity due to their chemo-profiles revealing the presence of essential oils/sesquiterpenes, terpenoids (α-pinene, limonene), and triterpene, respectively [152]. Aromatic oils, stored in the leaves, are composed of aroma monoterpenes, such as eugenol, thymol, carvacrol, and linalool, and exhibit potent antioxidant properties which may prevent in vivo oxidative damages such as lipid peroxidation associated with cancer, premature aging, atherosclerosis, and diabetes [36]. Besides, the essential oils, that is, green pesticides, are excellent alternatives to synthetic pesticides in order to reduce negative impacts to human health and the environment [37], notably the essential oils of *Pelargonium graveolens* showed insecticidal effects with a maximal mortality rate of 100 % [153].

Since ancient times, genus *Salvia* (*Lamiaceae*) has been used throughout the world, owing to its large spectrum of beneficial effects, such as its antineoplastic, antiviral, cardioactive, antidiabetic, and antiplasmodial activities [39, 40]. Among these species, *Salvia miltiorrhiza* (Chinese sage) with a rhizome possessing medicinal powers. Different molecules of *S. miltiorrhiza* (or Danshen in Chinese) are widely recommended in modern and traditional medicine for the treatment of various disorders, for example, blood-circulation diseases. The red pigment of its roots is mainly composed of numerous diterpenoid tanshinones, such as tanshinone IIA, major bioactive molecules of the *Salvia* species offering numerous pharmacological activities notably antineoplastic effects [41]. Tanshinone IIA induces apoptosis and inhibits proliferation, migration, and invasion of a number of neoplastic cell types belonging to hepatoma, osteosarcoma, leukemia, prostate cancer, gastric cancer, breast cancer, colon cancer, and glioma. Besides, the prevention and treatment of cerebral infarction by *S. miltiorrhiza* Bunge involves several action modes, including anti-atherosclerosis, anti-hypertensive, anti-platelet aggregation, anti-inflammatory, and anti-oxidative effects. Plant-derived natural products have provided many bioactive terpenoids, some of which have led to important pharmaceuticals available on the market or promoted in clinical trials by the emerging "biotech" companies [144].

13 Conclusion

Plants hold a strong potential for pharmaceutical and industrial applications, resulting from the great richness in secondary metabolites, notably in terpenes/terpenoids which represent the largest group of natural products. Potentially terpenoids/terpenes remain to be identified in numerous plant species, known or still unexplored. Plant transformation by *Agrobacterium rhizogenes* leads to the formation of hairy roots, that is, of well-differentiated roots presenting at once a high genetic stability, an unlimited propagation, and spontaneous regeneration in media devoid of growth regulators. Hairy roots and *A. rhizogenes*–derived plants are potentially promising bioreactors which can be used for producing biomolecules of high added value. Ri-plants make possible the production of secondary metabolites exclusively accumulated in the aerial parts of the plant. In the *Catharanthus roseus* leaves, the final step of terpenoid indole alkaloid (TIA) biosynthesis leads to vinblastine and vincristine (bisindole alkaloids), whereas their two precursors are produced in the roots. Moreover, Ri-regenerants can allow the creation of new varieties in horticulture/floriculture. Bacterial Ri-T-DNA, responsible for the genetic transformation, is a true secretion system based on the genetic horizontal transfer of foreign genes into the host plant genome. Thereby, hairy roots open large avenues for engineering terpenoid metabolism pathways or revealing novel genes by recent approaches as T-DNA activation tagging or MeJA-inducible system following transcriptome analyses. Nevertheless, due to the great complexity of these pathways, numerous terpenoid biosynthesis-related genes are always to be isolated and identified in plants. Overall, hairy roots produce terpenoids/terpenes at levels comparable to or higher than those found in the wild roots. The cultures of hairy roots assure serious safety advantages compared to those of plants cultured in the open field. Biotic or abiotic elicitors have been used to enhance terpenoid contents. Most often methyl jasmonate was found to be efficient to improve the secondary metabolite synthesis. Nevertheless, the major challenge for commercial exploitation of the hairy roots is scaling up at industrial level. Based on the cell suspension culture biomass concept, specific reactors have been altered to overcome the hurdles limiting the hairy root culture on a large scale. Nowadays medicinal plants provide therapeutically active terpenoids for treating more and less severe pathologies. A vast pool of higher plants biosynthesizing secondary products remain again to be identified. Certain biomolecules of known plants have not been screened for therapeutic properties. In the near future, drug discovery from plant species is a crucial investigation to treat, notably, severe pathologies.

Abstract

Monoterpenes resulting from the combination of two and sesquiterpenes from three branched, unsaturated C_5 units (isoprene) represent a large class of natural products with a wide range of biological activities. They include unsaturated hydrocarbons and their oxidation products as alcohol, aldehydes, ketones, and rarely ethers. Volatile compounds are constituents of essential oils that are accumulated by numerous plants in special structures in the tissue. Besides the conspicuous aromatic properties, a wide range of biological activities has been documented allowing a wide field of applications. In an ecological context, mono- and sesquiterpenes play an important role in the relations between organisms, for example, as attractants of pollinators or deterrents of herbivores. On a large-scale, monoterpene emissions from vegetation in nature can have ecosystem-wide influences. The further investigation and documentation of this high biodiversity and its sustainable use remains a promising task. This requires the further development of analytical and production techniques and the exact definition and characterization of the plant sources.

Keywords

Aroma compounds • Biological activity • Essential oil • Monoterpene • Sesquiterpene

1 Introduction

Terpenoids represent a large class of natural products with numerous biological functions. Although terpenoids are usually regarded as secondary (plant) products, some of them are widespread and are involved in basic biological processes as electron transport in mitochondria and plastides. The name terpenoids is derived from turpentine, the aromatic resinlike exudations obtained from various coniferous trees. The common feature of all terpenoids is that they are built up by branched C5 units, isoprene (= 2-methylbutadiene). Terpenoids derived from just one isoprene unit are called hemiterpenes.

Monoterpenes are built up by two isoprene units, sesquiterpenes by three. Figure 96.1 shows how two isoprene units may be joined together.

The most common linkage is the head-to-tail binding that results in the regular monoterpenes. Irregular monoterpenes display a tail-to-middle binding displaying a cyclopropane structure as, for instance, in the pyrethrins, natural insecticides from *Chrysanthemum* species. Tail-to-tail bindings occur in diterpenes as squalene where two monoterpenes are linked together [1].

Iridoids are monoterpenoids with a cyclopentane fused to a tetrahydropyran ring. In secoiridoids, the cyclopentane ring is opened. Most of these compounds are nonvolatile glycosides and will be reviewed elsewhere.

This chapter has its main focus on mono- and sesquiterpenes as volatile compounds in essential oils. Since the mid of the 1990 as reliable and easy to operate

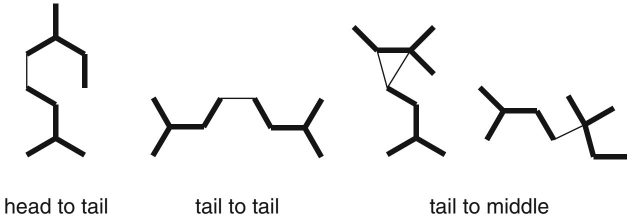

Fig. 96.1 Linking isoprene units together

gas chromatography–mass spectrometry systems became widespread, a great wealth of data on essential oils and volatile substances from all biological matrices has been generated and has become available in respective journals (e.g., Flavour and Fragrance Journal, Journal of Essential Oil Research, Journal of Essential Oil Bearing Plants, and Natural Product Communications) and handbooks [2–5].

Essential oils are complex mixtures of volatile constituents isolated from the plant material by hydrodistillation or steam distillation or expression in the case of citrus fruits. Extracts with apolar solvents yielding also the apolar terpenoids should not be designated as essential oils. Besides mono- and sesquiterpenes, essential oils may contain nonterpenoid hydrocarbons, phenylpropanoids, esters, lactones, phthalides, nitrogen- or sulfur-containing constituents, and isothiocyanates [5].

Plants rich in essential oils are mainly found in species of the families Apiaceae, Asteraceae, Cupressaceae, Lamiaceae, Lauraceae, Myrtaceae, Pinaceae, Piperaceae, Rutaceae, Santalaceae, and Zingiberaceae. As lipophilic compounds, essential oils are accumulated in particular structures as oil cells, secretory ducts, or glandular hairs. Frequently, the essential oils are associated with resins or gums.

Additionally, monoterpene glycosides have been reported in some plants. They are regarded as precursors of the volatile oil components [6]. As an example, among the glycosidically bound volatiles isolated from *Juniperus communis* were the monoterpenoids thymoquinone and p-cymen-8-ol [7].

The most conspicuous characteristics being their lipophilic and aromatic properties, essential oils are used as flavors and fragrances with a wide range of biological activities and applications.

2 Occurrence

Mono- and sesquiterpenes are produced by a wide range of organisms. The highest diversity has been recorded in higher plants, but terpenoids are also synthesized in bacteria, fungi, algae, and animals including marine organisms. Some prominent examples are given below:

Fungi: Among the odor compounds found in fungi, various oxidized sesquiterpenes have been reported from the mushroom *Lactarius hatsudake* in Japan [8].

As nonvolatile compounds, trichothecenes are prominent sesquiterpene mycotoxins produced mainly by *Fusarium*, *Trichoderma*, *Stachybotrys*, and

Myrothecium species. These compounds bear a tetracyclic structure with a 9,10 double bond and a 12,13-epoxy group. There are 8-hydroxytrichothecenes (e.g., T2 toxin), 8-ketotrichothecenes (e.g., nivalenol), and macrocyclic diesters [9].

Various marine organisms have been reported to produce terpenoids often with unique structures including monoterpenoids, sesquiterpenoids, sesquiterpene isonitriles, and mero-sesquiterpenoids. The latter are formed by condensation of a terpenoid with a nonterpenoid aromatic moiety [10]. Marine algae (sea weed) are living in an environment presenting a high availability of halogene ions as chloride and bromine. From these organisms, various halogenated terpenoids have been described [10].

Monoterpene hydrocarbons were produced and emitted by marine phytoplankton including α-pinene, β-pinene, myrcene, camphene, sabinene, and *p*-ocimene [11].

Liver mosses: the chemistry of liver mosses has been studied intensively during the past years. Among the volatile components, a range of terpenoids, often with a unique structure, have been reported [12]. (−)-Bicyclogermacrene has been identified as a constituent of various liverworts such as *Plagiochila asplenioides*, *Diplophyllum albicans*, and *Mylia* species [13].

Mosses: Among 38 volatiles identified by HR-SPME and GC/MS in the bryophyte *Rhodobryum giganteum* were α-pinene, limonene, camphor, and α-farnesene [14]. Besides various nonterpenoid volatiles, a wide range of mono- and sesquiterpenes have been found in the essential oils from the mosses *Tortula muralis*, *Homalothecium lutescens*, *Hypnum cupressiforme*, and *Pohlia nutans* [15].

Higher plants: Most of the reported mono- and sesquiterpenes origin from higher plants where a high diversity of these compounds has evolved. Examples of the occurrence are given below along with the presentation of the various compounds. The production of terpenoids and the accumulation of essential oils are governed by a range of factors as physiological variation concerning the plant development, type of secretory structure, seasonal variation, mechanical or chemical injury, or environmental factors as climate, diseases and pests, and edaphic factors [16]. Terpenoid pattern may be different in the various plant parts. As an example in *Laser trilobum*, limonene and perillaldehyde are the main compounds in the fruits whereas in the leaves and stems bornyl angelate dominated [17]. Often higher proportions of sesquiterpenoids as compared to monoterpenes were found in leaves than flowers and fruits. The pattern of oil components may change dramatically during fruit development as in the case of bitter fennel (*Foeniculum vulgare*) where with the formation of the fruit from the flowers, the percentages of fenchone and estragole in the essential oil increased while limonene, α-and β-phellandrene, and fenchyl acetate decreased [18]. Also within a plant, leaves of different age inserted at different heights of the stem may display distinct essential oil compositions. For instance, in oregano (*Origanum vulgare* ssp. *hirtum*), the *p*-cymene content was higher in the lower leaves and the carvacrol and γ-terpinene content were higher in the upper leaves [19].

Plants from a given species but of different origin may display quite different patterns of secondary compounds. These chemically different types that usually cannot be differentiated by morphological characters are called chemotypes.

The occurrence of chemotypes is quite frequent in essential oil-producing plants. For instance, in thyme (*Thymus vulgaris*), at least six different chemotypes according to the main monoterpenes in the essential oil are known [20, 21]. The respective monoterpenes are limonene, 1,8-cineol, linalool/linalyl acetate, sabinene hydrate, geraniol, thymol, and carvacrol.

The delimitation of chemotypes is often difficult. For practical reasons, often the distinction is done according to the main oil compounds, but the biogenetic pathways should also be considered.

Among the nonvolatile terpenoids, there is also a great variability of iridoids mainly in the families Apocynaceae, Gentianaceae, Lamiaceae, Loganiaceae, Plantaginaceae, Rubiaceae, Schrophulariaceae, Valerianaceae and Verbenaceae and of sesquiterpene lactones, especially in Asteraceae [9].

Some mono- and sesquiterpenoids are also found in animals. The most prominent examples are defensive secretion of insects. Iridoids are present in various beetles and cantharidin, a monoterpene derivative with skin irritating properties, in meloid beetles. Bitter tasting iridoid glycosides are found in some caterpillars. Also, the toxins of termites contain mono- and sesquiterpenes [9].

Anthozoa: Recently, 15 new guaiazulene type sesquiterpenes have been described in a Chinese gorgonian *Anthogorgia* species [22].

Mollusks: From *Aplysia kurodai* (Cyclopteridae), the monoterpene halogenated cyloethers aplysiapyranoid A–D have been isolated [9].

3 Phytochemistry

As mono- and sesquiterpenes contain 10 or 15 carbon atoms arranged in various branched and often cyclic structures, the chemical systematic nomenclature according to IUPAC [23] results in complex names that are used in handbooks and databases. For a practical use for frequently occurring or used compounds, common names have been applied, mostly derived from prominent plant sources, as pinene from *Pinus*, the genus of the fir trees or eucalyptol from the eucalyptus oils.

3.1 Isomers and Stereochemistry

The presence of double bonds and the possibility of an oxygen atom at different positions in the molecule account for the occurrence of isomers. There are structural isomers and frequently stereoisomers. Structural isomers as well as *cis–trans* isomers are usually separated in gas chromatography with standard columns, the method of choice for the analysis of essential oils. However, the separation of enantiomers needs specific chiral columns based on cyclodextrins. Therefore, in most publications where these columns were not used, there is no differentiation between the enantiomers.

Enzymes producing the final monoterpene are often stereospecific, so that in many cases only one of the two possible enantiomers is produced or predominates.

Nepeta cataria var. *citriodora*	0.4	0.1	99.9
Backhousia citriodora	0.1	17	83

[a] Percentage of citronellal in the essential oil

The following examples illustrate the significance of stereoisomers in this substance group (Fig. 96.2).

The two carvone enantiomers are a prominent example. They differ in optical rotation, circular dichroism, and aroma impact. S-(+)-carvone with typical caraway odor occurs in the fruits caraway (*Carum carvi*), whereas R-(−)-carvone is a minty aroma component in spearmint (*Mentha spicata*).

Table 96.1 presents the ratio of R-(+)-citronellal to S-(−)-citronellal in essential oils of various origin. The nearly exclusive occurrence of the (+)-form is a characteristic of lemon balm (*Melissa officinalis*) oils and can be used as criterion to detect adulterations [24].

Menthol composed of a cyclohexane ring substituted with a methyl- and an isopropyl group in para-position and an OH group displays three carbons centers with different ligands so that eight stereoisomers in four pairs of enantiomers exist (Fig. 96.2).

Humans were able to differentiate the odors of the (+) and (−) enantiomers of α-pinene, carvone and limonene but failed to differentiate between (+)- and (−)-menthol. Both menthol enantiomers have a peppermint odor quality but (−)-menthol has a much stronger cooling effect than (+)-menthol [25]. S-(−)-limonene has a turpentine odor impact and R-(+)-limonene an orange odor impact [25]. Neomenthol, isomenthol, and neoisomenthol do not present a cooling effect.

The enantiomeric distribution of chiral monoterpenes may greatly vary with the individual compounds. For instance, in higher plants, germacrene D is present as (−)-enantiomer, while the (+)-enantiomer is more likely to occur in lower organisms [22]. In a *Myrtus communis* essential oil from Algeria limonene was exclusively present in the (+)-enantiomeric form, α-pinene with more than 95% in the (+)-form, while β-pinene, β-phellandrene, and neomenthol occurred rather as a racemate [26].

3.2 Classification

Mono- and sesquiterpenes are often classified according to the structure of the carbon skeleton, acyclic or the various cyclization types, and the oxidation status as hydrocarbons, alcohols, aldehydes, ketones, or esters.

3.2.1 Monoterpenes

Acyclic

Hydrocarbons: Myrcene, *Z*-β-ocimene, and *E*-β-ocimene are branched hydrocarbons with three double bonds occurring in many essential oils (Fig. 96.3).

Oxygenated compounds: Linalool is a tertiary alcohol and can be found in many essential oils; it is accompanied by linalyl acetate. Linalool is the main compound in the oils from lavender (*Lavandula angustifolia*), coriander fruits (*Coriandrum sativum*), bergamot (*Citrus aurantium* var. *bergamia*), orange flowers (*Citrus sinensis*), and the linalool chemotype of thyme (*Thymus vulgaris*). Geraniol and nerol are two *cis–trans* isomers. Geraniol is widespread in essential oils, occurring mainly in *Cymbopogon* species. Geraniol is widely used in perfumery. Geranyl acetate is found in *Callitris* and *Eucalyptus* species.

Citronellol occurs free or as esters in many essential oils as in the leaves of *Pelargonium odoratissimum* and fresh flowers of *Rosa gallica* and *R. damascena* [27].

The aldehydes geranial (= *E*-citral, citral A) and neral (= *Z*-citral, citral B) are two *cis-trans* isomers with lemonlike scent present in lemongrass (*Cymbopogon citratus*) and the fresh peel of lemon (*Citrus limon*). They are used as food flavoring and in perfumery.

Citronellal, a further aldehyde, is a main constituent in citronella oils (*Cymbopogon nardus*) and can also be found in *Melissa officinalis* and in various *Eucalyptus* species as *E. citriodora*. It is mainly used in perfumery [27].

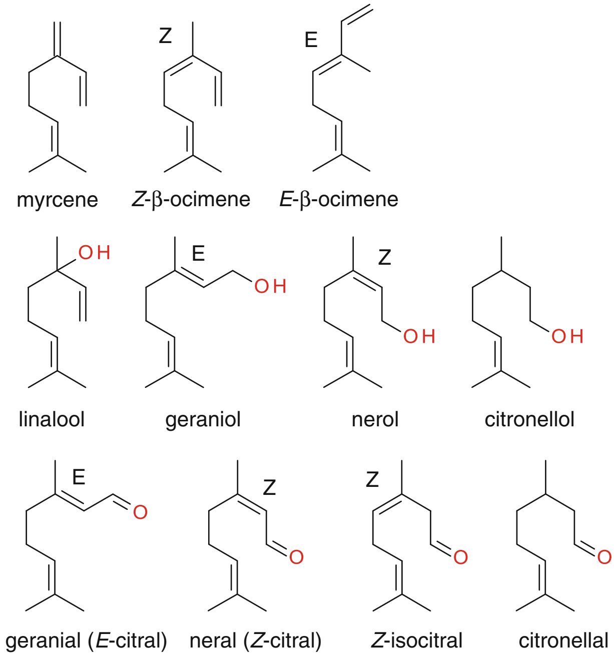

Fig. 96.3 Acyclic monoterpenes

Monocyclic Compounds with *p*-Menthane Skeleton

p-Menthane is the 1-methyl-4-isopropyl-cyclohexane skeleton (Fig. 96.4). Menthadienes result from different rearrangements of the α-terpinyl cation differing in the position of the two double bonds. As hydrocarbons, they comprise α-terpinene, γ-terpinene, α-phellandrene, β-phellandrene, α-terpinolene, and limonene and are frequent compounds in many essential oils. (+)-Limonene is a main compound in the expressed oil from *Citrus* fruits peels. (−)-Limonene occurs in needle oil of young fir twigs (*Abies alba*) and in some mint oils (*Mentha* sp.). α-Terpinene is a component of the cardamom fruit (*Elettaria cardamomum*). *p*-Cymene is an aromatic monoterpene. It occurs together with γ-terpinene and its hydroxylated derivatives thymol and carvacrol in *Thymus* and *Origanum* species.

The most important monoterpene alcohols are menthol, *cis*- and *trans*-piperitol, *cis*- and *trans*-pulegol, isopulegol, *cis*- and *trans*-carveol, thymol, carvacrol, terpinen-4-ol, and α-terpineol. The latter two bear a tertiary alcohol function. Terpinen-4-ol is a major antibacterial component of tea tree oil (*Melaleuca alternifolia*). α-Terpineol is a major compound in cardamom oil. (−)-Menthol is a main constituent in mint oils (*Mentha x piperita* and other *Mentha* species). Terpinen-4-ol is typically found in marjoram oils (*Origanum majorana*); α-terpineol occurs in various essential oils including those from *Melaleuca viridiflora* and nutmeg (*Myristica fragrans*). Thymol and carvacrol are

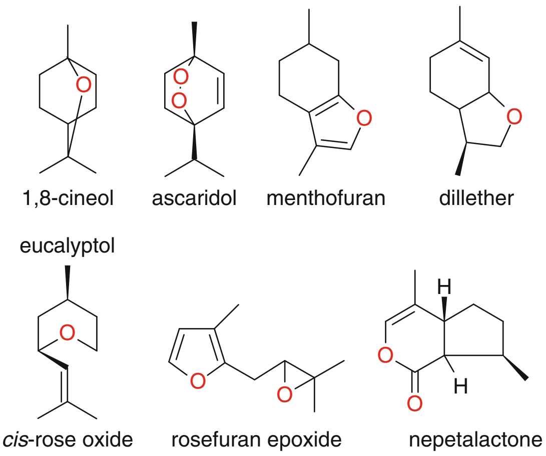
characteristic compounds of various *Thymus* species. Also the *Origanum* species are ordinarily rich in carvacrol. From India, a *Coleus aromaticus* oil rich in carvacrol has been reported [28].

Perillaldehyde is derived from limonene. In fruits of *Laserpitium siler* and *Laser trilobum*, it may account together with limonene for more than 80% of the essential oil [16]. It occurs also in *Perilla argata* and *Citrus reticulata* [27].

In analogy to the mentioned alcohols, the corresponding ketones are menthone, also present in *Mentha* oils, piperitone, pulegone, and carvone. (+)-Pulegone is the main constituent of pennyroyal oil (*Mentha pulegium*); piperitone occurs in *Mentha* oils, *Cymbopogon sennarensis*, *Lippia alba*, and *Eucalyptus dives*.

Thymoquinone is a major compound in the seed oil of *Nigella sativa* with antioxidative and protective properties.

Fig. 96.5 Oxidized monoterpenes with O-heterocycles



Mono- and Bicyclic Compounds with an O-Heterocycle

In the biosynthesis of some compounds with menthane structure, an intramolecular reaction of oxygen-containing groups leads to the formation of a second heterocylic ring (Fig. 96.5).

1,8-Cineol, eucalyptol with an ether bridge between C$_1$ and C$_8$, is the main compound of eucalyptus oil (*Eucalyptus globulus* and other species). 1,8-Cineol is as well component in numerous other essential oils, mainly in species of the genera *Thymus*, *Achillea*, and *Artemisia*.

Ascaridol presents a peroxide structure and displays anthelmintic activity and some toxicity to mammals. It is found in *Chenopodium ambrosioides* and some *Achillea* and *Artemisia* species.

A 5-membered oxygen containing heterocycle fused to the cyclohexane ring is the characteristic structure of menthofuran and dill ether. Menthofuran is an atypical compound of pennyroyal oil (*Mentha pulegium*) and appears in small amounts in mint oils. Dill ether is a major compound in the distilled oil from dill herb (*Anethum graveolens*) providing the typical dill odor.

Cis- and *trans*-rose oxide bear a tetrahydropyran ring and can be found in small amounts in *Pelargonium graveolens*, *Citrus paradisi*, and *Citrus sinensis* oils. Rosefuran epoxide occurs in small quantities as aroma component in *Alyosia triphylla*, and *Agastache rugosa* oils.

Nepetalactone as main oil component from catmint species (*Nepeta* sp.) occurs in three isomers (4aα,7α,7aα; 4aα,7α,7aβ; 4aα,7β,7aα) and is a powerful attractant and stimulant for cats. It is produced from iridodial.

Bicyclic Compounds with Carane and Thujane Skeletons

These compounds present a cyclopropane ring beside the cyclohexane structure (Fig. 96.6). In the carane skeleton, the cyclopropane structure arises from an additional bond between C3 and C8 of the menthane structure. The major

compound of this group is δ-3-carene that can be found in turpentine oils obtained from *Pinus*, *Picea*, and *Abies* species.

In the thujane derivatives, the cyclopropane occurs within the cyclohexane structure. The main hydrocarbons with these skeletons are α-thujene and sabinene, occurring in many essential oils.

Cis- and *trans*-sabinene hydrate, formerly called thujanol, are the two main tertiary alcohols. They are typical compounds in the marjoram oil (*Origanum majorana*) and a specific chemotype of thyme oils (*Thymus vulgaris*). Sabinol is found in the oil of *Juniperus sabina* and other *Juniperus* species. These alcohols occur as free compounds or as acetates.

α-Thujone (*cis*-thujone) and β-thujone (*trans*-thujone) are ketones and occur in various essential oils. The most prominent example is absinth from absinth wormwood (*Artemisia absinthium*), but they are also present in other *Artemisia* species, *Thuja occidentalis*, and *Tanacetum vulgare*. These compounds are of toxicological concern.

Bicyclic Compounds with Pinane Skeleton

Pinanes bear the [3.1.1] bicyclic structure and therefore a cyclobutane ring. α-Pinene and β-pinene are the hydrocarbons that occur widely in essential oils

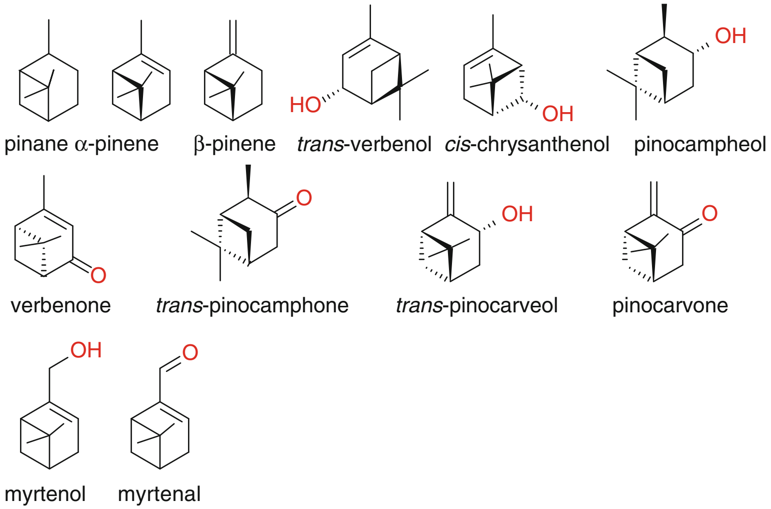

Fig. 96.7 Monoterpenes with pinane structure

and are abundant in turpentine oils from *Pinus* species (Fig. 96.7). Depending on the position of the double bond and the OH group, there are the secondary alcohols *cis*- and *trans*-verbenol, *cis*- and *trans*-chrysanthenol, *cis*- and *trans*-pinocarveol, and pinocampheol occurring occasionally in essential oils. For instance, *trans*-pinocarveol is a major compound in *Chenopodium ambrosioides* essential oil. The corresponding ketones are pinocarvone, verbenone, and chrysanthenone. Myrtenol is a primary alcohol and myrtenal the corresponding aldehyde.

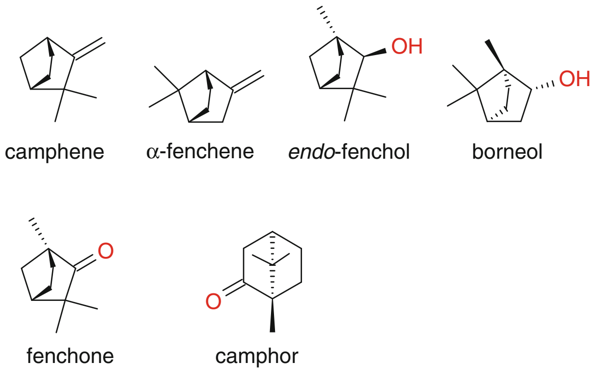
Bicyclic Compounds with Bornane, Camphane, and Fenchane Skeletons

Compounds of these groups possess a [2.2.1] bicyclic structure (Fig. 96.8). Camphene and fenchene are hydrocarbons occurring in various essential oils. (+)-Borneol is the main component in borneol camphor oil isolated from *Dryobalanops aromatica*; (−)-borneol occurs in Ngai camphor oil from *Blumea balsamifera*. Additionally, borneol and bornyl acetate are found in various oils including rosemary (*Rosmarinus officinalis*) and nutmeg (*Myristica fragrans*). Fenchyl alcohol (fenchol) occurs as endo-fenchol (α-fenchol) and exo-fenchol (β-fenchol) as minor components in various essential oils. (+)-Fenchone occurs in fennel fruits (*Foeniculum vulgare*) and *Lavandula stoechas* essential oil, (−)-fenchone in *Thuja occidentalis*. Camphor builds intensively smelling crystals. It is widespread in essential oils including those from the camphor tree (*Cinnamomum camphora*), feverfew (*Chrysanthemum parthenium*), and *Lavandula* and *Artemisia* species.

Tricyclic Skeletons

Tricyclene has a tricyclic [2.2.1.0] saturated hydrocarbon structure and is the main compound of the essential oil from the leaves of *Gossypium barbadense* [29].

Fig. 96.8 Monoterpenes with bornane, camphane, and fenchane structures



3.2.2 Sesquiterpenes

Acyclic Sesquiterpenes

The farnesenes are branched hydrocarbons with four double bonds (Fig. 96.9). *E,E*-α-farnesene and *E*-β-farnesene are widespread in essential oils, whereas *E,Z*-α-farnesene and *Z,Z*-α-farnesene are not reported to occur in nature. *Z,E*-α-farnesene is a constituent of the trail pheromone of the red fire ant. The oxidation products, farnesols as primary alcohols, as well as *E*- and *Z*-nerolidol as tertiary alcohol are occasional essential oil constituents.

The aldehydes α-sinensal and β-sinensal with a very low odor threshold occur as minor compounds in essential oils from various *Citrus* species.

Cyclic Sesquiterpenes

The folding of the farnesyl chain during biosynthesis allows to build up a great variability of cyclic skeletons. The most important are displayed in Fig. 96.10. In some structures as in the elemane and eremophilane skeletons, rearrangement occurs so that the original head-to-tail binding of the isoprene units is no longer obvious.

Monocyclic Compounds

The bisabolane derivatives bear a C6 ring formed in analogy to the menthane skeleton (Fig. 96.11). The bisabolene isomers (*Z*-α-bisabolene, β-bisabolene, *E*-γ-bisabolene, and *Z*-γ-bisabolene) occur in various essential oils. α-Zingiberene is a main constituent of ginger oil (*Zingiber officinale*). The pungent taste of this drug is due to the gingerols (phenols). β-Curcumene is a typical compound of curcuma oils (*Curcuma aromatica* and *C. longa*). The aromatic *ar*-curcumene is found in *Curcuma* species and ginger.

The oxidized bisabolene derivative α-bisabolol with antiphlogistic properties is a main active compound in German chamomile (*Matricaria recutita*). Depending on the origin of the plants and the chemotype or variety, varying proportions of the oxides (bisabolol oxide A, bisabolol oxide B, or bisabolone oxide A) may be present in the respective oils [30]. α-Bisabolol can also be found in larger

proportions in some other species as the candeia tree (*Eremanthus erythropappus*), *Populus deltoides*, *Plinia cerrocampanensis* [31], and the roots of *Laserpitium zernyi* [32].

The germacrenes bear a 10-membered ring system. Germacrene D is widespread in plants and often found in leaf oils while germacrene A and germacrene B occur occasionally in essential oils.

α-Humulene presents an 11-membered ring. It is found in the essential oils of hop (*Humulus lupulus*), in cannabis (*Cannabis sativa*), and in small amounts in many other essential oils.

Bi- and Tricyclic Compounds

Some bi-and tricylic sesquiterpenes are frequently found in essential oils:

The bicyclic bergamotenes display like the pinenes, a cyclobutane ring. *Trans*-α-bergamotene occurs in lemon oil, in lodgepole pine (*Pinus contorta*), and as main compound in the oil from *Pimpinella affinis* [33].

Cadinane, muurolane, and amorphane derivatives possess decalin ring system substituted with an isopropyl and two methyl groups. Of these, β-cadinene is one of the most common in essential oils. It is abundant in conifer oils.

β-Caryophyllene (*E*-caryophyllene) derived from α-humulene presents a C9 ring fused to a cyclobutane ring. It is widespread in plants including food plants. In the essential oils from cannabis, oregano, and rosemary, it represents a major compound. It is found in the vegetative parts of many plants. β-Caryophyllene

selectively binds to the CB(2) receptor so that it act as a functional CB(2) agonist. Also in vivo, this natural product exerts cannabimimetic effects with anti-inflammatory action [34]. Isocaryophyllene (*Z*-caryophyllene) occurs in clove oil and *Jasminum sambac* oil.

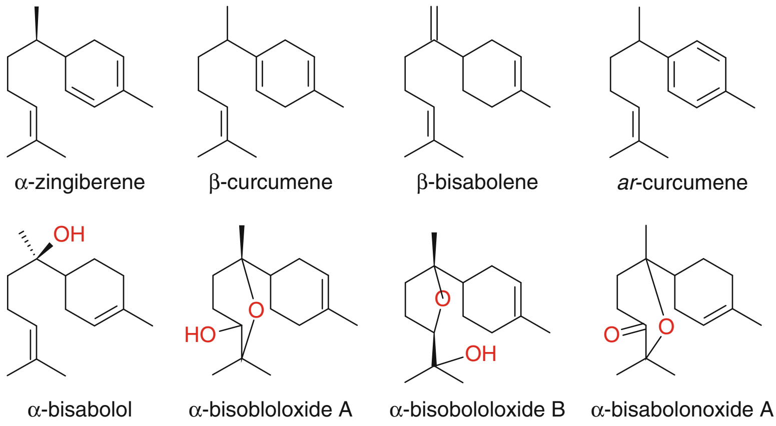

Fig. 96.11 Important bisabolane sesquiterpenes

The spiro compound α-chamigrene has been isolated from *Schisandra chinensis* fruits and β-chamigrene from *Chamaecyparis taiwanensis* [27]. β-Chamigrene was the main compound in *Trichilia connaroides* root oil [35].

Further bi- and tricyclic sesquiterpene hydrocarbons occurring in various essential oils are β-bourbonene, copaene, α-patchoulene (besides patchouli alcohol in patchouli oil from *Pogostemon cablin*), daucene, cyclosativene, β-cedrene (conifers, *Juniperus* sp.), bicyclogermacrene, aromadendrene, aristolene, α-ylangene, and longifolene.

The bicyclic C14 aromatic hydrocarbon chamazulene with antiphlogistic properties is a characteristic compound present in German chamomile and some *Achillea millefolium* agg chemotypes. Due to its system of conjugated double bonds, it confers a deep blue color to the essential oil. A blue azulene derivative is also present in the mushroom *Lactarius indigo*.

Oxidized Compounds

Among the oxygenated sesquiterpenes (Fig. 96.12), the oxidation product from β-caryophyllene, caryophyllene oxide, is widespread in plants. Also spathulenol is a widespread sesquiterpene alcohol. For example, it occurs in German chamomile and together with γ-eudesmol as major oil component in *Eucalyptus oleosa* [36]. Daucol and carotol are aroma components found in the fruit oils from carrots (*Daucus carota*) [27].

Davanone and related compounds bear a tetrahydrofuran ring. Davanone is a main compound in davana oil obtained from *Artemisia pallens* (Asteraceae). The oil has a unique flavor profile and is used in combination with various other natural flavors [37]. Davanone occurs also in specific chemotypes of other *Artemisia* species (Fig. 96.12).

Sesquiterpene lactones are nonvolatile compounds that do not occur in essential oils. Occurring mainly in Asteraceae, the sesquiterpene lactones that have interesting biological properties will be presented elsewhere.

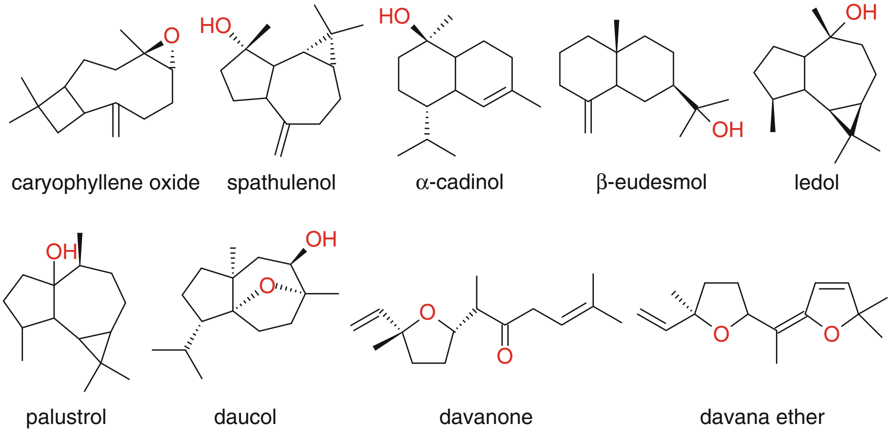

Fig. 96.12 Further selected oxidized sesquiterpenes

3.2.3 *nor*-Sesquiterpenoids

nor-Sesquiterpenoids are derived from sesquiterpenes by the loss of one or more carbon atoms. Some examples are given below (Fig. 96.13):

Ptaquiloside is an instable glucoside present in the widely distributed bracken fern (*Pteridium aquilinum*). Under alkaline conditions, it is converted in a conjugated diene-one which is readily added to various nucleophilic compounds. Therefore, it has a carcinogenic potency [9].

Geosmin and dehydrogeosmin are emanations from microorganisms (*Streptomyces* sp.) with an earthlike, musty smell. Geosmin is also present in some wines and the floral scent of cacti of the genus *Turbinicarpus* and some other genera [38].

(*E*)-4,8-dimethylnona-1,3,7-triene, a C11-nor sesquiterpene, is among the most widespread natural scent components [38].

Damascone, damascenone, and ionone are ketone aroma compounds derived from the breakdown of carotene. Damascone has a roselike aroma and is used in perfumery. β-Damascenone has been identified as an aroma compound in red wines with concentrations around 1–1.5 μg/L. The odor threshold is strongly dependent from the matrix, being very low in aqueous alcoholic solutions and much higher in wines. It acts as possibly enhancer of fruity aromas [39].

3.3 Rearrangements and Transformations

Terpenoids with double bonds can undergo various rearrangement and transformations as well as oxidation reactions. Some reactions proceed easily; others may be induced by acid, heat, or irradiation treatment. Some examples are given below:

β-Caryophyllene (*E*-caryophyllene) is oxidized when exposed to air, and after 5 weeks, nearly 50% of the original compound was consumed. The main oxidation product was caryophyllene oxide [40]. Limonene is easily oxidized to limonene

oxide, carveol, and carvone. Also linalool undergoes oxidation leading to various oxides as presented in Fig. 96.14.

Acid catalyzed rearrangements of *cis*- and *trans*-sabinene hydrate yielded terpinen-4-ol (56%), γ-terpinene (18%), α-terpinene (9%), terpinolene (3%), *p*-cymene (1%), α-terpineol (1%), and E/Z-*p*-menth-2-en-1-ol (1%) [41].

Major acid catalyzed rearrangements products of germacrene D include α-muurolene, (+)-γ-muurolene, (−)-α-amorphene, α-ylangene, α-copaene, selina-4(15),6-diene, opposite-4(15),7-diene, 4(15)-cycloaxene, isodauca-4,6-diene, and various cadinene isomers with the cadinanes predominating [22]. Some of such rearrangement products are eventually found as natural metabolites.

The transformation of terpenoids in food products can be the origin of "off-flavors" as in the case of orange juice where the metal catalyzed or photooxidation

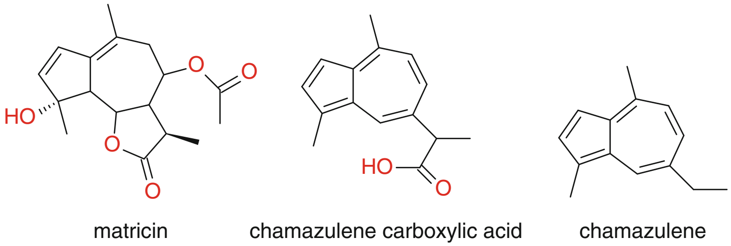

Fig. 96.15 Formation of chamazulene during hydrodistillation

of the sesquiterpene valencene affords nootkatone or when the juice gets a terpene note through the oxidation of limonene to carvone [42].

During production of essential oils through hydrodistillation, some transformations have been characterized. The most prominent example is the formation of the blue chamazulene in essential oils from German chamomile or yarrow (Fig. 96.15). The starting compound in the plant is the nonvolatile sesquiterpene lactone matricin that is converted to chamazulene carboxylic acid which in turn is decarboxylated to chamazulene [43].

Similarly, terpinen-4-ol present in the essential oil of marjoram (*Origanum majorana*) arises from rearrangement of sabinene hydrate during distillation [41].

4 Biosynthesis

The biosynthesis of terpenoids has been reviewed in a range of handbooks and compendia [1, 43–45]. A special chapter within this series will be devoted to this topic.

4.1 Biosynthesis of the Isoprene Units

As mentioned above, terpenoids can be seen as built up by isoprene units. In vivo, these units are the interconvertible isomers isopentenyl diphosphate IPP (isopentenyl pyrophosphate) and dimethylallyl diphosphate (DMAPP) (dimethylallyl pyrophosphate).

There are two ways to produce these biological isoprene units:

1. The mevalonic acid pathway producing IPP from acetyl CoA takes place in the cytosol of the cells. The steps include the formation of 3-hydroxy-3-methylglutaryl-CoA from three acetyl CoA, the reduction to mevalonic acid, the subsequent activation with ATP resulting in the formation of mevalonate diphosphate, and finally the decarboxylation of mevalonate diphosphate to release IPP.
2. The deoxyxylulose phosphate (DXP) pathway or more precisely the methylerythritol phosphate (MEP) pathway or non-mevalonate pathway in the plastids. The pathway begins with the condensation of glycerinaldehyde-3-phosphate

with pyruvate to yield 1-deoxy-D-xylulose-5-phosphate which is then reduced to 2-C-methyl-erythrose-4-phosphate (MEP). Then follows in three reactions the conversion to 2-C-methyl-D-erythritol-2,4-cyclodiphosphate and subsequently a reduction to form the linear 1-hydroxy-2-methyl-2(E)-butenyl-4-phosphate. The latter is finally converted to IPP and to a lesser extent to DMAPP.

4.2 Biosynthesis of Monoterpenes

The first step in monoterpene synthesis is the formation of geranyl diphosphate (geranyl pyrophosphate, GPP) from one IPP and one DMAPP by isoprenyl diphosphate synthases. The reaction mechanism of the monoterpene synthases starts with the ionization of GPP to give a carbocation that is involved in various cyclizations, hydride shifts, or rearrangement reactions before the reaction is terminated by deprotonation or water incorporation. For the production of cyclic monoterpenes, the geranyl cation is first converted to a linalyl cation intermediate that can yield the initial cyclic intermediate, the α-terpinyl cation. This α-terpenyl cation can subsequently be converted to the wide range of cyclic monoterpenes [46]. Terpene synthases have been intensively studied during the last two decades. The high number of monoterpenes produced arises from the high diversity of the terpene synthases and from the ability of these enzymes to produce more than one end product.

4.3 Biosynthesis of Sesquiterpenes

Sesquiterpenes are formed from three C5 units where a further molecule IPP reacts with GPP to form farnesyl diphosphate (farnesyl pyrophosphate, FPP). FPP is further converted to linear or cyclic products. By cleaving the diphosphate group, an allylic cation is produced that underlies an electrophilic attack on the central or distal double bond leading to cyclization. Due to the increased chain length and an additional double bond, a huge number of structures can be built up. Sesquiterpene cyclase enzymes typically produce a major product accompanied by a range of related structures [44].

5 Biological Activities

Due to their physiological and aromatic properties, a wide field of applications has been established for plants and plant products containing mono- and sesquiterpenes. To underline the importance of these compounds, an estimated world consumption of the main essential oil types is presented in Table 96.2. The traditional uses as spices and seasoning of food, the uses as flavoring agents in household products and in perfumery are well known. Uses in the so-called wellness area as additives in bath, oil lamps, or in massages encounter an increasing popularity.

Table 96.2 Estimated world consumption of major essential oils [5]

Oil type	Botanical species	Tons/year	Main terpenoids
Orange	*Citrus sinensis*	50,000	Limonene (92–97%)
Corn mint	*Mentha arvensis*	25,000	Menthol (70%)
Peppermint	*Mentha piperita*	4,500	(−)-Menthol (30–55%), menthone (14–32%)
Eucalyptus	*Eucalyptus globulus*	4,000	1,8-Cineol (>70%)
Lemon	*Citrus limon*	3,500	Limonene (60–80%), geranial (0.5–2%), neral (0.2–1.2%)
Citronella	*Cymbopogon winterianus*	3,000	Citronellal (30–45%), geraniol (20–25%), citronellol (9–15%)
Citronella	*Cymbopogon nardus*		Geraniol (15–23%), citronellol (3–9%), geranial (3–6%)
Eucalyptus	*Eucalyptus citriodora*	2,100	Citronellal (70–87%), citronellol (5–10%)
Spearmint	*Mentha spicata*	2,000	(−)-Carvone (50–80%)
Cedarwood (Virginia)	*Juniperus virginiana*	1,500	α-Cedrene (22–53%), thujopsene (10–25%), cedrol (5–30%)
Lime	*Citrus aurantifolia*	1,500	Limonene
Lavandin	*Lavandula angustifolia x L. latifolia*	1,000	Linalool (24–35%), lavandulyl acetate (28–38%)
Litsea	*Litsea cubeba*	1,000	Geranial (38–45%), neral (25–33%)
Cedarwood (China)	*Cupressus funebris*	800	α-Cedrene (13–29%), thujopsene (18–31%), cedrol (10–16%)
Coriander	*Coriandrum sativum*	700	(+)-Linalool (65–78)
Grapefruit	*Citrus paradisi*	700	Limonene
Patchouli	*Pogostemon cablin*	600	Patchoulol (27–35%)
Basil (Reunion type)	*Ocimum basilicum*	500	Estragol (75–87%), linalool (0.5–3%)
Basil (European type)	*Ocimum basilicum*		Linalool (45–62%), estragol (0–30%), eugenol (2-15%)
Mandarine	*Citrus reticulata*	500	Limonene (65–75%), γ-terpinene (16–22%)

Rational phytotherapy relies on active substances from plants. Classical essential oil-bearing medicinal plants are German chamomile (*Matricaria recutita*), thyme (*Thymus vulgaris*), peppermint (*Mentha x piperita*), caraway (*Carum carvi*), and fennel (*Foeniculum vulgare*) [43, 47]. They are not only used to cure human disease but are of increasing interest in veterinary phytotherapy.

Aromatherapy is mostly applied to procure alleviation of chronic pain, depression, cognitive disorders, anxiety, insomnia, and stress-related disorders [48]. In this context, the influence of essential oils on the nervous system is studied [49]. Linalool-containing essences are traditionally used as sedatives, analgesics, and anxiolytics [50].

Useful pharmacological effects of essential oils have been studied intensively and reviewed [51–53] and presented also in handbooks and textbooks of pharmacognosy [43, 47, 54]. However, many effects described in primary literature were observed in vitro or in specific test systems and are therefore not yet directly applicable. In the following, only a limited selection of activities can be presented.

5.1 Aroma Impact

The aromatic properties of essential oils are perhaps the most conspicuous and account for a wide range of traditional applications. Many terpenoids have characteristic odors, some of them are presented in Tables 96.3 and 96.4 [55–57]. The odor thresholds however may vary greatly and depend on the matrix. (−)-Limonene with citrus-like aroma is a key odorant of orange juice and neral/geranial the key odorants of lemons. 1-*p*-Menthene-8-thiol present in grapefruit juice and responsible for the grapefruit aroma has with 0.02 ng/L one of the lowest odor threshold values [42].

5.2 Antimicrobial Activity

The need of exclusion or elimination of pathogenic microorganisms, the appearance of resistances against antibiotics, and the request of ecological safe compounds has driven the research of antimicrobial activity of natural compounds. Within the last years, an increasing number of scientific papers describing the composition and biological activity of essential oils of various sources have been published. Various modes of action in the bacterial cell have been discussed including degradation of the cell wall, damage to cytoplasmic membrane and membrane proteins, leakage of cell contents, coagulation of cytoplasm, and depletion of proton motive force [51, 58–60]. The lipophilic character of the terpene skeleton combined with the hydrophilic character of the functional groups is essential for activity. Thus, a rank of activity has been proposed as follows: aldehydes > ketones > alcohols > esters > hydrocarbons [61]. In many instances, gram-negative organisms were slightly less susceptible than gram-positive bacteria. Effective components displayed minimum inhibitory concentrations (MICs) of 0.05–5 μl/ml in vitro [51].

Testing 25 different bacterial strains including animal and plant pathogens, food poisoning, and spoilage bacteria, the component with the widest spectrum of activity was found to be thymol followed by carvacrol, α-terpineol, terpinen-4-ol, eugenol, linalool, (−)-thujone, δ-3-carene, geranyl acetate, (*cis* + *trans*) citral, nerol, geraniol, menthone, β-pinene, (−)-limonene, α-pinene, α-terpinene, borneol, (+)-sabinene, γ-terpinene, citronellal, terpinolene, 1,8- cineole, bornyl acetate, carvacrol methyl ether, myrcene, β-caryophyllene, α-bisabolol, α-phellandrene, α-humulene, β-ocimene, aromadendrene, and *p*-cymene, in that order [58]. Antibacterial and antifungal activity was also described in oils with high levels of sesquiterpenes as cadinene, *Z*-β-farnesene, γ-muurolene, spathulenol, and α-selinene [61]. Linalool and citral were very efficient in inhibiting a wide range

Table 96.3 Odor impact (aroma descriptor) of selected monoterpenes [55–57]

Compound	Odor
Borneol	Woody-camphoraceous, dry-minty
Isoborneol	Camphoraceous, weak peppery and woody
Camphene	Camphoraceous, mild-oily
Camphor	Camphoraceous, fresh, warm-minty, ethereal
δ-3-Carene	Resinous, sweet, refined-limonene-like, spicy
Carveol	Fresh, caraway- and spearmint-like
S-(+)-Carvone	Spicy, caraway-like
R-(−)-Carvone	Spearmint-like
Citronellal	Minty, citrus-like
Citronellol	Floral, roselike
Cumin aldehyde	Sharp, acid, pungent, woody, oily
Cuminyl alcohol	Floral, oily-spicy, dillseed- and caraway-like
Cymen-8-ol	Weak citrus-like
p-Cymene	Fresh, weak citrus-like, lemon and bergamot notes
Geranial	Lemon, sweet
Geraniol	Floral, lemonlike, minty
Limonene	Fresh, citrus-like, mild lemon and orange notes
Linalool	Fresh, floral, clean, sweet, lemon notes
Myrcene	Mild, sweet, balsamic, plastic note
Neral	Sweet, lemon
Nerol	Rose, sweet
cis-β-Ocimene	Herbal, warm-herbaceous, sweet-floral, neroli-oil-like
trans-β-Ocimene	Herbal, weak floral
α-Phellandrene	Spicy, herbaceous, minty, peppery-woody, fresh, citrus
β-Phellandrene	Peppery, minty, refreshing, citrus-like
α-Pinene	Pine-like, sharp, woody, turpentine-like
β-Pinene	Dry-woody, pine-like, resinous-terpene-like, spicy
Piperitone	Fresh, minty, camphoraceous
Sabinene	Warm, oily-peppery, woody-herbaceous, spicy
cis-Sabinene hydrate	Mild, pleasant, warm, woody-balsamic
trans-Sabinene hydrate	Warm, balsamic-woody, mild
Terpinen-4-ol	Nutmeg-like, spicy, woody-earthy, liliac-like
α-Terpinene	Refreshing, lemon-citrus-like
γ-Terpinene	Fresh-herbaceous, citrus-like
α-Terpineol	Floral, liliac-like
Terpinolene	Sweet-piney, oily, petroleum-like
α-Thujene	Green, herbal, woody

of *Candida albicans* isolates. The terpenoids arrested the cells at different phases of the cell cycle, that is, linalool and linalyl acetate at G1 and citral and citronellal at S phase [62]. Also various synergistic and antagonistic effects have been observed. 1,8-Cineol and camphor had a synergistic antimicrobial effect on *Candida albicans* [61].

Table 96.4 Odor impact (aroma descriptor) of selected sesquiterpenes [55–57]

Compound	Odor
trans-α-Bergamotene	Weak woody, warm, tea-leaf-like
Bicyclogermacrene	Green, spicy, mushroom-notes, dry-woody
β-Bisabolene	Sweet, warm, balsamic, woody, spicy
α-Bisabolol	Sweet, mild floral
β-Bisabolol	Mild, sweet, weak herbal
Bulnesol	Weak woody, weak spicy
Cadina-1,4-dien-3-ol	Weak fruity, weak woody, spicy
Cadina-1,4-diene	Fruity, mango-like, spicy, woody
δ-Cadinene	Dry-woody, weak medicinal
α-Cadinol	Weak woody, medicinal, dry
Calamanene	Weak floral, weak spicy
β-Caryophyllene	Woody, spicy, terpene notes
Caryophyllene oxide	Weak woody, warm, mild, weak spicy
α-Copaene	Vegetable-like, hops-like, woody
α-Cubebene	Spicy, herbal
β-Cubebene	Herbal, woody
Cubenol	Spicy, herbal, green-tea notes
β-Elemene	Fresh, warm, weak woody
γ-Elemene	Mild, woody
δ-Elemene	Lime-oil-like, woody
β-Eudesmol	Woody
trans-β-Farnesene	Warm, mild, sweet
trans,trans-α-Farnesene	Mild, warm, sweet
cis,trans-α-Farnesol	Mild, sweet, oily, floral, fresh green
trans,trans-α-Farnesol	Weak fresh, fresh green, weak floral
Germacrene B	Earthy, mushroomlike
Germacrene D	Weak spicy, weak fruity, apple-like, weak dry-woody
α-Guaiene	Sweet-woody, balsamic, peppery
β-Guaiene	Balsamic, woody, spicy
Guaiol	Woody-balsamic, mild, sweet, weak floral
α-Gurjunene	Balsamic, woody
α-Humulene	Weak woody, weak spicy, herbal
γ-Muurolene	Weak spicy, weak herbal, woody
T-Muurolol	Weak woody, weak spicy, mild
trans-Nerolidol	Woody-floral, weak green
Spathulenol	Weak fruity, weak herbal
α-Zingiberene	Spicy, fresh, sharp

Among the antifungal activities, the antiaflatoxigenic effects of some essential oils merit attention. Out of various tested oils, *Thymus vulgaris* and *Citrus aurantifolia* inhibited the aflatoxin production and growth of *Aspergillus parasiticus* while *Carum carvi* inhibited the aflatoxin production but not the fungal growth [63].

Antiviral properties have been reported from several essential oils. Oils from *Melaleuca alternifolia* and *Santolina insularis* showed activity against *Herpes simplex* virus types 1 and 2. Some of this activity was also present in oils from peppermint and lemongrass [61].

5.3 Anthelmintic Activity

Ascaridol contains a 1,4-peroxide bridge. It is the main constituent of the volatile oil of American wormseed (*Chenopodium ambrosioides* var. *anthelminticum*, Chenopodiaceae). It has anthelmintic properties but is also toxic to mammals. Ascaridol can also be found in chemotypes of some *Achillea* species.

5.4 Anticancer Activity

Tumorigenesis is a complex multistep process influenced by many factors. There are some population-based studies indicating that a diet rich in isoprenoids play a role in the ability to avoid cancers [61]. In various experiments and test systems, some mono- and sesquiterpenes showed activity, where peril alcohol and D-limonene were of greatest interest. α-Bisabolol, the anti-inflammatory compound of chamomile oil, showed a strong time- and dose-dependent cytotoxic effect on glial cells [61]. β-Caryophyllene showed some potentiating effect on the anticancer activity of α-humulene, isocaryophyllene, and paclitaxel on various cell lines [53]. Further studies are necessary to evaluate the anticancer potential of thymoquinone [53].

5.5 Antioxidant Activity

Natural antioxidants have been studied intensively during the past years which are mainly phenolic compounds. Among the many essential oils with antioxidative properties, those containing phenolic compounds as thymol and carvacrol showed the highest activities [61, 64–66]. Various test systems have been used, and it has to be differentiated between the complete essential oil and individual components. α-Pinene and limonene show low activity in the DPPH (2,2-diphenyl-1-picrylhydrazyl) test system while terpinene and terpinolene display a high hydrogen-donating capacity against DPPH [53]. Geraniol has a high hydrogen-donating capacity toward DPPH, whereas terpinen-4-ol is a weak antioxidant. Germacrene D with its three double bonds as electron rich centers showed good ability to scavenge superoxoid radical anions [61]. However, linalool or nerolidol may also display pro-oxidant activity [64].

In many cases, the antioxidative activity of essential oils cannot be attributed to the main compounds; minor compounds and synergistic effect may significantly contribute to the activity.

5.6 Other Activities and Applications

Antinociceptive and Analgesic Effects. An example of analgesic effects is (−)-menthol which was able to increase the pain threshold, whereas (+)-menthol did not show such activity [53].

Enhancing the skin penetration of medicaments is an interesting topic in pharmacy. Among the essential oils tested, those from *Camellia oleifera*, fructus *Evodia*, rhizoma *Acori tatarinowii, s*emen *Myristicae*, and pericarpium *Citri reticulatae* showed to be effective [53].

Considerable research has been carried out to investigate the insect repellent properties of essential oils, a field that is of special interest in tropical developing countries. Out of 38 undiluted essential oils tested, those of citronella (*Cymbopogon nardus*), patchouli (*Pogostemon cablin*), clove (*Syzygium aromaticum*), and *Zanthoxylum limonella* were the most effective in repelling the mosquito *Aedes aegypti* [67]. However, the main problems for an efficient application arise from the fact that the oils are too volatile for a long-lasting effect and the short distance of repellency [53].

Within the last two decades, numerous trials have been carried out with aromatic plants as feed additives in animal husbandry. Firstly, the intention was a use of sensory additive and flavoring and appetizing substances to substitute for antibiotic growth promoters that have been forbidden and to promote digestion. Usually, the effects on growth performance are nonexistent or marginal. Nevertheless, various positive effects on the animals have been alleged and partly also achieved. In this context, improvements at three levels are aimed including the feed characteristics, optimization of digestion and performance, as well as the characteristics of animal products as, for example, oxidative stability of meat and eggs [68]. The influence of essential oils on ruminal fermentation is an example with promising outcomes. In in vitro experiments, thymol was able to inhibit the production of lactate and of the greenhouse gas methane [69]. Also the essential oil from *Salvia officinalis* showed some inhibition on methanogenesis [70].

5.7 Toxicity

Essential oils may display irritating properties. When used externally, some products as turpentine increase capillary blood flow, cause rubefaction, and give a sensation of heat. However, the acute toxicity by the oral way is generally low. Most oils have LD50 values above 5 g/kg [47]. The most toxic essential oils are those from boldo (*Peumus boldus*) containing ascaridol and causing convulsions, *Chenopodium*, thuja, and pennyroyal (*Mentha pulegium*). Some constituents as the thujones, pulegone, carvacrol, and carvone show LD50 values below 1 g/kg in animals [47]. However, serious intoxications are rare. Formerly, most accidents occurred with camphor.

Pulegone and menthofuran are hepatotoxic. Pulegone is first metabolized to menthofuran and then to electrophilic metabolites that may give adducts with cellular proteins. Therefore, the menthofuran content of peppermint oil should be as low as possible. Maximum levels for pulegone in foodstuff and beverages to which flavorings have been added were set to 25 mg/kg in foodstuff, 100 mg/kg in beverages, with the exception of 250 mg/kg in peppermint or mint flavored beverages, and 350 mg/kg in mint confectionery. Tolerated daily intake (TDI) of menthofuran and pulegone was set to 0.1 mg/kg body weight [71].

The thujones have neurotoxic properties leading to dose-dependent tonic-clonic seizures in animals [72]. Thujones from *Artemisia absinthium* are in the drink absinthe, which has been banned in most countries. However, a new reexamination of the concentrations of thujones in various absinthes puts into question whether the dosages for toxicity were achieved [73]. When using traditional herbal medicines containing thujone, the thujone intake should not exceed 3.0 mg/day and the duration of use should be limited to 2 weeks [74].

Ledol and palustrol are two aromadendrane derivatives in the essential oil from Labrador tea (*Ledum palustre*). This oil causes vomiting, gastroenteritis, and excitation in man but is also toxic for animals [9]. Recently, fraganol and fraganyl acetate, rare monoterpenes, were described as toxic essential oil components in *Achillea umbellata* [75].

5.8 Allergenic Properties

The search for allergens of plant origin has made considerable progress within the last years. Among the terpenoids, there are some sesquiterpene lactones being potent sensitizing agents including artemisifoline, anthecotulide, and alantolactone and others, showing an exocyclic methylene group on the lactone ring [9].

Alleged allergenic monoterpenes and sesquiterpenes are citral (neral + geranial), limonene, geraniol, linalool, citronellol, and farnesol. Among the sesquiterpene lactones, there are potent allergens [9].

Fragrances may also act as contact allergens. Among 26 substances tested, the terpenoids listed in decreasing frequency of sensitization were hydroxycitronellal, farnesol, citronellol, geraniol, linalool, and limonene [76].

Some monoterpenes such as limonene, linalool, and geraniol autoxidize on exposure to air and may form allergenic compounds. Geraniol itself is considered as weak contact allergen and is used for fragrance allergy screening among dermatitis patients. Compared to oxidized linalool and limonene, oxidized β-caryophyllene appeared to be a rather rare sensitizer [40].

The toxicity of terpene alcohols when used as fragrance ingredients has been intensively reviewed [77]. At concentrations likely to be encountered by consumers, these chemicals are considered nonirritating to human skin. At the present maximum use concentrations, their potential for eye irritation is considered minimal. 6,7-Dihydroxygeraniol is a potent skin sensitizer and has been prohibited in fragrance materials. Linalool may contain impurities or oxidation products that are strong sensitizers. Farnesol is a weak sensitizer so that its use in fragrance materials has been restricted [77].

Concentrations of α-pinene and β-pinene in indoor air range from 1 to 45 μg/m^3 (50 percentile values), and in Germany, based on toxicological data, indoor air guide values for bicyclic monoterpenes have been proposed including the health hazard guide value of 2 mg/m^3 (RW II) and the health precaution guide value of 0.2 mg/m^3 (RW I) [78]. Recently, the respective indoor air guide values for monocyclic monoterpenes (limonene) have been set at of 10 mg/m^3 (RW II) and 1 mg/m^3 (RW I) [79].

5.9 Ecological Functions of Volatile Mono- and Sesquiterpenes

In an ecological context where a community of individuals and species is considered, terpenoids play an important role. The most conspicuous relationship might be the emission of floral scents as complex mixtures to attract pollinators to flowers, guiding them to food resources and allowing them to discriminate between flowers. Within a species, the level of scent emission changes in response to endogenous diurnal rhythms, flower age, pollination status, and environmental conditions such as light, temperature, and moisture status [80, 81]. The observation that in many essential oil plants the highest oil contents occur during the preblooming or blooming stages may be related to this function.

Furthermore, volatiles are produced in response to damage and herbivore attack; they may directly affect herbivores' physiology and behavior due to their toxic, repelling, or deterring properties. They can also attract enemies of attacking herbivores, such as parasitic wasps, flies, or predatory mites, which can protect the signaling plant from further damage [80, 82]. Such semiochemical mono- and sesquiterpenes elicit the antennal response of the interacting insects, which can be studied by gas chromatography coupled to electroantennography [61]. For instance, α-farnesene and germacrene B are volatile signaling compounds in spruce (*Picea abies*). In gymnosperms, monoterpenes as α-pinene, β-pinene, myrcene, and limonene accumulate in resin ducts and are toxic to numerous insects including bark beetles [83].

The attack of herbivores induces changes in the volatile emission of plants. For example, in water mint (*Mentha aquatica*), undamaged plants emit pulegone, which attracts the beetle *Chrysolina herbacea*. Upon feeding, the plants start to build up and emit menthofuran, which is a repellent for the beetle [84]. Another aspect is that volatiles emitted from insect damaged plants attract the natural enemies of these herbivores [82]. In cotton (*Gossypium hirsutum*), terpenoid accumulation and synthesis is induced by foliar damage through mechanical injury or herbivore attack. The higher level of terpenoids was achieved by filling existing glands and production of additional glands [85]. Complex relationships exist between the Chinese Masson pine (*Pinus massoniana*), the sawyer beetle (*Monochamus alternatus*) which is the vector of the pinewood nematode (*Bursaphelenchus xylophilus*) causing pine wilt disease, and the fungi (*Sporothrix* sp.) which in turn are the food source of the nematode. In this interplay, the amount and ratio of α-pinene to β-pinene plays an important role [86].

Volatile emissions from plants may also have an ecosystem-wide impact when quantitative estimations of the emissions are considered. Within the last decades, it has been shown that natural vegetations emit considerable amounts of organic volatiles. Conifers release huge amounts of isoprene and monoterpene hydrocarbons [44]. Emissions may be dramatically enhanced when the plants are damaged. So it has been shown that wounded *Copaifera officinalis* emits a complex mixture of sesquiterpenes which is comparable to the sesquiterpene pattern found in the leaves determined by extraction with organic solvents [87]. Large amounts of volatiles are emitted by plants. The annual global emissions of isoprenes are estimated to 500 Tg [88] including isoprene and α-pinene. Biogenic emissions of volatile organic carbons from the Finnish forests are dominated by monoterpenes, mainly α-pinene and δ-3-carene [89]. Interactions with solar radiation are investigated especially in connection with the formation of ozone. The emissions are chemically oxidized or otherwise transformed into different aerosol compounds. The global significance of volatile emissions from boreal forests in atmosphere chemistry is discussed since these emissions may lead to aerosol formation and therefore have an overall cooling impact on climate [90].

6 Biotechnological Approaches

As mono- and sesquiterpenes are important natural products with a wide application range, great efforts have been undertaken for the biotechnological production of valuable compounds.

Although a range of transformations of terpenoids is accessible by the way of classical chemical synthesis [10], the use of (micro)organisms to perform such reactions yielding valuable products is nowadays again of great interest as these procedures meet the requirements of a environmentally friendly so-called green chemistry. The enormous progress achieved in this field has been recently reviewed [91, 92]. The transformation of the sesquiterpene valencene to nootkatone which is the grapefruit aroma that is used in foods, cosmetics, and pharmaceuticals is a classical example and can be achieved by various microorganisms [92]. The regiospecificity of microbial biocatalysts offers the possibility to obtain specific products. As an example, depending on the microorganism used, the biotransformation of D-limonene can yield carveol, carvone, perillalcohol, perillaldehyde, perillic acid, isopiperitenol, α-terpineol, limonene-1,2-epoxide, limonene-1,2-diol, or limonene-8,9-epoxide [93].

However, in the biotechnological production of specific mono- or sesquiterpenes, manifold difficulties have to be resolved including the lipophilic character of substrates and/or products; their toxicity, especially on the membranes of the microorganisms; and the formation of unwanted or toxic by-products. Additionally, in many cases, the targeted products are built at low rates, and the reactions depend on weakly active cofactors that are difficult to manage [94, 95].

Metabolic or pathway engineering aims to establish biosynthetic pathways for compounds of interests in heterologous organisms such as microbes and higher plants. Metabolic engineering of terpenoids in plants is attempted with various purposes including not only the production of a specific metabolite but also enhanced disease resistance, weed control by producing allelopathic compounds, better pest management, production of medicinal compounds, increased value of ornamentals and fruit, and improved pollination [96, 97]. By using bioinformatics and molecular databases, metabolic engineering largely contributes to a better understanding of biosynthetic pathways [88].

As microbial hosts, *Escherichia coli* and *Saccharomyces cerevisiae* have often been employed in pathway engineering of functional isoprenoids [95, 98].

Another example is the expression of *Fragaria vesca* nerolidol synthase 1 in *Arabidopsis thaliana*. The transgenic plants produced high levels of linalool and expressed also *E*-8-hydroxy linalool, *Z*-8-hydroxy linalool, and *E*-8-hydroxy-6,7-dihydrolinalool [96].

A promising approach is the prospect to upregulate terpene synthesis in the tree *Copaifera langsdorfii* which could result in an increase in the diesel-like resin that might prove beneficial to the global market of biofuels [88, 99]. A further example is transgenic *Eucalyptus camaldulensis* that has been established by introducing two expression constructs containing *Perilla frutescens* limonene synthase cDNA, whose gene products were designed to be localized in either the plastid or cytosol. The transgenic plant yielded 2.6–4.5 times more limonene and increased also the 1,8-cineol and α-pinene production as compared to the wild type [100].

7 Conclusion: Prospects

The biodiversity of essential oils including the low molecular terpenoids remains a fascinating field of research, and the sustainable use of this bounty in a wide field of applications presents some challenges in future [101].

Screening, characterizing, and managing this enormous biodiversity will need a continuing development of highly sensitive, high-throughput analytical methods including new advanced techniques.

The identification and authentication of the starting plant materials containing the active terpenoids for plant production and/or product manufacturing is an essential aspect that is often not sufficiently observed in quality assurance. This can be assessed by traditional morphological and phytochemical methods as used in pharmacognosy, as well as by new emerging DNA-based molecular methods. To give an example of possible confusions, under the name “oregano,” there are in the world dozens of species belonging not only to the genus *Origanum* but also to other genera and plant families but having similar sensorial properties as oregano [68].

The optimization and promotion of the cultivation and breeding of special crops producing terpenoids is a field that will be well established in the future. This plant production should be in accordance with good agricultural practice (GAP) [102].

The further development of biotechnology with the genomic and metabolomic analyses and genetic engineering will advance a variety of fields involving bioactive terpenoids ranging from food and animal nutrition to plant protection.

Exploiting new sources containing bioactive terpenes includes developing new methods to produce hemi-synthetic terpenoid components from waste materials arising in agriculture or in the food processing industry.

The high volatility and limited stability represent drawbacks of the storage and applications of essential oils and complicate the in vitro tests as well [59]. To overcome this, new developments are targeted on delivery systems as (micro) encapsulation as a way to control the release of volatile compounds with various purposes including pharmaceuticals as well as consumer products [103].

Although many biological activities as antimicrobial or antioxidative and other effects have been intensively studied and well documented, further tests are needed to evaluate interactions between individual compounds of the multicomponent mixtures [59]. The methods of systems biology offer a new approach to study these complex relationships.

When used as food and feed additives or as food supplements, new quality criteria must be defined regarding the identity of the material used and characteristic marker substances or/and chemical or DNA-based fingerprints.

Much effort must be done in promoting the transferability of in vitro to in vivo results.

In conclusion, the trend of the last years in the use of herbal products has shown that quality aspects and confidence in safe and healthy products including pharmaceuticals, cosmetics, household products, as well as foodstuffs of plant and animal origin have become a major issue. So, actually a well-balanced risk–benefit assessment of bioactive essential oils is one of the great challenges, and policymakers must be convinced that research on natural products as the volatile terpenoids in essential oils is an important task to guarantee future human and animal welfare [101].

Abstract

The chemistry and pharmacology of iridoids, a special class of cyclopentanoid monoterpenes, are highlighted. Occurrence of some typical members of iridoids, secoiridoids, and their derivatives from different plant sources with their physical constants is listed in Table 97.1. Structural classification, synthesis, biosynthesis, and important pharmacological activities of iridoids and secoiridoids such as antiallergic, antiarthritis, antibacterial, anticancer, anticoagulant, antidiabetic, anti-inflammatory, anti-osteoporosis, immunomodulatory, insecticidal, melanogenesis inhibitory, nerve growth factor-potentiating, neuroprotective, and wound-healing activities are briefly discussed.

1 Introduction

Iridoids represent a special and interesting class of cyclopentan [*c*] pyran monoterpenoids. The name "iridoid" is a generic term derived from the names of compounds iridomyrmecin, iridolactone, and iridodial, which were isolated from the defense secretion of the species of *Iridomyrmex*, a genus of ants. They are usually of plant metabolites and provide biologically and chemotaxonomically a structural link between terpenes and alkaloids [1]. More than 3,000 iridoids in various subclasses have been reported in the literature. Their potential pharmacological properties have created special attention to natural products chemists, biologists, and pharmacologists for understanding of their physiological functions in plants and animals and importance in human health and better use as herbal drugs.

2 Occurrence

Iridoids and their [2, 3] seco-derivatives (secoiridoids) are found usually as glucosides in a number of plants in families Acanthaceae, Apocynaceae, Bignoniaceae, Caprifoliaceae, Gentianaceae, Labiatae, Lamiaceae, Loasaceae, Loganiaceae, Oleaceae, Plantaginaceae, Rubiaceae, Saxifragaceae, Scrophulariaceae, Valerianaceae, and Verbenaceae. Plants of genera *Viburnum* and *Sambucus* (Caprifoliaceae), *Penstemon* (Scrophulariaceae), and *Valeriana* and *Patrinia* (Valerianaceae) are the rich sources of valeriana-type iridoids, whereas plants of genera *Allamanda* and *Plumeria* (Apocynaceae) and *Morinda* and *Pentas* (Rubiaceae) are the important sources of plumeria-type iridoids. Secoiridoids are found mainly in the plants of genera *Gentiana* and *Swertia* (Gentianaceae); *Lonicera* (Caprifoliaceae); *Fraxinus*, *Jasminum*, *Ligustrum*, and *Syringa* (Oleaceae); and *Galium* and *Isertia* (Rubiaceae). The plants of genera *Premna* (Verbenaceae) and *Paederia* (Rubiaceae) are the important sources of bis-iridoids. The plants of several genera of Rubiaceae and Scrophulariaceae are the potential source of simple iridoids. They are found in the plants which have folk medicinal values for the treatment of various kinds of diseases in different countries. Chemotaxonomically, they are useful as biochemical markers for the study of phylogeny of the plants.

3 Structural Classification

Structurally, iridoids are known as cyclopentan [c] pyran with a hydroxyl or glucosyloxy group at C-1 position of the pyran ring (**1**). Iridoids with a hydroxyl or acyl group at C-1 position are known as iridoid aglucones (**1a**) and with a glucosyloxy group as iridoid glucosides (**1b**). Iridoids may be monomeric, dimeric, trimeric, etc. according to the number of basic aglycone units present in a molecule. Monomeric iridoids are subgrouped into four types according to the number of carbons in the basic skeleton of the aglycone part: eight-carbon basic skeleton (**1c**), nine-carbon basic skeleton (**1d**), ten-carbon basic skeleton (**1e**), and 14-carbon basic skeleton (**1f**). Iridoids in each subgroup differ from each other by the presence or absence of hydroxy, epoxy or alkoxy, halo substituents in both cyclopentane and pyran rings and alkyl or alkyl-derived substituents (e.g., $-CH_3$, $-CH_2OH$, $-CHO$, $-COOH$) in C-4 and/or C-8 position. A β-*cis*-fused (H-5/H-9β) ring juncture is the most common structural feature of these compounds.

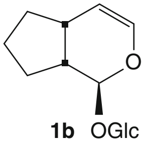
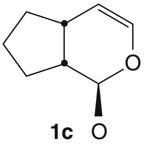
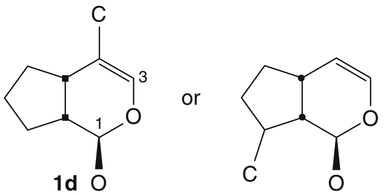
1a: R= H or acyl



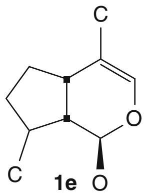
1b



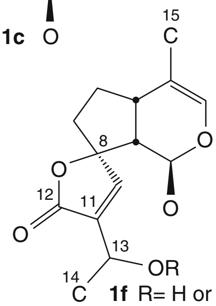
1c



1d



1e



1f R= H or acyl

Monomeric iridoids may be linked to each other through glucosyl hydroxyl group or phenolic or terpene hydroxyl group forming bis-, tris-, and tetrakis-iridoids. Sometimes monomeric iridoids are attached to alkaloid or terpene unit, producing iridoid alkaloid or iridoid terpenoid. Iridoids having isovaleroyl group at C-1 oxygen and glucosyl group at C-11 oxygen are known as valeriana-type iridoids (**1g**). Iridoids having five-membered spironolactone ring at C-8 position are called plumeria-type iridoids (**1f**), and if the spirolactone ring forms an ether linkage with C-1 oxygen, the iridoids are known as plumericin type (**1h**). If pyran ring of iridoids is converted into pyrone ring, iridoids are called iridolactone (**1i**).

(7,8)-Secoiridoids are represented by the structure **2**. Secoiridoids are subgrouped accordingly to the arrangement of C-7 and C-8 carbons. If C-7 carbon is esterified and C-8 carbon is connected to C-9 carbon by a double bond, secoiridoids are called oleosides (**2a**), and if C-8 carbon is connected to C-10 carbon by a double bond, these are called secologanin type (**2b**). If both C-7 and C-8 carbons are attached together by hemiacetal linkage, these are called morronisides (**2c**), and by a six-membered lactone ring, these are called kingisides (**2d**). When C-7 carbon is attached to C-11 carbon through a lactone ring, these are called sweroside type (**2e**), while if C-7 carbon is attached to C-1 by a lactone ring, these are called isoswerosides (**2f**). When both C-7 and C-8 carbons are attached together through a seven-membered lactone ring, these are called jasmolactone type (**2g**). Some iridoids are cleaved at C-3 position of pyran ring; these are called cerberidol type (**2h**). When cleaved at C-1 position, these are called crescentoside type (**2i**) or jiofuran type (**2j**). Some secoiridoids are cleaved in both cyclopentane and pyran rings (**2k**).

4 Isolation, Chemistry, and Structural Elucidation

Isolation of individual iridoids by traditional silica gel/alumina/charcoal/dianion/Sephadex column chromatography is tedious because of their close R_f values and polar nature. Application of HPLC techniques using octadecylsilanized (ODS)SiO_2/C_{18}Si gel column or HPLC coupled with a diode-array detector and a mass spectrometer (HPLC-DAD-MS) has achieved efficient separation

Scheme 97.2 Formation of furan iridoids

and isolation of pure iridoids [4–6]. Spots of individual components in thin layer chromatography (TLC) on glass plates were visualized by spraying the plates with methanolic-vanillin-HCl/H_2SO_4 or methanolic-anisaldehyde reagent followed by heating the plates at 100°C for 3–5 min.

Iridoids are very sensible to acids and are hydrolyzed in mild acidic conditions (Scheme 97.1) [7].

The presence of hydroxyl group at C-5 and C-6 positions results the formation of furan derivatives of iridoids in acidic solution (Scheme 97.2) [8].

Various spectroscopic techniques, namely, UV, IR, NMR, and MS, are frequently used for structure elucidation of iridoids. Especially NMR, spectroscopic techniques including 1D ^{1}H- and ^{13}C-NMR, 2D-HSQC, HMBC, NOESY/ROESY NMR, and 3D-3D-HSQC-TOCSY (heteronuclear single-quantum coherence-total correlation spectroscopy) NMR spectroscopy are very useful for structural elucidation of iridoids. The attachment of sugars or acyl moiety to the aglucone of the iridoid glucosides may be assigned by the study of cross peaks in ^{1}H-^{1}H NOESY or ^{1}H-^{1}H ROESY NMR spectrum [2, 3]. For determination of the absolute configuration of chiral acyl moiety, namely, 2-methyl butanoyl moiety, HPLC method may be used using chiral column (Daicel Chiral OD) [4, 9]. Sometimes X-ray crystallographic study is useful to assign the stereochemical structure of iridoids. For instance, the stereostructure of triohima A and jatamanin A was established by X-ray crystallographic study [10, 11]. Several review articles on the physical constants of iridoids are available in the literature [12–18]. However, the physical constants and plant source of some monomeric iridoids of different subgroups are listed in Table 97.1 to highlight their characteristic substitution and spectral patterns and natural occurrence in various genera of several plant families.

6 Synthesis

The diversity of biological activity exhibited by several iridoids has generated much interest for their synthesis. Due to difficulties of glycosidation of iridoid aglycones, only a few synthetic approaches in this area have been reported. Some of these synthetic routes for stereoselective synthesis of natural iridoids are discussed here briefly to make it inspiring among the synthetic chemists for their future plans.

Trost et al. reported an efficient method for synthesis of plumericin (**67**), allamcin (**68**), and antileukemic allamandin (**69**), applying a biomimetic strategy. The requisite key intermediates were synthesized using the concept of spiro-annulation and stereocontrolled geminal alkylation. Their strategy required 9, 13, and 14 steps from bicyclic ketone (**70**) for synthesis of allamcin, plumericin, and allamandin, respectively. The bicyclic ketone was synthesized from cycloocta-1,3-diene in three steps. The synthetic route is outlined in Scheme 97.3 [101].

MacMillan et al. reported total synthesis of iridoids, brasoside (**71**), and littoralisone (**72**), in 13 steps in 13% overall yield [102]. Both these iridoids were isolated earlier from *Verbena littoralis*, and littoralisone (**72**) was demonstrated to be the active agent for increased NGF-induced neurite outgrowth in PC12D cells [103]. They synthesized the iridolactone aglucone (**73**) using (–) citronellol (**74**) as starting material via the intermediate, formyl enal (**74a**). Proline-catalyzed intra-molecular Michael addition of the formyl enal was the key step of their synthesis (Scheme 97.4).

Recently, Vidari et al. synthesized 9-deoxygelsemide (**75**), which was isolated earlier from *Gelsemium elegans* by Takayama et al. [104, 105]. The key synthetic steps were the variant Woodward-Prevost reaction for installation of characteristic *cis*-α-1,2-dioxygenated system at C-6 and C-7, and construction of the dihydropyran ring via formylation of γ-lactone. The total synthesis of the iridoid was achieved in 11 steps and 6.6% overall yield from enantiomerically pure lactone (**76**) (Scheme 97.5).

Krische et al. reported an asymmetric synthesis of (+) geniposide (**77**) in 14 steps [106]. It may be noted that (+) geniposide showed significant antitumor [107] and anti-inflammatory activity [108]. Its aglycone, (+) genipin (**145**), was found to be effective for treatment of type II diabetes [109]. The key feature of this synthesis is the construction of *cis*-fused cyclopenta [c]-pyran ring of iridoid basic skeleton by a phosphine-catalyzed intermolecular [3 + 2] cycloaddition reaction of (*S*)-enone (**78**) and ethyl-2,3-butadienoate. One of the starting materials, (S)-enone (**78**), was synthesized from furfuryl alcohol in three steps. The steps of total synthesis of (+) geniposide are outlined (Scheme 97.6).

Lee et al. also reported a total synthesis of iridolactone, 7-hydroxy-8-(hydroxymethyl)-4-methylenehexahydrocyclopenta[c]-pyran-1-(3 H)-one (**79**) via intramolecular Pd(0)-catalyzed allylic alkylation [110]. This iridolactone was isolated from the roots and rhizomes of *Nardostachys chinensis* (Valerianaceae) [111]. The plant exhibited a variety of biological activities such as sedative, antimalarials, antinociceptive, cytotoxic, and enhancement of nerve growth factor activities [112].

Lupton et al. reported the total synthesis of (–) 7-deoxyloganin (**82**) in 18 steps from 2,5-dimethoxytetrahydrofuran in overall 0.8% yield. The key step of their synthetic strategy was the N-heterocyclic nucleophilic carbene-catalyzed rearrangement of α,β-unsaturated enol ester (**83**) to dihydropyranone (**84**) (Scheme 97.7) [114].

Hofferberth et al. reported diastereoselective synthesis of several ant-associated iridoids, namely, nepetalactol (**85**), dolichodial (**86**), dihydronepetalactone (**87**), and isoiridomyrmecin (**88**), from citronellal (**89**) using common laboratory reagents (Scheme 97.8) [115].

7 Biosynthesis

Several groups carried out tracer studies for the understanding of the biosynthesis of iridoid glycosides. Now we have reached to a point from which a fairly complete

picture can be drawn. Very early, Spurgeon and Porter suggested that isopentenyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP) are the universal building blocks for all terpenoids [116]. IPP and DMAPP are biosynthesized in two pathways – namely, the classical mevalonic acid (MVA) pathway and the novel

90

Scheme 97.9 MVA pathway for isoprenoid biosynthesis

2-methyl-D-erythritol 4-phosphate pathway. The MVA pathway was suggested to proceed from three molecules of acetyl CoA (**90**) in presence of nicotinamide-adenine-dinucleotide phosphate (NADPH) to form mevalonic acid as key intermediate, which in presence of adenosine triphosphate (ATP) was converted into isopentenyl pyrophosphate (IPP). IPP in presence of the appropriate enzyme was isomerized to β,β-dimethylallyl pyrophosphate (DMAPP) [117] (Scheme 97.9). The MEP pathway started from pyruvic acid (**91**) and D-glyceraldehyde 3-phosphate (**92**) via the formation of key intermediates 1-deoxy-D-xylulose 5-phosphate (DXP, **93**) and 2-methyl-D-erythritol 4-phosphate (MEP, **94**), which was converted into isopentenyl pyrophosphate (IPP) by a series of steps (Scheme 97.10) [118, 119]. Detailed tracer experiments have shown that these two pathways exist side by side in higher plants [120, 121].

In the investigation of the biosynthesis of secologanin in *Catharanthus roseus* cell culture using ^{13}C-labeled D-glucose as upstream precursor, Contin et al. established that the MEP pathway played a major role in its biosynthesis, whereas the MVA pathway was only involved in a minor way [122]. Eichinger et al. predicted a comparable result in their retro-biosynthetic ^{13}C-NMR study of loganin in *Rauwolfia serpentina* cells where they observed that the minor incorporation of mevalonate into loganin resulted from metabolic exchange between the two isoprenoid pathways [123].

Scheme 97.10 MEP pathway for isoprenoid biosynthesis

Further studies on the search of iridoid precursors by Inouye et al. and other groups it was univocally established that monoterpene geraniol was the true precursor. In the first committed step, geraniol derived from IPP is hydroxylated by geraniol-10-hydroxylase to 10-hydroxygeraniol followed by formation of iridodial and iridotrial intermediates in subsequent steps in biosynthesis of iridoids [124–127]. Oxidation of iridotrial followed by glucosylation gave deoxyloganic acid, which on hydroxylation and esterification produced loganin (**30a**). Loganin on oxidative cleavage by enzyme secologanin synthase yielded secologanin (**101**) in *C. roseus* cell culture [128].

Damtoft et al. studied the biosynthesis of iridoids of genus *Fraxinus* by incorporation of labeled [6,7,8,10–^{2}H]-iridodial, iridotrial, and deoxyloganic acid aglucone in *F. excelsior*. They observed that both iridodial and iridotrial gave a detectable incorporation (4.5%) into 7-ketologanin (**100**), and iridotrial in addition gave low incorporations (each 1%) into 7-glucosyl 11-methyl oleoside (**102**) and excelsioside (**103**). Feeding of labeled deoxyloganic acid aglucone gave only an incorporation of 2% into excelsioside (**103**) [129].

In another set of experiment, Damtoft et al. incorporated deuterium-labeled deoxyloganic acid, 7-*epi*-loganin, loganin, and 7-ketologanin in *F. excelsior* and observed that loganin was not incorporated whereas the other three compounds gave significant incorporations into the oleosides. They also administered deuterium-labeled deoxyloganic acid and 7-ketologanic acid into *F. excelsior* and found that both the compounds gave 7–8% incorporations into excelsioside but only 7-ketologanic acid gave significant incorporations into oleoside 11-methyl ester (**102a**) and ligstroside (**104**). On the basis of these results, they concluded that in *Fraxinus* oleosides were formed from iridodial and iridotrial via the formation of 7-*epi*-loganin and 7-ketologanin or their corresponding acids (**103**) [129].

Damtoft also studied the biosynthesis of oleosides in *Syringa* by administration of deuterium-labeled loganin, 7-*epi*-loganin, and 7-ketologanin in *S. josikaea* and found that except loganin, the other two compounds were both efficiently incorporated into oleosides. In another set of experiment, they administered deuterium-labeled deoxyloganic acid and 7-ketologanin into *S. vulgaris* and found that deoxyloganic acid gave incorporations into all iridoids except for secologanoside (**105**), whereas 7-ketologanin was mainly incorporated (>16%) into oleosides (e.g., oleoside 11-methyl ester). They repeated the experiment with deuterium-labeled deoxyloganic acid and 7-ketologanic acid and observed that both were incorporated into 8-*epi* kingisidic acid (**106**). Based on these results, they concluded that in *Syringa* oleosides were biosynthesized via deoxyloganic acid and 7-ketologanin. The deoxyloganic acid on hydroxylation gave 7-*epi*-loganic acid which on oxidation gave 7-ketologanic acid and on subsequent methylation gave 7-ketologanin. 7-Ketologanic acid or its Me ester could be the intermediate precursor of 8-*epi*-kingisidic acid and its Me ester [129].

Damtoft et al. carried out feeding experiments in *Forsythia viridissima* and *F. europaea* using deuterium-labeled deoxyloganic acid and found incorporation into forsythide (**36**). On the basis of the results, they concluded that deoxyloganic acid was oxidized at C-10 to adoxosidic acid followed by further oxidation at C-10 to forsythide in *Forsythia* spp. [71].

Damtoft et al. carried out feeding experiments with deuterium-labeled secologanin and oleoside 11-methyl ester in *Fraxinus excelsior* and observed that secologanin gave only a small incorporation (0.5%) into 7-glucosyl 11-methyl oleoside whereas oleoside 11-methyl ester gave incorporations into all iridoids except secologanoside (**105**) and 8-*epi*-kingiside. Based on this result, they concluded that oleoside 11-methyl ester was formed from 7 ketologanin as immediate precursor for all other secoiridoids in *Fraxinus* spp. They rationalized the formation of oleoside 11-methyl ester from 7-ketologanin via the formation of peroxide linkage at C-7 and its rupture due to cleavage of 7,8-bond and abstraction of H-9. The formation of 8-*epi*-kingiside may occur from the peroxide intermediate via the hydroxylation at C-8 followed by and cleavage of 7,8-bond and cyclization [130].

Based on these observations, it was believed that geraniol produced from IPP mostly by MEP pathway was the true precursor of iridoids. Geraniol via the formation of intermediates, iridodial, and iridotrial produced 7-deoxyloganic acid, 7-epiloganic acid, and 7-ketologanic acid or their methyl ester as intermediate precursors of other iridoids and secoiridoids in *Catharanthus*, *Fraxinus*, *Forsythia*, and *Syringa* species (Scheme 97.11). It was also established that although secologanin was not the effective precursor of other secoiridoids, it was the key intermediate for biosynthesis of indole alkaloids in *Catharanthus* species [131].

Recently, Li et al. also studied the biosynthesis of iridoid glucoside lamalbid (**106**) in *Lamium barbatum* using ^{13}C-labeled intermediates of MEP and MVA pathways, namely, [3,4,5-$^{13}C_3$] 1-deoxy D-xylulose 5-phosphate and [2-$^{13}C_1$] mevalonolactone (MVL), and observed that only the former was incorporated into lamalbid (Scheme 97.12) [132].

Biosynthetic studies on plumieride-type iridoids in *Allamanda* spp. by Schmid et al. and Inouye et al. demonstrated that these iridoids namely plumieride (**108**) and allamandin could be biosynthesized from 10-dehydrogardenoside (**107**) (Scheme 97.13) [125, 133, 134].

Therefore, on the basis of biosynthetic studies on iridoids by several groups, it may be inferred that both MVA and MEP routes are involved for the synthesis of acyclic monoterpene, geraniol, the key biosynthetic precursor of iridoids, but MEP route is the main route in most of the higher plants for synthesis of iridoid glucosides.

8 Pharmacology

Iridoids have been isolated from several folk medicinal plants which are used as bitter tonics, sedatives, antipyretic, cough medicine, remedies for arthritis, lumbago and muscular pains, wounds and skin disorders, etc. A good number of research papers on the bioactive iridoids isolated from several folk medicinal plants have been published in the last few decades. We have summarized here only some of the fundamental pharmacological activities of iridoids to create an interest on the importance of this class of natural products and for their wide applications in the formulations of several prospective herbal drugs.

8.1 Antiallergic Activity

Two secoiridoids, hydramacrosides A (**109**) and B (**110**), isolated from the leaves of *Hydrangea macrophylla var. thunbergii* (Saxifragaceae) showed inhibitory effect on the histamine release from rat mast cell induced by antigen-antibody reaction with inhibition of 9.1% and 21.3%, respectively, at a concentration of 10^{-5} M [135].

8.2 Antiarthritic Activity

The roots of Devil's claw, *Harpagophytum procumbens*, are widely used in European countries for supportive treatment of inflammatory and degenerative diseases such as osteoarthritis, low back pain, and rheumatic complaints [136].

Boje et al. isolated a few iridoids and other class of compounds and studied their activity against human neutrophile elastase, the enzyme responsible for damage of cartilage tissue and other matrix proteins causing arthritis and rheumatism. Only two iridoids, 8-p-coumaroylharpagide (**111**) and pagoside (**112**), significantly inhibited in vitro elastase activity with an IC$_{50}$ value of 179 μgml^{-1} (331 μM)

moderate level antibacterial activity against five bacterial strains, *Bacillus cereus*, *Citrobacter freundii*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus*, with MIC value in the range of 0.05–0.50 mgml^{-1} and also displayed activity against penicillin-resistant *E. coli* with an MIC value of 0.05 mgml^{-1} [138].

Non-glucosidic iridoid 1β-methoxymussaenin A (**116**) isolated from Chinese plant, *Cymbaria mongolica*, showed significant antibacterial activity against *Bacillus subtilis*, *Escherichia coli*, and *Staphylococcus aureus* with an inhibition zone of 14.5, 13.9, and

14.5 mm in diameter, respectively, at a concentration of 10 μg/disk in paper-disk-assay model. The standard antibiotic, chloramphenicol, at the same concentration showed inhibition zone of 14.5, 14.9, and 15.1 mm in diameter against the respective strain [139].

Ten iridoids were isolated by Yuan et al. from a Chinese plant, *Pedicularis kansuensis*, which has been used in folk medicine as cardiac tonic for treatment of collapse, exhaustion, and senility. Among the isolated iridoids, ixoroside (**26**), boschnaloside (**117**), 8-*epi*-loganic acid (**29**), and aucubin (**15**) at a concentration of 20 μg/disk exhibited strong antibacterial activity against *E. coli* and *S. aureus* by cup-plate method, having growth inhibition zone of 13–20 mm in diameter [140].

8.4 Anticancer Activity

Rehmaglutin D (**119**), 1β-hydroxy-4-epigardendiol (**120**), and 1β-methoxygardendiol (**121**) from *Cymbaria mongolica* acetone extract exhibited significant cytotoxic effect against human hepatoma (SMMC-7721), human uterine cervix carcinoma (HeLa), and mouse melanotic carcinoma (B16) cells in MTT assay model using vincristine as a positive control. The IC$_{50}$ values of compound

119 against SMMC-7721, HeLa, and B16 cells were 45.4, 60.7, and 71.2 μgml^{-1}, respectively, which were comparable to IC$_{50}$ of 63.2, 70.7, and 67.2 μgml^{-1}, respectively, of the control, vincristine [139].

Several iridoids have been isolated from the leaves of Bangladeshi evergreen shrub, *Prismatomeris tetrandra*, having folklore use in the treatment of stomachaches and fresh wounds. Among the isolated iridoids, prismatomerin (**122**) showed remarkable in vitro antitumor activity against four mammalian cancer L-929 (murine connective tissue), KB-3-1 (cervix carcinoma), A-549 (lung carcinoma), and SW-480 (colon adenocarcinoma) cells with IC$_{50}$ values of 0.21, 0.41, 1.41, and 0.06 μM, respectively, in sulforhodamine B (SRB) protein assay. This compound also showed killing effect of solid tumor A498 (renal), PC-3 (prostrate), and MCF-7 (breast) cells with LC$_{50}$ values in the range of 100–0.6 μM [142].

Aucubin (**15**) isolated from the leaves of *Aucuba japonica* exhibited cytotoxic effect against cancer A-549 cells by blocking the cell cycle progression in the G(0)/G(1) phase and inducing apoptosis. An enzyme-linked immunosorbent assay (ELISA) showed that the G(0)/G(1) phase arrest was possibly due to p53-mediated induction of p21[143].

Iridolactones – triohimas A (**61**), B (**123**) and C (**124**) – isolated from Chinese diuretic herb *Triosteum himalayanum* exhibited in vitro cytotoxicity against L1210 (mouse lymphocytic leukemia) cell by inhibiting proliferation about 13%, 11%, and 18%, respectively, in MTT assay at 50 μM concentration [10].

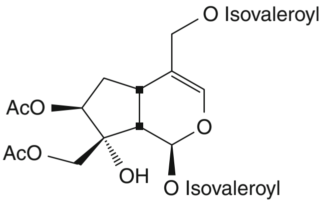
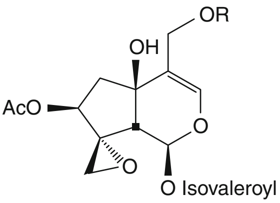
Picroliv, a mixture of iridoid glycosides, picroside 1 (**125**) and kutkoside (**126**) (1.0:1.5, w/w), isolated from the rhizomes of Indian plant, *Picrorhiza kurroa* (locally known as kutki), is a potential hepatoprotective and antitumor drug. Anand et al. studied the mechanism of therapeutic action of this herbal drug in

KBM-5, H1244, and A293 cancer cells at concentration range of 15–150 μgml^{-1} and found that it inhibited the nuclear factor–κB (NF-κB) activation pathway by modification of cysteine residue in p65 subunit in NF-κB and thus suppressed cell survival proteins and enhanced apoptosis. Their experimental results revealed that picroliv canceled tumor necrosis factor (TNF)-induced activation of NF-kB by mutation of Cys^{38} in p65 subunit and thereby inhibiting the binding of p65 to DNA. As a result, it led to suppression of NF-kB-regulated proteins including those linked with cell survival (inhibitor of apoptosis protein 1, Bel-2, Bcl-xL, survivin, TNF-receptor-associated factor 2), proliferation (cyclin D1 and Cox-2), angiogenesis (vascular endothelial factor), and invasion (IAP-1, MMP-9). Suppression of these proteins enhanced apoptosis of cancer cells [144].

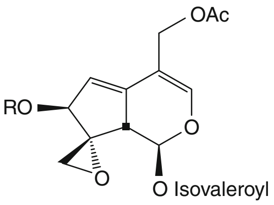
Valeriana jatamansi syn. *V. wallichii*, native to Mainland China and India, has been used for treatment of sleep problems, obesity, nervous disorders, epilepsy, snake poisoning, eye trouble, and skin diseases [145]. Lin et al. chemically investigated the plant and isolated 22 iridoids and examined their in vitro cytotoxicity against four cancer cells on MTT assay model using paclitaxel as positive control. Only five iridoids, namely, didrovaltrate acetoxy hydrin (**127**), IVHD-valtrate (**128**), 5-hydroxydidrovaltrate (**129**), valtrate (**130**), and acevaltrate (**131**), showed significant cytotoxicity against four tested A549, PC-3 M, HCT-8 (colon), and Bel 7402 (hepatoma) cancer cells with IC$_{50}$ values ranging from 1.0 to 7.4 μM. The most active compound was acevaltrate (**131**) which had IC$_{50}$ values of 2.9, 1.4, 1.0, and 1.7 μM against the A549, PC-3 M, HCT-8, and Bel 7402 cells, respectively [146].



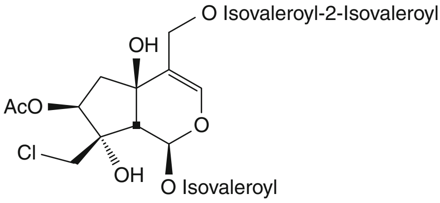
127



128 R = Isovaleroyl-2-O-Isovaleroyl
129 R = Isovaleroyl



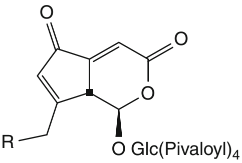
130 R = Isovaleroyl
131 R = Isovaleroyl-3-OAc



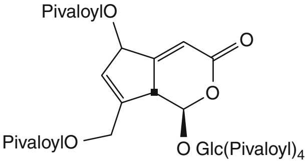
132

Volvaltrate B (**132**) isolated from both *Valeriana jatamansi* and *V. officinalis* also showed significant in vitro cytotoxic activity against A549, PC-3 M, HCT-8, and Bel 7402 cells with IC$_{50}$ values of 8.5, 2.0, 3.2, and 6.1 μM, respectively, in the MTT assay [147].

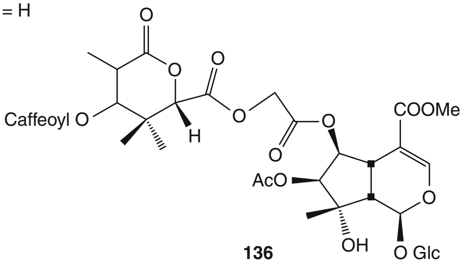
Rakotondramasy et al. and Mouries et al. prepared six unsaturated iridolactones from natural aucubin and studied their cytotoxicity against cancer L1210 and KB-3-1 cells. Among these lactones, three perpivaloyl glucosides (**133-135**) showed significant activity against L1210 cells with IC_{50} values of 3.0, 4.1, and 4.0 μM. The glucosides **135** and **136** also exhibited cytotoxicity against KB-3-1 cells of 0.56 and 0.42 μM, respectively, in MTT assay [148, 149].



133 R = OPivaloyl
134 R = H



135



136

Sanshiside D (**136**) isolated from the sepals of *Mussaenda dona-aurora* showed significant cytotoxicity against the growth of vero, HeLa, and SMMC-7721 cancer cells with IC_{50} values of 1.99, 0.12, and 1.53 μMml^{-1}, respectively. Sanshiside methyl ester (**137**) and lamalbid (**106**) showed weak cytotoxic effect against HeLa and SMMC-7721 cells with IC_{50} values of 6.29 and 16.21, 18.31 and 41.82 μMml^{-1}, respectively. Taxol used as positive control had IC_{50} of 2.05, 0.05, and 0.74 μMml^{-1}, respectively. Possibly the presence of caffeoyl and lactone moieties in sanshiside D could be accounted for its enhanced cytotoxicity [150].

Luzonoids A-D (**138-141**) and luzonoid glycosides (**142**, **143**) isolated from *Viburnum luzonicum* showed moderate cytotoxicity against HeLa S_3, (epithelial) cancer cell with IC_{50} values of 3–7 μM [151].

143 R = *Z*-p-Coumaroyl

Paederoside (**144**) isolated from *Paederia scandens* and genipin (**145**) and kutkoside (**126**) from *Picrorhiza kurroa* displayed significant antitumor-promoting activity by inhibiting 12-O-tetradecanoylphorbol-13-acetate (TPA)-induced Epstein-Barr virus early antigen (EBV-EA) induction in a nonproducer Raji cell line by a short-term in vitro assay at different molar concentrations [152].

The water extract of *Buddleja officinalis* (Buddlejaceae) inhibited vascular inflammation and atherosclerotic disorders. Recently, Tai et al. isolated several compounds from the flowers of the plant and tested their in vitro effects on the proliferation of rat aortic vascular smooth muscle cells (VSMCs). Among the tested compounds, two iridoids, namely, methylscutelloside (**146**) and methylcatalpol (**147**), showed significant inhibitory effects on homodimer platelet-derived growth factor beta polypeptide (PDGF-BB)-induced proliferation in rat aortic VSMCs. Methylscutelloside (**146**) decreased cell proliferation at 10, 30, and 50 μM, with inhibition of 39.1%, 42.0%, and 79.6%, respectively, while methylcatalpol showed significant inhibition (80%) only at 50 μM concentration. Their inhibitory effect on rat aortic VSMC proliferation may be useful for the treatment of atherosclerosis [153].

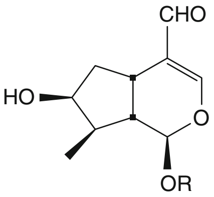
8.5 Anticoagulant Activity

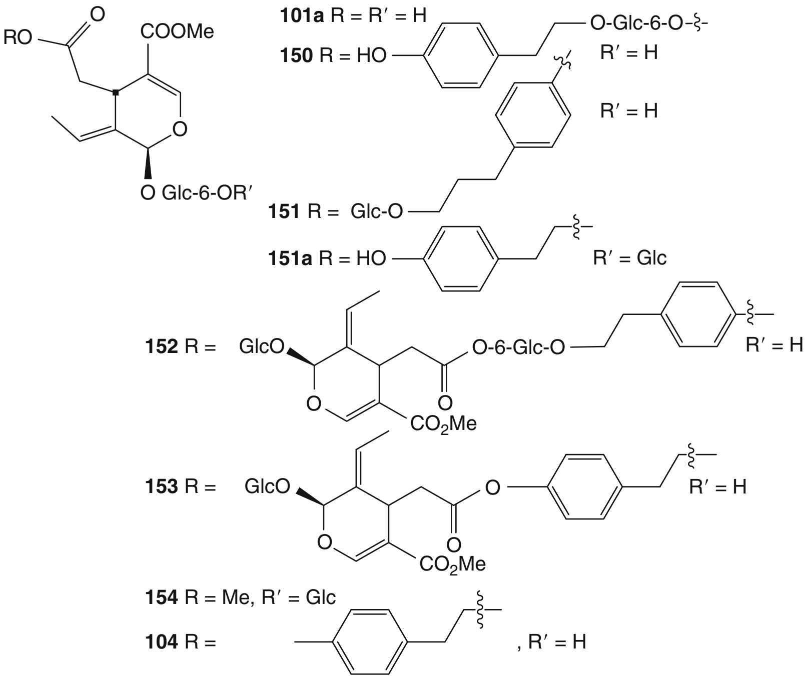
Non-glycosidic iridoids cachinol (**148**) and 1-O-methylcachinol (**149**) isolated from *Campsis grandiflora* (Bignoniaceae) leaves exhibited inhibitory activity on rat platelet aggregation with IC_{50} values of 43.2 and 38.4 μM, respectively, which were about 2-fold more inhibitory effect than that of acetylsalicylic acid (IC_{50}:75.2 μM) [154]. The leaves of the plant have been used as Chinese traditional drug for treatment of diseases caused by blood stagnation.



148 R = H
149 R = Me

8.6 Antidiabetic Activity

The aqueous seed extract of the ash tree, *Fraxinus excelsior* (FE) (Oleaceae), of temperate regions across Europe and Asia is recognized as an effective hypoglycemic and antidiabetic agent without significantly affecting insulin level [155]. Moreover, ash seed extract has hypoglycemic and antidiabetic effects in normal and streptozotocin-induced diabetic rats [156, 157]. To find out the potential active principle (s) of FE and evaluate their biological activity in adipocyte (3 T3-L1 cells) differentiation and peroxisome proliferator-activated receptor alpha (PPARα) activation, Bai et al. isolated a phenolic compound and nine secoiridoid glucosides and tested their activity. Their experimental results showed that eight iridoid glucosides, oleoside 11-methyl ester (**101a**), nuzhenide (**150**), $1'''$-O-β-O-glucosyl formoside (**151**), excelside B (**151a**), G13 (**152**), G15 (**153**), excelside A (**154**), and ligstroside (**104**), inhibited in vitro adipocyte differentiation in 3 T2-L1 cells as well as compounds excelside B, nuzhenide, G1-3, and GI-5 activated PPAR-α reporter cell system in the concentration of 10^{-4} M, which was comparable with the concentration 10^{-8} M of synthetic PPAR-α agonist, WY14.643. PPAR-α is the main target of fibrate drugs for treatment of hyperlipidemia and hyperglycemia. Possibly the inhibition of adipocyte differentiation and PPAR-α-mediated mechanism be the relevant pathways for antidiabetic activity of FE and its iridoids [158].

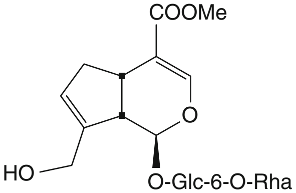


Later on, Ibarra et al. studied the health benefits of FE seed extract in obese mice that were fed a high-fat diet (HFD) over 16 weeks and observed the reduced gains in body weight by 32.3%, omental fat by 17.92%, and retroperitoneal fat by 17.78% as well as lowered fasting blood glucose level by 76.52% ($p < 0.001$) and plasma insulin level by 53.43% ($p < 0.005$) after 16 weeks. The positive effects on body weight and blood glucose level might be through the enhancement of fat metabolism through β-oxidation and inhibition of fat accumulation by the secoiridoids during the growth of the animals through PPAR-α activation in vivo. The HPLC analysis revealed that the major constituents of aqueous seed extract were nuzhenide and G13 [159].

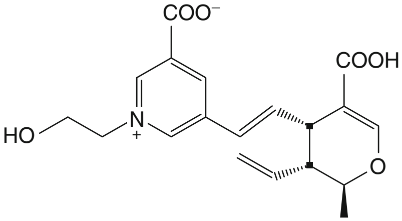
8.7 Anti-inflammatory Activity

Genipin diglycoside (**155**) isolated from the bark of *Adina polycephala* showed in vitro inhibitory rate of 44.8% against the release of β-glucuronidase in rat polymorphonuclear (PMN) leukocytes induced by platelet-activating factor (PAF) at a concentration of 10^{-5} M; the positive control ginkgolide B showed an inhibition rate of 78.8% at the same concentration [160].

Secoiridoid, lonijaposide C (**156**) isolated from *Lonicera japonica* also showed inhibitory activity against the release of glucuronidase in rat PMN leukocytes induced by PAF with an inhibition rate of 69.5% at 10 μM. Possibly the presence of pyridinium ion at C-7 position was responsible for this inhibitory activity [161]. These iridoids may be used as anti-inflammatory drugs.



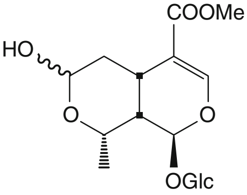
155



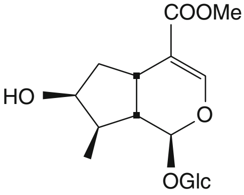
156

8.8 Anti-osteoporosis Activity

Chinese drug Liuweidihuang Wan (LW) containing the herb *Fructus corni* is used for clinical treatment of postmenopausal osteoporosis in women or elderly men. Li et al. carried out HPLC analysis of the MeOH extract of the drug LW and found morroniside (**51**) and loganin (**30a**) as major constituents. They isolated these iridoids from *Macrocarpium officinale* and evaluated their activity on clonal MC3T2-E1 cell line. This cell has the key role for bone formation and maintenance of bone mass. Its gradual loss results osteoporosis, a bone disease symptomized by reduction of bone mass, damage to the bone tissue microstructure, and consequence of the risk of bone fracture [162]. Both morroniside (**51**) and loganin (**30a**) at different concentrations (1, 10, 100 μgml^{-1}) had no effect on the proliferation of MC3T3-E1 cells, but improved the activity of alkaline phosphatase (ALP) and increased the contents of collagen type 1 and osteocalcin for the increase of the differentiation of osteoblasts. Simultaneously, the m-RNA expression of caspase 3, caspase 9, and RANKL (receptor activator of nuclear factor kappa–β ligand) was downregulated to inhibit apoptosis of osteoblasts, and that of bel-2 was upregulated to raise the survival rate of osteoblasts. All these sequences partly explained the anti-osteoporosis mechanism in MC3T3-E1 cells. Therefore, these two iridoids alone or in combination may be promising herbal drugs for treatment of osteoporosis [163].



51



30a

8.9 Antiprotozoal Activity

In some African countries, the leaves of *Morinda morindoides* have been used for treatment of malaria. Tamura et al. isolated a plumeria-type iridoid (**157**) from the leaves of this plant and evaluated its antimalarial efficacy. It showed potent antimalarial activity against *Plasmodium falciparum* with IC_{50} value of 0.1 μM. To improve the antimalarial efficacy, they prepared four analogues, and one (**158**) of them was found to be more active against *P. falciparum* with IC_{50} of 0.04 μM. Both the parent iridoid (**157**) and its congener (**158**) were little cytotoxic against human epidermoid carcinoma kB (KB-3-1) cells (9.3% and 6.1%, respectively) at a concentration of 150 μM. Possibly the presence of ketonic functionality at C-13 position enhanced the antimalarial potency in the congener [164].

Cimanga et al. isolated five iridoids from the leaves of *M. morindoides* and evaluated their antiamoebic efficacy against *Entamoeba histolytica*. All these iridoids, namely, epoxygaertneroside (**159**), methoxygaertneroside (**160**), gaertneroside (**161**), acetylgaertneroside (**162**), and gaertneric acid (**43**), possessed significant activity with IC_{50} values of 1.3, 2.3, 4.3, 5.4, and 7.1 μgml^{-1}, respectively. All these iridoids were not toxic against MT-4 cells at their highest test concentration of 250 μgml^{-1} [165].

8.10 Antiviral Activity

Viral infection is one of the major global health problems. Several millions of people are suffering from viral infections in every year. *Barleria prionitis* (Acanthaceae) is a traditional herbal drug in India and other Asian countries. A decoction of leaves and flowers of this plant is used to treat fever, while the green shoots are taken orally to treat whooping cough and asthma in infants and children [166, 167], as well as hot-water extract of the dried leaves and roots is also taken orally to treat bronchitis and coughs [168]. The most common cause of asthma-like symptom of infants is respiratory syncytial virus (RSV) infection in lungs [169]. Chen et al. isolated a few iridoids and other compounds and studied their activity against RSV. An inseparable *E*/*Z* mixture of 6-*O*-coumaroylbarlerin (**163** and **164**) in 3:1 M ratio exhibited anti-RSV (A2 strain) activity in a cell culture-based cytopathic effect (CPE) assay with EC_{50} of 2.46 μgml^{-1}. Under this assay condition, the mixture was moderately cytotoxic against Hep-2 cells (IC_{50}: 42 μgml^{-1}). *Barlerin* (**165**) was found to be inactive in the same assay. Therefore, the presence of coumaroyl unit at C-6 position was possibly responsible for this activity [170].

From another species of *Barleria*, *B. lupulina*, Suksamrarn et al. isolated nine iridoids from the flowers and tested their anti-HSV-1 activity. Only one iridoid ipolamiidoside (**166**) having C-5 hydroxy group was active with an IC_{50} of 41.1 μgml^{-1} [171].

8-O-acetylharpagide (**12a**), harpagoside (**13**), and scorodioside (**167**) isolated from *Scrophularia scorodonia* showed antiviral activity against vesicular stomatitis virus (VSV). The cell viability was 32.1% for 8-O-acetylharpagide at 500 μgml^{-1}, 43.3% for harpagoside at 450 μgml^{-1}, and 47.80% for scorodioside at 500 μgml^{-1}. Scorodioside also showed moderate in vitro anti-HSV-1 activity (30.6% cell viability at 500 μgml^{-1}) [172].

Chinese drug "Qing-Ye-Dan" containing aqueous extract of *Swertia mileensis* has been used to treat viral hepatitis with high alanine transaminase (ALT) and aspartate transaminase (AST) levels by the Yi and Hani minority groups of Mile and Kaiyuan countries. Geng et al. based on this fact carried out anti-HBV (hepatitis B virus) screening using both ethanol (50% and 90%) and aqueous extracts of the plant and found that ethanol extracts showed higher inhibitory activities against HBsAg secretion (IC_{50} of 0.61 and 0.33 $mgml^{-1}$) and HBeAg secretion (IC_{50} of 1.06 and 0.55 $mgml^{-1}$, respectively) than that of H_2O extract. From these ethanol extracts, they isolated two swerilactones A and B. Among these, swerilactone A (**168**) showed significant in vitro anti-HBV activity on HepG2.2.15 cell line by inhibition of HBsAg and HBeAg secretions with IC_{50} value of 3.66 and 3.58 mM, respectively. The antiviral agent 3TC (lamivudine) used as positive control showed inhibitory activity against HBsAg and HBeAg with IC_{50} values of 17.6 and 36.2 mM, respectively [173].

The aqueous extract of the flowering tops of Spanish plant *Lamium album* along with other herbs has been traditionally used for treatment of HCV (hepatitis C virus) infections [174]. Zhang et al. evaluated the anti-HCV activity of both aqueous and methanol extracts of the flowering tops of the plant and found their activity. Working on the methanol extract, they isolated iridoid glucoside lamalbid (**106**) as major constituent. Although this compound was inactive, its aglycone, inseparable epimers named lamiridosins A and B (**169**, **170**) present as major constituents in the aqueous extract showed significant in vitro inhibition in HCV assay with IC_{50} value of 2.31 μM and were found to be nontoxic to the HepG2, 2.2 cells at a concentration of 50 μgml^{-1}. The aqueous extract containing these iridoids showed ca. 50% inhibition at 100 μgml^{-1}. They also carried out anti-HCV screening on other 14 iridoids including free aglycone genipin (**145**) and found that only genipin showed significant inhibition at a concentration of 20 μgml^{-1}. Further study on anti-HCV screening of the enzymatic hydrolysis (with β-glucosidase) products of the tested iridoids revealed that only hydrolysis products of five iridoids, namely, shanzhiside methyl ester (**137**), loganin (**30a**), loganic acid (**30**), eurostoside (**170a**), and picroside-1 (**125**), showed significant inhibition activity after a 4-h enzyme incubation process. Possibly iridoid aglucones are the active pharmacophore for anti-HCV activity [175].

170a

8.11 Immunomodulatory Activity

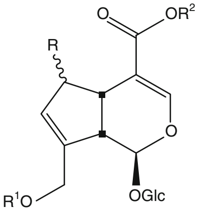
Aucubin (**15**) isolated from *Plantago major* showed immunomodulatory activity at a concentration less than 5 μM by stimulating human peripheral blood mononuclear cells (PBMC) and enhancing the secretion of interferon gamma (IFN-γ) in ELISA test [176].

8.12 Insecticidal Activity

Catalpol (**18**) isolated from *Buddleja cordobensis* showed a series of allelochemical effects related to DNA synthesis in the insect *Tribolium castaneum* by inhibition of tag DNA polymerase activity with an IC_{50} value of 47.8 μM. Thus, it exhibited post-ingestive toxic effects showing a reduction in the efficiency of conversion of injected food [177].

8.13 Melanogenesis Inhibitory Activity

Four iridoids, 9-*epi*-6α–methoxy geniposidic acid (**171**), asperulosidic acid (**172**), deacetyl asperulosidic acid (**173**), and scandoside methyl ester (**174**), isolated from noni fruits exhibited anti-melanogenesis activity in the B16 melanoma cells induced by α-melanocyte-stimulating hormone (α-MSH) with 40–50% reduction of melanin content at 100 μM. These were almost nontoxic to the cells at this tested concentration. Their inhibitory activity may be comparable to a known melanogenesis inhibitor, arbutin (with 29% reduction of melanin content at the same concentration), which has been recognized as a useful depigmentation agent for skin whitening in the cosmetic industry [178].



171 R = α-OMe, R^1 = H, R^2 = H

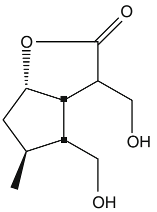
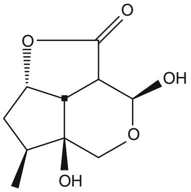
173 R = α-OH, R^1 = H, R^2 = H
174 R = β-OH, R^1 = H, R^2 = Me

8.14 Nerve Growth Factor-Potentiating Activity

Nerve growth factor (NGF) is one of the neurotrophic factors for neurodegenerative disorders. *Verbena littoralis* (Verbenaceae) was useful for treatment of dementia. To find out the bioactive chemicals, Li et al. isolated some iridoids from this plant and evaluated their NGF-enhancing activity in PC12D cells. Among the isolated iridoids, gelsemiol (**175**) and 7α-hydroxy semperoside aglucone (**176**) showed significant activity at the concentration of 100 μM, while littoralisone (**72**) exhibited moderate activity [179].



175

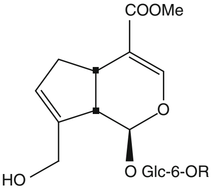


176

8.15 Neuroprotective Activity

Catalpol (**18**) showed neuroprotective efficacy in memory damage of mice induced by subcutaneous injection of D-galactose (150 mg/kg body weight) for 6 weeks and application of catalpol in the dose range of 2.5–10 mg/kg body weight for last 2 weeks [180]. It also exhibited neuroprotective effect on 1-methyl 4-phenyl pyridinium ion (MPP$^+$)-induced oxidative stress in cultured mesencephalic neurons, especially dopaminergic neurons in a dose-dependent manner [181]. Catalpol also protected the H_2O_2-injured astrocytes which have key role in neurodegenerative disorder in brain [182]. It was also effective for treatment of global cerebral ischemia in Mongolian gerbils at the dose range 1–10 mg/kg body weight [183]. Therefore, catalpol or its suitable congeners may be useful for the treatment of neurodegenerative disorder such as Alzheimer's disease and Parkinson's disease.

Geniposides, 6′-O-*trans*-p-Coumaroylgeniposide (**177**) and 6′-O-acetylgeniposide (**178**) isolated from the fruits of *Gardenia jasminoides* showed significant improvement of short-term memory capacity on an Ab42 transgenic drosophila model assay at a concentration of 7.6 μM [184].



177 R = *E*-p-Coumaroyl
178 R = Ac

Both 8-O–*E*-p-Methoxycinnmoyl harpagide (**179**) and 6′-O-*E*-p-methoxycinnamoyl harpagide (**180**) showed significant protective effect at a concentration of 1–10 μM against glutamate-induced neurodegeneration in primary cultures of rat cortical neurons. Their protective activity was comparable to that of MK-801, a noncompetitive antagonist of NMDA receptor [185].

8.16 Wound-Healing Activity

Scrophularia nodosa has been used in different parts of Ireland for the treatment of wounds [186]. Three catalpol derivatives, scopolioside A (**181**), scrophuloside A_4 (**182**), and scrovalentinoside (**183**), isolated from the dried seed pods of this plant were found to stimulate in vitro the growth of human dermal fibroblasts (HDF). Scopolioside A stimulated HDF growth over the full range (100–0.78 μgml^{-1}) of concentration tested, while the rest two compounds showed a negative dose-dependent response; the stimulation was highest at lower concentration (0.78 μgml^{-1}). It may be noted that HDF is involved in different phases of wound-healing, and hence these iridoids may be useful in formulation of wound-healing drugs [187].

9 Conclusion

The extensive isolation of iridoid glycosides from the plants of various families and exploration of their pharmacological potentials provide us new insights for utilization of these wild resources either the pure chemicals or their crude extracts for development of new natural drugs. Recent biosynthetic studies on iridoids also reveal us a new concept for synthesis of iridoid monoterpenoids via MEP pathway rather than well-known MVA pathway for terpenoid and steroid biosynthesis in higher plants. The traditional use of iridoid-rich plants as food, nutraceutical, cosmetic, and pharmaceutical industries is well justified, and their wide-scale use and cultivation may be popularized for maintenance of good health and as potential source of raw materials for pharmaceutical industries.

Acknowledgments The authors wish to express their appreciation to Sri Goutam Kulsi, Dr. Subhajit Dinda, and Manikana Dinda for their help in collecting the references.
