Preface

We are pleased to present a five volume treatise on “Natural products: phytochemistry, botany and metabolism”. Natural products are as diverse as plant biodiversity and it was a herculean task to bring together several hundred leading scientists distributed all over the world to contribute in this project.

This five volumes work on Natural Products is reference work providing state-of-the-art knowledge composed by highly renowned scientists in their field. The book is intended to serve the needs of graduate students, Ph.D. scholars, researchers in the field of phytochemistry, botany, agricultural sciences, pharmacy, nutrition, biotechnology and, industrial scientists and those involved in marketing phytochemicals, plants and their extracts. The present reference work will encompass the information about well established phytochemicals, biology and biotechnology of medicinal plants or their products, their biosynthesis, novel production strategies, demand and uses, metabolism and bioavailability. This book is a work of tertiary literature containing digested knowledge in an easily accessible format.

Use of medicinal plants is as old as human civilization and continuous efforts are being made to explore new and old medicinal plants for novel bioactive molecules or to produce these products in high amounts through modern technologies. About 200,000 natural products of plant origin are known and many more are being identified from higher plants and micro-organisms. Some plants based drugs are used since centuries and there are not many alternatives for some natural drugs as cardiac glycosides or morphine. Various facets of bioactive molecules have developed very rapidly in the last two decades particularly due to newer tools of isolation and identification as well as refined molecular techniques to establish the biological properties of isolated molecules. This endeavour is to timely compile this vast data generated in recent past. This is well reflected in 139 chapters running in over 4000 pages of text and vast literature cited in each chapter. The readers will find comprehensive information on almost all bioactive molecules. While planning this book our endeavour was to incorporate articles that cover the entire gamut of bioactive molecules of all the three major classes, viz., alkaloids, phenolics and terpenes. Each volume is further divided into sections such as General Biology and Biotechnology; Classes - Occurrence, Biosynthesis, Structure and Chemistry, Distribution; Methods of Analysis; (para) Pharmacology and Bioavailability; and Nutraceuticals and Functional Foods (in phenolics).

Some examples are sufficient to illustrate the spectrum of chapters in different sections such as: on alkaloids (Biotechnology and genetic engineering for alkaloid production, various classes of alkaloids e.g., Purine alkaloids, Ergot alkaloids, Terpenoid indole alkaloids, Pharmacological effects of ephedrine, Lycopodium alkaloids, Biological activities of pepper alkaloids, Neurotoxic alkaloids from cyanobacteria, Prevention of brain disorders by nicotine, Opioids and pain treatment, Ecological roles of alkaloids); on phenolics (Genetics of flavonoids, Functional foods: Genetics, metabolome and engineering, phytonutrient levels, Cocoa cultivation, directed breeding and polyphenolics, classes of phenolics, Polyphenols and anticancer activity, Tannins and anthocyanins of wine: phytochemistry and organoleptic properties, Polyphenols and beer quality, Wine polyphenols and vascular protective effects, Isoflavonoids and phytoestrogenic activity, Functional grapes, Potential neuroprotective actions of dietary flavonoids, Prospects of functional foods / nutraceuticals and markets), and on terpenes (Terpenes: Chemistry, biological role and therapeutic applications, Biotransformation of terpenoids and steroids, Production and genetic engineering of terpenoids production in plant cell cultures and organ cultures, Taxol-producing fungi, Metabolic engineering of isoprenoids biosynthesis, classes of terpenes, Cannabinoids: Chemistry and Medicine, Phytosterols: Beneficial effects, Ginsenosides: Biological activities, Ginkgolides and neuroprotective effects, Quassinoids: Anti-cancer and antimalarial activities, Phytoecdysteroids: phytochemistry and pharmacological activity, Brassinosteroids and their biological activity, and so on).

These compounds exhibit various ecological functions, provide protection against attack by herbivores and microbes, and serve as attractants for pollinators and seed-dispersing agents. Natural products are explored as sources of drugs, flavouring agents, fragrances and for a wide range of therapies. Rapid progress has been made in recent years in understanding natural product accumulation and synthesis, and regulation and functions. It is timely to bring this information together with contemporary advances in chemistry, plant biology, ecology, and pharmacology and metabolism of natural products in the form of a comprehensive treatise on natural products.

Because of the voluminous work for the treatise, this project was spread over almost two years, from concept to print. We would like to acknowledge cooperation, patient and support of our contributors who have put their serious efforts to ensure the high scientific quality of this book with up to date information.

This work could not be completed without active support of Springer team who took pains in streamlining the production process. We are particularly indebt to Drs. Marion Hertel, Lydia Muller, Sylvia Blago and Simone Giesler for their continuous support from very inception of the project.

March 2013 K. G. Ramawat
J.-M. Mérillon

About the Editors

Professor (Dr.) K. G. Ramawat, Former Professor & Head Botany Department, M.L. Sukhadia University, Udaipur, India

Professor K. G. Ramawat did his Ph.D. (1978, Plant Biotechnology) from the University of Jodhpur, India and joined as faculty member in January 1979. He joined M.L.Sukhadia University as Associate Professor in 1991 and became Professor in 2001. He served as Head, Department of Botany (2001-2004, 2010-2012), In charge, Department of Biotechnology (2003-2004), member task force on medicinal and aromatic plants, Department of Biotechnology, Government of India, New Delhi (2002-2005) and co-ordinator UGC-DRS and DST-FIST programmes (2002-2012). He did his Post-doctoral at the University of Tours, France (1983-85) and subsequently worked as visiting professor at University of Tours (1991) and University of Bordeaux2, France (1995, 1999, 2003, 2006, 2010). He visited Poland under INSA-PAN academic exchange programme (2005). During last 38 years of his career, he has published more than 170 peer reviewed papers and articles. He has edited books on Biotechnology of medicinal plants, secondary metabolites, Bioactive molecules, Herbal drugs, Plant defence: biological control, Desert plants; published by Science Publishers Inc, Enfield, USA and Springer Verlag, Germany. His research on recalcitrant woody legume trees of desert (*Prosopis, Zizyphus, Commiphora*), production of useful metabolites from woody plants (*Comiphora, Pueraria*) was funded by UGC, CSIR, ICAR, DBT and DST, New Delhi. Works related to use of novel growth modulators and elicitors on the production of guggulsterones, stibenes and isoflvonoids are well cited. He has supervised doctoral thesis of 25 students. He is member of several academic bodies, associations and editorial boards of journals.

Professeur Jean-Michel Mérillon, Directeur de l'EA 3675 (Groupe d'Etude des Substances Végétales à Activité Biologique + Polyphénols Biotech), Faculté de Pharmacie, Université de Bordeaux, Institut des Sciences de la Vigne et du Vin, Villenave d'Ornon, France

Professor J.M. Mérillon received his M.Pharma. (1979) and Ph.D. (1984) from the University of Tours in France. He joined the University of Tours as assistant professor in 1981, became associate professor in 1987, and a full professor in 1993 at the faculty of Pharmacy, University of Bordeaux, France. He is currently group leader of a “study group on biologically active plant substances” at the Institute of Vine and Wine Sciences, which comprises 25 scientists and research students. His group has worked for many years on phenolic compounds from vine and wine, mainly complex stilbenes and their involvement in health. He has supervised the doctoral theses of 18 students. He has published more than 125 research papers in internationally recognized journals. He has an H index of 29 according to the analysis of documents published between 1996 and 2013. He has co-edited four books on secondary metabolites and biotechnology (Science Publishers, USA; Springer, Germany). He is involved in developing teaching on plant biology, natural bioactive compounds and biotechnology. He has traveled widely as a senior professor. Scientists from several countries are working in his laboratory and his research is supported by funding from the Aquitaine Regional Government, the Ministry of Higher Education and Research, and various private companies. He founded a technology transfer unit in 2004, Polyphenols Biotech, providing support for R&D programs for SMEs and major groups from the cosmetic, pharmaceutical, agricultural and health-nutrition sectors.

Contents

Volume 1

Part I Alkaloids: General Biology and Biotechnology 1

1 **Microbial Production of Plant Benzylisoquinoline Alkaloids** . . . 3
Eitaro Matsumura, Motoki Matsuda, Fumihiko Sato, and Hiromichi Minami

2 **Alkaloids of Marine Macroalgae** 25
Kasım Cemal Güven, Burak Coban, Ekrem Sezik, Hüseyin Erdugan, and Ferda Kaleağasıoğlu

3 **Neurotoxic Alkaloids from Cyanobacteria** 39
Ralf Kellmann, Olivier Ploux, and Brett A. Neilan

4 **Bioproduction of Terpenoid Indole Alkaloids from *Catharanthus roseus* Cell Cultures** 85
Lorena Almagro, Mariana Sottomayor, and Maria Angeles Pedreño

5 **Bioactive Alkaloids from South American *Psychotria* and Related Rubiaceae** 119
Hélio Nitta Matsuura, Diogo Denardi Porto, and Arthur Germano Fett-Neto

6 **Ecological Role of Alkaloids** 149
Shaily Goyal

7 **Plant In Vitro Systems as Sources of Tropane Alkaloids** 173
Vasil Georgiev, Andrey Marchev, Strahil Berkov, and Atanas Pavlov

8 **Biotechnology and Genetic Engineering for Alkaloid Production** 213
Smita Srivastava and Ashok Kumar Srivastava

9 **Marine Pyrroloiminoquinone Alkaloids, Makaluvamines and Discorhabdins, and Marine Pyrrole-Imidazole Alkaloids** 251
Hiromichi Fujioka and Yasuyuki Kita

10 Internet Natural Product Trade, Business, and Risk of Damaged and/or Contaminated Products 285
Maria Laura Colombo, Maria Teresa Pinorini, and Ario Conti

Part II Alkaloids: Classes - Occurrence, Biosynthesis, Structure and Chemistry, Distribution **301**

11 Alkaloids Derived from Lysine: Piperidine Alkaloids 303
Éva Szőke, Éva Lemberkovics, and László Kursinszki

12 Alkaloids Derived from Ornithine: Tropane Alkaloids 343
Stefan Philipov and Tsvetelina Doncheva

13 Alkaloids Derived From Ornithine: Pyrrolizidine Alkaloids 359
Helmut Wiedenfeld

14 Alkaloids Derived from Lysine: Quinolizidine (a Focus on Lupin Alkaloids) 381
Giovanna Boschin and Donatella Resta

15 Alkaloids Derived from Tyrosine: Modified Benzyltetrahydroisoquinoline Alkaloids 405
Feroz Khan, Tabish Qidwai, Rakesh K. Shukla, and Vikrant Gupta

16 Alkaloids Derived from Tyrosine: Penethylisoquinoline (Autumnaline, Colchicine) 461
Pijush Paul, Mihir Halder, and Sumita Jha

17 Amaryllidaceae Alkaloids 479
Zhong Jin and Xiao-Hua Xu

18 Bioactive Alkaloids from Fungi: Psilocybin 523
Zafar Alam Mahmood

19 Alkaloids Derived from Tryptophan: Harmine and Related Alkaloids 553
T. D. Nikam, K. M. Nitnaware, and M. L. Ahire

20 Alkaloids Derived from Tryptophan: Terpenoid Indole Alkaloids 575
Shilpa Ramani, Nandadevi Patil, Suhas Nimbalkar, and Chelliah Jayabaskaran

21 Chemistry and Biology of Cinchona Alkaloids 605
Karol Michał Kacprzak

22 Chemistry and Biology of Camptothecin and its Derivatives 643
Karol Michał Kacprzak

23 Alkaloids Derived from Tryptophan: A Focus on Ergot Alkaloids 683
Peter Mai and Shu-Ming Li

24 Alkaloids Derived from Anthranilic Acid: Quinoline, Acridone, and Quinazoline 715
Maria Fátima das Graças Fernandes da Silva, João Batista Fernandes, Moacir Rossi Forim, Paulo Cezar Vieira, and Israel Cívico Gil de Sá

25 Alkaloids Derived from Histidine: Imidazole (Pilocarpine, Pilosine) 861
Ana Paula Santos and Paulo Roberto H. Moreno

26 Alkaloids Derived by Amination Reaction: Acetate-Derived (Coniine) 883
Rumen Binev

27 Ephedra Alkaloids-Alkaloids Derived by Amination Reaction: Phenylalanine Derived 909
Ali Parsaeimehr and Elmira Sargsyan

28 Terpenoid Alkaloids Derived by Amination Reaction 923
Krishna Prasad Devkota and Norbert Sewald

29 Purine Alkaloids, Cytokinins, and Purine-Like Neurotoxin Alkaloids 953
Hiroshi Ashihara, Takao Yokota, and Alan Crozier

30 Aziridine Alkaloids: Origin, Chemistry and Activity 977
Valery M. Dembitsky, Alexander O. Terent’ev, and Dmitri O. Levitsky

Volume 2

Part III Alkaloids: Methods of Analysis 1007

31 Methods of Analysis: Tropane Alkaloids from Plant Origin 1009
Philippe Christen, Stefan Bieri, and Strahil Berkov

32 Methods for Analysis of Pyrrolizidine Alkaloids 1049
Colin Crews

33 Methods of Analysis of Opium Alkaloids 1069
Carmen Cruces-Blanco, Diego Airado-Rodríguez, and Ana M. García-Campaña

34 **Analysis of Catharanthus Alkaloids** 1121
Qinhua Chen and Zilin Chen

35 **Methods for Analysis of Ergot Alkaloids** 1133
Colin Crews

36 **Analysis of Alkaloids by Capillary Electrophoresis** 1153
Roberto Gotti

Part IV Alkaloids: Pharmacology 1201

37 **Pharmacology of Macroalgae Alkaloids** 1203
Ferda Kaleağasıoğlu, Kasım Cemal Güven, Ekrem Sezik, Hüseyin Erdugan, and Burak Coban

38 **Pharmacological Effects of Ephedrine** 1217
Renata Pereira Limberger, Ana Laura Bemvenuti Jacques, Gabriela Cristina Schmitt, and Marcelo Dutra Arbo

39 **Lycopodium Alkaloids: Pharmacology** 1239
Elín Soffía Olafsdóttir, Elsa S. Halldorsdottir, N. M. Pich, and S. Omarsdottir

40 **Scope of Alkaloids in Antileishmanial Drug Discovery and Development** 1263
Bhuwan B. Mishra, Navneet Kishore, Rakesh K. Singh, and Vinod Kumar Tiwari

41 **Pharmacological/Biological Effects of Berberine** 1301
Eva M. Galvez, M. Perez, P. Domingo, D. Nuñez, V. L. Cebolla, M. Matt, and J. Pardo

42 **Alkaloids and Drug Discovery for Neurodegenerative Diseases** 1331
Melanie-Jayne R. Howes

43 **Opioids and Pain Treatment** 1367
Daniel Krashin, Andrea Trescot, and Natalia Murinova

44 **Pyrrolizidine Alkaloid-Induced Toxicity to the Liver** 1383
Manuela G. Neuman

45 **Biological Activities of Pepper Alkaloids** 1397
Krishnapura Srinivasan

46 **Antiangiogenic Alkaloids from Plants** 1439
Flávia Cristine Mascia Lopes, Luis Octávio Regasini, Manuel Nuno de Magalhães Pinheiro Alçada, and Raquel Soares

47 **Prevention of Brain Disorders by Nicotine** 1469
Karim Alkadhi, Samina Salim, and Karem Alzoubi

48 Aconitum Alkaloids and Biological Activities 1503
Ainura Chodoeva, Jean-Jacques Bosc, and Jacques Robert

49 Alkaloids and Inhibitory Effects Against Enzymes Linked to Neurodegenerative Diseases (Physostigmine, Galanthamine, Huperzine, etc.) 1525
Ilkay Erdogan Orhan and F. Sezer Senol

Part V Phenolics: General Biology and Biotechnology **1541**

50 Phenolic Compounds: Introduction 1543
Vincenzo Lattanzio

51 Metabolic Engineering for Functional Foods: Tomato Fruits and Stilbenes 1581
Giovanna Giovinazzo, Ilaria Ingrosso, Marco Taurino, and Angelo Santino

52 Cocoa Cultivation, Directed Breeding and Polyphenolics 1599
Reinhard Lieberei, Daniel Kadow, and David Seigler

53 Genetics of Flavonoids 1617
Ramesh Prasad Pandey and Jae Kyung Sohng

54 Isoflavonoid Production by Genetically Engineered Microorganisms 1647
Brady F. Cress, Robert J. Linhardt, and Mattheos A. G. Koffas

55 Bioproduction of *trans*-Resveratrol from Grapevine Cell Cultures 1683
Lorena Almagro, Sarai Belchí-Navarro, Ana Belén Sabater-Jara, Juan Carlos Vera-Urbina, Susana Sellés-Marchart, Roque Bru, and María Angeles Pedreño

56 Functional Foods: Genetics, Metabolome, and Engineering Phytonutrient Levels 1715
Tahira Fatima, Avtar K. Handa, and Autar K. Mattoo

Volume 3

Part VI Phenolics: Classes - Occurrence, Biosynthesis, Structure and Chemistry, Distribution **1751**

57 Flavanols: Catechins and Proanthocyanidins 1753
Joana Oliveira, Nuno Mateus, and Victor de Freitas

58 Anthocyanins 1803
Sonia de Pascual-Teresa, Maria Teresa Sanchez-Ballesta, and Cristina García-Viguera

59 Flavones and Flavonols: Phytochemistry and Biochemistry 1821
Qiang Zhang, Xinhuai Zhao, and Hongbin Qiu

60 Isoflavonoids 1849
Varsha Sharma and Kishan G. Ramawat

61 Minor Flavonoids (Chalcones, Flavanones, Dihydrochalcones, and Aurones) 1867
Masayuki Ninomiya and Mamoru Koketsu

62 Stilbenoids 1901
Tao Shen, Chun-Feng Xie, Xiao-Ning Wang, and Hong-Xiang Lou

63 Phenolic Acids 1951
Marta Goleniowski, Mercedes Bonfill, Rosa Cusido, and Javier Palazón

64 Hydrolyzable Tannins: Gallotannins and Ellagitannins 1975
Michaël Jourdes, Laurent Pouységu, Denis Deffieux, Pierre-Louis Teissedre, and Stéphane Quideau

Part VII Phenolics: Methods of Analysis **2011**

65 Preparative Extraction and Separation of Phenolic Compounds 2013
Winny Routray and Valérie Orsat

66 Mass Spectrometric Detection of Phenolic Acids 2047
Santi M. Mandal and Dipjyoti Chakraborty

67 Analytical Methods of Phenolic Compounds 2061
Ioana Ignat, Irina Volf, and Valentin I. Popa

68 Phenolic Compounds in *Catharanthus roseus* 2093
David M. Pereira, Patrícia Valentão, Mariana Sottomayor, Federico Ferreres, and Paula B. Andrade

69 Flavonoids by HPLC 2107
S. W. Annie Bligh, Olumuyiwa Ogegbo, and Zheng-Tao Wang

70 Polyphenol Purification by Solid Support-Free Liquid–Liquid Chromatography (CCC, CPC) 2145
Jane Hubert, Karen Plé, Mahmoud Hamzaoui, and Jean-Hugues Renault

Part VIII Phenolics: Biological Activity and Bioavailability **2173**

71 Cellular, Molecular, and Biological Perspective of Polyphenols in Chemoprevention and Therapeutic Adjunct in Cancer 2175
Sanjeev Banerjee and Paulraj Rajamani

72 **Tannins and Anthocyanins of Wine: Phytochemistry and Organoleptic Properties** 2255
Pierre-Louis Teissedre and Michael Jourdes

73 **Grapevine Stilbenoids: Bioavailability and Neuroprotection** 2275
Pierre Waffo-Téguo, Stéphanie Krisa, Alison D. Pawlus, Tristan Richard, Jean-Pierre Monti, and Jean-Michel Mérillon

74 **Proanthocyanidins of Cocoa: Bioavailability and Biological Activities** 2311
Manuel Rusconi, Maria Teresa Pinorini, and Ario Conti

75 **Polyphenols and Beer Quality** 2333
Sonia Collin, Vesna Jerkovic, M. Bröhan, and D. Callemien

76 **Wine Polyphenols and Vascular Protective Effects** 2361
Cyril Auger and Valérie B. Schini-Kerth

77 **Isoflavonoids and Phytoestrogenic Activity** 2381
Catherine Bennetau-Pelissero

78 **Phenolics in Human Nutrition: Importance of the Intestinal Microbiome for Isoflavone and Lignan Bioavailability** 2433
Thomas Clavel and Job O. Mapesa

79 **Bioavailability of Anthocyanins** 2465
Ana Faria, Iva Fernandes, Nuno Mateus, and Conceição Calhau

Volume 4

Part IX Phenolics: Nutraceuticals and Functional Foods 2489

80 **Prospects of Functional Foods/Nutraceuticals and Markets** 2491
Josep Valls, Nacho Pasamontes, Albert Pantaleón, Susana Vinaixa, Montse Vaqué, Arantza Soler, Silvia Millán, and Xavier Gómez

81 **Food Sources of Phenolics Compounds** 2527
Wende Li and Trust Beta

82 **Nutraceuticals and Antioxidants in Prevention of Diseases** 2559
Neelam Jain and Kishan G. Ramawat

83 **Functional Grapes** 2581
Maria Isabel Fernández-Marín, Raúl F. Guerrero, Belén Puertas, María Carmen García-Parrilla, and Emma Cantos-Villar

84 Potential Neuroprotective Actions of Dietary Flavonoids 2617
David Vauzour, Marcus Rattray, Robert J. Williams, and Jeremy P. E. Spencer

85 Improvement of Nutraceutical Value of Food by Plant Symbionts 2641
Manuela Giovannetti, Luciano Avio, and Cristiana Sbrana

Part X Terpenes: General Biology and Biotechnology **2663**

86 Terpenes: Chemistry, Biological Role, and Therapeutic Applications 2665
Priyanka P. Brahmkshatriya and Pathik S. Brahmkshatriya

87 Biosynthesis of Terpenoids 2693
Nelson L. Brock and Jeroen S. Dickschat

88 Biotransformation of Terpenoids and Steroids 2733
Wang-Yu Tong

89 Production and Genetic Engineering of Terpenoids Production in Plant Cell and Organ Cultures 2761
Mercedes Bonfill, Sonia Malik, M. Hossein Mirjalili, Marta Goleniowski, Rosa Cusido, and Javier Palazón

90 Taxol Producing Fungi 2797
Xiaoran Hao, Jiao Pan, and Xudong Zhu

91 Metabolic Engineering of Isoprenoid Biosynthesis 2813
Anne Pribat, Lisa Boureau, Anne Mortain-Bertrand, Linda S. Bert, Dominique Rolin, Emeline Teyssier, and Philippe Gallusci

92 Selection of Tomato Rich in Nutritional Terpenes 2853
Jaime Cebolla-Cornejo, Salvador Roselló, and Fernando Nuez

93 Volatile Oils from Marine Macroalgae 2883
Kasım Cemal Güven, Ekrem Sezik, Ferda Kaleağasıoğlu, Hüseyin Erdugan, Burak Coban, and Elif Karakaş

94 Ecological Functions of Terpenoids in Changing Climates 2913
Jarmo K. Holopainen, Sari J. Himanen, J. S. Yuan, F. Chen, and C. Neal Stewart Jr.

95 Hairy Root Culture: An Alternative Terpenoid Expression Platform 2941
Jocelyne Trémouillaux-Guiller

Part XI Terpenes: Classes - Occurrence, Biosynthesis, Structure and Chemistry, Distribution 2971

96 Regular Monoterpenes and Sesquiterpenes (Essential Oils) 2973
Remigius Chizzola

97 Monoterpenes: Iridoids 3009
Biswanath Dinda and Sudhan Debnath

98 Guaianolide Sesquiterpenoids: Pharmacology and Biosynthesis 3069
Henrik Toft Simonsen, Corinna Weitzel, and Søren Brøgger Christensen

99 Biosynthesis and Production of Artemisinin: A Novel Class of Molecule 3099
Athar Ali, Mather Ali Khan, and Mailk Zainul Abdin

100 Nivalenol (Fungal Sesquiterpenes) 3123
Yoshiko Sugita-Konishi and Makoto Kimura

101 Taxol and Related Compounds 3159
Hojjat Sadeghi-aliabadi and Afsaneh Yegdaneh

102 Diterpenes for Therapeutic Use 3173
Virginia Lanzotti

103 Diterpene Sweeteners (Steviosides) 3193
Akula Ramakrishna and Gokare Aswathanarayana Ravishankar

104 Triterpenoid Saponins: A Focus on Polygalaceae 3205
Marie-Aleth Lacaille-Dubois, Clément Delaude, and Anne-Claire Mitaine-Offer

105 Plant Steroidal Saponins: A Focus on Open-Chain Glycosides 3225
Victoria L. Challinor and James J. De Voss

106 Tetraterpenes: Carotenoids 3251
Shinichi Takaichi

Volume 5

Part XII Terpenes: Methods of Analysis 3285

107 Essential Oils: Analytical Methods to Control the Quality of Perfumes 3287
Alberto Chisvert, Marina López-Nogueroles, and Amparo Salvador

108 **Methods for Analysis of Triterpenoid Saponins** 3311
Jinlan Zhang and Feng Qu

109 **Methods of Isolation and Analysis of Forskolin from *Coleus forskohlii*** 3325
Mohamed Saleem A.

110 **Quassinoids: Chemistry and Novel Detection Techniques** 3345
Dipjyoti Chakraborty and Amita Pal

111 **Methods for Extraction and Analysis of Carotenoids** 3367
Siti Machmudah and Motonobu Goto

Part XIII Terpenes: Pharmacology and Bioavailability 3413

112 **Cannabinoids: Chemistry and Medicine** 3415
Giovanni Appendino and Orazio Taglialatela-Scafati

113 **Phytosterols: Beneficial Effects** 3437
Jonathan Santas, Rafael Codony, and Magda Rafecas

114 **Withanolides: Chemistry and Antitumor Activity** 3465
M. Iqbal Choudhary, Sammer Yousuf, and Atta-ur-Rahman

115 **Pharmacology of Ginsenosides** 3497
Kar Wah Leung

116 **Sesquiterpenes and Cytotoxicity** 3515
Ajay Sharma, Vivek K. Bajpai, and Shruti Shukla

117 **Tanshinones Against Cancer and Cardiovascular Diseases and their Biosynthesis** 3551
Lixin Zhang and Xueting Liu

118 **Strigolactones and Biological Activity** 3583
Koichi Yoneyama, Xiaonan Xie, and Kaori Yoneyama

119 **Biological Activity of Oleuropein and its Derivatives** 3605
Stefania Bulotta, Manuela Oliverio, Diego Russo, and Antonio Procopio

120 **Bacosides and Neuroprotection** 3639
Sukanya Majumdar, Amrita Basu, Pijush Paul, Mihir Halder, and Sumita Jha

121 **Garlic and Cardiovascular Diseases** 3661
Syed Haris Omar

122 **Ginkgolides and Neuroprotective Effects** 3697
Syed Haris Omar

123 **Cardiac Glycosides and Anticancer Activity** 3743
Yuan Lin, Dapeng Chen, Li Wang, and Dongmei Ye

124 **Terpenes and Improvement of Transdermal Drug Delivery** 3757
Lifeng Kang, Vaddi Haranath Kumar, Perry Fung Chye Lim,
Han Hui Cheong, and Sui Yung Chan

125 **Quassinoids: Anticancer and Antimalarial Activities** 3775
Emeline Houël, Didier Stien, Geneviève Bourdy, and
Eric Deharo

126 **Glycyrrhizic Acid: Biological Effects on Glucose and Lipid Metabolism** 3803
So Ha Ton, Chanchal Chandramouli, and Khalid BAK

127 **Phytoecdysteroids: Phytochemistry and Pharmacological Activity** 3827
Gert Laekeman and Arnold Vlietinck

128 **Brassinosteroids and their Biological Activities** 3851
Jana Oklešťková, Lucie Rárová, and Miroslav Strnad

Part XIV Terpenes: Parapharmaceutical Uses **3873**

129 **Lycopene in Cancer Prevention** 3875
Kazim Sahin and Omer Kucuk

130 **Xanthophylls and the Eye** 3923
Hannah E. Bartlett

131 **Triterpenoid Centellosides: Bioactivities and Uses in Healthcare Application** 3959
Puziah Hashim

132 **Essential Oils as Antimicrobial Agents** 3975
Vivek K. Bajpai, Shruti Shukla, and Ajay Sharma

133 **Menthol: Biological Effects and Toxicity** 3989
Demétrius A. M. Araújo, Darizy F. Silva, Humberto C. Joca,
José H. Leal-Cardoso, and Jader S. Cruz

134 **Eugenol as Local Anesthetic** 4001
Gehoon Chung and Seog Bae Oh

135 **Carotenoids as Colorants** 4017
Bernardo Dias Ribeiro and Raquel Grando de Oliveira

136 **Oleoresins from Pine: Production and Industrial Uses** 4037
Kelly Cristine da Silva Rodrigues-Corrêa, Júlio César de
Lima, and Arthur Germano Fett-Neto

137 Pyrethrins and Synthetic Pyrethroids: Use in Veterinary Medicine 4061
Arturo Anadón, Irma Arés, María Aránzazu Martínez, and María Rosa Martínez-Larrañaga

138 Essential Oils in Insect Control 4087
Catherine Regnault-Roger

139 Biological Activities of Selected Mono- and Sesquiterpenes: Possible Uses in Medicine 4109
Gerhard Buchbauer and Anja Ilic

Index 4161

Abstract

Higher plants produce diverse chemicals such as alkaloids, terpenoids, and phenolic compounds (phenylpropanoids and flavonoids) in secondary metabolism. Among these chemicals, benzylisoquinoline alkaloids (BIAs) are very important in medicine due to their high biological activities. However, extraction yields from plants are low because most of these metabolites accumulate at low levels in plant cells. There has been increasing interest in the microbial

production of plant metabolites by reconstructing plant biosynthetic pathways in microorganisms. Advances in synthetic biology and metabolic engineering have enabled "tailored" production of plant secondary metabolites in microorganisms. Recently, a platform to produce BIAs was constructed using bioengineered *Escherichia coli* or *Saccharomyces cerevisiae*, which could be useful for bulk production. Here, we review the fermentation platforms for low-cost production of many diverse alkaloids in microbes.

TH	Tyrosine hydroxylase
TKT	Transketolase

1 Introduction

The secondary metabolites of higher plants include diverse chemicals such as alkaloids, terpenoids, and phenolic compounds (phenylpropanoids and flavonoids), which are produced from primary metabolites such as amino acids or acetyl coenzyme A (acetyl-CoA). Although these compounds are widely used in the health and nutrition of humans, they are mainly obtained by plant extraction.

Table 1.1 Methods of BIA production

	Microbial production (*E. coli* or *S. cerevisiae*)	Chemical synthetic procedure	Genetically engineered plants and cultured plant cells
Advantages	High productivity	High productivity (increase in reaction steps reduce efficiency)	Moderate productivity but with large chemical diversity
	Short production time (within a few days)	Short production time (depends on number of steps)	Low environmental load (moderate reaction condition, such as neutral pH and medium temperature)
	Low environmental load (moderate reaction condition, such as neutral pH and medium temperature)	Space-saving	Space-saving for cultured plant cells
	Space-saving		
Demerits	Host-dependent enzyme expression; difficulty to express membrane-associated enzyme such as P450	High environmental load (dependence on starting chemical resources, specific catalysts, extreme reaction conditions, such as acidic or alkali, and high or low temperature)	Large culture field is needed for genetically engineered plants
	Limitation of available genes and substrates		Long production time (months to years)
			Extensive downstream purification of desired compound (except for some metabolic engineered plant/cells)

However, the yield is not high because of the low-level of accumulation of metabolites in plant cells. There have been many attempts to use metabolic engineering in plants to increase the amounts of alkaloids [1–8]. However, obtaining the desired products is very difficult because of the complicated and strict regulation of metabolic flows. Chemical synthesis has also been applied to obtain plant secondary metabolites. However, the complexity and chiral nature of these compounds have hampered the development of cost-effective methods.

Recently, microbial production of plant metabolites by reconstructing the plant biosynthetic pathway in microorganisms has garnered interest [9–12]. Microbial systems could improve not only the quantity but also the quality of secondary metabolites because they do not contain other plant metabolites. Microbial systems have a comparative advantage over chemical synthetic procedure or genetically engineered plants and plant cells (shown in Table 1.1). Although microbial systems offer several advantages for the biotransformation of chemicals, they also have disadvantages, such as limited availability of substrates (especially for plant metabolites), genes identified for biosynthesis, storage capacity, and tolerance to chemicals produced. Thus, the rational design of metabolic pathway using microbial- and plant-derived genes is needed for the establishment of efficient systems for the production of various compounds.

In this chapter, we have focused on current knowledge about the metabolic engineering of benzylisoquinoline alkaloids (BIAs) in microbes.

2 Metabolic Engineering of BIAs in Microbes

Among the secondary metabolites of higher plants, alkaloids are very important in medicine due to their high biological activities. Alkaloids are low-molecular-weight, nitrogen-containing compounds that are found in ~20% of plant species. Most alkaloids are derived from amines produced by the decarboxylation of amino acids such as histidine, lysine, ornithine, tryptophan, and tyrosine. One of the largest and most diverse groups of pharmaceutical alkaloids is the BIAs. These include the analgesic compounds morphine and codeine, and the antibacterial agents berberine and palmatine, which are produced via (*S*)-reticuline from L-tyrosine in Papaveraceae, Berberidaceae, Ranunculaceae, Magnoliaceae, and many other plant families. (*S*)-Reticuline is therefore a main branch-point intermediate in the biosynthesis of many types of BIAs. (*S*)-Reticuline also acts as a non-narcotic building block that is useful in the development of novel antimalarial and anticancer drugs.

2.1 Design of BIA Production Pathways in Bacteria and its Enzymes

Various types of BIAs are produced from L-tyrosine via (*S*)-reticuline in plants. (*S*)-Reticuline is a key intermediate of the biosynthesis of BIAs. The biosynthetic pathway of (*S*)-reticuline from L-tyrosine is shown in Scheme 1.1 and has nine steps:

I. Hydroxylation of the C-3 group of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA)
II. Decarboxylation of L-DOPA to dopamine
III. Decarboxylation of L-tyrosine to tyramine
IV. Deamination of tyramine to 4-hydroxyphenylacetaldehyde (4-HPAA)
V. Condensation of dopamine and 4-HPAA via the Pictet–Spengler reaction to norcoclaurine
VI. 6-*O*-Methylation of norcoclaurine to coclaurine
VII. *N*-Methylation of coclaurine
VIII. Hydroxylation of the 3′-C in *N*-methylcoclaurine
IX. 4′-*O*-Methylation of 3-hydroxy-*N*-methylcoclaurine

The several upstream biosynthetic genes in these steps, tyrosine/DOPA decarboxylase and tyrosine aminotransferase, have been isolated and characterized [13, 14].

BIA biosynthesis begins with the conversion of L-tyrosine to dopamine and 4-HPAA, which are condensed into (*S*)-norcoclaurine by norcoclaurine synthase (NCS) [15–21]. These first steps are difficult to reconstruct for the efficient production of divergent BIAs because the branched pathway from L-tyrosine to (*S*)-norcoclaurine is complicated to produce the desired product. Moreover, in many cases, producing active forms of plant cytochrome P450 enzymes in bacteria is difficult (even though the hydroxylation of 3′-C in *N*-methylcoclaurine (VIII) is catalyzed by P450 enzyme (CYP80B)). In fact, heterologous expression of CYP80B in *Escherichia coli* has not been reported. Therefore, these reactions involve the use of enzymes from other organisms or to design a "shortcut pathway" for the biosynthesis of compounds.

Bacteria do not possess the machinery to synthesize alkaloids like plants or fungi. Minami et al. first designed a shortcut pathway for the biosynthesis of (*S*)-reticuline via norlaudanosoline in bacteria based on providing dopamine (Scheme 1.2) [22]. The pathway has five reaction steps and is called the "NLS pathway":

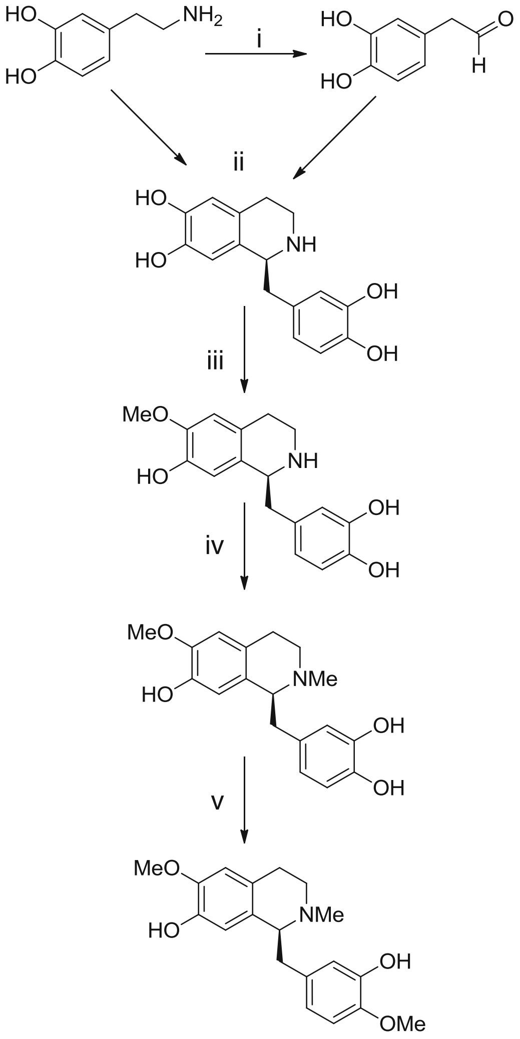
(i) Dopamine is converted to 3,4-dihydroxyphenylacetaldehyde (3,4-DHPAA) catalyzed by monoamine oxidase (MAO) from *Micrococcus luteus*.
(ii) Condensation of dopamine and 3,4-DHPAA into norlaudanosoline via the Pictet–Spengler reaction catalyzed by NCS.
(iii) The 6-*O*-methylation of norlaudanosoline to 6-*O*-methylnorlaudanosoline is catalyzed by norcoclaurine 6-*O*-methyltransferase (6OMT).
(iv) The *N*-methylation of 6-*O*-methylnorlaudanosoline is catalyzed by coclaurine *N*-methyltransferase (CNMT).
(v) The 4′-*O*-methylation of 6-*O*-methyllaudanosoline to reticuline is catalyzed by 3′-hydroxy-*N*-methylcoclaurine 4′-*O*-methyltransferase (4′OMT).

The coupling of dopamine and 3,4-DHPAA permits bypassing cytochrome P450 hydroxylase (CYP80B). Moreover, deamination catalyzed by microbial MAO means that reticuline can be obtained from a single substrate: dopamine. The biosynthetic pathway of reticuline from L-tyrosine in plants requires nine enzymes. However, the shortcut biosynthetic pathway from dopamine in microbial production requires only five enzymes.

MAO catalyzing the deamination of dopamine (i) has been isolated from various organisms. Most eukaryotic MAOs exist as membrane proteins, so expression of this enzyme in *E. coli* is difficult. Therefore, Minami et al. selected microbial MAO from *M. luteus*. This enzyme exists as a soluble protein in the cytosol, and its expression in *E. coli* is readily achieved [23].

NCS catalyzes isoquinoline formation via an asymmetric Pictet–Spengler reaction (ii). The reaction entails an acid-catalyzed electrophilic addition of an iminium ion. The mechanism is a two-step process in which the iminium ion is generated first from the condensation reaction between the aldehyde carbonyl (such as 4-HPAA) and dopamine. Two types of NCS (CjNCS1 and CjPR10A) have been isolated from *Coptis japonica* cells and characterized [21]. CjPR10A has been sufficiently expressed in an active form in *E. coli*. Conversely, CjNCS1 forms a larger complex in plant cells. Therefore, the recombinant enzyme expressed in *E. coli* cells has considerably lower activity than that of the native enzyme.

Scheme 1.2 Synthetic pathway of (*S*)-reticuline reconstructed in *E. coli* (NLS pathway)



These results indicate that CjPR10A is more suitable than CjNCS1 for microbial production systems. CjPR10A has been used as an NCS enzyme in reticuline biosynthesis.

The three steps of methylation of norlaudanosoline (iii, iv, v) are catalyzed by three kinds of methyltransferases (6OMT, CNMT, and 4′OMT). These enzymes need *S*-adenosyl-L-methionine (SAM) as the methyl donor. The 6OMT and CNMT from *C. japonica* have broad substrate selectivity. Therefore, 6OMT can catalyze the 6-*O*-methlyation of not only norcoclaurine (VI) but also norlaudanosoline (iii). Similarly, CNMT can catalyze the *N*-methylation of not only coclaurine (VII) but also 6-*O*-methylnorlaudanosoline (iv).

In conclusion, the pathway has three features that enable the efficient production of reticuline.

1. The starting material is only dopamine.
2. The 3′-hydroxylation of (*S*)-*N*-methylcoclaurine is bypassed.
3. The biosynthetic pathway can be constructed in *E. coli* cells by using selected enzymes.

2.2 Construction of Reticuline-Producing *E. coli* and Reticuline Production

E. coli cells containing the genes in the NLS pathway have been constructed using two types of plasmid vector. The genes of NCS and MAO are inserted into pKK223-3 vector, and 6OMT, CNMT, and 4′OMT are inserted into pACYC184 vector. The gene of MAO from *M. luteus* has not been expressed by a T7 promoter. Therefore, only the gene of MAO has been cloned with a taq promoter, and other genes have been cloned with a T7 promoter. However, Nakagawa et al. reported that a codon optimization MAO gene has been expressed by a T7 promoter [24].

E. coli BL21(DE3) containing pKK223-3-NCS-MAO and pACYC184-6OMT-CNMT-4′OMT have been prepared as reticuline-producing strains. This strain had been cultured with 5 mM dopamine in a medium and was shown to produce mainly (*R*,*S*)-reticuline at a yield of 11 mg/L medium. The growth of *E. coli* was not inhibited by dopamine and reticuline. The overall yield of reticuline from dopamine was 2.9 %, which was attributed to the instability of dopamine and certain reaction intermediates. These compounds are readily oxidized to be a melanin-like pigment without being introduced to *E. coli* cells. Improvement of the utilization efficiency of dopamine will be needed for in vivo large-scale production. An advantage of fermentative production is that (*R*,*S*)-reticuline is produced without the addition of SAM because the regeneration of SAM in microbial cells is known to maintain in vivo methylation activity during bioconversion [25].

The reticuline produced in this strain is in a racemic form. However, NCS is known to produce the (*S*)-form in a stereospecific manner [21]. This fact suggests that NCS cannot function efficiently in this strain, and that a spontaneous condensation reaction occurred to form norlaudanosoline. This hypothesis is supported by the fact that *E. coli* cells expressing the reticuline biosynthetic genes without NCS also produce racemic reticuline at the same level.

For the dominant production of (*S*)-reticuline, crude enzymes from transgenic *E. coli* cells were prepared and reacted with dopamine and SAM. As a result, stereospecific (*S*)-reticuline was synthesized from dopamine with crude enzymes without "fine tuning" of the level of each enzyme or purification of enzymes. The in vitro biomanufacturing system produced 55 mg/L (the overall yield was 14.4 %) of (*S*)-reticuline from 5 mM dopamine within 1 h. Hence, this system can produce optically active (*S*)-reticuline much faster (i.e., 1 h) than other methods (month to years for cultured plant cells and transgenic plants).

2.3 BIA Production Using *S. cerevisiae*

The NLS pathway has enabled the production of reticuline without CYP80B. However, transformation of reticuline to diverse alkaloids (e.g., berberine, magnoflorine, morphine) often requires P450 enzymes, which are difficult to express in active forms in *E. coli*. To solve the problem, Minami et al. used a two-step synthesis of alkaloids with *E. coli* and *S. cerevisiae* cells [22]. They prepared *S. cerevisiae* containing the genes of the berberine bridge enzyme (BBE) or the diphenyl ring bridging enzyme (corytuberine synthase: CYP80G2) as well as CNMT to produce two BIAs: magnoflorine and scoulerine (Fig. 1.1). For magnoflorine production, transgenic *E. coli* cells expressing reticuline biosynthetic genes were cultured with 5 mM dopamine in the medium, and *S. cerevisiae* cells expressing CYP80G2 and CNMT (which has relatively broad substrate specificity and can *N*-methylate corytuberine to synthesize magnoflorine) were added to the culture medium after certain period of *E. coli* culture. Magnoflorine was synthesized at a yield of 7.2 mg/L culture (overall yield, 1.9 %) within 72 h. For a protoberberine-type alkaloid, scoulerine was produced by coculture of transgenic *E. coli* cells expressing reticuline biosynthetic genes and *S. cerevisiae* cells expressing BBE. Scoulerine was synthesized at a yield of 8.3 mg/L culture (overall yield, 2.2 %) within 48 h. The conversion efficiency of magnoflorine from reticuline in *S. cerevisiae* cells was 65.5 % and of scoulerine from reticuline was 75.5 %. Yeast cells are more effective at expressing eukaryote genes (e.g., cytochrome P450) than *E. coli* cells. These results suggest that this combination system may be useful for the synthesis of various BIAs.

Smolke et al. reported that (*R*,*S*)-norlaudanosoline could be converted to (*R*,*S*)-reticuline at a yield of 164.5 mg/L culture using *S. cerevisiae* containing the genes of types of methyltransferase (6OMT, CNMT, 4′OMT) from *Thalictrum flavum* and *Papaver somniferum* [26]. Moreover, three additional enzymes from *T. flavum* and *P. somniferum* and a reductase partner from *Arabidopsis thaliana* had been expressed and had produced (*S*)-scoulerine (65.4 mg/L), (*S*)-tetrahydrocolumbamine (68.2 mg/L), and (*S*)-tetrahydroberberine (33.9 mg/L) from (*S*)-reticuline in *S. cerevisiae*. Furthermore, intermediate in the biosynthesis of morphine, salutaridine had been produced from (*R*,*S*)-reticuline at a yield of 24.5 mg/L culture by using a human P450 enzyme (CYP2D6) (Fig. 1.2).

3 Fermentative Production of BIAs from Simple Sources of Carbon

The previous section demonstrated the microbial synthesis of BIAs from aromatic intermediate such as dopamine or simple BIA norlaudanosoline. The production cost of using an expensive material as a substrate is relatively high. Hence, developing a new process that can convert BIAs from less expensive material such as renewable sources (e.g., glucose, glycerol) is important.

As described above, reticuline is a key compound for the production of BIAs. Analgesic compounds (e.g., morphine, codeine) and antibacterial agents

(e.g., berberine, palmatine) are produced mainly through (*S*)-reticuline with oxidation steps involved in cytochrome P450 oxidoreductases. For example, in morphine biosynthesis in plants, (*S*)-reticuline is converted to (*R*)-reticuline through two

enzymatic steps, and then a C-C- phenol linkage is formed by the oxidation of CYP719B1 to form salutaridine. The latter is converted to morphine with subsequent modification steps comprising five enzymatic and two spontaneous reactions [27, 28].

The P450-associated oxidations are important for the production of BIAs, but expressing P450 enzymes as active forms in microorganisms is still difficult [10, 29]. Therefore, P450-mediated oxidations are not suitable for the microbial production of plant alkaloids, whereas we need the future development of efficient expression systems for P450. Alternative pathways avoiding P450-mediated reactions should be employed. In this respect, the artificial synthetic pathway of BIAs described in the previous section should be employed for single microbial fermentation of BIAs from simple sources of carbon.

This section focuses on the strategy for the fermentation of dopamine (which is the starting compound for the artificial BIA synthetic pathway) from simple sources of carbon in *E. coli* cells. Dopamine fermentation is demonstrated in three steps: L-tyrosine fermentation, conversion of L-tyrosine to L-DOPA, and conversion of L-DOPA to dopamine.

3.1 L-Tyrosine Production from Simple Sources of Carbon

L-Tyrosine is used in various applications, including the synthesis of certain drugs, melanins, biodegradable resins, and phenylpropanoids [30]. Hence, the production of L-tyrosine has been promoted using traditional and genetic modification. Various microorganisms, such as *Corynebacterium glutamicum*, *Arthrobacter globiformis*, and *Brevibacterium lactofermentum*, were developed as overproducing strains of L-tyrosine using traditional mutagenesis methods [31–33]. On the other hand, plant BIAs are not naturally produced in microorganisms, so metabolic engineering for microbial production of BIAs needs the genes derived from plants producing BIAs and intensive genetic engineering of metabolism. Plant genes are now available from *P. somniferum* (opium poppy), *Eschscholzia californcia*, *Thalictrum* spp., and *C. japonica*. For the intensive genetic engineering, *E. coli* is an attractive host because more information is available on the biochemical pathway, the regulation mechanism, and the genetics, than any other microorganisms. Moreover, *E. coli* has been studied thoroughly and developed in molecular genetic methods to manipulate its genome, which can be readily constructed to the desirable mutants for overproduction of aromatic amino acids. Improvements in BIA productions are highly dependent upon increasing the carbon flow into the L-tyrosine pathway. L-Tyrosine-overproducing *E. coli* have been developed by metabolic engineering employing several strategies [30, 34–36].

L-Tyrosine biosynthesis starts with the condensation of phosphoenolpyruvate (PEP) and erythrose-4-phosphate (E4P), the intermediates of the glycolytic pathway and pentose phosphate pathway, respectively, which is catalyzed by 3-deoxy-D-arabino-heptulosonate-7-phosphate synthase (DAHPS: *aroF*/*aroG*/*aroH*). The resultant 3-deoxy-D-arabino-heptulosonate (DAHP) is converted into chorismate through the shikimate pathway with seven reactions. In plants, prephenate (PPA) is converted into L-arogenate by transamination whereas in *E. coli*, PPA is converted to *p*-hydroxyphenylpyruvate (HPP) by prephenate dehydrogenase, which is a bifunctional enzyme that behaves as chorismate mutase/prephenate dehydrogenase (CM/PDH: *tyrA*). The resultant HPP is transformed to L-tyrosine by a tyrosine aminotransferase (*tyrB*).

The first strategy is the elimination of *tyrR*, whose product is a "global regulator" of the shikimate pathway. The carbon flow of the L-tyrosine synthetic pathway is strictly regulated by a TyrR protein (Fig. 1.3). In *E. coli*, the TyrR protein acts as a repressor and activator in the transcription of several genes involved in the production of aromatic amino acids, including *aroF*/*aroG*/*aroH* (DAHPS), *aroL* (shikimate kinase), *tyrA*, and *tyrB* [37]. Therefore, disruption of the *tyrR* gene is expected to increase the production of aromatic amino acids. Furthermore, L-tyrosine and HPP inhibit the activity of three enzymes (DAHPS (*aroF*/*aroG*/*aroH*), 3-hydroquinate synthase (*aroB*), and CM/PDH (*tyrA*)) in the L-Tyr biosynthetic pathway of *E. coli*. There are reports that the mutation of the *tyrA* and *aroG* avoid the feedback inhibition. The feedback-resistant enzymes AroG$^{\mathrm{fbr}}$ (Asp$_{146}$ substituted with Asn [38]) and TyrA$^{\mathrm{fbr}}$ (Met$_{54}$ and Ala$_{354}$ substituted with Ile and Val, respectively [39]) were introduced into the *E. coli ΔtyrR* background, and resulted in an overall yield of ≤127 mg/L L-tyrosine [39].

Another strategy for overproduction of L-tyrosine is an increased supply of the precursors PEP and E4P to reduce the carbon flow for competitive pathways. Overexpression of phosphoenolpyruvate synthetase (PEPS: *ppsA*) and transketolase (TKT: *tktA*) is expected to improve the production of L-tyrosine. Using the *E. coli* transformant, which was eliminated in the TyrR regulation (by the deletion of *tyrR*) and overexpressing *aroG*^{fbr}, *tyrA*^{fbr}, *ppsA*, and *tktA*, up to 9.7 g/L L-tyrosine has been produced with a yield of 0.1 g/g glucose [30]. PEP is also used as a phosphate donor in the PEP: sugar phosphotransferase system (PTS) to induce the import of glucose in *E. coli*, thereby limiting the yield of aromatic compounds [40]. To avoid PEP consumption during glucose uptake, *E. coli* strains that lack PTS activity but consume glucose have been developed and improved by replacing PTS with galactose permease and glucokinase. These strains have accomplished higher yields and production capacities [41, 42].

3.2 Conversion of L-Tyrosine to Dopamine

The second step of dopamine production is hydroxylation of L-tyrosine to form L-DOPA. L-DOPA is a biologically important chemical employed for the treatment of Parkinson's disease, so L-DOPA has been produced employing chemical, enzymatic, or microbial processes [43–46]. In plants and animals, L-DOPA is mainly synthesized from L-tyrosine by tyrosine hydroxylase (TH). Since TH requires a tetrahydrobiopterin as a cofactor, TH cannot be utilized for the conversion of L-tyrosine to L-DOPA in *E. coli*. Therefore, tyrosinase or *p*-hydroxy phenylacetate 3-hydroxylase has been employed for the hydroxylation of L-tyrosine to form L-DOPA [43, 46, 47].

Tyrosinase is an enzyme belonging to major families of polyphenol oxidases, which contain the spectroscopic properties of metal ions. In general, tyrosinases catalyze the hydroxylation of monophenols to *o*-diphenols (monophenolase activity),

and also subsequently oxidize the resultant *o*-diphenols to *o*-quinones (*o*-diphenolase activity) (Scheme 1.3) [48]. The monophenolase activity of tyrosinase is usually coupled to *o*-diphenolase activity. Therefore, it is predicted that undesirable by-products (including L-dopaquinone and L-dopachrome) are produced during the conversion of L-tyrosine using a tyrosinase. However, the tyrosinase derived from *Ralstonia solanacearum* (RSc0337) has lower *o*-diphenolase activity than monophenolase activity [48]. Using RSc0337 for the conversion of L-tyrosine, effective production of L-DOPA without the formation of undesirable *o*-quinones (possibly melanin) is expected. In fact, when RSc0337 was overexpressed in an L-tyrosine-overproducing *E. coli*, 1.05 g/L of dopamine was produced with PpDODC as discussed below [24].

Production of L-DOPA using 4-hydroxyphenylacetate 3-hydroxylase encoded by *hpaBC* genes from *E. coli* was recently reported [46]. By using overexpressing *hpaBC* genes in the strain modified for L-tyrosine production, L-DOPA was produced ≤320 mg/L from glucose in minimal medium.

Dopamine is a key intermediate in the plant BIA biosynthesis pathway. It condenses with 4-HPAA, and forms a "BIA scaffold." In plants, tyrosine/DOPA decarboxylases catalyze the decarboxylation of L-tyrosine and L-DOPA to tyramine and dopamine, respectively [49]. Tyramine is an undesirable product for bacterial BIA synthetic pathways because its MAO product (i.e., 4-HPAA) combines with dopamine to form norcoclaurine, which needs CYP80B to be converted to reticuline. L-DOPA decarboxylase (PpDODC) from the *Pseudomonas putida* strain KT2440 exhibited a more than 10^3-fold preference for L-DOPA compared with other aromatic amino acids [unpublished data]. Therefore, conversion of L-DOPA with PpDODC is expected to reduce the formation of undesirable by-products, 4-HPAA, and the resultant norcoclaurine (Fig. 1.4). Using an L-DOPA-producing *E. coli* strain that overexpresses PpDODC, dopamine production reached 1.05 g. The conversion efficiency from L-tyrosine to dopamine was 29.1 % [24].

3.3 BIA Production from a Simple Source of Carbon in *E. coli*

The biosynthesis of reticuline from simple sources of carbon can be achieved by combining the artificial BIA synthetic pathway (which converts dopamine to reticuline) and the dopamine fermentation pathway (which consists of the three steps described in the subsections above). Only very recent study on microbial BIA fermentation has been reported using single *E. coli* cells [24]. In that report, reticuline

production was achieved from a simple source of carbon (e.g., glycerol, glucose) using modified *E. coli* BL21 (DE3), which had been adopted in the artificial BIA synthetic pathway (NLS pathway in Sect. 2.1) and the dopamine fermentation pathway (in this section). The reticuline-producing strain was developed to delete the *tyrR* gene and to introduce eleven genes (*aroG^{fbr}*, *tyrA^{fbr}*, *ppsA*, *tktA*, *RsTYR*, *DODC*, *MAO*, *NCS*, *CNMT*, *4′OMT*, *6OMT*) using three plasmid vectors. Reticuline has been produced from simple sources of carbon such as glucose and glycerol in the strain, and reached a maximum yield of 46.0 mg/L from glycerol in fed-batch cultures [24]. Interestingly, reticuline was mainly produced in the (*S*)-isomer but not the (*R*)-isomer in reticuline-producing *E. coli*, unlike observations in the dopamine-adding system [22]. Further analyses showed that the (*S*)-isomer was the main product in the strain, and that only small amounts of the (*R*)-isomer were formed when a low concentration of norlaudanosoline was used. Conversely, (*S*)-reticuline was produced with high stereoselectivity under almost all culture conditions.

The above production system is manipulated by a jar fermenter system but it is difficult to manipulate this system with numerous samples in parallel. Many samples can be cultured in parallel using shake flask cultures, allowing optimization of production conditions. Using shake flask cultures, bench-top production of (*S*)-reticuline and optimization of culture conditions are examined [50]. Using this bench-top method, a sufficient amount of (*S*)-reticuline (a yield of 33.9 mg/L in 60 h, a similar yield to that obtained using the jar fermenter culture) can be readily prepared without a jar fermenter system. Thus, the bench-top method for production of (*S*)-reticuline may facilitate research on BIAs.

4 Conclusion

In this chapter, three kinds of multistep BIA production systems are reviewed (shown in Table 1.2). These microbial systems should open a new field in which microbial cells can be given the ability for low-cost production of many diverse alkaloids. The bacterial platform for BIA fermentation has been established, but further applications face problems. Further metabolic engineering (such as optimization and modification of the pathway) may overcome the productivity of alkaloids and enhance the field of applications for microbial alkaloid fermentation. The widespread application may lead to further progress with microbial systems for use in the pharmaceutical industry, which needs a diverse chemical library to develop more advanced tools for chemical therapy.

Abstract

Marine alkaloids have their origins from marine organisms including marine macroalgae. On the other hand, some marine algal alkaloids such as phenylethylamine derivatives were previously isolated from terrestrial plants. The other groups of alkaloids like indole derivatives and halogenated alkaloids are specific for algae. Most of the indole group alkaloids are concentrated in red algae. Green algae are rich of bromine- and chloride-containing alkaloids. These halogenated alkaloids of algae are not present in terrestrial plants and are specific for algae and sea organisms. Marine algae contain 44 alkaloids, consisting of 1 phenylethylamine, 41 indole, and 1 naphthyridine derivates. In the halogenated alkaloid group, there are 25 bromine-containing compounds, among which 7 have chlorine and 5 have sulfur, additionally.

TYR	Tyramine

1 Introduction

Alkaloids are a large group of naturally occurring organic compounds. The first alkaloid was isolated from opium, terrestrial plant *Papaver somniferum*, by

Serturner in 1805 [1] and 164 years later, in marine algae by Guven et al. [2, 3]. The term "alkaloid" was proposed by Meissner in 1819 [4], which originated from the words of Arabic *al kaly* and the Greek *eidos*, meaning alkali-like. Alkaloid definition has evolved through years. Initially, alkaloid was defined as a nitrogen-containing heterocyclic compound. Later, a compound with a biological amine group was included, and recently, Br-, I-, Cl-, and S-containing heterocyclic nitrogenous compounds were also defined as alkaloids. Alkaloids possess important pharmacological activities, which are presented in another chapter. Alkaloids are produced by large variety organisms, basically terrestrial plants, including bacteria, fungi, and marine algae and animals.

Most of the alkaloids, around 30,000, have been isolated from terrestrial plants, but marine algae contain only 44 alkaloids. The origins of some alkaloids in plants are oxidation products of amino acids, whereas others' origins remain unknown, especially halogenated alkaloids in marine algae.

Alkaloids can be extracted from the materials by acid–base extraction technique, then various purification techniques were applied. The obtained pure marine algal alkaloids were identified by IR, HPLC and MS, GC-MS, and NMR and comprehensively reviewed time to time [5, 6].

An important feature of an algal alkaloid is that it is either a natural component or a host product. Some alkaloids were produced by host organisms on algae. For example, communesin was isolated from the mycelium of a strain of *Penicillium* sp. on the *Enteromorpha intestinalis* [7], citrinadin A was isolated from *Penicillium citrinum* separated from a marine red algae [8], and Nb-acetyltryptamine and oxaline were isolated from unidentified fungus collected from the surface of the red alga *Gracilaria verrucosa* [9]. *N*-hydroxy-2-pyridone was isolated from *Penicillium* sp. on brown alga *Xiphophora gladiata* [10]. Ascosalipyrrolidinone was isolated from fungus *Ascochyta salicornia* on green alga *Ulva* sp. [11]. These host alkaloids are not presented in this chapter.

TYR, DOP, and HORD are biological amines, and among these, only HORD is defined as an alkaloid. These amines were included in this chapter because all are derived from the parent compound PEA and have important pharmacological activities.

2 Classification and Natural Occurrence of Alkaloids

The alkaloids nomenclature has not been systematized. The commonly used systems for alkaloid classification are designed according to the plant genera or to the basis of molecular structure similarities.

In this chapter, the alkaloids were classified as follows:

1. 2-Phenylethylamine derivatives
2. Indole derivatives
3. Halogenated indoles
4. 2,7-Naphthyridine derivatives

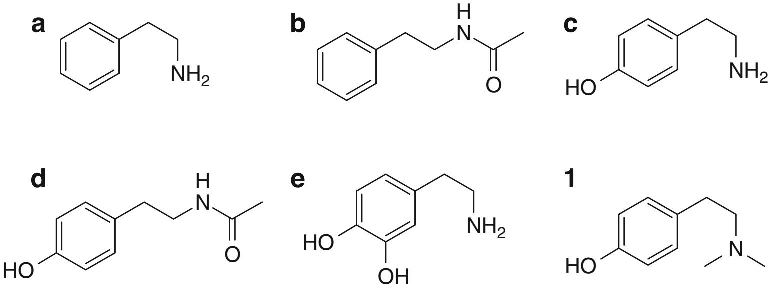

Fig. 2.1 PEA and related amines (**a**–**e**) and alkaloid (**1**)

2.1 PEA and Related Amines and HORD

2.1.1 PEA

PEA (a) consists of a benzene ring and an ethylamine side chain. Its structure permits substitution on the aromatic ring α (1-) and β (2-) carbon atoms. Among PEA derivatives (5 amines) in algae are *N*-ACPEA, TYR, *N*-ACTYR, and DOP (Fig. 2.1). Phenylethylamine is a decarboxylation product of phenylalanine. They were firstly found in terrestrial plants and later in marine algae. The distribution of PEA in plants and eight algae was reviewed by Smith [12]. PEA-contained algae are brown (*Desmerestia aculeata*, *Desmerestia viridis*) and red (*Ceramium rubrum*, *Cystoclonium purpureum*, *Delesseria sanguinea*, *Dumontia incrassata*, *Polysiphonia urceolata*, *Polyides rotundus*) [13]. PEA content was investigated in two green, five brown, and ten red algae, and it was reported to be present only in six red algae as *Gelidium crinale*, *Gracilaria bursa-pastoris*, *Halymenia floresii*, *Phyllophora crispa*, *Polysiphonia morrowii*, and *Polysiphonia tripinnata*. PEA amount varied in these algae as 0.34–30.42 $\mu g/g^{-1}$, and the highest amount was found in *Gelidium crinale* and trace in *Phyllophora crispa* [14].

2.2 PEA Group Amines

2.2.1 *N*-ACPEA (b)

N-ACPEA is *N*-2-phenylethylacetamide. *N*-ACPEA was first isolated from the red alga *Gelidium crinale* [15].

2.2.2 TYR (c)

TYR is 4-hydroxyphenylethylamine. TYR occurs in many plants, fungi, and animals but is rare in algae. It was found in brown alga *Laminaria saccharina* and in red algae *Chondrus crispus* and *Polysiphonia urceolata* [16].

2.2.3 *N*-ACTYR (d)

It was isolated for the first time from marine algae *Phyllophora crispa* [15].

2.3 DOP

DOP (e) is 3,4-dihydroxyphenethylamine. DOP is a catecholamine, carrying two hydroxyl groups in the position 3 and 4 of the phenyl ring. DOP was found in animals and several terrestrial plants [12]. It was found in the green alga *Monostroma fuscum* [17] and recently in *Ulvaria obscura*, a prominent component of green tide blooms in Washington. Green tide is stimulated as a result of dopamine release to the sea by *U. obscura* [18].

2.4 PEA Alkaloid

2.4.1 HORD

HORD (1) is 4-(2-dimethylaminoethyl)phenol, *N*-dimethyl derivative of tyramine. Exceptionally, hordenine contains a quaterner amine group. HORD was first isolated from red algae *Phyllophora nervosa* [*Phyllophora crispa*] [2, 3] and later from *Ahnfeltia paradoxa* [19], from *Gigartina stellata (Mastocarpus stellatus)* [20], and from *Gelidium crinale* [21]. HORD amount was determined in *Gelidium crinale* [21] and *Phyllophora nervosa* [22].

2.5 Indole Derivatives

Indole Derivatives are shown in Fig. 2.2.

2.5.1 ICA (2) and HAI (3)

ICA and HAI were extracted from the marine red alga *Peyssonnelia* sp. [23].

2.5.2 ALM *E* (4) and *Z* (5)

ALM is a disubstituted oxazolindole derivate and was isolated from the red alga *Haraldiophyllum* sp. collected in Dakar (Senegal) and synthesized *E* and *Z* stereoisomers [24].

2.5.3 FRG (6)

FRG is a 3-substituted indole and corresponds to an *N*-methylhomoisoleucyl unit and a *p*-hydroxybenzyl group attached to the indole unit C-3. The amide NH was connected to a *cis* disubstituted carbon-carbon double bond and was extracted from the red alga *Martensia fragilis* [25].

2.5.4 MRF A (7)

MRF A displays a 3-oxazolylindole structure. It was isolated from the red alga *Martensia fragilis* [26] and was also synthesized [27].

2.5.5 MRT A (8), B (9)

MRT A (**8**) is a 3-substituted indole bound to a 5-membered lactam ring, and MRT B (**9**) contains two carbonyl as a γ-lactam and a heterocyclic ketone group. MRT A and B were extracted from the red algae *Martensia fragilis* [25].

16
17

Fig. 2.2 Indole derivatives, alkaloids

2.5.6 DTC A (10), B (11), and C (12)

DTCs are 3-subsituted indole derivates named DTC A, B, and C. These alkaloids contain sulfonic acids which are rarely found in alkaloids. DTCs were isolated from *Martensia denticulate* [28].

2.5.7 CLP (13)

CLP (**13**) is a dimethyl-6,13-dihydrodibenzo[b,i]phenazine-5,12-dicarboxylate methyl ester. CLP (I) **(13)** contains two indole groups linked by a cyclic ring containing eight carbons with two carboxy groups. CLP (I) was first isolated from *Caulerpa racemosa* var. *clavifera*, C. *sertularioides*, and *C. serrulata* [29], and it was also synthesized [30]. Its two analogues CLP (II) (**14**) and CLP (III) (**15**) were also isolated from *Caulerpa racemosa*. CLP contains two COOMe, but CLP analogue I contains two COOH and CLP II one COOH and COOMe [31].

CLP-containing algae are listed as follows: in green algae *C. lamourouxii* [32], *C. prolifera*, *C. ashmeadii*, *C. racemosa var. macrophysa*, *C. racemosa var. laetevirens* [33], C. *paspaloides, C. microphysa* [34], *C. decorticatum* [35], *C. taxifolia* [36], *C. peltata* [37], *C. scalpelliformis* [38], and *Halimeda incrassate* [39], and in red algae, *Chondria armata* [40], *Laurencia majuscula, Hypnea concornis, Caloglossa leprieurii* [41], *Laurencia cartilaginea, Eucheuma muricatum*, and *Colpomenia sinuosa* [42].

2.5.8 CLS (16)

CLS is a bisindole alkaloid with central ring of seven members and two antiparallel indole cores. CLS was isolated from *Caulerpa serrulata* [43]. CLS has three isomers A, B, and C and was also synthesized [44].

2.5.9 CAL A (17)

CAL is a 2-(4-hydroxybenzyl)-2,3,4,9-tetrahydro-1 H-pyrido[3,4-b]indole-3-carboxylic acid.

CAL is a tetrahydro-*β*-carboline. It was isolated from the red algae, *Callophycus oppositifolius* [45]. The similar steroidal alkaloid was found in tomato (*Lycopersicum esculentum*) [46].

3 Halogenated Indole Alkaloids

Halogens, bromine, and chlorine were found in the same compound. Some of them contained Br, and some of halogenated alkaloids contain two different halogens as Br and Cl.

HLI alkaloids were isolated only from marine organisms and algae. Many HLI alkaloids were isolated from red algae and only one from a green alga. These alkaloids contain an indole group substituted by bromine and chlorine atoms. Sulfur-containing bromo alkaloids were also extracted from red algae.

27

Fig. 2.3 Bromoindole alkaloids

3.1 BRI

The BRI isolated from algae are shown in Fig. 2.3.

From red alga *Laurencia brongniartii* collected from Caribbean Sea [47] and Okinawan Sea [48], 2,3,6-tribromo-1-methyl indole (**18**) [47], 2,3,5-tribromo-l-methyl indole (**19**) [49], 2,3,5,6-tetrabromo-l*H*-indole (**20**) [47], 2,3,5,6-tetrabromo-l-methyl indole (**21**) [47], 2,4,6-tribromo-l*H*-indole (**22**) [48] and 2,3,4,6-tetrabromo-l*H*-indole (**23**) [48] were isolated. Compounds **20** and **23** were also identified in the red alga *Laurencia similis* collected from Pulau Gaya, Malaysia [49], and compound **19** was isolated from a red alga *Laurencia decumbens* collected from Weizhou Island (South China Sea) [50]. 3,5,6-tribromo-l*H*-indole (**24**) [51], 3,5,6-tribromo-l-methylindole (**25**) [51] and 2,3,6-tribromo-1*H*-indole (**26**) [51] were isolated from red alga *Laurencia similis* collected from Sanya, China [51]. 2,3,4,6-tetrabromo-l-methylindole (**27**) was isolated from the red alga *Laurencia decumbens* collected from Weizhou Island (South China Sea) [50].

3.2 Sulfur-Containing Bromoindole Alkaloids

The formulas of sulfur-containing bromoindole alkaloids are given in Fig. 2.4. Thiobromoindoles 3-thiomethyl 2,4,6-tribromo-1 *H*-indole (**28**), 3-thiomethyl 2,4,5,6-tetrabromo-1 *H*-indole (**29**), 2,3-dithiomethyl-4,6-dibromo-1 *H*-indole (**30**),

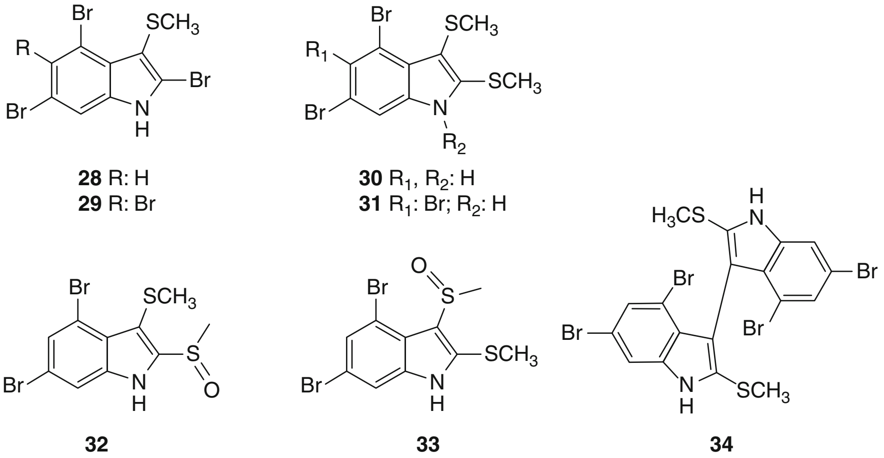

Fig. 2.4 Sulfur-containing bromoindole alkaloids

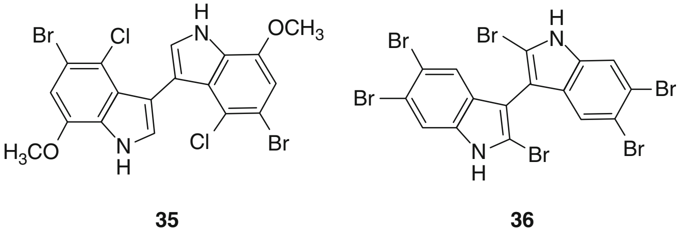

Fig. 2.5 Polyhalogenated bisindoles

and 2,3-dithiomethyl-4,5,6- tribromo-1 *H*-indole (**31**) were isolated from *Laurencia brongniartii* [47, 48].

Thiomethyl and sulfoxide-containing bromoindoles 2-thiomethyl-3-sulfoxymethyl-4,6-dibromoindole (**32**) and 2-sulfoxymethyl-3-thiomethyl-4,6-dibromo-1 *H*-indole (**33**) were also isolated from *Laurencia brongniartii* [47]. 3,3′-Bis(4,6-dibromo-3-methylthio) indole (**34**) was isolated from *Laurencia brongniartii* collected in Okinawa Sea [48].

3.3 Polyhalogenated Bisindole

4,4′-Dichloro-5,5′-dibromo-7,7′-dimethoxy-3,3′-bis-1 *H*-indole (**35**) was identified from the green alga *Chaetomorpha basiretorsa* [52]. 2,2′,5,5′,6,6′-Hexabromo-3,3′-bis-1 *H*-indole (**36**) was identified from *Laurencia similis* collected from the coast of Sanya, Hainan Island (China) [42] (Fig. 2.5).

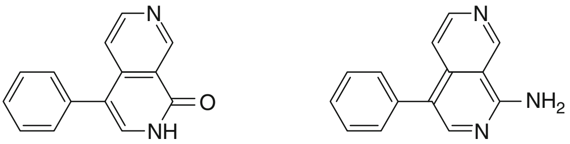
Fig. 2.6 Polyhalogenated indoles



43 Lophocladine A

44 Lophocladine B

Fig. 2.7 Lophocladines

3.4 Polyhalogenated Indoles

Many polyhalogenated indoles (**37–42**) were identified in *Rhodophyllis membranacea* collected from the Kaikoura coast (New Zealand). The fractions (**37**, **38**, **39**, **40**, **41**, and **42**) obtained from the extract of *R. membranacea* contain polychlorinated and polybrominated alkaloids [53] (Fig. 2.6).

3.5 2,7-Naphthyridine Derivatives

3.5.1 LO A (43) and LO B (44)

There are two derivatives, lophocladine A (4-phenyl-[2, 7]-naphthyridine-1(2 *H*)-one) and lophocladine B (4-phenyl-[2, 7]-naphtyridine-1-amine), which were isolated from a red alga *Lophocladia* sp. [54] (Fig. 2.7).

4 Conclusion

Alkaloids are very important compounds. They have been isolated exclusively from plants and marine organisms and rarely from macroalgae. The main difference between the alkaloids present in terrestrial plants and algae is that indoles and halogenated alkaloids are found specifically in algae. The highest number of alkaloids is present in the indole group, followed by the phenylethylamine group.

In total, marine algae contain 44 alkaloids, consisting of 1 phenylethylamine, 41 indole, and 1 naphthyridine derivates. In the halogenated alkaloid group, there are 25 bromine-containing compounds, among which 7 have chlorine and 5 have sulfur, additionally. Alkaloids are more abundant in red than green algae but are found rarely in brown algae.

Acknowledgment The authors wish to thank M.Sc. E. Karakaş for her assistance in preparation of the manuscript.

Abstract

Cyanobacteria produce a wealth of secondary metabolites that are very diverse in chemical structure and in biological activity. A number of neurotoxins have been identified in strains of cyanobacteria including anatoxin-a and its higher homologue homoanatoxin-a, anatoxin-a(S), saxitoxins, and related paralytic shellfish toxins. This chapter focuses on these neurotoxic alkaloids from cyanobacteria, with emphasis on the chemical, biochemical, toxicological, and biosynthetic aspects. Anatoxin-a and homoanatoxin-a are two deadly potent agonists of the nicotinic acetylcholine receptor at the neuromuscular junction, provoking the rapid death of animals after respiratory failure. The chemistry and the pharmacology of these neurotoxins have been well studied, while their biosynthesis was recently deciphered. Our knowledge concerning anatoxin-a(S), an irreversible inhibitor of acetylcholine esterase, lies far behind and future work will be needed. Saxitoxin and its analogues, the paralytic shellfish toxins, have been associated with massive intoxication episodes in marine environment. They act as blockers of voltage-gated sodium channels provoking death in animals at low doses. The chemistry, pharmacology, and biosynthesis of saxitoxins have been well described. The genetic origin of the biosynthetic genes of this ancient toxin has been studied by detailed phylogenetic analysis.

Keywords

Acetylcholine esterase inhibitor • Anatoxin-a • Anatoxin-a(s) • Cyanobacteria • Homoanatoxin-a • Neurotoxins • Nicotinic acetylcholine receptor activator • Saxitoxin • Voltage-gated sodium channel blocker

PST	Paralytic shellfish toxin

1 Introduction

The cyanobacteria produce a plethora of natural products with a wide variety of bioactivities. Many of these compounds are potent toxins and pose a significant hazard to human health and the environment. In freshwater systems, blooms of hepatotoxic cyanobacteria are of greatest concern, while in marine environments neurotoxic species are more problematic. More than 65 neurotoxins have been isolated from cyanobacteria to date. Most notably, these include the highly potent alkaloids anatoxins and saxitoxins (also known as paralytic shellfish toxins, PSTs); however, a variety of other neurotoxic substances have also been isolated from cyanobacteria including the lipopeptides, jamaicamide, antillatoxin, and kalkitoxin, as well as the nonproteinogenic amino acid, β-*N*-methylamino-L-alanine (BMAA).

Cyanobacterial neurotoxins primarily target cholinergic synapses or voltage-gated ion channels. For example, anatoxin-a and homoanatoxin-a are nicotinic acetylcholine receptor agonists [1–3], while anatoxin-a(s) irreversibly inhibits acetylcholinesterase activity [4, 5]. The saxitoxins, on the other hand, exert their toxicity via the inhibition of voltage-gated sodium, calcium, and potassium channels [6–8]. Despite their different modes of action, when ingested in acute doses, the alkaloid neurotoxins impart similar symptoms of paralysis and respiratory failure.

The lipopeptides jamaicamide and kalkitoxin also inhibit voltage-gated sodium channels [9, 10]; however, cases of acute human poisonings are rare. Conversely, antillatoxin is a sodium channel activator and one of the most potent ichthyotoxins isolated from nature [11, 12]. The neurotoxic amino acid BMAA activates AMPA/kainate receptors [13], which in chronic cases may contribute to the development of amyotrophic lateral sclerosis-Parkinsonism dementia (for review see [14]).

The cyanotoxins display remarkable structural diversity, however, most can be classified as cyclic peptides, depsipeptides, lipopeptides, or alkaloids [15–17]. Among the alkaloid neurotoxins, which are the focus of this chapter, anatoxin-a and homoanatoxin-a can be described as low molecular weight secondary bicyclic amine alkaloids [18, 19]. While anatoxin-a(s) is a guanidine methyl phosphate ester [20]. Saxitoxin is a tricyclic perhydropurine alkaloid containing guanidinium moieties [21], and is the parent compound of more than 57 naturally occurring derivatives differing at four positions that may be hydroxylated, sulfated, or carbamylated [22].

The enzymes responsible for cyanotoxin biosynthesis, modification, and transport are usually encoded within large gene clusters ranging in size from around 25 to 58 kb. A common theme in cyanotoxin biosynthesis is the occurrence of nonribosomal peptide synthetases (NRPSs) and polyketide synthases (PKSs). NRPSs and/or PKSs constitute the core biosynthesis enzymes in the production of several cyanobacterial hepatotoxins [23–25], as well as in the production of the neurotoxins anatoxin-a, homoanatoxin-a, and jamaicamide [9, 26]. Saxitoxin biosynthesis also involves a novel PKS-like enzyme [27]. Other enzymes associated with cyanobacterial neurotoxin gene clusters include those that transfer functional groups (e.g., methyl-, sulfo-, carbamoyltransferases), cyclases, and transporters. Transposase genes are also commonly associated with cyanotoxin gene clusters including the anatoxin-a and saxitoxin clusters [26, 27], and may play a role in their genetic mobilization via horizontal transfer.

This chapter provides an overview of the current status of cyanobacterial alkaloid neurotoxin research, with specific focus on the chemistry, toxicology, and biosynthesis of these potent compounds.

2 Anatoxin-a and Homoanatoxin-a

2.1 History

(+)-Anatoxin-a (systematic name: (1*R*,6*R*)-1-(9-azabicyclo[4.2.1]non-2-en-2-yl)) ethanone, Fig. 3.1, which was first coined Very Fast Death Factor (VFDF) because it provoked the rapid death of animals after ingestion, was isolated from *Anabaena flos-aquae* strains by Gorham and coworkers in the 1970s (as reviewed in [28]). The structure and configuration of the toxin was elucidated by X-ray crystallography of its *N*-acetyl derivative [29], and confirmed by other spectroscopic means [28] and by synthesis from (−)-cocaine [30]. Carmichael and coworkers rapidly showed that anatoxin-a provoked the rapid death of animals by acting as a depolarizing neuromuscular blocking agent [31]. Homoanatoxin-a, the higher homologue of anatoxin-a (Fig. 3.1), was synthesized as a potent analogue of anatoxin-a [3], and detected in cultures of *Oscillatoria formosa* [32] and of other strains. In the years following the discovery of anatoxin-a, several syntheses of anatoxin-a, homoanatoxin-a, and analogues were published, and numerous pharmacological studies allowed defining the pharmacology and toxicology of these deadly natural neurotoxins. The biosynthesis of anatoxin-a and homoanatoxin-a, by cyanobacteria, was only deciphered recently when the biosynthetic cluster of genes was identified and sequenced [33].

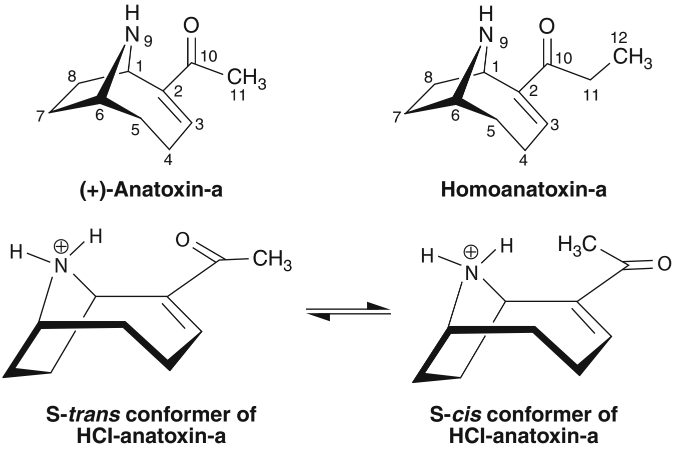

Fig. 3.1 Chemical structure of (+)-anatoxin-a and of homoanatoxin-a and representation of the two major side chain conformers proposed for HCl-anatoxin-a (adapted from [34])

2.2 Chemistry

2.2.1 Synthesis

Synthetic chemists have long been attracted by the structure and the pharmacological properties of anatoxin-a, and have thus proposed numerous syntheses of anatoxin-a and analogues, including homoanatoxin-a. The group of Rapoport has proposed several approaches and has synthesized the two enantiomers of anatoxin-a as well as a number of analogues that were used as pharmacological probes [34–37]. The group of Gallagher has prepared anatoxin-a, homoanatoxin-a, and other analogues [3, 38, 39], while the group of Parsons has proposed a simple and efficient synthesis of racemic anatoxin-a and analogues, from cyclooctadiene [40]. The reader is referred to the report by Mansell, 1996 [41], covering this literature before 1996, and to more recent synthetic approaches [42–49].

2.2.2 Molecular Properties

Anatoxin-a is a homotropane alkaloid with a monoisotopic mass of 165.11536 Da ($C_{10}H_{15}NO$). Its hydrochloride salt is soluble in water, methanol, and chloroform, and its amino group has a pKa of 9.36 ± 0.06, thus being almost fully protonated at physiological pH [34]. The natural enantiomer shows a specific rotation of $[\alpha]_D = + 43.2$ (c 0.676, ethanol) [36]. Due to its conjugated ketone, anatoxin-a shows specific absorptions in the UV range ($\lambda_{max} = 227$ nm, $\varepsilon = 10\,700\ \text{cm}^{1}\ \text{M}^{-1}$) and in the IR range (1 665 cm^{-1}) [36]. Its ^{1}H and ^{13}C NMR spectra have been fully interpreted [34]. The conformation of anatoxin-a as a solid has been elucidated, by X-ray crystallography, and in solution by NMR, as well as by calculations [34, 50]. The molecule seems to adopt the same conformation in solution and in the crystal with the seven-membered ring in a twist chair form. However, the side chain adopts two possible orientations, s-*cis* and s-*trans*, in solution (Fig. 3.1). Unfortunately, homoanatoxin-a has not been fully characterized even if its synthesis has been described, and its molecular properties have not yet been reported.

2.2.3 Reactivity and Stability

The secondary amine of anatoxin-a and homoanatoxin-a has similar chemical properties as other amines, and can form various salts, such the fumarate salt, which is a commercially available form of anatoxin-a. Modification of the amine has been used to derivatize these alkaloids for their detection, using diverse techniques (see below), as their *N*-acetyl- [51, 52], *N*-butyl- [53], *N*-(7-nitro-2,1,3-benzoxadiazole)-4- [54] or *N*-fluorenylmethyloxycarbonyl derivatives [55]. The double bond can easily be reduced by hydrogen in the presence of a catalyst, leading to a mixture of *cis*- and *trans*-dihydroderivatives [56] (Fig. 3.2). Epoxidation of this double bond is readily achieved by oxidation with hydrogen peroxide, probably yielding to a mixture of diastereoisomers [56] (Fig. 3.2). The reactivity of the methyl ketone of anatoxin-a has been largely used by Gallaghers and coworkers for the preparation of numerous side chain analogues [39]. Anatoxin-a, in aqueous solution, is photosensitive and degrades to unknown compounds, with a half-life of about 100 min, when irradiated with sunlight. This process is oxygen independent but pH dependent and light intensity dependent [57]. In this study, it was also noted that the degradation of anatoxin-a, at pH 9 in the dark, has a half-life of about 4 days. This dark degradation process is accelerated in the presence of oxygen and Cu^{2+} ions. Unfortunately, the degradation compounds have not been characterized but it was shown that they were nontoxic [57]. The oxidation of anatoxin-a by Advanced Oxidation Processes (AOPs), such as VUV photolysis or combination of UV and H_2O_2, or by other oxidant (chlorine, permanganate, ozone, etc.) has been studied, in view of detoxifying contaminated water. Anatoxin-a is oxidized very rapidly by ozone ($k = 9.42\ s^{-1}$, at pH 7 and 20 °C), while chlorine oxidation is slow. However, while the kinetics of this process is well characterized, the by-products formed by oxidation have not yet been identified [58–65].

2.2.4 Detection and Quantification Methods

Because the presence of anatoxin-a and homoanatoxin-a in the environment represents a risk for animals and humans, several analytical methods have been designed to detect these toxins as well as their natural derivatives (Fig. 3.2). GC-MS was first used to detect and quantify anatoxin-a or its *N*-acetyl derivative [51, 52, 66]. High Pressure Liquid chromatography (HPLC) coupled to UV detection was also used, although this detection method is not very sensitive [67]. Thus, to improve the sensitivity, several authors have used pre-derivatization with a fluorophore, which reacts on the amine of anatoxin-a or of homoanatoxin-a, followed by separation by HPLC coupled to a fluorescence detector [56, 68, 69]. However, the derivatization might lead to false positives even if the technique was improved to remove primary amines present in the sample [70] or by concentration by extraction of anatoxin-a prior to analysis [71, 72]. It is now accepted that the best analytical technique relies on the use of HPLC coupled to tandem mass spectrometry (LC-MS^2, or even LC-MS^n) without derivatization to avoid

false positives [68, 73–76]. Improvement of this technique with preconcentration of the toxins has also been described [77]. Table 3.1 summarizes the major techniques published to date. Surprisingly, the use of specific antibodies against anatoxin-a in analytical methods has not yet been described, although the synthesis of an analogue of anatoxin-a for monoclonal antibody production was recently proposed [78].

2.3 Distribution and Isolated Producing Strains

Since the discovery of anatoxin-a in Canada, this toxin and its higher homologue, homoanatoxin-a, have been detected in bodies of water (lakes, reservoirs, rivers,

estuaries, etc.) all over the world. The literature published up to 2006 has already been reviewed [81] and we have summarized in Table 3.2 the reports published since 2006. Clearly, anatoxin-a and homoanatoxin-a have been detected in various part of the world suggesting that cyanobacteria producing these neurotoxins have probably colonized the entire surface of the globe. However, it is difficult to compare the data because the detection methods differ and the units used are not always consistent (values are reported in gram per liter or per gram of dry weight or wet weight). Nevertheless, the important point is that the concentration of anatoxin-a or homoanatoxin-a is sometimes very high (1.7 mg L^{-1}; 1.3 mg g^{-1} dry weight), thus confirming the importance of surveying these neurotoxins in bodies of water. From the toxic blooms, researchers have isolated strains and identified the cyanobacteria producing these neurotoxins. The producers belong to different genera such as *Anabaena*, *Aphanizomenon*, *Oscillatoria*, *Phormidium*, *Cylindrospermum*, and *Raphidiopsis* [81]. Selected examples are summarized in Table 3.4 together with the concentration of anatoxin-a or homoanantoxin-a found in the cells. Interestingly, the strains can be classified into two groups according to the neurotoxin produced, but the concentration of the toxin varies greatly from strain to strain. There are currently no explanations for these observations.

2.4 Pharmacology and Toxicology

The toxicology and pharmacology of anatoxin-a and homoanatoxin-a have been extensively studied and reviewed [39, 81], and we only present here the main facts and review the relevant literature since 2006. Anatoxin-a is highly toxic and provokes the rapid death of animals after ingestion or intraperitoneal (i.p.) injection [31]. Several animals have been tested (rats, mice, calves, ducks, fish) and they all show the same type of toxicity although with different sensitivity [81]. The mouse has been thoroughly used as a model in toxicological studies, and it shows a minimal lethal dose (LDmin i.p.) of 0.25 mg kg^{-1} and death occurs in 2–7 min. Homoanatoxin-a shows the same toxicological profile as anatoxin-a [39]. These alkaloids act as potent agonists of the muscular and neuronal nicotinic acetylcholine receptor (nAChR). The acute toxicity of anatoxin-a and homoanatoxin-a is the result of their binding to the nAChR at the neuromuscular junction, leading to the opening of the channel of this ionotropic receptor and thus to the flow of cations (K^+, Na^+, Ca^{2+}), provoking the depolarization of the cell membrane. Because these agonists are not degraded, their prolonged presence sustains the desensitized state of the receptor and provokes muscle paralysis and respiratory failure. Anatoxin-a binds to the muscular nAChR with Kd of 0.1–0.2 μM, and to the neuronal nAChR with Kd from 0.05 to 0.6 μM depending on the receptor subtype [39, 102]. Homoanatoxin-a shows similar binding capacities. Because these alkaloids have their conformation restricted, due to the aza-bicyclic moiety, they have been used as pharmacological probes to study the nAChR. It has been shown that (−)-anatoxin-a, the nonnatural enantiomer, does not bind to the receptor and that methylation of the amine decreases affinity by a 1,000 fold [39]. Many analogues with different

side chains have been described. They have helped to define the bioactive conformation of anatoxin-a, which appears to be the s-*trans* congener (Fig. 3.1) [39]. Other toxic effects of anatoxin-a have been studied such as developmental [103], genotoxic [104], or apoptopic [105] but the observed effects were limited.

2.5 Biosynthesis and Degradation

The first conclusive experiments concerning anatoxin-a and homoanatoxin-a biosynthesis were reported by Hemscheidt and colleagues in 1995 [106]. They used acetate and glutamate labeled with ^{13}C at different positions, in feeding experiments using *Anabaena flos-aquae* 37 and *Oscillatoria formosa* CYA-92 strains, the former producing anatoxin-a and the latter homoanatoxin-a. By purifying the toxins and recording their ^{13}C NMR spectra, these authors proposed a biosynthetic route starting from glutmate that would be reduced to (*S*)-pyrroline-5-carboxylate, which in turn would serve as the starter of a polyketide synthase that would incorporate three units of acetate. A decarboxylation and further unspecified steps were proposed to lead to anatoxin-a. It was proposed that homoanatoxin-a was formed by methylation of anatoxin-a on position C11. If the polyketide starter is in fact proline rather than (*S*)-pyrroline-5-carboxylate, the implication of PKS involvement would be correct (see below). The origin of the methyl group of homoanatoxin-a was also confirmed by feeding experiments, with *Raphidiopsis mediterranea*, using deuterium labeled methionine on its methyl group [107]. Later on, Méjean and coworkers used degenerate primers to amplify, by PCR, sequences coding for ketosynthase domain of PKSs, in the genome of *Oscillatoria* PCC 6506, a homoanatoxin-a producer [108]. Three sequences were identified and designated *ks1*, *ks2*, and *ks3*, all coding for KS-AT domains of PKS of unknown function. However, using a panel of 50 axenic strains taken from the PCC collection, these authors showed that the presence of *ks2* in the genome of a particular strain correlated perfectly with its ability to produce anatoxin-a or homoantoxin-a. This specific sequence was then identified in a cluster of nine genes that was identified in the genome sequence of *Oscillatoria* PCC 6506 [109]. This cluster, designated *ana*, was thus proposed to be responsible for the biosynthesis of anatoxin-a and homoanatoxin-a. Then, Ploux and colleagues proposed a complete biosynthetic scheme for anatoxin-a and

homoanatoxin-a by using a combination of bioinformatic analysis, feeding experiments as well, as in vitro biochemical experiments on isolated enzymes (Fig. 3.3) [33]. The biosynthesis starts from free proline, which is tethered to an acyl carrier protein (ACP) and oxidized to pyrroline-5-carboxyl-ACP. It is proposed that this molecule is then transformed by three consecutive PKSs. The first PKS, AnaE, should add one acetate unit that is completely reduced. The second PKS, AnaF, should add one acetate unit and should catalyze a Mannich cyclization that forms the azabicyclic homotropane structure of anatoxin-a and homoanatoxin-a. It has been proposed, on the basis of bioinformatics, that the protein coded by *orf1* participates in the cyclization reaction. The last PKS, AnaG, should add one acetate unit without any reduction, to yield 11-carboxylanatoxin-a or 11-carboxylhomoanatoxin-a, tethered to the ACP domain as thioesters. 11-Carboxylhomoanatoxin-a thioester would be formed by methylation on AnaG, which contains a methylation domain. The last step would be the hydrolysis of the thioesters to give 11-carboxyanatoxin-a or 11-carboxyhomoanatoxin-a that would give the corresponding toxin by decarboxylation. It is not yet clear if AnaA, a type II thioesterase, is implicated in these steps, but 11-carboxyanatoxin-a has actually been detected in extracts of *Aphanizomenon issatchenkoi*, an anatoxin-a producer [110]. The first steps of this biosynthesis, catalyzed by AnaC and AnaB, have been completely reconstituted in vitro, thus validating the predicted functions [111, 112]. AnaC is an adenylation protein very specific for proline, and AnaB is a flavoprotein oxidase homologous to isovaleryl-CoA dehydrogenase in terms of reaction mechanism and structure. The *ana* cluster has been recently identified in *Anabaena flos-aquae* 37 an anatoxin-a producer [113]. In that *ana* cluster, the genes *anaB, C, D, E, F, G* share strong sequence identity with those of *Oscillatoria* PCC 6506 and are arranged in the same manner. However, the gene *orf1* and *anaA* are located 7 kilobases downstream of the *ana* cluster. Thus, the *ana* cluster seems to be conserved in *Anabaena* and *Oscillatoria* genera, suggesting a common origin. The *ana* genes, or part of them, have been successfully used as genetic markers to track anatoxin-a or homoantoxin-a producers, in some reports [87, 100, 108, 113]. No transporter has been identified for anatoxin-a, and it is thus assumed that the toxin is released when the cells lyse during senescence. Several derivatives of anatoxin-a and homoanatoxin-a have been detected in cultures of cyanobacteria or in environmental samples (Fig. 3.2) [56, 66, 67, 107, 114]. The oxidized compounds, epoxy- hydroxyl-, or oxo-derivatives are thought to be degradation products after oxidation, although nothing is known about the reactions (catalyzed or not) leading to these derivatives. These compounds are not toxic. The reduced compounds, the dihydroderivatives, have been detected in environmental samples and are also assumed to be degradation products, although we still do not know how they are formed. However, it has been shown that dihydroanatoxin-a as a mixture of diastereoisomers, is quite toxic, retaining 10% of the toxicity of anatoxin-a [35, 37]. There is thus a need to determine these dihydroderivatives in the environment. Very little is known on the biodegradation of anaatoxin-a in the environment [115].

3 Anatoxin-a(s)

3.1 History, Chemistry, and Toxicology

Anatoxin-a(s) (Fig. 3.4) was discovered by Mahmood and Carmichael as a metabolite of *Anabaena flos-aquae* NRC 525-17 [4, 5]. This toxin was implicated in the death of wild animals (ducks, birds, swine) after ingestion of contaminated water. This cyanotoxin is a neurotoxin, but different from anatoxin-a, and this unique alkaloid is an irreversible inhibitor of acetylcholine esterase with a toxicology similar to that of known anticholinesterases such as paraoxon [116–119]. Anatoxin-a(s) provokes salivation (thus the suffix (s)), chromodacryorrhea, fasciculation, and urinary incontinence, and death within 7–20 min, on rats treated with 0.25–1.0 mg kg^{-1} (i.p.). The lethal dose LD_{50} (mouse, i.p.) is 50 μg kg^{-1} making

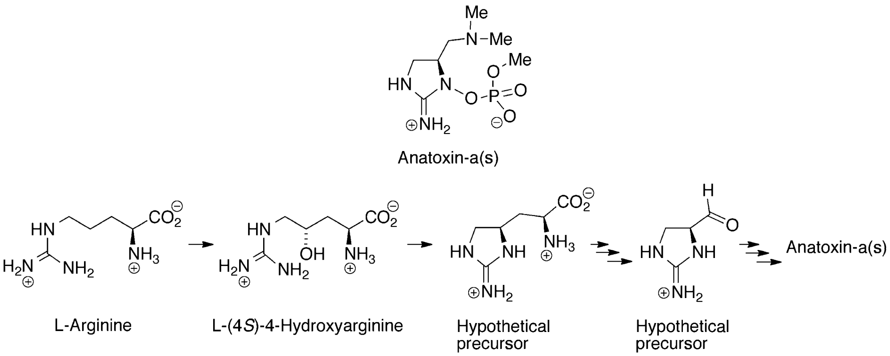

Fig. 3.4 Chemical structure of anantoxin-a(s) and the proposed biosynthetic pathway leading to this neurotoxin (Adapted from [122])

this toxin a very powerful poison. However, anatoxin-a(s) does not cross the blood-brain barrier and acts on peripheral acetylcholine esterase. The structure and the configuration of this compound were elucidated by Moore and colleagues [120]: anatoxin-a(s) is a unique guanidine methyl phosphate ester with a molecular weight of 252.0987 ($C_7H_{17}N_4O_4P$). Based on this structure, these authors proposed that anatoxin-a(s) inactivates acetylcholine esterase by reacting with the active-site serine that would be phosphorylated. Anatoxin-a(s) is dephosphorylated in basic solution but quite stable at neutral or acidic pH [120]. The total synthesis of anatoxin-a(s) has not yet been described but the synthesis of the cyclic moiety of anatoxin-a(s) has been reported [120, 121].

3.2 Occurrence and Detection

Anatoxin-a(s) has been detected in toxic blooms in lakes in Canada [4], Denmark [123, 124], and Brazil [125, 126]. So far, only a few cyanobacterial strains producing anatoxin-a(s) have been characterized: *Anabaena flos-aquae* [4], *Anabaena crassa* [126], and *Anabaena lemmermannii* [124]. The detection methods used to assay anatoxin-a(s) rely on the colorimetric assay for acetylcholine esterase [5], or on an electrochemical biosensor based on acetylcholine esterase activity [127, 128], or more recently on the use of LC-MS^2 [129].

3.3 Biosynthesis

Not much is known regarding the biosynthesis of anatoxin-a(s). Using radiolabeled arginine and deuterium labeled arginine and (4*S*)-4-hydroxy-arginine, Moore and coworkers have proposed a pathway starting from arginine and involving (4*S*)-4-hydroxy-arginine and further steps to yield to anatoxin-a(s), as shown in Fig. 3.4 [122, 130].

4 The Saxitoxin Family

4.1 History

Saxitoxin and its analogues are the causative agents of paralytic shellfish poisoning (PSP), which is one of the five major phycotoxin poisoning syndromes with a global impact. The paralytic shellfish toxins (PSTs) have historically been associated with blooms of saxitoxin-producing dinoflagellates in marine environments. Toxic mass-proliferating dinoflagellates can have devastating effects, such as mass mortalities of marine organisms, and cause substantial financial damage to aquaculture industries and fisheries. One of the most important aspects of these toxins is that they can accumulate to very high levels in marine invertebrates, which are utilized as seafood. PSP is usually caused by marine shellfish, which filter feed on toxic dinoflagellates, and thus accumulate the toxins [131]. Shellfish are highly resistant to the toxins [132], and may accumulate levels that can be fatal for humans, and a range of shellfish predators. Marine invertebrates other than shellfish [133, 134], as well as some fish species [135–138], may also accumulate PSTs to high levels that can cause illness or death when they are consumed [139]. The global incidence of PSP has been estimated at 2,000 cases per year globally with a mortality rate of 15% [140].

PSP is the longest known form of poisoning by phycotoxins. The earliest medical record dates back over 300 years [141, 142], and outbreaks of PSP with, at times, epidemic proportions, have been regularly reported from the eighteenth to the twenty-first century [143–145]. For a long time, the reason for the unpredictable and sporadic occurrence of shellfish toxicity was a mystery, until Sommer and coworkers identified certain species of dinoflagellates as the toxin producers [146, 147]. Since that discovery, it took almost 40 years until the chemical structure of saxitoxin, which was purified from the giant butter clam, *Saxidomus giganteus*, and cultured dinoflagellates could be determined by X-ray diffraction [21, 148], and a further decade before a highly unusual biosynthesis pathway for saxitoxin was inferred from isotope-labeled precursor feeding studies in conjunction with NMR [149, 150].

Although PSP is generally associated with marine dinoflagellates, they are not the only organisms that produce saxitoxin analogues. The first observation of a PSP-toxic cyanobacterial bloom of *Aphanizomenon flos-aquae* was made in the late 1960s in a freshwater body in New Hampshire (USA). A water-soluble toxin that was purified from this bloom, labeled aphantoxin, had similar chemical and pharmacological properties as saxitoxin [151–153]. Additional studies confirmed the identity of aphantoxin as saxitoxin and neosaxitoxin [154, 155]. Like dinoflagellates, cyanobacteria may form extensive blooms, and their toxins may accumulate in filter-feeding invertebrates, such as fresh water shellfish [156, 157], and their predators. PST-producing blooms of cyanobacteria can threaten the safety of drinking water supplies, potentially causing mass mortalities of aquatic organisms, livestock, and other animals consuming the water [158, 159].

4.2 Chemistry

4.2.1 Structural Diversity of Paralytic Shellfish Toxins

Saxitoxin is the principle component of more than 57 chemically related compounds that form the PST family [22]. They share a tricyclic perhydropurine backbone [21, 148], which can carry different functional groups at positions R1–R5 (Table 3.3). The carbamate toxins have a carbamoyl side chain at R1, and comprise saxitoxin (STX), neosaxitoxin (neoSTX), and gonyautoxins-1 to -4 (GTX-1 to -4). neoSTX differs from STX by an N1-hydroxylation (R2). GTX-2/-3 are the corresponding C-11-sulfated analogues of STX, whereas GTX-4/-1 are the corresponding sulfated C-11 analogues of neoSTX. The sulfated C-11 becomes a chiral center, where GTX-1 and GTX-4, and GTX-2 and GTX-3 are epimers of each other, respectively. *N*-sulfocarbamoyl toxins carry an N-linked sulfate group at the carbamate side chain. GTX-5 and GTX-6, which are also sometimes referred to as B-1 and B-2 toxins, are the corresponding *N*-sulfocarbamoyl toxins to STX and neoSTX, respectively. C-1/2 to C-3/4 toxins are the corresponding *N*-sulfocarbamoyl toxins to GTX-2/3 and GTX-1/4, respectively. Further adding to the diversity, toxins may have a hydroxyl group instead of a carbamoyl side chain (decarbamoyl analogues), or lack the hydroxyl group (deoxy toxins). Most of the aforementioned analogues have been detected in both cyanobacteria and dinoflagellates [160–162]. Some more unusual derivatives have been described and are listed in Table 3.4. In addition to the usual carbamate and decarbamoyl toxins, six new saxitoxin derivatives have been isolated from the cyanobacteria *Lyngbya wollei*, including derivatives that provide an acetyl side chain instead of the typical carbamate, or lack one of the C-12 hydroxyl moieties [163]. *N*-sulfocarbamoyl toxins that were C-11 hydroxylated were isolated from mussels [164]. Unusual modifications, such as the presence of a C-11 ethanoic acid side chain [165], or the *N*-hydroxylation of the carbamoyl side chain [166], have also been described for saxitoxin derivatives from several species of xanthid crabs, and from the freshwater puffer fish, where the carbamoyl side chain is *N*-methylated [167]. Three PSTs isolated from *Gymnodinium catenatum* possessed a hydroxybenzoate side chain, instead of a carbamoyl side chain [168]. The most unusual saxitoxin analogue is zetekitoxin AB (Scheme 3.1) from the Panamanian golden frog *Atelopus zeteki*. Its chemical structure has been a mystery for over 30 years and was recently confirmed to be a novel analogue of saxitoxin [169].

Like saxitoxin, zetekitoxin AB is a selective sodium channel blocker; however, its sodium channel blocking activity was 580-fold higher than that of saxitoxin [169]. Sadly, the Panamanian golden frog is now extinct.

4.2.2 Chemical Properties and Stability

PSTs are highly polar molecules. STX has two pKa values of 8.22 and 11.28 in aqueous solution, which belong to the 7,8,9 and 1,2,3 guanidinium groups, respectively [171]. neoSTX has an additional pKa of 6.75 due to its N-1 hydroxylation. The 1,2,3 guanidinium group is fully protonated at physiological pH, whereas the 7,8,9 guanidinium group is partially protonated. The C-12 hydroxyls are in

equilibrium between the hydrated and the keto form [21, 172]. At pH 7.7, only 1% of STX molecules are in the keto form, whereas that proportion rises to 24% at pH 8.4, and 36% at pH 9.8 [173]. Saxitoxin is highly stable under physiological conditions, but degrades slowly under alkaline conditions [171, 174]. The *N*-sulfocarbamoyl toxins are more labile, and readily hydrolyze the N-linked sulfate group. N-sulfocarbamoyl toxins, such as GTX-5, GTX-6, and the C-toxins, are thereby transformed to the corresponding carbamate toxins.

4.2.3 Synthesis

Chemical synthesis of saxitoxin analogues is challenging, in part because the unusual heterocyclic backbone is highly functionalized and susceptible to oxidation, and in part because of the high polarity of synthetic intermediates, which limits the range of suitable solvents for the chemical reactions [175]. The first chemical synthesis involved 20 steps, and had a total yield of only 0.25% [176]. Saxitoxin synthesis was improved in a later study [177]. Further studies focused on the selective synthesis of the natural (+)-enantiomers of STX and dcSTX [178–180], and the unnatural (−)-enantiomer of dcSTX [175]. These studies revealed that only the natural (+)-enantiomers had biological activity [181]. Other studies achieved the synthesis of GTX-3 [182]. The initial successful synthesis of saxitoxin triggered much debate with regard to potential misuses of this substance, and it was therefore scheduled as a chemical warfare agent of the highest category in the international chemical weapons convention, which came in effect in 1997.

4.2.4 Detection and Quantification

The detection and quantification of PSTs is challenging, because of the naturally low concentrations at which they occur, the high diversity of saxitoxin analogues, and some of their chemical properties, such as a small molecular weight, and high water solubility.

4.3 Biological and Biochemical Assays for PSTs

The Association for Official Analytical Methods (AOAC) has approved the mouse bioassay [183] as a standard method for the screening of PSTs in seafood. It involves the intraperitoneal injection of 1 ml acid extract into a 20 g mouse, and the recording of symptoms and time to death. One mouse unit (MU) is defined as the toxin amount that kills a 20 g mouse in 15 min, which is equivalent to 0.18 mg saxitoxin. An obvious drawback of this method is animal cruelty. In addition, this method is not specific for PSTs, and it is prone to interference from substances that are unrelated to PSTs. Also the dose-response relationship is not always linear.

Other biological assays have been developed that avoid the sacrifice of animals. The mouse neuroblastoma assay measures PSTs by the survival of cultured neuroblastoma cells after addition of extract. In this assay, Na^+/K^+-ATPase inhibitor ouabain and the sodium channel activator veratridine are added to neuroblastoma cells prior to the addition of toxin extract. PSTs that are present in the extract prevent the veratridine-induced influx of sodium ions into the cells, and thus prevent cell death. A commercially available kit version of this assay, the MIST shippable cell bioassay kit [184], showed good agreement in a comparative study to the mouse bioassay [185]; however, it performed unsatisfactorily in an AOAC international collaborative study in 1999, and there have been quality problems related to the shipping of the kit. The MIST kit was eventually replaced by the MIST Alert kit, which is an immunological assay that utilizes antibodies to STX, neoSTX, GTX1-4 [186]. Various other immunoassays exist [187].

The reversible nature of the binding of STX to voltage-gated sodium channels and the PST-binding protein, saxiphilin, is utilized in radioreceptor assays. The competitive displacement of tritiated saxitoxin from voltage-gated sodium channels or saxiphilin by PSTs from extracts is measured by a decrease in radioactivity in these assays [188–190].

4.4 Chemical Analysis of PSTs

A rapid and sensitive fluorescence spectroscopy method has been described that may be useful for applications, such as screening chromatographic fractions for the presence of PSTs [191].

Chemical methods that are based on high-pressure liquid chromatography (HPLC) with either fluorescence (HPLC-FLD), or tandem mass spectroscopic (LC-MS^2) detection are the methods of choice with regard to sensitivity and specificity, and have been used extensively in routine biotoxin monitoring programs [192]. The fluorometric detection of PSTs requires their oxidation, as only the oxidation products are fluorescent. Prechromatographic oxidation can be carried out in PSTs extracts prior to injection into the HPLC system [193, 194]; however, the chromatograms are not easily interpreted. Different PSTs may produce the same oxidation products, whereas some PSTs produce multiple oxidation products [195]. In HPLC methods with post-column oxidation, the toxins are oxidized after they have been separated and eluted from the column, but before they enter the detector [160, 192, 196]. Post-column oxidation methods require additional instrumentation, and careful control of flow rates and chemical composition of reagents and mobile phases. Separation of all saxitoxin analogues, including that of stereoisomers, can be achieved by using three separate runs with different isocratic elution conditions [160], or by using a solvent gradient [196]. Although HPLC-FLD is regarded as highly specific, there are cases where fluorescent compounds that are unrelated to PSTs can interfere [197]. Mass spectroscopic detection of PSTs can confirm the chemical identity, as well as quantify measured compounds. Several methods for the mass spectroscopic measurement of PSTs have been described [198–202]. Most of these methods are based on HPLC and electrospray ionization (ESI) in the positive mode. The most promising LC-MS^2 methods use hydrophilic interaction chromatography (HILIC) for the separation of PSTs prior to detection [199]. HILIC has high resolving power, and involves mobile phases with high concentrations of organic solvent, which favors the ionization of analytes in ESI, and thus the sensitivity of the method. Triple quadrupole-type MS^2 mass spectrometers are particularly suitable for the quantitative determination of known compounds [200]; however, the low mass resolution of these instruments prevents the detection of unknown compounds. Benchtop orbitrap mass spectrometers have become affordable, and their high mass resolution, sensitivity, and speed make them prime instruments for the quantitative measurement of PSTs, as well as for the unambiguous confirmation of known and novel toxins [198].

4.5 Phylogenetic Distribution of Paralytic Shellfish Toxins

Most cyanobacteria that produce PSTs belong to the order Nostocales, and include *Anabaena* spp. [161, 203], *Aphanizomenon flos-aquae* [154, 204–206], *Cylindrospermopsis raciborskii* [159, 207], and *Scytonema* [208]. There is also at least one PST-producing species, which belongs to a phylogenetic order that is distant from the Nostocales, such as the Oscillatoriales species, *Lyngbya wollei* [163, 209]. Furthermore, different isolates of the same species variably produce PSTs. A geographic segregation of toxin production has been observed for the species *Anabaena circinalis*, of which only Australian strains produce PSTs [210], while strains from America and Europe produce anatoxin-a [1, 5, 211].

In light of the biochemical uniqueness of PSTs, it is intriguing to find that cyanobacteria as well as dinoflagellates, which are not related to one another, are capable of producing these toxins. As with cyanobacteria, the capacity for PST production among dinoflagellates is distributed in an irregular manner. The majority of PSP-toxic dinoflagellates belong to the order Gonyaulacales; however, at least one representative from the distantly related order Gymnodiniales, *Gymnodinium catenatum*, is also known to produce PSTs [168, 212]. Species that include toxic strains also include strains that are nontoxic, whereas the toxin profile, which is considered to be constant in clonal isolates, differs between strains [213].

The divergent and irregular phylogenetic distribution of PST producer organisms sparked much debate regarding the primary source for these toxins, and their evolutionary origin. Proposals included that endo- or ectosymbiotic bacteria may be the original toxin producers [214–218]. A bacterial origin of PSTs may also explain the occurrence of PSTs in organisms, where cyanobacteria or dinoflagellates are unlikely the source. Examples include the calcareous red alga, *Jania* sp. [219, 220], xanthid crabs from coral reefs [166, 221], freshwater as well as marine puffer fish [135, 167, 222], and the Panamanian golden frog *Atelopus zeteki* [169]. The chemical identity of bacterial compounds suspected to be PSTs has not been determined conclusively, and a bacterial production of PSTs remains controversial.

4.6 Biosynthesis of Paralytic Shellfish Toxins

The structural resemblance between saxitoxin and purines of primary metabolism confounded efforts to determine the biosynthetic pathway for saxitoxin. Isotope-labeled precursor feeding studies revealed that saxitoxin is produced from arginine, acetate, and *S*-adenosylmethionine (SAM) by a unique pathway [149, 150, 223].

Arginine, minus its carboxylate group, the guanidino group of a second molecule of arginine, and an intact acetate unit form the tricyclic backbone. The methyl side chain is derived from SAM, whereas the origin of the carbamoyl side chain was uncertain but proposed to be derived from the guanidino group of a third molecule of arginine.

The loss of the arginine carboxyl suggested that acetate is linked to arginine by a Claisen-condensation in the initial step of biosynthesis (Fig. 3.5). The resulting intermediate would receive a guanidino group at its α-amine, whereby three heterocycles are formed. It was further proposed that the methyl side chain is introduced after cyclization, which gets subsequently epoxidized, opened to an aldehyde, and dehydrogenated to a hydroxyl. The reaction steps are: (1) Claisen-condensation between acetate and arginine; (2) amidino transfer from a second arginine to the α-amino group of intermediate B; (3) and (4), cyclization; (5), introduction of S-adenosyl methionine (SAM) methyl-derived side chain, involving the loss of one methionine methyl hydride; (6) 1,2-H shift; (7) epoxidation of methylene side chain; (8) opening of epoxide to an aldehyde; (9) reduction of the aldehyde to hydroxyl; (10) carbamoyl transfer and dihydroxylation of C-12

methyl and its hydroxylation has been studied in detail. Only one methionine methyl-derived hydrogen is retained in saxitoxin, and a 1,2-hydride shift was observed between acetate-derived C-5 and C-6. Shimizu [224] proposed that this incorporation pattern resulted from an electrophilic attack of methionine methyl (see step 5 in Fig. 3.5) on the double bond between C-5 and C-6, which would have formed during the preceding cyclization (see step 4 in Fig. 3.5). Subsequently, the new methylene side chain would be epoxidated, followed by opening to an aldehyde and subsequent reduction to a hydroxyl (see steps 7–9 in Fig. 3.5). This scheme should also lead to a 1,2-H shift between C-1 and C-5; however, this has not been observed [224]. Finally, the saxitoxin precursor is di-hydroxylated at ring carbon C-12, and receives a carbamoyl group at its hydroxymethyl side chain. Modifications at other positions may produce a great diversity of saxitoxin derivatives (Table 3.3).

4.7 Molecular Genetics of PSTs

The unique biochemistry of PSTs, combined with the divergent phylogenetic distribution of PST-producer organisms, made the identification of biosynthesis genes and enzymes an attractive and challenging target [225–229]. Kellmann and coworkers discovered the saxitoxin biosynthesis (*sxt*) genes in cyanobacteria [27, 230–232]. Saxitoxin biosynthesis is initiated by a novel modular polyketide synthase (SxtA), which has four catalytic domains that are related to *S*-adenosylmethionine-dependent methyl transferase (SxtA1), GNAT-acetyl transferase (SxtA2), acyl carrier protein (ACP) (SxtA3), and class II aminotransferase (SxtA4). The predicted function of SxtA was that SxtA2 would load SxtA3 with acetate from acetyl-CoA or malonyl-CoA, followed by a methylation of the distal methyl group of ACP-bound acetate by SxtA1. SxtA4 would catalyze a subsequent Claisen-condensation of the resultant ACP-bound propionate to arginine, and the first intermediate metabolite, 4-amino-3-oxo-guanidinoheptane, is released [27]. This compound was the predicted substrate for the amidinotransferase, SxtG, which would transfer an amidino group from arginine to its α-amine. Following the transfer, the SAM-derived methyl group gets desaturated by SxtD. The resulting double bond becomes epoxidated, and opened to an aldehyde with concomitant formation of two heterocycles. This scheme is consistent with the lacking 1,2-hydride shift between C-1 and C-5 as observed by Shimizu et al. [149]. The latter sequence of reactions is catalyzed by the α-ketoglutarate-dependent dioxygenase SxtS, which produces succinate from α-ketoglutarate. The aldehyde side chain becomes reduced to a hydroxymethyl side chain by SxtU, a short-chain alcohol dehydrogenase, and carbamoylated from carbamoylphosphate by the *O*-carbamoyltransferase, SxtI. Two highly similar dioxygenases, SxtH and SxtT, finalize biosynthesis by introducing two hydroxyl groups at C-12. SxtH and SxtT require regeneration after each catalytic cycle, which may be performed by the succinate dehydrogenase-like enzyme SxtV, with the involvement of a ferredoxin (SxtW). The revised scheme for saxitoxin biosynthesis is depicted in Fig. 3.6. In addition to these core biosynthesis enzymes, the *sxt* gene cluster encodes proteins with functions that are related to the modification of saxitoxin or its intermediates to produce the various analogues, to cellular transport of PSTs, transcriptional regulation, and other functions.

Fig. 3.6 Revised pathway for saxitoxin biosynthesis and the putative functions of *sxt* genes (adapted from Kellmann et al. [27]). Abbreviations used were: *ACP* acyl carrier protein, *ACTF* acetyltransferase, *AONS* 8-amino-7-oxononanoate synthase, *CARBP* carbamoyl phosphate, *MTF* methyltransferase, *NAD(P)* nicotinamide adenine dinucleotide (phosphate)

The new molecular genetic data indicated that saxitoxin biosynthesis proceeded in a different sequence than previously proposed [149], and would consequently involve different intermediate metabolites. Such metabolites were detected by LC-MS^2 analysis in cyanobacterial extracts, which supported the putative functions of *sxt* genes [27].

Phylogenetic analysis revealed that the majority of *sxt* genes have evolutionary origins from within cyanobacteria, whereas the remainder originated in other bacteria [27, 230]. More detailed phylogenetic analysis suggests that saxitoxin is an ancient metabolite that may have evolved in cyanobacteria early in the evolutionary divergence of the Nostocales at least 2,100 Ma ago [233]. The apparent cyanobacterial roots of PSTs are intriguing and raise the question how dinoflagellates, which are eukaryotic organisms, have evolved or acquired the capacity to produce the same toxins. Mass sequencing of expressed sequence tags have revealed *sxt* homologues in the genomes of PST-producing dinoflagellates [234]. The study by Stüken et al. suggests that dinoflagellates have acquired an entire metabolic pathway from cyanobacteria in one or multiple ancient horizontal gene transfer events. One can only speculate that the ancient cyanobacterial ancestors to extant chloroplasts might have been the donors for *sxt* genes in dinoflagellates.

4.8 Toxicology and Pharmacology

Saxitoxin and its analogues are potent blockers of voltage-gated sodium channels that reside in the membranes of excitable cells [235]. They also block or modulate cardiac ion channels, such as L-type calcium channels [7], and hERG potassium channels [8], although at a much lower potency. The intraperitoneal LD_{50} of saxitoxin is 10 μg/kg body weight in mice, while human death has occurred following the ingestion of as little as 1 mg of the toxin [236]. The toxicity of saxitoxin derivatives varies greatly. The carbamate toxins (STX, neoSTX, GTX-1 to -4) are 10–200 times more potent than corresponding *N*-sulfocarbamoyl derivatives (GTX-5/-6 and C-toxins). *N*-sulfocarbamoyl analogues are labile, however, and may easily be converted to their corresponding carbamates [237, 238]. Structure-activity relationships of PSTs are reviewed in detail by Llewellyn [239].

The clinical effect of saxitoxin is restricted to acute symptoms, which generally occur within minutes of ingestion. Poisoning invariably begins with a tingling or numbness of the lips, tongue, and throat [240]. This altered sensation may spread to the neck and extremities, and progress to muscular weakness, loss of motor coordination, and an ascending paralysis of the body. Gastrointestinal symptoms, such as nausea, vomiting, and diarrhea, may sometimes occur during the early stages. PSP may also cause severe hypertension in victims [241], and animal experiments indicated that PSTs alter dopamine levels in the brain [242]. In severe cases, PSP may lead to sudden death of previously fully conscious victims, due to cardiopulmonary failure. So far, there is no clinically approved antidote to saxitoxin. The drug, 4-aminopyridine, is in experimental stages, and produced a striking reversal of saxitoxin-induced cardiopulmonary depression in guinea pigs without serious side effects [243–245]. Treatment of PSP remains symptomatic until a drug has been approved. Removal of unabsorbed toxin by emesis or lavage, and treatment with activated charcoal, which effectively absorbs saxitoxin at gastric pH, are important during early stages of poisoning. Artificial respiration is the most vital treatment in moderate cases; however, it may not be sufficient to save the victim's life, if the poisoning is more severe [246]. The first 12h are most critical for the survival of a victim [247]. Permanent or chronic effects of PSP have not been reported; however, muscular weakness may persist for several weeks.

4.8.1 Voltage-Gated Sodium Channel

Various isoforms of voltage-gated sodium channels exist. They are encoded by nine genes in the human genome as reviewed by Catterall [248]. $Na_v1.1$, $Na_v1.2$, $Na_v1.3$, and $Na_v1.6$ are primary sodium channels of the central nervous system, whereas $Na_v1.7$, $Na_v1.8$, $Na_v1.9$ are primarily expressed in peripheral neurons. $Na_v1.4$ and $Na_v1.5$ are primarily expressed in skeletal and heart muscle, respectively.

Voltage-gated sodium channels are multi-subunit proteins, where the ion channel consists of a 260 kDa large α-subunit, which may bind β-subunits that modify the gating behavior [249, 250]. The α-subunit consists of four homologous domains. Each domain provides six membrane-spanning regions, and three loops that protrude from the membrane into the extra- and intracellular space. The three-dimensional structure of voltage-gated sodium channels has been examined by X-ray crystallography and NMR [251], and by cryo-electron microscopy [252]. The membrane-spanning regions are arranged circumferentially around a central pore, whereas the loops form a bell-shaped structure that provides a network of channels, which connects the central pore to the intra-, and extracellular spaces. The loop that connects segments 5 and 6 of each of the four domains is part of the selectivity filter. It protrudes into the outer vestibule of the central pore, and is also termed the pore (P-) loop. The P-loop represents toxin-binding site 1, which binds site 1 toxins, such as saxitoxin, tetrodotoxin, and μ-concotoxins [253]. Specific interactions of saxitoxin with amino acids of the P-loop have been mapped by mutational studies, homology modeling, and ligand docking [254–260]. Each P-loop has a conserved sequence motif with saxitoxin-binding residues. The 7,8,9 guanidinium group of saxitoxin binds to D400 of domain I, and E755 of domain II via salt bridges, whereas the 1,2,3 guanidinium group makes a salt bridge to D1532 of domain IV. Hydrogen bonds are formed between the two hydroxyls at C-12 and E758 of domain II, as well as between the carbamoyl amine and E403. Hydrophobic interactions between M1240 of domain IV and hydrophobic regions of saxitoxin also make an important contribution to the binding of saxitoxin in the channel [257]. A schematic drawing of the orientation of gonyautoxin-4/1 in the outer vestibule is shown in Fig. 3.7.

The various functional groups of saxitoxin analogues have different effects on their affinity to the channel. The N-1 hydroxyl of neoSTX, a lacking carbamoyl

side chain, or its replacement by a bulky hydroxybenzoate has little effect on toxicity. On the other hand, the *N*-sulfocarbamoyl side chain reduces toxicity over 200-fold. The sulfate at C-13 in turn decreases toxicity only slightly, whereas there is a notable difference in the response between α- and β−epimers [239, 261, 262].

4.8.2 The Pharmacological Potential of PSTs

The useful pharmacological properties of PSTs for medical treatment have been recognized for over three decades, and motivated the development of a variety of patented medical and cosmetic treatments (Table 3.5). They include local injection of PSTs to treat chronic anal fissures [263–267], tension headaches [268], and local anesthesia [269–271]. A major advantage in using site 1 sodium channel blocking toxins is that they lack central nervous system, cardiac, and

Table 3.5 Examples of patented medical applications of PSTs

Title	Patent or application number (date)	Type of PST analogue	Application
Sensory-specific local anesthesia and prolonged duration local anesthesia	US 044549 (2009)	STX, neoSTX, dcTSX, GTXs	Local anesthesia
Phycotoxins and uses thereof	US 0021051 A1 (2008)	GTX-1 to -5	Muscle spasm, facial cosmetics
Transdermal administration of phycotoxins	US 0045553 A1 (2008)	STX, dcSTX, neoSTX, GTXs	Muscle relaxation facial cosmetics
Methods of treating wounds with gonyautoxin	US 0280970 (2007)	GTXs	Chronic anal fissures
Prolonged suppression of electrical activity in excitable tissues	US 0202093 A1 (2005)	STX, neoSXT, dcSTX, GTXs	Epilepsy
Method of local anesthesia and analgesia	US 6599906 (2003)	STX	Local anesthesia
Method of anesthesia	US 6030974 (1998)	STX, neoSTX, GTXs	Local anesthesia (veterinary medicine)
Local anesthetic formulations	US 6326020 B1 (1998)	STX, dcSTX, neoSTX	Local anesthesia
Pharmaceutical local anesthetic composition employing saxitoxin	US 4001413 (1977)	STX	Local anesthesia
Spinal anesthesia using small amount of saxitoxin	US 3892847 (1975)	STX	Local anesthesia

Abbreviations used were *STX* saxitoxin, *neoSTX* neosaitoxin, *dcSTX* decarbamoylsaxitoxin, *GTXs* gonyautoxins

local neurotoxicity [271–273]. Local injection of saxitoxin has been shown to provide a prolonged nerve block with minimal systemic and local toxicity that can be utilized in periprocedural care and pain management [269].

5 Conclusion

More than five decades of research have revealed the chemistry, toxicology, and distribution of the most clinically relevant cyanobacterial neurotoxins. More recently, the genetic basis for the biosynthesis of the alkaloid neurotoxins, anatoxin-a, homoanatoxin-a, and saxitoxin have been elucidated [27, 33]. Advances in analytical techniques and molecular genetic methods are continuing to reveal novel toxin isoforms in a wide range of producing organisms. In particular, PCR-based methods exploiting conserved regions of cyanotoxin biosynthesis genes are being used to screen environmental samples for candidate toxin pathways. These techniques are also being developed for the routine monitoring of water bodies and seafood destined for human consumption [274, 275], and to determine the environmental conditions under which favorable toxin production occurs (for review see [276]).

While the gene clusters responsible for the biosynthesis of several of the most toxicologically important cyanobacterial neurotoxins have been identified and sequenced (with the notable exception of anatoxin-a(S)), most of the individual genes encoded therein have not been functionally verified. Conventional characterization via mutagenesis is hampered by the fact that most of the producing organisms are difficult to culture and/or are not readily amenable to genetic manipulation. Therefore, most of the experimentally characterized steps in these neurotoxin biosynthesis pathways have been investigated using a biochemical/enzymatic approach. Nonetheless, detailed characterization of these enzymes will broaden our understanding of the mechanisms of neurotoxin biosynthesis, modification, and transport and may additionally provide us with a means to bioengineer these pathways to produce novel compounds for the treatment of neurological disease. For example, anatoxin-a has been identified as a good core structure for the symptomatic treatment of Alzheimer's disease as it activates nicotinic acetylcholine receptors and readily crosses the blood-brain barrier [37]. Bioengineering of the anatoxin-a pathway could potentially yield a novel anatoxin-a analogue for the treatment of patients with reduced nicotinic acetylcholine receptor function.

Another interesting field of research is the evolution of neurotoxin biosynthesis. The presence of transposase genes in or proximal to neurotoxin gene clusters suggests that neurotoxicity may be transferred horizontally between cyanobacteria and perhaps to other organisms. The recent discovery of saxitoxin biosynthesis gene clusters in eukaryotic dinoflagellates provides evidence in support of this theory [234]. Remarkably, this is the first and only example of a secondary metabolite pathway shared across two kingdoms of life.

While the anatoxins and saxitoxins are generally considered to be the most toxicologically significant of the cyanobacterial neurotoxins, recent interest in other neurotoxin pathways has generated some interesting data. For example, the gene cluster responsible for the biosynthesis of the lipopeptide jamaicamides was recently characterized in *Moorea (Lyngbya) majuscula* [9]. This remarkable set of collinear genes includes novel biosynthesis and tailoring enzymes that create the various unusual functional groups in jamaicamide A, such as the rare alkynyl bromide moiety. Another cyanobacterial neurotoxin that has generated recent interest as well as controversy is the nonproteinogenic amino acid BMAA [14]. While a biosynthesis pathway for BMAA in cycads has been postulated [277], research by Cox et al. revealed that it is the cyanobacterial endosymbionts rather than their plant hosts that are the original producers of BMAA [278]. The discovery of a BMAA pathway in cyanobacteria is anticipated in the near future.

In conclusion, while many of the details pertaining to the chemistry and toxicology of the cyanobacterial neurotoxins have been elucidated, there are still significant knowledge gaps relating to their biosynthesis and evolution. Furthermore, we are yet to discover the true function of these mysterious compounds in their native blue-green algal hosts.

Abstract

Catharanthus roseus is an ornamental plant belonging to the Apocynaceae family which produces flowers of different color for most of the year. Besides its importance as an ornamental plant, its interest today is centered on its capacity to biosynthesize a great variety of terpenoid indole alkaloids (TIAs), which have a high added value due to their wide spectrum of pharmaceutical applications. The most important TIAs are the two antitumoral alkaloids, vinblastine and vincristine. Likewise, *C. roseus* also produces ajmalicine used as antihypertensive and serpentine used as sedative. The high cost of these alkaloids is due to the very small amounts that occur in *C. roseus* and the difficulty of their extraction which is carried out in the presence of many other compounds. This problem has created the need to find alternative sources to produce these compounds. In this respect, plant tissue/cell cultures could be a useful alternative source of pharmacologically active *C. roseus* alkaloids, but, even so, these have only been obtained in very low concentrations and after a substantial amount of research. This problem has stimulated intense research into the biosynthesis of TIAs and in the regulation of its pathways, with the aim of increasing the production of these high-value compounds by biotechnological approaches.

The aim of this chapter is centered on different strategies to improve TIA production which have been developed, including screening and selection of high-yield cell lines, optimization of culture conditions, feeding and elicitation strategies, and the metabolic engineering of TIA biosynthetic pathway. An up-to-date view on the biosynthesis of TIAS is also given. Although not yet successful, metabolic engineering offers the most promising perspective for improving TIA production in the future, as increases the knowledge of the genetic determination and regulation of the TIA pathway.

VH	Vinorine hydroxylase
VS	Vinorine synthase

1 Introduction

Alkaloids are secondary metabolites containing nitrogen in their molecules, usually in a heterocyclic configuration. The nitrogen atom is usually basic conferring alkalinity to the molecule and hence the name alkaloids. Alkaloids were initially isolated exclusively from higher plants, and until the middle of this century, they were referred to as typical plant products. Later, they were also found in bacteria, fungi, algae, and even in animals. Nevertheless, flowering plants, especially dicotyledonous species, are the main source of alkaloids. As secondary metabolites, alkaloids are thought to play a defensive role against herbivores and pathogens. This group of natural compounds exhibits some of the most complicated molecular structures and also strong physiological activity in humans and animals. Owing to their potent biological activity, alkaloids have been exploited as pharmaceuticals, stimulants, narcotics, and poisons. Alkaloid biosynthesis in plants involves many steps, catalyzed by enzymes that belong to a wide range of protein families. The characterization of alkaloid biosynthetic enzymes in terms of biochemistry, molecular biology, and biotechnological applications has been the focus of extensive research in recent years.

C. roseus is an ornamental and medicinal plant of enormous pharmaceutical interest because it is nothing less than a chemical factory, producing more than 130 TIAs, some of which exhibit strong and important pharmacological activities [1]. The most important TIAs are the two antitumoral alkaloids, vinblastine (used in the treatment of Hodgkin's disease, non-Hodgkin lymphomas, and several kinds of carcinomas) and vincristine (used against acute children leukemia, Hodgkin's disease, non-Hodgkin lymphomas, some types of sarcomas, and breast cancer). In fact, these two alkaloids were the first natural products used in anticancer chemotherapy and, together with a number of semisynthetic derivatives, are universally known as the vinca alkaloids. Likewise, *C. roseus* also produces ajmalicine used as an antihypertensive to combat heart arrhythmias and to improve blood circulation in the brain and serpentine used as a sedative [1, 2]. The great pharmacological importance of vinblastine and vincristine, allied with their low availability in *C. roseus* (approximately half a ton of dry leaves is needed to obtain 1 g of vinblastine), has stimulated intense research into the biosynthesis of TIAs and in the regulation of its pathways, with the aim of increasing the production of these high-value compounds by biotechnological approaches. At present, much is known about TIA biosynthesis, despite the length and the complexity of the pathway involved. Starting from the amino acid tryptophan and the monoterpene geraniol, TIA biosynthesis in *C. roseus* involves at least 35 intermediates and 30 enzymes [2]. All TIAs in *C. roseus* are derived from the central precursor strictosidine, which is a fusion product of the shikimate-pathway-derived tryptamine moiety and the plastidic nonmevalonate pathway-derived secologanin moiety. After deglycosylation of strictosidine, the TIA biosynthetic pathway splits into several branches, among them, a short pathway leading to ajmalicine, and two long branches leading to vindoline and catharanthine, the monomeric precursors of vinblastine and vincristine. Quite a few enzymes have been isolated, and several genes are now well identified. TIA biosynthesis also involves at least seven different intra- and intercellular compartments indicating that extensive transport of intermediates is required, as evidenced from the cell-type-specific expression of biosynthetic genes [3, 4]. Likewise, TIA biosynthesis is under strict developmental and environmental control. Lastly, transcription factors have been identified in *C. roseus* as being responsible for coordinating gene expression in response to external and internal signals [5].

The application of genomics to alkaloid metabolism has accelerated the discovery of cDNAs encoding enzymes implicated in their biosynthetic pathway [6, 7]. Also, large-scale gene expression analyses and metabolic engineering approaches with transgenic plants have provided new insights into the regulatory architecture of the alkaloid metabolism. The integration of genome-wide transcript and metabolic profiles will enable not only to visualize most of the genes involved in TIA biosynthesis but also to draw the nondescribed gene-to-gene and gene-to-metabolite networks and so to design biotechnological strategies to improve the production of these compounds [7]. In this chapter, we discuss recent advances toward understanding the complex TIA biosynthetic pathway, its regulation, and how to gain knowledge from biotechnological, genomic, and metabolic approaches in order to improve the production of these much desired compounds.

2 Distribution of Terpenoid Indole Alkaloids in Plants

The TIAs form a family of more than 3,000 representatives. These alkaloids, which are unique in plants, have been found in several plant families such as Apocynaceae, Loganiaceae, Nyssaceae, and Rubiaceae, which belong all to the Gentianales order. The most important and well-known plants that produce TIAs are *Tabernaemontana divaricata*, *Rauvolfia serpentina*, and *C. roseus* [1].

Catharanthus is a perennial plant belonging to the Apocynaceae family and comprises eight species, seven endemic to Madagascar (*C. coriaceus*, *C. lanceus*, *C. longifolius*, *C. ovalis*, *C. roseus*, *C. scitulus*, *C. trichophyllus*), and one, *C. pusillus*, from India. Specifically, *C. roseus* has been extensively cultivated in subtropical and tropical areas of the world [1] as an ornamental plant and now has a pantropical distribution. It is naturalized in continental Africa, the North and South America, Asia, Australia and southern Europe, and on some islands in the Pacific Ocean. Today, more than 100 cultivars are commercially available.

3 The Biosynthetic Pathway of Terpenoid Indole Alkaloids

The biosynthesis of TIAs in *C. roseus* is extraordinarily complex, involving more than 50 metabolic steps to synthesize the most important alkaloids. To date, only about 20 of the 50 enzymes required for their biosynthesis have been determined and characterized [2]. Thus, there are still a number of important enzymes that need to be characterized, which can only be done after the isolation and cloning of the relevant genes. It is also of fundamental importance to elucidate the regulatory aspects of TIA biosynthesis, both at the cellular and the molecular level, in order to address the question of their function in the plants and to improve their production by biotechnological approaches.

3.1 The Biosynthesis of the Terpenoid Indole Alkaloid Precursors, Tryptamine and Secologanin

The two main metabolites from which the TIAs found in *C. roseus* are biosynthesized are tryptamine and secologanin. They arise from two independent metabolic pathways and require the coordination of the intermediate levels supplied by the TIA pathway. The indole precursor, tryptamine, is derived from the shikimate pathway, whereas the monoterpene glucoiridoid precursor, secologanin, involves a much more complex branching route than the shikimic acid pathway used to supply tryptophan for tryptamine biosynthesis. Plants have two independent routes to biosynthesize the precursor used for monoterpene formation, isopentenyl diphosphate (IPP), which in turn, work in different cellular compartments: the classical pathway of acetate/mevalonate in the cytoplasm and the route of 1-deoxy-D-xylulose-5-phosphate in the plastids. According to Contin et al., secologanin mainly comes from the IPP produced via the plastidic pathway, which involves the formation of 2-methyl-erythritol 4-phosphate (MEP) [8]. However, data in the literature suggest that the mevalonate pathway also participates in the biosynthesis of this monoterpene which is essential to the biosynthesis of secologanin, although to a lesser degree [9]. IPP is turned into its isomer, dimethylallyl diphosphate (DMAPP) by the isopentenyl-diphosphate isomerase (IPP isomerase) (Scheme 4.1). The condensation of DMAPP with one molecule of IPP generates geranyl diphosphate (GPP) in a reaction catalyzed by geranyl diphosphate synthase (GPP synthase), initiating the biosynthesis of monoterpenes. The next step of the iridoid pathway is the conversion of GPP into geraniol by a phosphatase. Geraniol is the first product to channel the carbon skeleton toward the biosynthesis of monoterpenes. Then, geraniol is converted to 10-hydroxygeraniol by geraniol-10-hydroxylase (G10H), which is a P450 monooxygenase [10]. It has been suggested that this enzyme compromises the geraniol carbon skeleton to the biosynthesis of secologanin and represents an important regulatory point. Accordingly, G10H activity is induced under conditions that produce an increase in the alkaloid content and is inhibited by the addition of phosphates, which causes a decrease in the alkaloid content. Also, G10H is the only enzyme that is inhibited by the accumulation of catharanthine, showing a feedback inhibition. From 10-hydroxygeraniol to the biosynthesis of secologanin, there are at least 10 enzymatic steps. However, only six are known, and most enzymes have not been fully characterized. In fact, the steps after G10H in the secologanin pathway have not been well characterized, although it is known that the formation of loganin is produced from 7-deoxyloganin acid in a reaction catalyzed by loganic acid methyltransferase (LAMT). The last step to the conversion of loganin into secologanin is catalyzed by secologanin synthase (SLS), a second P450 monooxygenase (Scheme 4.1) [2].

The amino acid tryptophan produced by the shikimate pathway is decarboxylated to tryptamine by tryptophan decarboxylase (TDC) using pyridoxal phosphate as cofactor. TDC has been purified from suspension cultures and hairy roots of *C. roseus* and was shown to be a cytosolic enzyme whose activity is modulated by a variety of factors [11, 12]. In fact, TDC activity increases in cultures of *C. roseus* in response to fungal elicitors and the addition of hydrolytic enzymes, by increasing both gene transcription and mRNA levels [13]. However, auxins repress *tdc* gene expression [14]. In addition to being regulated by external factors including UV light, TDC is also tissue-specific and developmental regulated [15]. The *tdc* gene occurs in a single copy in *C. roseus*. The amounts of

TDC in seedlings and cell suspensions show that both gene expression and enzymatic activity are induced in a transient form, suggesting that TDC activity is regulated at transcriptional, translational, and posttranslational levels [2, 16].

3.2 The Biosynthesis of Strictosidine, a Universal Glucoalkaloid Precursor of all Terpenoid Indole Alkaloids

Tryptamine and secologanin are condensed to form strictosidine (Scheme 4.2), the universal glucoalkaloid precursor of all the TIAs isolated from *C. roseus*. The enzyme that catalyzes this condensation is strictosidine synthase (STR). This enzyme is highly specific for its two substrates, and it is inhibited by the end products of this metabolic route [17]. STR is a soluble enzyme and has different isoenzymes distinguishable by their catalytic activities and their pI. The occurrence of these isoenzymes is not related to the developmental stage or to tissue-specific regulation since they are expressed equally in suspension cultures, leaves, stems, and roots [18]. These data suggest that these isoenzymes could be the result of different patterns of glycosylation of the protein, although the types of carbohydrates present have not yet been characterized. The function of these STR isoforms is not known. STR is encoded by a single gene, suggesting that isoforms are the result of posttranslational modifications of a single precursor [19]. In *C. roseus*, the s*tr* gene is regulated by a wide variety of signals including auxins, methyl jasmonate (MeJa), and fungal elicitors in cell cultures and by tissue-specific control in plant organs [16]. However, it is not yet clear if this enzyme is regulated by the developmental process. Some evidence suggests that STR does not constitute a limiting step in TIA biosynthesis in seedlings of *C. roseus*. In fact, when *C. roseus* suspension cells were transferred from a maintenance medium into an induction medium in order to produce alkaloids, the increase in the accumulation of alkaloids does not correlate with an increase in STR activity. On the other hand, in *C. roseus* callus transformed with s*tr* gene, a direct correlation between the increase of the enzymatic activity and the accumulation of alkaloids was observed [20]. These results suggest the possibility that the STR may indeed be a rate-limiting step of the TIA pathway. Nevertheless, the information is imprecise and sometimes contradictory, which emphasizes the necessity to expand the investigation that allow us to establish the real role of STR in TIA biosynthesis [2, 9, 16].

3.3 The Biosynthesis of Terpenoid Indole Alkaloids from Strictosidine

The following step in the biosynthesis of the TIAs consists in the deglycosylation of strictosidine by strictosidine β-glucosidase (SGD) to form the strictosidine aglycone, which is an unstable product rapidly transformed into 4,21-dehydrogeissoschizine (Scheme 4.2). SGD is a glycoprotein localized in the endoplasmic reticulum and is highly specific for strictosidine [21]. This enzyme

is codified by a single gene that has recently been cloned, and it is expressed at different levels in flowers, stems, leaves, and roots, suggesting a tissue-specific regulation [9]. In addition, the enzymatic activity in each organ is proportional to the mRNA amount detected. Since the level of SGD expression is induced by MeJa, and its activity is increased in cultures that accumulate TIAs, this enzyme is considered a key step in the biosynthesis of these compounds [2, 9, 19]. On the other hand, 4,21-dehydrogeissoschizine represents a key intermediate that leads to the biosynthesis of several TIAs including catharanthine, tabersonine, ajmalicine, and ajmaline (Fig. 4.1).

The biosynthesis of ajmaline involves several enzymatic steps (Scheme 4.3) [2, 9]. The first metabolic step is the oxidation of 4,21-didehydrogeissoschizine to geissoschizine in a reaction catalyzed by geissoschizine dehydrogenase (GD), followed by the formation of polyneuridine aldehyde through the action of sarpagan bridge enzyme (SBE). The resulting polyneuridine aldehyde is transformed by polyneuridine aldehyde esterase (PNAE) into epi-vellosimine, which is acetylated to form vinorine by vinorine synthase (VS). Then, vinorine is hydroxylated by vinorine hydroxylase (VH) to form vomilenine. VH is completely dependent of NADPH and oxygen, and it is located in the microsomal fraction [22]. VH is inhibited by typical inhibitors of cytochrome P450 proteins so that this monooxygenase is surely a cytochrome P450 protein. The last known step in ajmaline biosynthesis is the saturation of the indolamine double bond of vomilenine to produce 1,2-dihydrovomilenine by 1,2-dihydrovomilenine: NADP$^+$ oxidoreductase (VR) which is a NADPH-dependent enzyme [23]. The last steps leading to ajmaline biosynthesis are not well known.

4,21-Dehydrogeissoschizine may also be converted to cathenamine in a reaction catalyzed by cathenamine synthase (CS) [24]. This compound is the basis for the formation of ajmalicine by the action of the enzyme cathenamine reductase (CR), and then, ajmalicine is thought to be oxidized to serpentine by class III peroxidases (Prx) localized in the vacuoles, with its production being strongly regulated by light (Scheme 4.4, [25]).

While the biosynthesis of catharanthine and tabersonine is poorly characterized (Scheme 4.5), the biosynthetic pathway from tabersonine to vindoline has been extensively studied [2]. Thus, the hydroxylation of tabersonine at position 16 represents the first reaction leading to vindoline (Scheme 4.6), and it is catalyzed by tabersonine 16-hydroxylase (T16H), a cytochrome P450-dependent enzyme

localized in the endoplasmic reticulum [26]. Then, 16-hydroxytabersonine is *O*-methylated by 16-hydroxytabersonine 16-*O*-methyltransferase (16OMT), which has been found both in plants and cell cultures of *C. roseus* [27]. The third reaction is a hydration of the 2,3 double bond, and the subsequent step involves a *N*-methylation of 16-methoxy-2,3-dihydro-3-hydroxytabersonine by a partially characterized *N*-methyltransferase (NMT) to produce desacetoxyvindoline. This enzyme, which is localized in the thylakoids, requires *S*-adenosyl-methionine as methyl donor and is highly specific for its substrate [28]. Desacetoxyvindoline is then converted to deacetylvindoline by the cytosolic enzyme desacetoxyvindoline-4-hydroxylase (D4H), and the last step consists in the acetylation of deacetylvindoline by deacetylvindoline-4-*O*-acetyltransferase (DAT) to form vindoline [29].

The biosynthesis of vindoline is regulated by developmental processes and is restricted to the young leaves and cotyledons of adult plants. In these tissues, high mRNA levels as well as enzymatic activity have been detected [30]. In cell cultures of *C. roseus*, enzymatic activity of T16H and 16OMT, but not NMT, D4H, and DAT, has been detected [31, 32]. Also, in plantlets of *C. roseus*, the effect of light on D4H and DAT activity is mediated by phytochrome since these proteins are activated by a pulse of red light (660 nm), and this activation is reverted by a pulse of far red light (710 nm [33]). In fact, after exposing plantlets to light, the transcript levels, the protein amount, and the activity of D4H and DAT increased significantly. MeJa also induces the vindoline accumulation and increases the enzymatic activity of D4H and DAT, STR, and TDC [34].

Finally, the monomeric precursors vindoline and catharanthine are coupled in a reaction thought to be catalyzed by a class III Prx, namely, CrPrx1, to yield the dimeric alkaloid 3′,4′-anhydrovinblastine, which is converted into vinblastine and then into vincristine (Scheme 4.7) [35, 36].

4 Compartmentalization and Cellular Differentiation in the Biosynthesis of Terpenoid Indole Alkaloids

In *C. roseus*, TIA biosynthesis is a highly dynamic, complex, and compartmentalized process in which different branching routes are expressed in a tissue-specific form. The enzymes that have been characterized are associated to different cell types and found in different subcellular compartments [4]. The compartmentalization and localization involved in the TIA pathway is considered another regulatory mechanism, since this localization requires the transport of different metabolic intermediates from one point to another, for their transformation. TDC, SLS, and STR are localized in the epidermal cells of aerial organs and root apical cells, while D4H and DAT are restricted to the laticifer cells and idioblasts of leaves, stems, and floral buds, and G10H is found in the internal phloem parenchyma of aerial organs [3, 37]. This means that, at least during vindoline biosynthesis, alkaloid intermediates must be translocated from one leaf cell type to another. In fact, vindoline biosynthesis is organ-tissue-cell regulated, since it is detected in the aerial organs, mainly in juvenile tissues, but not in roots, while catharanthine as well as strictosidine, ajmalicine, and serpentine are isolated from both roots and leaves. Moreover, enzymes involved in TIA biosynthesis in *C. roseus* are localized in different subcellular compartments (Fig. 4.2). Thus, the cytochromes P450 as G10H, SLS, and T16H are located in membranes, most likely from endomembrane systems, specifically from endoplasmic reticulum (ER) similar to the localization has been determined for SGD, a soluble enzyme associated to the cytoplasmic face

of the ER [4]. The reactions catalyzed by the enzymes TDC, 16OMT, D4H, and DAT are carried out in the cytoplasm, while STR and class III Prx implicated in AVLB and serpentine synthesis are located in the vacuoles, and NMT in the thylakoids [4, 36, 38]. The complex cellular and subcellular compartmentalization of the TIA pathway indicates a transfer of intermediates among different types of cells and cell compartments, revealing a high complexity that may hinder its biotechnological manipulation.

5 Biotechnology Approaches to Improve Terpenoid Indole Alkaloid Production from *Catharanthus roseus* In Vitro Cultures

Higher plants are a rich source of bioactive compounds, many of which are used in the pharmaceutical industry. Some plant-derived bioactive products include drugs such as morphine, codeine, TIAs, tropane alkaloids, among others. Many of these pharmaceuticals are still in use today, and no synthetic substitutes have been found that possess the same pharmacological efficacy. The most common strategies used to produce these natural compounds are their direct extraction from plants and their chemical synthesis. However, such strategies are not exempt of problems. Production by plants is not always satisfactory as may be restricted to one species or genus and might be activated only during a particular development stage or under specific seasonal, stress, or nutrient availability conditions, and, in some cases, it may even lead to the risk of the plant's extinction [39]. In the case of chemical synthesis, the complexity of the pathways, the stereospecificity, the strict conditions of the reactions involved, and high costs represent the main difficulties for the production of these high-value metabolites. For these reasons, much effort has been devoted to in vitro cultures as an attractive biotechnological method to produce secondary metabolites of commercial interest. The advantages of such a system for the industrial production of plant secondary metabolites are also the uniform quality of the products, the independence from disease and climatic changes, the stability of supply, and a closer relationship between supply and demand. In some cases, the production of secondary metabolites using large-scale in vitro cultures is technically feasible, when the generation and maintenance of the cell biomass is achieved together with a high yield of these metabolites. However, the use of in vitro cultures is limited in most cases by the economy of the process determined by the low yields of secondary metabolite obtained.

In this sense, *C. roseus* and TIAs have become an important model system in plant biotechnological research. In fact, the low levels of the TIAs with anticancer activity found in the plant stimulated intense research, aiming to obtain *C. roseus* in vitro cultures with high production of these TIAs. Technologically, Zhao and Verpoorte showed that although *C. roseus* cells can be cultured in large-scale, the levels of TIAs produced are too low to favor commercial production [40]. To increase the production of TIAs using in vitro cultures, different approaches have been tried, such as the screening and selection of high-producing cell lines, the optimization of culture conditions and feeding, elicitation, and cell immobilization. Genetic modification or metabolic engineering is also promising biotechnological approach to improve the production of these compounds [1].

5.1 Importance of Screening and Selection of *Catharanthus roseus* In Vitro Culture Lines and Level of Cell Differentiation to Improve the Production of Terpenoid Indole Alkaloids

The selection of genotypes starts with the selection of the plant from which cell and tissue cultures are to be initiated. Deus and Zenk showed that TIA levels in *C. roseus* plants could vary from almost undetectable to more than 1% in a dry weight (DW) basis [41]. High alkaloid-producing plants gave rise to cell cultures with higher alkaloid content. Kurz et al. investigated over 2,000 cell lines obtained from three *C. roseus* cultivars and observed significant cultivar-dependent differences between TIA-producing cell lines [42]. Differences observed were not only on the alkaloid levels but also in the TIA types produced. Naaranlahti et al. analyzed the leaves of 70 plants of *C. roseus* belonging to three cultivars and selected three plants with high vindoline levels for inducing callus [43]. One third of the 60 established cultures when screened with a vindoline-specific radioimmunoassay showed vindoline contents of about 10^{-5}% DW. Suspension cultures derived from the five most immunopositive calli, and cultivated in an alkaloid production medium, seemed to contain vindoline. Suspension cells also present a high degree of variability in alkaloid levels, no matter if they are derived from a single plant or even a single mother colony, so the selection of cell lines with suitable and uniform genetic, biochemical, and physiological characteristics is also an important approach to improve the production of TIAs. Screening of high-yielding cell lines with selection along successive subculture has enabled the selection of cell lines producing higher levels of TIAs [41, 42, 44]. However, the selection of high-yielding cell lines is hindered by the same variability that enables it. Actually, selected cell lines are usually unstable and tend to lose their productivity during long-term subcultures. The reason for such variability and instability is not known, and so far the process to overcome this problem has been the preservation of cell lines by cultivation as slow-growing callus and by techniques of cryopreservation and storage under mineral oil. Otherwise, continuous selection for high yields has to be performed over successive subcultures [1]. Several studies carried out using whole plants, shoot, callus, and cell cultures of *C. roseus* have demonstrated that the level of cell differentiation and organogenesis plays an important regulatory role in the pattern of TIA production [16, 45]. Endo et al. observed that the pattern of TIA production in root and shoot cultures of *C. roseus* was similar to that found in roots and leaves from intact plants [46]. However, many TIAs cannot be produced by *C. roseus* cell cultures since the activation of biosynthetic pathways is tissue-specific and developmentally regulated. In fact, as observed for many other plant species, *C. roseus* cultures present a much simpler alkaloid pattern than intact plants, with vindoline and anticancer TIAs detected very seldom, and in extremely low levels, in accordance with the high organ-cell-developmental regulation of these TIAs. Naaranlahti et al. reported the presence of vindoline ($10^{-5}\%$ on a DW basis) in suspension cultures newly established [43], and O'Keefe et al. reported a stable production of vindoline for a period of 6 years, in undifferentiated suspension cell lines of *C. roseus* transformed with *Agrobacterium tumefaciens* and *A. rhizogenes*, but also in low levels (of about $10^{-5}\%$ DW) [47]. Otherwise, vindoline and anticancer TIAs were only detected in organ cultures. Shukla et al. demonstrated that vindoline and catharanthine production increased in *C. roseus* in vitro cultures as the level of cell differentiation increased (suspension-cultured cells < callus culture < shoot/leaf tissue) [45]. However, these compounds were only detected in elicited conditions, the highest amounts of catharanthine and vindoline occurring in shoots (0.0039% and 0.0013% on a DW basis, respectively) compared with the levels found in callus (0.00019% and 0.00015% on a DW basis, respectively). Although catharanthine was detected in trace amounts in the suspension-cultured cells, vindoline was not detected in the cells or the medium in any conditions. Miura et al. found that the vinblastine content was higher in shoot cultures (around 0.015 mg g DW^{-1}) than in young callus cultures, although vinblastine was mostly found in leaf tissue cultures, suggesting that the production of this compound is closely associated with morphological and cellular differentiation phenomena [48]. In fact, Shukla et al. did not detect vinblastine in either control or elicitor-treated in vitro cultures [45].

The culture of hairy roots is an attractive alternative to the use of undifferentiated cell cultures to obtain secondary metabolites, since roots grow rapidly in hormone-free liquid medium, they are genetically stable and are differentiated cells potentially able to produce more secondary metabolites than undifferentiated cells. Hairy root cultures produce a broad spectrum of TIAs. Production of ajmalicine, serpentine, and catharanthine has been repeatedly reported by different authors, sometimes with levels superior to nontransformed root cultures (around 0.2–0.4% DW) [49, 50]. Production of vindoline has been surprisingly detected in hairy roots, in levels which are not so low (0.04–0.08% DW) [49, 51]. Very recent work with *C. roseus* hairy roots include elicitation treatments, overexpression of TIA genes, and regulatory transcription factors, but although vindoline is reported in some cases, the occurrence of anticancer TIAs was never reported, and vindoline levels were always below 0.08% DW [52–55].

5.2 Optimization of Culture Conditions to Improve the Production of Terpenoid Indole Alkaloids

Composition of the culture medium, as well as the physical environmental conditions, and the addition of specific factors have been proved to be able to increase TIA yields in *C. roseus* cultures, sometimes in a dramatic way. In fact, reducing or even deleting nitrate and/or phosphate from the medium strongly enhances TIA accumulation but inhibits cell growth [56]. On the other hand, the addition of KCl (4 g L^{-1}) did not inhibit cell biomass accumulation and increased the production of ajmalicine (33.5 mg L^{-1}), serpentine (11.9 mg L^{-1}), and catharanthine (12.3 mg L^{-1}) to levels that were threefold those of the control in compact callus cluster cultures of *C. roseus* The highest levels of alkaloids in these cultures were obtained by adding 250 mM mannitol (four- to fivefold higher compared with the controls) [57]. The production of TIAs from *C. roseus* cell cultures is also associated with the carbon source concentration. Schlatmann et al. showed that the presence of a low glucose concentration (40 g L^{-1}) correlated with a high ajmalicine production level [58]. Zhao et al. observed an increase of ajmalicine, serpentine, and catharanthine in both cells and medium (a total alkaloid yield of over 43 mg L^{-1}), when the concentration of sucrose (40–60 g L^{-1}) increased in the culture medium of compact callus clusters of *C. roseus* [59]. In addition, Jung et al. observed an increase in catharanthine accumulation when the carbon source was changed, using 3% sucrose instead of 3% fructose in *C. roseus* hairy root cultures [60].

It is well established that inoculum size greatly affects secondary metabolite production in plant cell cultures. Several authors have investigated the production of ajmalicine from *C. roseus* cell cultures at different cell inoculum densities, observing that ajmalicine production using a low cell inoculum density is significantly lower than when high cell densities are used [61, 62]. Plant hormones affect both culture growth and TIA production in *C. roseus* in vitro cultures. The addition of auxins to the culture medium had a negative influence on the TIA biosynthetic pathway. In fact, the addition of 2,4-dichlorophenoxyacetic acid (2,4-D) inhibits TIA production especially during the growth phase [63], even when *C. roseus* cell cultures are fed with the precursors, loganin and tryptamine [64]. Zhao et al. also observed a decrease in TIA production when the culture medium of compact callus clusters of *C. roseus* were supplemented with 2,4-D [65]. However, in those cultures, the combination of benzyladenine (BA) or kinetin with indole-3-acetic acid (IAA) led to the highest TIA production (total alkaloid yield of over 45 mg L^{-1}). Moreover, Satdive et al. analyzed the effects of different concentrations of both IAA and BA on ajmalicine production in *C. roseus* shoot cultures [66]. They found that in the presence of a high concentration of BA (8.90 μM) and a low concentration of IAA (2.85 μM), shoot cultures released high levels of ajmalicine (over 0.85 g L^{-1}) into the culture medium after 15 days of cultivation, whereas the addition of a high concentration of IAA (11.42 μM) and a low concentration of BA (2.22 μM) resulted in high levels of ajmalicine (over 0.40 g L^{-1}) being accumulated in the shoots. In addition, exposure to light, together with IAA and BA, improved TIA biosynthesis in *C. roseus* callus, especially vindoline (0.19 mg g DW^{-1}) and serpentine (0.53 mg g DW^{-1}) compared with callus that was not exposed to light [65].

On the other hand, some gaseous growth regulators may play a critical role. Indeed, the accumulation of ethylene in *C. roseus* cell cultures seemed to inhibit the production of ajmalicine [67].

Physical factors like aeration, gas-phase composition, and light (mentioned above) may promote an enhancement of the biosynthesis of TIAs. Lee-Parsons and Shuler studied the effect of O_2 and CO_2 on the production of ajmalicine in immobilized cell cultures of *C. roseus* [68]. They observed that low and high O_2 concentrations (10%, 90% and 95%) had either inhibitory or toxic effects to cell growth and decreased ajmalicine production. The effects of CO_2 depended on O_2 concentration. At low O_2 concentrations (21%), increasing the CO_2 concentration decreased both cell growth and ajmalicine production, while at high O_2 concentrations (78%), increasing the CO_2 concentration decreased cell growth, although ajmalicine production was not affected. The extracellular ajmalicine concentration was maximized with a gas mixture of 50% O_2 + 0.03% CO_2.

5.3 Feeding Strategies to Improve the Production of Terpenoid Indole Alkaloids

Sometimes, precursor feeding has proved to be a successful approach to increase the levels of TIAs in in vitro cultures. In particular, feeding with loganin, secologanin, and tryptamine has been extensively studied [64, 69]. El-Sayed and Verpoorte demonstrated that feeding *C. roseus* cell cultures with tryptamine and loganin resulted in a high accumulation of strictosidine (95.6 ng g DW^{-1}) [64]. Furthermore, El-Sayed et al. observed that adding stemmadenine to *C. roseus* cell cultures resulted in the accumulation of catharanthine and tabersonine, suggesting that stemmadenine is an intermediate precursor in the biosynthetic pathway of these TIAs [69]. Zhao et al. also carried out feeding experiments in compact callus clusters cultures of *C. roseus* [57]. They found that the addition of succinic acid, tryptamine, and tryptophan to the culture medium significantly increased the production of ajmalicine (41.5, 36.9, and 31.8 mg L^{-1}, respectively) and catharanthine (21.1, 17.2, and 18 mg L^{-1}, respectively), while geraniol feeding inhibited cell biomass and alkaloid accumulation. Zhao et al. also showed a maximal production of ajmalicine (over 50 mg L^{-1}), catharanthine (over 10 mg L^{-1}), and serpentine (over 20 mg L^{-1}) in *C. roseus* cell cultures treated with 0.5 mM malic acid for 3 days. Succinic and malic acids are involved in the citric acid cycle, and at the concentration tested, they greatly improved TIA production but inhibited cell growth [70].

Precursor feeding studies with *C. roseus* hairy root cultures also pointed to a limitation of the TIA pathway by the monoterpenoid precursors. In fact, after feeding geraniol, 10-hydroxygeranioll or loganin, a significant increase of tabersonine was observed. Thus, the addition of 80 mg L^{-1} geraniol to the culture medium provoked a tabersonine increase of around 1.4 mg g DW^{-1} [71].

5.4 Immobilization Strategies to Improve the Production of Terpenoid Indole Alkaloids

Another approach is to immobilize plant cells since it is thought that improved cell-to-cell interaction may increase TIA productivity. In fact, cells of *C. roseus* have been immobilized into various carriers such as alginate, agarose, agar, and polyurethane foam [1]. Immobilization leads to diffusional resistance and could lead to higher local concentrations of TIAs, particularly in high-density cell cultures. For example, Asada and Shuler reported a significant enhancement of ajmalicine production and excretion to the medium when *C. roseus* cells were immobilized with calcium alginate [72]. It was observed that the effects of immobilization adsorption and elicitation were synergistic, with the amount of ajmalicine in the medium reaching 90 mg L^{-1}, compared to 2 mg L^{-1} for suspension cultures under identical conditions. Also, Lee and Shuler observed that a high inoculum density in *C. roseus* cultures in which cells are immobilized on alginate beads increased ajmalicine concentration throughout the experiment, the maximum production of ajmalicine reaching more than 120 mg L^{-1} [62]. Lee-Parsons and Shuler also studied the effect of O_2 and CO_2 on the production of ajmalicine in immobilized cell cultures of *C. roseus* observing an increase of ajmalicine production (over 160 mg L^{-1}) on day 33 using 21% O_2 + 1.5% CO_2 [68].

5.5 Elicitation Strategies to Improve the Production of Terpenoid Indole Alkaloids

Several strategies have been adopted to enhance the levels of TIAs in cultures and produce them on an industrial scale. One of the most effective strategies to increase their productivity in a short period of time has been the use of biotic or abiotic stimuli as elicitors. The elicitors most frequently used include fungal extracts, metal ions, jasmonic acid and its derivative, MeJa, and irradiation with UV light [73, 74]. It is well documented that *C. roseus* cell cultures respond to jasmonates by increasing the production of TIAs. Lee-Parsons et al. showed that *C. roseus* cell cultures respond to MeJa by increasing the extracellular accumulation of ajmalicine in a way that was dependent on the MeJa dose and elicitation time [73]. In fact, the maximum ajmalicine production (10.2 mg L^{-1}) was obtained with 100 μM MeJa after 6 days, a 300% increase over that obtained with nonelicited cultures. Almagro et al. also described the high production of ajmalicine (137.2 mg L^{-1}) on day eight when *C. roseus* cell cultures were elicited with 100 μM MeJa using a high cell density (200 g fresh weight (FW) L^{-1}) [61]. Furthermore, in these cultures, the extracellular accumulation of ajmalicine increased to over 200 mg L^{-1} in the presence of cyclodextrins, which are modified cyclic oligosaccharides derived from starch with seven glucose residues linked by α 1→4 glucosidic bonds. The treatment of *C. roseus* cell cultures with a fungal preparation derived from *Penicillium citrinum* resulted in increased catharanthine production, reaching the highest level (20.1 mg L^{-1}) after 1 day of treatment, which was threefold the production of control cells [74]. In this case, too, treatment with cyclodextrins provoked an increase of catharanthine production (84.9 mg L^{-1}).

On the other hand, the addition of 1 mM of acetylsalicylic acid, which is an important plant signaling derivate of salicylic acid, provoked an important enhancement of total alkaloids released to the culture medium and accumulated in tumor *C. roseus* cells transformed with *A. tumefaciens* [75]. However, in nontransformed *C. roseus* cell cultures, acetylsalicylic acid also stimulated ajmalicine and serpentine accumulation, but the effects were not significant.

It has also been shown that UV light induces an enhancement of TIAs in *C. roseus* cell cultures. Ramani and Jayabaskaran observed an enhanced production of catharanthine (0.12 mg g DW^{-1}) and vindoline (0.06 mg g DW^{-1}) from *C. roseus* cell cultures irradiated with UV-B light [76]. Also, Almagro et al. used UV-C light irradiation to promote the production of TIAs in *C. roseus* cell cultures. A production of 90 mg L^{-1} ajmalicine and 49.5 mg L^{-1} catharanthine was obtained when high-cell-density cultures were exposed to 15 min of UV-C light, and these production levels of ajmalicine and catharanthine were maintained for 96 h [61].

The combined effect of elicitors is a widely used strategy to increase the production of TIAs. Indeed, the use of fungal and chemical elicitors separately or in combination is considered an effective strategy for enhancing TIA production in *C. roseus* cell cultures. Zhao et al. observed a synergistic effect on alkaloid accumulation in *C. roseus* cell cultures when *Aspergillus niger* mycelium and tetramethylammonium bromide were jointly used as elicitors, since they gave the highest levels of ajmalicine (63 mg L^{-1}) and high levels of catharanthine (17 mg L^{-1}). Also, the combination of malate and sodium alginate resulted in a high ajmalicine (41 mg L^{-1}) and catharanthine (26 mg L^{-1}) yield [57, 59, 65].

Recently, Almagro et al. described a new strategy for enhancing ajmalicine and catharanthine production from *C. roseus* cell cultures, combining the addition of cyclodextrins and MeJa. The addition of 50 mM cyclodextrins and 100 μM MeJa to high-cell-density cultures led to a release of ajmalicine and catharanthine to the culture medium of 450.1 and 155.5 mg L^{-1}, respectively. This effect was even greater when these chemical compounds were combined with short UV light exposure [61]. In fact, Almagro et al. demonstrated that *C. roseus* cell cultures irradiated with UV light (A or C) and elicited with cyclodextrins in combination with MeJa increased the production of ajmalicine to 1,040.5 mg L^{-1} (85 mg g DW^{-1}) and of catharanthine to 196.3 mg L^{-1} (10 mg g DW^{-1}) [77].

5.6 Large-Scale Production of Terpenoid Indole Alkaloids

Large scaling is the last step for the development of an industrial process for the production of the medicinal TIAs of *C. roseus*. Although present levels of TIAs still do not make such a process commercially viable, some research on large scaling of *C. roseus* cultures has already been performed, in view of possible future achievements. The major factors affecting TIA production in *C. roseus* cell cultures during a scale-up process are the components of the medium, growth regulators, pH, dissolved O_2 and gas composition, and culture conditions including temperature, light, aeration, and stirring regime [40]. Elicitation is also very important to consider, since it not only improves TIA biosynthesis in a short time but also causes excretion of the products into the medium, enabling fast isolation of the TIAs and the possibility of a continuous process. The combination of two or more elicitors can synergistically induce metabolic fluxes toward TIAs, as observed by Almagro et al. and even further improving the productivity of target compounds and the performance of bioreactor processing [61]. However, large scaling may affect negatively TIA production. Godoy-Hernández et al. observed that TIA total production in *C. roseus* cell cultures maintained in 250-ml batch cultures was around 60 mg L^{-1} [78]. These values rapidly decreased in a 14-L bioreactor (15 mg L^{-1}), especially when cultures entered in the active growth phase. In addition, the exposure to *A. niger* mycelium homogenates did not result in any increase of TIA production, but the combination of osmotic stress (2.50% sucrose plus 1.25% mannitol) and 1 mM cinnamic acid restored the original TIA levels. Zhao et al. studied ajmalicine production in elicited *C. roseus* cell cultures both in stirred flasks and bioreactors [70]. By using a combined elicitor treatment consisting of a homogenate of *A. niger* with tetramethylammonium bromide, the yield of ajmalicine was 48, 52, and 33 mg L^{-1} in 0.5-L flasks, 1-L flasks, and a 20-L airlift bioreactor, respectively. In the same conditions and same flasks, catharanthine production was 25, 32, and 22 mg L^{-1}, respectively. These results reflect by 3.1-, 3.5-, and 2.2-fold increase in ajmalicine levels over the controls without elicitation and a 3.1-, 3.9-, and 2.7-fold higher production of catharanthine, respectively.

In another experiment, the treatment of 7-day-old *C. roseus* cell cultures with abscisic acid produced an 82.25 mg L^{-1} accumulation of catharanthine after 3 days of cultivation in a 30-L airlift bioreactor [79].

5.7 Metabolic Engineering as a Strategy to Improve the Production of Terpenoid Indole Alkaloids

Successful metabolic engineering in plants requires an extensive knowledge of the whole biosynthetic pathway and a detailed understanding of the regulatory mechanisms controlling the flux of the pathways. Such information is not yet available for the vast majority of plant secondary metabolites, which is why only limited success has been achieved by metabolic engineering. Nowadays, only a few pathways in plants are well understood, following many years of classical biochemical research [80]. Usually, enzymes of the biosynthetic pathway can be selected as targets for gene cloning and then manipulated by genetic engineering, e.g., to increase the metabolic flux to a desired secondary metabolite and thus improve its productivity in the whole plant or in plant cell cultures. Despite our limited knowledge on the TIA pathway and genes involved in *C. roseus*, the information that is available has provided the tools to carry out metabolic engineering of TIA biosynthesis [40]. Therefore, among the strategies used to enhance the production of TIAs in *C. roseus* in vitro cultures, the overexpression of transcription factors and enzymes and also the incorporation of TIA biosynthetic pathway genes in other organisms may be highlighted.

The molecular cloning of a number of TIA biosynthetic pathway genes has been achieved using several approaches. STR is one of the key enzymes of this pathway that has been studied by many research groups. Indeed, it was the first gene involved in alkaloid biosynthesis to be cloned. The pathway leading to several TIAs (ajmalicine, serpentine, ajmaline, tabersonine, vindoline, catharanthine, and the dimeric anhydrovinblastine) has been partially elucidated, and several of the responsible genes have been cloned and their enzymes characterized, more specifically TDC, G10H, LAMT, STR, SGD, T16H, PNAE, 16OMT, DAT, D4H, and a class III Prx implicated in the condensation of vindoline and catharanthine into anhydrovinblastine [36, 81]. Several transcription factors implicated in the regulation of TIA biosynthesis genes have also been isolated and studied, and their genetic manipulation was performed in some cases [5].

5.7.1 Overexpression of Enzymes Involved in Terpenoid Indole Alkaloid Biosynthesis

Several attempts have been published stating the successful genetic transformation in cell and tissue cultures of *C. roseus*, resulting in higher yields of some TIAs [40, 82]. In the past decades, several transformation methods have been developed for the genetic transformation of cell and tissue cultures of *C. roseus* [83]. Although efficient direct transformations using particle bombardment have been carried out in *C. roseus* cell cultures, indirect transformations using genetic vectors such as *A. tumefaciens* have also been successfully developed. The genes mostly overexpressed in *C. roseus* include *tdc*, *str*, *dat*, *g10h*, and those expressing apoplastic Prx [40, 82, 84–86]. Along these lines, extensive research has been conducted in *C. roseus* cell cultures overexpressing *tdc* and/or *str* [17]. Cell cultures overexpressing *str* showed a tenfold higher STR activity than nontransformed cell cultures, leading to an increase in total TIAs to 300 mg L^{-1}, strictosidine, ajmalicine, serpentine, catharanthine, and tabersonine, being the major alkaloids found in all the transgenic *C. roseus* cell cultures studied. However, the overexpression of *tdc* did not increase TIA levels. Whitmer et al. also studied the overexpression of *tdc* in *C. roseus* cell cultures and only observed an increase in tryptamine levels over the levels recorded in nontransformed cell cultures. In addition, when loganin or secologanin was added to these transgenic cultures, the production of serpentine, catharanthine, and strictosidine increased, resulting in a total alkaloid production of 1,250 μM (ca. 600 mg L^{-1}) [84].

In a similar way, Peebles et al. constructed *C. roseus* transgenic hairy root cultures overexpressing genes of the monoterpenoid and indole precursors pathway, as well as *g10h*, alone or in combination, and obtained increases and decreases of different TIAs, pointing to the need for overexpressing multiple genes within the TIA pathway to obtain significant results [54]. In recent studies, *g10h* was introduced independently or cointroduced with ORCA3(octadecanoid-responsive Catharanthus AP2/ERF domain) in *C. roseus* hairy roots cultures [85]. The results showed that catharanthine production increased (1,250 μg g DW^{-1}) through the overexpression of *g10h* alone or in combination with ORCA3, representing a 6.5-fold increase when compared with nontransformed cultures. Similarly, Magnotta et al. described that the overexpression of *dat* in *C. roseu*s hairy root cultures provoked an increase in the production of hörhammericine (8 μg g DW^{-1}) [87]. Jaggi et al. studied the impact of overexpression of a Prx gene in *C. roseus* hairy root cultures [86]. Through metabolite analysis, higher levels of ajmalicine (350 μg g DW^{-1}) and serpentine (3,700 μg g DW^{-1}) were detected in these overexpressed cultures. These results indicated the involvement of Prx gene expression in the regulation of TIA biosynthesis.

5.7.2 Overexpression of Transcription Factors Involved in Terpenoid Indole Alkaloid Biosynthesis

The identification and subsequent manipulation of transcription factors has become a very attractive research tool for the metabolic engineering of TIAs. As mentioned above in Sect. 5.5 concerning elicitation strategies, jasmonic acid and MeJa induce the biosynthesis of TIAs. Both are capable of activating the gene expression that codifies enzymes which catalyze the formation of TIAs, including TDC, SGD, G10H, and STR. ORCA3 was isolated as jasmonate-responsive AP2-domain transcription factors that could promote the transcription of several TIA biosynthetic genes [5, 88]. In *C. roseus* cell cultures, the overexpression of ORCA3 led to an increase in the levels of the genes *tdc*, *str*, *sgd*, and *d4h*. However, the gene expression of *g10h* and *dat* was not affected by ORCA3 overexpression [88]. In addition, tryptamine and tryptophan levels increased upon overexpression of ORCA3, but no TIAs were detected, suggesting that the monoterpenoid branch of the TIA pathway remained limiting. This was confirmed by the fact that when cells were fed with the monoterpenoid precursor loganin, ORCA3 overexpression indeed caused an increase in TIA production.

The overexpression of ORCA3 has also been carried out in hairy root cultures of *C. roseus* by Peebles et al. [89]. This study showed that ORCA3 overexpression did not significantly increase the accumulation of ajmalicine, serpentine, catharanthine, tabersonine, hörhammericine, or lochnericine, although the mRNA transcript levels of *str* and *sls* increased, the levels of *tdc*, *g10h*, and *ORCA2* remained constant, and the levels of *sgd* decreased. The increase of *str* transcript levels and the constant levels of *g10h* transcripts agree with the results observed in *C. roseus* cell cultures overexpressing ORCA3 [88]. The decrease in *sgd* transcripts and the maintenance of *tdc* transcripts detected in hairy root cultures of *C. roseus* differ from the results observed in *C. roseus* cell cultures, where both transcripts increased [88]. Therefore, differences in mRNA accumulation between hairy roots and cell cultures seem to indicate the existence of different control mechanisms of the TIA pathway between culture types. In any case, the levels of TIAs in the manipulated cultures did not suffer a remarkable increase, meaning that the regulation of TIA accumulation must involve other key transcription factors, yet to be discovered.

5.7.3 Incorporation of Genes from the Terpenoid Indole Alkaloid Biosynthesis in Other Plants and Microorganisms

Some genes of the TIA pathway have been expressed in other plants apart from *C. roseus*. Hallard et al. obtained a transgenic cell culture of tobacco expressing *tdc* and *str* genes from *C. roseus* [90]. The TDC activity was constant in transgenic tobacco cells, while a two- to sixfold increase in STR activity was observed in comparison with nontransformed tobacco cells. This increase in enzymatic activity correlated with an increase in the production of tryptamine (12.6 μg g FW^{-1}). Similarly, *tdc* and *str* genes were overexpressed in *Morinda citrifolia* cell cultures, resulting in an increase of strictosidine when cells were fed with tryptamine and secologanin [91]. In addition, *tdc* and *str* genes obtained from *C. roseus* were introduced in *Cinchona officinalis* hairy root cultures. The results showed that *C. officinalis* transgenic hairy root cultures accumulated high amounts of tryptamine (1,200 μg g DW^{-1}), strictosidine (1,950 μg g DW^{-1}), quinine, and quinidine (around 500 and 1,000 μg g DW^{-1}, respectively) [92]. Unfortunately, such production proved not to be a stable trait.

On the other hand, as the slow growth of plant cells is an important constraint for an economically feasible TIA production, their production in microorganisms would be an interesting alternative [39]. In this sense, Geerlings et al. tried overexpressing *str* and *sgd* obtained from *C. roseus* in yeast (*Saccharomyces cerevisiae*) [93]. The STR activity was mainly found in the medium of the transgenic yeast, whereas the SGD activity was mainly found in cells. When this transgenic yeast was fed with tryptamine and secologanin, a greater amount of strictosidine (2 g L^{-1}) was secreted into the medium in 3 days. By breaking up the yeast cells, strictosidine was converted into cathenamine by the action of SGD. The transgenic yeast was able to grow on a juice of snowberries, which is a rich source of secologanin, confirming the interest of this approach as an alternative for TIA production. On the other hand, when *str* was overexpressed in *E. coli*, the strictosidine produced was converted to vallesiachotamine and isovallesiachotamine, which are TIAs that have been isolated in plant extracts of the Apocynaceae family [94].

6 Conclusions

The commercial production of valuable metabolites by in vitro culture techniques largely depends on the economics of the production process, which in turn, depends on productivity. In the case of TIA production in *C. roseus* in vitro cultures, the productivity obtained is not sufficient for the economically feasible large-scale production. Since the low productivity of TIAs in *C. roseus* in vitro cultures is one of the bottlenecks for their commercial production, different strategies to improve TIA productivity have been developed, such as the selection of high-yield cell lines, elicitation of *C. roseus* in vitro cultures, feeding strategies using precursors, and the metabolic engineering of TIA biosynthetic pathway and regulatory transcription factors. Although not yet successful, metabolic engineering offers the most promising perspectives for improving TIA production in the future, as knowledge of the genetic determination and regulation of the pathway increases. Therefore, improvement of such strategies should continue to be investigated, using TIA high-yield cell lines and transformation by stable genetic overexpression of genes or regulators of the biosynthetic pathway, together with inhibition of competitive pathways. Moreover, there is still a need of improving bioreactor performance, namely, by using elicitation and precursor feeding and by performing optimization of growth of engineering *C. roseus* in vitro cultures, as well as optimization of the release of TIAs into the medium for efficient recovery by processing technologies.

include emetic, cytotoxic, analgesic, anxiolytic, antidepressant, psychotropic, antipsychotic, antipyretic, anti-inflammatory, antioxidant, antimutagenic, immunomodulatory, vasorelaxant, antiviral, antimicrobial, and antiprotozoal. Indole alkaloids are widely represented in these plant groups. Detailed studies *in planta* and in vitro on the dynamics of biosynthesis, accumulation, and distribution of some of these metabolites in *Psychotria* of Southern Brazil have revealed complex regulatory controls, encompassing responses to both developmental and environmental signals. In addition, even closely related alkaloids may present distinct dynamic profiles of accumulation, varying from constitutively produced to highly responsive to environmental signals.

1 Introduction

Plants are a rich source of bioactive molecules, partly as a result of their immobile nature. A driving force for evolution of higher photosynthetic organisms is the need to respond *in situ* promptly and effectively to a variety of stimuli, both biotic and abiotic, as well as to attract pollinators, seed dispersers, and microbial/fungal mutualists. Metabolic pathways leading to final compounds have several steps, yielding a number of intermediates. One or more of these metabolites may confer adaptive advantage, fixing the pathway in populations. Environments that are prone to host a high biodiversity are often also conducive to higher selective pressures for chemical diversification. This combination may explain why the Neotropics and some genera of Rubiaceae converge to be a rich reservoir of bioactive alkaloids. This chapter focuses on the alkaloids of *Psychotria*, *Uncaria*, and *Cinchona* and their structural diversity, pharmacological properties, and applications.

2 Biodiversity and Drug Discovery Potential in the Neotropics

The largest fraction of global biodiversity is located in the Neotropics, with the Atlantic Forest and the Amazon being a rich untapped reservoir of plants that may lead to new drug discovery [1]. The Atlantic Forest biome is considered one of the key global hotspots of biodiversity, hosting thousands of endemic species [2], spread along 194,524 km^2 in three countries (Brazil, Paraguay, and Argentina), which corresponds to only 12.9% of the original forest cover [3–5]. Amazon is one of most biodiverse biomes in the world [6] comprising eight countries, among which Brazil holds the largest forest area; deforestation and forest fires, however, are major concerns for the integrity of its biodiversity. The Atlantic Forest is also under high levels of pressure, sharing space with the most populated areas of the South American Atlantic Coast; deforestation of this biome may reach annual rates of 0.5% [7].

Reducing Amazon deforestation, besides biodiversity conservation, is linked to a possible and reachable reduction in global greenhouse-gas emissions (2–5%) [8], making this biome an important target in the worldwide scenario. One billion US dollars from the Amazon Fund, pledged by Norway, are committed to reducing deforestation through reduced greenhouse-gas emission in sustainable fashion [9] and also by excluding Amazon deforesters from the beef- and soy-industry markets, mainly by stimulating environmental and social certification of these products [10].

Unexplored biodiversity and high levels of endemism [2, 11], combined with ethnopharmacological knowledge from traditional communities [12], lead to high potential for drug discovery in this region. Some plants from the Neotropics are already booming in the international scenario, and some examples are the fruit pulp from *Euterpe oleracea* (Arecaceae) and *Myrciaria dubia* (Myrtaceae) with antioxidant effects after consumption [13, 14], being a rich source of anthocyanins and vitamin C, respectively; *Peumus boldus* leaves (Monimiaceae) with the alkaloid boldine conferring hepatoprotection [15]; the resin extracted from *Copaifera officinalis* (Fabaceae) with anti-inflammatory properties [16, 17]; *Bertholletia* *excelsa* (Lecythidaceae) as fatty acids and selenium source in food supplementation [18]; stimulant effects from caffeine-rich drinks prepared with *Paullinia cupana* (Sapindaceae) fruits and *Ilex paraguariensis* (Aquifoliaceae) leaves [19, 20]; *Annona muricata* (Annonaceae) with antitumor activity conferred by the presence of acetogenins [21]; and *Stevia rebaudiana* (Asteraceae) as a stevioside source, a low calorie sweetener used as safe substitute for sugar [22].

Despite capable of controlling core technologies in drug discovery and development in a geographical region of megabiodiversity, South American scientists and government officials face significant delays in finding and developing new bioactive compounds from the Neotropical flora. This scenario is at least in part due to a lack of cooperation among South American organizations as well as among those with more industrialized countries [1]. There are many barriers for natural products of the Neotropical region to reach international markets, including historical, cultural, regulatory, scientific, and economic [1].

3 Bioactive Alkaloids from South American Rubiaceae Plants

South American biomes are among the most diverse of the world. Besides the well-known Amazonian biodiversity, other tropical and subtropical ecosystems contain very rich plant communities. One of these is the Brazilian Atlantic Forest, today reduced to a fraction of its original distribution, making it very important to engage in cataloguing, evaluating, and prospecting its species in a sustainable way [23].

One plant family with considerable chemical potential is the Rubiaceae. It is a large plant family, with 13,143 registered species distributed in 611 genera [24]. Rubiaceae species are distributed mostly in tropical and humid locations. Plants belonging to this family can be easily recognized in the field by their opposite leaves, interpetiolar stipules, and inferior ovary (Fig. 5.1). The most widely known Rubiaceae representative is the coffee plant, *Coffea arabica*. Its main active constituent, caffeine, is one of the most extensively studied plant compounds [25].

Bioactive molecules are often isolated from Rubiaceae species [26–33]. In South America, two genera are of special interest due to the bioactivities of their phytochemicals along with their importance to local human populations: *Uncaria* and *Cinchona*.

3.1 *Uncaria* Genus

The *Uncaria* genus includes 34 species of vines and shrubs and is a rich source of medicinal natural products. *Uncaria* plants are traditionally used to heal wounds, headaches, and ulcers and to fight infections [34]. Over 150 compounds have been isolated from *Uncaria* tissues, and the most prominent of those are alkaloids.

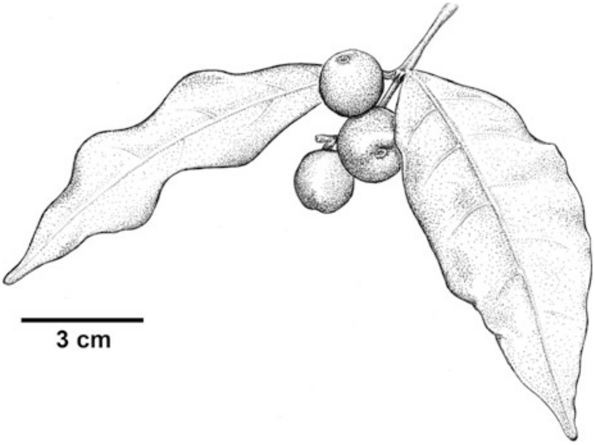

Fig. 5.1 Fruit-bearing shoot of *Psychotria brachyceras*

Numerous bioactive alkaloids have been isolated from *Uncaria* [35–47], but two species yielded a considerable number of active compounds: *U. rhynchophylla* and *U. tomentosa*.

Extracts of *U. rhynchophylla* have been shown to be anticonvulsive, antioxidant, neuroprotective, and cytotoxic [34, 38–40]. Some of these activities are attributed to the tetracyclic oxindole alkaloids rhynchophylline and isorhynchophylline. They have been shown to inhibit NMDA receptors [41]. These receptors are transducers of postsynaptic signals in the central nervous system of mammals. Inhibitors of NMDA receptors could be used to treat disorders caused by excessive activation of this pathway, like cerebral ischemia, Parkinson's, and Huntington's diseases [42].

U. tomentosa is the richest source of molecules among *Uncaria* plants, with over 50 compounds isolated [43]. The species is endemic to Central and South America and is known as "uña-de-gato" (cat's claw) by Peruvian populations, which use extracts from *U. tomentosa* bark for a variety of illnesses, from viral infections to arthritis.

Extracts of *U. tomentosa* have been shown to have anti-inflammatory, antioxidant, antiviral, immunomodulatory, and cytostatic activities [43–50]. Some of these effects appear to be derived from alkaloids. Kurás et al. [48] tested alkaloid-rich and alkaloid-free extracts from *U. tomentosa* for mitosis inhibition and observed that both fractions were cytostatic, with a stronger activity of alkaloid-rich extracts. In a similar study, *U. tomentosa* alkaloids were shown to have antiviral properties on dengue virus infections, as well as immunomodulatory activity [46]. However, alkaloids seem not to participate on antioxidant and anti-inflammatory activity of cat's claw extract [47]. In fact, immunostimulant activity of the alkaloid fraction can even counteract the anti-inflammatory polar fraction [51].

3.2 *Cinchona* Genus

Cinchona plants yielded a crucial phytochemical resource to nineteenth century European people involved in trade and colonization of tropical lands – quinine [52]. Before quinine, malaria was a major health issue in the new world, lowering quality of life by causing severe discomfort and even death. Quinine is an alkaloid present in the bark of several *Cinchona* species known as "quina quina" by native populations. It is most concentrated in *Cinchona calisaya*; however, the most widely known "quina quina" plant became *Cinchona officinalis* (*officinalis* means "medical herb"). Besides quinine, *Cinchona* plants produce other antimalarial alkaloids, namely, quinidine, cinchonine, and cinchonidine. *Cinchona* alkaloids can be found in other Rubiaceae genera as well, as described for *Remijia peruviana* [53].

Cinchona alkaloids have other bioactivities besides antimalarial. Quinine has been used to treat cramps [54]. Cinchonine is an inhibitor of MDR [55]. MDR is a detoxification mechanism present in certain cancer cell lines that renders them less sensitive to chemotherapeutic medications. Administration of cinchonine along with chemotherapeutic agents would result in better efficiency of treatment on MDR cancer cells.

3.3 Brazilian Medicinal Plants

Traditional medicine in Brazil relies on hundreds of plant species, and for a great number of them, standardized preparations are recorded in at least one of the five editions of Brazilian Official Pharmacopeia [56–60]. The first edition, published in 1929, presents 713 monographs about medicinal plants. This number falls to 193 in the second edition, published in 1956, and then to 23 in the third edition (1977). This decrease in the number of monographs about medicinal plants coincides with increased numbers of monographs on synthetic drugs and with a time of accelerated industrialization of the country [61]. The fourth edition published in 1996 has 44 monographs on medicinal plants and the fifth edition, published in 2010, has 53.

Eight Rubiaceae species appear in the first four editions as medicinal plants: *Remijia ferruginea, Borreria centranthoides, Chiococca brachiata, Cephaelis ipecacuanha, Cephaelis acuminata, Cinchona calisaya, Cinchona succirubra*, and *Cinchona pubescens*. The first four species are native of the Brazilian flora, and the others are common in South American tropical forests. In the fifth edition, the only Rubiaceae is *C. calisaya*, for which the powder from bark tissues is characterized and protocols for its chemical analysis (mainly the alkaloids) are described. The bark from *Cinchona* species and *R. ferruginea* is used for treatment of fever and malaria [62]. *B. centranthoides* root decoction is used to treat problems of the urinary tract [63]. *C. brachiata* root preparations have diuretic properties and ameliorate cutaneous infections [64]. Finally, both *C. ipecacuanha* (also known as *Psychotria ipecacuanha*) and *C. acuminata* dried roots yield the drug "ipecac," which is a potent emetic, used in the treatment of gastrointestinal diseases, intoxications, and also as expectorant and vasoconstrictor [65, 66].

4 The *Psychotria* Genus

Psychotria is the largest Rubiaceae genus and one of the most species-rich genera of flowering plants, with 1,834 species [24, 67, 68]. *Psychotria* species are mostly understory shrubs, i.e., small woody plants growing in lower strata of dense forests. Taxonomy of *Psychotria* plants is complicated since the genus is a grouping of Rubiaceae species, many of which lacking distinctive features that would otherwise classify them in other genera [67]. Since morphological traits alone do not provide enough basis for classification, data from DNA [68] and phytochemicals [69] have been useful for the systematic analysis of the taxa.

South American *Psychotria* belongs to the subgenus Heteropsychotria that comprises Neotropical species, being the presence of MIAs a constant; with exception of *P. colorata* and *P. glomerulata*, polyindoline-type alkaloids are not found in Neotropical P*sychotria*. Southern Brazilian species MIAs have the peculiar characteristic of retaining a glucoside residue. *P. borucana* and *P. ipecacuanha* are separated from the Heteropsychotria clade, and both share the presence of dopamine-iridoid alkaloids instead of tryptamine-iridoid (MIAs) [67], similarly to *P. klugii* [70]. *P. stachyoides* MIAs isolated from leaves show unusual skeleton formed by the condensation through N-1, and not N-4 [71], similar to *P. correa* [72].

Ethnobotany studies may provide clues to direct the prospection of bioactive molecules of interest. Among reports of traditional uses, *P. papantlensis* in Mexico is used for treating inflammatory diseases [73]; *P. tenuicaulis*, *P. pilosa*, *P. poeppigiana*, *P. marcgraviella*, and *P. carthagenensis* in Peruvian Amazon are used for different purposes such as uterine hemorrhage, vomits, fever, diarrhea, spasms, painkiller, sedative, and health tonic [74, 75]; in a local community in Papua New Guinea, *P. microlabastra* is used for malaria treatment, stomachache, boils, sores, and venereal diseases [76]; and in a West Indonesian archipelago, *P. malayana* is used for skin diseases [77].

Some *Psychotria* species, such as *P. microlabastra* [76], *P. capensis* [78], *P. rostrata* [79], and several species from the Atlantic Forest [80], have known antibiotic properties. Antiviral (*P. serpens*) [81], antiviral/antifungal, anti-inflammatory (*P. hawaiiensis* [82] and *P. insularum* [83]), and antiparasitical activities (*P. camponutans* [84] and *P. klugii* [70]) have also been reported. Other bioactivities include cytotoxic properties (*P. prunifolia*) [85] and regulation of human growth hormone release (*P. oleiodes*) [86]. The active molecules produced by *Psychotria* species include pigments [87], peptides [88], naphthoquinones [89], benzoquinones [90], and alkaloids [91].

Psychotria species that are well known for their bioactive compounds include *P. ipecacuanha*, producing the isoquinoline alkaloid emetine, with well-characterized emetic effect (inducer of vomiting) [92]. Isolated emetine is also effective in the treatment of amoebiasis [93]. The alkaloid, however, has severe side effects, like muscle weakening and cardiac damage.

Another *Psychotria* species worth noting is *P. viridis*. Leaves of this plant, along with the vine *Banisteriopsis caapi*, are used in the preparation of ayahuasca, a hallucinogenic beverage that is consumed in some indigenous-derived religious rituals [94]. The decoction made from these two species is rich in the β-carboline alkaloid harmine, produced by *B. caapi*, and in the alkaloid DMT, from *P. viridis*. Harmine is thought to inhibit the action of monoamine oxidases, enzymes that process DMT in the liver and brain. DMT itself is a strong psychoactive, and harmine also has activity by itself. When in combination, the effect is amplified through increased availability of DMT caused by monoamine oxidase inhibition by harmine.

Plant extracts are continuously being tested for bioactivity, and in cancer research, major enterprises for screens of antiproliferative activity are sometimes carried out. In one of these screens, nearly 70,000 species of terrestrial plants were tested against leukemia cell lines [95]. The authors labeled plant genera as “hot” if they yielded three or more plant species that showed activity in the screens. Six *Psychotria* species gave active extracts, so *Psychotria* earned the title of “hot genus” [95]. This type of approach, extensive analysis of plant extracts in the search of bioactive phytochemicals, is very expensive, time-consuming, and labor-intensive, but can unveil precious new drug leads, as was the case with paclitaxel [96].

Another type of approach, the ethnopharmacological, can abbreviate a considerable amount of effort by, instead of testing extracts of all plant materials available, concentrating the experimentation on plants used by traditional communities. The knowledge accumulated by these people, who lived for hundreds, even thousands of years in contact with native plants and often depending on them for health care and other needs, is taken as a starting point for bioactive phytochemical prospecting. This approach has resulted in several important discoveries, including the antitumoral alkaloids vincristine and vinblastine from *Catharanthus roseus*, the antimalarial artemisinin from *Artemisia annua*, and the neuroactive reserpine from *Rauwolfia serpentina* [97].

An ethnopharmacological survey was conducted in order to chemically investigate a *Psychotria* species, *P. colorata*, for analgesic activity. The plant is used by the “caboclos,” local rural communities in the state of Pará, northern Brazil, to alleviate pain. The molecules discovered in this plant were the first of a fruitful endeavor: phytochemical prospection of *Psychotria* species.

4.1 Bioactive Alkaloids from South American *Psychotria*

South American *Psychotria* are a rich source of alkaloids displaying various bioactivities. Examples are shown in Table 5.1.

4.1.1 *Psychotria ipecacuanha* (Brot.) Stokes: Emetine and Cephaeline

P. ipecacuanha, native to South and Central America, is a well-known species used in therapy since the early seventeenth century due to emetic and expectorant activity and later as a medicine for amebic dysentery [98], being widely used as ingredient in pharmaceutical industry. Traditional communities use this plant for intoxication treatment due to its emetic effect [99], as well as stimulant and “antidote to opium” [100].

GPV		*P. leiocarpa*	Antioxidant	[Unpublished]
Strictosamide		*P. bahiensis* *P. nuda* *P. myriantha* *P. suterella*	Anti-inflammatory	[138]

This plant contains ipecac alkaloids, comprising the monoterpene isoquinoline alkaloids emetine, cephaeline, and psychotrine being the main components responsible for emetic properties [101]. In addition, emetine is also used for amebic dysentery treatment [102], displaying cytotoxic activity, inhibiting protein synthesis, and with potential applications in drug-induced apoptosis [92]. Currently, synthetic analogues of emetine with less adverse effects are used in the treatment of amoebiasis [93]. These ipecac alkaloids are present in all parts of the plant but in a greater quantity in the roots [92, 93, 98–103]. Initial ipecac alkaloid biosynthesis is analogous to other MIA, with secologanin and dopamine, instead of tryptamine, condensation. After some methylations through *O*-methyltransferases, cephaeline is generated; and downstream, with the addition of another methyl group, emetine is formed (Scheme 5.1) [104].

4.1.2 *Psychotria viridis* (Ruiz & Pav.): DMT

P. viridis grows naturally in Amazonian tropical forests in Central and South America, and the leaves are used as one of the main components in the preparation of the hallucinogenic drink "ayahuasca." This plant is a rich source of the psychedelic indole-alkaloid DMT [94] in the mixture that also contains *β*-carboline alkaloids provided by *Banisteriopsis caapi* (Malpighiaceae), mainly harmine, harmaline, and tetrahydroharmine, that besides psychoactive properties, act as reversible MAOIs. MAO acts as a detoxifying enzyme [105], and when inhibited by MAOIs, DMT inactivation is prevented in the gut [106] enabling it to reach the CNS site of action, affording significant psychotropic effect. DMT biosynthesis is relatively simple and is summarized in Scheme 5.2.

Ayahuasca recent popularization led to several debates including mental health issues and drug abuse, as well as religious freedom [107, 108]. In Brazil, the religious use of the ayahuasca drink is free since January 2010 [109]. Interestingly, *P. carthagenensis* is regarded as a substitute for *P. viridis*, although no evidence of alkaloids in plants [110] or activity of key enzymes of secondary metabolism in cell cultures were detected in *P. carthagenensis* from Southern Brazil [111]. However, the possibility of its presence in individuals from other geographical origins cannot be ruled out before extensive analyses are carried out.

4.1.3 *Psychotria colorata* (Willd. ex Roem. & Schult.) Müll. Arg.: Hodgkinsine, (+)-Chimonanthine, meso-Chimonanthine, and Psychotridine

An ethnobotanical survey identified several species used as painkillers among traditional rural communities from Brazilian Amazon, and different parts of *P. colorata* were reported for therapeutical uses among the Amazonian traditional rural communities, being flowers used for earache treatment and roots/fruits for abdominal pain [112]. Similar qualitative composition is present in flowers and leaves of *P. colorata* [113, 114], being the highest content of alkaloids found in flowers (0.7% DW) followed by leaves (0.6% DW) and lower concentrations in roots (0.05% DW) [115].

Scheme 5.2 *N*,*N*-dimethyltryptamine biosynthesis

Preliminary tests with *P. colorata* extract from flowers indicated alkaloids as the major responsibles for its analgesic effect, probably with opioid-like activity [113], and later, hodgkinsine, a pyrrolidine indole alkaloid, was identified as the major component among several pyrrolidine indole and quinoline alkaloids present in the flowers of this species [116]. Hodgkinsine was first isolated from *Hodgkinsonia frutescens* (Rubiaceae) [117], and it is a potent analgesic, with results comparable to morphine in hot-plate and tail-flick models [118, 119]. Both tests measure the animal response time to heat stimulus. Hodgkinsine is also present in *P. muscosa* [115] and in the Indonesian *P. malayana* (also as the major alkaloid) [77].

The pyrrolidine indole alkaloids (+)-chimonanthine, *meso*-chimonanthine, and psychotridine also showed analgesic activity [120, 121], but the *P. colorata* quinoline alkaloids did not present positive results to the nociceptive tests, suggesting strong structure-activity relationship [115]. Capsaicin (the active component in pepper)-induced pain models suggest alkaloid action on opioid and glutamate receptors [119–121].

4.1.4 *Psychotria umbellata* Vell.: Psychollatine

P. umbellata is a woody species that occurs in the Brazilian Southern Coast Atlantic Forest [122]. Due to promising results with *P. colorata*, investigations of Southern Brazilian subtropical species of *Psychotria* were performed, including *P. umbellata*; a dose-dependent opioid-like analgesic activity was described for the foliar ethanolic extract from the latter species [123].

Psychollatine is a monoterpene indole alkaloid, the major alkaloid from *P. umbellata*, being restricted to shoots (nearly 4% of dry weight in leaves). The alkaloid structure suggests an alternative biosynthetic pathway, STR-independent, by the condensation of tryptamine and a geniposide derivative [124].

The alkaloid accumulation seems to be regulated by developmental stage with the highest levels in inflorescences and the lowest in seeds, followed by fruit [125], suggesting a defense role.

In light/dark and hole-board models for anxiety (which basically measure inhibition on mice exploratory behavior in the presence of different stimuli), the alkaloid presented anxiolytic activity (7.5 and 15 mg kg^{-1}); in a forced swimming test, the antidepressant effect (3 and 7.5 mg.kg^{-1}) was comparable to that of imipramine (15 mg kg^{-1}) and fluoxetine (20 mg kg^{-1}). Antipsychotic and amnesic effects were also observed in mice models presumably by alkaloid modulation of serotonergic (5-$HT2_{A/C}$) [126] and NMDA glutamate [127] neurotransmitter systems. Administration of higher doses of the alkaloid (100 mg kg^{-1}) impaired the acquisition of learning and memory consolidation [126].

Other properties of psychollatine include antimutagenic properties in *Saccharomyces cerevisiae* [128] and antioxidant activity against a variety of ROS [125, 128]. The alkaloid was also capable of improving survival of antioxidant defense-deficient strains of yeast upon oxidative stress [128].

Due to its properties, psychollatine has high pharmacological potential. Postharvest stability experiments showed high stability of the molecule in temperatures below 65°C [73], highlighting an extra useful feature in future alkaloid applications.

4.1.5 *Psychotria brachyceras* Müll. Arg.: Brachycerine

P. brachyceras is native from tropical and subtropical forests of Brazil [129]. Brachycerine is a MIA, present only in shoots with levels generally varying from 0.02% to 0.1% of DW [130] reaching up to 1.8% DW under UV radiation stress [131]. Its biosynthetic pathway differs from usual MIAs, being the terpenic fraction derived from epiloganin instead of secologanin. Epiloganin is condensed with tryptamine through a putative STR-like enzyme. Antioxidant activity against most physiologically relevant ROS in plants is a feature of this alkaloid [131–133]. Unlike *Nicotiana sylvestris*, in which nicotine is whole-plant-induced [134], brachycerine is accumulated only in damaged sites. In vitro assays showed that brachycerine has antimutagenic activity in *S. cerevisiae* [132]. Other interesting results were nonspecific analgesic activity of *P. brachyceras* leaf ethanolic extract [135].

4.1.6 *Psychotria myriantha* Müll. Arg.: Strictosidinic Acid

P. myriantha is common in Southern Brazilian forests [129] and produces the MIA strictosidinic acid, being the major alkaloid present in *P. myriantha* leaves. Oral administration of strictosidinic acid in mice has analgesic and antipyretic effects [136], and it is also an efficient inhibitor of PMN chemotaxis in vivo [137], having anti-inflammatory properties [138].

Opioid-like analgesic activity was observed after intraperitoneal injection of this alkaloid in hot-plate and tail-flick models [137]. Also, intraperitoneal injection of 10 mg kg^{-1} reduces 5-HT and DA levels (followed up by an increase of 5-HIAA, DOPAC, and HVA levels), showing relevant effect in the central nervous system [139]. Opioid-like denomination suggests morphine-similar effect, being blocked with naloxone-like antagonists.

4.1.7 *Psychotria leiocarpa* (Cham. & Schltdl.): GPV

P. leiocarpa is native to Argentina, Paraguay, and Brazil [129]. The MIA GPV is the major alkaloid present in the ethanolic extract of this plant, and it is detected only in shoots being the highest levels in leaves, reaching up to 2.5% DW [140]. Nonspecific analgesic activity from foliar crude ethanolic extract was reported in tail-flick test [135]. An uncommon configuration for MIAs, with a glucose residue attached to the indole ring nitrogen, was first described in GPV.

4.1.8 *Psychotria suterella* Müll. Arg.: Lyaloside, Naucletine, and Strictosamide

P. suterella is found in the coast of tropical forests in Southern Brazil [122]. Lyaloside, naucletine, and strictosamide are MIAs present in *P. suterella* leaves, being absent in roots. In the tail-flick assay, no analgesic effects of the alkaloid extract obtained from leaves (100 or 300 mg kg^{-1}), or isolated lyaloside (10 or 30 mg kg^{-1}) were observed; in addition, the higher doses of extract and lyaloside lead to convulsions followed by death [141].

4.1.9 *Psychotria nuda* (Cham. & Schltdl.) Wawra: Strictosamide

P. nuda is common in tropical forests from Southern Brazil [142]. The MIA strictosamide is the major alkaloid from *P. nuda* [143], being previously isolated from other plants [144]. It is considered an important biosynthetic precursor of the antitumor alkaloid camptothecin, from *Camptotheca acuminata* [145]. From South American *Psychotria* species, strictosamide was isolated from *P. leiocarpa*, *P. suterella*, *P. bahiensis*, and *P. myriantha* [137, 141, 146, 147].

The alkaloid-rich extract obtained from *P. nuda*, as well as isolated strictosamide (major alkaloid from *P. nuda*), shows in vitro antichemotactic activity on PMN in vivo [138]. PMNs are recognized as the first cells to arrive at the sites of inflammation [148], these results being related to anti-inflammatory effects.

4.2 Regulation of *Psychotria* Alkaloid Biosynthesis

Alkaloid biosynthesis can be a very complex and highly regulated biological process. It may encompass various cell types [149], intensify in certain developmental stages, and be influenced by circumstantial factors, like nutritional status or stress [150–152]. Some alkaloid biosynthetic pathways, due to their importance, are meticulously studied, as is the case with *Catharanthus roseus, Nicotiana tabacum, Papaver somniferum*, and many others. The main goal of alkaloid (and other phytochemicals) research is to establish the genes and enzymatic steps needed for building a valuable compound, as well as what influences its production rate. This information could be used, for example, to manage phytochemical exploration of intact plants or to engineer controlled bioprocesses for their synthesis (e.g., bioreactors) [153].

Despite progresses in alkaloid research, some of the most demanded alkaloids are still produced in large scale by land-cultivating alkaloid-containing plants and purifying the compounds, in a very expensive and laborious process. The commonest first attempt for switching production into a more efficient and controlled way is to establish in vitro tissue-culture protocols for the species of interest. There are many examples of strong inhibition or total lack of biosynthesis of alkaloids and other phytochemicals in such conditions [154], including for *Psychotria* species [125], reinforcing the evidence for tight regulation of alkaloid biosynthesis and requirement of specialized tissues for its completion. This underlines the need to investigate distribution of alkaloids among tissues of adult plants as well as to determine the influence of various treatments on alkaloid production.

Seedlings of in vitro cultured *P. leiocarpa* were exposed to different sucrose concentrations in the medium along with presence or absence of white light. GPV production, restricted to shoots, was strongly induced by light and inhibited by sucrose supply, indicating that photoautotrophic metabolism plays a major role in alkaloid accumulation [140]. GPV also seems to be developmentally regulated since its content in older (150 days) seedlings is significantly higher than in younger ones (100 days). The alkaloid is most concentrated in leaves and reproductive structures [140].

Brachycerine accumulation in *P. brachyceras* also is restricted to shoots. It is most concentrated in inflorescences (0.3% over dry weight) but is also present in fully expanded leaves (0.18%), stems (0.18%), younger leaves (0.12%), and fruit pulp (0.04%). Leaf brachycerine concentration in adult field-grown plants varies seasonally, with lower concentrations in summer months. In vitro germinated seeds yield seedlings with alkaloid accumulation as observed in leaves of adult plants [155].

Brachycerine accumulation is highly responsive to environmental signals. Mechanic damage and also jasmonic acid, a hormone related to signaling of herbivory [156], induce brachycerine production in cuttings [155]. The same happens with UV radiation but with higher fold induction. Brachycerine is a strong antioxidant, and its up regulation in stress situations suggests a protective role for it *in planta* [131].

For *P. umbellata*, the opposite dynamic profile is observed. The plant alkaloid content does not respond to almost any environmental stimuli. Psychollatine, however, accumulates constitutively at high levels in leaves (1–4% of dry weight). The alkaloid is strongly accumulated in inflorescences and fruit [125]. An in vitro somatic embryogenesis protocol was established for *P. umbellata*. It employs a hormonal balance and physical variable manipulation, notably light, that is capable of driving direct embryo development from somatic cells of rhizogenic calli, resulting, after further growth and acclimation to ex vitro conditions, in fully differentiated plants. *P. umbellata* plants established in in vitro cultures had psychollatine concentrations similar to field-grown shrubs [153].

5 Conclusions

Taken together, data to date indicate that a number of common general features can be identified in MIAs from *Psychotria* of Southern Brazil. These alkaloids are relatively simple structures, which probably represent primitive forms of this class of metabolites, compared to the more elaborate MIAs of *Catharanthus roseus*, for example. The MIAs of Southern Brazilian *Psychotria* species usually retain glucose residues, a characteristic that is not common in most MIAs, but can be useful for pharmacological applications, considering solubility and bioavailability issues. Other features often associated with these alkaloids include antioxidant and antimutagenic properties and high concentration in plant reproductive structures. A shoot-specific distribution and strong dependence on differentiated photosynthetic tissue for biosynthesis are probably connected with the plastid-located source of isopentenyl diphosphate which is needed for synthesizing the terpene moieties required for alkaloid production. Some of these MIAs are formed by condensing tryptamine with unusual non-secologanin terpene moieties (epiloganin derivatives in brachycerine and geniposide aldehyde in psychollatine). This observation implies that new STR-like enzymes are likely involved in the biosynthesis of these particular alkaloids. In addition, different strategies of accumulation are found in these plants and alkaloids, ranging from highly constitutive to strongly inducible upon environmental stimuli. Therefore, it is likely that distinct transcription factors orchestrate the expression of genes encoding enzymes leading to the production of these related alkaloids. Clearly, in spite of significant progress, large efforts are still required to fully understand *Psychotria* alkaloid production and its multitude of applications.

Acknowledgments We are grateful to our collaborators in *Psychotria* alkaloid research Dr. A. T. Henriques (UFRGS) and Dr. G. Pasquali (UFRGS). Financial support for preparing this chapter was from grants by the National Council for Scientific and Technological Development (CNPq-Brazil) to A.G. Fett-Neto.

Abstract

Plant secondary metabolites are well recognized to provide protection against harmful organisms. Alkaloids are one of the most diverse groups of secondary metabolites. They are produced by a large variety of organisms, including bacteria, fungi, plants, and animals. Positive or negative effects of alkaloids can be seen among different herbivores and insects. Alkaloids being toxic in nature help the plants, herbivores, and insects to ward off their enemies or competitors and facilitate their own survival in the ecosystem. Some herbivores and insects sequester them to defend against their own enemy illustrating the flow of alkaloids through different trophic levels. Among plants, alkaloids work as allelopathic compounds, and this property makes some of the plants a potential natural weedicide. This chapter highlights the ecological roles of alkaloids and their possible role in chemical management of pests.

Alkaloids • allelopathy • endophytes • pyrrolizidine alkaloids • quinolizidine alkaloids

Abbreviations

BIA	Benzylisoquinoline alkaloids
MLA	Methyllycaconitine
PA	Pyrrolizidine alkaloids
QA	Quinolizidine alkaloids

1 Introduction

Plant secondary metabolites are structurally highly diverse chemical compounds. They exert various biological effects even at very low concentration and, hence, play an important role in ecological communications. Unlike in the twentieth century, ecologists now are well aware of the impact secondary metabolites (SM) can have through their interaction with the biotic and abiotic environment in which they exist [1]. SM provides protection against harmful organisms like herbivores, insects, and microbes and helps the plant to tolerate stress and to survive in the ecosystem [2, 3]. Such roles of SM are important as the plants have to compete with their competitor plants for light, water, and nutrients. In nature, SM play different ecological functions, e.g., they serve as signal compounds to attract pollinating or seed dispersing insects and animals and can mediate the interactions between symbiotic bacteria and their plant hosts (e.g., rhizobia) [4]. They can also perform some physiological functions such as nitrogen storage, nitrogen transport, and UV protection. As secondary metabolites have group-specific distribution in the plant kingdom, these physiological functions are not common to all but are unique and additional to certain compounds.

Plants are attacked by herbivores and pathogens. They deter both by direct and indirect defenses. These organisms often share the same individual plant, mainly when feeding insects are vectors or their feeding wounds allow establishment of pathogens. Thus, there are many opportunities for direct interactions to affect the fitness and ecology of plants [5, 6]. Plants themselves are not simply passive hosts. They participate truly in these three-way interactions. As part of direct defenses morphological structures or SM are used to inhibit attack by insects and pathogens [7]. With indirect defenses, against herbivores, damaged plants emit volatile compounds that attract the enemies of their enemies [8].

Variations in plant nutrients and herbivore-deterrent plant secondary metabolites (PSMs) across a landscape create a chemically complex environment that may influence the distribution and abundance of animal species [9]. The defensive and nutritional chemistry of not majority, but many plant populations are highly variable [10]. Spatial hotspots of highly palatable or highly unpalatable plants are ecologically important, because the probability of a plant being eaten depends not only on its own characteristics but also on the environment in which it occurs [11]. Plants experience associational defense or associational resistance from unpalatable neighboring plants when herbivores make foraging decisions at the scale of a patch of plants, or by association with palatable neighbors if they act as attractant-decoys when herbivores forage at an individual-plant scale. Some plants can experience associational susceptibility if the association is disadvantageous [12] whether such associational effects occur, and whether spatial patches of trees of similar palatability are of any significance to foraging herbivores thus depends upon the scale of the herbivore's foraging movements [13].

In comparison with flavonoids, the distribution of alkaloids is more restricted, with only 20–30 % of plants (mostly angiosperms) producing this major class of metabolite. A subdivision of the alkaloids with respect to their biosynthetic origin from a particular amino acid precursor (usually phenylalanine/tyrosine, tryptophan, ornithine, lysine, histidine, or anthranilic acid) further restricts the distribution of each subclass. More information about alkaloids types and distribution is available in other chapters of the book. Most alkaloids are physiologically active compounds having a variety of toxic effects on animals and allelopathic effects on plants. Alkaloids with allelopathic properties include aconitine, berberine, caffeine, cinchonine, colchicine, cytisine, ergometrine, gramine, harmaline, hyoscyamine, lobeline, lupanine, narcotine, nicotine, papaverine, quinidine, quinine, salsoline, sanguinarine, sparteine, strychnine, theophylline, and yohimbine [14, 15]. These compounds are originated from aerial parts of plants and released into the environment through foliar leaching by rain, residue decomposition, and debris incorporation. However, some alkaloids of plant origin are produced by roots and are released directly into the soil and have marked effects on positive and negative interactions between plants and soil-borne organisms [16].

2 Ecological Role of Alkaloids on Plants

The absence of secondary metabolites generally does not immediately kill plants but can have profound effects on a species' ecology and evolution. It is often found that particular secondary metabolites are restricted to individual species or narrow sets of species within a phylogenetic group, providing the potential for biochemically mediated behavior almost as diverse as the plant kingdom. Alkaloids strengthen the competitiveness of invasive plant species by inhibiting the growth of neighboring plants (this phenomenon is known as allelopathy). Most of the structural types of alkaloids can exhibit allelopathic effect. Allelopathy in crop plants can help in warding off weeds. In plants, allelopathy is often related to harmful effects on germination and seedling growth [17]. Some authors suggest that allelopathic effects can also contribute to promote shifts in density, dominance, and spatial patterns of plant populations [18, 19]. Thus, allelopathic plants may have a differential role in species coexistence and in forest succession [20, 21].

Soil is arguably the most complex and difficult system to choose for the study of ecological functions of secondary metabolites. However, soil is also the ecosystem in which chemical interactions play the most substantial role, and from where major insights into the role of leaching alkaloids on neighboring plants can be revealed. There are many examples which show the effect of alkaloids on other plants. Some of the earlier studies showed numerous examples of allelopathic effect of Solanaceae family members, e.g., the germination of *Medicago sativa* L. (lucerne) was inhibited by *Solanum tuberosum* extract; the germination of *Triticum aestivum* L. (wheat) was inhibited by seeds of *Solanum melongena* L. (eggplant) and *Nicotiana tabacum*, while a mixture of 200 g of dried plant material from *Lycopersicon esculentum* in 100 mL of water inhibited the germination of *T. aestivum* by 42 %, and significantly reduced radicle and coleoptile growth. Studies on *Solanum rostratum* Dun. showed that fresh, alkaloid containing extract of *S. rostratum* had inhibitory action against symbiotic nitrogen-fixing bacteria (*Rhizobium* species), with a slightly less marked inhibition of the free-living nitrogen-fixing bacterium *Azotobacter*. The inhibition of symbiotic nitrogen-fixing bacteria by this weed could aid in its competition with plants relying on nodulation for their nitrogen supply [22, 23].

Alleopathic studies by Hussain and coworkers [24] showed that *Datura innoxia* significantly inhibited germination and growth of test species by root exudates, aqueous extracts from various aboveground parts, and substances volatilizing from the shoots. Gressel and Holm [25] found that aqueous extracts of ground seeds of *Datura stramonium* (thornapple) inhibited the germination of many crop species. It is generally believed that alkaloids of *Datura* often leach from seeds into the surrounding soil and make the surrounding environment toxic to some plants and may be favorable to others due to decreased competition. *D. stramonium* inhibits germination and root growth of *Helianthus annuus*; the strength of its effects depends on the amount of alkaloid adsorbing clay in the soil [26]. As compared to leached alkaloids, the inhibitory effect can be absent for the endogenously produced alkaloids, as was reported for quinolizidine alkaloids in lupins [27] and colchicines in *Colchicum autumnale*. However, in case of alkaloid sensitive plants, both high and low concentration of alkaloid in soil is harmful. At lower concentration they inhibit or stimulate the growth of radicles and hypocotyls and at higher concentration marked reduction in the germination of seeds can be seen. The presence of *Datura* near wild cucurbits and other members of the complex of starchy seeds used by prehistoric occupants of the Eastern Woodlands [5] suggest that not all crop plants would be deleteriously affected by its proximity. By poisoning weeds in agricultural fields, *D. stramonium* instead might have had a positive effect on the growth of certain crop plants that can tolerate leached alkaloids. Depending on the susceptibility of various cultigens in the Eastern Woodlands to alkaloid poisoning and its deleterious effects on harmful invaders, prehistoric Americans may have left *Datura* as a useful weed.

Another plant with great allelopathic effect is the Barley. It is integrated with other crops to inhibit weed growth which is mediated by alkaloids released from barley plant components and/or exuded from living roots. High allelopathic effectiveness of barley has resulted in its wide adoption as a cover crop in sustainable agricultural systems for weed management. The allelopathic effectiveness varies among the barley cultivars, hence, selection programs might improve the allelopathic potential of new cultivars used for weed management [28]. In barley, alkaloids gramine (*N*,*N*-Dimethyl-3-aminomethylindole) and hordenine (*N*,*N*-dimethyl-4-hydroxyphenylethylamine) confer heritable self-defense capabilities against other plants [29]. In a study, effects of gramine and hordenine on white mustard were studied. The release of alkaloids by barley was quantified by HPLC. The alkaloids had a negative effect on white mustard which included reduction of radicle length and apparent reduction in health and vigor of radicle tips. The evidence of the morphological and primary effects of barley allelochemicals at the levels released by living plants indicates that the biologically active secondary metabolites of barley may lead to a significant role in self-defense by the crop [30]. In an experiment by Ovesi and coworkers [31] 17 Iranian barley cultivars of different developmental stages were undertaken to determine their allelopathic potential, and it was observed that barley leachates and residues decreased emergence and Germination Rate Index (GRI) of wild mustard (*Sinapis arvensis*) as the test plant. Although there were some fluctuations in the GRI value with time, the germination inhibitory effect has decreased as new, higher-yielding cultivars have been released. Taking into account of various laboratory studies on alkaloids, they have proved to play an important role in influencing neighboring plants. But in some cases there are discrepancies between the field and laboratory experiments. For example, in a study, the germination of *Ocimum* (a tropical herb), *Spermacoce* and *Catharanthus* (two tropical, alkaloid-producing plants), and *Cinchona* itself was strongly inhibited by the quinoline alkaloids of *Cinchona*, when applied at concentrations higher than about 0.3 mM. Although the roots of the plants contain high concentrations of these alkaloids (ca. 10 mM), only very low concentrations were found (ca. 0.02 mM) in the soil. Further, upon germination of seeds sown close by the plants, no toxic effects were observed. So, although several studies have reported inhibition of seed germination by *Cinchona* alkaloids under laboratory conditions, such results indicate that this property does not play a role under natural circumstances at realistic concentrations [32].

Similariły, *Lupinus albus* L. was mentioned to have allelopathic effects, limiting the growth of *Spergula arvensis* L., *Rumex obtusifolius* L., and *Chenopodium album* L. Such effect was attributed to the presence of quinolizidine alkaloids in *L. albus*. Some crops such as barley (*Hordeum vulgare* L.) [33] and pearl millet (*Pennisetum glaucum* (L.) R.Br.) [34] were reported to have self-toxicity effects and that type of effect was expected in *Lupinus* species because alkaloids are present in all plant components. However, in a work by Nava and coworkers [35] the occurrence of plants of *L. campestris* in the experimental areas before seed sowing did not affect seed germination. This result suggested that *L. campestris* does not present self-toxicity despite having alkaloids. There are many experiments which showed allelopathic effect of different plants, e.g., alkaloid content of mesquite (*Prosopis juliflora*) leaves showed allelopathic activity against root growth of lettuce (*Lactuca sativa*) and barnyard grass (*Echinochloa crus-galli*) [36]. Caffeine (1,3,7-trimethylxanthine), a purine alkaloid found naturally in over 100 plant species showed to possess phytotoxicity against plant species. A study proved the effect of caffeine on the rooting of hypocotyl cuttings of mung bean (*Phaseolus aureus*) and the associated biochemical changes. At 1,000 μM caffeine concentration, there was a 68 % decrease in the number of roots/primordia per cutting and 80 % decrease in root length. However, no root formation occurred at 2,000 μM caffeine [37]. Research on wheat allelopathy has progressed rapidly from the initial evaluation of allelopathic potential to the identification of allelochemicals and genetic markers associated with wheat allelopathy. Benzoxazinones, a novel class of alkaloids, along with other allelochemicals were identified as biologically active agents conferring weed suppression. Recent advances in metabolomics, transcriptomics, and proteomics will greatly assist in the identification of novel allelopathy genes. Ultimately, the allelopathy genes could be manipulated to regulate the biosynthesis of allelochemicals, thereby resulting in better weed suppression via elevated levels of allelopathic potential in commercial wheat cultivars [38].

3 Ecological Role of Alkaloids on Herbivores and Insects

Plant allelochemicals are nonnutritional compounds, synthesized by a plant species that are able to affect growth, health, and behavior or population biology of another species either as a stimulator or an inhibitor [39]. Most progress in the past decade in understanding how secondary metabolites influence herbivores has come from systems where the plant chemistry is well characterized through partnerships between chemists and ecologists [40, 41]. Up to 90 % of the energy flow through feeding in terrestrial ecosystems occurs at the interface between plant primary producers and animal primary consumers, thus this sector of the system includes many alkaloids produced by plants to repel, reduce, regulate, or redirect the pressure put on them by herbivores (consumers). Most known alkaloids in almost all classes were first isolated from edible parts of photosynthetic plants and have notable effects on the physiology and behavior of animals that normally or potentially feed on these plant parts (leaves, stems, sap, bark, roots, flowers, shoots, fruits, seeds). Among plant secondary metabolites, pyrrolizidine alkaloids (PAs), mainly those with a 1,2-double bond in the necine base moiety (1,2-dehydropyrrolizidines), are one of the best-studied examples of the flux of chemical compounds through trophic levels (In ecology, the trophic level is the position that an organism occupies in a food chain). In natural contexts, PAs are important elements of ecosystem and plant–animal relationships [42]. PAs flow through different trophic levels, suffering metabolic modifications and mediating many ecological interactions. Herbivorous species that are associated with PA-plants may have developed different ways to deal with these potentially toxic compounds. Some species like *Tyria jacobaeae, Zonocerus variegatus, Oreina* leaf beetles, *Mitopus morio*, and many more became PA-specialists and overcame this chemical barrier by detoxifying and incorporating PAs in their tissues [43]. Moreover, they use these toxic compounds for their own benefit as odor signal in intraspecific communication, and as a taste signal in interspecific interactions [44]. The reason behind the tolerance to toxic PAs by the organisms can be that the PAs are almost always stored as their *N*-oxides and not as a free base. Because PA *N*-oxides cannot diffuse freely across biomembranes, they can be easily stored and retained in specific organs or tissues, in general the integuments (as seen in different species of arctiid moths: *Spilosoma lubricipeda, Arctia caja, Phragmatobia fuliginosa, Callimorpha dominula, Diacrisia sannio*, and *T. jacobaeae, Creatonotos transiens*) [45]. In plants, PAs and other toxins occur in low concentrations (usually less than 1 % of the dry weight), so they are assumed to be a cheap defense. Digestibility reducers (e.g., trypsin protease inhibitor) occur in higher concentrations and are more expensive for the plant to produce [46] as the costs of secondary metabolites increase with their concentration [47]. Besides being beneficial traits, defense products can also lead to so-called ecological costs, such as increased susceptibility to other types of herbivores and pathogens, and deleterious effects on pollinators and herbivore predators and parasitoids [48].

The ragwort species, common or Tansy ragwort (*Jacobaea vulgaris*, formerly *Senecio jacobaea*), Marsh ragwort (*S. aquaticus*), Oxford ragwort (*S. squalidus*), and Hoary ragwort (*S. erucifolius*), members of Asteraceae family, are native to Europe, but invaded North America, Australia, and New Zealand as weeds. The abundance of ragwort species is increasing in west-and central Europe. Ragwort species contain different groups of secondary plant compounds defending them against generalist herbivores, contributing to their success as weeds [49]. They are mainly known for containing pyrrolizidine alkaloids, which are toxic to grazing cattle and other livestock causing considerable losses to agricultural revenue. Consequently, control of ragwort is obligatory by law in the United Kingdom, Ireland, and Australia. Cattle confront alkaloid poisoning primarily through the consumption of hay poisoned with *Senecio* material. The livers of mammals can be severely damaged by toxic pyrrols, the breakdown products of PAs, which are formed in the gut. Ragwort is one of the most frequent causes of plant poisoning of livestock. It is responsible for over 90 % of the complaints on injurious weeds in the United Kingdom [50, 51]. PAs also occur in other families, e.g., Boraginaceae and Leguminosae. Besides herbivores and insects, microorganisms are also affected by PAs [52].

For controlling *Senecio* different factors affecting its growth were explored. A study showed that nutrients level in soil can determine the outcome of competition between plants. For example, *Chenopodium album* competes most successfully with the *S. vulgaris* when potassium levels are high [53]. In agriculture, one might want to reduce weed pressure of *Senecio* species by adapting nutrient supply. Nutrients affect both the variety and the levels of PAs in the plant. Nutrient-poor pastures were found to be much more invaded by the weeds *S. jacobaea* and *S. aquaticus* than nutrient-rich pastures [54]. Apparently, the low amount of nutrients caused gaps in the vegetation which enabled propagules to invade the pastures. The effect of nutrients on competitiveness of *Senecio* even depends on its species, e.g., *S. madagascariensis* actually has increased competitive advantage over oats with increasing nitrogen and phosphorus levels [55]. Moreover, improved nutrient status in the field lowers the PA concentration in the *Senecio* plants and thereby pathogen did respond positively to the plants, and such plants are more susceptible to pathogens, though it remains to be seen whether this can improve biocontrol of *Senecio* weeds [52].

The most prominent insect for control of common ragwort is the cinnabar moth (*Tyria jacobaeae*, Arctiidae). The larva of cinnabar moth is specialized on feeding on common ragwort. It uses the PAs contained for host detection, sequestering, and detoxifying them through N-oxidation [43]. The cinnabar moth can have a major impact on the population dynamics of *S. jacobaea*. The caterpillars periodically completely defoliate their host plant and in certain years cause extinction of *S. jacobaea* on a local scale [56]. If the cinnabar moth has been a selective force in the evolution of different PAs of its host plant *S. jacobaea*, we expect that structurally related PAs differ in their effects on the moth. Other insects capable of deterring PA effect are Ragwort stem and crown boring moth (*Cochylis atricapitana*) and Ragwort plume moth (*Platyptilia isodactyla*) [51]. Toxins are rare within natural communities, but they exert profound effects on species interactions at multiple trophic levels and thus could function in keystone roles [57].

In a study, induced direct defenses in wild populations of the alpine plant *Adenostyles alliariae*, a species that possesses constitutive chemical defense (pyrrolizidine alkaloids mainly seneciphylline and senecionine) and specialist natural enemies (two species of leaf beetle, *Oreina elongata* and *Oreina cacaliae*, and the phytopathogenic rust *Uromyces cacaliae*), were tested. The host plant suffers a high proportion of leaves consumed by leaf beetles, and infection by the phytopathogenic rust. *O. cacaliae* spends the entire reproductive season on *A. alliariae*, whereas *O. elongata* also feeds on *Cirsium spinosissimum*. It was observed that the beetles were not deterred by the PAs in their host, and in fact sequestered them for their own defense. Such plants possesses inducible resistance involving the jasmonic acid and salicylic acid pathways that is capable of reducing the rate of beetle and rust attack that were undeterred by the pyrrolizidine alkaloids produced by the plant [11].

During the study on other specialist organisms, Van Dam and coworkers [58] observed adults of the monophagous weevil, *Mogulones cruciger* (Curculionidae) feeding preferentially on young leaves of *Cynoglossum officinale* (Boraginaceae) with a high PA (heliosupine, echinatine, and 30-acetylechinatine) content. Concerning the adult stage, PAs were demonstrated to be an oviposition stimulant to females of *T. jacobaeae* and the danaine butterfly, *Idea leuconoe*. In 1982, Eisner demonstrated for the first time that PAs were involved in the chemical defense of warning colored insects. He showed that the orb-weaver spiders *Nephila clavipes* (Nephilidae) and the domesticated scrub jays *Aphelocoma coerulescens* (Corvidae) rejected adults of the arctiid moth *Utetheisa ornatrix* as a food source, which contain PAs sequestered from their larval host plants, *Crotalaria* spp. When the larvae of *U. ornatrix* fed on artificial diet without PAs, the adults were predated by the orb-weaving spiders [59]. Cardoso [60] showed that mealworms treated with monocrotaline were tasted and afterward visually rejected by the pileated finch, *Coryphospingus pileatus* (Emberizidae). Thus, the unpalatability was learned, since in subsequent trials the birds started to reject visually palatable prey with the same coloration as the unpalatable ones. The insectivorous bat *Eptesicus fuscus* (Vespertilionidae) is also deterred by PAs present in arctiids. This bat species learned to associate the sounds emitted by PA-containing moths with unpalatability, thus using auditory cues signaling aposematism [61]. The protection conferred by these alkaloids is not totally effective. Tanager birds (*Pipraeidea melanota*, Thraupidae) have been found preying heavily on distasteful species of ithomiine butterflies, by discarding the cuticle and ingesting the abdominal contents, which is suggested to have a low PA content. In the overwintering sites of the danaine butterfly, *Danaus plexippus* in Mexico, these butterflies were preyed upon by the mouse *Peromyscus melanotis* (Cricetidae) that presented the same predatory behavior as the tanager birds [62]. The PA-derivatives, dihydropyrrolizines and b- and c-lactones have a sexual function as pheromones in males of ithomiines, danaines and arctiids. In these butterflies, females choose mate depending upon the amount of PAs on their bodies. This is ecologically significant, since males transfer PAs to females during mating. In turn females transfer PAs to the eggs, conferring protection for both [63]. These examples depict the flow of PAs through different trophic levels. Further example of tritrophic interaction can be seen in Ladybirds (*Coccinella*). These insects sequestered PA from *Aphis jacobaeae* feeding on PA rich *S. jacobaea*. It is likely that in ladybirds, besides the endogenously produced coccinellines the PA also serve as chemical protectants.

Some plants contain a diverse array of alkaloids that deter vertebrate herbivores. However, mammalian folivores have evolved a complex of physiological and behavioral strategies to counter these compounds, leading to the development of an "evolutionary arms race." Many alkaloids exhibit a bitter or pungent taste for vertebrates and a bitter or pungent diet is normally instinctively avoided [64]. Unlike most mammals, insect herbivores are more selective feeders. The majority of insects are specialized feeders of some sort, specializing on particular plant species, genera, or families or on particular plant organs [65]. As for example, lupins occur in two varieties, one which is alkaloid free (sweet lupins) and the other which is alkaloid rich (bitter lupins). They produce quinolizidine alkaloids (QA) in leaf chloroplasts and export them via the phloem all over the plant where they accumulate in epidermal tissues and especially in reproductive organs. Aphids passively feed on sap of phloem vessels in plants. Aphid like, *Myzus persicae* only suck sap from phloem of "sweet" lupins but not from alkaloid-rich varieties with high alkaloid contents in the phloem. Also many other animals, from leaf miner flies (Agromyzidae) to rabbits (*Oryctolagus cuniculus*) showed a similar discrimination. Sweet lupins were always highly susceptible and selected as favorable food [64]. The defense potential of bitter lupin is due to quinolizidine alkaloids which interfere with the nervous system of animals, affecting mainly nicotinic and muscarinic acetylcholine receptors and inhibiting Na^+ and K^+ channels.

Bitter lupins are not used as a diet because of their toxicity. However, they may have alternative uses as potential sources of natural insecticides. In a study, quinolizidine alkaloids of three Mexican *Lupinus* species: *L. montanus* (HBK), *L. stipulatus* (Agardh), and *L. aschenbornii* (Schauer), were analyzed by capillary

Gas chromatography-mass spectrometry. Sparteine was found in high amounts in both *L. montanus* and *L. aschenbornii* while aphylline and an epiaphylline-like compound in *L. stipulatus*. When extracts of these plants were tested for their insecticidal activity using larvae of the Fall Armyworm, *Spodoptera frugiperda* (Smith); (Lepidoptera, Noctuidae) as a model pest; it was found that extract of *L. stipulatus* was most toxic against the larvae of *S. frugiperda* in comparison to two others. This suggests that the various QA act differently on caterpillars, and could be used to control *Spodoptera* populations [66].

Besides being toxic, alkaloids of lupins are helpful to some plants and animals in direct or indirect ways. For example, specialized aphid, *Macrosiphum albifrons*, which lives on lupins and sequesters the dietary alkaloids and uses them for defense against predators [67]. Another beneficial effect of bitter lupin in maintaining the ecology of an area can be anticipated by studies on *Castilleja indivisa*, a hemiparasitic annual plant. Herbivory can result in decreased pollination by reducing resources available for floral displays, or by damaging attractive tissues. Preference of pollinators for less damaged plants has been found in systems with floral herbivory and with leaf herbivory [68]. Decreased pollination indirectly results in low seed set and disturb the normal seed number and thereby ecology of the particular area. In a study by Adler [69] alkaloids were manipulated experimentally in the *Castilleja indivisa* by growing these parasites with bitter or sweet alkaloid isogenic lines of the host *Lupinus albus* in the field. Over the flowering season, pollinators visited a greater percentage of *C. indivisa* with bitter (high-alkaloid) hosts than sweet (low alkaloid) hosts, and also visited more *C. indivisa* that had been sprayed with insecticide compared to natural herbivory controls, regardless of alkaloid content. Analysis indicated that the benefit of alkaloids was due to their effect on herbivory. Herbivory and pollination had both direct and indirect effects on lifetime seed set of a parasitic plant, *Castilleja indivisa*. Similar host plant effects on herbivores of a hemiparasite were seen in generalist herbivore cabbage looper (*Trichoplusia ni*) and the specialist Nymphalidae butterfly (*Euphydryas anicia)*. Both type of herbivores showed decreased performance on *Castilleja sulphurea* containing alkaloids from the host *Delphinium occidentale* compared to *Castilleja* parasitizing hosts without alkaloids [68].

Besides avoiding, some insects can tolerate the defense chemistry of their host. The potato beetle (*Leptinotarsa decemlineata*) lives on *Solanum* species containing steroidal alkaloids, which are tolerated but not stored by this species. The bruchid beetle, *Bruchidius villosus*, predates seeds of QA rich plants, such as *Laburnum anagyroides*. This beetle eliminates most of the dietary cystisine with the faces. Certain aphids can store the dietary alkaloids, for example, QA in *Aphis cytisorum*, *A. genistae*, and *Macrosiphum albifrons* and PA in *Aphis jacobaeae* and *A. cacaliaster* [70].

There are many examples which show that besides pyrrolizidine and quinolizidine alkaloids other classes of alkaloids are also quite toxic to herbivores and insects. In North America, reed canarygrass (*Phalaris arundinacea*) is important livestock forage on wet and poorly drained soils. It is often unpalatable and supports lower animal performance than would be predicted from its nutrient content. It contains at least eight different alkaloids, including five indole alkaloids and three *p*-carbolines. These alkaloids all contain an indole nucleus. Reed canarygrass also contains hordenine. Marten and coworkers [71] concluded that the threshold level for total indole alkaloid concentration in reed canarygrass at or above which diarrhea and reduced growth rate occurs is about 0.2 % of the dry weight. The low palatability of reed canarygrass is associated with the hordenine content. *Phalaris* spp. has caused animal mortalities in various parts of the world by affecting the animals in different ways. Low larkspurs (*Delphinium nuttallianum* Pritz., *Delphinium andersonii* Gray) and plains larkspur (*Delphinium geyeri* Greene) often poison cattle grazing on western North American rangelands. The dominant toxic alkaloid in larkspur is methyllycaconitine (MLA); other very toxic alkaloids in low and plains larkspurs are nudicauline and geyerline. Concentrations of toxic alkaloids in *D. nuttallianum*, *D. andersonii*, and *D. geyeri* often did not significantly decline during the growing season as typically found in tall larkspurs. Thus, risk to grazing cattle may remain high until these plants are dormant [72].

Despite such toxic effects, alkaloids are sequestered by herbivores and insects for their own benefit which in a way is important in maintaining the ecosystem of the habitat. Pitohuis, a passerine bird, is thought to sequester the alkaloid, homobatrachotoxin, from beetles in their diet into the feathers and skin. The utilized batrachotoxin helps the bird in deterring its predators and avoidance of this bird as food by natives of New Guinea. It is predicted by a group of workers that the rarity of examples of secondary metabolites sequestration in birds and mammals demonstrates that other predator-avoidance strategies such as cryptic behavior and physical “fight or flight” mechanisms are less costly than ingesting and sequestering these toxic compounds in these mobile animals [73]. Another example of alkaloid driven benefit was seen in wild tobacco. As assumed short visitation (time period of visits) times by legitimate pollinators due to increased level of alkaloid and phenols, do not necessarily represent a fitness disadvantage for plants. For example, nicotine in floral nectar of wild tobacco was found to decrease consumption rates by certain pollinators but consequently increased the number of individual visits and, thus, the number of successful pollen transfers. Likewise, nectar odors play a role in the attraction of mutualists to both floral nectar and extrafloral nectar, but repellent functions have to protect nectar from unintended consumption. Nectar chemistry serves both, the attraction of nectar visitors that exert a positive effect on plant fitness and the repellence or putative intoxification of exploiting organisms [74].

Numerous plant alkaloids with antiherbivore properties are classified according to their mode of action (e.g., toxins, antifeedants, antidigestive proteins, etc.) and have been used in agriculture to control insect pests. The pyridine alkaloid nicotine is one of the best-studied putative plant resistance traits. Because it can interact with the acetylcholine receptors in the nervous systems of animals, nicotine is extremely toxic to most herbivores and, consequently, was one of the first insecticides used to control pests in agriculture. Evidence for the resistance value of nicotine arises from the agricultural practice of using nicotine sprays and genotypes of cultivated tobacco differing in nicotine levels [75]. Similarly, experiments indicate a statistically significant dose dependent decrease in the survival rate and an increase in the percentage mortality of ants and aphids in the presence of *Datura alba*. This property of *Datura* suggests that alkaloid-rich extract of *Datura alba* at suitable concentration could potentially be useful to local farmers [76]. Another alkaloid, caffeine has recently been viewed as a safe chemical for management of pests including molluscs, slugs, snails, bacteria, and as a bird deterrent.

Work by Chaniago and coworkers [77] showed that barley has the potential for self-defense against broiler chickens and other species through its biologically active secondary metabolites, gramine and hordenine. Similar type of defense was also seen against aphid *Rhopalosiphum padi* (L.). The population growth rate of *R. padi* was negatively correlated with gramine content in leaves of barley seedlings. In wheat indole alkaloids and phenolics are important in the resistance to insects. The indole alkaloid (i.e., gramine) can be toxic to *Schizaphis graminum*, *R. padi*, and *Sitobion avenae*. Compared to total phenolics, the indole alkaloid content is highly correlated with the number of *S. avenae* infesting wheat ears [78]. Cotton bollworm is one of the most important pest insects in many countries of world and is responsible for destroying a lot of crop plants. In an experiment, when secondary compound gramine was incorporated into artificial diets of cotton bollworm (*Helicoverpa armigera*) larvae. The results showed that it decreased the mean larval and pupal weights of cotton bollworm [79]. Such types of studies make the background to attempt to breed crop varieties with increased level of allelochemicals that would be resistant to pests.

4 Ecological Role of Alkaloids on Microorganisms

The existing evidence on the role of alkaloids against microorganisms is scarce especially in comparison to ecological studies on insects. However, there are many classes of alkaloids known to show antimicrobial activities, one of such classes is benzylisoquinoline alkaloids (BIAs). It is a large and diverse alkaloid group with more than 2,500 defined structures. The BIAs berberine, sanguinarine, and palmatine were specifically shown to confer protection against herbivores and inhibit the multiplication of bacteria, fungi, and viruses [80]. Other class with potential antibacterial activity is quinolizidine alkaloids. Recently, Erdemoglu and coworkers [81] reported that quinolizidine alkaloid extracts from the aerial parts of *Lupinus angustifolius* and *Genista vuralii* showed significant activity against several different bacterial species and moderate activity against the fungi; *Candida albicans* and *C. krusei*. In a work, alkaloid extracts of aerial parts and seeds of *Sophora alopecuroides* showed promising antimicrobial activities against different bacteria tested [82]. Tyski and coworkers [83] tested lupin alkaloids against a number of Gram-positive and Gram-negative bacteria, including one strain of *Bacillus thuringiensis* isolated from soil and concluded that the alkaloids present in lupins may have an allelopathic function against bacteria. Sepulveds and

Table 6.1 Selected examples of alkaloid containing plants and animals and their role in ecology

Alkaloid	Plants/animals	Ecological roles
Gramine, Hordenine	 *Hordeum vulgare* L. (Barley)	Allelopathic potential; Weed management
Quinolizidine alkaloids	 *Lupinus* sp. (Bitter lupins)	Allelopathic potential, natural insecticides
3-oxo-juliprosine, secojuliprosopinal, etc.	 *Prosopis juliflora*	Allelopathic potential
Benzoxazinones	 *Triticum* sp.	Allelopathic potential
Pyrrolizidine alkaloids	 *Jacobea vulgaris*	Toxic to cattles and other livestock

(*continued*)

Table 6.1 (continued)

Alkaloid	Plants/animals	Ecological roles
Indole alkaloids	 *Phalaris arundinacea* (Reed canarygrass)	Animal mortalities
Methyllycaconitine, nudicauline, geyerline	 *Delphinium* sp. (Low Larkspurs)	Cattle poisoning
PA-derivatives (dihydropyrrolizines, b- and c-lactones)	 Ithomiines, danaines, arctiids males	Phermones
Pyrrolizidine alkaloids	 *Coccinella* (ladybirds)	Sequester PA
Homobatrachotoxin	 Pitohuis (a passerine bird)	Sequester from beetles and deter its predators

Corcuera [84] identified gramine as being inhibitory to the growth of the bacterium *Pseudomonas syringae*, and Krischik and group [85] found nicotine to be toxic to five species of *Pseudomonas*: *P. syringae*, *P. syringae* pv. *angulata*, *P. syringae* pv. tabaci, *P. fluorescens*, and *P. solanacearum*, all plant pathogens. Wink [86] listed 183 alkaloids with antibacterial properties but indicated that many of these may have been investigated for possible pharmaceutical use rather than to elucidate their ecological roles.

Alkaloids also exhibit antifungal effects. There are many bioassay experiments which proved their efficacy. Ma and coworkers [87] showed that the isoquinoline alkaloids, corynoline and acetylcorynoline, inhibited the fungal growth of *Cladosporium herbarum*. Zhou and group [88] reported that steroidal alkaloids from the rhizomes and roots of *Veratrum taliense* inhibited the growth of the phytopathogenic fungi, *Phytophthora capisis* and *Rhizoctonia cerealis*. The alkaloid extract of the seeds of the plant *Sophora alopecuroides* showed significant activity against *Candida krusei* (MIC = 62.5 μg/mL) [89]. PAs produced by *Heliotropium subulatum* showed to be active against *Aspergillus fumigatus, Aspergillus niger, Rhizoctonia phaseoli*, and *Penicillium chrysogenum* [90].

Alkaloidal plant extracts from *J. vulgaris*, when tested never stopped fungal growth totally. After initial growth-delay the fungi were able to adapt and grow normally within 30 days. Hol and van Veen [91] hypothesized that this temporary growth-delay may have serious ecological significances. This delay may impact the competition between microorganisms in the rhizosphere and will give plant roots extra time to raise its defenses or escape. Experimental studies have proved that high-PA-containing plants (1.13–3.92 mg/g dw) with jacobine as the major root PA suppressed the development of some microorganisms in the rhizosphere and thereby play a role in the selection processes. This selection might favor those microorganisms that are tolerant or resistant to these defense compounds or in some cases even can degrade or utilize them. Such selections shape the soil-borne microbial community present in the rhizosphere. Despite all such findings the exact role that alkaloids play in plant protection against root-infecting bacteria and fungi is still not fully understood. Measuring low levels of chemical compounds that occur in the rhizosphere of the plant is still a challenge study area because of inadequate methods for analysis. Some examples of alkaloid containing plants and animals have been shown in (Table 6.1).

5 Ecological Role of Endophytic Alkaloids

Symbiotic interactions of green plants with bacteria and fungi are widespread. Enhanced nutrient uptake, greater stress tolerance, and protection from pests are among many benefits obtained by infected hosts. Most endophytes (organism that lives inside of a plant) produce one or more alkaloid classes that likely play some role in defending the host plant against pests. The bioprotective alkaloids in grass/endophyte symbiota are generally grouped as pyrrolizidines, ergot alkaloids, indole diterpenes, and pyrrolopyrazines. Such a production of alkaloid toxins by endophytes provides a clear mechanism for altered host physiology and ecology. Controlled and natural experiments suggest that endophyte symbiosis can have large effects on plant communities and their associated consumers [92]. An interesting example can be seen in ergot alkaloids. These alkaloids are mainly produced by saprophytic fungi: *Claviceps purpurea* and related species (Clavicipitaceae) which are symbionts on grasses. Rye is especially affected among cereals. *Claviceps* is a symbiotic organism that takes nutrients from its host but provides chemical defense against herbivores as compensation. Field experiments have shown that such a fungal infection is an ecological advantage for grasses in the wild.

The endophyte that has sparked the greatest research interest is *Neotyphodium coenophialum* (formerly *Acremonium coenophialum*), which is a ubiquitous symbiont of tall fescue (*Festuca arundinacea* = *Lolium arundinaceum*; a long-lived perennial bunchgrass species). It provides a wide range of host benefits and produces three of the four known classes of endophyte associated alkaloids which provide them protection against various pathogens. For example, infected tall fescue is more resistant to seedling blight caused by *Rhizoctonia* and crown rust caused by *Puccinia coronata* relative to uninfected plants [93]. The widespread occurrence of all four alkaloid classes among asexual endophyte species, and the hybrid origins of many such endophytes, it is reasonable to speculate that hybridization may have led to the proliferation of alkaloid-production genes among asexual endophytes, favoring hybrids. The ergot alkaloids ergovaline, lolitrems, and lolines are produced by only a single sexual species, *Epichloe festucae*, but they are common in seed-transmitted endophytes, suggesting that *E. festucae* contributed genes for their synthesis [94]. Alternatively, asexual hybrids may also be favored by the counteracting of the accumulation of deleterious mutations.

Other symbiotic fungi such as *Balansia* and *Myriogenspora* (Clavicipitaceae) also infect grasses and produce alkaloids. Ergot alkaloids (such as agroclavine, chanoclavine, ergine, ergosine, and ergometrine) are also common in some genera of the Convolvulaceae (including *Argyreia*, *Ipomoea*, *Turbina corymbosa*, *Stictocardia tiliafolia*). This is due to the ergot alkaloid formation by endophytic clavicipitaceous fungus, which is in symbiotic relationship with certain species in this plant family [95]. Loline, another alkaloid found in a grass *Lolium pratense*, e.g., *Festuca pratensis*, which has symbiotic relation with endophytic fungus *Neotyphodium uncinatum*. A study proved that endophyte infection increased persistency and competitive ability of *F. pratensis* [96] thus; help the grass and its hemiparasite to ward off herbivores. Besides endophyte/grass symbiota, loline alkaloids have also been identified in some other plant species; namely, *Adenocarpus* species (Fabaceae) and *Argyreia mollis* (Convolvulaceae). Loline alkaloids are less widely distributed among endophyte-infected grasses than ergot alkaloids but are generally found in higher concentrations than other alkaloids (exceeding 1 % of plant dry weight biomass. Further, Peramine, the only pyrrolopyrazine alkaloid found in endophyte-infected grasses, is more widely distributed in *Epichloe* and *Neotyphodium* host grasses than other alkaloids. Peramine has a relatively even distribution in the plant and over the growing season, and there is evidence of host genotype control of peramine concentrations [97]. Recently, a fungal endophyte, *Embellisia* spp., was isolated from locoweeds (*Astragalus* and *Oxytropis* spp.) and shown to produce toxic alkaloid swainsonine [98].

Endophytic symbionts need to cope with the secondary metabolites of their host plant. Usually fungi inactivate the toxins of its host by the ability to utilize the compounds as substrate for energy and biomass production or storage for their own defense against attackers. Werner and group [99] showed that endophytic fungi were able to metabolize the polyamine alkaloid aphelandrine. Several fungi were capable to use part of the polyamine alkaloid as nitrogen source. Nearly all fast-growing endophytes of the family of Nectriaceae were able to degrade and to grow on this alkaloid while slow-growing endophytes could only partially degrade aphelandrine.

Endophyte infection affects the host plants and these changes may negatively affect co-occurring plant species and their consumers as seen in some greenhouse experiments. White clover (*Trifolium repens*) was competitively suppressed by perennial ryegrass in infected pastures but not in uninfected pastures, making endophyte-infected grass/clover mixtures difficult to sustain [100]. Grasses and grasslands are dominant features of our landscape and some endophyte symbioses potentially have large-scale consequences. Clay and Holah [101] showed how infected tall fescue in successional fields increased in dominance over a 4-year period, resulting in a decline in plant species richness compared to plots with uninfected tall fescue. Large tall fescue grasslands in the eastern United States present a good example of endophyte-induced dominance.

Much attention has been focused on endophyte alkaloids during the last 25 years as these alkaloids play direct or indirect role in changing the ecology of the environment in which it exists. Toxicity in cattle grazing tall fescue and of sheep grazing perennial rye grass by endophytic infection is quite common. Chinese grass *Achnatherum inebrians* (drunken horse grass), infected by a *Neotyphodium* endophyte, is rapidly increasing its geographic range and frequency of afflicted livestock. Indigenous livestock rarely eat the grass because they have learned to avoid it, but naive animals are frequent victims of intoxication or death. Endophyte-infected *Echinopogon* species native to Australia are reported to cause stock poisonings much like those seen with perennial ryegrass [102]. Besides them, wild herbivores such as voles and rabbits, and Canada geese are also negatively affected by endophyte-infected tall fescue. In an experimental study, sex ratio and the reproductive status of female prairie voles was significantly affected by endophyte infection in field plots of tall fescue [103]. Laboratory studies with several passerine birds found strong avoidance of endophyte-infected tall fescue seeds in choice tests, and reduced survival and weight gain in nonchoice tests [104].

Community-wide effects on endophytes may be extended beyond herbivores to their associated parasites and predators in other trophic levels. For example, *Neotyphodium* endophytes of *Lolium multiflorum*, lower plant quality, reduce the densities of aphid herbivores, and indirectly reduce the rate of parasitism on aphids by parasitoids [105]. The potential for alteration of the interactions of grasses with herbivores and their natural enemies will clearly depend on many factors, including the frequency of infected hosts within the community, the types and relative levels of bioprotective alkaloids, and the spatial distribution of grasses and herbivores.

However, little is currently known about the impact of endophytes on food web dynamics in any natural ecosystem. There is a potential for the grass/endophyte symbiosis to impact more than the associated animal and plant communities. The ecosystem level consequences of endophytes have begun to be considered by a few researchers [106]. These consequences include carbon flow into soil food webs, such as the endophyte effects on litter decomposition and soil microbial activity and changes in soil nutrients availability and secondary compounds that may feedback to the plant community. The two agronomic species *L. arundinaceum* and *L. perenne* investigated the most are not native to places where they have been studied (United States and New Zealand) [106]. Further studies in natural ecosystem remain to be done before realistic ecological impact of endophytes can be studied.

6 Conclusion

Although the biological activities of many alkaloids have not yet been studied and their ecological functions remain to be discovered or proven, alkaloids have proved to play an important role in the ecosystem. Recognizing the potential of alkaloids, studies on the ecological effects of alkaloids have received considerable attention over the last few decades. Some alkaloid-rich plants, such as *Senecio* spp., *Crotalaria* spp., *Lupinus* spp., wheat, and barley, have provided a concise background to understand how alkaloids mediate ecological interactions. Most of the structural types of alkaloids can exhibit allelopathic effects. Numerous examples of allelopathic effects can be seen in members of the Solanaceae plant family. In crop plants, allelopathy can help in warding off weeds. Allelochemicals in barley make it a potential candidate as a natural herbicide. Integrating barley cover cropping with other cultural practices can possibly improve the sustainable agricultural systems for weed management. Taking into account various laboratory studies on alkaloids, they have proved to play an important role in influencing neighboring plants. But in some cases there are discrepancies between the field and laboratory experiments, as in the case of *Cinchona* and *Lupinus campestris*. However, recent advances in metabolomics, transcriptomics, and proteomics will greatly assist in the identification of novel allelopathy genes. Ultimately, the allelopathy genes could be manipulated to regulate the biosynthesis of allelochemicals, thereby resulting in better weed suppression via elevated levels of allelopathic potential. Among plant–animal relationships, pyrrolizidine alkaloids and quinolizidine alkaloids are the most studied examples of the flux of chemical compounds through trophic levels. Herbivorous species that are associated with alkaloid-rich plants may have developed different ways to deal with these toxic compounds. Some species became alkaloid specialists and overcame this chemical barrier by detoxifying and incorporating these toxins in their tissues. Regardless of this, there are numerous plant alkaloids with antiherbivore, insecticidal, and antimicrobial properties and are classified according to their mode of action (e.g., toxins, antifeedants, antidigestive proteins, etc.) and have been used in agriculture as safe chemicals for management of pests including molluscs, slugs, snails, bacteria, and as a bird deterrent. Thus, the field of alkaloids in relation to ecology presents a great potential for research and development of environmental friendly weeds/herbivores/insects/microbes management practices, without disturbing the ecosystem.

Abstract

The number of known tropane alkaloids exceeds 200. They are tertiary or quaternary (*N*-oxides) bases having in common the tropane nucleus as the key structural element. The tropane alkaloids are mainly distributed in the genera of Solanaceae family and they are frequently used in medicine because of their valuable pharmacological activities. The main representatives of this group of bioactive substances are hyoscyamine (its racemate atropine), scopolamine, and cocaine. These alkaloids have been investigated in details during the last two decades. In this chapter we summarize the knowledge about distribution of tropane alkaloids in plant kingdom and their biosynthetic pathway that has already been elucidated at enzyme and gene level, as well as the methods for their qualification and quantification. Biotechnological approaches for tropane alkaloids production are also discussed in details.

Keywords

Artificial polyploidy • bioreactor • hairy roots • hyoscyamine • plant cell cultures • scopolamine • tropane alkaloids biosynthesis

TLC	Thin-layer chromatography
TR	Tropinone reductase
UV	Ultraviolet

1 Introduction

Tropane alkaloids are frequently used in medicine because of their valuable pharmacological activities [1]. To this group belong hyoscyamine **1**, its racemate atropine **5**, scopolamine **6**, and cocaine **2** [2, 3]. Hyoscyamine **1** and scopolamine **6** are widely applied as parasympatholytic agents who antagonize acetylcholine binding in a competitive manner [1, 4, 5]. Therapeutic doses of atropine **5** possess antispasmodic properties and are used in treatment of cardiac and gastrointestinal diseases [1, 4]. It is used to treat acute bronchitis, to control the symptoms of Parkinson's disease, and as an antidote in cases of poisoning by organophosphates [1, 6]. The better activity on the central nervous system at lower therapeutic doses of scopolamine **6** supported with less side-effect than atropine **5** [1, 4] determines its greater demand on the market than hyoscyamine **1** and atropine **5** [1, 7].

Tropane alkaloids are exclusively distributed in many Solanaceae species – *Mandragora, Brugmansia, Duboisia, Hyoscyamus, Datura, Atropa*, and *Scopolia* [4, 7, 8]. Cocaine **2** is produced by *Erythroxylum coca* Lam.[8, 9]. Tropane alkaloid content in plants differs according to the species and varies about 0.01–3% [1]. However, climate changes and other ecological problems lead to disruption and even to disappearance of natural habitats of medicinal plants, which has resulted in difficulties to obtain plant-derived bioactive substances. Promising alternative for commercial scale production of tropane alkaloids appears to be cultivation of plant in vitro systems in controlled conditions [7, 10]. To improve the production of secondary metabolites, different strategies like high productive line selection or culture condition optimizations are performed [11]. Another successful way to increase the productivity in plants or their in vitro systems is the application of genetic engineering. The detailed elucidation of the intermediates and enzymes that influence the biosynthetic pathway, and increasing the number of the regulatory genes, provides efficient approach to increase or decrease the amount of the target metabolites by enhancing the rate-limiting steps or by blocking competitive pathways [1, 5, 11, 12]. Changes in the plant ploidy are also useful approaches for improving the yields of valuable secondary metabolites [13].

2 Distribution of Tropane Alkaloids

The number of tropane alkaloids known from natural sources exceeds 200. They are tertiary or quaternary (*N*-oxides) bases having in common the tropane nucleus (8-azabicyclo[3.2.1]octane) as the key structural element [14].

Their distribution is among plants of the families Solanaceae, Erythroxylaceae, Convolvulaceae, Proteaceae, Rhizophoraceae, Brassicaceae, and Euphorbiaceae [15].

The greatest range of tropane alkaloids has been found in the Solanaceae family. Characteristic alkaloids for this family are mono-, di-, or tri-esters of tropine **27** or pseudotropine **25** (the OH group at C3 is in *β*-position). A number of organic acids, such as formic, acetic, hydroxyacetic, propionic, tiglic, methylbutyric, phenyllactic, tropic, senecic, angelic, mesaconic, cinnamic, etc., form esters with the alkamines [14, 16, 17]. Many solanaceous species from genera *Datura*, *Brugmansia*, *Hyoscyamus*, *Scopolia, Atropa*, and *Duboisia* accumulate the pharmacologically active hyoscyamine **1** and scopolamine **6** as main compounds in their alkaloid profiles and therefore, they have been used as industrial sources for their production [15]. As many tropane alkaloids, hyoscyamine **1** is a chiral molecule wherein chirality is introduced by the tropic acid. Only the *R* form of tropic acid occurs in natural tropane alkaloids. Racemization, however, readily occurs during isolation procedure. The racemic mixture of (*R*,*S*)-hyoscyamine is known as atropine **5**. Dimeric tropane alkaloids (belladonnine) and polyhydroxy nortropane alkaloids (calystegines) have been found in *Atropa belladonna.* Calystegines have been found in other species from the family such as *Physalis, Hyoscyamus, Scopolia*, and *Solanum* [15, 18]. Often, monocyclic analogues such as the pyrrolidinyl alkaloids hygrine **16**, cuscohygrine **4**, and their derivates have been detected as minor compounds in the alkaloid profiles of plants and in vitro cultures from genera *Datura*, *Hyoscyamus*, *Brugmansia*, etc. [16, 17, 19]. The main structures and some representatives of the tropane alkaloids (**1–7**) are given below.

Along with 3α-tropine derivatives, characteristic for the plants of the family Erythroxylaceae are the esters of 3*β*-tropine (pseudotropine) and ecgonine with benzoic, phenylacetic, 3,4,5-trimethoxybenzoic, 3,4,5-trimethoxycinnamic acids, etc. Dimeric esters of methylecgonine (truxillines) and tropine (mooniines) have been also reported [15].

Unusual pyronotropane tropane alkaloids have been found in the family Proteaceae. Tropine and pseudotropine esters of benzoic acid have been isolated from the family Euphorbiaceae. Novel dithiolane esters, along with tropine esters of acetic, propionic, *n*-butyric, isobutyric, isovaleric, and benzoic acids have been found in the Rhizophoraceae. Calystegines, as well as a 3-hydroxybenzoate ester, have been found in Brassicaceae. The calystegines have been used as chemotaxonomic markers in the Convolvulaceae family [20]. Tropine esters with methoxy-substituted benzoic acids are also characteristic for the later family.

3 Qualification and Quantification of Tropane Alkaloids

3.1 Sample Preparation Procedures

The tertiary tropane alkaloids can be extracted from the plant material in the form of salt with acidic aqueous solutions or as bases at pH $>$ 8–9 with organic solvents such as methanol, ethanol, chloroform, etc. Sample purification procedures for tropane alkaloids before chromatographic analyses are based usually on liquid-liquid extraction (LLE) or solid-phase extraction (SPE). The choice of solvents depends on the solubility (p*Ka* and p*Kb*) in water of the target alkaloids. For quantitative analyses, exhaustive extraction or the use of suitable internal standard should be ensured.

Columns packed with diatomaceous earth (Extrelut®) are often used for the preparation of a large number of samples from various biological materials [21, 22]. In this case, the alkaloids are extracted with acidic aqueous solution which has to be basified before application on the column. The alkaloids are eluted with chloroform and chloroform:methanol (3:1).

N-oxide forms of the tropane alkaloids, found in many plants, are analyzed after reduction with dithionite. For that reason, two aliquots of the acid alkaloid extract are taken, and the first one is treated with dithionite. After basification of the extracts and partition of the alkaloids (as tertiary bases), the amount of the *N*-oxides is calculated after instrumental analysis by subtracting the yield of total alkaloids (first aliquot) minus yield of tertiary alkaloids (second aliquot). The method is proved to be quantitative [21].

The hydrophilic calystegines are extracted with water or methanol-water solutions. After centrifugation, the volume of the supernatant is reduced, treated with skin powder, filtered, and then applied to columns of strongly acidic cation exchange resin for purification. The nonbinding compounds are removed with water and alkaloids are eluted with 3.5% aqueous NH_3. After drying, the alkaloid fraction has to be silylated for further GC-MS analysis [20].

3.2 Chromatography of Tropane Alkaloids

Quantitative and qualitative analyses of the tropane alkaloids are based on their efficient separation. The pure compounds, obtained after preparative chromatography (column or thin-layer), are subjected to spectroscopic analysis for identification. NMR (1 and 2D mono- and hetero-atom experiments) is applied for structure elucidation. While relative configuration of chiral centers can usually be assigned by NMR (NOESY and/or NOE) experiments, the determination of the absolute configuration is much more difficult due to the identical NMR spectra of enantiomers. It can be determined by measuring the specific rotation [α] and circular dichroism or using chiral auxiliary reagents. Only X-ray crystallography provides direct access to the chirality of compounds but obviously relies on the ability to form crystals [23].

GC-MS is the method of choice for identification of the components in complex mixtures of tropane alkaloids combining the high resolution power of capillary columns with the specificity of the mass detectors. It allows identification of tropane alkaloids without using of standard compounds. Isomers (at positions C3 and C6/7) are tentatively identified by Kovats retention indexes and cochromatography with reference compounds [16, 17]. In some cases, tentative identification of new tropane alkaloids has been possible by GC-MS [16, 24–26]. In fact, this is the only way to assess the minor or trace compounds, which are difficult or impossible to isolate. More than 30–40 tropane alkaloids can be detected in a single species by GC-MS [19]. GC-MS chromatogram of alkaloid extracts of *D. stramonium* L. hairy roots and representative MS spectra are presented in Fig. 7.1.

The major MS characteristics of the tropane alkaloids and related compounds are as follows:

- The monocyclic (pyrrolidinyl) alkaloids (hygrine **16**, hygroline, cuscohygrine **4**, etc.) have M^+ with low intensity. The most characteristic ion fragments of these alkaloids are the base ion at *m*/*z* 84 and ions at *m*/*z* 85, 83, 82, 70, 55, and 42.
- The main fragments, characteristic for the tropane ring system, are at *m*/*z* 124, 113, 112, 96, 95, 94, 83, 82, and 42.
- The type of substitutions could be determined according to the base ion. For 3-monosubstituted tropanes, the base peak is at *m*/*z* 124; for 3,6-disubstituted, 3,6,7-trisubstituted, and 3-monosubstituted-6,7-epoxytropanes, at *m*/*z* 94; for nortropanes, at *m*/*z* 110; and for 6,7-epoxynortropanes, at *m*/*z* 122. For alkaloids without ester substitution at C-3, the base peak is at *m*/*z* 82. Each of these subgroups of alkaloids has characteristic fragmentation as well as ion fragments indicating the substituents (Fig. 7.1).
- Many tropane esters appear as double peaks in the gas chromatograms and show identical mass spectra. They are isomeric tropine and pseudotropine esters. The stereochemistry of substituents at C-3 of the tropane alkaloids could be determined by GC comparison with reference material only.

It should be mentioned that hyoscyamine **1** and littorine **26** are poorly separated by GC, and they have very similar mass spectral fragmentation. They could be distinguished by the characteristic ion fragments at *m*/*z* 91 and 142 for littorine **26**

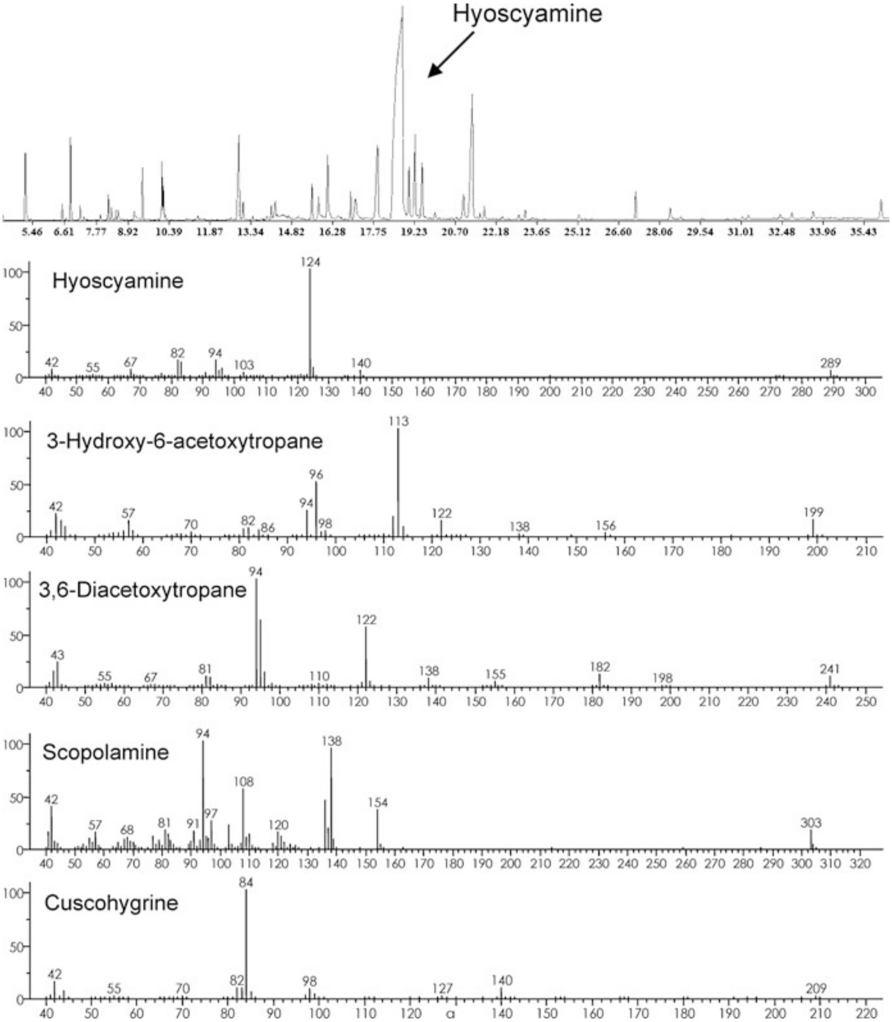

Fig. 7.1 GC-MS chromatogram of alkaloid extract of *Datura stramonium* L. hairy roots and representative MS spectra of monosubstituted (hyoscyamine **1**), disubstituted (3-hydroxy-6-acetoxytropane, 3,6-diacetoxytropane), epoxytropanes (scopolamine **6**) tropanes, and their monocyclic analogues (cuscohygrine **4**). The GC-MS analyses were performed with a Hewlett Packard 6,890+/MSD 5975 instrument operating in EI mode at 70 eV. An HP-5 MS column (30 m × 0.25 mm × 0.25 μm) was used. The temperature program was: 100–180 °C at 15 °C/min, 180–300 at 5 °C/min, and 10 min hold at 300 °C. Injector temperature was 250 °C. The flow rate of carrier gas (helium) was 0.8 mL/min. 1 μL of the solution was injected

and at *m*/*z* 271 (the lost of water) for hyoscyamine **1** [16]. Good separation of hyoscyamine **1** and littorine **26** can be obtained after silylation [27].

GC-MS has been applied for quantitative and qualitative analysis of tropane alkaloids in various plant species and in vitro cultures [17, 24]. The MS detector,

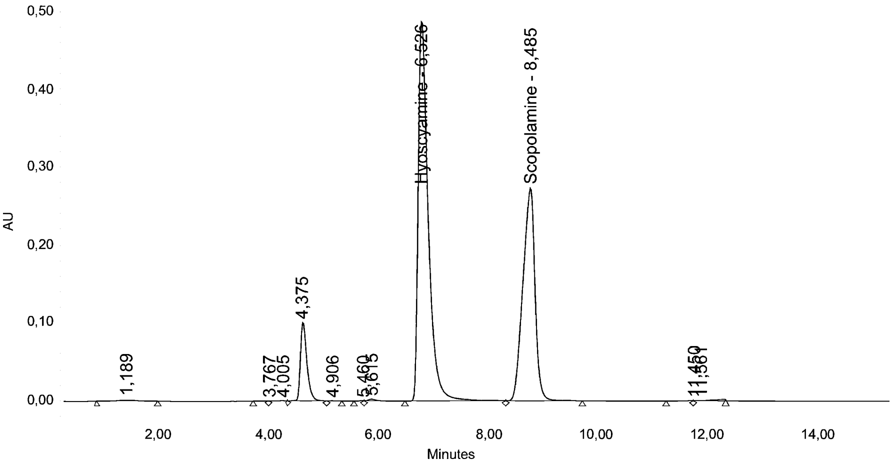

Fig. 7.2 HPLC separation of hyoscyamine **1** and scopolamine **6**. The analysis was performed by using Waters HPLC system, equipped with Waters 1,525 binary pump, a Dual λ Waters 2,487 absorbance detector, and Symmetry® C18 reversed phase chromatographic column (250 mm × 4.6 mm, 5 μm). The operation temperature was 26 °C. The mobile phase consisted of acetonitrile:methanol:0.05 mol ammonium acetate (20.9:27.9:51.2), and elution speed was 0.6 mL min^{-1} in isocratic regime

especially in selected ion monitoring (SIM), provides a high sensitivity allowing quantification of target compounds at ppb levels [28]. The main disadvantages of GC-MS, however, are the degradation of some thermally unstable compounds (hyoscyamine may lose water and form apoatropine under GC conditions), derivatization of nonvolatile compounds such as the calystegines, and impossibility for resolution of enantiomers.

In contrast to GC-MS, a wide range of tropane alkaloids, including *N*-oxides and calystegines, can be analyzed by HPLC without prior derivatization. Enantiomeric separation of atropine **5** and scopolamine **6** racemic mixtures has been also achieved [22]. A number of HPLC methods have been published for routine quantification of the major tropane alkaloids hyoscyamine **1** and scopolamine **6** in plant samples. The use of UV detectors however is limited to compounds with UV adsorbing (aromatic or other) functionality. This disadvantage, however, is easily overcome by using HPLC coupled with MS detectors [22]. A typical HPLC separation of hyoscyamine **1** and scopolamine **6** is presented on Fig. 7.2.

In the recent years, capillary electrophoresis (CE) is widely used in alkaloid analysis because the nitrogen is easily charged. In the analysis of tropane alkaloids, it is applied for enantiomeric separation of atropine **5** and for analysis of pharmaceutical substances [22].

Despite that thin-layer chromatography (TLC) is less informative as compared to the above-mentioned methods, it is frequently used in the laboratories for screening of plant samples and alkaloid fractions. TLC is a low-cost, simple, fast, and with high-throughput approach. It is less sensitive and less reproducible than other

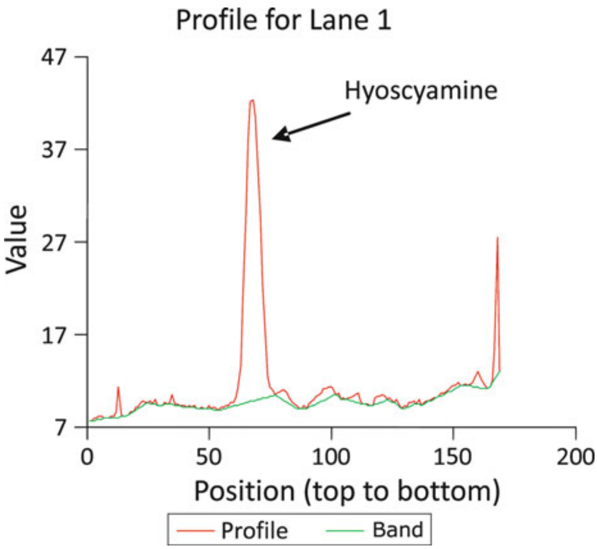

Fig. 7.3 TLC chromatogram of *Atropa belladonna* L. root extract. 20 μL of extracts were spotted on Silicagel G60 TLC plate. Hyoscyamine and scopolamine standards were spotted in concentrations of 2, 5, 10, and 20 μg on the same plate as well. The chromatogram was developed by using chloroform: methanol:26% ammonia (in proportion of 85:15:0.7) as mobile phase, and Dragendorff's reagent was used for spots visualization. The alkaloid contents were quantified densitometry by QuantiScan® software

chromatographic methods, and it has been considered as semiquantitative method for a long time. Usually, Dragendorff's reagent is used for visualization of the tropane alkaloids. The levels of alkaloids in the solanaceous intact plants and in vitro cultures, however, are high enough, and recently quantitative TLC methods for tropane alkaloids have been developed for analyses of plant tissues [29–31]. A TLC chromatogram of alkaloid extracts of *A. belladonna* L. roots is presented on Fig. 7.3.

It is worth mentioning that the recent work of Talaty et al. [32] uses desorption electrospray ionization (DESI), a nonchromatographic method, for detection of various alkaloids from *D. stramonium* L. and *A. belladonna* L. Using DESI, no sample preparation is required because native fresh tissues can be directly analyzed. The mass spectra are recorded under ambient conditions, in times of a few seconds.

4 Biosynthetic Pathway of Tropane Alkaloids

Tropane alkaloids are biosynthesized in the roots and transported to the aerial parts of the plant through xylem [1, 6, 7]. They comprise of pyrrolidine and piperidine ring with shared nitrogen and two carbon atoms [1]. The ring skeleton is considered to be an assembly of the amino acid ornithine **8**, acetate, and methionine. The C-1, C-5, C-6, C-7, N-8 of the five-membered ring derive from ornithine **8**, the *N*-methyl group from methionine, and C-2, C-3, C-4 come from acetate-derived C3 fragment [33, 34]. Over the last years, a lot of evidences have been gained providing data that 4-(L-methyl-2-pyrrolidinyl)-3-oxobutanoate **19** is the direct precursor on the pathway to tropine **27** but not hygrine **16** as considered before [7, 34, 35].

Tropane alkaloids share a similar biosynthetic pathway with nicotine although it is not part of them (Scheme 7.1) [36]. The pyrrolidine part of tropane alkaloids is formed from ornithine **8** or arginine **12** [1]. Ornithine decarboxylase (ODC; EC 4.1.1.17) is responsible for the direct formation of putrescine **9** via ornithine decarboxylation, while arginine **12** is firstly transformed to agmatine **11** and then to *N*-carbamoylputrescine **10** by arginine decarboxylase (ADC; EC 4.1.1.19) [1, 2, 7]. They are flux-limiting enzymes [1], since putrescine **9** formation is a common step with polyamine metabolism [2]. Using specific inhibitors, it has been demonstrated that in *Datura* both alternative routes for putrescine **9** formation are possible. However, the ADC activity is more important than ODC [1]. Arginine **12** seems to be the most preferred source for C_4N fragment C-1, C-5, C-6, C-7, *N*-8 than ornithine **8** [34].

While ODC is found in all living organisms, ADC has limited distribution to bacteria and plants [1]. Cloning of ODC cDNA from *D. stramonium* L. and its expression in *E. coli* revealed that the enzyme is highly similar with other prokaryotic and eukaryotic ODCs, and it is presented by more than one gene copy in the plant genome [1, 2].

The next step of the pathway is the *N*-methylation of putrescine **9** to *N*-methylputrescine **13** by putrescine *N*-methyltransferase (PMT; EC 2.1.1.53) [1, 5]. This is the key enzyme and the first committed step in the biosynthesis of tropane and nicotine alkaloids in which a methyl group from *S*-adenosyl-L-methionine (SAM) is transferred to an amino group of putrescine **9** [3, 7]. The PMT is a unique enzyme detected only in tropane and related to alkaloid-producing plants. The reaction is a flux-limiting step during which putrescine **9** is being removed from the polyamine pool and pointed toward alkaloid production [7] instead of polyamines such as spermidine and spermine [1]. Monoamines like *n*-butylamine or cyclohexylamine are competitive inhibitors of PMT [1, 4]. The PMT activity has been detected within branched roots of tropane alkaloid-producing *A. belladonna* L., *H. niger* L.*,* *D. stramonium* L., and *D. inoxia* L. and was absent in other plant organs [4, 6]. A cDNAs coding for this enzyme has been isolated from *H. niger* L., *A. belladonna* L., and *Solanum tuberosum* L. [37].

PMT expression occurs in the root pericycle of *A. belladonna* L. and *H. muticus* L. [2, 36, 37] and in endodermis, outer cortex, and xylem in *Nicotiana sylvestris* L. [36, 37]. The localization of PMT to the pericycle would facilitate the access to arginine **12** or ornithine **8** [2, 6]. In the same way, *N*-methylputrescine **13** or some biosynthetic intermediate could then be transported to the endodermis for further elaboration into tropine **27** [6].

Further step in the pathway is reaction catalyzed by the diamine oxidase enzyme, *N*-methylputrescine oxidase (MPO; EC 1.4.3.6). This enzyme leads to oxidatively deamination of *N*-methylputrescine **13** to 4-(methylamino)butanal **14**, which after spontaneous cyclization forms the reactive precursor of the tropane nucleus – *N*-methyl-Δ^1-pyrrolinium cation **20** [2, 7, 36]. This enzyme requires copper as a cofactor and belongs to a class of amine oxidases. cDNA was isolated from tobacco [37]. This enzyme has been isolated by root cultures of *H. niger* L.,

Scheme 7.1 Biosynthetic pathway of tropane alkaloids

D. stramonium L., and *N. tabacum* L. Its activity is suppressed to very low level by exogenous supply of plant hormones and subsequent cell dedifferentiation. The activity decreases also after feeding with tropine **27** [1].

No enzyme has been found so far which would catalyze the formation of tropinone **24** from *N*-methyl-Δ^1-pyrrolinium cation **20** [1]. It was demonstrated that the pathway most probably passed by formation of 4-(1-methyl-2-pyrrolidinyl)-3-oxobutanoate **19**, its cyclization to give 2-carboxytropinone **21**, was followed by decarboxylation step to form tropinone **24** [35].

The next step from the biosynthetic pathway is a branch point of the tropane alkaloid pathway [1, 2]. Tropinone **24** is the first intermediate with a tropane ring, and it is converted into intermediates that lead to hyoscyamine **1** or calystegines production depending on the stereochemistry of the reduction [37]. Two stereospecific tropinone reductases (TR; EC 1.1.1.236) – tropinone reductase I (TR-I) reduces the 3-carbonyl group of tropinone **24** to the 3α-hydroxy group of tropine **27** and tropinone reductase II (TR-II) to the 3β-hydroxy group of pseudotropine **25**. TR-I leads to hyoscyamine **1** and scopolamine **6** formation via tropine **27**, whereas pseudotropine **25** produced by TR-II is converted into calystegines and other nortropane alkaloids [1, 7, 36].

It should be noted that encoding TR-I and TR-II genes have been indentified in *A. belladonna* L. and *H. niger* L., but not in nicotine-synthesizing plants. cDNA clones for TR-I and TR-II isolated from *D. stramonium* L. and expressed in *E. coli* revealed that the proteins exhibit 64% amino acid identity and to be member of short-chain, nonmetal dehydrogenase family [34, 36]. The exchange of various domains of TR-I and TR-II revealed that the stereo- and substrate specificity are determined by the orientation of the tropinone at the substrate-binding site which consists mainly of carboxyl-terminal domain. The N-terminal region constitutes the NADPH-binding site [1, 2]. In the amino-terminal region there are glycine residues which form tight turns, called Rosmann folds, in the cofactor-binding domain. The carboxyl-terminal region contains reaction centers, with a tyrosine and a lysine residue [4]. The substrate-binding site consists of 120 amino acids, mostly hydrophobic which is present in both TRs [1–3] and 53 differ [4]. The presence of different charged residues gives different electrostatic environment on TR-I and TR-II [1].

TRs' activities are at very high levels in developing young branched roots [4]. TR-I is found in the endodermis and nearby cortical cells which determines the transport of the intermediates of tropane alkaloid metabolism between cell types. TR-II is localized to companion cells of sieve elements in the phloem of potato [36, 37]. TR-I is not considered to be a rate-limiting activity [1]. The TRs' activities differ with species which means that in this way, the flow at this branching point may be determined [4]. Demonstration of this has been done by Richter et al. [38] overexpressing TR-I and TR-II in *A. belladonna* L. Higher pseudotropine **25** concentration led to an increased accumulation of calystegines, while higher tropine **27** production resulted in several times higher tropane alkaloid levels and a 30–90% decrease in calystegine accumulation compared with controls [38]. Trihydroxylated calystegines are classified as the calystegine A-group, tetrahydroxylated calystegines as the B-group, and pentahydroxylated derivatives form the calystegine C-group [1].

In the next reaction, the tropate ester moiety of hyoscyamine is derived by condensation of tropine with the phenylalanine-derived (*R*)-phenyllactate to form littorine **26** [7, 37]. Patterson and O'Hagan [39] suggested that the rearrangement of littorine **26** into hyoscyamine **1** does not occur with a vicinal interchange process as previously considered. Recently, a multifunctional cytochrome P450 has been identified from *H. niger* L., classified as Cyp80F1 and catalyzes the oxidation of

(*R*)-littorine **26** with rearrangement to hyoscyamine aldehyde **29** [7, 37, 39]. In this way, the free tropic acid is not considered to be an intermediate in hyoscyamine biosynthesis [1].

The final step in the tropane alkaloid pathway is the formation of scopolamine **6**, which is the 6,7β-epoxide of hyoscyamine via two-step reaction. Both reactions are catalyzed by hyoscyamine 6β-hydroxylase (H6H; EC 1.14.11.11) which is a bifunctional enzyme. This dioxygenase first hydroxylates the tropane ring of hyoscyamine **1** by 6β-hydroxylation forming 6β-hydroxyhyoscyamine **30**, followed by intramolecular epoxide formation via removal of the 7β-hydrogen [2, 3, 7, 37]. The hydroxylase activity of H6H is 40 times higher than its epoxidase activity. H6H is a 2-oxoglutarate-dependent enzyme that requires alkaloid substrate, 2-oxoglutarate, Fe^{2+}, molecular oxygen, and ascorbate for catalysis [1]. H6H is a rate-limiting enzyme in scopolamine biosynthesis. Overexpression of H6H in low scopolamine *A. belladonna* L. increased the scopolamine **6** content [40]. In the same way, hyoscyamine **1** was favored to scopolamine **6** in *A. beatica* Wilk [41].

H6H is localized to the pericycle in the roots of *A. belladonna* L. and *H. muticus* L. and not found in stem, leaves, or cultured cells of the same species. Thus, the scopolamine **6** produced in the pericycle can be readily translocated to the leaves via the adjacent xylem [2, 3, 37].

5 Biotechnological Approaches for Tropane Alkaloids Production

Higher plants are valuable sources of diverse metabolites, many of which are used as pharmaceuticals. Further, in recent years, worldwide market has preferred natural products; thus, the market for natural plant products has expanded, and this trend will continue. However, the production of plant-derived substances is limited by environmental, ecological, and climatic conditions. These problems could be overcome using plant in vitro systems, which were introduced at the end of the 1960s as promising matrices for both producing and studying plant secondary metabolites [42]. At the moment, several problems still complicate industrial implementation of these systems. Instability of their secondary metabolite profiles and yields of the target molecules are the main problems. Nowadays, bioprocess engineering approach for development and optimization of plant in vitro system-based processes is well developed. Algorithms for media optimization, elicitation, bioreactor constructions adaptation, environmental conditions optimization, etc., have been described in details [43].

Hyoscyamine **1** and scopolamine **6** are the tropane alkaloids with the most important therapeutic value. The current commercially exploited sources for their production are different plants belonging to *Atropa* or *Datura* species in Europe and *Duboisia myoporoides* R.Br. in Australia [8]. Faced with the described above problems accompanying the production process based on plant material, many research groups focused their attention on development of alternative biotechnological process for tropane alkaloids production.

5.1 Plant Cell Suspensions

As the plant cell suspensions could be easily cultivated in common bioreactor systems, used in microbial biotechnology, several investigations were performed on initiation of callus and cell suspension cultures by different Solanaceae plants (Table 7.1) [44–49]. In general, once initiated, plant cell suspensions are easily adapted to submerged cultivation conditions and are amenable to subsequent scale-up in bioreactors [50]. Cell suspension of *H. muticus* L. showed fast growth and accumulates between 10 and 11 g dry biomass L^{-1} when cultured in both 5.0 L stirred tank and 9.0 L plastic-lined vessels bioreactors [51]. Following the scale-up process, a 40.0-L low-cost plastic air-lift bioreactor system, which produced 199 g dry weight of *H. muticus* L. cells in 13 days, was developed. This biomass yield was indistinguishable from the achieved in submerged cultivation of the same culture in shake flask [51]. However, as it is showed in Table 7.1, the overall content of produced alkaloids in Solanaceae callus and cell suspension cultures is rather low. Different strategies for obtaining of calli and cell suspension cultures with incensed production potential of target tropane alkaloids have been applied. It was demonstrated that during callogenesis, the different plant organs used as explants could generate calli with different potential to produce tropane alkaloids [49]. As example, the contents of scopolamine **6** in callus cultures, induced from leaf, stem, and root parts of *D. metel* L., varied between 14.15 and 0.06 mg g^{-1} dry biomass. At the same way, only the callus cultures induced from *D. metel* L. roots biosynthesized hyoscyamine **1** in concentration of 0.2 mg/g dry biomass [49]. Exposure of light could affect on tropane alkaloids accumulation as well. Transferring and cultivation of *H. niger* L. callus and cell suspension cultures under continuous illumination (3,000–5,000 lx) decreased almost three fold their scopolamine **6** contents, without any significant changes in hyoscyamine **1** levels (Table 7.1) [47]. The increased contact between the plant cells can also increase alkaloids production. Immobilization of *D. innoxia* L. cell suspension in Ca-alginate leads to almost six fold increase of both hyoscyamine **1** and scopolamine **6** levels, whereas the addition of pure alginate into the cultivation medium altered only scopolamine **6** content (almost by three fold higher than in control), probably due to increased viscosity and oxygen limitation [44]. Despite of all efforts made, in most of the cases, the undifferentiated Solanaceae callus and cell suspension cultures failed to biosynthesize considerable amounts of hyoscyamine **1** and scopolamine **6**.

5.2 Soot Cultures

Searching for other producing systems, differentiated shoot cultures of *H. albus* L., *Duboisia leichhardtii* F.Muell., *D. myoporoides* R.Br., *Datura metel* L., and *Scopolia parviflora* (Dunn.) Nakai. were initiated on different media (B5 or MS, supplied with 10 μM BAP alone, or in combination with 0.1 or 1.0 μM NAA) [45, 48, 49, 52, 53]. Analyses showed that hyoscyamine **1** and scopolamine **6** were not presented or were detected at extremely low concentrations in these plant

[b] Value is on mg g^{-1} DW

in vitro systems. This observation is not surprising, as it is well known that these alkaloids are synthesized in the roots [37]. When young roots were formed after transferring the *D. leichhardtii* F.Muell. shoots on root regeneration media (B5, supplied with 10 μM IBA), the appearance of tropane alkaloids in shoots biomass was recorded. With the increase of root biomass (2–3 weeks after root initiation), the hyoscyamine **1** and scopolamine **6** were accumulated at levels of 0.36% and 0.30% of dry shoots weight, respectively [48]. The biosynthesis of tropane alkaloid could occur in cultured shoots without root initiation, but in this case, the addition of appropriate phytohormone combinations, providing a suitable cell differentiation (development of xylem cells), is necessary [46, 52]. However, as the enzymes involved in tropane alkaloid biosynthesis are scattered in different specialized root tissues (PMT and H6H are localize to the pericycle in the roots, whereas TR-I resides in the endodermis and nearby cortical cells [37]), the mature roots remain the best system for their production.

5.3 Adventitious Root Cultures

Several adventitious root cultures have been obtained by direct cultivation of sterilized young root tips [45, 54–56], rhizomes [57, 58], calli [46, 52], or even single cells [59] of different Solanaceae plants in media (B5 or MS), supplied with higher auxin concentrations. In contrast with the case of plant cell suspensions, the growth of plant root cultures in bioreactors is accompanied by several difficulties. Thus, developments of new bioreactor designs or improvements of the existed apparatus constructions should be performed as an essential step for successful realization of such cultivation process. Adventitious root culture of *H. niger* L. was cultivated in 5.0 L stirred tank bioreactor, modified by addition of support mesh and in 5.0 L mist bioreactor [60]. In both cultivation systems, the levels of produced tropane alkaloids were not altered and remained to the similar levels, registered in shaking flasks (between 0.32% and 0.37% of dry weight for scopolamine **6** and 0.05–0.075% of dry weight for hyoscyamine **1**). However, significant decreases in obtained growth indexes in stirred tank (GI = 12.9) and mist reactor (GI = 4.76), compared to submerged cultivation in flasks (GI = 21.4), were observed [60]. The lower root growth in mist bioreactor was explained by the limited nutrient supply in these type cultivation systems. Small-scale (0.6 L) bubble column bioreactor has been developed for cultivation of *S. parviflora* (Dunn.) Nakai. adventitious roots [58]. It was found that the increased inoculum density from 3.0 g fresh weight to 15.0 g fresh weight stimulated scopolamine **6** production in the roots (from 1.44 to 1.82 mg g^{-1} dry weight) and negatively correlated with their hyoscyamine **1** content (from 3.29 to 2.66 mg g^{-1} dry weight) [58]. Large-scale stirred tank bioreactor (500 L with 300 L working volume), equipped with special inoculation and mixing systems, has been developed and applied for cultivation of *A. belladonna* L. adventitious roots as well [55]. After 60 days of cultivation (agitation for 30 min at 30 rpm in every 3 days was started after the 26th day), a total amount of 35.0 kg fresh roots, containing 334.0 μg g^{-1} dry weight scopolamine, were produced [55].

The long cultivation times and the low alkaloid yields make these in vitro systems inappropriate for commercial application. Moreover, the supplement of additional phytohormones, essential for support of the adventitious roots growth, could promote the appearance of culture instabilities, manifested by unpredictable alkaloid yields.

5.4 Hairy Roots

Hairy root cultures seem to be the most promising alternative to overcome the above- mentioned difficulties. These in vitro systems are obtained by genetic transformation of plant cells with the soilborne phytopathogenic bacteria *Agrobacterium rhizogenes* [61]. During this process, a small part of bacterial root-inducing plasmid (Ri plasmid), named transfer DNA (T-DNA), is introduced and permanently integrated into the random site of plant genome [62, 63]. Most of the *A. rhizogenes* strains contain only one fragment of T-DNA in their plasmids, whereas the plasmids of some super-virulent strains (as example, agropine strains) have two completely different T-DNA fragments (T_L-DNA and T_R-DNA), which could be transferred independently into the plant cell [61, 63]. However, only T_L-DNA encodes the genes, responsible for neoplastic root formations. The T_R-DNA encodes few genes (*aux1*, *aux2*, *RolB* TR, *mas1*, *mas2*, and *ags*) responsible for control of opine and auxin biosynthesis in plants; thus, it was considered that it could be required only to extend the host range in *A. rhizogenes* strains [64, 65]. For realization of T-DNA transfer, the agrobacteria should be in close contact with damaged plant tissues. When this happens, the release of plants phenolic compounds (mainly acetosyringone) and sugars acts as inducers for expression of several *chv* and *vir* genes, located in bacterial chromosome and Ri plasmid, respectively. These signals triggered the beginning of several processes including T-complex formation, its further transport into the plant cell, nuclei localization, and T-DNA integration. The molecular mechanisms involved in each steps of this complex interkingdom horizontal gene transfer are well studied and described elsewhere [63, 64]. In general, the T-DNA consists of left and right border sequences and several oncogenes flanked by eukaryotic regulatory sequences, encoded between them [66]. The availability of both left and right border sequences is crucial for successful implementation of T-DNA integration, no matter which genes were encoded between them [67]. This made T-DNA an attractive system for introducing and expression of foreign genes in plants [7, 68]. However, only the expression of *A. rhizogenes* oncogenes (the “root locus” *rolA*, *rolB*, *rolC*, *rolD*, as well as the ORF3n, ORF8, and ORF13) can perturb the signal transduction pathway involved in auxin perception in plant cells, increasing their sensitivity to endogenous phytohormone levels [61, 65, 66]. As results, a fast growing, laterally branched roots named “hairy roots” are formed by each transformed cell [62]. These roots are able to rapidly grow on phytohormones-free medium and accumulate similar or even higher amounts of secondary metabolites compared to nontransformed plant roots [62, 65, 69].

Most of the Solanaceae plants were susceptible to *Agrobacterium*-mediated transformation. Successful establishing of hairy root cultures has been reported for several genera including *Atropa*, *Anisodus*, *Brugmansia*, *Datura*, *Duboisia*, *Hyoscyamus*, and *Scopolia* [1, 24, 70–74]. The direct infection and cocultivation of sterile plant explants with *A. rhizogenes* seems to be the most effective procedure for hairy root induction by Solanaceae plants (Fig. 7.4). This method is relatively simple for implementation and does not require any special laboratory equipment. To induce hairy roots, sterilized explants or sterile in vitro plants are wounded and inoculated with *A. rhizogenes* suspension.

All known plant organs could be used as explants for transformation, but the young leaves and stems are preferred for Solanaceae plants [72, 75, 76]. Several *Agrobacterium* strains including *A. rhizogenes* ATCC 15834, ATCC13333, 8196, 1724, 2659, 1855, AR-10, TR-105, A41027, A4, LBA 9402, LBA 1334, R1601, and MAFF 03-01724 as well as *Agrobacterium tumefaciens* C58 C1 carrying the pRi 15834 plasmid have been reported to induce hairy roots formation in different members of Solanaceae family [69, 70, 72, 75, 77–80]. Double transformation by using two *A. rhizogenes* strains (ATCC 15834 and MAFF 03-01724) was reported as well. The obtained doubly transformed *A. belladonna* L. hairy roots have intermediate alkaloid content as compared to the singly transformed hairy root lines but showed improved growth [81]. However, the different *Agrobacterium* strains manifested varying capability to transform plant cells, depending on the current plant species. Moreover, different *Agrobacterium* strains have a great influence on the root morphology and degree of tropane alkaloids accumulation in obtained hairy root clones. Thus, the choice of appropriate *Agrobacterium* strain is very important and should be performed experimentally [1, 62, 70, 72, 75, 82]. Two or three days after infection, the explants should be transferred into solid media (B5 or MS) with antibiotic (usually cefotaxime in concentrations between 100 and 500 mg L^{-1}) to eliminate redundant bacteria (Fig. 7.4). The young hairy roots will be induced within a period of 1 week to over a month depending on different plant species. When their size reaches 2–3 cm, the individual root tips can be separated for detached growth on phytohormone-free media. After transformation, in many Solanaceae plants, an intensive callus formation could be observed simultaneously with hairy roots induction (Fig. 7.4). These calli (often referred as "rhizogenic" calli) could be formed directly on some separated hairy root tips as well. However, the hairy root lines carrying such callus formations often possess tendency toward dedifferentiation, which significantly increase their genetic instabilities and reduce the amounts of accumulated alkaloids [70, 71, 75, 82, 83]. Thus, when isolating single hairy root clones, it is essential to select those lines which do not form callus. It was reported that there were great differences in growth rate, morphology, and alkaloid production between individual hairy root clones, even isolated from the same explants [69, 70, 82]. As example, 500 hairy root lines of *D. stramonium* L. were isolated from the same mother plants and screened for growth, morphology, and total alkaloid content [69]. The levels of total alkaloids accumulated in their dry biomasses varied between 0.63% and 1.5%. In addition, only 8 lines showed high growth potential and stable alkaloid production for more

than 5 years [69]. Substantial somaclonal variation was found to exist even in single-selected individual hairy root clones [82, 84]. This observation made possible the application of strategies of repeated selection or single protoplast selection for obtaining and screening of hairy root lines with high capabilities to accumulate biomass and tropane alkaloids. As example, after 8 repeated selections, the scopolamine **6** content in dry biomass of *D. myoporoides* R.Br. hairy root line was increased to 3.5% of dry weight, compared to a 0.15% at the parent line but decreased the growth from 7.0 to 2.2 g dry biomass L^{-1} [84]. Such negative correlation between tropane alkaloid contents and culture growth has been often reported and is thought to be the main reason for the observed low overall productivity [1, 70, 75, 84]. To overcome this substance, the growth and production conditions should be optimized individually for every selected hairy root line. Since each hairy root line is different, also its basic nutrient requirements could vary in some ranges. The growth and tropane alkaloids production of hairy root cultures could be differently affected by the type of basal culture media used for their cultivation [71, 83, 85–87]. Optimization of micro- and macronutrients of cultivation medium for selected hairy root line could have great effect on its overall tropane alkaloids productivity as well [86, 88, 89]. As example, after optimization of MS macronutrients composition for maximal biosynthesis of hyoscyamine by tetraploid and diploid *D. stramonium* L. hairy root cultures, the tetraploid hairy roots accumulated 24.7% more hyoscyamine **1** than the diploid culture, whereas before optimization, the last one has been found to produce 20.7% more hyoscyamine **1** than the former [89, 90]. The addition of exogenous growth regulators could have significant effects on both root morphology and tropane alkaloids content. In general, the addition of auxins stimulates disorganization of hairy root tissues and drastically decreases their tropane alkaloid productions [91, 92]. However, it has been reported that the exogenous supply of IAA or NAA at low concentrations (between 0.01 and 5.0 μmol L^{-1}) resulted in two fold increase of the alkaloids accumulation in hairy root cultures of *H. muticus* L., without affecting significantly the hairy root growth and morphology [1, 75]. On the other hand, the exogenous supply of GA was found to increase the roots lateral branches but to suppress significantly the tropane alkaloids production [93–95]. The elicitation with different biotic and abiotic elicitors has contradictory effects on tropane alkaloids accumulation in hairy root cultures of different Solanaceae species, but in all cases, they had increased the effects on alkaloids secretion in the culture medium [1, 62, 73, 77, 88, 96–98].

Introducing of genes encoding key enzymes of tropane alkaloids biosynthesis pathway in different Solanaceae hairy root cultures was applied as perspective strategy for increasing their scopolamine **6** and hyoscyamine **1** productions [1, 7, 68, 99]. Hairy root cultures of *Datura, Duboisia, Hyoscyamus*, and *Scopolia*, and overexpressing PMT have been obtained by introduction of *pmt* gene under the control of cauliflower mosaic virus 35S promoter (CaMV35-S) in their genomes [1, 7, 11, 100–102]. In general, the overexpression of *pmt* led to increase in both hyoscyamine **1** and scopolamine **6** levels in transformed hairy root lines, but in some cases, it was found to increase only the accumulation of the direct metabolite (*N*-methylputrescine **13**), while no effect on alkaloid production was observed [7, 101, 103]. The cDNA of TR-I and TR-II from *D. stramonium* L. was cloned into the binary plasmid pBI121 carrying a kanamycin resistance gene, a b-glucuronidase (GUS) reporter gene, and the CaMV 35-S-promotor. The constructs were introduced separately into *A. belladonna* L. and transformed hairy root cultures were obtained [38]. The hyoscyamine **1** and scopolamine **6** levels in hairy root lines overexpressing *trI* were increased three and five fold, respectively. On the other hand, the lines overexpressing the *trII* do not increase their hyoscyamine **1** or scopolamine **6** levels but elevated significantly the accumulation of pseudotropine-derived alkaloids (calystegines) [38]. In order to increase the scopolamine **6** levels in hyoscyamine **1** producing plants, the overexpression of H6H represents a promising target for obtaining transgenic hairy root cultures. The *h6h* gene under the control of CaMV 35-S-promotor was introduced in several transgenic hairy root lines of *Atropa*, *Duboisia*, *Hyoscyamus*, and *Scopolia* [41, 57, 102, 104, 105]. As general, the *h6h* overexpression led to a higher production of scopolamine **6**, whereas the hyoscyamine **1** content remained unaltered, which demonstrates that the *h6h* altered not only the last step of hyoscyamine **1** to scopolamine **6** conversion, but the overall alkaloid production of transgenic hairy root lines [7, 104, 105]. However, the most effective strategy for genetic engineering of tropane alkaloids producing hairy roots seems to be the simultaneous introduction and overexpression of couple genes, encoding different rate-limiting enzymes of scopolamine biosynthesis pathway in Solanaceae plants. Transgenic *H. niger* L. hairy root lines overexpressing both *pmt* and *h6h* were obtained after simultaneous introduction of genes encoding the PMT and H6H enzymes, both under control of CaMV 35-S promoter [12]. The best line produced over nine fold higher amount of scopolamine **6** (411 mg L^{-1}), compared to the wild-type hairy roots. This productivity was more than two fold higher than the scopolamine **6** content, registered in the *h6h* single-gene transgenic hairy root line as well [12]. On the other hand, the simultaneous overexpression of both *pmt* and *h6h* in transgenic *A. belladonna* L. hairy roots increased predominantly the hyoscyamine **1** production (11-fold, compared to control hairy roots), whereas the scopolamine **6** production was less improved (only 5 fold higher, compared to the control hairy root cultures) [10]. Recently, simultaneous introduction and overexpression of *pmt* and *trI* genes into *Anisodus acutangulus* C.Y. Wu & C. Chen hairy roots was reported [106]. The best producing transgenic line overexpressing both *pmt* and *trI* genes accumulated 8.104 mg g^{-1} DW tropane alkaloids, which was 8.66-, 4.04-, and 3.11-fold higher amount than the alkaloids in control hairy root line (0.935 mg g^{-1} DW), *pmt* single-gene transgenic hairy root line (2.004 mg g^{-1} DW), and *trI* single-gene transgenic hairy root line (2.604 mg g^{-1} DW), respectively [106].

The key point for successful realization of hairy root based-biotechnology for tropane alkaloid production is the large-scale cultivation in bioreactors. Since the hairy root cultures are sensitive to shear stress, which can cause disorganization of root tissue and decrease of tropane alkaloid productivity, the more complicated bioreactor systems should be used for their cultivations [107]. Several bioreactor systems were developed and applied for cultivation of hairy root cultures of different Solanaceae plants (Fig. 7.5, Table 7.2.) [107–114]. As can be seen on Table 7.2, the 14-L trickle-bed bioreactor (Fig. 7.5 position 8) operating in oxygen enrichment mode provides the highest biomass density (36.2 g L^{-1}) [111]. However, even the remarkably low energy costs for operation of this type bioreactor system, the presence of bed with support rings for root immobilization complicates the harvesting of accumulated biomass and confined the scale-up of the process. The problem with harvesting of immobilized root biomass was partially solved by development of detachable support matrix for large-scale (500 L) droplet

bioreactor (Fig. 7.5 position 9) [107]. Hairy root culture of D. *stramonium* L. was successfully cultivated in this type bioreactor systems for 40 days with sucrose feeding. As a result, a 39.5-kg fresh hairy root biomass was produced [107]. Up to date, this is the largest bioreactor system used for cultivation of hairy root cultures reported in literature. During the last years, the low-cost bioreactors received increased attention for cultivation of hairy root cultures [115]. In our laboratory, we applied the temporary immersion RITA systems for cultivation of diploid and tetraploid hairy root cultures of D. *stramonium* L. [114]. The main advantages of these cultivation systems compared to conventional bioreactors are the simple

construction, lack of complicated control system, and the relatively low price. When *D. stramonium* L. diploid and tetraploid hairy roots were cultivated in this temporary immersion system, they produced 2.8- and 1.9-fold more dry biomass, compared to when the same cultures were cultivated in standard bubble column bioreactor, respectively (Table 7.2) [114]. However, despite of all progress made with selection of high hyoscyamine **1** and scopolamine **6** producing hairy root lines, genetic engineering for improvements of alkaloid contents and design of bioreactor systems with specific constructions, the overall productivities of available hairy root cultures, is not sufficient for development of industrial process. Additional alternative strategies for improvement of hairy roots productivities should be applied.

5.5 Artificial Polyploidy as a Useful Tool for Tropane Alkaloids Production

While approaches for optimizing the yields of target metabolites are now well studied and appropriate strategies have been developed, the progress of modern science in understanding and controlling the profiles of produced metabolites is relatively small [50]. One way of changing the profiles of biosynthesized secondary metabolites is by artificial polyploidization [116]. Induced polyploidy makes possible both the increase in the yields of target metabolites and synthesis of new biologically active substances that are not normally synthesized in the source intact plants [13].

Polyploidy is a phenomenon that is part of the evolution of the plant kingdom [117, 118]. A polyploid is an organism that has more than two sets of chromosomes [119]. In nature, this phenomenon is rare in animal cells but widespread in plants. The term "polyploidy" or "polyploidy level" refers to the number of chromosome groups and is indicated by "x." An organism with two sets chromosomes is diploid (2x), with three sets of chromosomes – triploid (3x), with four sets of chromosomes – tetraploid (4x), etc. Polyploids may occur spontaneously (due to somatic mutation or abnormal mitosis, expressed in duplication of the chromosome number in the meristem cells) or may be induced in vivo or in vitro (with mitotic inhibitors or alteration of plant growth regulators) [120, 121]. It is important to note that induced polyploidy in plant cells does not introduce new genetic material but produces extra copies of existing chromosomes. This additional DNA replicates in subsequent cell divisions, and thus stable polyploids are obtained. Induced polyploidy has been intensively developed since the early 1930s (when the first mitotic inhibitors were discovered) in relation to improvement of agricultural crops [119].

The increase in the ploidy level often causes anatomical and structural changes, such as changes in the leaves, cell size, number of chloroplasts in cells, etc. [122, 123]. These effects of polyploidy may influence photosynthesis [124], the enzyme activities, the photosynthetic electron transport, and isoenzyme activity [13]. All these manifestations of polyploidy often lead to gigantism, i.e., to increased accumulation of plant biomass [116] and a change in secondary metabolism [13].

The general model to explain these changes is based on the assumption that the lower nuclear membrane: chromatin ratio is responsible for better contact between the chromatin and the nuclear envelope. Therefore, the gene activity increases, which improves the hormonal status and photosynthetic activity of the cell [125]. All these factors can affect the secondary metabolism and the yield of biologically active substances [13]. The data obtained by researchers over the years reveal that, with a few exceptions, polyploidy leads to a significant increase in the yields of biologically active substances. In addition, artificial polyploidy leads to a change in the chemical profile of secondary metabolites [126]. This fact itself is of particular importance both from practical (possibility to obtain new substances with high biological activity) and from fundamental points of view (an approach for studying the regulatory mechanisms of secondary metabolism of plant cells).

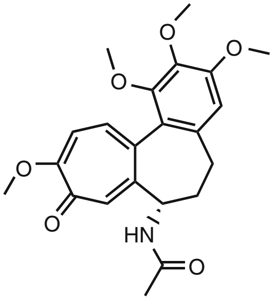
At present, plant in vitro systems are not used efficiently to study the relationship between the ploidy level and secondary metabolism. Research aimed at studying genetic stability suggests that most cells in a *Taxus* cell suspension are aneuploid within a 2-year period [127]. As far as ploidy variations in cell suspensions are cyclical, they can be related to the observed transient asymmetric cyclicity of the profiles of the biosynthesized secondary metabolites [128]. It is known that this cyclicity in the secondary metabolism subsides over time [129]. Plant cell cultures are not suitable matrices for exploiting the relationship between the ploidy level and secondary metabolism because they are inherently mixoploid systems and the achieved yields of target metabolites, and the analyzed metabolic profiles are a statistically average response of a heterogeneous cell association [50, 127]. Unlike plant cell suspensions, transformed root cultures are characterized by high genetic stability [130, 131], and it is adopted as a rule that their metabolic profile is identical to that of the intact plants from which they are derived [132]. This defines these cultures as promising systems both for fundamental research related to the regulation of secondary metabolism by means of artificial polyploidy and for applied research related to analysis of the relationships between ploidy levels and yields of target products and/or metabolic profiles of the studied in vitro systems.

5.5.1 Methods for Obtaining Polyploid-Transformed Root Cultures

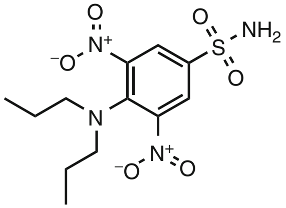
For polyploidization, both under in vitro and in vivo conditions, most frequently, the mitotic inhibitors colchicine **31** and oryzalin **32** are used. They inhibit the polymerization of the microtubules of the mitotic spindle, thereby preventing the duplicated genetic material from being divided between two daughter cells [133].

Colchicine **31** is an alkaloid synthesized by *Colchicum autumnale* L., which binds to tubulin (the polymer that makes up the microtubules of the mitotic spindle), thus preventing the formation of the mitotic spindle. This alkaloid is active in millimolar concentrations [133, 134].

Oryzalin **32** is a dinitrophenyl herbicide, which also exhibits high tubulin binding affinity, thereby inhibiting the polymerization of the microtubules of the mitotic spindle. Oryzalin **32** is active in micromolar concentrations [133].



Colchicine
31



Oryzalin
32

Two approaches are currently known for obtaining transformed root cultures of different ploidy level: transformation of autopolyploid intact plants and in vitro polyploidization of transformed root cultures obtained from diploid intact plants.

The methods of polyploidization of intact plants were developed in the second half of the last century and were well described in a number of articles [135]. The methods for obtaining transformed root cultures by transforming plant tissue with *Agrobacterium rhizogenes* have also been described in detail in numerous survey and scholarly articles [61, 136].

The approach of in vitro polyploidization of transformed root cultures obtained from diploid intact plants is presented schematically on Fig. 7.6. Most often, for in vitro polyploidization of transformed root cultures, colchicine **31** and oryzalin **32** are used in concentrations of 0.002–0.005% and 0.0002–0.0005%, respectively. Our experience shows that about 8–10% of the newly obtained lines are of different ploidy than the source line.

5.5.2 Biosynthetic Potential of Transformed Root Cultures with Different Ploidy Levels

Many years of research in our laboratory [24, 30, 89, 90, 114] on the impact of artificial polyploidy on the biosynthesis of tropane alkaloids from diploid- and tetraploid-transformed root cultures of *D. stramonium* L. have revealed that induced polyploidy makes it possible to obtain higher yields of target metabolites as well as to achieve biosynthesis of new biologically active substances that are normally not synthesized in the intact plants (Table 7.3). The comparative analysis of the alkaloid profile of diploid and tetraploid intact *D. stramonium* L. plants and transformed roots derived from them (Table 7.3) established 39 alkaloids, 33 of which were identified.

D. stramonium L. plants accumulate various alkaloids in different plant organs. However, no differences are detected in the alkaloid profiles of diploid and tetraploid plants. There are differences in the alkaloid spectra of plants of different ploidy levels in the minority alkaloids (less than 1% of the ion current).

In transformed root cultures, the influence of the ploidy level on the qualitative composition of the biosynthesized alkaloids is clearly defined (Table 7.3). There are certain differences in the alkaloid profiles of intact roots and in the corresponding transformed root cultures of *D. stramonium* L., which contradicts the widespread assertion about the identity of the secondary metabolism of transformed root cultures and the respective intact roots [132, 134, 137]. Intact roots produce 3-monosubstituted, 2,3-disubstituted, 3,6-disubstituted, 3,6,7-trisubstituted alkaloids, and 3-substituted-6,7-epoxytropanes, while transformed roots biosynthesize mainly 3-monosubstituted and 3,6-disubstituted alkaloids (Table 7.3).

These results clearly indicate that induced polyploidy is a powerful approach to establish selection algorithms for obtaining highly productive lines of transformed root cultures as well as for biosynthesis de novo of unknown and/or secondary metabolites not synthesized in the respective intact plants (entries 1, 2, 3, 4, 13, 14, 15, 16, 17, 18, 23, 24, 28, 37 and 38, Table 7.3) that could carry new biological activities.

It should be noted that the two ploidy levels of the transformed root cultures of *D. stramonium* L. show significant differences as regards the spectrum of the biosynthesized alkaloids. Unlike the diploid, tetraploid-transformed roots biosynthesized ten alkaloids. One of them (entry 15, Table 7.3) was not detected in the diploid root culture of *D. stramonium* L. The pharmacologically active alkaloid hyoscyamine **1** is the principal alkaloid biosynthesized by both root cultures at 78.8% and 56.6% of the total ion current in the diploid and tetraploid-transformed roots of *D. stramonium* L., respectively (entry 9, Table 7.3). In contrast to diploid roots, which accumulate 7.12% apoatropine, the tetraploid-transformed root culture biosynthesize 3-acetoxytropane (28.4%) as a second alkaloid in terms of amount. C-3 monosubstituted tropanes dominate in the alkaloid mixture accumulated by the tetraploid culture, while disubstituted tropanes dominate in the alkaloid mixture biosynthesized by the diploid root culture of *D. stramonium* L. The significant differences established in the secondary metabolism of the diploid- and tetraploid-transformed root cultures of *D. stramonium* L. are probably due to differences in the genome organization of plant cells with different chromosome sets as well as to various physiological characteristics of both cultures that originate from their different ploidy level.

The subsequent detailed analysis of the alkaloid profiles of diploid- and tetraploid- transformed root cultures of *D. stramonium* L., cultivated in liquid medium, revealed that the studied cultures biosynthesized alkaloids that are untypical of intact plants: 3-tropoyloxy-6-acetoxytropane **33** (new for *Datura* genus), methylecgonine **34** (new for the Solanaceae family), and 3-tigloyloxy-6-propionyloxy-7-xydroxytropane **35** (a new tropane ester) [24].

		R_1	R_2	R_3	R_4
3-tropoyloxy-6-acetoxytropane	**33**	H	H O − COC −C_6H_5 I CH_2OH	O −$COCH_3$	H
methylecgonine	**34**	O −$COCH_3$	OH	H	H
3-tigloyloxy-6-propionyloxy-7-xydroxytropane	**34**	H	O − COC =CH I \\ CH_3 CH_3	O −COC_2H_5	OH

After optimization of the nutrient media for maximum yield of hyoscyamine **5** from diploid- and tetraploid-transformed root cultures of *D. stramonium* L. [90], the tetraploid root culture of *D. stramonium* L. accumulated 24.7% (2.01 g L^{-1}) more hyoscyamine **1** than the diploid culture (1.51 g L^{-1}), while in cultivation in standard MS nutrient medium [89], the diploid-transformed root culture synthesized 20.7% higher amounts. Therefore, it is not only the higher amount of nuclear DNA but also the optimal conditions for its expression that are essential for obtaining maximum yields of the target tropane alkaloids.

6 Conclusion

Despite of all progress made in the area of tropane alkaloids biotechnology, the overall productivities of available plant in vitro systems are not sufficient for development of industrial process. Hairy roots are the most promising plant in vitro culture that could be used as a technological matrix for development of an industrial process for hyoscyamine and scopolamine production. To realize this however, an integrated approach, based both on well- developed up to now strategies (selection of high-producing lines, genetic engineering for improvements of alkaloid contents, media optimization, and design of bioreactor systems with specific constructions) and on alternative strategies for improvement of hairy roots productivities (artificial polyploidy, cell cycle management, etc.), should be developed and applied.

As scopolamine is the constituent with a higher added value in the pharmaceutical market, more efforts on biotransformation of hyoscyamine to scopolamine should be done. This could happen either by genetically engineering cultures [138] or by using interspecies and/or intergenus organ cocultures [139]. Moreover, the genetic engineering of polyploidy hairy root cultures may prove an attractive source of new tropane alkaloids with better therapeutic value and higher biological activities.

importance, inefficiency of extracting alkaloids from a myriad of other metabolites remains a significant barrier toward inexpensive bioprospecting for drug development. Furthermore, the yield is inconsistent in the natural resource due to heavy dependence on genetic and geographical diversity and also on climatic conditions. Chemical synthesis has been successful for the class of indole alkaloids. However, it is still a challenge and also impractical on industrial scale to construct other commercially important class of alkaloids. In lieu of the given limitations, plant cell/tissue cultures serve as alternative production platforms in which the biosynthesis of alkaloids has been improved through various elicitation and culture manipulation strategies. In addition, recent advances made in metabolic engineering and systems biology now have the potential to more effectively maximize the alkaloid biosynthesis in such in vitro production systems. In this respect, the chapter provides information regarding recent advancements made in bioprocessing and genetic engineering of cellular systems for large-scale alkaloid production.

SMT	(*S*)-scoulerine 9-*O*-methyltransferase
STR	Strictosidine synthase
TDC	Tryptophan decarboxylase

1 Introduction

Alkaloids are a diverse group of low-molecular-weight, complex organic molecules containing heterocyclic nitrogen ring. Alkaloids are produced by many different organisms, including plants, animals, and microbes, but a particularly diverse array of alkaloids is produced by plants. Approximately 10% of all plant species are thought to produce alkaloids as secondary metabolites. Many of the ≈12,000 alkaloids for which structures have been described function in the defense of plants against herbivores and pathogens [1–3]. The potent biological activity of alkaloids has led to their commercial exploitation as pharmaceuticals, stimulants, narcotics, and poisons (Table 8.1). Plant-derived alkaloids currently used as pharmaceuticals include morphine and codeine as analgesics, vinblastine and Taxol as anticancer agents, colchicines as gout suppressant, (C)-tubocurarine (muscle relaxant), ajmaline (antiarrythmic), sanguinarine as antibiotic, and scopolamine (a sedative). Other well-known alkaloids of plant origin include caffeine, nicotine, cocaine, and the synthetic *O,O*-acetylated morphine derivative heroin.

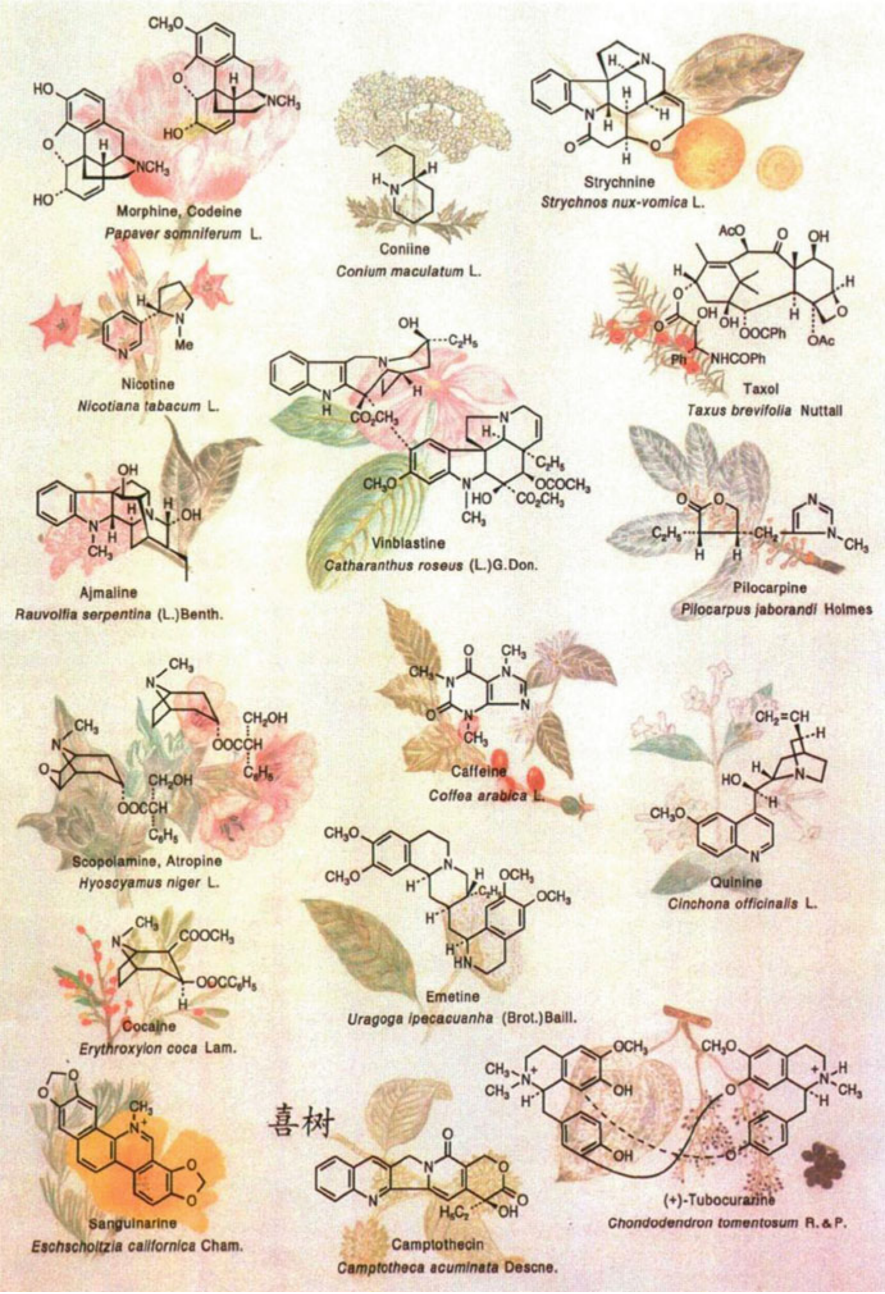
Alkaloids are mainly isolated from plants and produced commercially as fine chemicals. The complexity of these molecules means that it is in most cases impossible and impractical to produce them by total chemical synthesis, so extraction from the source plant remains the most economically viable strategy. However, plants often produce mixture of alkaloids with low yields; as a result, some commercially important alkaloids are highly expensive. With recent advances made in genetic engineering, research in manipulation of plants at genetic level has focused on the engineering of alkaloid biosynthesis to generate transgenic plants or cell lines that overproduce specific plant alkaloids. This has been proposed to be done via increasing the synthesis of a particular alkaloid and/or inhibiting the synthesis of related compounds for easier downstream processing. However, development of metabolic engineering strategies to enhance alkaloid biosynthesis in plants requires a thorough understanding of the endogenous biosynthetic pathways of alkaloids and its regulation mechanisms in plants. Plant cell and tissue cultures cannot only be used as model systems to elucidate the biosynthetic mechanisms of various secondary metabolites including alkaloids at cellular level but also as invaluable means of providing suitable biomass for large-scale production of these high-value alkaloids. Apart from this plant cell culture, investigations have also been done for biotransformation of alkaloids for enhanced bioactivity [4]. Despite the advantages, plant cell technology is not widely used as alternative production platforms for commercial production of alkaloids. The reason being that the level and manner of production of wide array of alkaloids in plants does not necessarily correlate with production in cell cultures. Moreover, issues related to slow growth and genetic and biochemical instability of plant cell cultures have been limiting their popular usage in industry. In this regard, the present chapter hence discusses some of the recent developments made in the bioprocessing and genetic engineering of plant cells/tissues for enhanced alkaloid production in cellular systems.

Table 8.1 Pharmacological applications of some important plant-derived alkaloids

Alkaloid	Plant source	Medicinal properties
Ajmaline	*Rauvolfia serpentina*	Antiarrhythmic, antihypertensive
Berberine	*Berberis vulgaris*	Antimicrobial
Caffeine	*Coffee arabica*	Stimulant, Insecticide
Camptothecin	*Camptotheca acuminate*	Antineoplastic
Cocaine	*Erythroxylon coca*	Analgesic, narcotic, local anesthetic
Codeine	*Papaver somniferum*	Analgesic, antitussive
Emetine	*Uragoga ipecacuanha*	Antiamoebic, expectorant, emetic
Hyoscyamine	*Atropa belladonna* and others	Anticholinergic
Irinotecan	Semisynthetic derivative of camptothecin	Chemotherapeutics
Morphine	*Papaver somniferum*	Analgesic, narcotic
Nicotine	*Nicotiana tabacum*	Stimulant
Noscapine	*Papaver somniferum*	Analgesic, antitussive
Oxycodone	Semisynthetic derivative	Analgesic
Oxymorphone	Semisynthetic derivative	Analgesic
Papaverine	*Papaver somniferum*	Vasodilator
Pilocarpine	*Pilocarpus jaborandi*	Cholinergic
Quinidine	*Cinchona* spp.	Antiarrhythmic
Quinine	*Cinchona* spp.	Antimalarial
Reserpine	*Rauvolfia serpentina*	Tranquilizer, antihypertensive
Sanguinarine	*Sanguinaria canadensis*	Antibacterial
Scopolamine	*Hyoscyamus niger* and others	Sedative, anticholinergic
Strychnine	*Strychnos nux-vomica*	Stimulant, poison
Taxol	*Taxus brevifolia*	Antineoplastic
Topotecan	Semisynthetic derivative	Chemotherapeutics
Vinblastine and vincristine	*Catharanthus roseus*	Antineoplastic, chemotherapeutics
Vindesine	Semisynthetic derivative	Chemotherapeutics
Vinflunine	Semisynthetic derivative	Chemotherapeutics
Vinorelbine	Semisynthetic derivative	Chemotherapeutics
Yohimbine	*Pausinystalia yohimbe*	Erectile dysfunction treatment

1.1 Chemical and Physical Characterization of Alkaloids

Alkaloids are a chemically heterogenous group of nitrogen containing substances found predominantly in higher plants. They occur in plants and are typically combined with sugars or simply as amides. They are also found in lower plants, animals, microorganisms, and marine organisms. Alkaloids exhibit dozens of different skeletal types. The structures of over 16,000 different alkaloids have been elucidated. Selected few important alkaloids are shown in Fig. 8.1 [5].



Morphine, Codeine
Papaver somniferum L.
Coniine
Conium maculatum L.

Have heterocyclic ring with nitrogen
Does not have heterocyclic ring with nitrogen
Have heterocyclic ring with nitrogen
derived from amino acids
Not derived from amino acids

Fig. 8.2 Classification of alkaloids on the basis of heterocyclic ring and amino acid (Adopted from Ref. [6])

No other class of natural products possesses such an enormous variety of structures. The term alkaloid was first coined in 1819 by a pharmacist, W. Meissner and meant simply, *alkalilike* (Middle English alcaly, from Medieval Latin *alkali*, from Arabic *alqaliy* = ashes of saltwort, from *qualey*, to fry). The first modern definition by Winterstein and Trier in 1910 [6] describes these substances in a broad sense as basic, nitrogen-containing compounds of either plant or animal origin [6]. Chemical, pharmacological, and botanical properties are usually considered when classifying these compounds as an alkaloid. "True alkaloids" were defined as compounds that fulfilled the additional four given criteria: (a) nitrogen atom being or not being a part of a heterocyclic system, (b) complex molecular structure, (c) manifesting significant pharmacological activity, and (d) restricted to plant kingdom. Compounds satisfying the definition of true alkaloids are restricted to certain families and genera of plant kingdom rarely being distributed in large group of plants. Though about 40% of all plant families contain at least one alkaloid-bearing species, true alkaloids have been reported in only 9% of over 10,000 plant genera. Other heterocyclic nitrogenous bases not classified as true alkaloids include the purines, of which caffeine, xanthine, and bromine are few examples.

Presently, alkaloids are classified into three main categories as shown in Fig. 8.2 [6]. This chemical classification of alkaloids is universally adapted and mainly depends on the type of heterocyclic ring structure present (Fig. 8.3). Alkaloids are further classified according to the amino acids (or their derivatives) from which they originate (Fig. 8.4) [6]. The most important classes are derived from the amino acids, ornithine and lysine, or from the aromatic amino acids, phenylalanine and tyrosine, or from tryptophan and a moiety of mavelonoid origin. A number of alkaloid-based compounds are also derived from anthranilic acid or from nicotinic acid.

Although majority of alkaloids and their derivatives are colorless, crystalline, nonvolatile solids, a few such as *cotinine* and *nicotine* are liquids, and few are even colored, for example, *berberine* is yellow. Alkaloids are insoluble in water but soluble in most organic solvents. Most of the alkaloids are levorotatory

(optically active); however, a few are also known to be dextrorotatory (optically inactive), for example, *conine* and *papaverine*. Generally, the alkaloids are bitter in taste and have pronounced physiological activity.

1.2 Biosynthesis of Alkaloids in Plants

The pharmacological and commercial significance of alkaloids has motivated the characterization of their biosynthetic pathways. Also, before considering engineering strategies to exploit alkaloid biosynthesis, it is necessary to have a thorough understanding of its endogenous biosynthetic pathways. Research in the field of plant alkaloid biochemistry began with the isolation of morphine in 1806.

However, the structure of morphine was not elucidated until 1952 owing to the stereochemical complexity of the molecule. The technological advances made since then have significantly brought to light the underlying endogenous mechanisms of alkaloid formation in plants. The introduction of radiolabeled precursors has allowed the chemical elucidation of alkaloid biosynthetic pathways. The use of plant cell cultures as an abundant source of biosynthetic enzymes (which can be isolated, purified, and characterized) and widespread application of molecular techniques to the alkaloid field have facilitated the isolation of several genes involved in indole, tropane, and benzylisoquinoline alkaloid biosynthesis as shown in Table 8.2 [3].

Genomic and transcriptomic technologies have been used to rapidly identify biosynthetic steps. There are currently over 40,000 expressed enzyme tags (ESTs) generated from alkaloid-producing plants that have been used to isolate genes involved in the alkaloid pathway [7]. Some alkaloid biosynthetic steps occur as spontaneous chemical reactions without the use of enzymes, for example, conversion of the intermediate neopine into codeinone in the morphine biosynthetic pathway. Also, some enzymes may catalyze two or more separate reactions in the pathway, for example, hyoscyamine 6-hydroxylase, which carries out two consecutive steps in the scopolamine biosynthetic pathway. Alkaloid biosynthesis also involves compartmentalization. Tissue-specific localization studies have shown that sequential biosynthetic enzymes can occur in distinct cell types [8, 9]. During the biosynthesis of the indole alkaloids vinblastine and vincristine in *Catharanthus roseus*, different enzymatic steps are carried out in different cellular compartments (Fig. 8.5) [10]. Various steps in the pathway are carried out in different types of cell. This requires the intercellular transport of metabolic intermediates. Similarly, scopolamine biosynthesis also involves two different cell types.

To date, biosynthetic pathway for four classes of plant alkaloids has been characterized to some extent: the benzylisoquinoline, monoterpenoid indole, purine, and tropane alkaloids. Benzylisoquinoline alkaloids (BIAs) are derived from tyrosine and are comprised of ~2,500 defined structures found mainly in the *Papaveraceae, Ranunculaceae, Berberidaceae*, and *Menispermaceae* [11]. First step of BIA biosynthesis begins with the stereoselective Pictet-Spengler condensation of dopamine and 4-hydroxyphenylacetaldehyde to form (*S*)-norcoclaurine. Subsequently, through a series of methylations and hydroxylations, (*S*)-norcoclaurine gets converted into (*S*)-reticuline, which is the pivotal intermediate for many pharmaceutically important BIAs formed further down in the pathway (i.e., downstream pathways) (Fig. 8.6) [3].

Monoterpenoid indole alkaloids (MIAs) are derived from tryptophan metabolism. MIAs are one of the most structurally diverse class of compounds with over 2,000 structures. They are mostly found in the *Apocynaceae, Loganiaceae*, and *Rubiaceae* family of plants [12]. Similar to BIA biosynthesis, the committed step of MIA biosynthesis begins with the condensation of tryptamine (derived from tryptophan) and secologanin (derived from terpene biosynthesis) to form strictosidine

Table 8.2 Alkaloid biosynthetic enzymes for which the corresponding genes have been cloned (Adopted from Ref. [3])

Enzyme	Plant source
3′-Hydoxy-*N*-methylcoclaurine 4′-*O*-methyltransferase (4′OMT)	*Coptis japonica*

(Fig. 8.7) [3]. After the deglucosylation of strictosidine, equilibrium of the unstable aglycon intermediates leads to the formation of 4,21-dehydrogeissoschizine, the branchpoint precursor of MIAs [13].

Tropane alkaloids are found mainly in the *Solanaceae* [14] plant family. First biosynthetic step of tropane alkaloids starts with *N*-methylation of putrescine (derived from L-ornithine) to form *N*-methylputrescine. After the conversion to 1-methyl-Δ1 pyrrolinium cation, its condensation with nicotinic acid gives rise to nicotine synthesis, while other chemical conversions lead to the formation of tropinone, the precursor of many tropane alkaloids through branched pathways (Fig. 8.8a) [15].

The fourth class of alkaloids is derived from purine nucleotides instead of amino acids. A well-known example of a purine alkaloid is caffeine, whose biosynthetic

2 Production of Alkaloids Via Plant Cell Bioprocessing: Pregenomic Approach

The alkaloids are known as specialty chemicals, as their worldwide production volume is limited. Alkaloids such as quinine and quinidine have a yearly production of 300–500 metric tons, ajmalicine around 3,600 kg, and for the compounds like vinblastine and vincristine annual production is only in the range of few kilograms [17]. The market value of every known major alkaloid can be estimated to be in the range of several hundred million dollars. These specialty chemicals are conventionally produced by extraction from plant material that is cultivated or collected from the wild. There are several problems associated with this production method. Variable quantities and qualities of the plant material or plants that need to grow for several years before they are ready for harvesting (e.g., *Cinchona* bark), and overcollection of endangered species (e.g., *Taxus hevifolia)* are some of the few problems to mention. The amounts of plant material needed for the extraction of these compounds are also growing to fulfill the market demand which also calls for the need of alternative production methods. For example, it is in the

[15])

order of 5,000–10,000 metric tons of *Cinchona* bark for the extraction of quinine and quinidine and 200–300 t of *Catharanthus roseus* roots for the production of ajmalicine [18].

Looking into the increasing demand for high-value plant-derived products like alkaloids, alternative production methods are thus of great interest. As a consequence, a lot of investigations have been directed on the synthesis of natural products as an alternative to extraction. Although complete synthesis for most natural products including indole alkaloids has been shown to be possible, it is usually economically not feasible. Semi-synthesis of alkaloids from readily available precursors, has been successful in some cases, e.g., the coupling of monomers for the production of the dimeric alkaloid vinblastine [17, 19]. Also, novel useful compounds have also been developed in this way, for example, Taxotere as a result of the breakthrough on the chemical synthesis of Taxol [20]. Due to their complex structures, alkaloids are still most efficiently produced by plants. In the past few decades, the focus has shifted on plant cell biotechnology (cultured cells/tissues) as a possible alternative production method for alkaloids against conventional plant extraction (Table 8.3) [17]. As a promising alternative to produce plant secondary metabolites, plant cell culture technology has many advantages over traditional field cultivation and chemical synthesis. Large-scale plant cell culture is an attractive alternative as it offers following advantages: (1) controlled supply independent of plant availability, (2) a renewable and environmentally friendly resource, and (3) a biological factory for the production of high-quality products under strictly controlled conditions. Plant cell/tissue culture is also amenable to process optimization, scale-up and genetic engineering for yield and productivity enhancement of the desired metabolite. However, for industrial feasibility, plant cells should be grown in large fermenters and the price of the product from such a large-scale plant cell cultivation should be competitive with the existing production methods. Scaling up seemed to be a challenge when the first successful in vitro growth of plant cells and tissues was described almost 50 years ago [21]. However, many success stories on large-scale bioreactor cultivation of plant cells have been reported since then. The first successes were published in 1960 by Tulecke and Nickel [22], culturing cells of various plant species in a 134-l bioreactor. In 1977, Noguchi et al. [23] reported the culture of tobacco cells in a 20-m^3 tank mixed by aeration. In the past few decades, most work on large-scale culture has been directed toward the use of various types of low-shear bioreactors and configurations which facilitate effective mass transfer of nutrients/oxygen to the growing culture (e.g., airlift bioreactors). However, large investments in all sorts of new ingenious bioreactors can be a constraint in the commercialization of plant cell biotechnology. For the industrial applicability of plant cell cultures, it is of great importance that plant cells are tolerant to shear effects in stirred-tank reactors, which are currently the most exclusively used reactors in fermentation industry. Efforts have been made to overcome this issue by selecting more shear-tolerant cell lines which can be grown without any problem in stirred tanks [24–27]. Though shear sensitivity of most plant cell lines could limit the applicability in large-scale fermentations, Meijer and coworkers [26, 27] noted that "healthy" good-growing cell cultures were more shear resistant than apparently "stressed" (e.g., rapidly browning) cell cultures. As a matter of fact, the industrial production of shikonin is performed in 750-l stirred-tank bioreactors [28], and in Germany the Diversa company and Phyton Biotech GmbH. have successfully grown plant cell cultures in 60-m^3 and 75-m^3 working-volume stirred tanks, respectively [29].

Plant cells can be cultured on a large scale, and although the price of the products obtained is high, this price is still of the order of magnitude of that of many specialty chemicals. In order to have a commercially viable and reliable technology, it is important to obtain a stable, high-producing plant cell line. To further enhance the productivity of the culture, manipulation in the culture environment is recommended through exogenous additions (growth regulators, elicitors, precursors, permeability enhancers, etc.) and optimization of cultivation conditions like medium, pH, temperature, rpm, light, etc.

2.1 Screening and Selection of a High-Yielding Stable Cell Line

In a screening program a large number of cell lines are developed from high-producing plant variety. Subsequently, the yield of the desired compound in these cell lines is determined, and the cell line producing the maximum product is selected. However, the high production in plants does not always ensure high production in cell cultures. For example, highest berberine producing *Coptis japonica* cell culture was obtained from the cell line developed from a low berberine producing plant variety [30, 31]. Screening can also be done at the level of cell aggregates or even single cells or protoplasts. In case of the *C. japonica* cell cultures, it was found that at least three to four cloning steps were necessary before a stable, high-producing strain was obtained [32]. However, similar selection protocol for high-producing strains in *Catharanthus roseus* failed with respect to stability [33]. Stability is a major problem encountered in plant cell cultures. Hence, for selection, cultivation conditions are established in which only certain desired cell type can survive. For example, cells of *C. roseus* were grown on media containing the toxic compound 4-methyltryptophan to obtain cell lines that had a high alkaloid production capacity. Only cells that contained a high level of tryptophan decarboxylase, and thereby were able to convert the selection agent into the less toxic 4-methyltryptamine, survived. Although, the selected cell lines did have a higher tryptamine production, but only in one single case was terpenoid indole alkaloid production increased too [34].

2.2 Culture Condition Optimization

An important approach to increasing productivity is to improve the growth and production conditions. The production of alkaloids in cell suspension cultures is controlled by environmental conditions as well as by the genotype of the plant material. Medium optimization has also been shown to be an effective means to improve productivity. Single-factor and/or statistical optimization of medium composition with respect to major and minor nutrient level is carried out to model and optimize the independent and synergistic effect of various medium nutrients for maximum biomass density and product levels in the culture. Optimization of medium composition has been done for growth and production of indole alkaloids [35–38]. In many cases, production phase and growth phase are not correlated. Hence, a two-step cultivation process is often used. Initially, the biomass is maximized under optimal conditions, and then the medium is changed to a production-inducing composition. Developing a separate production medium is a useful and less cumbersome approach than manipulating a medium that is both suited for growth and production. The effect of any change in production medium is immediately observed after transferring the plant cells to the production medium, whereas in growth media, the effect of a change in medium composition is only observed after few cycles of subcultures. Use of production medium has been reported by Zenk et al. [39] and Knobloch et al. [40] for the induction of ajmalicine production in *C. roseus*. In *Tabernaemontana divaricata* cell cultures, replacement of auxin 2,4-Dichlorophenoxyacetic acid (2,4-D) with 1-naphthaleneacetic acid (NAA) in the medium resulted in an increasing alkaloid production observed in five subculture cycles. This was followed by a decrease and eventually stabilization after 10 subcultures at a level that was not much higher than in the original medium [41]. However, manipulation in medium composition for high productivity is recommended only if a minimum basal level of the desired compound(s) is found in the cell culture.

The alkaloid productivity and the storage capacity in cultured plant cells can be influenced by the pH gradient between the medium and the accumulation sites inside the plant cell (vacuoles). A shift in the medium pH from low to high value was used to release the intracellularly stored alkaloids into the culture medium in cell suspension culture of *C. roseus* [42]. Similarly, transient modifications in the medium pH value led to the release of indole alkaloids in culture medium during immobilized cell cultivation of *C. roseus* [43].

Contradictory results like complete inhibition, stimulation, or no effects have been reported with respect to alkaloid production at lower temperatures in plant cell suspension cultures [44–46]. The effect of the temperature on alkaloid production happens to be cell line dependent. Use of open-loop temperature trajectories during the cultivation of plant cells in bioreactor can lead to an increase in alkaloid production and a shortening of the culture period [38]. It was shown that a single switch in the temperature increased the alkaloid accumulation by 22 % above that obtained at the optimum constant temperature [47].

Light is an important regulatory factor in the production of alkaloids in plant cell cultures. The light is known not only to affect the alkaloid production but also the accumulation site in cell culture of *C. roseus*. Through various studies, it is known that in *C. roseus* cell/tissue cultures, light influences the ajmalicine/serpentine accumulation ratio and also vindoline and catharanthine production [38]. However, in large-scale production in stirred-tank bioreactors, such conditions are difficult and costly to realize. Therefore, production conditions on small scale should preferably be optimized with dark-grown cultures.

The gaseous environment, mainly the availability of oxygen and carbon dioxide, significantly affects the production of secondary metabolites in plant cell cultures. It has been observed that increasing the dissolved oxygen concentration in high cell density cultivation of *C. roseus* stimulated the oxidative metabolism responsible for high production of ajmalicine [48]. Similarly, increasing the concentration of CO_2 up to 4 % of saturated air resulted in increased accumulation of indole alkaloids in cell suspension cultures of *C. roseus* [49]. In transferring results from batch-wise cultures in shake flasks to bioreactors, it has to be kept in mind that the gas phases in the two systems are completely different, thus possibly influencing the productivity. This may be illustrated by the recent finding that productivity of *C. roseus* cell cultures in bioreactors is drastically improved by recirculation of the air used for the aeration of the cells in the bioreactor [50].

Plant growth regulators, or phytohormones, like auxins, cytokinins, abscisic acid, gibberellins, and ethylene are known to affect growth and differentiation and thus affect secondary metabolism of cultured cells. Several studies have been carried out on the influence of the concentration of various growth regulators, especially auxins, on alkaloid production by *C. roseus* cultures [38]. Exogenous hormone addition like gibberellic acid in the growth medium results in higher accumulation of alkaloids in *C. roseus* plants [51].

Secondary metabolite yield in in vitro cultures can also be enhanced by exposing the cultures to stress factors like osmotic shock, addition of inorganic salts, heavy metal ions, fungal homogenates, and UV irradiation. As a response to the stress, the enzymes of secondary metabolism which is usually related to plant defense gets induced, as a result hyperaccumulation of secondary products is observed. These stress-inducing compounds are normally referred as elicitors. It is one of the most successful strategies employed to enhance secondary metabolite production in cultured plant cells/tissues. Several *C. roseus* cell lines upon elicitation have resulted in increased accumulation of indole alkaloids [35]. However, the response to elicitation is highly dependent on the cell line. It has been reported that by adding elicitors such as cell wall constituents of microorganisms, enzymes (e.g., cellulase and pectinase), or heavy metals, alkaloid biosynthetic pathways get induced (e.g., sanguinarine). Recently, Gundlach et al. [52] showed that jasmonic acid, functioning in signal transduction pathway, can be used to induce secondary metabolite pathways as well. The production of sanguinarine in *Eschscholtzia californica* and of raucaffricine in *Rauvolfia canescens* could be induced using the same. Addition of sodium chloride and sorbitol enhanced the production of catharanthine in cell suspension culture of *C. roseus* [53]. Similarly, addition of vanadyl sulfate could affect the ratio of catharanthine, serpentine, and tryptamine production in cell culture of *C. roseus* in a dose-dependent manner. Exposure to heavy metals has also been reported to enhance the production of alkaloids in *C. roseus* cultures [38]. Synergistic effect of combined addition of selected elicitors have also been studied using statistical tools for enhanced alkaloid production in plant cell suspension cultures [54].

Based on the knowledge of the regulation of alkaloid biosynthetic pathways, several organic compounds have been added to the culture medium in order to enhance the availability of alkaloid precursors. Two different approaches have been employed: directly feeding precursors into the culture medium or by addition of compounds interfering with precursor metabolism. For example, the alkaloid production was found to be significantly improved upon addition of secologanin to cell cultures of *C. roseus* [38]. Similarly, Moreno et al. [55] reported enhanced accumulation of ajmalicine and strictosidine in *C. roseus* cell culture upon addition of terpenoid precursor secologanin and its precursors loganin and loganic acid in the medium. Feeding of tryptophan to immobilized cultures of *C. roseus* increased tryptamine accumulation [56].

The immobilization of plant cells leads to larger cell aggregates in which cell-to-cell contact occurs. In some plant cell cultures, this results in higher productivity, probably due to a certain level of differentiation. Immobilization has been done in alginate, in small polyurethane (PUR)-foam cubes, or by “natural” immobilization by growing the cells as aggregates [57, 58]. The occurrence of differentiation was, for example, shown in the so-called compact-globular structures, which are large cellular aggregates formed by *Cinchona* cells. These aggregates do produce quinoline alkaloids such as quinine, but only in the outer layer, which has according to microscopic analysis similar morphology as the stem of the tree, that is the major source of these alkaloids in the plant [59]. However, limitations associated with immobilized cells are that they are expensive to produce on large scale and that for an economic continuous production process, excretion is needed into the medium [60].

2.3 Use of Differentiated Cultures for Enhanced Production of Alkaloids

By definition, secondary metabolism is a form of differentiation. In plants there is a clear correlation between cellular differentiation and secondary metabolism. The activation of many alkaloid biosynthetic pathways is tissue specific and a function of developmental stage [61]. Hence, plant tissue cultures apart from cell cultures have also been investigated as alternative production platforms [62–64]. In this context, the plant hairy root cultures are worth mentioning. These cultures are obtained by infection of the plant tissue with *Agrobacterium rhizogenes*, a soil bacterium that introduces root-inducing genes into the plant cells. These genes transform the cells into hormone-independent tumorous roots that can produce secondary metabolites similar to that of the natural plant.

The growth rate of hairy root culture for some species is comparable to their cell suspension culture. High productivity of tropane alkaloids has been reported in hairy root cultures [65]. An interesting aspect of the use of *A. rhizogenes* is that at the same time one can use these bacteria to introduce new genes into the cells. This approach was applied in *Atropa belladonna* hairy roots in which the enzyme that converts hyoscyamine into scopolamine was overexpressed [66, 67] and also in improving alkaloid productivity in *Cinchona* hairy roots [68]. A major disadvantage of differentiated organ cultures is that they are difficult to grow on a large scale. Hairy roots require specialized bioreactors, such as rolling drum fermenters or mist fermenters [69]. In these bioreactors the working volume is quite large as compared to the active biomass. Consequently, production costs are very high. Wilson et al. [70] and Rodriguez-Mendiola et al. [71] have proposed different solutions for the large-scale culture of hairy roots. A number of bioreactor configurations have been developed to facilitate mass cultivation of hairy roots for large-scale secondary metabolite production [72]. As a matter of fact, with very few exceptions like ROOTec bioactives Ltd. in Germany, the application of hairy roots is probably restricted to serve as models for in vitro studies like regulation of the biosynthesis.

3 Metabolic Engineering for Engineering Alkaloid Biosynthesis in Cellular Systems: A Genomic Approach

There are three basic goals of metabolic engineering: (1) producing more of a specific compound, (2) producing less of undesired compound, and (3) producing a novel compound (this can be a known compound that is heterologous in the expression system being used or a completely novel compound). Strategies for achieving these goals can involve the engineering of single steps in a pathway to increase or decrease metabolic flux to target compounds or block competitive pathways and modulation of multiple enzymatic steps. An alternative is to stimulate or inhibit the catabolism of the target compound as suggested by Kutchan [5].

As depicted in Fig. 8.9 [5], plant alkaloid genes can be functionally expressed in microorganisms to produce either single biotransformation steps or short biosynthetic pathways.

Similarly, using overexpression or antisense or cosuppression technologies, medicinal plants can also be tailored to produce important pharmaceutical alkaloids by introducing side pathways, eliminating side pathways, or by accumulating biosynthetic intermediates. For example, as shown in Fig. 8.9, suppose a known plant biosynthetic pathway contains an enzyme encoded by gene G3 that catalyzes a transformation step, of compound C to alkaloid D, which is difficult to achieve by chemical synthesis. The G3 gene can be heterologously expressed in a microorganism and the gene product used in a biomimetic synthesis of alkaloid D (i.e., the microorganism is supplied with compound C and produces alkaloid D). Likewise, a short pathway consisting of enzymes encoded by genes G1, G2, G3, and *G*4 could be expressed in a microorganism to produce alkaloid E directly from

precursor A. Many alkaloid biosynthetic pathways involve 20–30 enzymes. Our current knowledge of these pathways indicates that the genes encoding the biosynthetic enzymes are neither clustered nor coordinately controlled by one operon. Expression of an entire, long alkaloid pathway in a single microorganism is currently a technical challenge. However, it is possible to alter the pathway in the plant cell and produce the desired alkaloid either in culture or in the field. For example, to accumulate alkaloid Z, which is not normally produced in a particular plant species, a transgene (from another plant or a microorganism) can be introduced. To accumulate alkaloid E, a side pathway that also uses precursor D may have to be blocked. If intermediate alkaloid C is the target for accumulation, catabolism to D could be interrupted [5].

3.1 Single-Step Engineering

The simplest strategy to increase the levels of a specific target alkaloid is to increase the metabolic flux toward that compound. As discussed above, this requires a thorough understanding of the endogenous pathway because it is necessary to identify the rate-limiting step in the pathway and to use this as the primary target for engineering. For example, consider the biosynthesis of terpenoid indole alkaloids such as vinblastine and vincristine in *C. roseus*. Although, these valuable alkaloids are synthesized in whole plants, but they are not produced in cell culture due to the tissue-specific compartmentalization. The universal terpene indole alkaloid precursor strictosidine is produced in culture and is metabolized to form other alkaloids such as ajmalicine and catharanthine. For indole alkaloid biosynthesis,

a rate-limiting step is the conversion of the amino acid tryptophan to tryptamine, catalyzed by the enzyme tryptophan decarboxylase (TDC). Tryptamine is then condensed with the terpenoid molecule secologanin to produce strictosidine. To alleviate the regulation of TDC, the *C. roseus* TDC gene was overexpressed under the control of a strong and constitutive promoter. The resulting transgenic cultures produced high levels of tryptamine [9]. Single-step engineering has also been used to extend a metabolic pathway in a heterologous plant. The alkaloid scopolamine is produced in *Hyoscyamus niger* but not in *Atropa belladonna*, where the tropane alkaloid pathway stops at L-hyoscyamine. However, introduction of a cDNA from *H. niger* encoding hyoscyamine-6-hydroxylase into *A. belladonna* resulted in the production of scopolamine in this plant. As shown in Fig. 8.10, the enzyme hyoscyamine-6-hydroxylase (H6H) is responsible for two reactions that convert L-hyoscyamine into scopolamine. *A. belladonna* accumulates L-hyoscyamine because the enzyme H6H is not produced in this species. However, by transferring the enzyme from another plant such as *H. niger*, which produce scopolamine, the metabolic pathway in *A. belladonna* could be extended till scopolamine.

3.2 Multiple-Step Engineering

Recently it has become increasingly common to introduce multiple genes in plants either by crossing independent single-gene transgenics or by simultaneous multiple gene transfer. Such experiments use to mostly involve marker genes; however, simultaneous transfers of multiple genes conferring resistance to different pests and pathogens have now been attempted and reported [9]. One way to overcome the limitations of the single-gene approach is to simultaneously transform plants with genes encoding enzymes that act at different steps of a biosynthetic pathway. For example, transgenic tobacco (*Nicotiana tabacum*) plants and *C. roseus* cell cultures have been generated with simultaneous overexpression of tryptophan decarboxylase (TDC) and strictosidine synthase (STR) transgenes. The *C. roseus* cell culture demonstrated increased accumulation of strictosidine when fed with loganin [9]. Particle bombardment has been used to transform plants simultaneously with 13 different genes, so it is theoretically possible to transfer genes encoding the enzymes of an entire pathway into a suitable expression host. Leech et al. [73] used the particle gun to introduce the TDC and STR genes into tobacco plants. In the transgenic tobacco seedlings, a 24-fold variation and a 110-fold variation were found in TDC and STR activity, respectively.

3.3 Engineering Regulatory Genes

The intricate relationships among metabolic pathways and regulatory schemes in plant cells and tissues can hinder the metabolic engineering design used for the overproduction of the desired target compound. As an important feature of the regulatory system, a number of downstream genes are coordinately regulated, either in response to the organism's developmental process or in response to external inductive signals. A number of external stimuli are known to induce alkaloid biosynthesis, including UV light, fungal elicitors, auxin starvation, and the signaling molecules like jasmonic acid. It has been shown that the *C. roseus* genes for tryptophan decarboxylase (TDC), strictosidine synthase (STR), geraniol-10-hydroxylase (G10H), NADPH: cytochrome P450 reductase (CPR), strictosidine b-D-glucosidase (SGD), deacetylvindoline 4-*O*-acetyltransferase (DAT), and desacetoxyvindoline 4-hydroxylase (D4H) are all inducible by methyl jasmonate and/or fungal elicitor in cell culture [9].

In most organisms, transcription factors act as master regulators of complex pathways involved in development, signal transduction, and metabolism. The common regulation of many of the genes involved in terpenoid indole alkaloid biosynthesis in *C. roseus* suggests that a useful strategy for increasing the levels of alkaloids in this system would be to identify and manipulate transcription factors that control the expression of these genes [9]. Alkaloid metabolic regulatory machineries have been probed by using transcriptome analysis, leading to the identification of several transcription factors in monoterpenoid indole alkaloid (MIA) biosynthesis [74, 75]. This information can potentially be useful in determining metabolic engineering targets that can efficiently bring about the desired improvement in a specific alkaloid branch pathway. For instance, a metabolic engineering strategy to increase MIA production was devised to exploit the utility of the ORCA3 transcription factor to upregulate the expression of many MIA biosynthetic genes simultaneously [74]. However, initial ORCA3 overexpression in *C. roseus* cell cultures did not significantly improve MIA synthesis. It was discovered that even though ORCA3 positively regulates the expression of many genes that lead to the synthesis of strictosidine, it does not upregulate the expression of geraniol 10-hydroxylase (G10H), the enzyme in the terpenoid pathway that leads to the synthesis of secologanin [74–77]. Upon supplemental feeding of loganin, the precursor of secologanin, the overexpression of ORCA3 resulted in ~0.6% of dry weight of MIAs (~threefold increase). However, in a similar study in *C. roseus* hairy root cultures, it was discovered that although the MIA biosynthetic enzymes that were upregulated upon ORCA3 overexpression were similar to those upregulated upon ORCA3 over-expression in the cell lines, no significant improvement in MIA biosynthesis could be observed in hairy roots. The reason being that the transcriptional repressors ZCT1 and ZCT2 also got upregulated in the hairy root lines unlike in *C. roseus* cell lines [78]. The study reveals the complexity of MIA biosynthetic control by a variety of transcriptional regulators.

3.3.1 Metabolic Engineering for Indole Alkaloids

Most efforts in engineering of terpenoid indole alkaloid pathway have been concentrated on mapping the early part of the pathway and on overexpression of early genes, aiming to increase the metabolic flux into the alkaloid pathway [79]. In particular, the genes encoding tryptophan decarboxylase (TDC) and strictosidine synthase (STR) have been studied extensively in *Catharanthus roseus* cell cultures [4]. Overexpression of TDC resulted in higher levels of the immediate product tryptamine, but not in increased levels of alkaloids, while in the case of STR, higher levels of alkaloids were reported [80]. Feeding the transgenic cell lines with tryptophan and terpenoid intermediates showed high alkaloid production (up to 1,100 μmol/L) [81], indicating that the terpenoid branch of the pathway is limiting. Such studies indicate that there may be multiple rate-limiting steps. TDC and/or STR were also expressed in various other nonalkaloid-producing plants [82, 83]. Feeding transgenic tobacco cell cultures with secologanin [83, 84] led to the production of strictosidine, but this glucoalkaloid is excreted to the medium instead of being stored in the vacuole as in the indole-alkaloid-producing *C. roseus* cell cultures. This illustrates the importance of physiological aspects in secondary metabolism besides biosynthesis. Thus, not only genes that encode enzymes catalyzing biosynthetic steps are involved but also genes involved in, for example, pH regulation and transport. Cell cultures of *Weigelia*, capable of secologanin biosynthesis, upon overexpression of TDC and STR genes, also produced small amounts of ajmalicine and serpentine. This shows that indole alkaloid biosynthesis in otherwise nonalkaloid producing plants is feasible via expression of one or more heterologous pathway genes [83].

3.3.2 Metabolic Engineering for Isoquinoline Alkaloids

Yamada and coworkers [14] hypothesized that overexpression of an enzyme at a branch point in a pathway could lead to an increased flux through the affected branch. In the biosynthesis of berberine, the enzyme (*S*)-scoulerine 9-*O*-methyltransferase (SMT) is such an enzyme that might control the ratio of coptisine: berberine plus columbamine in *Coptis japonica* cells [14]. Overexpression of this gene resulted in a 20% increase in enzyme activity, with an increase of berberine and columbamine from 79% of the total alkaloid content in wild-type cells to 91% in transgenic cells. This observation proved that fluxes at a branch point can be changed by metabolic engineering. Overexpression of the *C. japonica* SMT gene in cell culture of *Eschscholzia californica*, a plant lacking this enzyme, resulted in the production of columbamine, which is normally not found in this species. Opening up a new pathway at the intermediate scoulerine apparently channeled the flux away from the sanguinarine branch, resulting in considerably lower levels of this alkaloid. An interesting approach for the production of new compounds in plants is to introduce enzymes with different substrate specificity (combinatorial biochemistry) [79]. For example, recombining *Thalictrum tuberosum O*-methyltransferase subunits to form heterodimeric enzymes with substrate specificity different from that of the homodimers was proposed as a possible way to generate new isoquinoline alkaloids [85].

3.3.3 Metabolic Engineering for Tropane Alkaloids and Pyrrolidine Alkaloids

Reasonable amount of research has been done on the genetic engineering of the pharmaceutically important tropane alkaloids [65]. The conversion of hyoscyamine to more valuable scopolamine has been the ultimate aim of these studies. The enzyme hyoscyamine-6β-hydroxylase (H6H) catalyzes this conversion. By the overexpression of the gene encoding H6H in *Hyoscyamus muticus* hairy root cultures, a 100-fold increase of scopolamine levels could be reached compared to control which produced hyoscyamine as the major alkaloid [86]. Recent efforts have been aimed at increasing the flux through the biosynthetic pathways [14, 79]. The tobacco putrescine *N*-methyltransferase (PMT) gene was overexpressed in *Atropa belladonna* and *Nicotiana sylvestris*, with the aim of increasing the production of tropane alkaloids and pyrrolidine alkaloids, respectively. For both types of alkaloids, the formation of methylputrescine is the first committed step. However, despite a modest increase in the PMT activity (up to 3.3-fold) in the transgenic *A. belladonna* plants, no increase in alkaloid levels was observed and only the level of the methylputrescine could be increased. In some transgenic *N. sylvestris* plants, the PMT activity was increased four- to eightfold, whereas in others cosuppression was noted. The transgenic lines showed a 40% increase in nicotine level, whereas in the case of cosuppression the nicotine level was only 2% of wild type. The latter plants had a clear increase in polyamine levels. A certain step in a pathway might appear to be rate limiting, but overexpression of the encoding gene in most cases immediately revealed new rate-limiting steps [79].

3.3.4 Metabolic Engineering for Eliminating Undesired Metabolites and its Unpredictability

Metabolic engineering strategies have also been used to eliminate undesired metabolite. For example, a transgenic coffee cultivar with 70% reduction of caffeine content was created by the introduction of RNA interference (RNAi) constructs in order to downregulate theobromine synthase (MXMT) [87]. A more pest-resistant tobacco cultivar has also been engineered by expressing three N-methyltransferases from coffee to divert flux from xanthosine to synthesize caffeine [88]. Although there are many examples of successful attempts to achieve a desired alkaloid production phenotype, the outcome of plant metabolic engineering strategies is often unpredictable. For instance, the downregulation of codeinone reductase with RNAi was a strategy which was expected to lead to suppression of morphine formation and the accumulation of codeinone and morphinone, the immediate precursors of codeinone reductase. Although the amount of the morphinan alkaloids was decreased, biosynthesis of (S)-reticuline, an early upstream metabolite in the pathway, was increased instead of codeinone and morphinone [89]. On the other hand, the overexpression of another enzyme in the pathway, the cytochrome P450 monooxygenase (*S*)-*N*-methylcoclaurine 3′-hydrolase (CYP80B3), resulted in hyperaccumulation of morphinan alkaloids [90]. This suggests that although there are multiple control points in the BIA pathway, CYP80B3 is an important target toward improving morphine biosynthesis. The suppression of the gene by an antisense construct led to reduced alkaloid content in transgenic opium poppy [90]. Similarly, by overexpressing the gene, *COR1*, the morphine and codeine content in transgenic opium poppy could be moderately increased by ∼22% and ∼58%, respectively [91]. However, thebaine, an upstream metabolite in the morphine branch pathway, was also unexpectedly and significantly amplified [15, 91].

3.3.5 Biotransformation of Alkaloids for Enhanced Bioactivity

The important pharmacological activity of many alkaloids has attracted and motivated chemists to make many derivatives of these natural compounds. The semisynthetic preparation alkaloids has resulted in the production of drugs with improved properties, such as the addition of a 14-hydroxy group to the morphine alkaloid structure which has been found to dramatically increase its potency [92]. However, the chemical synthesis of such compounds is often difficult to achieve on a commercial scale due to the chemical complexity of the starting material, cost, and environmental issues, in addition to the limited supply of the precursors required. Biotransformation can offer a number of advantages over conventional chemical processes. The specificity of enzyme-catalyzed reactions allows the stereospecific transformation of defined functional groups. The use of recombinant DNA technology has a substantial impact on biotransformation processes, resulting in the development of new approaches using biological systems. Recent advances made in the understanding of the genetic and biochemical basis of alkaloid biosynthetic pathways have made biotransformation of complex alkaloid molecules more feasible and credible.

3.4 Mutasynthesis of Novel Alkaloid Analogs

Functional group substitution in natural alkaloid structures have lead to the generation of compounds with improved pharmacological properties. For example, vinflunine (4′-deoxy-20′,20′-difluoro-C′-norvincaleukoblastine), a new compound was created by introducing two fluoro groups in vinblastine [93]. The current availability of novel alkaloids, however, remains limited because they are still semisynthetically derived from naturally isolated precursors. Precursor-directed biosynthesis, or a "mutasynthetic" approach, is a powerful strategy for increasing the availability of alkaloid derivatives. Several fluorinated tropane alkaloids could be produced by simply feeding fluorinated phenyllactic acid analogs to *Datura stramonium* root cultures [94]. Similarly, a wide variety of tryptamine and secologanin analogs could be introduced into *C. roseus* root cultures and seedlings in order to synthesize unnatural MIAs [95, 96]. The apparent flexibility of downstream alkaloid pathways opened the possibility of generating enzyme variants with increased selectivity toward unnatural substrate analogs, thereby improving the efficiency of precursor-directed biosynthesis and increasing the generation of novel alkaloids. Several STR variants with altered substrate specificity have been successfully engineered. For example, the structural elucidation of *Rauvolfia serpentina* STR led to the identification of several amino acid residues that form the binding pocket of *C. roseus* STR [97, 98]. An enzyme variant exhibiting increased selectivity toward an analog of secologanin (with a pentynyl group) was identified. Similarly, functional STR mutants were identified that can accept tryptamine analogs [99]. By applying a saturation mutagenesis strategy on several residues that form the binding pocket, two STR mutants (V214M and F232L) that turned over unnatural tryptamine compounds to synthesize β-carboline analogs were identified [98]. When the newly synthesized strictosidine analogs were fed to *C. roseus* hairy root cultures, a number of novel MIA analogs were obtained. As shown in Fig. 8.11 [15], STR mutants (identified from the development of colorimetric medium-throughput assay) that can efficiently turn over substrate analogs were used to synthesize unnatural strictosidine from unnatural tryptamine and secologanin. Unnatural complex alkaloids could be generated from feeding the unnatural strictosidine into *C. roseus* hairy root culture. Analogs of tryptamine could also be directly converted into complex alkaloids by metabolically reprogramming *C. roseus* hairy root [100].

4 Engineering Alkaloid Biosynthesis in Microorganisms

Owing to the smaller genome size, the degree of complexity in microorganisms is significantly lower than that of plants. Moreover, microorganisms have fewer intracellular organelles compared to plant cells. Hence, metabolite transport between enzymatic steps can be negligible. With the ability to express alkaloid biosynthetic enzymes (difficult to achieve by chemical means), heterologously in microorganisms having better fermentation characteristics than plants, it is possible to achieve unlimited quantities of these enzymes required for synthesis of important drugs. The cDNAs for enzymes that catalyze the biosynthetic steps can be isolated from plants and heterologously expressed in microbes. Alternatively, instead of single transformation steps, microorganisms can be engineered to express short pathways, thus producing an end product alkaloid of interest.

The bacterium *E. coli* and yeast *S. cerevisiae* have been recently explored as production hosts of plant alkaloids [15, 101, 102]. In both cases, the metabolic engineering efforts in microorganisms entailed the reconstruction of the plant biosynthetic pathways (Fig. 8.12) [101]. To assemble an artificial pathway to achieve (S)-reticuline biosynthesis in *E. coli*, *Micrococcus luteus* monoamine oxidase (MAO) was introduced together with *Coptis japonica* norcoclaurine

[101])

synthase (NCS), 6-*O*-methyltransferase (6-OMT), coclaurine-*N*-methyltransferase (CNMT), and 3′-hydroxy-*N*-methylcoclaurine-4′-*O*-methyltransferase (4′-OMT) in plasmid-based expression systems [101]. Upon induction of enzyme expression and supplementation of ~780 mg l^{-1} dopamine, nearly 11 mg l^{-1} of (*R*,*S*)-reticuline could be produced in the cell culture of the recombinant *E. coli*. Also, by coculturing the reticuline-producing *E. coli* with *S. cerevisiae* expressing the *C. japonica* berberine bridge enzyme (BBE) or plant cytochrome P450 CYP80G2, in the presence of dopamine, (*S*)-scoulerine and magnoflorine could be obtained in a short period of time (48–72 h). However, the use of two microbial systems for pathway construction relatively reduces the level of alkaloid production on account of metabolite transport required between the cells.

In another study, *S. cerevisiae* was used as a sole host organism for the assembly of artificial BIA pathways [103]. In this work, the biosynthesis of (*R*,*S*)-reticuline from (*R*,*S*)-norlaudanosoline was enabled by expressing 6-OMT, CNMT, and 4′-OMT derived from either *Thalictrum flavum* or *Papaver somniferum*. After stable insertion into the yeast genome under a reduced strength promoter variant [104], the heterologous gene expression resulted in the creation of an artificial plant pathway with reduced transcriptional activities while maintaining high catalytic activities. Furthermore, the plasmid-based expression of *P. somniferum* BBE together with *T. flavum* (*S*)-scoulerine 9-*O*-methyltransferase (SMT) in (*R*,*S*)-reticuline-producing yeasts resulted in the synthesis of ~60 mg l^{-1} (*S*)-tetrahydrocolumbamine from ~1 g l^{-1} of (*R*,*S*)-norlaudanosoline in 48 h. Additional plasmid-based expression of the *C. japonica* P450 enzyme CYP719A1 and the integration of the *A. thaliana* P450 redox partner protein in the genome gave rise to the accumulation of an estimated ~30 mg l^{-1} (*S*)-canadine, the direct precursor of the pharmaceutically important berberine. The synthesis of (*R*,*S*)-reticuline by the engineered yeast strain also enabled the synthesis of salutaridine, an intermediate in the branch pathway of morphine, through a shorter route. In plants, the synthesis of salutaridine from S-reticuline includes multiple enzymatic steps, many of which are not characterized. However, by expressing a human cytochrome P450 involved in morphine metabolism together with human CPR1 reductase in the reticuline-producing yeasts, ~20 mg l^{-1} salutaridine could be synthesized from (*R*,*S*)-norlaudanosoline. Yeast has also been engineered to accommodate the biosynthesis of high-value MIAs from feeding tryptamine and secologanin [105].

Transgenic yeast have also been created by expressing *C. roseus* STR and strictosidine β-glucoside (SGD) using a plasmid-based expression system. On feeding of the STR substrates, ~2 g l^{-1} of strictosidine could be detected in the medium on account of the presence of the heterologously expressed STR. Yeast has the ability to support the functionality of plant membrane-bound cytochrome P450 enzymes which is difficult in *E. coli* due to the absence of the endoplasmic reticulum required for anchorage. However, recently reported protein engineering strategies have allowed the functional expression of plant P450s in *E. coli* also [106, 107].

The recent demonstrations of engineering alkaloid pathways in microbes are promising but are limited by the need to provide expensive intermediate precursors exogenously. Thus, the complete elucidation of alkaloid biosynthesis is a necessary prerequisite to enable the synthesis of complex downstream alkaloids from simple precursors. However, this strategy will likely entail the implantation of numerous biosynthetic steps, which is a technical challenge. There are several other challenges that must be met before microorganisms can be used as an industrial alkaloid production platform. For example, many steps in alkaloid biosynthesis require methylation, and high-level production in microbial systems can be limited by the intracellular availability of *S*-adenosyl-L-methionine (SAM). Therefore, further metabolic engineering efforts are required to increase the SAM pool in the microbial hosts. Also, the cytotoxicity of alkaloids in yeast has also been reported [105] and is presumably present in other microbes as well. Therefore, practical and effective strategies need to be devised to mitigate cellular toxicity in order to generate alkaloid-overproducing microbes. A transcriptomic approach has been recently used to diagnose the effect of metabolite toxicity and resulted in a strategy to dampen the negative impact of the toxicity on growth [108]. Moreover, a new strategy to increase microbial tolerance toward toxic metabolites by engineering transcription factors can be applied in alkaloid-producing microbes [109]. In general, the current technology of supplying alkaloids from engineered microorganisms is not economical because it still relies on the supplementation of expensive intermediate metabolites. However, the complete elucidation of alkaloid biosynthetic pathways from the early amino acid precursors can lead to the generation of economically viable microbial production platforms. In fact, to some extent, the feasibility of plant metabolite biosynthesis from inexpensive precursors has been demonstrated in both *E. coli* and *S. cerevisiae* [110, 111].

5 Conclusion

The feasibility and success of industrial-scale production of scopolamine and berberine from cell culture by Sumitomo Chemical Industries and Mitsui Petrochemical Industries [112, 113] supports the applicability of plant cell/tissue culture bioprocesses for commercial production of alkaloids. However, one major limitation of plant tissues and cell lines is the inability to produce certain alkaloids owing to the lack of specialized cell types [114]. Metabolic reconstruction is feasible now for increasing the utility of plant cell lines and tissues for commercial production of alkaloids. Recent advances made in developing genetic tools for plant transformation can overcome the long-standing problems of slow growth, low yields, and instability in routine plant cell cultures. There have been some successful efforts on application of metabolic engineering strategies for enhanced alkaloid production (Table 8.4) [3]. However, pathway compartmentalization and the existence of multiple alkaloid biosynthetic pathways and regulatory control mechanisms can limit the robustness of the metabolic engineering strategies used for enhanced

Table 8.4 Metabolic engineering of plants for alkaloid production using genes involved in alkaloid biosynthesis (Modified and adopted from Ref. [3])

Transformation done in plant species	Source of gene	Enzymes involved	Result of metabolic modification
Nicotiana tabacum	*Catharanthus roseus*	Tryptophan decarboxylase (TDC)	Increased tryptamine
Solanum tuberosum	*Catharanthus roseus*	Tryptophan decarboxylase (TDC)	Redirection of shikimate metabolism; reduced phenylalanine; increased disease susceptibility
Catharanthus roseus	*Catharanthus roseus*	Tryptophan decarboxylase (TDC)	Increases tryptamine in crown gall tissue
Catharanthus roseus	*Catharanthus roseus*	Tryptophan decarboxylase (TDC), (STR)	Increases terpenoid indole alkaloids
Cinchona officinalis	*Catharanthus roseus*	Tryptophan decarboxylase (TDC), Strictosidine synthase (STR)	Increased quinoline alkaloids in root culture
Nicotiana tabacum	*Catharanthus roseus*	Tryptophan decarboxylase (TDC), Strictosidine synthase (STR)	Strictosidine production when supplied with exogenous secologanin
Brassica napus	*Catharanthus roseus*	Tryptophan decarboxylase (TDC)	Reduced indole glucosinolates
Brassica napus	*Papaver somniferum*	Tyrosine decarboxylase (TYDC)	Increased cell wall-bound tyramine; decreased cell wall digestibility
Nicotiana tabacum	*Saccharomyces cerevisiae*	Ornithine decarboxylase (ODC)	Increased putrescine and nicotine
Nicotiana tabacum	*Avena sativa*	Arginine decarboxylase (ADC)	Increased agmatine
Atropa belladonna	*Hyoscyamus niger*	Hyoscyamine 6 _-hydroxylase (H6H)	Increased scopolamine
Hyoscyamus muticus	*Hyoscyamus niger*	Hyoscyamine 6 _-hydroxylase (H6H)	Increased scopolamine
Peganum harmala	*Catharanthus roseus*	Tryptophan decarboxylase (TDC)	Increased serotonin
Nicotiana tabacum	*Hafnia alvei*	Lysine decarboxylase (LDC)	Increased cadaverine and anabasine
Peganum harmala	*Catharanthus roseus*	Tryptophan decarboxylase (TDC)	Increased serotonin and Camptothecin

alkaloid production in plant cell cultures. Complete elucidation of the complex alkaloid biosynthetic networks is hence required to design an effective metabolic engineering scheme without any unpredictability. The development of mathematical models of plant metabolism together with systems biology analyses can eventually be used to aid in determining effective metabolic engineering strategies [115, 116]. The inherent complexity of plant cellular systems often causes single-gene manipulations to be ineffective for altering a biosynthetic phenotype. Therefore, methods that are capable of effecting simultaneous changes in multiple metabolic points, such as the use of transcription factors, seem to be promising [117].

Microbes are even more scalable than plant tissue and cell cultures, with a long and successful history as chemical factories for the large-scale production of both bulk and specialized chemical products. The degree of complexity in microorganisms is significantly lower than that of plant systems, in terms of lack of preexisting branch pathways and transcription factors which simplifies the design of the metabolic engineering approach. Recent advances in synthetic biology and metabolic engineering have enabled tailored production of these secondary metabolites in microorganisms, but these methods often require the addition of expensive substrates.

In conclusion, both plant cell/tissue and microbial systems offer tremendous advantages as scalable alkaloid production platforms. Moreover, because the characteristics and metabolic capacities of plant cell/tissue and microbial systems are inherently different, they can serve as complementary unit operations in order to solve the long-standing problem of robust alkaloid production. However, better understanding of regulatory mechanisms and refinement for robust cellular and metabolic engineering of plant cells/tissues will further provide an impetus to popular use of plant cell technology in industry.

TMSOTf	trimethylsilyl trifluoromethanesulfonate
TrCl	triphenylmethyl chloride

1 Introduction

Natural products isolated from marine organisms, which contain various compounds that are used to sustain life and relationships with other organisms, have gained great attention because of their potential as new medicinally valuable agents, agricultural chemicals, cosmetics, and health foods [1–5]. Among these organisms, marine sponges of the genera *Latrunculia*, *Batzella*, *Prianos*, and *Zyzzya* are rich sources of alkaloid metabolites. This chapter focuses on the biological origin and synthesis of makaluvamines and discorhabdins, and imidazole, pyrrole-imidazole alkaloids.

2 Marine Pyrroloiminoquinone Alkaloids, Makaluvamines, and Discorhabdins

Several reviews have appeared describing the structures, biological activities, and synthesis of the pyrroloiminoquinone alkaloids and their analogues [6–10]. Because most substances in this family, including makaluvamines and discorhabdins, exhibit strong cytotoxicities toward human tumor cell lines, they serve as lead compounds for developing new anticancer drugs and have attracted the attention of several synthetic organic chemistry groups (Fig. 9.1).

2.1 Biosynthesis

The putative biosynthetic pathway linking the marine pyrroloiminoquinone and related metabolites, described by Munro et al., is shown in Scheme 9.1 [6, 11]. The route begins with oxidation of tryptamine to introduce hydroxyl groups at C-4 and C-7. Next, oxidation affords a quinone, which produces the iminoquinone intermediate by imine formation between the carbonyl group and the side chain amine. Further oxidation gives makaluvamines A-C, H, I, and N (Path A). In a branch of this pathway (Path B), thyrosine adds to the iminoquinone to generate makaluvamines D, E, G, J-M, and P. Furthermore, two additional routes exist to yield the discorhabdins, one of which produces makaluvamine F by early introduction of sulfur followed by phenol coupling to give the sulfur-containing fused hexacyclic discorhabdins A, B, I, Q, D, and L. The other route via discorhabdins C, E, F and O, which are generated by phenol coupling, involves sulfur introduction to produce discorhabdins S, T, U, A, B, I, Q, D, and L.

2.2 Natural Makaluvamines and Discorhabdins

Makaluvamine alkaloids, representative structures of which are shown in Fig. 9.2, were isolated from marine sponges collected in Fijian, Micronesia, Australia's

makaluvamine F

N-1-β-D-ribofuranosylmakaluvamine I

Fig. 9.2 Representative makaluvamine alkaloids

Great Barrier Reef, Indonesia, the Philippines, and Vanuatu areas [12–17]. The configuration of the stereogenic center in makaluvamine F has not yet been determined. *N*-1-*β*-D-ribofuranosylmakaluvamine I, which contains a carbohydrate moiety, was also isolated from a South African sponge [18].

The discorhabdin alkaloids, structures of whose representative members are given in Fig. 9.3, were isolated from marine sponges, including those from New Zealand of the genus *Latrunculia*, the Okinawan sponge *Prianos melanos*, the Fijian sponge *Zyzzya* cf. *Marsailis*. Discorhabdin Z was isolated from the Korean marine sponge *Sceptrella* sp. [19], and dihydrodiscorhabdin B and discorhabdin Y were isolated from a deep-water Alaskan sponge of the genus *Latrunculia* [20]. Among the various discorhabdins (A-X), discorhabdins A [21], B [21], D [22], H [23], I [24], J [6], L [24], M [6], N [6], Q [25], R [26], and X [27], and prianosins B and D [28] have sulfur-containing fused ring system. Fig. 9.3 Discorhabdin alkaloids

S, T, and U [29] possess methyl sulfide moieties, discorhabdin W [30] is a dimeric structure linked by a disulfide bond, while other members of this series do not contain sulfur. Furthermore, discorhabdins F [31], Q, S, and T and prianosin B contain a 16,17-dehydropyrroloiminoquinone moiety. The enantiomeric pairs of discorhabdins B, G*/I, L, and W were also isolated from *Latrunculia* species sponges [32]. A study focusing on the elucidation of the absolute stereochemistry of several discorhabdins was reported by Copp et al. [33].

2.3 Approaches to Syntheses of Makaluvamines

Makaluvamines A [34], B [35], C [36], D [37], E [38], I [34], and K [34], and *N*-1-*β*-D-ribofuranosyl-makaluvamine I [37] have been synthesized until now. Most of these syntheses were reported prior to 2000 and following that time, most attention in this area has been given to preparation of analogs and probing their biological activities.

For the most part, the routes developed for the synthesis of members of the makaluvamine family have mimicked the proposed biosynthesis route shown in Scheme 9.1. Specifically, pathways have been devised that involve construction of the pyrroloiminoquinone skeleton through initial formation of the quinone moiety followed by either imine formation, oxidation of the cyclic amine, or direct iminoquinone formation of substrates possessing an azide side chain.

One example is found in the synthesis of makaluvamine A-E, reported by Yamamura and Nishiyama (Scheme 9.2). The route begins with conversion of indole **1** to lactam **2**. In the route to makaluvamines A, B, and E, **2** (R^1 = Me, R^2 = H) was transformed to pyrroloiminoquinone **3** by using a reduction and oxidation sequence. In a closely related fashion, makaluvamine C was prepared from **2** (R^1 = H, R^2 = Me) and makaluvamine D was synthesized from the iminoquinone **4** derived from **1** (R = Bn) [38].

Kraus et al. described a total synthesis of makaluvamine C that proceeds through initial formation of quinoline ring followed by formation of the indole moiety and Fremy's salt promoted oxidation of the 4-methoxyaniline group (Scheme 9.3) [36]. In this approach, the 6,6-bicyclic compound **6** was formed first.

In 1994, we discovered a process involving inter- and intramolecular nucleophilic addition of aromatic compounds that is mediated by a hypervalent iodine reagent in either CF_3CH_2OH or $(CF_3)_2CHOH$ [39]. In 2006, Nishiyama et al. used the hypervalent iodine reagent, prepared from iodobenzene under electrolytic conditions, as part of a new method for the synthesis of tetrahydroquinolines. This process was applied to syntheses of the pyrroloiminoquinones, makaluvamines D and I, and *N*-1-*β*-D-ribofuranosylmakaluvamine I (Scheme 9.4). In the synthetic pathways, arylpropionamide **10**, prepared from 3-benzyloxy-2-nitrotoluene (**8**), was converted to the quinolinone **11** when subjected to the hypervalent iodine prepared by anodic oxidation of PhI in CF_3CH_2OH. Quinolinone **11** was then transformed to aldehyde **12**, which gave **13** by reaction with Zn/AcOH, followed by treatment with TsCl–NaH and catalytic hydrogenolysis. Oxidation of the 2-hydroxyaniline moiety in **13** with

Scheme 9.3 Kraus's synthesis of makaluvamine C

Fermy's salt produced the α-diketone **14**, which was subjected to exhaustive deprotection to afford damirone C, a natural pyrroloiminoquinone alkaloid. Furthermore, amination of damirone C provided makaluvamine I and reaction of this substance with tyramine hydrochloride yielded makaluvamine D. In addition, reaction of **15**, obtained by deprotection of the amine functions in **14**, with a chloro-glycoside produced the desired glycosides **16-β** and **16-α** in 50 % yield as a 23:2 mixture. Removal of the TBS-protecting group in **16-β** afforded **17** and *N*-1-*β*-D-ribofuranosylmakaluvamine I was obtained by treatment of **17** with ammonia [37].

Among members of the makaluvamine family, makaluvamine F has been found to exhibit the most potent biological activity, exemplified by its cytotoxicity toward the human colon tumor cell line HCT-116 ($IC_{50} = 0.17$ mM) and inhibition of topoisomerase II.

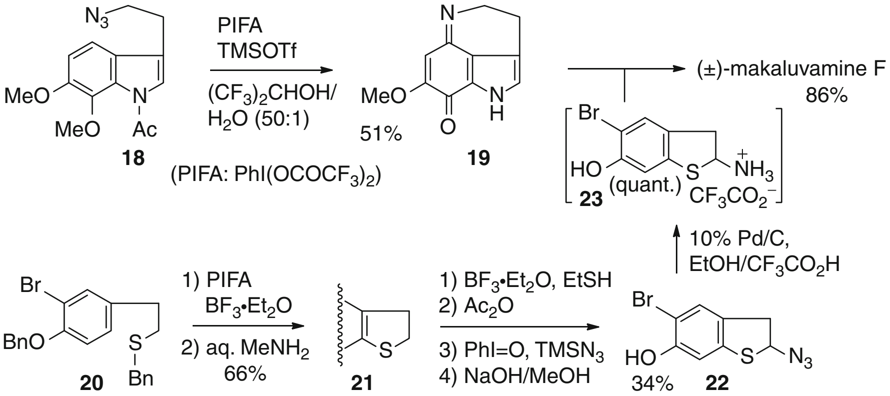
N-1–β-D-ribofuranosylmakaluvamine I

Scheme 9.4 Syntheses of the pyrroloiminoquinones, makaluvamines D and I, and *N*-1-*β*-D-ribofuranosylmakaluvamine I



Scheme 9.5 Total synthesis of (±)-makaluvamine F

As a consequence of the presence of a labile *N,S*-acetal moiety, mild reactions are needed for the synthesis of makaluvamine F. We have developed two new methods that are valuable for the synthesis of complex pyrroloiminoquinone alkaloids. The processes involve hypervalent iodine-induced nucleophilic substitution of *p*-substituted phenol ethers via reactive cation radical intermediates. One involves reactions of quinone imine dimethylacetals or quinine imines from phenyl ethers with an alkylazido group [40, 41], and the other reactions of α-azidodihydrobenzothiophenes derived from dihydrobenzothiophenes [42]. The route devised for synthesis of makaluvamine F, utilizing the two new methods as key reactions, is shown in Scheme 9.5. The sequence begins with reaction of the 1-protected indole **18** with PIFA–TMSOTf in the presence of H_2O to afford the corresponding *N*-deprotected pyrroloiminoquinones **19**. In a parallel process, treatment of the phenol ether **20** bearing an alkyl sulfide side chain with PIFA–BF_3·Et_2O followed by the treatment with aq. $MeNH_2$ provided 5-bromo-6-benzyloxydihydrobenzothiophene **21**. Azidation of **21** gave only a trace amount of the expected α-azido compound. As a result, a new pathway was developed that involved debenzylation of **21** followed by acetylation of the resulting phenol to give a product that reacted with PhI = O and Me_3SiN_3 followed by hydrolytic deprotection to provide the desired 2-azido-5-bromo-6-hydroxydihydrobenzothiophene **22**. Catalytic hydrogenation of **22** using 10 % Pd-C in the presence of 4 equivalents of trifluoroacetic acid (TFA) resulted in complete reduction leading to the TFA salt **23** in quantitative yield. In the final step, coupling reaction in MeOH between **23** and **19** proceeded to give the TFA salt of makaluvamine F [43, 44].

2.4 Synthetic Approaches to the Discorhabdins

Discorhabdin alkaloids have the richest structure-diversity among the marine pyrroloiminoquinone alkaloids. Although many synthetic studies have been carried

discorhabdin C

Scheme 9.6 Final steps of the synthesis of discorhabdin C

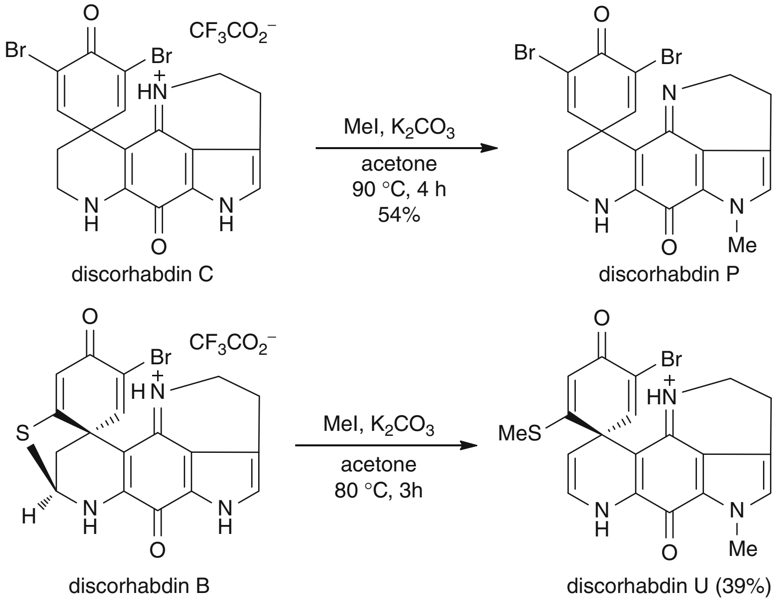
out, only a few total syntheses of the natural discorhabdins have been reported. Routes for the preparation of discorhabdin C have been developed by our group and Yamamura's group at almost the same time, and later by the group headed by Heathcock. Heathcock et al. also synthesized discorhabdin E, a 4-debromo derivative of discorhabdin C, using essentially the same procedure.

In Scheme 9.6 are shown the final steps of each of the completed synthetic pathways targeted at (±)-discorhabdin C. In our approach [45], the phenolic aminoindoloquinone imine **24** (R = H) was converted to its corresponding silyl ether, which subsequently underwent oxidative coupling using PIFA to form discorhabdin C in 42 % yield. In Yamamura's synthesis, discorhabdin C was generated in 24 % yield upon anodic oxidation of the bromophenol derivative **24** (R = H) [46]. Finally, in the route developed by Heathcock, discorhabdin C was produced by a phenolic coupling reaction of **24** (R = Ts) with $CuCl_2$ and Et_3N under O_2 followed by detosylation [47].

Copp et al. have also described the semi-synthesis of discorhabdins P and U starting with the natural discorhabdins C and B (Scheme 9.7) [48].

Sequences for the synthesis of the more complex discorhabdins, discorhabdin A and prianosin B, have been developed only in our laboratory. Discorhabdin A, which has a unique sulfur-containing fused ring structure, incorporating azacarbocyclic spirocyclohexanone and pyrroloiminoquinone systems, displays the most powerful cytotoxic activity among isolated members of the discorhabdin family.

The synthetic approach we developed for the preparation of discorhabdin A involved a strategy in which the spirodienone system was preconstructed using a hypervalent iodine(III) reagent and final introduction of the sulfur to the cross-linked system (Scheme 9.8). The route began with tritylation of L-tyrosine methyl



Scheme 9.7 Semi-synthesis of discorhabdin P and U

ester hydrochloride **25** followed by mono-bromination to yield **26**. Reduction of **26** with DIBAH followed by silylation gave the bis-silylated intermediate **27** that underwent coupling reaction with pyrroloiminoquinone **28**, prepared by using our previously developed method, to form **29**. Transformation of **29** to the spirodienone was promoted by treatment with PIFA in the presence of montmorillonite K10 (MK10) to give a diastereomeric mixture of **30** and **31**. The major isomer **30** has the same absolute stereochemistry (*S* configuration) at the C-6 spirocenter as that present in natural discorhabdin A. Oxidative fragmentation reaction of the α-amino alcohol, obtained from **30** by desilylation, with bis(trifluoroacetoxy)iodo (III) pentafluorobenzene ($C_6F_5I(OCOCF_3)_2$) in the presence of $NaHCO_3$, afforded the *N,O*-acetal **32** in 79 % yield. Introduction of the *p*-methoxybenzylthio group led to the unstable *N,S*-acetal **33** as a diastereomeric mixture, which was treated with 30 % HBr-AcOH followed by aqueous $MeNH_2$ work up to produce the *N*-tosyl derivative **34** of discorhabdin A. Removal of the tosyl group in **34** with NaOMe gave discorhabdin A in optically pure form (Scheme 9.8). In the same effort, we also completed a total synthesis of the unnatural discorhabdin A, (−)-discorhabdin A, starting from the D-tyrosine methyl ester by using the same general strategy (Scheme 9.9) [49, 50].

Prianosin B is a C16-17 dehydro-derivative of discorhabdin A. Thus, treatment of intermediate **34** in the discorhabdin A synthetic pathway (Scheme 9.9) with NaN_3 brought about simultaneous detosylation and dehydrogenation to produce prianosin B in 48 % yield. (Scheme 9.10) [51].

3 Marine Pyrrole-Imidazole Alkaloids

The pyrrole-imidazole alkaloids, mainly isolated from various species of the *Agelasidae*, *Axinellidae*, *Dyctionellidae*, and *Hymeniacidonidae* sponge families, contain characteristic pyrrole-2-carboxamide and 2-aminoimidazoline moieties or derivatives thereof. Their architectural complexity ranges from simple, achiral, monomeric oroidin to the 16-stereocenter-containing tetrameric stylissadines A and B (Fig. 9.4). Because many reviews have appeared describing these alkaloids [52–56], we provide only a short discussion of some biosynthetically and synthetically pertinent information.

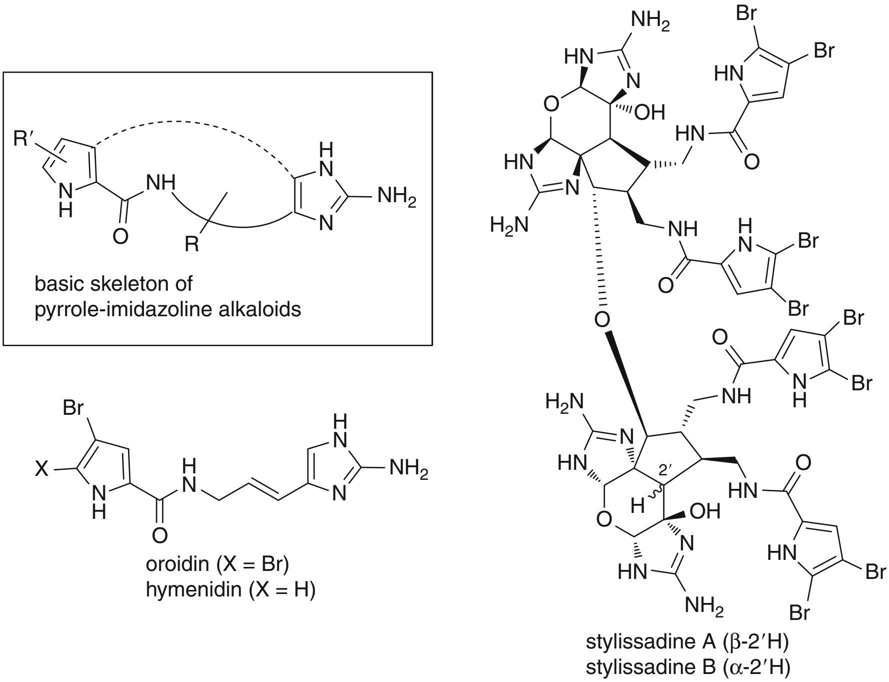

Fig. 9.4 General skeletons, monomeric and tetrameric pyrrole-imidazol alkaloids

3.1 Biosynthesis

The proposed biosynthetic route for formation of pyrrole-imidazole alkaloids is shown in Fig. 9.5. Amino acids, such as proline, histidine, ornithine, lysine, and arginine, are thought to be incorporated into simple monomeric intermediates in the route used to generate these substances in organisms [57, 58]. Indeed, feeding studies using ^{14}C-labeled amino acids by Kerr et al. demonstrated that histidine and ornithine (or proline) are the amino acid precursors of the oroidin alkaloids [59]. However, the radioactivity and specific incorporation levels were observed to be low. Based on the results of synthetic studies, Al-Mourabit et al. proposed that proline or arginine is the early precursor of both the pyrrole-carboxylic acid and the 2-aminoimidazole moieties [60]. In 2001, Al Mourabit and Potier reported that simple proposed monomeric intermediates were enzymatically converted to complex monomeric alkaloids and the and cyclized dimers [61]. Köck, Baran et al. also reported that oroidin is converted to the cyclized dimers, such as the palau'amines [62]. Furthermore, in 2010, Molinski and Romo et al. provided the first experimental evidence supporting the veracity of the common assumption that clathrodin/oroidin is the precursor to more complex pyrrole-imidazoline alkaloids, monomers, dimers, and tetramers [63].

3.2 Natural Pyrrole-Imidazole Alkaloids

3.2.1 Monomers

Representative acyclic and cyclic monomers in the pyrrole-imidazole alkaloid family are shown in Fig. 9.6. Oroidin and hymenidin, from the sponge *Agelas oroides*, are acyclic while others members are cyclic [64]. Oroidin, the most abundant alkaloid in this group and considered to be the biogenetic precursor of the other alkaloids (Fig. 9.5), was found to inhibit larval metamorphosis of the barnacle *Balanus amphitrite*. Hymenidin is a mono-debromo derivative and clathrodine is the debromo analogue of oroidin [65, 66]. Dispacamides A and B, from the sponge *Agelas dispar*, are potent, noncompetitive, antihistaminic agents and dispacamide B was shown to display antihistaminic activity against the guinea pig ileum [67, 68]. (*Z*)-Hymenialdisine, from the sponges of the genera *Hymeniacidon, Acanthella, Axinella*, and *Pseudoaxinyssa*, has been observed to be potently active as a kinase inhibitor and to have utility for not only the treatment

of cancer but also for illnesses such as Alzheimer's disease and type 2 diabetes [69]. (*E*)-Axinohydantoin and (*E*)-debromoaxinohydantoin have been isolated from the sponges *Axinella* sp and *Monanchora* [70, 71]. (Z)-Axinohydantoin and (*Z*)-debromoaxinohydantoin, isolated from the sponge *Stylotella aurantium*, are structurally similar to hymenialdisine [72, 73]. (−)-Dibromophakellstatin, isolated from the Indian Ocean sponge *Phakellia mauritiana*, is a tetracyclic monomeric pyrrole-imidazole alkaloid that showed interesting cell growth inhibitory activity against a minipanel of human cancer cell lines [74]. The structures of dibromophakellin and monobromophakellin are similar to that of dibromophakellstatin, and exist in nature as both enantiomers. The (−)-enantiomers were isolated from the marine sponge *Axinella vaceleti*, [75], and (+)-enantiomers were isolated from *Pseudoaxinyssa* cantharella [76]. Four closely related compounds, agelastatin A, its brominated congener agelastatin B isolated in 1993 from the marine sponge *Agelas Dendromorpha*, [77] agelastatin C, and agelastatin D isolated from the extracts of the sponge *Cymbastela* sp. [78], possess the same tetracyclic skeleton. Agelastatin E and F were isolated from the New Caledonian sponge *A. dendromorpha* [79]. In addition, (−)-agelastatin A was found to exhibit significant antitumor activity, toxicity toward arthropods, and selective inhibition of the glycogen synthase kinase-3b, which is a potential target in the treatment of Alzheimer's disease and bipolar disorder. The agelastatins are the only isolated pyrrole-imidazole alkaloids having C4–C8 and C7–N12 connectivities between oridin monomers.

3.2.2 Dimers

In Fig. 9.7 are displayed acyclic and cyclic dimeric members of the pyrrole-imidazole family. Nagelamide D, from Okinawan marine sponges of the genus *Agelas*, is a dimer comprised of oroidin monomer units connected between the C-10 and C-15′ positions [80]. However, the assigned structure of this substance is questionable (see below). Sceptrin, isolated in 1981 by Faulkner and Clardy from *Agelas sceptrum*, is the first reported symmetric dimer comprised of hymenidin subunits [81].

The ageliferins, isolated from the sponge *Agelas conifer*, are bicyclic, nonsymmetrical dimers that possess antibiotic and antiviral bioactivities [82]. Nagalamide E is a stereo-isomer of ageliferin [80]. Palau'amine, isolated in 1993 from the sponge *Stylotella agminata*, is a hexacyclic bisguanidine alkaloid that is the most well-known member of the pyrrole-imidazole alkaloid family. This substance, which has been observed to have exciting cytotoxic and immunosuppressive properties, was first assigned to be a diastereomer of the natural product [83]. This assignment was later questioned based on the known structure of carteramine A [84, 85], which is a structural component of palau'amine. The correct stereostructure of palau'amine was finally correctly assigned in 2007 [86]. Axinellamines A and B are the first reported tetracyclic pyrrole-imidazole alkaloids [87]. (−)-Massadine is a second tetracyclic pyrrole-imidazole alkaloid [88]. (−)-Massadine chloride is postulated to be a precursor of massadine [89].

3.2.3 Tetramers

The structures of two tetrameric alkaloids, stylissadine A and B that are ether-linked dimers of massadine, are shown in Fig. 9.4. Although these substances are antagonists of the P2X7 receptor involved in inflammatory diseases, no reports have appeared describing their syntheses, perhaps because they have the most complex structures of pyrrole-imidazole alkaloids discovered so far.

3.3 Synthetic Studies

Many studies have been targeted at the synthesis of marine pyrrole-imidazole alkaloids. As a result, in the chapter below, we will discuss only representative publications describing total and not partial syntheses of these alkaloids (Figs. 9.6 and 9.7). In addition, when several reports exist on the preparation of one of the alkaloids, we will cite only the most recent work.

3.3.1 Synthetic Studies Focusing on the Monomers

Ando et al. developed a route for the total syntheses of the simple monomeric pyrrole-imidazole alkaloids, oroidin, hymenidin, dispacamide, monobromodispacamide, and ageladine A (Scheme 9.12) [90]. In the pathway, 3-bromo-1,1-dimethoxypropan-2-one (**36**) was converted to aldehyde **38**, which was then coupled with sulfone **39** by using the Julia/Kociensky olefination reaction to produce (*E*)-olefin **40**. Deprotection of **40** with hydrazine followed by introduction of pyrrole unit afforded **41** and **42**, which were acid-hydrolyzed to give oroidin and hymenidin, respectively. Catalytic reduction of **40** followed by removal of the phthaloyl group and the two imidazole Boc groups gave amine **43**, which was oxidized with tetrabutylammonium tribromide (nBu_4NBr_3) followed by Boc-protection of primary amine to afford the carbamate **44**. Sequential deprotection and acylation of the pyrrole units gave dispacamide and monobromodispacamide, respectively. Furthermore, **45**, generated from **37** by way of **40** prior to Boc-protection, was used for the synthesis of ageladine A. Thus, nitroaldol condensation of **45** followed by lithium aluminum hydride reduction gave the histamine derivative **46**, which was coupled with **47** through Pictet/Spengler reaction to give **48**. Dehydrogenation of **48** using IBX or activated MnO_2 gave the same results. Simultaneous removal of both the SEM and the Boc groups gave the TFA salt of ageladine A.

Although the syntheses of oroidin and hymenidin described above are the latest published, it would be remiss not to cite the preparation of these targets by Al-Mourabit's group, which is very short [91].

(±)-Dibromophakellin has been prepared using a two step sequence from the known alkene intermediate **50**, derived from pyrrole in seven steps (Scheme 9.13). Treatment of alkene **50** with NBS in the presence of Boc-protected guanidine **51**, followed by removal of the Boc group using trifluoroacetic acid afforded dibromophakellin as its TFA salt [92].

Nagasawa's group accomplished asymmetric total syntheses of (+)-phakellin, (+)-dibromophakellin, and (+)-dibromophakellstatin by utilizing a strategy that

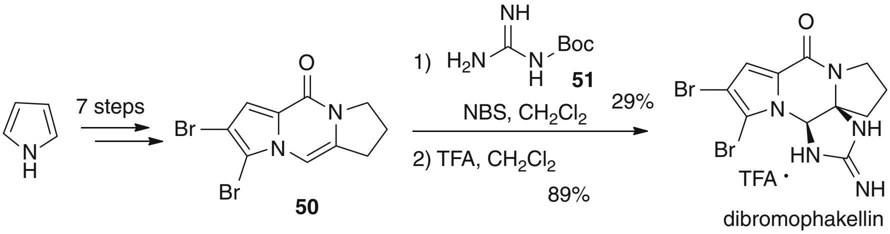

Scheme 9.13 Synthesis of (±)-dibromophakellin

models the proposed biosynthetic pathway (Scheme 9.14). Accordingly, 4-hydroxy-L-proline (**52**) was converted to **53**, which then undergoes Overman rearrangement via **54** to give the aminal **55** as a single diastereomer. This aminal was then converted to **56** in four steps involving alkaline hydrolysis, TBS-protection, DIBAH reduction, and hydrogenation. Guanidination of **56** using **57**, followed by removal of TBS-ether group and treatment with MsCl in the presence of Et_3N, gave cyclic guanidine derivative **58**. Acid hydrolysis of **58** in methanolic HCl then gave (+)-phakellin, which upon NBS treatment followed by acid hydrolysis afforded (+)-dibromophakellin. Furthermore, **56** was converted to (+)-phakellstatin and (+)-dibromophakellstatin by suing a route that was initiated by treatment of amine **56** with benzyloxycarbonyl isothiocyanate followed by methylation to generate thiopseudourea **59**. This substance was converted to the cyclic thiopseudourea **60** by reaction with TBAF followed by addition of MsCl. m-CPBA oxidation of **60** and removal of the benzyloxycarbonyl group by hydrogenolysis furnished (+)-phakellstatin in 89 % yield. Bromine introduction at the C4 and C5 positions of (+)-phakellstatin was accomplished using two equivalents of NBS generated (+)-dibromophakellstatin in 90 % yield [93].

Although many efforts have succeeded in synthesizing the agelastatins, especially agelastatin A, Movassaghi's group recently described total syntheses of all known (−)-agelastatins, including the first total syntheses of agelastatins C, D, E, and F (Scheme 9.15) [94]. In the sequence, pyrrole (+)-**61** was brominated with NBS and the product was reacted with chlorosulfonyl isocyanate followed by desulfonylation to afford amide (+)-**62** in 75 % yield. Reaction of **62** with $NaBH_4$ followed by TsOH treatment and reaction with 4-methoxybenzenethiol and $AlMe_3$ led to the production of thioester **63** in 83 % yield. Reaction of thioester (+)-**63** and triazone **64** in the presence of copper(I)-thiophene-2-carboxylate (CuTC) followed by acid hydrolysis gave (+)-*O*-methyl-pre-agelastatin A in 85 % yield with 99 % ee. Acid hydrolysis of (+)-*O*-methyl-pre-agelastatin A afforded agelastatin A in 49 % along with *O*-methyl-di-*epi*-agelastatin A in 22 % yield. (−)-*O*-methyl-di-*epi*-agelastatin A was converted to agelastatin A in 66 % yield by treatment with acid. Bromination of (−)-agelastatin A afforded (−)-agelastatin B in 84 % yield. (−)-*O*-methyl-di-*epi*-agelastatin A was transformed to (−)-agelastatin C in three steps, involving heating in pyridine at 115 °C, oxidation with dimethyldioxorane, and heating in an aqueous solution containing a Brøonsted acid. thioester (+)-**63** with stannylurea **65** and CuTC, followed by exposure of the product to methanolic hydrogen chloride and acid treatment, gave the desired (−)-agelastatin D in 16 % yield. Heating a methanolic solution of (−)-agelastatin A in the presence of a Bronsted acid afforded (−)-agelastatin E in 96 % yield, and bromination of (−)-agelastatin D gave (−)-agelastatin F in 86 % yield.

3.3.2 Synthetic Studies Targeted at the Dimers

The assigned structure of nagelamide D (Fig. 9.7), isolated from a marine sponge by Kobayashi et al., does not agree with data obtained from analysis of the synthesized natural product prepared by Lovely et al. (Scheme 9.16) [95]. The putative

nagelamide D structure is a dimer comprised of oroidin monomeric units connected between C-10 and C-15′. The route employed by Lovely et al. to synthesize nagelamide D utilized coupling of two imidazoyl units. One fragment, **67**, was synthesized from diiodoimidazole **66** utilizing a four step-sequences, involving formylation, Horner-Wadsworth-Emmons reaction, DIBAL reduction, and protection as TBS-ether. The other fragment, **68**, was also produced from the same diiodoimidazole **66** through a three steps pathway, involving regioselective reduction of iodide, Sonogashira reaction using TBS-protected propargyl alcohol, and hydrostannylation. A Stille cross-coupling method was used to join the two fragments. The product generated in this manner was subjected to removal of the TBS-ethers, giving a substance that was hydrogenated to afford diol **69**. Protection of the diols as bis silyl ethers, followed by azidation at the C2 positions of imidazole rings

and removal of the TBS-ethers, gave diol **70**. Double Mitsunobu reaction of **70** with the dibromopyrrolehydantoin derivative **71** gave **72**, which upon alkaline hydrolysis followed by treatment with methanolic HCl and then reduction of the azide groups generated the putative nagelamide D.

The first total syntheses of the dimeric pyrrole-imidazole alkaloids, including sceptrin, ageliferin, nagelamide E, nakamuric acid (and its methyl ester), and oxysceptrin, were reported by the group headed by Baran (Scheme 9.17). In addition, the first enantioselective total syntheses of sceptrin and ageliferin were accomplished by this group utilizing a strategy that relied on programmed fragmentation of an oxaquadricyclane [96]. A hallmark of the approach to these alkaloids is the minimal use of protecting groups. Diels-Alder reaction of dimethyl acetylenedicarboxylate **73** and 2,5-dimethylfuran **74** followed by enzymatic desymmetrization gave monoester **75** with 75 % ee. Esterification of **75** with 2-propanol, selective hydrolysis, and benzyl amide formation gave **76** in 80 %

yield. UV irradiation of **76** gave rise to oxaquadricyclane **77**, which was immediately subjected to fragmentation to give cyclobutane **78** in 50 % yield and 75 % ee, which was recrystallized to produce a >95 % ee. Heating **78** with toluenesulfonic acid and methanol, followed by protection of the ketone moieties, DIBAL reduction, mesylation, and displacement with sodium azide, produced the key azide **79**. Ketalization of **79**, followed by reduction with Lindlar catalyst and acylation with pyrrole unit **80**, gave **81** in 70 % yield. Heating of **81** with benzyl trimethylammonium iododichloride gave chloroketone **82**, which underwent reaction with sodium diformimide followed by hydrolysis and the reaction with cyanamide to produce (−)-sceptrin. Microwave irradiation of (−)-sceptrin in water afforded (−)-ageliferin and (−)-nagelamide E.

Although (−)-palau'amine is an architecturally daunting natural product, its synthesis was finally accomplished by the Baran group in 2010. In the publication describing this work, Baran et al. also described the asymmetric syntheses of other

(–)-axinellamine B (4.3%)

Scheme 9.18 Asymmetric total syntheses of dimeric pyrrole-imidazole alkaloids, (−)-palau’amine, (−)-axinellamines, and (−)-massadines dimeric pyrrole-imidazole alkaloids, including (−)-axinellamines, and (−)-massadines, that relied on a bio-inspired approach (Scheme 9.18) [97]. In the route, highly enantioselective [4 + 2]-cycloaddition (95 % ee) of TIPS diene **83** and dienophile **84** was achieved by employing the Ishihara catalyst **85** to give the cyclohexene **86** in 89 % ee. This substance was recrystallized to give optically pure **86** prior to its conversion to a thioester, which was subjected to $LiAlH_4$ reduction, mesylation, displacement with azide, and TIPS deprotection to produce cyclohexenol **87** in 60 % yield. Protection of the alcohol moiety in **87**, followed by ozonolytic cleavage of the olefin, bromination, and cyclization, produced the fully substituted cyclopentane **88** in 57 %. Conversion of bromoketone **88** to chloroketone was followed by deprotection of PMB group, and exposure to sulfuryl chloride to afford the enone **89** in 43 % yield. Luche reduction of **89** followed by displacement of the allylic bromide with bis-Boc-guanidine and oxidation with IBX delivered the allylic guanidine **90** in 39 % yield. Treatment of **90** with $NaN(CHO)_2$ followed by removal of the Boc group furnished aminoketone **91** in 36 % yield. Reaction of **91** with silver(II) picolinate under acidic conditions, followed by treatment with H_2NCN, afforded **92** in 45 % yield. Oxidation of **92** with dimethyldioxirane and acid treatment gave **93** in 15 % yield, which was converted to (−)-massadine chloride and (−)-massadine in a 2:1 ratio by reduction of the azides and acylation with (trichloroacetyl)pyrrole **94**. Mild heating of (−)-massadine chloride in aqueous media afforded (−)-massadine quantitatively. Intermediate **92** was also converted to (−)-palau'amine, by a route involving initial bromination, attachment of the pyrrole surrogate **95**, and then pyrrole generation to afford **96** in 24 % yield. Hydrogenation of the azide moieties in **96**, condensation by using EDC, and then TFA exposure gave (−)-palau'amine in 17 % yield. Aminoketone **91** reacted with H_2NCN to afford **97** in 71 % yield, which upon oxidation with dimethyldioxirane followed by acid treatment gave the tetracyclic intermediate **98**. Treatment of **98** with silver(II) picolinate under acidic conditions followed by the reduction with propanedithiol and acylation with (trichloroacetyl)pyrrole (**99**) provided enantio-enriched axinellamine A and axinellamine B in 11 % and 4.3 % yields from **97**, respectively.

4 Conclusion

Marine organisms produce many types of biologically active compounds. Among them, the sponge-derived pyrroloiminoquinone alkaloids, makaluvamines and discorhabdins, and marine pyrrole-imidazole alkaloids are discussed in this chapter. Since these alkaloids have a wide variety of biological activities and unique structural architectures, they have been identified as lead compounds for developing new drugs. We hope that the studies focusing on structure-activity relationships and modes of action of these substances and their analogues will lead to the development of active drug candidates.

supplements used recreationally can have a wide spectrum of clinical effects, ranging from euphoric and stimulant effects to hallucinogenic experiences. Despite the potential for abuse, addiction, and serious adverse effects, there may be a false perception that these products are all safe, legal, and organic. These perceptions and the ease of accessibility to herbal products could result in greater potential for recreational abuse and subsequent complications presenting to emergency departments. Health care professionals must be cognizant of this emerging problem as increased media coverage and marketing have made these products accessible and recognizable to many young adults and teenagers. Consumers may assume that because a label claims that something is good or right because it is natural, or that something is bad or wrong because it is "synthetic" or "industrial."

The use of food supplements containing herbal ingredients by athletes has become common, even though the scientific rationale is often insufficient. It is obvious that the uncontrolled use of food supplements can represent a risk for health, and this is particularly true when the herbal ingredients have known pharmacological effects. Moreover, the abuse of stimulant substances could represent an illicit way to improve performance during competitions, considering that herbal ingredients cannot always be detected by anti-doping tests. Other illicit uses of herbal ingredients are their inclusion among recreational drugs and, in some cases, among tools in criminal actions.

Keywords

Botanical food supplements • botanical dietary supplements • illicit drugs • plant toxins

1 Introduction

Foods play a critical role in the health of human beings and are often an important part of social, religious, and cultural activity. Several expressions illustrate the importance of foods in daily life, the most famous being "We are what we eat." Most traditions have a particular, easily recognizable cuisine, which is sometimes the focus of epidemiological studies (Mediterranean diet, vegetarian diet, etc.). More recently, foods have been identified as a means of decreasing crime and violence, since healthy food can reduce aggressive behavior. "We are what we eat" has become "we do what we eat." Thus, subjects on a vegetarian diet are often considered less aggressive than omnivorous ones. On the other hand, foods can pose a risk to human health if they contain unusual or unsuspected ingredients. Numerous cases of accidental food poisoning have been described in the scientific and popular literature, in particular the ingestion of poisonous mushrooms or plants harvested by inexpert collectors. Since ancient times, food and water have been used as tools for homicide, both because victims usually have confidence in their meals and because detecting the fatal agent can be difficult. Traditional poisons such as salts of arsenic have often been used in murder, but more recent investigations have hypothesized poisonous plants as the causative agent or identified them analytically. The most recent criminal approach involving foods is to use them to mask illicit substances, facilitating their transport across borders and wide distribution. Food supplements play an important role here, in particular those containing herbal ingredients. The use of food supplements has increased enormously in recent years since consumers believe that natural products are good or right for the body, whereas something of synthetic or industrial origin is bad or wrong. The use of food supplements containing herbal ingredients has become common among athletes even when the scientific rationale is non-existent. The uncontrolled use of food supplements can represent a health risk, particularly when the herbal ingredients have known pharmacological properties. Herbal ingredients are often undetectable by the usual anti-doping tests, which make those with stimulant properties particularly attractive to those seeking performance enhancement without penalty. The main hazards in the use of herbal supplements include effects due to the specific pharmacological properties (agitation, insomnia, tachycardia); the risk of exceeding the appropriate dose to obtain a pronounced enhancing effect; the risk of allergy and intolerances – several products specifically developed for sport activities actually contain proteins from animal and vegetable sources that are listed as major allergens; and finally, the possible presence of banned ingredients (hormones, etc.) that have been added to enhance the desired effects. Food supplements containing plants with known stimulant substances must be regarded as potential health hazards. The use of food supplements has increased enormously in recent years; among the different products present on the market, consumers show a special interest in those containing herbal ingredients.

In the twenty-first century, an ever-growing number of men and women are flocking to the Internet and World Wide Web to make purchases of products and to engage services from different providers. One type of product line that now is offered in abundance on the Internet is that of vitamins and dietary, food, and nutritional supplements. At the present time there are literally thousands of different website venues that cater to people who are interested in purchasing and utilizing vitamins and other nutritional supplements.

Unfortunately, there is also a segment of the Internet market consisting of scams and “flim-flam” artists. There are people who have created less than reputable sites in the vitamin and nutritional supplement business. Naturally, if one is new at seeking these types of products online, it is better to avoid these types of disreputable sites. Consumers may be misled by vendors’ claims that herbal products can treat, prevent, diagnose, or cure specific diseases, despite regulations prohibiting such statements. Physicians should be aware of this widespread and easily accessible information. More effective regulation is required to put this class of therapeutics on the same evidence-based footing as other medicinal products [1].

There are some tips and pointers that should be kept in mind when seeking reputable sites on the Internet that are involved in the vitamin and nutritional supplement trade. First, only visit websites that have been established in business for a reasonable amount of time. Of course, there are websites that deal in these products that crop up all of the time and many of these sites are very good.

However, until you get your feet wet and understand what to look for in regard to legitimate websites that market vitamins and nutritional supplements, you will be better served by relying on those sites that are well established.

Second, as you go about looking for a reliable website from which to make the purchase of vitamins and nutritional supplements, get references from other people. In many ways, referrals and recommendations are the best way to make reasonable and educated decisions about which websites to select when you are in the market for vitamins and nutritional supplements for your use and for use by your family. By educating yourself and by taking the time to research different websites, you will be able to find a reliable and reputable venue through which you can make the purchase of vitamins and nutritional supplements [2].

2 Designer Drugs and Legal Highs

The Internet has put the world at people's fingertips, but in some cases it has also allowed banned or controlled substances to slip within their grasp, British researchers warn. Their study, published online in *Drug Testing and Analysis*, looked at so-called "legal highs," where certain drugs sold online contain ingredients other than those claimed and can be hazardous. These products are quickly becoming big business for manufacturers and suppliers, who market them toward recreational drug users [3].

> "It is clear that consumers are buying products that they think contain specific substances, but that in reality the labels are unreliable indicators of the actual contents," Dr. Mark Baron, of the School of Natural and Applied Sciences at the University of Lincoln in England, said in a news release from the journal's publisher.

Although these "legal highs" are often readily available for purchase on the Internet, they are potentially dangerous for consumers, the study authors pointed out. The investigators found that these drugs, sometimes marketed as bath salts or plant food, commonly contain controlled substances and are being sold illegally. In investigating these drugs, Baron bought an array of pills from UK websites and analyzed their contents. Six out of seven products purchased did not contain the active ingredients advertised. In fact, in five out of seven cases, the products actually contained a controlled substance combined with caffeine. Among them was benzylpiperazine, a stimulant drug that is illegal in the United States and can cause anxiety, increased blood pressure, rapid heart rate, and blurred vision, among other side effects.

Although the United Kingdom and other governments have taken steps to crack down on these "legal highs," suppliers continue to market these drugs, sidestepping current regulations. As a result, Baron cautioned buyers to be wary of any products they buy online.

No guidelines exist as to what is sold and in what purity, and consumers are led to believe that purchased goods are entirely legal. The product name cannot be used as an indication of what it contains as there is variation in the content of the same product name between different Internet sites. The findings should serve as a red flag for consumers, as well as the lawmakers attempting to curb the illegal sale of controlled substances, the study authors noted. “As legislation deals with the current crop of products we can expect to see new products appearing that try to find a route of supplying previously banned substances,” Baron warned.

Many new drugs are produced in apartmentsand basements in large cities. Designer drugs are considered dangerous. They are difficult to detect and virtually unknown at the chemical level. This is a new phenomenon that frightens the authorities of all countries, which are seeing an increase in new pharmaceutical products based on substances that already exist but used for non-therapeutic purposes. Recent years have seen the appearance of a large number of synthetic substances on the Internet, including so-called legal highs. What are “legal highs”? This is huge number of new substances that circumvent legal controls and almost always are purchased on the internet. They are synthetic drugs used for fun, the so-called “party pills.” Sometimes they are called natural drugs to entice consumers who presume they cannot hurt.

For example, there is a whole series of drugs called “spice.” Spice represents herbs adulterated with many synthetic substances more potent than THC and very dangerous. These products may be sniffed, smoked, or inhaled [4].

3 Athletes and Natural Products as Enhancing Substances

Athletes use ergogenic products to face physical and emotional stress in a sport competition, but products need to be conscientiously evaluated in terms of the risk/benefit ratio. All athletes, whether beginners or professionals, must fully understand that the intake of some substances can have severe adverse effects, particularly products obtained in “alternative” markets that are only interested in profit. Continuous monitoring of the products present in these markets is the only effective tool to prevent the distribution of food supplements containing banned ingredients, and the availability of suitable analytical methods is critical if this goal is to be attained.

In fact, the use of food supplements containing herbal ingredients by athletes has become common even though the scientific rationale is often insufficient to support it. It is obvious that the uncontrolled use of food supplements can represent a risk for health, and this is particularly true when the herbal ingredients have known pharmacological effects. Moreover, the abuse of stimulant substances could represent an illicit way to improve performance during competitions, considering that herbal ingredients cannot always be detected in occasion of anti-doping tests. The main reasons to suggest caution in the use of herbal supplements include: (1) the side effects due to the specific pharmacological properties of a specific ingredient (agitation, insomnia, etc.); (2) the risk of exceeding the dose to obtain a certain effect (searching for improvement of performance); (3) allergy and intolerances; (4) the possible presence of illicit ingredients to enhance the effects (iodine, hormones, etc.).

Food supplements, containing plants or herbs with stimulant substances, must be regarded as potential health hazards, as stated in 2003–2004 by the FDA, and applied in Europe, Japan, Australia, and other countries to ban the sales of supplements containing ephedrine alkaloids [5].

The best-known case regarding dietary supplements is that of those containing *Ephedra* derivatives. Substantial evidence of harm emerged in 2003, when a major study reported more than 16,000 adverse events associated with the use of *Ephedra*-containing dietary supplements, including heart palpitations, tremors, and insomnia. The study also found little evidence of the claimed efficacy of *Ephedra* in boosting physical activities and weight loss. In 2004, the FDA banned sales of dietary supplements containing ephedrine alkaloids (*Ephedra* species) because such supplements presented an unreasonable risk of illness or injury for the consumers, and in the US the sale of products containing *Ephedra* alkaloids is now considered criminal unless they have been medically prescribed. Ephedrine is banned as an ingredient of food or food supplements in the European Union. This international ban, based as it is on data illustrating adverse effects of *Ephedra* alkaloids, stimulated a series of activities to monitor food supplements present on the market and developed for sport. There are thousands of products on the market containing herbal ingredients. The quality control of these products is often unsatisfactory and their market is wide and complex, with modern ways of distribution including athletes' training centers and direct delivery from purchase on the Internet.

Some of today's problems are without a solution. For example, in February of 2010, the Fédération Internationale de Football Association (FIFA) expressed concerns that some African herbs might enhance World Cup players' performance, thus providing them with an unfair advantage over other competitors. FIFA officials and team doctors have suggested that the use of some botanicals might go undetected by tests currently used in laboratories accredited by the World Anti-Doping Agency (WADA). They have also mentioned that some plants might produce byproducts that are not currently included on WADA's list of banned substances. FIFA has expressed its concerns to WADA, and WADA has been encouraging transnational programs that focus on traditional medicine usage. The chemistry and pharmacology of many of the functional foods and medicinal plants of the world are not at all well researched, and the net effect of complex polymolecular substances on sports performance is even less understood [6].

An actual problem without a solution (at this moment) are some food or dietary supplements that contain dimethylamylamine often list as rose geranium oil, geranium oil, or geranium stems on the label, putatively extracted from *Pelargonium graveolens* and from other *Pelargonium* species. Some supplement manufacturers claim that this is because rose geranium oil contains a small amount of dimethylamylamine. Dimethylamylamine is a drug originally synthesized by Eli Lilly in 1950s and used as a stimulant nasal decongestant. There is concern that it might be associated with adverse cardiovascular events, similar to other stimulants such as synephrine in bitter orange *Citrus aurantium* var. *amara* and ephedrine alkaloids from *Ephedra* species. Although some supplement manufacturers claim that dimethylamylamine is a natural compound found in geranium oil, this has not been verified by laboratory analysis. Some laboratories have not been able to detect dimethylamylamine in geranium oil. There is concern that some supplement manufacturers may be artificially spiking their supplements with this synthetic drug. The New Zealand government restricted sales of supplements containing dimethylamylamine to prevent the sale to people under 18 years of age due to concerns about safety [7]. Dimethylamylamine was added to the World Anti-Doping Agency's prohibited substances list for 2010, under the name methylhexaneamine [8].

4 Natural Substances for Date Rape

Belladonna, *Atropa belladonna* L., also known as deadly nightshade (Solanaceae family), is one of the most lethal, toxic plants known to man. The berries of the plant (which bear a slight resemblance to blueberries) have a low alkaloid concentration, generally requiring a minimum of three berries to poison a small child. However, the concentration of poison alkaloids (atropine, scopolamine, josciamine) in the leaves is much higher, with a single leaf capable of killing an adult human in a fairly short amount of time. The leaves feel like poison ivy to the touch, having an oily texture that is taken by some as a sign of being toxic. The roots have the highest concentration of alkaloids, though the berries are often seen as the most dangerous, as they can easily be mistaken for any number of non-poisonous berries by untrained eyes. The toxin works on the nervous system once ingested, targeting areas that control involuntary functions of the body, such as breathing and the heart. In essence, belladonna toxin shuts down the basic systems of the body. Scopolamine, also known as hyoscine, is a tropane alkaloid with muscarinic antagonist effects, obtained from plants of the same Solanaceae family (nightshades), such as *Hyoscyamus niger* (henbane) or *Datura stramonium* (jimson weed) and other Datura species. The drug can be highly toxic and should be used in minute doses. For example, in the treatment of motion sickness, the dose, gradually released from a transdermal patch, is only 0.33 mg of scopolamine per day. An overdose can cause delirium, delusions, paralysis, stupor, and death. Scopolamine, in common with the large percentage of anticholinergics that cross the blood-brain barrier such as diphenhydramine, dicyclomine, trihexyphenidyl, and related drugs, is said to produce euphoria at and around therapeutic doses as well as to potentiate this and other effects of morphine, methadone, hydromorphone, oxycodone, and other opioids. It is therefore occasionally seen as a recreational drug.

The use of medical scopolamine (most often in the form of tablets) for euphoria is uncommon but does exist and can be seen in conjunction with opioid use. The euphoria is the result of changes in dopamine and acetylcholine levels and ratios and appears to be related to some part of the chemical structure of the drug and other factors. Another separate group of users prefer dangerously high doses, especially in the form of Datura or Belladonna preparations, for the deliriant and hallucinogenic effects. The hallucinations produced by scopolamine, in common with other potent anticholinergics, are especially real-seeming and create a perception of a new world filled with frenzied, violent energy. The difference in realism of hallucinations caused by anticholinergics such as scopolamine and other hallucinogens such as the phenethylamines or dissociatives like PCP is quite large. Additionally, an overdose of scopolamine can often be fatal, unlike other more commonly used hallucinogens. For these reasons, naturally occurring anticholinergics are rarely used for recreational purposes. The use of scopolamine as a *truth drug* was investigated in the 1950s by various intelligence agencies, including the CIA.

In Colombia a plant admixture containing scopolamine called *Burundanga* has been used shamanically for decades. In recent years the criminal use of scopolamine has become an epidemic. Approximately 50% of emergency room admissions for poisoning in Bogotá have been attributed to scopolamine. Also in Caracas, Venezuela, crime related to *Burundanga* techniques has multiplied in the last years. Targets are easily approached and just with physical contact they administer the drug to the victim. Reports of techniques of administration include wafting the powder to the victim with a puff of air, drugged chewing gum, or even craftily dropping the powder into the collar of a shirt or the front of a woman's low-cut dress. Victims of this crime are often admitted to a hospital in police custody, under the assumption that the patient is experiencing a psychotic episode. A telltale sign is a fever accompanied by a lack of sweat. Scopolamine is used criminally as a date rape drug and as an aid to robbery, the most common act being the clandestine drugging of a victim's drink. It is preferred because it induces retrograde amnesia, or an inability to recall events prior to its administration or during the time of intoxication.

Scopolamine is being investigated for its possible usefulness alone or in conjunction with other drugs in assisting people in breaking the nicotine habit. The mechanism by which it mitigates withdrawal symptoms appears to be at least partially different from that of clonidine, meaning that the two drugs can be used together without duplicating or canceling out the effects of each other. Scopolamine (hyoscine) causes memory impairments to a similar degree as diazepam.

A date rape drug is a drug that can be used to assist in the execution of a sexual assault, such as date rape. Drugs used to facilitate rape may have sedative, hypnotic, dissociative, and/or amnesiac effects, and can be added to a food or drink without the victim's knowledge. The act of adding such substances to drinks is known as "drink spiking." The reasons for drink spiking range from personal amusement or maliciousness to theft or sexual assault.

The illicit uses of herbal ingredients are their inclusion among recreational drugs and, in some cases, among tools in criminal actions, such as date rape. Scopolamine, as such or as a herbal ingredient (*Datura* species), has been used in both illicit activities. In fact, scopolamine crosses the blood-brain barrier producing anticholinergic effects, such as euphoria and hallucinogenic effects; its use between young people is due to visual, auditory, and tactile hallucinations that may last for 24–48 h. The use of scopolamine and other similar alkaloids can also induce a victim to commit a crime they cannot remember committing.

In this context, food and food supplements can represent an “innocuous” carrier of criminal activities, both for international transport and for the administration in a specific crime. An example of this possibility is the case that occurred in 2005, when a herbal ingredient imported from India (*Coleus forskolii*), contaminated by scopolamine was then distributed on the Italian market. The chromatographic analysis of herbal ingredient, as usually performed in the quality control for forskolin, was not capable of easily detecting the presence of scopolamine, permitting its distribution and inclusion in different kinds of products (galenic preparations, food supplements, sport supplements, etc.). Even though this event in Italy was probably an accident, it is clear that the use of such a of vehicle could permit easier international distribution of illicit substances and a possible new way to criminally administer psychotic drugs [9].

5 Plant Toxins: Gender-Selective

Differences in exposure, anatomy, physiology, biochemistry, and behavior between males and females are a dominant theme in biology, transcending the plant and animal kingdoms. Information regarding gender-based differences in response to phytochemicals in both humans and animals are very important. Gender should be identified not only as a critical factor in human and animal responses to exogenous agents, but gender may be the most important factor regulating mammalian development. Gender-related differences and the dynamics of gender-based growth and development over the entire life cycle are topics of concerm. The potential interactions of dietary supplements and other exogenous agents that can act as drugs or modulate the potential effects of drugs differently in men, women, and developing children of both sexes must be taken into consideration. To this end, the health benefits of genistein or soy and the effects of dietary agents containing these plants mainly effect women.

Clivorine, a pyrrolizidine alkaloid (PA) from *Ligularia hodgsonii* Hook has been reported to cause hepatotoxicity and carcinogenicity in rodents and a positive mutagenic response in the Ames test in the presence of rat liver homogenates, suggesting the importance of hepatic metabolic activation in its intoxication. The toxicity of clivorine was revealed to be caused by cytochrome P450 mediated biotransformation to generate a chemically reactive “pyrrolic ester” (e.g., dehydroclivorine), which can further react with vital cellular macromolecules such as proteins and DNA to form bound pyrroles or DNA cross-linking, leading to toxicities. Female rats are reported to be less susceptible to clivorine intoxication than male rats. However, the biochemical mechanism causing such gender difference is largely unknown. The severity of PA intoxication depends upon an overall balance between the metabolic activation and detoxification pathways, which vary with enzyme systems and species. On the other hand, any factors, such as enzyme induction and/or inhibition caused by diets, dietary supplements, drug-drug and herb-drug interactions, may alter the metabolic balance in the body and thus have significant impacts on PA intoxication to human health.

6 Natural Toxins

Herbs, herbal products, food additives, and other dietary supplements derived from plants are widely consumed in many countries. The literature on intoxications from such behavior is increasing. Many and different are the factors predisposing to intoxication from the use of herbs, with examples drawn largely from pyrrolizidine and diterpenoid alkaloid-containing plants. Poisonings occur because of the misidentification of a plant, or the unknown or ignored toxicity of a correctly identified plant, or the poisoning is voluntary. A preliminary distinction must be drawn between "voluntary" and "involuntary" intoxication. If a person had an unexpected reaction to medicine or unwittingly consumed intoxicants, the accused is said to have been "involuntarily" intoxicated; such an accused could tender intoxication evidence to demonstrate that they lacked the fault for a crime, or that they could not have voluntarily performed the criminal act and so could not be liable. Factors contributing to problems include the difficulties of identifying chopped, processed herbs or plant mixtures, persistent use of a toxic plant, variability in the toxic constituents of a plant, problems of nomenclature, adulteration of a plant, and the difficulty in establishing the chronic toxic potential of a plant. Certain users of herbs are at high risk of intoxication. These include chronic users, those consuming large amounts or a great variety, the very young, the elderly, the sick, the malnourished or undernourished, and those on long-term medication.

Everything from herbal tea to natural muscle relaxants is touted as the new and better alternatives to more conventional medication. Everyone seems to have fallen into this new craze, even if most people don't quite understand what they're getting themselves into. However, nature can provide humanity with much more than natural muscle relaxants and stimulants, as anyone who has had experience with plant and animal toxins can likely attest to. Spiders, scorpions, and a variety of other animals all carry their own natural toxins, often with effects that rival the death rate and potency of even the most powerful manmade neurotoxins. The plant world also has an abundance of toxins, some of which are well known, some have played roles in history, and others have been adapted to serve medicinal roles in modern herbal lore, usually as sedatives and muscle relaxants.

One of the more famous herbs with potentially lethal toxic properties would be hemlock (*Conium maculatum* L.). Historically, doses of hemlock were used as a means of executing criminals in various ancient Greek city-states, with Socrates being the most notable victim of the practice. Plato, one of Socrates' contemporaries, wrote a detailed account of the effects that the hemlock serum had on the ancient philosopher, which were seen as being consistent with the effects of a suitable quantity of hemlock used as a poison. The herb has a powerful effect and, in small doses with low concentration, can serve as a substitute for most muscle relaxants. However, in the right mixture or in high enough concentrated dose, it makes for a very deadly drug. Lethal hemlock mixtures are relatively easy to prepare, provided one has the enough quantities of the said plant.

Curare is also known as a deadly plant, but can also act as a muscle relaxant. In high enough doses, curare can effectively paralyze the entire body.

The concentrations of poison in any given combination can vary: the concentration in the various organs of the plant can differ from specimen to specimen. Curare is made up of compounds that are not digestible by the body, however, so anyone who ingests the toxin is not going to feel the effects. The only way to be poisoned by curare is to have the toxin be mixed with the blood directly, either through an injection or through an open wound. Curare is usually used as a hunting poison in South America, both because it does not render meat toxic and because it is a quick, effective poison.

Other common plants associated with poisoning include oleander and foxglove. Both contain glucosides that exert a similar effect to *Digitalis purpurea* or *Digitalis lanata* and have been used in suicides for centuries. Ingestion of plant toxins may not only be for recreational purposes, as cases have been described where poisonings have occurred from toxins in homemade toothpaste, in wild vegetables, in herbal medicines, and in children experimenting.

A retrospective analysis of the plant poisonings in Northern Italy over a period of 11 years (1995–2006) was performed by the Poison Control Centre of Milan Niguarda Hospital. The registered cases of plant exposures were 10,959, about 1,000 per year. The more serious cases usually occurred in adolescents or adults who either mistook a plant as edible or deliberately ingested a toxic plant. Severe intoxications with plant materials occurred in adults with aconite (30 cases), meadow saffron (8 cases), and hemlock (21 cases) ingestions, some of which had lethal consequences. Atropa (108 cases), datura (93 cases), cherry laurel (133 cases), laurel (93 cases), autumn mandrake (41 cases), elder (127 cases), and mistletoe (238 cases) were the cause of severe reactions. The incidence of plant poisoning varies a great deal depending on local traditions, lifestyle, nutritional factors, climate, and the presence of wild plants. Notwithstanding plant species containing psychoactive toxins, the ingestion of a toxic plant is almost invariably accidental. The true problem is that many people currently believe that all natural substances are inherently safe and useful for human health, because they are not “true drugs.” Because of this, it is possible to observe an increasing number of poisoning cases, starting from the mid-1990s to the present time, thanks to the wide Internet diffusion of misleading information. Comparable results are reported in the Annual Report of the American Association of Poison Control Centers’ National Poison Data System (NPDS).

7 Plants as Crime-Solvers: Forensic Botany

Today, many criminal investigators are resorting to techniques used in the scientific world to accumulate evidence against the accused. The use of science to answer questions relevant to the legal system is termed *forensics*, and has branched into the many specialties seen in the scientific world. These include anthropology, ballistics, bloodstain analysis, botany, DNA fingerprinting, economic crime, entomology, and the list goes on. The area of forensic botany is a relatively new and untouched specialty. The first criminal investigation that included the analysis of plant material wasn't until 1935 and, today, few investigators rely on the science of plant material, although it is becoming more common. Forensic botanists examine plants and plant matter to determine their species and origin. In some cases, suspects may leave behind plant parts, spores, or seeds that had adhered to their clothing. If the plant species in question is found only in limited areas, its presence at the crime scene may indicate where suspects have been or where they live.

8 Natural Toxins and Bioterrorism

Toxin weapons are primarily illness-inducing chemicals formed from living creatures, such as bacteria, fungi, plants, and animals. Toxins range from disabling to acutely toxic. The most deadly compound currently known, botulinum toxin, is a bacterial toxin. Toxins are more potent than chemical weapons, requiring less material to produce equivalent casualties, but they are not self-reproducing, so more material is required than for a biological weapon. Symptoms from toxin exposure typically occur on a timescale intermediate between chemical and biological weapons, generally appearing over the course of several hours. Chemical, biological, and toxin weapons also differ in their medical treatment and the availability of effective prophylaxis. Chemical weapons, with their quick acting effects, must be treated as promptly as possible. Because of the large range of potential effects caused by chemical weapons, there is no universal treatment for chemical weapon exposure [10]. Exposure to nerve agents can be directly treated with medication to prevent or reduce symptoms. Exposure to vesicants, such as mustard gas, better known as Yprite, is generally untreatable; most people exposed will exhibit the agent's effects. The mustard gas is an irritant compound derived from the dried ripe seed of *Brassica (Sinapis) alba*, *B. nigra*, or *B. juncea*, and contains toxic allyl isothiocyanate in nontoxic glycoside form, though the plant also contains myrosinase, an enzyme that converts the glycoside into the toxic form. It was one of the most lethal of all the poisonous chemicals used during the World War I. It took 12 h to take effect. Yprite was so powerful that only small amounts had to be added to high-explosive shells to be effective. Once in the soil, mustard gas remained active for several weeks.

Ricin toxin is found in the beans of the castor plant, *Ricinus communis.* It is one of the most lethal and easily produced plant toxins. The toxin is present in the entire plant but is concentrated in its seeds. Ricin can be in the form of a powder, mist, or pellet, or dissolved in water or weak acid. It is a very stable substance and is not affected by extremes in temperature. Castor beans are processed throughout the world to make castor oil. Ricin is part of the waste "mash" produced when castor oil is made. Ricin irreversibly blocks protein synthesis. Ricin has some potential medical uses, such as bone marrow transplants and cancer treatment (to kill cancer cells).

Abrin and ricin are natural toxic protein toxins isolated from plant seeds, that is, they are phytotoxins. Both proteins are composed of two peptide chains, signified as A-chain and B-chain, which are linked by a disulphide bond. Both toxins have large scale molecular similarity, and the A-chains of abrin and ricin have a 102 conserved amino acid homology; it is possible to create hybrid toxins (in a reciprocal manner) between the A- and the B-chains of abrin and ricin. Also, the mechanism of their toxic action is the same. The A-chain inhibits protein synthesis, whereas the B-chain binds to cell surface receptors containing terminal galactose and acts as an immunotoxin. The A-chain contains the toxic activity and the B-chain gives the toxin a cell recognition and binding function to facilitate transport across the cell membrane. The A-chain is not active until it is internalized by the cell, where it halts protein synthesis.

Three routes of ricin exposure are known to exist for humans and animals: inhalation, natural infection by ingestion, and injection. Depending on the route of exposure (such as injection), as little as 500 μg of ricin could be enough to kill an adult. A 500-μg dose of ricin would be about the size of the head of a pin. A much greater amount would be required to kill a human being by either the inhalation or ingestion routes. Toxins are not usually transmitted person-to-person or animal-to-animal. Secondary aerosolization is not thought to be of concern.

The incubation period for ricin is dependent on the route of transmission. If the toxin is inhaled, the incubation is about 8 h. The incubation period for ingestion is a few hours to days. If ricin is injected under the skin, the incubation period could be immediate to several hours, depending on the location of injection and the dose of toxin injected.

The initial symptoms associated with inhalation of ricin toxin are cough, weakness, fever, nausea, muscle aches, chest pain, and cyanosis. Pulmonary edema occurs about 18–24 h after inhalation, and severe respiratory distress and death from hypoxemia ensues at 36–72 h.

The least toxic form of poisoning is by ingestion. Symptoms are also less severe if the seeds are swallowed whole, as they have a thick coating that limits absorption of the toxin. Less than a few hours after ingestion, severe gastrointestinal signs occur, including nausea, vomiting, intestinal cramps and headache. These signs are followed by diarrhea and hemorrhage from the anus and dilation of the pupils. This generally leads to vascular collapse and death in 3 days or more. The seeds of the castor bean are very attractive, which is why they are popular in certain costume jewelry. Unfortunately, they also look good enough to eat, which is why small children are the most common victims of castor poisoning.

There are no specific data on injection of ricin into humans, and likely human symptoms are based on those of animal models. Initially it would be expected that a person would experience local pain and necrosis at the site of injection, followed by systemic signs. Death would likely ensue at 3 or more days after exposure.

The diagnosis of ricin toxicosis is often based on clinical symptoms. Detection of the toxin in serum or respiratory secretions can be done by ELISA and immunohistochemistry on infected tissues. Ricin is very immunogenic, thus the toxin can be detected via serology.

There is no treatment or vaccine currently available for ricin poisoning. Supportive care is recommended based on the route of exposure, and includes respiratory support for inhalational exposure, gastric washing (cleaning), and cathartics to remove the toxin from the GI tract if ingestion has occurred.

Ricin can affect all domestic animals. Clinical signs were observed in experimental studies in laboratory animals. Inhalation of ricin would likely cause pulmonary edema, respiratory distress, and death within 36–72 h. Ingestion of ricin is the most common form of naturally occurring infection. If the seeds are eaten whole the severity of signs is decreased and seeds may pass with no ill consequences occurring. Severe vomiting and diarrhea are often seen, with depression, weakness and shortness of breath. Trembling and incoordination accompanied by sweating or shivering can be seen. The diagnosis and treatment of animals infected with ricin are similar to that of humans with ricin toxicosis, which is based on the clinical signs. Research is being conducted on vaccines that are immunogenic and can offer protection against aerosolized ricin.

Promising research is being conducted in animals for ricin antisera and vaccination. If exposure is suspected, decontamination of the area or exposed skin should be done with soap and water or with a 0.1% sodium hypochlorite bleach solution. A protective mask is effective against aerosol exposure. Standard safety precautions should be followed by all health care workers if exposure is suspected. Because of ricin's extreme ease of production, wide availability, and the fact that it is one of the most potent plant toxins known, it is considered to be a potential agent that could be used for bioterrorism.

9 Conclusions

The findings from this survey indicate that botanical food supplements or dietary supplements can be marketed for recreational purposes and as alternatives to illicit drugs. Some products presented in the web can be likened to marijuana or Ecstasy, and most claimed to have hallucinogenic or stimulating properties. Products containing stimulant compounds, performance-enhancing drugs, herbal drugs of abuse, and natural alternatives to Viagra were the most commonly encountered. Physicians, chemists, and healthcare professionals should be familiar with these products so that they are better able to identify products, ingredients, and causes of toxicity in persons utilizing food supplements for recreational purposes.

Abstract

The biosynthesis, occurrence, and biological activities of piperidine alkaloids arising from lysine have been studied (*Punica granatum*, *Piper* species, and *Lobelia inflata*). The isolation process, chromatographic purification/analysis, and structure elucidation of the significant alkaloids are discussed.

Common characteristics in the biosynthesis of these alkaloids, that they are elaborated from the lysine derived Δ^1-piperideine, coupling either to an aliphatic- (from acetyl-CoA precursor, e.g., pelletierine and co-alkaloids), or an aromatic part (from cinnamoyl-CoA precursor, e.g., piperine and other amides; lobeline, lobelanine and related alkaloids).

The biological activities of piperidine alkaloids are summarized as follows:

– The pomegranate alkaloids, like isopelletierine, have anthelminthic activity and were used primarily as a taenicide.

- Due to the pungency of the fruits of *Piper* species, among them the most frequently used black pepper, is one of the most ancient spices and also known as a preservative food additive. Piperine, the chief constituent, increases the bioavailability of numerous therapeutical drugs (e.g., propranolol, theophylline, curcumine, β-carotene) perhaps by increasing intestinal absorption or by exerting an antioxidant effect during the first pass through the liver. The piperine can reverse MDR by multiple mechanisms and may be a promising lead compound for future studies.
- Lobelin, the chief alkaloid of *Lobelia inflata*, is a respiratory stimulant, which enhances and accelerates the respiratory movements. It has been used in asthma, gas poisoning, and narcotic poisoning. Lobeline is currently the subject of renewed interest for the treatment of drug abuse and neurological disorders, like Alzheimer's or Parkinson's disease, which pose an important public health problem in industrial countries. Lobeline is a competitive nicotinic receptor antagonist and is still commercialized in antismoking preparations. Interest in Lobelia alkaloids, and in particular the most active (-)-lobeline, has increased in recent years due to their activity on the central nervous system (CNS) and the multidrug-resistance (MDR).

1 Introduction

The piperidine, quinolizidine, indolizidine alkaloids derived from lysine are belonging to so-called "true alkaloids" because their nitrogen atoms originate from an amino acid, and in general, the carbon skeleton of the particular amino acid precursor is also largely retained intact in the alkaloid structure. Relatively few amino acid precursors are actually involved in alkaloid biosynthesis, the principal ones being also lysine [1].

While for developing of simple piperidine alkaloids, e.g., pelletierine (*Punica granatum*), piperine (*Piper nigr*um et *longum*), and lobeline (*Lobelia inflata*), only one molecule of lysine is necessary, for quinolizidine alkaloids – e.g., lupinine (*Lupinus luteus*), sparteine of antiarrhythmic activity (*Sarothamnus scoparius*), and cytisine of respiratory stimulant effect (*Laburnum species*) – two molecules of lysines are indispensable. It was also proved that lycopodine (*Lycopodium tristachyum*, clubmoss) of quinolizidine structure has no polyketide origin, but it is a modified dimer of pelletierine, which, in turn, is derivable from lysine and acetate.

For completeness it could be mentioned that indolizidine alkaloids, e.g., castanospermine (*Castanospermum australe*) derived from pipecolic acid which is also a lysine derivate. Castanospermine, as a polyhydroxylated indolizidine alkaloid, displayed activity against the AIDS virus HIV, by its ability to inhibit glycosidase enzymes involved in glycoprotein biosynthesis.

Lysine has also a role in the biosynthesis of Nicotiana alkaloids, e.g., anabasine, in which beside nicotinic acid, the precursor of pyridine ring, lysine formed the piperidine core.

At the same time, there are alkaloids of piperidine skeleton which are derived from acetic acid or nicotinic acid pathways, e.g., coniine (*Conium maculatum*) or arecoline (*Areca catechu*) and anatabine (*Nicotiana tabacum, Lobelia inflata*) [1].

In this chapter, we intensively studied the Punica, Piper, and Lobelia piperidine alkaloids. These plants and their main alkaloids are undoubtedly known and used in therapy for ages, but at present, numerous scientific results were also born on their biological activities and pharmacological and clinical tests; further, new alkaloids were isolated and semisynthetic analogues prepared, which could be important in the modern phytotherapy.

2 Piperidine Alkaloids Derived from Lysine

L-lysine is α- ε-diaminocarbon acid, the homologue of L-ornithine, contains with one methylene group more than that.

While L-ornithine is the precursor of pyrrolidines, L-lysine is that of piperidine alkaloids (Fig. 11.1). Lysine is formed from aspartic acid, one of the members of Krebs cycle (Fig. 11.2). From lysine, the carboxyl group is lost; the ε-amino is retained in the ring. Lysine thus supplies C_5N-building block for alkaloids (Fig. 11.3) [1].

2.1 Punica Alkaloids

2.1.1 Biosynthesis of Pelletierine and its Co-alkaloids

The biosynthesis starts from Δ^1-piperideine-derived lysine. From lysine by decarboxylation cadaverine then 5-aminopentanal by oxidative deamination and finally Δ^1-piperideine are developed respectively (Fig. 11.4). To Δ^1-piperideine an acetoacetyl-CoA is connected providing an intermediate. From it, by hydrolysis and decarboxylation, pelletierine is formed, then *N*-methylpelletierin by methylation. This biosynthetic pathway was supported by C^{13}-NMR spectroscopic investigation already in 1999 [2]. *N*-methylpelletierine gave pseudopelletierine (homatropine) by *intramolecular* Mannich reaction. In the present of another Δ^1-piperideine molecule, pelletierine could give also anaferine by *intermolecular* Mannich reaction, but anaferine is firstly the characteristic alkaloid of *Withania somnifera* (Solanaceae) [1]. We have to mention that *N*-methylpelletierine, pseudopelletierine, and anaferine are the homologues of the pyrrolidine alkaloids derived from ornithine as the hygrine, tropinone, and cuscohygrine.

Fig. 11.1 Pyrrolidine and piperidine alkaloids derived from ornithine and lysine

The barks contain about 0.5–0.9 % of total alkaloids, which are volatile liquid. The alkaloids are bounded to tannins, in about 22 % [3].

In the barks of *Punica granatum which* originated from the region of Yugoslavia, Neuhofer et al. [4] found also other piperidine alkaloids beside pelletierine, *N*-methylpelletierine, and pseudopelletierine, namely, norpseudopelletierine, sedridine, and further hydroxypropyl and hydroxypropenyl Δ^1-piperideines (Fig. 11.5). *N*-methylsedridine and *N*-methylpelletierine were also detected in *Picea breweriana* [5]. For identifying of alkaloids, they use capillary GLC-MS method. It is interesting that pyrrolidine alkaloids – hygrine and norhygrine – were also detected by them but only in the root bark.

In 1963, Beyerman and Maat [6] already described the synthesis and absolute configuration of Tanret's (-)-pelletierine. The synthesis is described of (-)-pelletierine picrate as identical with *Tanret's* pelletierine picrate from *Punica granatum* L. and its antipode by oxidation, respectively, of (-)- and of (+)-sedridine. The sedridines are alkaloids with known absolute configuration of the piperidine asymmetric carbon atom. From this follows the D_S-configuration of (-)-pelletierine.

2.1.2 Occurrence of Punica Alkaloids: *Punica granatum* L. (Pomegranate)

The pomegranate (*Punica granatum* L., Punicaceae) is a shrub widespread in North Africa and West Asia but it is cultivated in South Europe, region of the Mediterranean Sea. Its flowers, which have five to seven bright red petals, and its

fruit – a rounded corticos berry, with the teeth from the calix remaining on top – make it easy to identify. The fruit (Fig. 11.6) pulp is eatable; it is the starting material for authentic grenadine syrup [7]. The stem and root barks and the fruit rind and seeds all are found in medicinal use. Both barks are used and occur in curved or channeled pieces about 5–10 cm long and 1–3 cm wide. The outer surface of the stem bark shows longitudinal corky furrows, a few shallow depressions, and bark apothecia of lichens, while that of the root bark shows depressions where the outer layers have exfoliated. The barks are smooth and yellowish on their inner surfaces and break with a short granular fracture.

2.1.3 Biological Activity and Therapeutical Use of Punica Alkaloids

The *root bark* was already recommended in the Ebers Papyrus and later in more Pharmacopoeias (e.g., pelletierine tannate in BP 1948) to treat worm infestations and was used as an anthelmintic, primarily against tapeworm, until the first half of the twentieth century. The greatest anthelmintic activity of Punica extracts was chiefly due to isopelletierine [8]. Our daily harmful effects due to the fraction absorbed in the intestine have led to full abandonment of the drug and also its alkaloids [7].

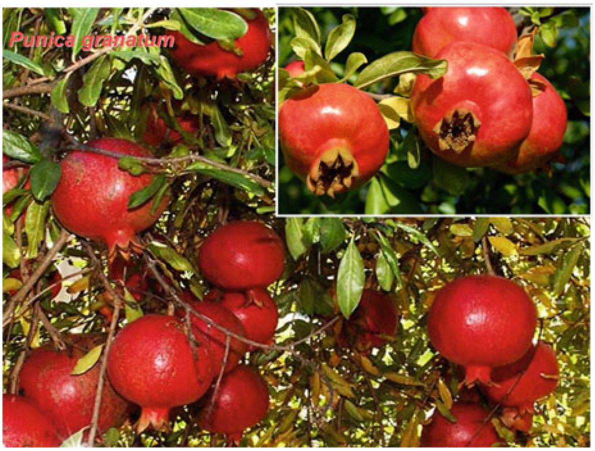

Fig. 11.6 *Punica granatum* L.

The *dried pericarp* of the fruit occurs in thin, curved pieces about 1,5 mm thick, some of which bear the remains of the woody calyx or a scar left by the stalk. The outer surface is brownish-yellow or reddish and the inner surfaces bear impressions left by the seeds. The height tannin content (28 %) affords its use as an astringent in the treatment of diarrhea.

The *seeds* have been studied for their glyceride content, and the validity of a seed extract for use in the treatment of diarrhea, as practiced in traditional Indian and Bangladesh medicine, has been experimentally verified [3].

2.2 Piper Alkaloids

2.2.1 Biosynthesis of Piperidine Amide: Piperine

Piperine consists from a piperidine part (tertiary amide) and a phenolic part: the piperic acid. During the biosynthesis, the piperidine formed from Δ^1-piperideine is connected to piperic acid. Piperic acid is developed from methylenedioxy cinnamoyl-CoA (Fig. 11.7), [1].

2.2.2 Occurrence of Pepper: *Piper nigrum* L. (Pepper)

Pepper (*Piper nigrum* L., Piperaceae) is one of the most ancient spices. Used since time immemorial in India, it was known in the Greece and Rome of antiquity. It is the fruit of *Piper nigrum*, a perennial plant originally from the south-west of India (Malabar Coast) and now cultivated in India (Kerala), Indonesia, Malaysia (Sarawak), Sri Lanka, and also South America (Brazil) (Fig. 11.8).

The pepper vines have a ligneous voluble stem affixed to their support by secondary branches. The leaves have an oval acute blade and are alternate.

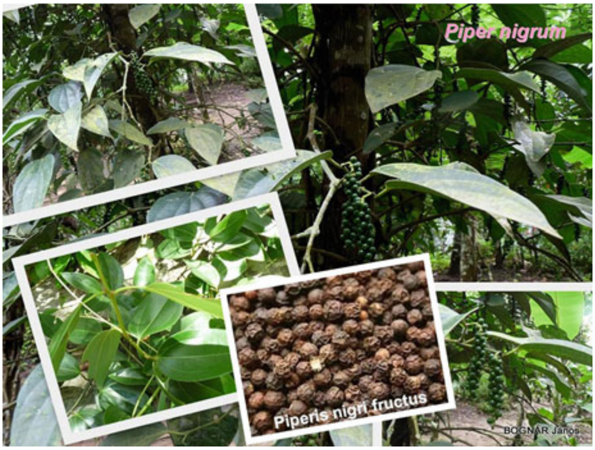

Fig. 11.8 *Piper nigrum* L.

The sessile flowers have no perianth and are grouped by 20–30 units into dangling spikes. The fruit is a berry of 4–8 mm in diameter, which turns from green to red as it ripens.

The different kinds of pepper (fruit of plant) are well recognized:

– Green pepper consists of whole fresh berries. Generally conserved in acidic aqueous solution (or frozen, or pasteurized), it is highly aromatic.
– White pepper consists of the fruits collected at full maturity. After being soaked in water for several days, the fruits' pericarp and the external layers of mesocarp are removed and the fruits are dried.
– Black pepper is prepared from the spikes collected immediately after the first berries turn red. After drying, the fruits are separated from the stalks. The dried fruits are spherical (3–6 mm) and particularly hard. Their surface is brownish-black and extremely wrinkled [7].

2.2.3 Ingredients of Pepper

The peppery odor is due to 1–3.5 % of an essential oil rich in terpenoid hydrocarbons, firstly β-caryophyllene sesquiterpene (22–27 %), then numerous monoterpenes: limonene (21–22 %), sabinene (8.5–17.5 %) β-pinene (9–11 %), α-pinene (5–6 %), myrcene (2.2–2.3 %), p-cymene (0–0.2 %), and oxygenated constituents (3–5 %). Recently, about 40 compounds were identified in oil [3].

The pungency of pepper is ascribed to piperidine amides (5–10 %).

The chief constituent is piperine (amide of piperidine and piperic acid) and its geometric isomer chavicine (amide of piperidine and chavicic acid). The other piperidine amides are piperanine (instead of two double bond, only one is in the side chain) and piperettine, a piperine homologue (the side is longer with two methylene group); further, a pyrrolidine amide, the piperylline, is also findable in piper (Fig. 11.9). In *Piper longum* beside piperidine amides, also not amide alkaloids, as the cepharadine A and B of 4,5-dioxoaporphins skeleton were found [9].

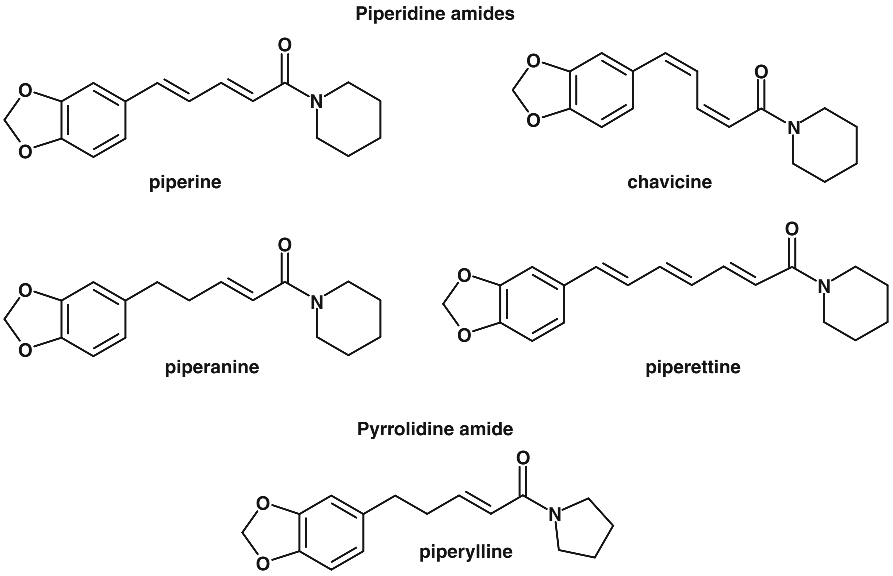

Fig. 11.9 Characteristic alkaloids of pepper

2.2.4 Isolation and Structure Elucidation of Piperine from *Piper nigrum, P. longum*, and *P. officinarum*

Piperine was firstly isolated in 1819 from *P. nigrum*, but it was later found in *P. longum* (long pepper) and Ashanti pepper, the fruits of *P. guineense* [3].

Regarding the therapeutical (digestive, anodyne) and antioxidant antibacterial activities of piperidine amides – and that the piperine and piperic acid could be used as natural agents in both food preservation and human health – more isolation methods were used for them from *Piper* species [10]. From *P. longum* fruits, Shihua et al. [11] carried out the preparative isolation and purification of amides by upright countercurrent chromatography (CCC) and reversed-phase liquid chromatography (RPLC) (Fig. 11.10). They isolated nine target amides with over 95 % purity (Fig. 11.11). Structures of all compounds were identified by electrospray ionization MS, electron impact ionization MS, and one- and two-dimensional NMR spectra.

Kanaki et al. [12] worked out a rapid, economical method for isolation of piperine from *Piper nigrum* L. The method involves extraction of the fruit powder with glacial acetic acid from which piperine was partitioned into chloroform and subsequently crystallized.

Pedalkar et al. [13] extracted piperine from *P. nigrum* by aqueous solutions of surfactant plus hydrotrope mixtures. They established that the combination of butyl benzene sulfonate as hydrotrope and sodium dodecyl sulfate (SDS) gave increased percentage extraction of piperine as compared to the hydrotrope alone. The piperine crystallized from aqueous solutions of surfactants and hydrotrope also showed cleaner structures with sharp edges, unlike the particles crystallized from organic solvents. Chen et al. [14] studied a preparative high-performance centrifugal

partition chromatography (HPCPC) method for isolation and purification of the bioactive component piperine directly from the ethanol extract of *Piper nigrum* L. was successfully established by using n-hexane-ethyl acetate-methanol-water as the two-phase solvent system. The upper phase of n-hexane-ethyl acetate-methanol-water (6:5:6:5 *v*/*v*) was used as the stationary phase of CPC. Under the optimum

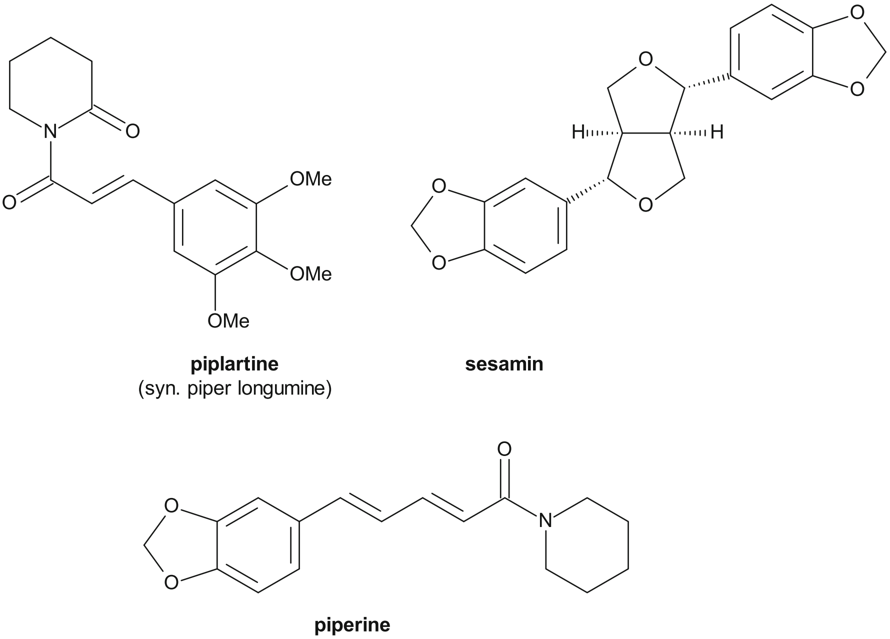

Fig. 11.12 Isolated compounds from *Piper officinarum*

conditions, 40 mg of piperine at 98.5 % purity, as determined by HPLC, was yielded from 300 mg of the crude extract in a single CPC separation. The peak fraction of CPC was identified by (1) H NMR and (13) C NMR.

Mrutyunjaga and Venkateswartu [15], from the dichlormethanic root extract of *Piper officinarum*, isolated three compounds after column chromatographic fractionation. Of the three compounds, piplartine and piperine were alkaloids and sesamin a lignin derivate (Fig. 11.12).

In the last decades, several reports were found about the potential of piperine to increase the bioavailability of drugs in humans. For example, Bano et al. [16] reported an increase in oral bioavailability of propranolol and theophylline by piperine in healthy volunteers. Shoba et al. [17] showed that piperine increases oral bioavailability of curcumin (*Curcuma longa*) also in rats. Increased serum β-carotene levels by piperine were also reported by Badmaev et al. [18].

In an attempt to further study, Bajad et al. [19] searched the differences of urinary metabolites of piperine – as omnipresent food component – between human and animal (rat) organisms. They detected a new major urinary metabolite in rat urine and plasma using HPLC. The metabolite was partially purified using reversed-phase column chromatography on Sephadex-LH 20 and characterized as 5-(3,4-methylenedioxyphenyl)-2 *E*, 4 *E*-pentadienoic acid-*N*-(3-yl propionic acid)-amide with the help of LC/NMR/positive ESI-MS studies (Figs. 11.13–11.15]. Complete mass fragmentation pattern could be assigned with MS/MS studies (Fig. 11.16).

2.2.5 Pharmacological and Therapeutical Activities of Piperine and its Derivates

Lee et al. [20] established that piperine and its related compounds, methylpiperate, (piperic acid methyl ester) guineensine, and piperlonguminine (Fig. 11.11), showed significant MAO inhibitory activities. Piperlonguminine is a novel therapeutic agent for Alzheimer's disease. The mix of piperlonguminine and dihydropiperlonguminine significantly inhibit the expression of amyloid precursor protein (APP). The decreased production of the peptide amyloid β (Aβ) in SK-N-SH cells is a beneficial effect to Alzheimer's disease [21].

During the newest researches, the inhibition of lipopolysaccharide (LPS)-induced inflammatory responses by piperine was intensively studied. The results suggested that piperine inhibited LPS-induced endotoxin shock through inhibition of type 1 IFN (interferon) production [22].

Piperine is known to modify the biotransformation of drugs. Piperine-treated rat liver microsomes demonstrated a tendency to enhance [3H]-aflatoxin B1 binding to calf thymus DNA in vivo. The effect of piperine on aflatoxin B1 metabolism thus closely resembles the mode of action of SKF 525-A on biotransformation of foreign compounds [23].

Pradeep and Kuttan [24] established that piperine is a potent inhibitor of nuclear factor – κB (NF- κB), c-Fos, CREB, ATF-2, and proinflammatory cytokine gene expression in B16F-10 melanoma cells.

The antidepressant-like effects of piperine was proved by pharmacological test in chronic mild stress-treated mice [25].

Piperine significantly enhanced accumulation and decreased the efflux of ethidium bromide in *Mycobacterium smegmatis*, which suggests that it has the ability to inhibit mycobacterial efflux pumps [26].

It was also established that piperine has paralyze effect for CNS (central neurosystem) and has also spasmolytic activity. Its semisynthetic compounds are used as antiepilepsy remedy in China.

Recently was studied the multidrug-resistant (MDR) activity of piperine and established it can reverse MDR by multiple mechanisms.

Summary: Black pepper is used not only in human dietaries but also for a variety of other purposes such as medicinal, as a preservative, and in perfumery. Many physiological effects of black pepper, its extracts, or its major active principle, piperine, have been reported in recent decades. Dietary piperine, by favorably stimulating the digestive enzymes of pancreas, enhances the digestive capacity and significantly reduces the gastrointestinal food transit time. Piperine has been demonstrated in in vitro studies to protect against oxidative damage by inhibiting or quenching free radicals and reactive oxygen species. Black pepper or piperine treatment has also been evidenced to lower lipid peroxidation in vivo and beneficially influence cellular thiol status, antioxidant molecules, and antioxidant enzymes in a number of experimental situations of oxidative stress. The most far-reaching attribute of piperine has been its inhibitory influence on enzymatic drug biotransforming reactions in the liver. It strongly inhibits hepatic and intestinal aryl hydrocarbon hydroxylase and UDP-glucuronyl transferase. Piperine has been documented to enhance the bioavailability of a number of therapeutic drugs as well as phytochemicals by this very property. Piperine's bioavailability-enhancing property is also partly attributed to increased absorption as a result of its effect on the ultrastructure of intestinal brush border. Although initially, there were a few controversial reports regarding its safety as a food additive, such evidence has been questionable, and later studies have established the safety of black pepper or its active principle, piperine, in several animal studies. Piperine, while it is non-genotoxic, has in fact been found to possess antimutagenic and antitumor influences [27].

2.3 Lobelia Alkaloids

The piperidine ring – the core of Lobelia alkaloids – is derived generally from lysine; but their biosynthetic pathways are depentent on the type (phenolic or aliphatic) of side chains, although the piperidine core seldom could be derived from nicotinic acid (similarly to pyridine alkaloids), e.g., in case of anatabine.

2.3.1 Biosynthetic Pathways of Lobelia Alkaloids

In biosynthesis of Lobelia alkaloids, the two basic compounds (direct precursors) are Δ^1-piperideine and benzoylacetic acid. Δ^1-piperidine is derived from lysine via two pathways: direct from the cadaverine or the 5-aminopentanal, a cadaverine derivate (Fig. 11.17).

The possible pathway for the biosynthesis of benzoylacetic acid as building block of phenolic side chain is the following (Fig. 11.18). Phenylalanine is converted into trans-Cinnamic acid by the enzyme phenylalanine ammonia-lyase (PAL). Hydroxylation of Cinnamic acid gave 3-hydroxy-3-phenylpropanoic acid which is transformed to benzoylacetic acid by β-oxidation (chain degradation).

Biosynthesis of Lobelia Alkaloids of Phenolic Side Chains

Δ^1-piperideine and benzoylacetic acid is condensated by Mannich reaction, hydrolysis, and decarboxylation. Intermediate-1 (phenacylpiperidine) furnished sedamin alkaloid by reduction, lobinaline by dimerization, and intermediate-2 by oxidation. From the latter, compound norlobenanine developed with another molecule of benzoylacetic acid by Mannich reaction, hydrolysis, and decarboxylation too. From norlobelanine, lobelanine was formed by methylation, and from it lobeline by reduction (Fig. 11.19), [1, 28].

Biosynthesis of Lobelia Alkaloids of Aliphatic Side Chains

The aliphatic side chains of Lobelia alkaloids derived from acetate. The 3-oxohexanoic acid formed from three units of acetate reacted with Δ^1-piperideine to yield intermediate-1 and its imine, in which subsequent condensation of another molecule of 3-oxohexanoic acid generated the dipenthyldione derivate. Demethylation of the side chains, then *N*-methylation, and reduction of the carbonyl functions provided 8,10-diethyllobelidiol (Fig. 11.20).

Similarly is the biosynthesis of 8-methyl-10-ethyllobelidiol, but one of its side chain is formed from 3-oxobutanoic acid instead of 3-oxohexanoic acid. For biosynthesis of 3-oxobutanoic acid, two acetate units are enough [28].

Biosynthesis of Lobelia Alkaloids with Core of Δ^3-Dehydropiperidine

The biosynthetic pathways of Lobelia alkaloids in which the core is Δ^3-dehydropiperidine (tetrahydropyridine) ring instead of piperidine have not been studied, except of the anatabine.

It is interesting that anatabine was not derived from lysine, but nicotinic acid. (This alkaloid is characteristic for *Nicotiana* plants but was also detected in *Lobelia inflata*) (Fig. 11.21), [1].

2.3.2 Occurrence of Lobelia Alkaloids: *Lobelia inflata* L. (Indian Tobacco)

Lobelia inflata L. (Fig. 11.22) belongs to the order *Campanulales* and to the family *Lobeliaceae*. There are 400 species in Lobelia genus and 2 of them are native in Europe (*Lobelia dortmanna* L. and *Lobelia urens* L.) [29]. The Lobelia can grow as a biennial but usually grows as an annual [30, 31].

The habitat of *L. inflata* L. is North America, where it grows wild in forest, pastures, and at roadsides, though in many countries (the USA and Holland) it is also cultivated [3, 32] because of its active ingredients.

L. inflata is grown from seed which is shown either in the autumn or in March and April. It is a 40–60 cm high annual plant flowering from June to August. It bears alternate leaves 3–8 cm long and pale blue and about 7 mm long bilabiate flowers. The inferior ovary develops into an inflated capsule. The drug is supplied by the flowering shoot. After drying, the drug is exported in bales or compress packets. The seeds are sometimes separated by thrashing.

The plant was given its Latin name after Mathias von L'Obel, Flemish physician and botanist (1538–1616), who was the first to describe it. The term "inflata" refers to the bladder-like inflated capsule [33].

Lobelia has long been used by the North American Indians. It was recommended for use in asthma by Cutler in 1813 and was introduced to the English medical

Lobelia inflata

Fig. 11.22 *Lobelia inflata* L.

profession by Reece in 1829. The drug is known under several designations: e.g., in America the leaves of the plant are used in pipe by name of "Indian tobacco" (they recall the smell of tobacco), or are put into circulation as "*emetic herba*" owing to their nauseating effect [34].

2.3.3 Analysis of Lobelia Alkaloids

The Lobelia alkaloids were first detected by Procter in 1850. At the beginning of the twentieth century, Wieland and Scheuing isolated the first alkaloids from *L. inflata*. The most important alkaloid of the family Lobeliaceae is lobeline, which is an α, α_1-disubstituted piperidine. Further, other alkaloids of *L. inflata* have been isolated, with their structures described [29, 34, 35].

The typical alkaloids of the family Lobeliaceae have a piperidine skeleton. There are alkaloid bases disubstituted in the α, α_1-position (i.e., in C_2 and C_6) and those monosubstituted in the α-position (C_2) (Figs. 11.23, 11.24] [36].

Alkaloid Extraction

The efficiency of the extraction methods in acid-aqueous media (0.1 M HCl, or 0.1 M HCl-methanol) or in chloroform solution (for pre-alkaline samples) was investigated. Various devices (ultrasound device, shaking machine, Soxhlet-apparatus) were used for the extraction. The best method was the extraction with 0.1 M HCl- methanol (1:1, *v*/*v*) in ultrasound device.

The alkaloid extraction method was suitable for the extraction of polyacetylenes as well; in this way, several kinds of effective substances could be analyzed from one stock solution.

Samples of this solution were filtrated and purified by solid-phase extraction (SPE) before HPLC analysis.

Determination of Total Alkaloid Content by Spectrophotometric Method

The total alkaloid content was determined by spectrophotometry after Mahmud El-Masry [37] and Krajewska [38, 39]. 0.01 % methyl-orange solution was added to the neutralized extract and then it was transferred to the separating funnel and extracted with chloroform. The chloroform layer was removed and transferred to another separating funnel and extracted with 0.1 N HCl solution containing 5 % NaCl. The absorption of the red color solution was measured at 510 nm. Total alkaloids were calculated as lobeline base.

SPE Purification

Solid-phase extraction (SPE micro-columns) was efficient for the purification of alkaloidous solutions. Aliquots were passed through a pre-activated (by methanol than water) SPE cartridge (Supelclean LC-8 columns 500 mg, 3 mL, supplied by Supelco) which was then washed with water. Extraction was performed on a vacuum manifold processor (LiChrolut extraction unit; Merck).The alkaloid (lobeline)-containing fraction was eluted from the tube with methanol. On the basis of the HPLC determination, the recovery of lobeline from the SPE step was total [40].

HPLC-DAAD Analysis: Quantitative Determination of Lobeline

An HPLC-DAD method was developed for determination of lobeline from in vitro and in vivo cultures of *L. inflata*.

HPLC analysis was performed on a Surveyor (Thermo Finnigan) HPLC system consisting of a quaternary gradient pump with an integrated degasser, a PDA detector, and an autosampler. Compounds were separated on a Knauer Eurospher 100-C8 (5 μm) reversed-phase column (250 × 3 mm i.d.) integrated with a precolumn (5 × 3 mm i.d.). The column temperature was 25 °C and the injection volume 5 μL. The mobile phase was 30:70 (*v*/*v*) acetonitrile-0.1 % trifluoroacetic acid. The flow rate was 0.8 mLmin^{-1}. The lobeline peak was identified by the addition of authentic standard (lobeline base) and by diode-array detection [40].

Quantitative Determination of Lobeline

Quantitative determination of lobeline was performed by the external standard method. Standard solutions containing lobeline at 2.25, 5, 12.5, 20, 40, and 80 μg mL^{-1} were prepared in 0.1 N HCl. Each standard solution was injected (5 μL) in triplicate on to the HPLC column and the absorbance was recorded at 250 nm. The calibration graph for lobeline was constructed by plotting the peak areas against the corresponding concentrations. The concentration of lobeline in samples was calculated from its peak area by use of the calibration plot [41].

Validation studies proved that the repeatability of the method was good and the recovery was satisfactory [40].

HPLC-MS/MS Characterization of Piperidine Alkaloids of *Lobelia inflata*

For direct characterization of disubstituted piperidine alkaloids in extracts of *L. inflata*, tandem mass spectrometric method was developed using electrospray ionization. Analysis was performed in positive ion mode on a triple quadropole LC/MS system. The identification and structural elucidation of the alkaloids were performed by comparing their changes in molecular mass (Δ*M*), full-scan MS-MS spectra with those of lobeline, lobelanine, norlobelanine, and lobelanidine. These alkaloids and ten other derivatives were identified in the plant extracts.

Analysis was performed in positive ion mode on an Agilent 6410 Triple Quad LC/MS system (Wilmington, DE, USA) using electrospray ionization. Alkaloids were separated on a Knauer Eurospher 100-C8 (5 μm) reversed-phase column (250 mm x 3 mm I.D.), with precolumn (5 mm x 3 mm I.D.). The column temperature was set at 25 °C. The mobile phase was 30:70 (*v*/*v*) acetonitrile-30 mM ammonium formate, pH 2.80. The solvent flow rate was 0.8 mLmin^{-1}. The injection volume was 5 μL. By solvent splitting, 40 % eluent was allowed to flow into the mass spectrometer. The conditions of the LC-MS/MS analysis were as follows: nebulizer pressure 45.0 psi, drying gas flow rate 9 Lmin^{-1}, drying gas temperature 350 °C, capillary voltage 3500 V, and scan range from *m*/*z* 50–700 at collision energy of 15 or 20 eV, depending on the molecular structure [40].

LC-MS and LC-MS/MS Analysis of Lobeline and Norlobelanine Standards

At beginning of the investigations the chromatographic and mass spectrometric conditions were optimized by using alkaloid standards. The voltage for fragmentation and collision energy was optimized using dead volume in LC-MS and MS/MS experiments. Full-scan analysis provided information about the molecular ion of standards. Molecular ions were then used as precursor ions for product ion analysis. The MS/MS spectra obtained provided information about the characteristic fragment ions and neutral losses which were the bases for identification of analytes in the extract of *L. inflata*.

The mass spectra of lobeline and norlobelanine standards revealed a base peak at *m*/*z* 338 and 322, respectively, corresponding to the molecular ions $[M + H]^+$. The product ion mass spectra were obtained by choosing the molecular ions as the precursor ions (Fig. 11.25).

Fragmentation of the protonated molecular ion of lobeline in the instrument led to product ions of *m*/*z* 320, 218, 216, 200, 105, 98, and 96 (Fig. 11.25). The subordinate product ion at *m*/*z* 320 was formed by loss of H_2O from the molecular ion at *m*/*z* 338. The ion at *m*/*z* 218 was produced by the loss of a phenyl-2-ketoethyl side chain ($C_8H_8O_1$, 120 Da). The more abundant product ion at *m*/*z* 216 was formed by loss of a phenyl-2-hydroxyethyl unit ($C_8H_{10}O_1$, 122 Da). A loss of water can be observed at *m*/*z* 200 (218-18). The most abundant product ion at *m*/*z* 96 was formed by loss of both side chains and corresponds to *N*-methylated 1,3-dihydropyridine ion.

Fragmentation of the molecular ion at *m*/*z* 322 of norlobelanine led to product ions at *m*/*z* 202 and 82. These fragment ions and their characteristic neutral losses 120 Da (322 → 202) and 2x120 Da (322 → 82) indicated that two phenyl-2-ketoethyl side chains were present in the molecule. The daughter ion at *m*/*z* 82 was 14 Da less than the daughter ion at *m*/*z* 96 for lobeline, indicating that norlobelanine is a *N*-demethyl derivative of lobelia alkaloids.

These characteristic product ions and neutral losses were the sound bases to identify derivates of lobeline.

LC-MS/MS Identification of Alkaloids in the Herb of *L. inflata* (In Vivo)

The total ion chromatogram of an extract of *L. inflata* is presented by method of Kursinszki et al. [40] in Fig. 11.26. The LC–MS/MS spectrum of each analyte is presented in Fig. 11.27. The LC-ESI-MS data are shown in Table 11.1.

Among them, the retention time and the MS and MS-MS spectra of the molecular ions at *m*/*z* 338 (Peak **j**, Fig.11.27j), 340 (Peak **h**, Fig. 11.27h), and

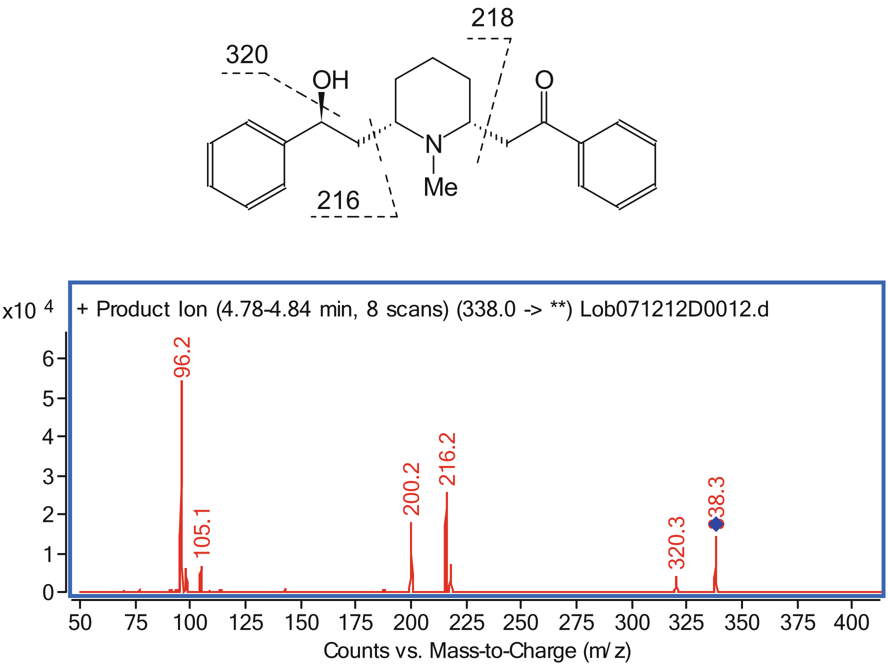

Fig. 11.25 Predominant fragmentation pattern and MS-MS product ion spectrum of (−) lobeline

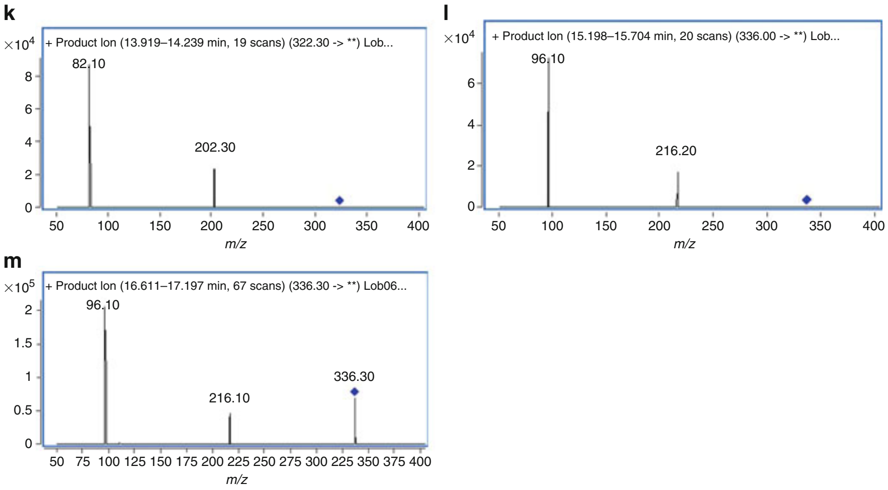

Fig. 11.27 (**a**–**m**) HPLC-MS/MS product ion spectra of alkaloids detected in the extract of the herb of *Lobelia inflata* cultivated in the field

Table 11.1 LC-ESI-MS data of the alkaloid extract of *Lobelia inflata*

Peak	t_R(min)	$[M + H]^+$	MS-MS (*m*/*z*)
a	4.95	276	82.1; 84.1; 138.2; 156.2
b	7.41	290	84.1; 152.2; 170.2
c	8.00	304	83.9; 84.3; 96.1; 98; 140.3; 158; 182.1; 200.3; 218.1; 286.2; 304.3
d	8.66	354	84.1; 188.2; 354.1
e	9.07	368	98.1; 202.2
f	10.29	326	82.2; 143; 185.9; 186.4
g	10.70	324	82.1; 143; 186.2; 202.1
h	11.86	340	98.2; 200.3; 202.2; 218.1; 322.3; 340.3
i	12.54	338	96.1; 98.1; 216.1; 218.2; 338.2
j	13.23	338	96.1; 98.1; 105.1; 200.2; 216.1; 218.1; 320.3; 338.2
k	14.06	322	82.1; 202.3
l	15.53	336	96.1; 216.2
m	16.87	336	96.1; 216.1; 336.3

322 (Peak **k**, Fig. 11.27k) were almost the same as those of lobeline, lobelanidine, and norlobelanine standards, respectively. Peak j can therefore be confirmed as lobeline, Peak **h** as lobelanidine, and Peak k as norlobelanine.

Above lobeline (Peak **j**), another chromatographic peak of *m*/*z* 338 was also detected in its LC-MS-MS chromatogram with retention time of 12.54 min (Peak **i**, Fig. 11.27i). The characteristic product ions at *m*/*z* 218, 216, and 96 were the same in both cases. Therefore, Peak **i** could be identified as an isomer of lobeline (lobelidine).

The molecular ion at 324 (Peak **g**, Fig. 11.27g) and its daughter ions at *m*/*z* 202, 186, and 82 were all 14 Da less than the molecular ion *m*/*z* 338 of lobeline standard and its daughter ions *m*/*z* 216, 200, 96, respectively. Therefore, Peak g could be identified as *N*-demethyl derivative of lobeline (norlobeline).

The molecular ion at *m*/*z* 326 (Peak **f**, Fig. 11.27f) was 14 Da less than the molecular ion at *m*/*z* 340 for lobelanidine. The fragment ions at *m*/*z* 186 and 82 could be formed by concomitant loss of two phenyl-2-hydroxyethyl units. Peak **f** can therefore be confirmed as norlobelanidine.

Two chromatographic peaks of *m*/*z* 336 were detected in its LC-MS-MS chromatogram with retention times of 15.53 min (Peak **l**, Fig. 11.27l) and 16.87 min (Peak **m**, Fig. 11.27m). Fragmentation of their molecular ions showed the same pattern. Their product ions at *m*/*z* 216 and 96 and their characteristic neutral losses 120Da and 2 × 120Da, respectively, indicated that two phenyl-2-ketoethyl side chains were present in the molecule. The product ion at *m*/*z* 96 can be *N*-methylated 1,3-dihydropyridine ion. Therefore, Peak **l** and Peak **m** should be lobelanine isomers.

Fragmentation of the molecular ion at *m*/*z* 276 (Peak **a**, Fig. 11.27a) led to product ions at *m*/*z* 156, 138, 84 and 82. The most abundant product ion at *m*/*z* 156 was formed by loss of a phenyl-2-ketoethyl part (120 Da, 276 → 156). A loss of water can be observed at *m*/*z* 138 (156-18). The ion at *m*/*z* 82 can be produced by loss of an ethyl-2-hydroxyethyl unit (74 Da, 156 → 82). Therefore Peak **a** can be identified as 8-ethyl-10-phenyl-norlobelionol.

The molecular ion at *m*/*z* 290 (Peak **b**, Fig. 11.27b) and the characteristic product ions at *m*/*z* 70 and 152 are all 14 Da more than *m*/*z* 276 and its daughter ions *m*/*z* 156 and 138, respectively. Therefore, Peak b could be identified as an *N*-methyl derivative of Peak **a** (8-ethyl-10-phenyllobelionol).

The molecular ion at *m*/*z* 304 (Peak **c**, Fig. 11.27c) can lead to six characteristic product ions at *m*/*z* 286, 218, 200, 182, and 96. The ion at *m*/*z* 286 was formed by loss of water from the molecular ion at *m*/*z* 304. The daughter ion at *m*/*z* 182 can be due to loss of a phenyl-2-hydroxyethyl unit (122 Da). Similar fragment loss 122 Da could be possible at *m*/*z* 96 (218-122). The *m*/*z* 182 ion could lose neutral fragment 86 Da to produce ion at *m*/*z* 96. This neutral fragment is 14 Da more than an ethyl substituted 2-ketoethyl unit characteristic to ethyl substituted lobelidion or lobelionol alkaloids of *L. inflata*. The results indicate that Peak **c** could be 8-propyl-10-phenyllobelionol. Our assumption is promoted by the fact that 8,10 dipropyllobelidione is described as a reaction product of 3-oxohexanoic acid and 2,3,4,5-tetrahydropiperidine and is considered as an intermediate in the biosynthesis of ethyl substituted lobelia alkaloids.

The fragmentation of the molecular ion at *m*/*z* 354 (Peak **d**, Fig. 11.27d) led to daughter ions, only two at *m*/*z* 188 and 84. The ion at *m*/*z* 188 might be explained by a neutral loss of 3-hydroxy-3-phenylpropanoic acid from its ester form resulting in dehydroxylated norallosedamine. This acid has been isolated from *L. inflata* and is considered as an intermediate in the biosynthesis of the phenyl-2-hydroxyethyl side chains of lobelia alkaloids. A possible fragment loss of 104 Da at *m*/*z* 84 (188–84) can correspond to the removal of dehydroxylated phenyl-2-hydroxyethyl unit. Further, the ion at *m*/*z* 84 can be an indicator of that the parent piperidine ion was monosubstituted. Peak **d** can therefore be an ester of 3-hydroxy-3-phenylpropanoic acid and norallosedamine (3-hydroxy-3-phenylpropanoic norallosedaminate). This proposed structure has not been described in *L. inflata*.

The molecular ion at *m*/*z* 368 (Peak **e**, Fig. 11.27e) and its daughter ions at *m*/*z* 202 and 98 were all 14 Da more than *m*/*z* 354 (Peak **d**) and its daughter ions *m*/*z* 188 and 84, respectively. Therefore, Peak **e** could be identified as *N*-methylated derivative of Peak **d** (3-hydroxy-3-phenylpropanoic allosedaminate).

Summarizing, the HPLC-DAD method of Kursinszki et al. [40] is reliable, simple, and sensitive. It can be used for determination of lobeline in the extracts of *L. inflata*. LC-MS-MS quadropole with electrospray ionization method was very suitable for the identification of lobeline and related piperidine alkaloids in *L. inflata*.

Piperidine Alkaloids in Culture of *Lobelia inflata* Under In Vitro, Greenhouse, and Field Conditions

Previously, the biosynthetic activity of cell suspension, callus, and genetically transformed hairy root cultures of *L. inflata* have been reported [34, 42–44]. The establishment of *L. inflata* in vitro cultures with high amount of active ingredients was an important precondition of investigating the in vivo cultures. With the aim of establishing the large-scale production of pharmaceutically important active ingredients, *L. inflata* was cultivated in greenhouse and in the field.

The secondary metabolite production of *L. inflata* was studied under in vitro, greenhouse, and field conditions. In vitro organized cultures with intensive growth and considerable secondary metabolite production were suitable objects for the cultivation of plants in greenhouse and in the field. The alkaloid content of greenhouse grown plants increased. The survival rate of the plants cultivated in the field was 100 %.

In Vitro Cultivation of *L. inflata*

The organized plants were cultured on solid Murashige-Skoog media [45] containing 3 % sucrose. Intensive growth could be observed for in vitro cultivation (Fig. 11.28) [44, 46, 47].

Cultivation in Greenhouse

In vitro cultures were transplanted to greenhouse after 2.5 weeks. The cultures were transplanted into a mixture of soil, perlite, and peat (2:1:1, *v*/*v*/*v*). Acclimatization of the plants was achieved by cultivation in greenhouse for 4 weeks (Fig. 11.28) [48].

Cultivation in the Field

After 4 weeks of greenhouse cultivation, *L. inflata* seedlings were transplanted to the field with a small soil ball, in early July, in Hungary. The distance between the plants was 5 cm (in every line) and between the lines it was 30 cm. After the first week of field cultivation, the plants were watered only rarely (Fig. 11.28) [48–51].

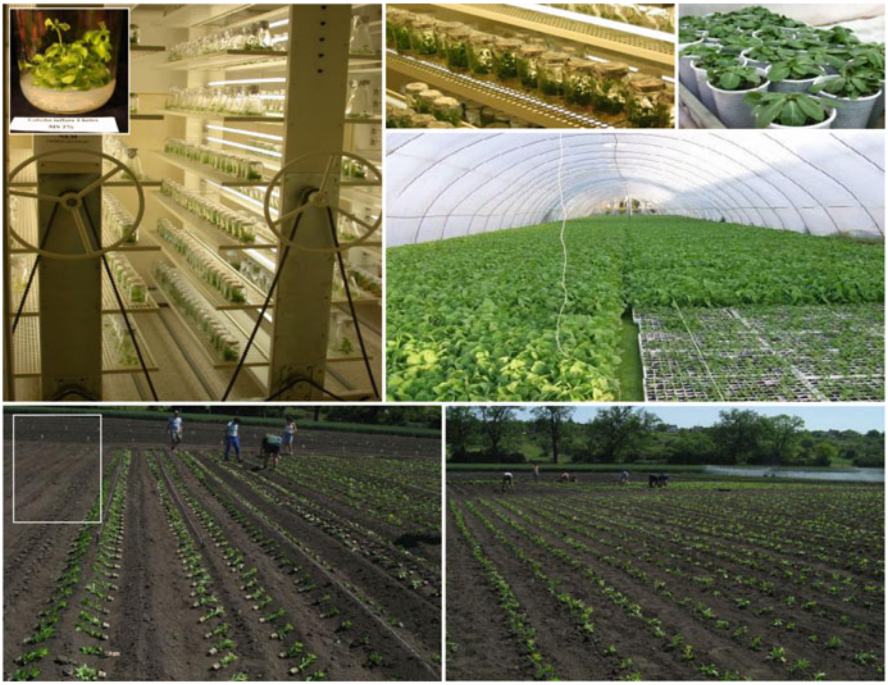

Fig. 11.28 Propagation of *Lobelia inflata* organized cultures in vitro and their acclimatization in greenhouse and cultivation in the field

The aim of experiments was the in vivo cultivation of *L. inflata*, in Hungary. In view of the good in vitro biosynthetic activity of cultures, it seems promising to start the experiments with in vivo cultures. The total alkaloid and lobeline content increased during the greenhouse cultivation. The total alkaloid production was three- to fourfold higher in both organs, and the lobeline production was 12-fold higher in the shoots of the plants cultivated in greenhouse than in the in vitro cultures. The total alkaloid and lobeline content was lower in plants cultivated in the field than in the seedlings cultivated in greenhouse.

For identification of alkaloids of plant obtained by vegetative micro propagation, the LC-MS/MS quadropole with electrospray ionization method was very suitable. In plant cultivated on field, 52 alkaloids (lobeline and related piperidine alkaloids) were found and identified. Of them, as main component, was identified the 8-ethyl-10-phenyl-lobelienonol isomer of molecular ion $[M + H]^+$ of m/z 288 (Fig. 11.29), [52].

It can be concluded that the in vitro organized cultures of *L. inflata* with intensive growth and considerable secondary metabolite production were suitable objects for the cultivation of plants in greenhouse and in the field. The highest alkaloid content was measured in the cultures cultivated in greenhouse.

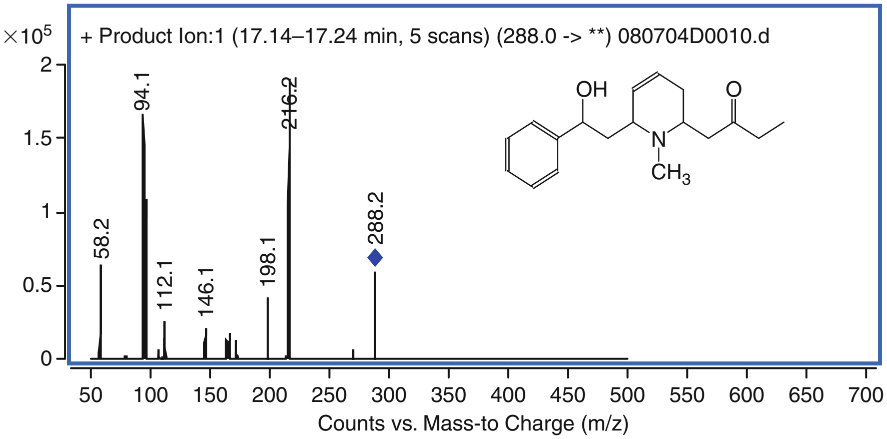

Fig. 11.29 HPLC-MS/MS product ion spectra of 8-ethyl-10-phenyl-lobelienonol isomer (*m*/*z* 288) detected in the extract of the herb of *Lobelia inflata* cultivated in the field

NMR Characterization of Lobeline

On the basis of qualitative and quantitative chromatographic results – isolation and spectroscopic (^{1}H-NMR, ^{13}C-NMR, MS/MS) identification of compounds, as well as comparison with an intact plant and authentic substances – it demonstrated that organized cultures have the ability to synthesize the characteristic alkaloids of the intact plant.

Identification of lobeline by ^{13}C-NMR spectroscopy is presented in Fig. 11.30 [53].

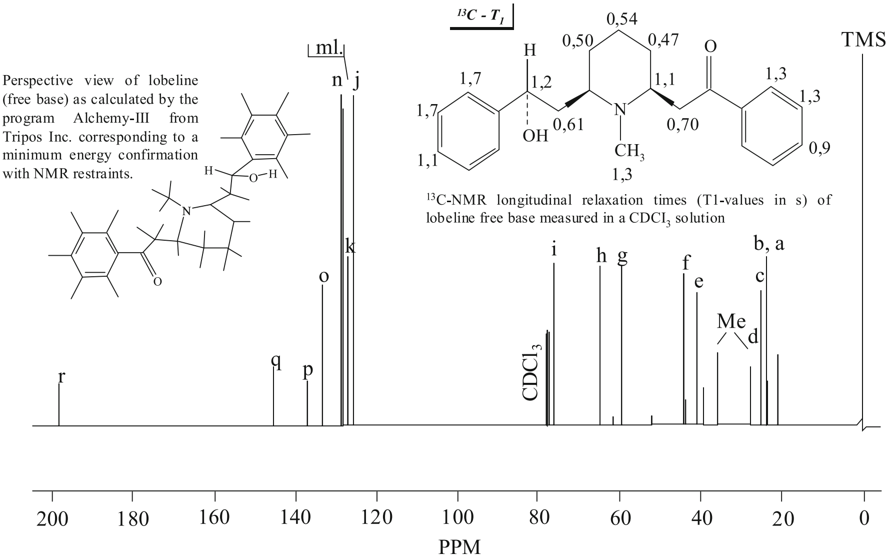
2.3.4 Biological Activity of Lobeline

L. inflata L. is a traditional medicinal plant native to North America. It contains several piperidine alkaloids. The main alkaloid is lobeline which has a stimulatory effect on the respiratory center and it is applied in the cases of asthma, gas- and narcotic-poisoning. Thus, lobeline is currently the subject of renewed interest for the treatment of drug abuse and neurological disorders, like Alzheimer’s or Parkinson’s disease, which pose an important public health problem in industrial countries. As lobeline can act as a competitive nicotinic receptor antagonist, it is frequently used in antismoking preparations. Interest in Lobelia alkaloids, and in particular (-)-lobeline, the most active of them, has increased in recent years due to their activity on the central nervous system (CNS).

Respiratory Stimulant

For a long time, lobeline was known as a powerful respiratory stimulant. This important property has been explained by the activation of the carotid and aortic body chemoreceptors at therapeutic doses.

This alkaloid on the respiratory system has therefore been used with success in numerous applications. Chronic pneumonia, asthma, bronchitis, and laryngitis are all conditions in which lobeline has been a great service.



Perspective view of lobeline (free base) as calculated by the program Alchemy-III from Tripos Inc. corresponding to a minimum energy confirmation with NMR restraints.

^{13}C-NMR longitudinal relaxation times (T1-values in s) of lobeline free base measured in a $CDCl_3$ solution

Fig. 11.30 NMR characterization of lobeline from *Lobelia inflata* in vitro cultures (^{13}C-NMR spectrum of lobeline at 75 MHz in $CDCl_3$ solution)

Lobeline has also been advantageous for the treatment of victims who have been electrocuted or asphyxiated by toxic gasses. Moreover, it was useful in the case of the paralysis of respiratory centers after drug poisoning with alcohol, soporifics, or morphine or after narcosis. Lastly, it has also been used to treat asphyxia in newborn infants.

In 2011, Anand et al. [54] investigated the influence of codeine on lobeline-induced respiratory reflexes and sensations and on ventilation with exercise in healthy subjects. In 15 healthy subjects, the effect of 60 mg oral codeine and placebo was examined on intravenously injected lobeline-elicited respiratory reflexes and sensations. Its influence was also studied on ventilation and appearance of distressful respiratory sensations with modest but incremental exercise. This is the first report of an attenuation of lobeline-elicited respiratory reflexes and sensations that are attributable to J receptors (pulmonary C fibers) by a pharmacological entity. It also suggests that codeine decreased these receptors' known contribution to respiratory augmentation and motor inhibition during exercise, which was seen as a delay in the onset of and a decrease in the magnitude of respiratory discomfort during treadmill walking and an increase in the duration walked by more than half the subjects.

In conclusion, the attenuation of respiratory influences that arose with i.v. lobeline and during treadmill walking by oral codeine suggests that an amelioration of respiratory distress as well as an increase in the duration of exercise undertaken by the latter could be achieved in situations or clinical conditions in which the J receptors would be naturally stimulated.

Drug Abuse

Lobeline has been reported as a useful agent to treat dependency on drugs such as cocaine, amphetamine, caffeine, phenylcycline, opiates, barbiturates, benzodiazepines, cannabinoids, hallucinogens, alcohol, and, especially, nicotine. Dwoskin [55] described a novel mechanism of action and potential use for lobeline as a treatment for psychostimulant abuse.

The most promising area in this field is the ability of lobeline to be a substitute of nicotine. Lobeline produces several physiological effects similar to those produced by nicotine. The use of it as a smoking deterrent was reported in 1936, but several later studies led to a dispute between positive and negative reports.

In 2010, Glover et al. [56] investigated the safety and efficacy of sublingual lobeline sulfate for smoking cessation. A multicenter (3 sites), double-blind, parallel, placebo-controlled, phase 3 smoking cessation trial of sublingual formulation of lobeline sulfate. A total of 750 smokers (250 per site) were randomized to either treatment (lobeline sulfate) or placebo with individual smoking cessation counseling lasting up to approximately 10 min. Results: Efficacy revealed no statistical significance ($P = 0.62$) for lobeline sulfate as a smoking cessation aid. Conclusion: Sublingual formulation of lobeline sulfate does not appear to be an effective smoking cessation aid.

Of late years, several results were born on methamphetamine abuse using pyrrolidine nor-lobelane analogues as lobeline derivates (Fig. 11.31), [57].

Both lobeline and lobelane attenuate methamphetamine self-administration in rats by decreasing methamphetamine-induced dopamine release via interaction with vesicular monoamine transporter-2 (VMAT2). A novel derivative of nor-lobelane, cis-2,5-di(2-phenethyl)-pyrrolidine hydrochloride (UKCP-110), and its transisomers, (2*R*, 5*R*)-trans-di-(2-phenethyl)-pyrrolidine hydrochloride (UKCP-111) and (2*S*, 5*S*)-trans-di-(2-phenethyl)-pyrrolidine hydrochloride (UKCP-112), were evaluated for inhibition of [(3)H]dihydrotetrabenazine binding and [(3)H]dopamine uptake by using a rat synaptic vesicle preparation to assess VMAT2 interaction. Compounds were evaluated for inhibition of [(3)H]nicotine and [(3)H]methyllycaconitine binding to assess interaction with the major nicotinic receptor subtypes.

The most promising compound, UKCP-110, was evaluated for its ability to decrease methamphetamine self-administration and methamphetamine discriminative stimulus cues and for its effect on food-maintained operant responding. It is noteworthy that UKCP-110 decreased the number of methamphetamine self-infusions, while having no effect on food-reinforced behavior or the methamphetamine stimulus cue. Thus, UKCP-110 represents a new lead in the development of novel pharmacotherapies for the treatment of methamphetamine abuse.

Central Nervous System (CNS) Disorders

The most promising bioactivity of lobeline concerns its use as an agent in the treatment of central nervous system (CNS) diseases and pathologies [28].

The effect of lobeline on the CNS was extensively exploited by the Native Americans, who smoked the dried leaves of Lobelia plants. Several studies have

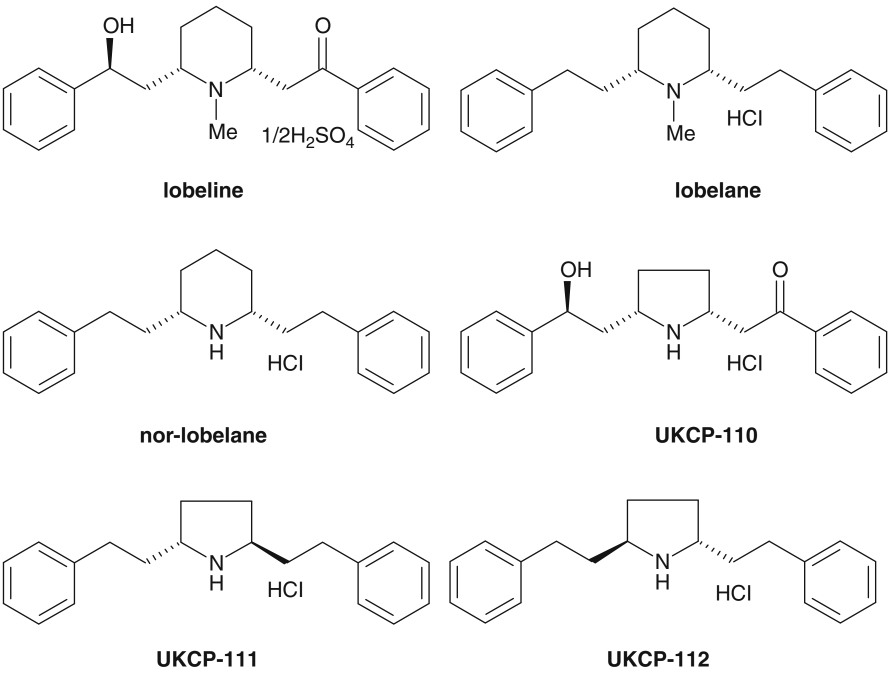


Fig. 11.31 Structures of pyrrolidine norlobelane analogues (UKCP110-112) as lobeline derivates

shown that lobeline improves memory in rodents, probably due to its involvement in cholinergic mechanisms of neurotransmission.

This pharmacological profile may be of great importance in the treatment of learning disorders like Alzheimer's disease (AD), the most common cause of dementia in the elderly.

Indeed, 2 years ago, the cholinergic hypothesis was claimed to explain the cognitive symptoms of AD. Thus, the development of new agents that selectively interact with cholinergic receptors could offer a new opportunity for AD therapy. AD is characterized by a gradual and progressive decline in intellectual function and behavioral abnormalities.

Multidrug-Resistant (MDR) Activity

The emergence of natural products as potential anti-MDR molecules is of particular significance. Many of these essential components may possibly represent a new generation of MDR modulators.

Cancer cells can develop resistance to the anticancer drugs used in cancer therapy. Furthermore, the cells become resistant to other chemotherapeutic drugs whose structures and functions are unrelated. This phenomenon is called multidrug resistance (MDR) [58, 59]. MDR is multifactorial, but P-gp, also known as P-glycoprotein, Pg-170 or P-170, plays an important role in MDR.

Recently, numerous publications were presented which were interested in the multidrug-resistant activity of piperidine like lobeline, piperine [60, 61], and other alkaloids, e.g., cinchonine and acridone [62, 63].

Ma and Wink [60] investigated Lobelia extracts, chiefly lobeline as a new multidrug resistance reversal agent. MDR can limit efficacy of chemotherapy. The best-studied mechanism involves P-gp-mediated drug efflux. This study focuses on MDR reversal agents from medicinal plants, which can interfere with P-gp. Lobeline, a piperidine alkaloid from *L. inflata* and several other *Lobelia* species, inhibited P-gp activity. MDR reversal potential of lobeline could be demonstrated in cells treated with doxorubicin in that lobeline can sensitize resistant tumor cells at nontoxic concentrations. However, lobeline cannot block BCRP (Breast Cancer Resistance Protein)-dependent mitoxantrone efflux. Lobeline could be a good candidate for the development of new MDR reversal agents.

Chemotactic Activity

Chemotactic activity of substances extracted from *L. inflata* was investigated in the frequently used eukaryotic ciliate model, *Tetrahymena pyriformis* GL [64, 65]. The chemotactic activity of cells was measured in a concentration course study ($v/v\% = 10^{-7}$–10^{-1}) by capillary assay [66]. The extracts of *L. inflata* (total extract in methanol, lobeline HCl, and polyacetylenes) proved to elicit diverse migratory responses: (1) a wide range chemoattractant character of the total extract was registered while (2) lobeline HCl and polyacetylene had strong chemorepellent effects (Fig. 11.32).

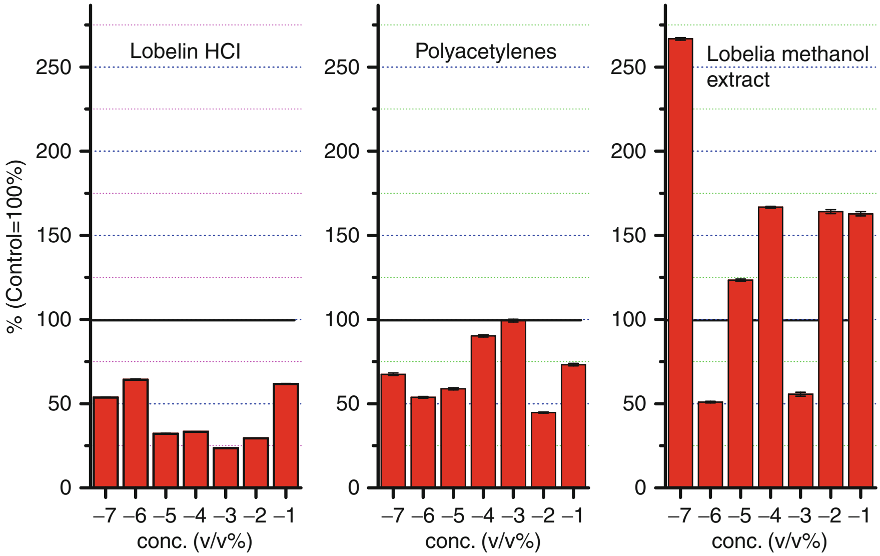

Fig. 11.32 Chemotactic activity of lobeline (repellent), polyacetylenes (repellent) and *Lobelia inflata* extract (attractant) in *Tetrahymena pyriformis*

However, the molecular backgrounds of the detected cell physiological responses and their diversities are still not known the presented data may explain the well known physiological/clinical effects of the extracts prepared from *L. inflata*. The registered chemorepellent characters of extracts have a good correlation with the presence of the generally chemorepellent aromatic R groups [67] in the more than 20 piperidine skeleton alkaloids of Lobelia.

3 Conclusion

In *Punica granatum* beside the long since known compounds as pelletierine, *N*-methylpelletierine, anaferine, and pseudopelletierine, other alkaloids – sedridine, norpseudopelletierine, hydroxypropyl – and propenyl-Δ^1-piperideine were also detected; further, the absolute configuration of (-)- and (+)-sedridine and (-)-pelletierine were determined.

The greatest anthelmintic activity of Punica extracts was chiefly due to isopelletierine but the harmful side-effects led to full abandon of the drug (root bark) and its alkaloids.

In *Piper nigrum* beside piperine were detected its geometric isomer chavicine, then other piperidine amides piperanine, piperettine, and also a pyrrolidine amide the piperylline. From *Piper longum*, nine piperidine amides were isolated, between guigeensine and piperlonguminine, which showed significant MAO inhibitory activities. Piperlonguminine is a novel therapeutic agent for Alzheimer's disease. From *Piper officina*rum, beside piperine, the piplartine piperidine amide and sesamin lignin derivate were detected. A new major urinary metabolite of piperine the 5-(3,4-methylenedioxyphenyl)-2*E*, 4*E*-pentadienoic(3-yl propionic acid)-amide was identified in rat urine and plasma and certified the similar mass fragmentation by MS/MS studies.

Of the numerous new pharmacological and therapeutical activities of piperine are summarized as follows:

– Piperine inhibited LPS-induced shock trough inhibition of type 1 IFN (interferon) production.
– Piperine-treated rat liver microsomes demonstrated a tendency to enhance [3H]-aflatoxin B1 binding to calf thymus DNA in vivo.
– Piperine is a potent inhibitor of nuclear factor κB.
– The later studies have established that black pepper could be safety used as a food additive, regarding the piperine is non-genotoxic and possess antimutagenic and antitumor influences.
– The piperine can reverse MDR by multiple mechanisms and may be a promising lead compound for future studies.

In *Lobelia inflata*, two types of piperidine alkaloids were detected: alkaloids of phenolic side chaines, as lobeline, lobelanine, norlobelanine, sedamine, and the dimer lobinaline; further, alkaloids of aliphatic side chains: diethyllobelidiol and methyl-ethyllobelidiol. It is important to mention that lobelane and nor-lobelane as reduced derivates of lobeline and the three pyrrolidine analogues of nor-lobelane are metamphetamine abuse agents, respectively.

Lobeline, the main alkaloid of *Lobelia inflata*, has the following important biological activities and therapeutical uses:

- Like respiratory stimulant was used success in chronic pneumonia, asthma, bronchitis, laryngitis
- Useful agent against drug abuse
- Promising agent in the treatment of central nervous system (CNS) disorders, like Alzheimer's disease, attention deficit, restlessness, impulsiveness, hyperactivity
- Positive effects in the treatment of multidrug-resistant tumor cells
- Strong chemorepellent effect of lobeline HCl; chemoattractant character of Lobelia alkaloid extract

Abstract

The tropane alkaloids are among the first ones detected in nature that have a wide application as various remedies. In this chapter, the tropane alkaloids are classified according to their subsequent biosynthetic pathway of formation. From this point of view, the alkaloids are described as derivatives of four main intermediates – tropinone, ecgoninone, 4-benzyltropanone, and pyronotropane. The derivatives of tropinone are the largest group of tropane alkaloids and are typical for family Solanaceae and Convolvulaceae. By the number of substituents in the tropane ring, they are divided into five subgroups: mono-, di-, and trisubstituted tropanes, epoxytropanes, and calystegines. Alkaloids derived from ecgoninone are mostly distributed in family Erythroxylaceae. 4-Benzyltropanes and pyronotropanes are small groups typical for family Proteaceae. Dimeric and

TR II	Tropinone reductase II

1 Introduction

The tropane alkaloids comprise a large well-defined structurally group of natural products, occurred mainly in family Solanaceae but also are found in the families Convolvulaceae, Erythroxylaceae, Proteaceae, Rhizophoraceae, etc. [1]. Common structural element of these alkaloids is the tropane skeleton, consisting of a pyrrolidine and piperidine ring sharing the nitrogen atom and two carbon atoms. The systematic name of the tropane skeleton is 8-methyl-8-azabicyclo[3.2.1.]octane (Fig. 12.1). Currently, the number of these alkaloids is more than 200 [2–4].

Precursor in the biosynthesis of tropane alkaloids is the amino acid L-ornithine (**1**) [5–8]. It was found that ornithine undergoes enzymatic decarboxylation to putrescine (**2**) which then is methylated to *N*-methylputrescine (**3**) [9–12]. The oxidation of *N*-methylputrescine (**3**) leads to 4-methylaminobutanal (**4**) that is further converted in the *N*-methyl-Δ^1-pyrrolinium cation (**5**). From the last compound, the four carbon atoms C-1, C-5, C-6, and C-7 and *N*-methyl group in tropane skeleton are originated [9, 13, 14] (Scheme 12.1).

The next steps of formation of the tropane skeleton require addition of two acetate units to *N*-methyl-Δ^1-pyrrolinium cation (**5**) to obtain tropinone (**6**) – dominating pathway for alkaloids in plants belonging to family Solanaceae [15, 16] and ecgoninone (**7**) dominating pathway for alkaloids in plants belonging to family Erythroxylaceae [11, 17, 18]. On the other hand, biogenetically tropinone (**6**) is

formed and by decarboxylation of ecgoninone (**7**). (Scheme 12.2) [15]. The derivatives of 4-benzyltropanone (**8**) and pyronotropane (**9**) detected in plants belonging to family Proteaceae are assumed to be built up by addition of two acetate units and benzoate and oxaloacetate units to *N*-methyl-Δ^1-pyrrolinium cation (**5**) [19].

2 Tropane Alkaloid Classification

2.1 Alkaloids Derived from Tropinone

By the action of tropinone reductase I (TR I) and tropinone reductase II (TR II), tropinone (**6**) is reduced to tropine (**10**) and pseudotropine (**11**), respectively [20–23] (Scheme 12.3). The correlation between the two enzymes is essential for the diversity of the alkaloid spectrum of the plants producing 3-monosubstituted, 3,6- or 3,7-disubstituted, 3-substituted-6,7-epoxy- and 3,6,7-trisubstituted tropane alkaloids, respectively [24, 25]. It is determined that TR I is dominant for the species of family Solanaceae; therefore, the alkaloids of α-series, derived from tropine, are prevailing [26]. It is established the configuration of the substituents at C-6 and C-7 is always β- [27]. The obtained tropine (**10**) and pseudotropine (**11**) further is esterified with various aliphatic and aromatic carboxylic acids such as tropic, apotropic, tiglic, propionic, butyric, isobutyric, and other acids [19].

3α,6β,7β-trisubstituted tropanes
3β,6β,7β-trisubstituted tropanes

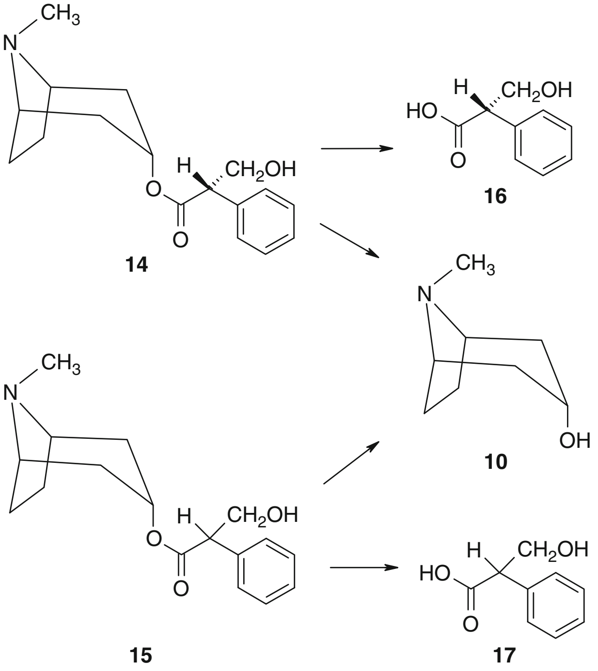
Scheme 12.3

2.1.1 3-Monosubstituted Tropanes

All members of the monosubstituted tropane group are derived from tropine (**10**), pseudotropine (**11**), and their norderivatives nortropine (**12**) and pseudonortropine (**13**).

	R_1	R_2	R_3
10	CH_3	H	OH
11	CH_3	OH	H
12	H	H	OH
13	H	OH	H

The most important representative of this group is the alkaloid (*S*)(-)-hyoscyamine (**14**). The alkaloid is ester of tropine with tropic acid. The α-carbon atom of tropic acid is asymmetric, so that two stereoisomers are possible. The natural form, the one occurring in pharmacologically active hyoscyamine, is the (-)-form. The alkaloid is



Scheme 12.4

easily racemized, yielding atropine ((±)-hyoscyamine) (**15**), which has the same pharmacological effects as (-)-hyoscyamine (**14**), but with less pronounced effect. The hydrolysis of **14** results in **10** (optical inactive) and (±)-tropic acid (**16**), and **14** to **10** and (-)-tropic acid (**17**) (Scheme 12.4). Atropine (**15**) is one of the first isolated alkaloid from the tropane group as the name "tropane" comes from the species in which it is found – *Atropa belladonna* L. [28].

2.1.2 3,6- and 3,7-Disubstituted Tropanes

The main building unit of disubstituted tropane alkaloids are 3α,6β-, 3β,6β-dihydroxytropane (**18**, **19**) and 3α,7β-, 3β,7β-dihydroxytropane (**20**, **21**) and their corresponding norderivatives (**22**, **23**, **24**, **25**). The alkaloids belonging to this group are mono- or diester derivatives of these intermediate products.

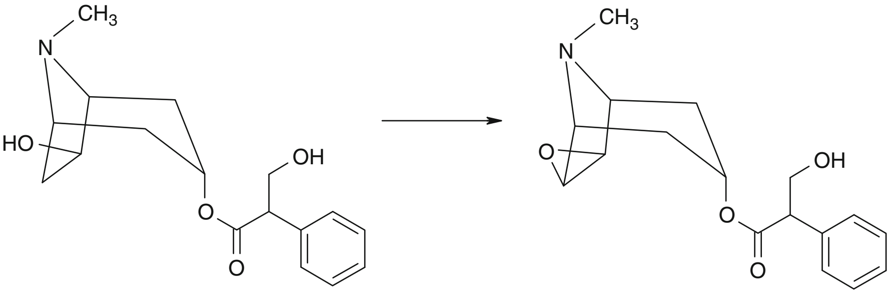
24	H	H	OH	H	OH
25	H	OH	H	H	OH



26 **27**

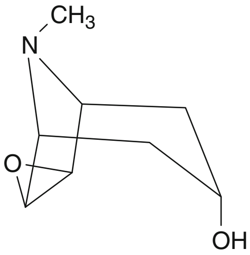
Scheme 12.5

One of the important representatives of this group is the alkaloid 3-tropoyloxy-6-hydroxytropane (**26**) which is the biosynthetic precursor of scopolamine (**27**) (Scheme 12.5).

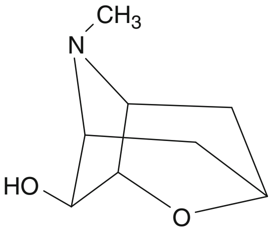
2.1.3 3-Substituted-6,7-Epoxytropanes

A characteristic feature of this group of alkaloids is that they contain 6β,7β-epoxy ring.

Hydrolysis of esters of 6,7-epoxytropane alkaloids depending on the conditions of the process resulted in obtaining scopine (**28**) (by mild conditions with pancreatic lipase) and oscine (**29**) (by alkaline or acidic hydrolysis) [29].



28



29

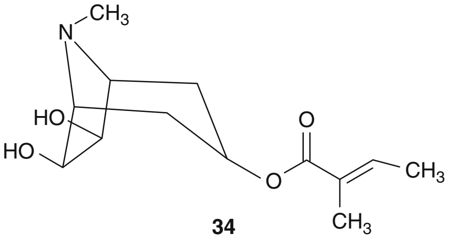
The most noted representative of this group is the alkaloid scopolamine (**27**), whose name comes from the species of the genus *Scopolia* from where it was originally isolated [30].

2.1.4 3,6,7-Trisubstituted Tropanes

Trisubstituted tropanes are formally derived from 3α,6β,7β- and 3β,6β,7β-trihydroxytropane (**30**, **31**) as well as their corresponding norderivatives (**32**, **33**).

	R_1	R_2	R_3	R_4	R_5
30	CH_3	H	OH	OH	OH
31	CH_3	OH	H	OH	OH
32	H	H	OH	OH	OH
33	H	OH	H	OH	OH

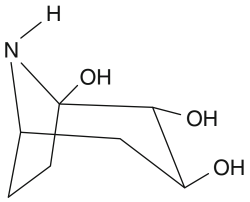
One of the early identified representative of this group is the alkaloid meteloidine-3-tigloyloxy-6,7-dihydroxytropane (**34**) whose name comes from the species *Datura meteloides* from where it was isolated for the first time [31].



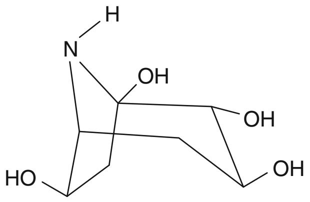
34

2.1.5 Calystegines

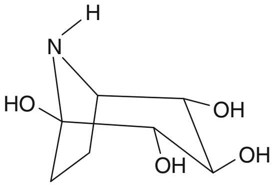
Pseudotropine, product of TR II, is the specific precursor of calystegines, alkaloids which originally were isolated from different species of genus *Calystegia* (fam. Convolvulaceae) and later from several genera of families Solanaceae, Moraceae, etc. (Scheme 12.3) [32–35]. They are polyhydroxylated nortropane derivatives where the hydroxyl groups are situated on various positions. The trihydroxylated calystegines are summarized as calystegine A-group, the tetrahydroxy derivatives as the calystegine B-group, and the pentahydroxy respectively calystegine C-group [33, 36–38]. In contrast to the most tropane alkaloids, their hydroxyl groups are not esterified [39]. Widespread representatives of calystegine group are the alkaloids calystegine A$_3$ (**35**), calystegine B$_1$ (**36**), calystegine B$_2$ (**37**), and calystegine C$_1$ (**38**)



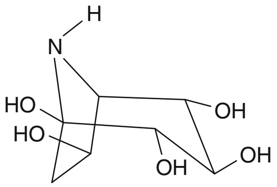
35



36

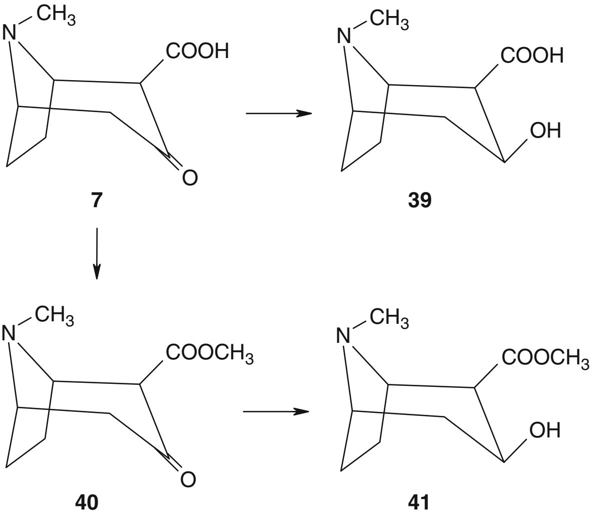


37



38

Scheme 12.6

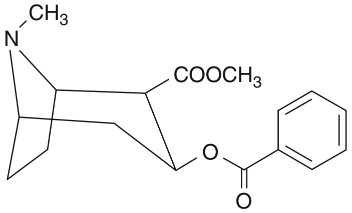


2.2 Alkaloids Derived from Ecgoninone

All members of this group of alkaloids are biosynthesized through the reduction of ecgoninone (**7**) to ecgonine (**39**) and subsequent esterification of the hydroxyl group at C-3 with various aliphatic and aromatic acids. In some cases, this stage is preceded by methylation of carboxylic group to methylecgoninone (**40**), which is then reduced to methylecgonine (**41**) (Scheme 12.6).

The alkaloids derived from ecgonine are typical for the plants of the family Erythroxylaceae. It is established the configuration of the substituents at C-2 and C-3 in all identified alkaloids of this type is always β- [27].

Well-known alkaloid of this group is cocaine (**42**), whose name comes from the species *Erythroxylum coca* from where it was originally isolated [40].



42

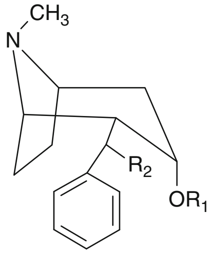


Fig. 12.2 3-Substituted-4-benzyltropanes

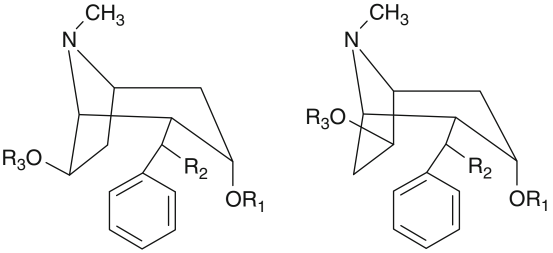
Fig. 12.3 3,6- and 3,7-Disubstituted-4-benzyltropanes



2.3 Alkaloids Derived from 4-Benzyltropanone

The members of this small group of tropane alkaloids according to the number of substituents are divided into two subgroups – monosubstituted- and disubstituted-4-benzyltropane alkaloids.

2.3.1 3-Substituted-4-Benzyltropane Alkaloids

The general formula of these alkaloids is presented in Fig. 12.2.

Most often the substituent at C-3 is acetyl group, but it also can be a benzoyl or cinnamoyl group. R_2 can be hydrogen, hydroxy group, or its acyclic derivatives. In all identified alkaloids of this group it is determined that the configuration of the substituent at C-3 can be α- or β-, and at C-4 it is always α- [27].

2.3.2 3,6- and 3,7-Disubstituted-4-Benzyltropanes

This group is derived from 3-substituted-4-benzoyltropane alkaloids with one additional functional group R_3 at C-6 or C-7, most often benzoyl, which is always in β-position (Fig. 12.3).

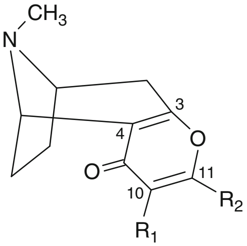


Fig. 12.4 Pyronotropanes

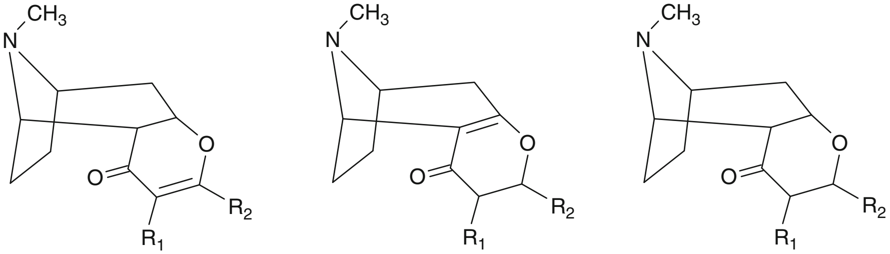

Fig. 12.5 Dihydro- and tetrahydropyronotropane

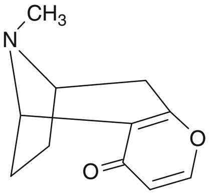
2.4 Pyronotropane Alkaloids

Pyronotropane alkaloids are natural compounds with γ-pyrone ring condensed with tropane ring at C-3 and C-4 (Fig. 12.4).

The substituents R_1 and R_2 at C-10 and C-11 most often are hydrogen atom or methyl group, and rarely phenyl or hydroxyl group [27].

One of the earliest found pyronotropane alkaloid is strobiline (**43**) isolated from *Knightia strobilina* (family Proteaceae) [19].



43

To the group of pyronotropanes also are included the alkaloids in which the γ-pyrone ring has hydrogenated double bond at C-3, C-4, and/or at C-10, C-11 (Fig. 12.5) [41].

2.5 Dimeric and Trimeric Tropane Alkaloids

The dimeric tropane alkaloids are a small group of natural compounds structurally composed by enzymatically catalyzed process of two tropane nuclei derived from tropinone or ecgoninone, linked by dicarboxylic acid, such as mesaconic, itaconic, truxillic, etc., at C-3, C-3' or C-3, C-6' or C-3, C-7' [27, 42]. Typical examples for these types of linkage are the alkaloids α-truxilline (**44**) and schizanthine D (**45**) [42]. Another type of linkage of the two tropane nuclei can take place between the nitrogen atoms via CH_2-CH_2 or > C=O bridge as in subhirsine (**46**) and convolvidine (**47**) [27, 42–45].

Till now the only known trimeric tropane alkaloid is grahamine (**48**) found in *Schizanthus grahamii* (Solanaceae) [43]. The structure of **48** is composed of three 3,7-disubstituted tropane rings and one unit truxillic acid.

3 Conclusion

The tropane alkaloids are a large important class of natural products which have variety of chemical structures and interesting pharmacological activities. These alkaloids are characteristic secondary metabolites for the families Solanaceae, Convolvulaceae, Erythroxylaceae, Proteaceae, and Rhizophoraceae, and they have been used as chemotaxonomical markers. The intensive investigations in the branch of tropane alkaloid chemistry continue and by the use of modern physical detection techniques, the number of new compounds steadily increases.

Abstract

Pyrrolizidine alkaloids (PAs) occur in about 5% of all flowering plants. They are esters of a basic moiety ("Necine") and esterifying acids ("necic acids"). Up to now, about 500 different PAs are described. PAs can be hazardous to man and domestic animal. They can show cancerogenic, mutagenic, teratogenic, and fetotoxic properties. Many intoxications by PAs are described. The level of the toxicity of each single PA is dependent from its concrete chemical structure. This chapter gives an overview about the chemistry, biosynthesis, and toxicity of PAs.

1 Introduction

The term “pyrrolizidine alkaloids” (PAs) is used for all ester compounds of the hydroxy and/or dihydroxy and/or hydroxymethyl derivatives from pyrrolizidine (hexahydro-1*H*-pyrrolizine) or from 1,2-dehydro-pyrrolizidine (2,3,5,7a-tetrahydro-1*H*-pyrrolizine).

PAs occur in 13 plant families and in about 5% of all flowering plants. Toxic PAs can be found in six plant families: Apocynaceae, Boraginaceae, Asteraceae (Compositae), Leguminosae (Fabaceae), Ranunculaceae, and Scrophulariaceae. These PAs are hepatotoxic, genotoxic, teratogenic, carcinogenic, and pneumotoxic.

Toxic PAs are only those derived from the unsaturated moiety 1,2-dehydropyrrolizidine and are mainly esters of the aminoalcohols (= necines) retronecine, heliotridine, or the untypical aminoalcohol (no bicyclic five-membered system, but an eight-membered monocycle) otonecine. Some few toxic PAs are esters from crotanecine. Of minor toxicity are the esters of the 1-hydroxymethyl-1,2-dehydropyrrolizidine supinidine.

A very large range of pyrrolizidine alkaloids can theoretically be obtained by combining the known necines and the esterifying acids (= necic acids). So far, more than 500 alkaloids have been found and their structures determined. With the exception of the approximately 35 otonecine alkaloids that cannot form N-oxides, if the N-oxides of these alkaloids are taken into consideration, more than 900 structures are known.

The first intoxication was reported by Gilruth who found that a chronic liver disease in livestock was caused by *Senecio jacobaea* [1, 2]. It was further shown that other *Senecio* ssp. as well as *Crotalaria* ssp. led to the same disease [3]. Already in 1920, it was proven that a widespread chronic liver disease in humans was caused by grain contaminated with seeds of *Senecio* ssp. [4, 5]. Several severe intoxications, all caused by the contamination of food (mainly bread), were reported: In the 1950s, severe intoxications in the former USSR were found to be caused by seeds and dust of *Heliotropium lasiocarpum* which contaminated grain [6, 7]; similarly, the same species was the reason for the intoxication of 4,000 people in Tadjikistan [8, 9]. The severest incident was observed in the 1970s in Afghanistan where about 8,000 people were affected from a wheat contamination by seeds of *Heliotropium popovii*, subsp. g*illianum*; more than 3,000 died [10, 11].

It can be assumed that seeds and dust from PA-containing plants are a major source for a human PA exposure [12, 13]. In industrialized countries, grain cleaning methods reduce the PA contamination under a level where acute intoxications can occur, but the dust components are still remaining and there are indications that diseases such as cirrhosis, cancer, and pulmonary arterial hypertension are due to a long-time exposure of low doses of PAs [14].

Besides this, medicinal plants are a further source of a PA intoxication [15–18]. Especially herbal preparations (so-called bush-teas) were found to be the reason for different liver diseases observed in Jamaica and the West Indies as well as in Africa in the 1950s [19–21].

PA intoxications by herbal preparations are mainly observed in developing countries where the use of traditional medicines is common; however, in the last three decades also, in industrial countries like the USA, the UK, Switzerland, Austria, and Germany PA intoxications were reported due to the increased and uncontrolled use of herbal medications. In the 1980s, hand in hand with the so-called green wave, several practitioners claimed that herbal medicine would show only benefits without undesirable side effects which led to several fatal intoxications, mainly in infants who show a higher susceptibility to PA than adults.

Other foods can also be contaminated with PAs and are, therefore, a potential hazard for humans. Milk was shown to be a source for a PA intoxication in a case where the milk-producing animals had access to PA containing feed (hay, silage) [22–30]. Human milk from women exposed to pyrrolizidine alkaloids has caused veno-occlusive disease in neonates and infants [31]. Honey has become of increased importance as it could be shown that, in commercial products, levels of PAs were found which exceeded tolerable values. Here, pollen seems to be the pathway of contamination [31–37].

Recently, in Germany it was found that salads (especially ready-packed rocket salads (*Eruca sativa*), sold in supermarkets) and salad mixtures can be contaminated with PA containing plants, mainly *Senecio vulgaris*, a typical weed of field crops [38].

1,2-dehydropyrrolizidine esters and their N-oxides are carcinogenic, mutagenic, genotoxic, fetototoxic, and teratogenic to varying degrees. The toxicity level of each single PA is dependent on its chemical structure and also physical properties such as lipophilicity, hydrophilicity, and pharmokinetics. PAs prior to metabolic activation show a more or less low acute toxicity, but in vivo they undergo a metabolic toxification process in the liver, which is, as a result, the first target organ for the toxicity. This toxication process is well investigated.

PAs are considered to be toxic contaminants and have no well-recognized uses on their own. In the 1970s, the PA indicine-*N*-oxide was found to show antitumor activities, but on account of severe toxic side effect (especially observed in children) its use was no longer justified [39–41].

1.1 Chemical Structures of PAs

PAs are esters and consist of two parts: the basic aminoalcohols (“necines”) and one or more acids (“necic acids”) that esterify the OH groups of the necines [42–44].

Necines consist of a five-membered bicyclic ring system with a bridgehead nitrogen and – at least – a hydroxymethyl group at position 1 (Fig. 13.1). They can occur as saturated systems or possess a double bond in position 1,2. Most of the PAs show a further OH group at position 7. Further hydroxylation can take place at positions 6 and 2; in the case of saturated PAs a few molecules show hydroxylation at position 1 and in one case the (+) isomer of isoretronecanol (R_3 = ß-H; α-hydroxymethyl at position 1) is reported. Chiral carbons can be at positions 1 and 2 (saturated necines) and 6,7,8 (all necines). Mainly all PAs belong to the 8-α series (only two times the 8-ß position is reported). In nature, the PAs mainly occur in their *N*-oxide form (water-soluble; transport form).

Fig. 13.1 Structures of necines

An untypical necine can be found in the otonecine PAs: This necine occurs not in form of a bicycle but as a 1-methylazocan-5-one. On account of the results by X-ray analysis, it could be found that there exists a transannular binding between carbonyl and the nitrogen leading to the same behavior as the typical bicycle PAs. All PAs showing a double bond in position 1,2 act as natural toxins.

Necic acids are structurally highly variable. Besides the simple acetic acid they consist mainly of 5–10 carbon atoms. They can form mono-, di-, or macrocyclic diesters and can show more or less branched carbon chains. The carbon atoms can bear different functional groups like hydroxyl, alkoxy, epoxy, and carboxyester groups. Double bonds at different positions are also possible. On account of this situation a theoretically high number of different unique structures are possible, including a large range of stereo isomers [42–44].

Necines with only one OH group can only form PA monoesters like supinine. If there exists a second OH group both can be found: mono as well as diesters as demonstrated for lycopsamine and its acetyl derivative or as in lasiocarpine. These examples demonstrate the variability of the stereochemistry (Fig. 13.2).

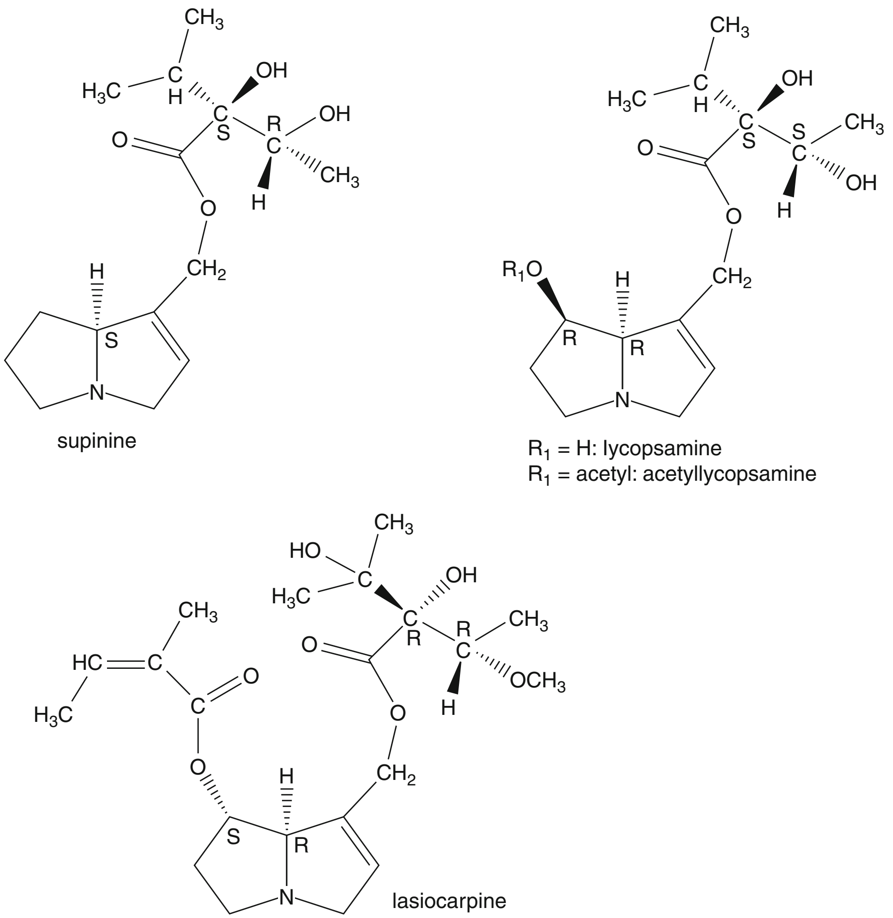

Fig. 13.2 Structures of PA mono- and diesters

With dicarboxyclic acids, the double esterification leads to macrocyclic diesters which can occur as 11–13-membered ring systems. A typical example for an 11-membered PA is monocrotaline, the main PA occurring in *crotalaria* species, or crispatine. Most of the PAs show a 12-membered ring system; this can be found, for example, in senecionine or senkirkine, both contained in many *senecio* species. A typical 13-member ring is demonstrated in the PAs doronenine (also isolated from *senecio*) and in madurensine (from *crotalaria*). Very rare is the 14-member macrocycle: It is found in the PA parsonsine (from *parsonsia*-species); this structure is possible on account of a further ester group within the necic acid chain. It is interesting to mention that until now in all cases of macrocyclic diester PAs only the 7-ß-OH isomer (mainly retronecine) is described and not the α-isomer (heliotridine) (Fig. 13.3).

Fig. 13.3 Structures of macrocyclic PA

Theoretically, an innumerable amount of different structures is possible. So far, more than 500 PAs have been isolated and their structures described.

1.2 Biosynthesis

The first experiments concerning the biosynthesis of PAs were done in the 1960s: [2-^{14}C]ornithine, [1-^{14}C]acetate, and [1-^{14}C]propionate were fed to *Crotalaria* species [45]. Similarly, labelled ornithine was incorporated into the alkaloids from *Senecio* species [46, 47]. In all cases, ornithine was incorporated specifically into the basic moiety retronecine, whereas acetate and propionate could be found in the acidic parts of the alkaloids. Bale and Crout used a double isotope technique for a comparison between ornithine and arginine [48] showing that ornithine is the more efficient precursor than arginine. It could be found that ornithine and arginine were incorporated into retronecine via putrescine: Experiments gave evidence for the formation of putrescine from argine in *Heliotropium* species, whereas in *Crotalaria* and *Senecio* species, the main pathway to putrescine is from ornithine [49, 50]. Further experiments came to the conclusion that retronecine is derived from two molecules of putrescine, which can be formed from ornithine or arginine [51, 52]. The use of ^{13}C-^{15}N double-labelled putrescine gave evidence for a further symmetrical intermediate which was then found to be homospermidine. This was proven by feeding experiments with labelled homospermidine which was incorporated into the retronecine moiety of the PAs from *Senecio isatideus* [53–55]. It could be shown that a PA-special enzyme – the homospermidine synthase (HSS) – is essentially involved in the biosynthesis of homospermidine [56–58]. This HSS is responsible for the transfer of the aminobutyl moiety of spermidine into putrescine leading to the symmetric triamine homospermidine; this reaction is NAD$^+$ dependent. Via the 1-(4-aminobutyl)-3,4-dihydro-2*H*-pyrrolium salt the necines trachelanthamidine and further retronecine were generated [59].

Besides, it was shown that trachelanthamidine as well as retronecine were both efficient precursors for the necine otonecine, the base moiety of the PA emiline from *Emilia flammea* [60].

Trachelanthamidine as well as isoretronecanol can be generated from the imminium salt. There exists evidence that the saturated necine rosmarinecine is generated via isoretronecanol and that trachelanthamidine is the precursor for retronecine as well as heliotridine [61]. Isoretronecanol has been shown to be also the precursor of those PAs which have the untypical 8*ß* stereochemistry (instead of 8α) as found in the PAs from *Cynoglossum australe* [62] (Scheme 13.1).

Whereas the biosynthesis of the necines (Scheme 13.1) seems to be clear and intensively investigated, fewer reports can be found for the necic acids. Still some aspects have to be investigated.

In 1966, labelled L-threonine and L-isoleucine were observed to be incorporated into the seneciphyllic acid [63]. Similarly, it was described that labelled DL-valine is a precursor of echimidinic acid [64]. The five-membered angeloylic acid is

found often as a structure part in PAs. L-isoleucine was shown to be a precursor of the angelate component in PAs [65]. Crout et al. reported that in general C_{10} necic acids are derived from isoleucine [66, 67]. This was demonstrated in case of seneciphyllic acid and senecic acid, both forming 12-membered macrocyclic PAs. Monocrotalic acid, the acidic part of monocrotaline – a 11-membered macrocycle – was reported to be built from L-isoleucine and L-threonine [68].

dim ethylhexanedioic acid = senecic acid

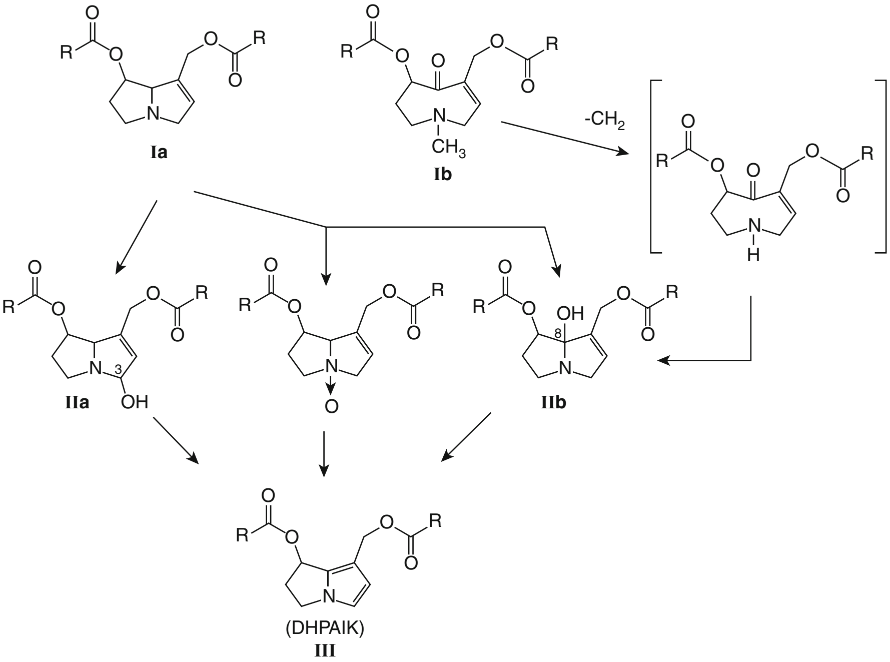
Scheme 13.2 Biosynthetic pathway of senecic acid

Similar findings were reported for the acidic part in the PA strigosine [69] and for angeloylic and tigloylic acid [70]. In the case of the acidic part in the PA monocrotaline, it was shown that not acetate, mevalonate, or glutarate (as reported earlier) are involved but it is only formed via isoleucine [71]. Stereospecific aspects were also studied in the case of senecic and isatinecic acid [72, 73]. The biosynthesis of trichodesmic acid was studied and it was shown that one part of the C_{10} acid was formed by (2*S*)-isoleucine or its biosynthetic precursor (2*S*)-threonine and the other C_5 unit from (2*S*)-leucine or (2*S*)-valine [74]. The complete labeling pattern of senecic acid (the acidic part in the PAs rosmarinine and senecionine) was studied by NMR experiments and it was stated that the biosynthesis of this acid is processed via two molecules of isoleucine (Scheme 13.2) [75].

1.2.1 Metabolic Toxication of PAs

PAs are ester alkaloids derived mainly from the necines retronecine and otonecine. They are carcinogenic, mutagenic, genotoxic, fetotoxic, and teratogenic.

PAs themselves show a more or less low acute toxicity but in vivo they undergo a three-step metabolic toxication process in the liver, which is, as a result, the first target organ for the toxicity.



Scheme 13.3 Metabolism of PAs to Pyrrols

This toxication process is well investigated [12, 75–81].

After oral uptake and absorption of the PAs (Scheme 13.3: Ia and Ib), a hydroxyl-group is introduced adjacent to the nitrogen atom in the necine (position 3 or 8) by the cytochrome P-450 monoxogenase enzyme complex in the liver (Scheme 13.3: IIa and IIb).

These hydroxyl PAs (OHPAs) are unstable and undergo a rapid dehydration to the dehydropyrrolizidine alkaloids (DHPAlk; Scheme 13.3: III). This dehydration results in a second double bond in the necine followed by spontaneous rearrangement to an aromatic pyrrole system III.

PAs occur mainly as their N-oxides in the plants and these cannot be directly converted to the OHPA, but on oral ingestion they are reduced by the gut enzymes or the liver microsomes and NADH or NADPH to the free bases and therefore they show equal toxicity to that of the free bases [82–87].

Otonecine-type PAs (Scheme 13.3: Ib) are metabolized to the OHPAs [80, 88, 89]. These otonecine-PAs possess a methyl function at the nitrogen and a quasi keto function at the bridge carbon 8. After hydroxylation of the N-methyl group it is lost as formaldehyde leaving a NH-function which undergoes condensation with the C8 keto group to produce product IIb (Scheme 13.3) which spontaneously dehydrates to the DHPAlk III.

Scheme 13.4 Metabolism of the dehydropyrrolizidine alkaloids

The metabolites III are able to generate stabilized carbonium ions (Scheme 13.4: IV and VI) by loss of hydroxy groups or ester functions as hydroxyl or acid anions. These carbonium ions can react rapidly with nucleophiles (Scheme 13.4: VII).

In the case of necine-diesters (as shown in Ia and Ib, Scheme 13.3), typical of *Senecio* species, the formation of the reactive carbonium ions is facilitated because the necic acid groups provide good leaving groups that facilitate rapid formation of the carbonium ions IV and VI in high yield. Where one of the hydroxy groups at C7 or C1 of the necine is not esterified, formation of the carbonium ions is not so spontaneous. In these cases, the carbonium ions are most readily formed after protonation of the hydroxyls and loss of H_2O [90].

The metabolites IV and VI react rapidly with nucleophilic groups of proteins and the amino groups of the bases in nucleosides like DNA and RNA which leads to abnormal functions showing finally the veno-occlusive disease (VOD) in which the veins are narrowed. Typical macrocyclic diester PAs (like senecionine, seneciphylline, retrorsine, and senkirkine which are PAs commonly found in *Senecio* species) have been shown to produce liver damage due to cross-linking of DNA [84, 91–99]. In case of PA monoesters (e.g., derived from the necine supinidine which lacks a C7 hydroxyl, Fig. 13.2), cross-linking is not possible and they show a lower toxic potential. It has also been shown that the nucleophilic activity at C7 is higher than at C9 resulting in the primary nucleophilic attack at C7 followed by an attack at C9 (Scheme 13.4) [43].

As shown, the DHPAlks can also react with SH groups found in more soluble components like glutathione and cysteine (Scheme 13.4: VIII). High levels of glutathione and cysteine therefore reduce the toxic potential of PAs [88, 100–102].

Furthermore, hydrolysis can take place where the DHPAlks (Scheme 13.4) yield dehydronecine alcohols (DHNecs) (Scheme 13.4: IX) which are more water soluble and less reactive like the DHPAlks but still display a moderate level of alkylating activity [103, 104]. This higher water solubility and lower reactivity can lead to the escape from the liver tissue and subsequent reaction in other organs [12, 105, 106]. DHNecs like dehydroretronecine and dehydroheliotridine have also been shown to produce rhabdomyosarcoma, skin, liver, and lung tumors [24, 107–110].

1.2.2 Detoxication of PA

As well as the metabolic activation, detoxication of PAs also occurs in vivo: Hydrolysis of the ester bonds in PAs from type Ia or Ib by esterases leads to necic acids and to the free necines. Both are nontoxic products and – on account of their higher water solubility – can be renally excreted. The rate of hydrolysis is dependent on the level of steric hindrance of the ester linkages; and it has been shown that the more highly branched necic acids are more resistant to hydrolysis [43, 111]. This means that macrocyclic diesters with more complex acid moieties are more hazardous on account of their lower rate of hydrolytic detoxication.

The N-oxides of PAs (the form occurring most commonly in plant sources) are highly water soluble and can therefore be renally excreted. Besides their natural occurrence, N-oxidation of PAs also takes place in the liver and can be seen as a detoxication process (Scheme 13.3) [76, 78, 82, 112, 113]. However, it has been shown that the N-oxides – besides excretion – can be converted by dehydration or by acetylation followed by elimination of acetic acid to the DHPAlk (Scheme 13.3: III) [43, 90].

In conclusion, it can be stated that the toxicity level of different PAs in non-ruminants is dependent on the following three aspects:

- The efficiency of metabolic activation to form the key intermediate III (Scheme 13.3)
- The efficiency of ester hydrolysis to form nontoxic and water-soluble necines and necic acids
- The efficiency of N-oxidation and excretion via urine

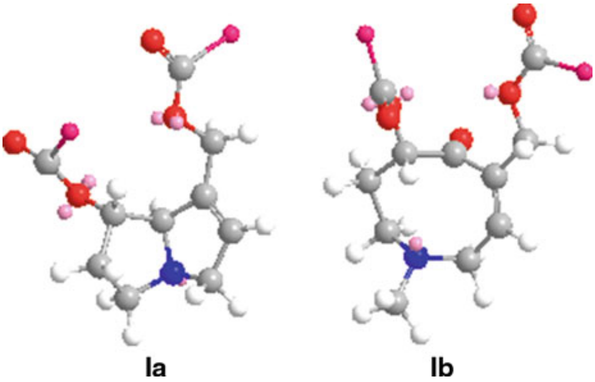

Fig. 13.4 *X-rays of Ia and Ib*

1.2.3 Structure and Toxicity

As mentioned, the key fragment didehydropyrrolizidine (e.g., III) is also generated from pyrrolizidine alkaloids of the otonecine type (e.g., Ib, Scheme 13.3).

These otonecine derivatives do not show a C8-N bond but possess a keto function at C8 and a methyl group at the nitrogen atom. Surprisingly, these seco alkaloids are of identical toxicity as the PA of type Ia (1,2-dehydro-retronecine and heliotridine esters).

On the other hand, for energetic reasons, these seco compounds should occur in a different necine conformation than type Ia PA: The missing C8-N bond should lead to a stable eight-membered macrocycle which generally prevents the metabolization via an intermediate to IIb (Scheme 13.4).

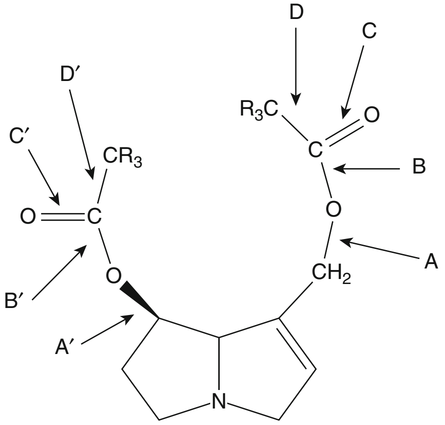
Molecular modeling experiments prove this assumption and show the energy minimized structure as depicted in Fig. 13.3 (energy minimization: Chem 3D ultra; V. 10.0; Cambridge Soft).

Interpretation of the X-ray structure analysis data helps to explain the identical toxicity of PA of type Ia and Ib: In all nine otonecine-type alkaloids measured to date, a necine conformation was found which is identical to those found in those having the C8-N bond (type Ia).

Both the distances between C8 and N are similar and equal values can be found for the plane angles built between plane C1-C3-N-C8 and plane C7-C5-N-C8 (∼125°). This indicates that the seco 1,2-dehydroesters do not exist in the optimal, energy minimized form (Ib, Fig. 13.4) but are of an equal conformation to PA of type Ia, which finally enables the metabolization as shown in Scheme 13.3.

Furthermore, X-ray data show that the dedihydro metabolites (e.g., III, Scheme 13.3) derived from 1,2-dehydrodiester have a high toxic potential compared with the low or missing toxicity of the monoesters of retronecine or heliotridine. As already mentioned, a possible detoxification mechanism is the hydrolysis of the ester bindings by esterases and the subsequent building of dehydronecine (IX, Scheme 13.4) which – due to their higher water solubility – can be easily excreted renally.

Fig. 13.5 Bonds in PAs



On the other hand, the metabolization to C7 as well as to C9 carbonium ions (especially the speed rate of this metabolization) and the subsequent reaction with nucleophiles are seen as a key step concerning the level of toxicity. The concrete binding situation concerning the ester function can be found analyzing the X-ray data. Interpretation of the bond lengths shown in Fig. 13.5 leads to the following results:

In pyrrolizidine alkaloids of type Ia and Ib (1,2-dehydropyrrolizidine diesters) the C-O bonds A and A´ occur in a normal range of 1.45 Å; the following C-O bonds B and B´ are considerably shortened, whereas the keto functions C and C´ show a moderate shortening. The C-C bonds D and D´ show – similar to A and A´ – normal values of about 1.54 Å.

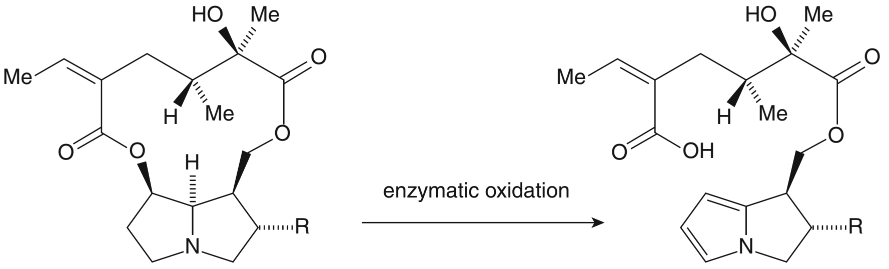
In contrast to these findings, the data for monoesters with retronecine or heliotridine give evidence of a different situation: Here, the A and A´ (C9 as well as C7) bonds are elongated and the corresponding keto bonds C or C´ are of nearly ideal length (1.21 Å).

These results show that in 1,2-dehydro diesters, the ester functions are a conjugated system leading to the conclusion that the bonds C9-O and C7-O (= A and A´) are the target breaking points within the molecule, which makes possible a quick and easy metabolization and further reaction with nucleophiles as described in Scheme 13.4.

Contrary to that, in PA of 1,2-dehydro monoesters, more stable ester bonds are found (no conjugation), which leads to the fact that the building of the didehydrometabolites is more difficult and time consuming. In this case, a hydrolysis by esterases can take place in higher amounts what leads to the detoxification via dehydronecines, which explains the missing or low toxicity of 1,2-dehydro monoester.

1.2.4 Metabolism of 1,2-Saturated Pyrrolizidine Alkaloids

Metabolism of saturated pyrrolizidine alkaloids (necic acid esters of platynecine, hastanecine, rosmarinecine and isoretronecanol (Fig. 13.1)) by mammals has not yet been extensively studied, in part because the saturated ester alkaloids and their necines do not display mammalian toxicity.



R = H : Platyphylline
R = OH : Rosmarinine

Fig. 13.6 Metabolism of saturated PAs

While 1,2-dehydropyrrolizidine alkaloids are metabolized by liver P-450 isozymes into hazardous dihydropyrrolizines (e.g., III) with a pyrrolic A ring, saturated pyrrolizidine alkaloids produce nontoxic, metabolites [79, 111]. The saturated alkaloids platyphylline and rosmarinine (Fig. 13.6), for example, are converted by liver microsomes into pyrrolic metabolites with an aromatic B-ring [79]. These are devoid of biological alkylating properties and are nontoxic.

2 PA Toxicity in Humans

PA poisoning of humans can be described by three dose-related levels: acute, subacute, and chronic. These levels can be progressive resulting in irreversible chronic toxic effects [12, 99, 106, 110, 114–116].

On account of the low toxicity of the PAs themselves, acute poisoning has been reported only in very rare cases; it occurs only in infants and neonates due to their higher susceptibility for a PA poisoning. It is characterized by hemorrhagic necrosis, hepatomegaly, and ascites; death is caused by liver failure [12, 106, 110, 115].

Subacute levels are characterized by hepatomegaly and recurrent ascites; endothelial proliferation and medial hypertrophy leading to an occlusion of hepatic veins, resulting in the so-called veno-occlusive disease (VOD) which can be seen as a characteristic histological sign for PA poisoning [12, 99, 106, 110, 115]. The VOD causes centrilobular congestion, necrosis, fibrosis, and liver cirrhosis, the end-stage of chronic PA intoxication.

As well as the liver VOD, other organs can be affected by PAs. It has been shown that the pyrrolic metabolites (DHPAlks and DHNecs) can escape from the liver into pulmonary arterioles where they can produce damages similar to the VOD changes in the liver [115]. It could be shown that from 62 tested PAs all can produce (dose-dependent) lung lesions [111] and it is speculated that pulmonary damage results from long-term and low-level exposure to PAs [12, 115].

PA intoxication in humans is not only related to the amount and the duration of the exposure but also to age and gender: Males react more sensitive than females, and fetuses and children (especially neonates or infants) show the highest sensitivity to PA poisoning: In 2003, it was shown that the daily uptake of ~ 7 μg PA (from a herbal spice containing comfrey) during pregnancy did not show a toxic effect in the mother's liver but damaged the fetal liver in such a way that the newborn child died after 2 days [117].

It has also been observed that cofactors can exacerbate the PA poisoning: liver damaging agents, bacterial, or viral infections but also medical drugs like barbiturates or metals like copper or mycotoxins like aflatoxins can increase the severity and likelihood of PA liver damage [42, 118–122].

There is a large number of reports in the literature about different liver diseases (mainly VOD) possibly connected with PA poisoning. But in most cases, the connection could not be proven because the outbreak of the liver disease and a possible ingestion of PA-containing material were often separated by a long time period.

3 Conclusion

PAs are widespread in the plant kingdom. They occur in a great variety of different structures. They show no physiological and/or pharmacological properties, but they are of importance on account of possible severe side effects. These side effects are dependent on their chemical structures and range from low or missing toxicity up to strong severe and hazardous problems. PAs themselves are more or less nontoxic but undergo a metabolic toxication process. As a result cancerogenic, mutagenic, teratogenic, and fetotoxic effects can be observed. Many episodes are reported describing intoxications in humans, sometimes even epidemic. These cases were caused mainly by contaminations of food and feed by PA-containing plant material or by the uncontrolled use of herbal medical preparations. Therefore, to avoid those contaminations, special efforts should be made on a global scale to improve food control management.

Abstract

Quinolizidine alkaloids (QAs) are usually known as lupin alkaloids because they mainly occur in lupin species and other plants of the Genisteae tribe. They are secondary metabolites synthesized by plants from lysine, for defense against pathogens and other predators. QAs are biosynthesized in green tissues of the plant, transported via phloem and stored in all organs of the plant, including seeds. QAs content depends on genotype, presence of pathogens, and

pedo-climatic conditions such as environmental effects and soil characteristics. More than 170 QAs have been identified in different *Lupinus* species, being the alkaloid pattern highly variable among species; sparteine and lupanine are the most common ones. QAs show neurotoxicity and for this reason Food Authorities of some countries have fixed a limit of 200 mg kg^{-1} of total QAs in lupin seeds and foods. The level of QAs in lupin seeds can be reduced by debittering processes involving soaking or washing with water; moreover, some lupin varieties producing low levels of QAs have been selected and bred.

1 Introduction

Quinolizidine alkaloids (QAs) are plant secondary metabolites synthesized as part of a defense strategy against predators, such as herbivores and pathogen microorganisms [1–3]. They also have allelopathic functions in relation to a biocenosis, that is, they can be used to influence other plants [2]. Moreover QAs, together with basic amino acids and biogenic polyamines, are nitrogen reserves in plants [3–5].

Their chemical structure is based on quinolizidine ring (Fig. 14.1).

They are prominent among species of the "genistoid alliance," group of legumes, tribes Genisteae, Crotalarieae, Podalyrieae, Liparieae, Thermopsideae, Euchresteae, Brongniarieae, and Sophoreae [6]. QAs are commonly referred to as "lupin alkaloids," since they occur throughout the species of the genus *Lupinus* that belongs to the Fabaceae (or Leguminosae) family, Genisteae tribe. They are the main antinutritional factors that confer unpalatability, in particular bitter taste, and toxicity to lupin seeds.

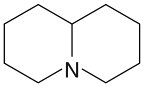

Fig. 14.1 Quinolizidine ring structure

Lupin is a leguminous plant usually used for feed or manure in agriculture practice for its nitrogen fixation capability. Lupin seeds have comparable nutritive characteristics, especially protein content (30–40 %), in respect to soybean. For this reason lupin has been discussed as possible alternative of soybean in human foodstuffs.

From the genus *Lupinus* more than 400 species are known, but only four have been domesticated and are of agronomic and commercial interest: *Lupinus albus* (white lupin), *Lupinus angustifolius* (narrow leaf or blue lupin), *Lupinus luteus* (yellow lupin), and *Lupinus mutabilis* (Andean lupin).

Lupins are mainly distributed in South and North America, whereas only 12 taxa occur in Europe and North Africa. In Europe, especially *L. albus* and *L. luteus* are used as green forage, as manure or are intended for human nutrition. In Australia the main lupin species is *L. angustifolius*.

L. albus plant is annual, more or less pubescent, 30–120 cm high, and has a wide distribution in the Mediterranean regions. It is widely spread as wild plant throughout the southern Balkans, the Italian islands of Sicily and Sardinia, the French island of Corsica, and the Aegean Sea, as well as in Palestine and western Turkey. It occurs in meadows, pastures, and grassy slopes, predominantly on sandy and acid soils. It is cultivated over all the Mediterranean regions and also in Egypt, Sudan, Ethiopia, Syria, Central and Western Europe, the USA and South America, Tropical and Southern Africa.

L. angustifolius is native to Europa, Asia, and Northern Africa, but it is cultivated also in North America and Australia, that is nowadays the major producing country.

L. luteus is known as European yellow lupine. It is native to the Mediterranean regions of Southern Europe; it grows in the Mediterranean countries, including Morocco, Portugal, Spain, Italy, Greece, and Egypt.

L. mutabilis is cultivated in tropical and subtropical zones and it is still cultivated using traditional methods by the native peoples of Ecuador, Peru, and Bolivia.

Each of the about 450 lupin species which have been identified differs in both content and composition of QAs. The problem of great difference of QAs content is further complicated as it can fluctuate among the different genetic varieties of the same species. QAs content depends also from environmental conditions, soil characteristics, drought, etc. Moreover, substantial variations are found in the alkaloid patterns of different organs: seeds, leaves, pods, roots, flowers.

1.1 Differences Among Quinolizidine Alkaloids

More than 170 alkaloids of the quinolizidine group have been identified in different *Lupinus* species [7]. They can be divided into different classes in according to their chemical structure: sparteine and its derivatives (Fig. 14.2), lupanine and its derivatives

(Fig. 14.3), angustifoline and its derivatives (Fig. 14.4), multiflorine and its derivatives (Fig. 14.5), aphylline and its derivatives (Fig. 14.6), lupinine (Fig. 14.7).

Sparteine is a tetracyclic QA formed by two quinolizidine rings; lupanine is similar to sparteine but it has a carbonyl group on the C1 of the first ring. Its main derivative is hydroxylupanine, in particular 13-hydroxylupanine (3-hydroxylupanine is less abundant) that is the precursor of a large number of esters. Angustifoline, tetrahydrorhombifoline, and albine (Fig. 14.4) are tricyclic molecules because the fourth ring does not exist. Multiflorine (Fig. 14.5) is characterized by a conjugated carbonyl group on the third carbon atom of the first ring. Aphylline and its derivatives are characterized by a carbonyl group on the second ring of the molecule (Fig. 14.6).

Tetracyclic QAs such as sparteine (Fig. 14.2), lupanine, and 13α-hydroxylupanine (Fig. 14.3) are the major alkaloids present in almost all *Lupinus* species [8, 9].

Angustifoline (Fig. 14.4) occurs as a major alkaloid only in some lupin species such as *L. angustifolius*. Quite often angustifoline is seen as a minor component in Old World species (*L. albus*, *L. micranthus*), in South American species (*L. mutabilis*, *L. gibertianus*), and in North American species (*L. elegans*, *L. leucophyllus*, *L. perennis*).

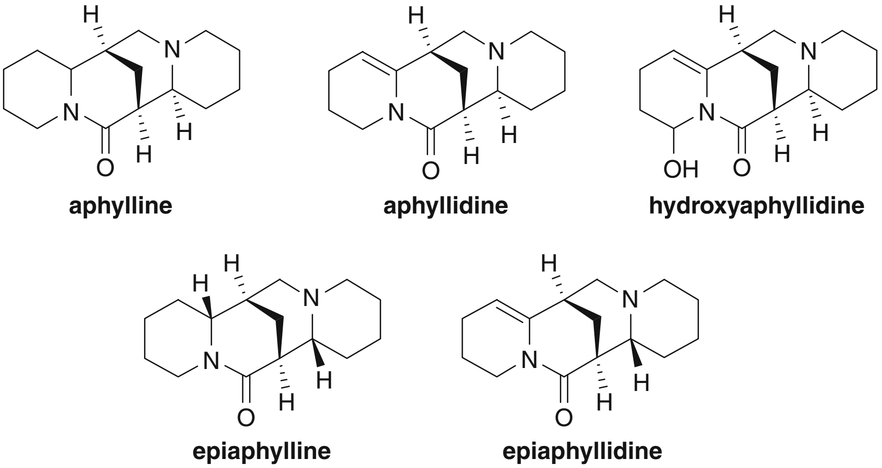

Fig. 14.6 Chemical structure of aphylline and its derivatives

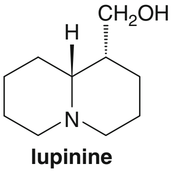

Fig. 14.7 Chemical structure of lupinine

Multiflorine (Fig. 14.5) and its derivatives have a restricted distribution and were found in Old World lupins such as *L. albus L. atlanticus*, *L. cosentinii*, *L. varius*, and also in some American taxa such as *L. albescens*; North American lupins do not accumulate these alkaloids in substantial amounts.

Aphylline (Fig. 14.6) and its derivatives occur as major alkaloids in a limited number of North American lupins such as *L. campestris*, *L. argenteus*, and *L. leucophyllus*.

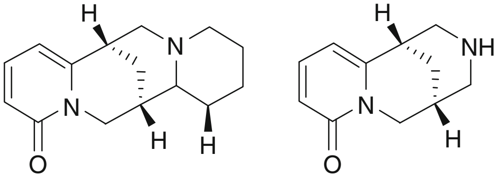
Lupinine (Fig. 14.7), a byciclic QA, is characteristic of *L. luteus* and it is abundant in Old World lupins such as *L. luteus*, *L. hispanicus*, *L. cosentinii*, *L. pilosus*, and *L. varius*.

QAs of the α-pyridone skeleton such as anagyrine and cytisine (Fig. 14.8) are typical for many genera of Papilionoideae, but usually absent in lupins, even if some few taxa can accumulate them.

Some lupin taxa produce also piperidine alkaloids such as ammodendrine (Fig. 14.9) that is abundant in *L. elegans*, *L. sulphureus*, and *L. bakeri*.

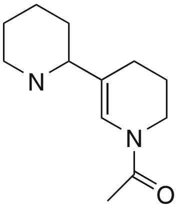
1.2 Alkaloids Fingerprint in Different Lupin Species

The alkaloid profiles are typical and characteristic for a given lupin species producing the so-called alkaloid fingerprint.



anagyrine **cytisine**

Fig. 14.8 Chemical structure of anagyrine and cytisine



ammodendrine

Fig. 14.9 Chemical structure of ammodendrine

Generally, Old World and South American lupins have profiles without much intraspecific variation, whereas a lot of lupins from North America present a high degree of intraspecific variation [10].

Great differences can also occur among different organs of the plant such as seeds and leaves (see the Sect. 5) [8].

A work by Wink and coworkers (1995) describes the complete alkaloid pattern of the main lupin species [8]. The QAs composition of the four main lupin species is reported above.

The main QAs of *L. albus* seeds are albine, lupanine, multiflorine, 13α-hydroxylupanine; minor quantities of sparteine, tetrahydrocytisine, isoangustifoline, tetrahydrorhombifoline, angustifoline, α-isolupanine, 5,6-dehydrolupanine, 11,12-seco-12,13-didehydromultiflorine (formerly *N*-methylalbine), 17-oxolupanine, 13α-hydroxymultiflorine, and different esters of 13-hydroxylupanine such as 13-propyloxylupanine, 13-isobutyryloxylupanine, 13-butyryloxylupanine, 13-isovaleroyloxylupanine, 13-angeloyloxylupanine, 13-tigloyloxylupanine, and of 13-hydroxymultiflorine such as 13-angeloyloxymultiflorine, 13-tigloyloxymultiflorine are detected [8].

In *L. angustifolius* seeds the main QAs are angustifoline, lupanine, 13α-hydroxylupanine; minor quantities of sparteine, isoangustifoline, tetrahydrorhombifoline, α-isolupanine, 17-oxolupanine are usually detected [8].

The main QAs in *L. luteus* are lupinine and its esters (E/Z isomers of (4′-hydroxy-3′-methoxycinnamoyl) lupinine) and ((4′-hydroxycinnamoyl)lupinine) and sparteine; minor amounts of β-isosparteine, tetrahydrorhombifoline, 17-oxosparteine, lupanine, feruloyllupinine are present [8, 11].

In *L. mutabilis* seeds there are sparteine, 11,12-dehydrosparteine, ammodendrine, tetrahydrorhombifoline, angustifoline, lupanine, 3β-hydroxylupanine (formerly nuttaline or 4-hydroxylupanine), 13α-hydroxylupanine, 13α-angeloyloxylupanine, 13α-tigloyloxylupanine as main alkaloids. Minor amounts of 17-oxosparteine, α-isolupanine, multiflorine, 3-propionyloxylupanine, 13-benzoyloxylupanine, 3,13-dihydroxylupanine, *cis* 13α-cinnamoyloxylupanine, *trans* 13α-cinnamoyloxylupanine are detected [8, 12].

1.3 Alkaloid-Poor and Alkaloid-Rich Lupin Species

Some cultivars belonging to *L. albus*, *L. angustifolius*, *L. luteus*, and *L. mutabilis* have been selected and bred to produce varieties with low concentration of QAs and, consequently, produce seeds that are less toxic and more palatable. These varieties are also known in literature as low-alkaloid or feed or alkaloid-free or sweet lupin, definition that was originally based on their taste. These varieties contain low levels of QAs in vegetative parts as well as seed and, not surprisingly, have considerably lower resistance to disease and predation compared with "bitter," wild germplasm [3].

The bitter and sweet cultivars are similar in the case of traits such as flowering time and pod shattering, but differ for the alkaloids content. The bitter and the sweet cultivars have a similar background, but the sweet cultivars are homozygous for the mutant iuc allele, which results in low-alkaloid phenotypes [13].

In agriculture practice, the QAs content of 0.05 % DM (Dry Matter) of seed is taken as the division between alkaloid-rich "bitter" and alkaloid-poor "sweet" white lupins [14].

In the case of white lupin, von Baer and Perez [14] proposed a classification according to which the alkaloid content of the sweet lupin is less than 0.05 % DM, the semisweet is in the range 0.05–0.10 % DM, the semibitter in the range 0.10–0.20 % DM, and the bitter lupin over 0.2 % DM. This definition of "sweet," however, appears to be rather misleading from a toxicological viewpoint [15].

Considering all the physiological experience up to now, it was proposed that for human consumption lupin seed should not exceed an alkaloid content of 0.02 % [16].

The Food Authorities of some countries, such as Australia and New Zealand [17], France [18], and Great Britain [19] have decided to fix at 0.2 mg/g the minimal risk level (MRL) of alkaloids in lupin flour and food products (see Sect. 4).

The total QAs content is only a crude indicator and it is not enough to induce whether a particular lupin is fit for direct use in human nutrition. In fact it is important to know the content of particular alkaloids such as anagyrine (Fig. 14.8), cytisine (Fig. 14.8), and ammodendrine (Fig. 14.9). Anagyrine and cytisine are α-pyridone alkaloids, whereas ammodendrine is a piperidine alkaloid. They are usually extracted and analyzed with quinolizidine ones. All of them have shown teratogenic activity (see Sect. 4) [8].

Considering the great variability of the concentration of the alkaloids in commercial cultivars, the increasing use of lupin-based ingredients in food manufacturing encourages to establish a homogeneous regulation at least in all countries were lupin is produced or utilized.

2 Biosynthesis

In general, alkaloids derive from the metabolism of amino acids such as phenylalanine (Phe), tyrosine (Tyr), tryptophan (Trp), ornitine (Orn), or lysine (Lys). Quinolizidine alkaloids derived from L-lysine. Its decarboxylation by means of the enzyme lysine decarboxylase gives cadaverine (Cad), the first detectable intermediate of this biosynthetic pathway (Scheme 14.1).

Subsequently, the quinolizidine byciclic system is formed from the cyclization of two molecules of cadaverine; from this intermediate all the bicyclic alkaloids (e.g., lupinine) are formed.

The cyclization of three or more molecules of cadaverine yields the formation of tetracyclic alkaloids (e.g., lupanine and sparteine). These cyclic alkaloids are then transformed by cellular enzymes through dehydrogenation, oxygenation, hydroxylation, glycosydation, or esterification to yield a variety of alkaloids [20–23].

QAs are biosynthesized in the green tissues of the plant, in the mesophyll chloroplasts, then transported via the phloem and stored in all organs of the plant, including seeds in which they cause the bitter taste.

Recently, the biochemical localization of two acyltransferases that catalyze the last two acylations of (+)-p-coumaroylepilupinine and (−)-13α-tigloyloxymultiflorine showed that one enzyme occurs in the cytoplasm, whereas the other resides in the mitochondria of *L. albus* [24].

Although the quinolizidine nucleus appears to be synthesized in the stroma of leaf chloroplasts, subsequent modifications can occur only after alkaloid intermediates are transported to the cytosol and mitochondria. QAs are thought to accumulate in vacuoles of lupin epidermal cells, where their defensive properties are most effective [24].

Like many secondary metabolites, QAs are not the end product of the metabolism, but show a high degree of turnover. As alkaloid synthesis takes place in the chloroplasts, it follows a diurnal light-regulated cycle, with a stimulated period during the day and low values during the night [25].

Then they are transported via the phloem and stored in vacuoles in all the organs of the plant [26], preferentially in epidermal and subepidermal tissues of stems and leaves; the seeds are especially rich in alkaloids. Alkaloids tend to disappear during maturation from all parts except the seeds; the concentration dropped 90 % during senescence.

2.1 Differences in Biosynthesis in Alkaloid-Poor and Alkaloid-Rich Lupin Plants

The total content of QAs in alkaloid-poor plants is uniformly lower than that of the bitter ones, suggesting that the differences of alkaloid pattern between bitter and sweet plants are quantitative, but not qualitative.

Scheme 14.1 Biosynthetic pathway of quinolizidine alkaloids

The limiting step of the biosynthetic pathway in sweet plants, causing a sweet phenotype, is the reaction from cadaverine to the first cyclic alkaloid in both *L. luteus* and *L. albus* [20].

It is not surprising that the concentration of lysine does not change in bitter and sweet plants because protein-amino acid biosynthesis is strictly regulated in the plant cells.

Contents of cadaverine are much lower than those of lysine and are similar in bitter and sweet plants. This suggests that lysine decarboxylase responsible for the formation of cadaverine is controlled in the same manner and does not substantially change its activity in bitter and sweet plants.

The enzyme or the enzymes involved in the formation of initial cyclic alkaloids (lupinine and lupanine type) are suppressed in the sweet plants to cause low alkaloid accumulation. The same amounts of acyltransferase activities of post-ring closure steps are detected in sweet plants as well as in bitter ones, while the concentrations of lupinine and 13α-hydroxylupanine decreased in sweet plants [27].

These results suggest that the suppressed step for formation of alkaloids in sweet plants is the ring closure reaction from cadaverine to initial bicyclic and tetracyclic alkaloids, but neither the steps prior to the formation of cadaverine nor the specific reaction of cyclic alkaloids.

Moreover enzymatic activities of a post-ring cyclization step are still intact in sweet plants as well in the bitter ones [20, 27].

3 Factors Influencing Quinolizidine Alkaloids Synthesis

QAs are constitutive metabolites and their presence and abundance can vary during growth stage and depend on plant organ [1, 28, 29].

Seed alkaloids concentration may fluctuate depending both on genotype and environment and important variations in alkaloid content between different lots of lupin can be unpredictable [15, 30]. This variability is a potential hindrance to the wider use of lupin for human consumption and a toxicological topic for consumers safety.

During the vegetation period, alkaloid content undergoes changes, the peak coinciding with the flowering. At the end of vegetation, alkaloids accumulate mainly in seeds.

Some factors can affect alkaloid production: environmental effects such as drought, state of sunlight, temperature, season, site elevation, soil characteristics (moisture and levels of fertilizing), or presence of pathogens, such as insects or herbivores.

Significant environmental effects on QAs content are reported both on *L. angustifolius* [31] and *L. albus* cultivars [15]. In the first paper, large environmental effects were reported, substantially unrelated to rainfall amount. In particular, early drought stress tends to increase the alkaloid content, whereas terminal stress has the opposite effect; these effects are mainly observed when stress was present during the vegetative growth stage [32]. The results gained in Boschin et al. [15] on 48 ecotypes from 11 regions, show that the selective pressure that leads to greater or lower alkaloid content, varied markedly within each region.

Regarding sweet cultivars, a major environmental effect was consistent between cultivars grown in the subcontinental climate site relative to the Mediterranean location. The main difference between these cropping environments concerned the extent of low temperatures during winter [15].

One of the factors that may affect seed alkaloids content is soil nutrient deficiency. For example, K deficiency may induce high alkaloid contents in seeds both of sweet and bitter varieties, while it seems not to affect alkaloid production in the vegetative portions of the plant [33].

High alkaloid levels of seeds of both sweet and bitter lupins grown in glass house are observed, compared with seeds produced in field experiments. This may be due to the synergistic effect of other environmental stresses, such as light energy and air temperatures in the glasshouse, together with the limited rooting space available in the pots [33].

Also the differences in nitrogen forms used as fertilizer can influence alkaloid production [34]. In *L. albus*, differences are observed between sweet and bitter cultivars in relation to the different forms of nitrogen used for soil fertilization. For a sweet variety, the highest accumulation is observed when nitrogen is uptaken in NO_3^-, NH_4^+, or N_2 form; whereas, for other N forms, the alkaloid production is lower. On the contrary for a bitter cultivar, only uptaken in NO_3^- or N form cause less alkaloid production than the control [34].

Soil P deficiency reduced seed alkaloid concentration in sweet, but not in bitter varieties [35]. Furthermore, sweet varieties change their alkaloid pattern mimicking the bitter ones. That is 13α-hydroxylupanine content is larger than lupanine one. With adequate or abundant P, lupanine is the predominant alkaloid in sweet varieties.

Germination involves a great number of physiological changes, including synthesis, degradation, and transformation of different compounds. This process can reduce the presence of antinutrients such as α-galactosides or phytic acid in legume seeds, but also alkaloid content [29].

During germination, esterification reactions take place. In *L. albus*, for example, levels of albine and 13α-hydroxylupanine decreased, whereas lupanine and its ester 13α-tigloyloxylupanine increased [21]; the latter one also increased during germination of *L. angustifolius*.

Lupanine is transformed into 13α-hydroxylupanine both in *L. angustifolius* and in *L. albus*, but the reaction is more active in the first one. In *L. albus*, the synthesis of lupanine is more intense than its transformation, since its level increase during germination. The decrease of 13α-hydroxylupanine in *L. albus* and *L. angustifolius* indicates a subsequent progressive degradation of this compound during the germination process.

In *L. angustifolius*, lupanine is highly transformed into angustifoline, isoangustifoline and its direct derivatives, 13α-hydroxylupanine, and 5,6-dehydrolupanine.

On the contrary, in *L. albus*, lupanine content is very high with less transformation into its derivatives [29].

In *L. campestris*, hydroxyaphylline and hydroxyaphyllidine increased at the expense of epihydroaphylline and dehydroepihydroxyaphylline. The optimal germination period seems to be three days in order to minimize the presence of antinutritive factors and avoid formation of quinolizidine esters [36].

Defensive chemicals, mainly secondary metabolites, can be constitutively present, but can be de novo synthesized or their concentration can increase, triggered by external stimuli, that is, chemical induction. Traditional bitter varieties have inductive increases in their alkaloid concentration after damage. In particular, lupanine is the most abundant alkaloid also after the induction, whereas minor alkaloids changed scarcely after damage.

QAs production can be stimulated by applying abiotic, for example, $CuCl_2$, or biotic elicitors, so-called phytoalexins, prepared, for example, from cells of fungal mycelium [37].

Changes in alkaloid profile have been detected for *L. albus* and *L. angustifolius* cultivars as a response to mechanical damage, such as biomass removal mimicking large herbivore action on aerial parts of the plants [38]. Both sweet and bitter varieties showed an increase in total alkaloids content, but sweet varieties increase is greater than bitter varieties one: from 58.8 % to 67.9 % versus from 22 % to 32.8 %, respectively.

Seed multiplication is exposed to risk of genetic shift toward higher alkaloid content due to pollen flow from bitter material, which increases over generations of multiplication as a consequence of higher advantage of greater bitterness under natural selection. In this context, the need to carefully monitor the alkaloid content of seeds is of outmost importance. This control is necessary not only in production lots, but also across the various stages of seed multiplication of the varieties; it is also important to consider the different environmental conditions of their cultivation.

4 Toxicity

The majority of the acute studies has been performed on the common lupin alkaloids sparteine and lupanine [39–41]. They both display moderate acute toxicity, the former being the more toxic one. The observed symptoms suggest that alkaloids cause neurological effects leading to loss of motor coordination and muscular control. The effects are generally reversible.

Lupanine and other lupin alkaloids show moderate toxicity in vertebrates. In mammals, acute intoxications with sparteine, lupanine, or angustifoline cause convulsions, shaking and trembling, and death from respiratory and cardiac arrest [15].

QAs exert a blocking effect on the nicotinic cholinergic receptor and they are weak antagonists at the muscarinic cholinergic receptor [42], displaying similar agonistic activities as the alkaloid nicotine. Neurological (weakness, dizziness, mydriasis, anxiety, confusion, malaise, loss of coordination, visual disturbances, and dry mouth), cardiovascular (dysrhythmias) and gastrointestinal (nausea, vomiting) symptoms are due to these anticholinergic effects.

Some QAs can inhibit Na^+ and K^+ channels, inducing gastrointestinal, nervous, and respiratory symptoms in humans and animals.

Sparteine and lupanine, when administered by intravenous rout, inhibit ganglionic transmission of the sympathetic nervous system, assessing their neurotoxicity [17].

L. angustifolius alkaloids have been found to be neither carcinogenic nor teratogenic and their LD_{50} levels are above the levels that would be consumed in a normal diet.

In a 90-day feeding study, rats were fed with diets supplemented with 20 % lupin protein from sweet varieties of *L. albus* and *L. luteus*, containing 0.05 % (0.5 g kg^{-1}) and 0.09 % (0.9 g kg^{-1}) of lupin alkaloids, respectively. The actual levels of alkaloids present in the diets were not reported, but taking into account the protein levels in sweet lupins of 35 % and 39 % and assuming full incorporation of the alkaloids into the diet, the lupin flour dietary levels would amount to about 290 and 460 mg alkaloids kg^{-1} diet, respectively, resulting in dietary intakes of about 14.5 and 23 mg lupin alkaloids kg^{-1} bw day^{-1}. No adverse effects were observed in terms of food intake, organ weight, and microscopic examinations [43].

The acute oral LD_{50} (lethal dose for 50 % of the population) values in rats for lupanine is 1,664 mg kg^{-1} bw [44].

At high doses, lupanine showed a moderate acute oral toxicity due to neurological effects leading to loss of motor coordination and muscular control; in mammals, the intoxication is characterized by trembling, shaking, excitation, and convulsion [45].

Effects on human health reflecting neurological, cardiovascular, or gastrointestinal symptoms can be observed either if lupin seeds are eaten unripe or not debittered. Symptoms of intoxication after ingestion of lupin seeds with high alkaloids content appear 1–14 h after consumption and include dry mouth, muscular weakness, disturbed balance, sweating, palpitation, blurred vision, mydriasis (i.e., dilated pupils), urine retention, gastric and intestinal troubles, and abundant ventricular extrasystoles [45].

A few poisoning cases have been reported in literature, all related to the consumption of raw lupin seeds [46, 47]. There are some cases of acute toxicity in humans who ate lupin beans, which had not been previously debittered. These subjects suffered from blurry vision, dry mouth, facial flushing, and confusion [46, 47].

Marquez et al. [48] reported a single case of a young man who drank 0.5 L of water that had been used for lupin seeds debittering process. He suffered from sudden weakness, palpitations, extrasystoles, and different anticholinergic symptoms.

Very little research has been done on chronic QAs toxicity. It is generally assumed that, being them water soluble, an organism can easily eliminate them and therefore prevent any cumulative toxic effect. Little data is available on the metabolism and excretion of alkaloids in animals and humans. In one human study, orally administered lupanine was excreted unchanged in the urine with a half-life of 6–7 h [17].

A study on rats fed with *L. albus* flour (with 0.025 % lupanine) for two generations showed no harmful effects. In addition, rats which survive a lethal dose, recover completely, manifest no signs of clinical abnormality and subsequently attain normal weight and physiological maturity, comparable to those of untreated rats [49].

Tolerable daily intake (TDI) values for QAs have not been established, although taking the NOAEL (no observed adverse effect level) of 12.5 mg kg^{-1} bw day^{-1} and a MOS (margin of safety) of 100, it may conclude that a daily intake of 0.125 mg lupin alkaloids kg^{-1} bw day^{-1} would not be of safety concern.

This value is in the same range as the provisional tolerable daily intake of 0.035 mg lupin alkaloids kg^{-1} bw day^{-1} derived by ANZFA (Australia and New Zealand Food Authority) based on traditional use of lupin seeds. ANZFA concluded that traditional use of lupin seeds in Europe suggests that a daily dose of 0.35 mg lupin alkaloids kg^{-1} bw (20 mg lupin alkaloids day^{-1}) can be tolerated in human adults without adverse effects. If an uncertainty factor of 10 is applied to account for the uncertainties in the data and particularly to take into account likely human variation, the provisional tolerable daily intake for humans is 0.035 mg lupin alkaloids kg^{-1} bw day^{-1} [17].

This would imply that for a 60 kg person, a daily intake of 2.1–7.5 mg alkaloids can be tolerated.

Given that the seeds of modern cultivars contain 200 mg alkaloids kg^{-1}, this would imply a daily consumption of at most 10.7–37.2 g of sweet lupin seeds. This estimate suggests that good quality control of lupin-containing foods is necessary.

Regulations in France [18], Great Britain [19], and Australia and New Zealand [17] demand to comply with a maximum contamination of 200 μg g^{-1} (i.e., mg kg^{-1}) alkaloids in lupin-based foods.

A different matter is the toxicity of other alkaloids occurring in some lupin species like α-pyridone alkaloids, such as cytisine and anagyrine, or piperidine alkaloids, such as ammodendrine. All of them have a high toxicity, mainly teratogenicity [50]. In particular, anagyrine and ammodendrine are responsible of the so-called crooked calf disease.

Historically, acute intoxication from lupin was a major cause of sheep death [51]. Ingestion of lupin by cattle was first reported to cause congenital birth defects in calf, called crooked calf disease, in the late 1950s. This disease was described as a condition in which calves were born with some deformities such as scoliosis, arthrogryposis, torticollis, and cleft palate.

Anagyrine and some piperidine alkaloids such as ammodendrine were shown to reduce fetal movement during a period of gestation causing the spine and limbs to develop in contracted or misaligned positions. *L. leucophyllus*, *L. sulphureus*, and *L. sericeus* can contain anagyrine, but it does not occur in the domesticated lupin varieties [51].

5 Different Alkaloids in Different Plant Parts

Alkaloid profiles generally show variations among plant parts. As already reported, QAs synthesis occurred in leaves and, via phloem and xylem, they are translocated in the other parts of the plant [27]. The highest concentration of alkaloids was revealed in stems, leaves, flowers, and pods, lowest concentration in roots [27].

A higher diversity and concentration of QAs is revealed in seeds in comparison with leaves; in fact, seeds are the reproduction organs of plants, so they need higher protection.

Usually leaves have different alkaloid profiles than seeds. Generally the hydroxylated alkaloids predominate in seeds, whereas esters of 13-hydroxylupanine, 3-hydroxylupanine, and 13-hydroxymultiflorine are abundant in leaves. In particular, these esters are generated by specific acyltransferases during germination.

In *L. albus* leaves the main QAs are albine, angustifoline, and lupanine; other alkaloids usually present are sparteine, 11,12-dehydrosparteine, isoangustifoline, tetrahydrorhombifoline, 17-oxosparteine, α-isolupanine, 5,6-dehydrolupanine, 13-angeloyloxymultiflorine, 13-tigloyloxymultiflorine. 13-Hydroxylupanine that is usually very abundant in seeds, in leaves is almost totally esterified [8].

For *L. angustifolius*, the main QAs of leaves are angustifoline, lupanine, 13-hydroxylupanine, 13-*cis*-cinnamoyloxylupanine; other QAs are isoangustifoline, tetrahydrorhombifoline, α-isolupanine, 17-oxolupanine, 13-benzoyloxylupanine, dihydroxyaphyllidine, dihydroxylupanine, dehydrolupanine [8].

In *L. luteus* leaves the main QAs are lupinine, sparteine, feruloyllupinine, p-coumaryllupinine; other QAs are gramine, α-isosparteine, 11,12-dehydrosparteine, tetrahydrorhombifoline, 17-oxosparteine, lupanine [8].

L. mutabilis leaves mainly contain sparteine, tetrahydrorhombifoline, angustifoline, lupanine, 3β-hydroxylupanine (formerly nuttaline or 4-hydroxylupanine), 13-hydroxylupanine, 13-isovaleroyloxylupanine, 13-tigloyloxylupanine. Other QAs are 11,12-dehydrosparteine, 17-oxosparteine, α-isolupanine, 13-valeroyloxylupanine, 13-benzoyloxylupanine, 13-*cis*-cinnamoyloxylupanine, 13-*trans*-cinnamoyloxylupanine, dihydroxylupanine, 3,13-dihydroxylupanine [8].

Lupinus aschenbornii different organs were recently analyzed obtaining different results for seeds, stems, flowers, and leaves [52]. The authors do not detect QAs in roots, whereas pods show sparteine as the main alkaloid. Total QA contents of different organs are very different: 3.3 mg DM^{-1} in seeds, 2.8 mg in flowers, 1.9 mg in leaves, 1.5 mg in stems, and 1.4 mg in pods. These results confirm that QAs accumulate in the reproductive organs, playing an important role in its defense, and also contribute to N metabolism [5].

Also the alkaloid profile is very different: seeds of *L. aschenbornii* contain mainly *N*-formylangustifoline, whereas stems, leaves and flowers contain mainly sparteine. The explanations proposed by the authors for this diversity are: (1) “one predator, one organ,” that is a variability of QAs can confer to lupin plants higher possibility to survive and reproduce in an adverse environment and (2) the transport of QAs through the plant is uneven [52].

Few data are available for plant roots. In roots of *L. albus* mainly lupanine and its ester 13-tigloyloxylupanine were detected followed by minor amounts of angustifoline, 11,12-seco-12,13-didehydromultiflorine, and 17-oxolupanine [37].

6 Biological Activities

Over 12,000 alkaloids are known, most of all displaying potent pharmacological activities, and several widely used as pharmaceuticals. There are a large number of reports on the biological activities of lupin alkaloids having antipyretic, hypoglycemic, cardiotonic, and antiulcerogenic activity, inhibitors of edema, inhibitors of natural killer cell growth and of acetylcholinesterase [53–55].

Antimicrobial activity is well known. For example, sparteine is reported to possess antimicrobial activity against bacteria and phytopathogenic fungi. In particular, antibacterial and antifungal activity of lupin leaves extracts were shown on *B. subtilis*, *S. aureus*, *P. aeruginosa*, and *C. albicans* [55].

L. albus seeds are used as diuretic, anthelmintic, and tonic in folk medicine; they are also used in the treatment of liver disorders, diabetes, hemorrhoids, and eczema [55].

Oral administration of *L. termis* and *L. angustifolius* reduces high blood pressure and hyperglycemia in rabbits, rats, and mice [54].

The addition of lupin seeds to the food of diabetic-hypercholesterolemic rabbits decreases cholesterol levels and postprandial hyperglycemia. Sparteine sulfate administered by intravenous infusion to normal men increases either basal or glucose-induced secretion; sparteine administration to patients with type 2 diabetes causes a fall in plasma glucose levels [56].

QAs show a wide range of biological activities: they can inhibit the multiplication of viruses, the proliferation of bacteria, and the growth of some fungi.

Some allelopathic (phytotoxic) effects of QAs have been described, including the inhibition of the growth of competing plants. They can also deter number of herbivores (nematodes, caterpillars, beetles, aphids, locusts, snails, rabbits, and cows), but also pollinators such as bees.

Natural compounds such as alkaloids derived from wild plants may represent interesting alternative bio-rational pesticides against phytophagous insects. QAs can be used as insecticides either alone or in combination with other classes of pesticides such as pyrethroids. They can be rapidly degraded by UV and hence posses low persistence in the environment. Moreover, some of them are very specific as insecticides and/or deterrents [1].

Sparteine, lupanine, and 13-tigloyloxylupanine were investigated in detail and sparteine was found to have toxic as well feeding deterrent properties for some Lepidoptera.

Extracts from leaves of *L. montanus*, *L. aschenbornii*, *L. stipulatus* grown in Mexico showed insecticidal activity toward larvae of the Fall Armyworm (*Spodoptera frugiperda*) [57]. The extracts of *L. montanus* and *L. aschenbornii* contain sparteine as the major constituent, while the major alkaloids in *L. stipulatus* extract are aphylline and an epiaphylline-like alkaloid. This last one was found to be the most effective against larvae of *S. frugiperda*. Extracts of *L. montanus* and *L. aschenbornii* were found to have toxicity similar to sparteine [57].

The differences in alkaloid composition between species indicate a broad range of defense strategies against predation. Moreover, the fact that some intraspecific variations in alkaloid composition occur with the season and the altitude at which the plants grow, may explain why the proportions and sometimes even the composition of alkaloid, vary among published studies.

7 Debittering Processes

As previously described, by mean of hybridization it is possible to reduce the alkaloid level and to develop alkaloid-poor varieties also known in literature as sweet varieties or alkaloid-free lupins.

Unfortunately, sweetness is a genetically recessive characteristic, hence in the regions where lupin is spontaneous, a progressive cross-pollination induce rebittering, and residual levels of alkaloids in the new varieties can tend to increase [58].

Already in ancient times it was known that when lupins are soaked in water, the water-soluble alkaloids can be leached out. This old finding was already practice in ancient Greece and by Indians in the Andes.

As an alternative, treatments such as cooking, soaking, germination, and fermentation are known to eliminate QAs. To remove significant amounts of alkaloids, it is necessary to cook and wash the seeds for several days; this preparation eliminates the toxicity and makes the seed more palatable for human consumption. Usually, the seeds are soaked in running water for a few days and afterward they are cooked.

In particular, aqueous, alkaline, and acid thermal treatments are tested for debittering processes [49]. In the case of aqueous thermal treatment, a 56 % decrease is obtained after 3 h, whereas in the case of alkaline treatment a greater decrease (76.5 %) is observed.

In alkaline environment, the seed hydration was greater than in aqueous one (78 % and 62 %, respectively). After 5 h of alkaline treatment, the total alkaloid concentration is 0.03 %, which means that about 99 % of alkaloids has been eliminated. For aqueous treatment, this level was obtained only after 6 h. The final concentration of QAs in debittered seeds with alkaline thermal treatment is 0.002 %, which represents 99.9 % of QAs elimination. After technological treatment, QAs content decreased by 89 % in the aqueous thermal treatment, 88 % in the acidic treatment, and 95 % in the alkaline treatment [59]. During both the steps of soaking and cooking, the total content of QAs in seeds diminished by 55 % and 35 % for *L. campestris* and *L. mutabilis*, respectively. Seeds that are soaked, cooked, and fermented for 24 h showed a decrease of 70 % and 81 %, of total QAs, respectively. The greater total QAs losses occur during soaking and cooking of the seed (>50 %).

Fermentation causes a general improvement in the nutritional value of legume seeds and may result in the breakdown of some of the antinutritional endogenous compounds. For example, *Rhizopus oligosporus*, used for fermentation step during the production of tempeh, decreases QAs content from seeds of *L. campestris* and *L. mutabilis* at levels of 95 % and 91 %, respectively [60]. In conclusion, the fermentation method could be a good alternative for debittering of lupines seed since it is faster, less expensive, and without environmental contamination.

Other scientists proposed the removal of QAs from *L. albus* flours using bacteria able to catabolize lupanine and to degrade other lupin alkaloids in culture media [58]. The obtained results suggest that enzymatically active bacterial lysates or purified enzyme complex may possess a high potential for the detoxification of QAs, being an alternative debittering process.

8 Analytical Methods

The extraction of alkaloids from vegetative samples (seeds, leaves, pods, etc.) or food ingredients is usually performed in acidic aqueous medium; then the solution is basified, and the QAs are extracted with unpolar solvents, usually dichloromethane.

In alternative to solvent extraction, a SPE (Solid Phase Extraction) on Extrelut© columns is performed in order to avoid the formation of resistant emulsions and, at the end, to maximize and standardize QAs extraction [15].

The chromatography of QAs on thin-layer plates (Thin Layer Chromatography, TLC) and their following detection by Dragendorff reagent has been used in many studies, especially in older ones [7]. This technique has some limitation in the analyses of mixture of alkaloids in which there are both major and minor QAs.

A good alternative can be the gas chromatography equipped with FID, that is, flame ionization detector [61] or with mass spectrometer, used in the majority of papers. Wink and coworkers [8], have studied the QAs profile of 56 species of lupin by GC-MS reporting Kovat’s index and fragmentation ions of more than 100 quinolizidine alkaloids.

Usually nonpolar or low-polarity columns were used, as a consequence of the low polarity of QAs. No derivatization is required, even if some papers used it when the analysis was hampered by matrix peaks or lack of analytes detectability without derivatization [61].

Very few papers use HPLC for alkaloids quantitation [9, 62]. An alternative to these methods could be the nonaqueous capillary electrophoresis (NACE) coupled with UV or MS detection; this technique shows high separation efficiency, economic performance, and versatility [63].

The quantification of QAs is complicated by the fact that commercial standard of QAs are not easily available; for this reason the isolation of alkaloids from extracts is necessary to obtain single alkaloids.

Usually, single alkaloid contents were expressed in percentage respect to total alkaloid content, or in absolute values using calibration curve of lupanine or sparteine depending on the chemical structure and adjusting for molecular weight of single alkaloids [30, 37, 58, 64].

The identification of a single structure after isolation is mainly performed with spectral analysis: mass spectrum, IR and Raman spectra, NMR spectra both of ^{1}H and ^{13}C, both mono- and bi-dimensional ones [36].

9 Conclusion

QAs are a large family of molecules, generally known as lupin alkaloids as they occur in lupin and other plants of the Leguminosae family. They act as a defense against biotic and abiotic stresses, such as predators, pathogens, or adverse climatic events. They are biosynthesized in the vegetative parts of the plants, but they accumulate in seeds that are the raw material for the production of lupin ingredients to be included in human foodstuffs. As these ingredients are gaining outmost importance as source of proteins, a maximum limit of total QAs content has been fixed in some countries, in order to assure the safety of lupin foods.

A lot of chemical and analytical work has been performed on QAs in order to determine chemical structures of single compounds and of biochemical work to determine pharmacological or biological activities of both single compounds and complex extracts. Moreover, this issue has yet great potentiality both for analytical and synthetic chemists, biologists, and phytopharmacological scientists.

Abstract

Secondary metabolites are produced by plants in response to biotic or abiotic interactions with their environment and confer protection through a variety of antimicrobial, pesticidal, and pharmacological properties. Alkaloids are a class of plant secondary metabolites that traditionally have been classified as basic compounds derived from amino acids that contain one or more heterocyclic nitrogen atom. About 20 % of plant species accumulate alkaloids, which are mostly derived from amino acids, e.g., phenylalanine, tyrosine, tryptophan, and lysine. The alkaloids are popular for their medicinal importance. The pharmaceutically important representatives of secondary metabolites are mostly alkaloids derived from tyrosine. In this chapter, we summarized the prior information, basic knowledge about the alkaloids, origin, physicochemical properties, uses, classification, biosynthetic reactions, and distribution of tyrosine-derived alkaloids especially opium alkaloids and their biosynthetic pathways in plants. We have also reviewed different web resources related to alkaloids and secondary metabolic pathway databases such as KEGG.

1 Introduction

Plants produce a vast array of secondary metabolites in response to biotic or abiotic interactions with their environment, which impart flavor, color, and fragrance and confer protection through a variety of antimicrobial, pesticidal, and pharmacological properties. About 20 % of plant species accumulate alkaloids, which are mostly derived from amino acids, e.g., Phe, Tyr, Trp, and Lys. In addition, the monoterpenoid indole alkaloids, which form a large class of complex compounds, are derived from tryptophan and terpenoid precursors [1]. They are assumed to play indispensable roles for the survival of plants producing these metabolites as defense compounds against pathogenic organisms or predators and allelopathic metabolites for competing with other plants. These are natural products of non-peptidic origin containing nitrogen that have had the major impact throughout history on the economic, medical, political, and social affairs of humans. In fact, they are the skeleton framework of about 60 % of the modern drugs, such as atropine for tropicamide, quinine for chloroquine, and cocaine for procaine and tetracaine, that are available today. Thus, there has been a resurgence in the screening of plant extracts for pharmacological activities as part of industrial drug development programs in recent years.

Their basic character is reflected in the name derived from alkaline which means basic. The ease with which they can be extracted from plants, fungi, or insects where they occur naturally coupled with their sometimes profound biological effects on human have made them a very early focus of systematics chemical research. Given the commercial value of the alkaloids, the processes and genes involved in their biosynthesis and secretion are attractive targets for genetic engineering. In the course of studying the biosynthesis of these metabolites at biochemical, genomic, and systematic level, life scientists recently listed the following questions: (a) to what extent is the genomic pathways conserved among different species? (b) is there a minimal set of pathways that are required by all organisms? (c) how are organisms related in terms of the distance between pathways rather than at the level of DNA sequence similarity? At the core of such questions lies the identification of pathways in different organisms. So in a way pathway knowledge in public databases enables us to examine how individual metabolites are connected via chemical reactions and what genes are implicated in those processes. Given the commercial value of the alkaloids and the processes and genes involved in their biosynthesis and secretion which are attractive targets for genetic engineering, very little is known about how plants synthesize these substances and so far little is known about how the synthesis is regulated at the genetic level. Moreover, owing to the cost of sequencing and their relatively large size, the full genome sequences of only a few plants are currently available. Recent progress in the many plant sequencing projects; there is an imperative need to integrate functional genomics data to obtain a more comprehensive system-biology view of the results. Besides, biochemical pathway maps composed of genes, proteins, and metabolites are powerful tools around which one can compile the biological context of functional genomics datasets. Several metabolic pathway databases are available to facilitate our understanding of transcriptome and metabolome data such as KEGG (http://www.genome.ad.jp/kegg), MetaCyc (http://metacyc.org), AraCyc (http://www.arabidopsis.org/tools/aracyc), BioCyc (http://biocyc.org), and Reactome (http://reactome.org), but the pathways and reactions involved in alkaloid biosynthesis are not well represented and the information contained in these databases does not meet the unique data requirements for plant researchers, especially those involved in plant alkaloid metabolism studies. Alkaloids have an enormous structural and biosynthetic diversity, and these are identified and quantified using a wide range of technology platforms. In this chapter, alkaloid structure, classification, biosynthesis, and function and their role in disease therapy like malaria and cancer have been covered.

1.1 Natural Product

A natural product is a chemical compound or substance produced by a living organism found in nature that usually has a pharmacological or biological activity for use in pharmaceutical drug discovery and drug design. Not all natural products can be fully synthesized, and many natural products have very complex structures that are too difficult and expensive on an industrial scale such as penicillin, morphine, paclitaxel, and vincristine. To avoid side effects of many nonnatural and synthetic drugs, active molecules derived from secondary metabolites are harvested through medicinal plants. Figure 15.1 represents the synthesis of natural products derived from plants. Prior reports describe the biosynthesis of different natural medicinal products [2].

2 Secondary Metabolites

Because of their sessile way of life, plants have developed a rich arsenal of chemicals, encompassing some 200,000 known compounds [2]. These metabolites participate in all kinds of biotic and abiotic interactions with the environment, predominantly with regard to defense against herbivores and pathogens, and are considered “secondary metabolites” because they are not involved in the primary processes of growth and development [3, 4]. They have traditionally been of interest only due to their pronounced and various physiological activities in animals and humans [5]. They are low molecular weight organic compounds that possess

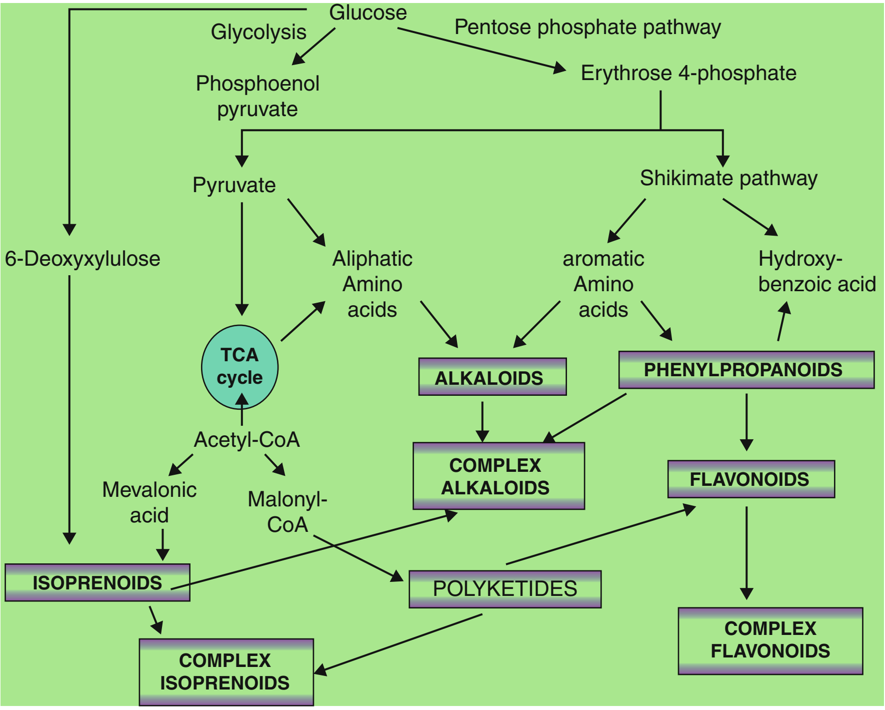
interesting biological activities and fine applications, such as pharmaceuticals, insecticides, dyes, flavors, and fragrances. Higher plants produce a wide variety of secondary metabolites, including more than 25,000 terpenoids, about 8,000 phenolic compounds, and about 12,000 alkaloids [6]. One of the most conspicuous features of secondary metabolites is that they are often restricted to individual species or related groups of species, rather than being broadly distributed in the plant kingdom. Figure 15.2 represents the biosynthetic relationships of major groups of secondary compounds.

2.1 Classification of Secondary Metabolites

Most of the secondary metabolites of interest belong to the following categories. These categories are broad categories which classify secondary metabolites based on their biosynthetic origin.



Glucose
Glycolysis
Pentose phosphate pathway
Phosphoenol pyruvate
Erythrose 4-phosphate
Pyruvate
Shikimate pathway
6-Deoxyxylulose
Aliphatic Amino acids
aromatic Amino acids
Hydroxy-benzoic acid

Alkaloids (derived from amino acids):

- Hyoscyamine, present in *Datura stramonium*
- Atropine, present in *Atropa belladonna*
- Cocaine, present in *Erythroxylon coca*
- Codeine and morphine, present in *Papaver somniferum*

Terpenoids (come from semiterpene oligomerization):

- Azadirachtin, present in seeds of *Azadirachta indica* (neem)
- Artemisinin, present in *Artemisia annua*
- Tetrahydrocannabinol, present in *Cannabis sativa*

Steroids (terpenes with a particular ring structure)
Glycosides (heavily modified sugar molecules)
Phenols
Phenazines

3 Alkaloids

Alkaloids are a class of secondary plant metabolites that traditionally have been classified as basic compounds derived from amino acids that contain one or more heterocyclic nitrogen atom. Although this definition holds for most known alkaloids recently, any *N*-containing secondary compound is considered an alkaloid if it cannot readily be classified otherwise – i.e., not an amine, cyanogenic glycoside, glucosinolate, etc. The original definition for alkaloids is pharmacologically active, *N*-containing basic compounds of plant origin. Ergot alkaloids are toxins and important pharmaceuticals and have been identified in two orders of fungi and three families of higher plants [7]. The most important producers are fungi of the genera Claviceps, Penicillium, and Aspergillus (all belonging to the Ascomycota). Chemically, ergot alkaloids are characterized by the presence of a tetracyclic ergoline ring and can be divided into three classes according to their structural features, i.e., amide or peptide-like amide derivatives of D-lysergic acid and the clavine alkaloids. Significant progress has been achieved on the molecular biological and biochemical investigations of ergot alkaloid biosynthesis in the last decade. By gene cloning and genome mining, gene clusters for ergot alkaloid biosynthesis have been identified in at least 8 different ascomycete species. The functions of most structure genes have been assigned to reaction steps in the biosynthesis of ergot alkaloids by gene inactivation experiments or biochemical characterization of the overproduced proteins. An overview of the studies related to the biosynthesis of alkaloids has been published [8]. Several biologically active alkaloids (1–4, 6), including a new quinazoline-6-carboxylic acid (1), were isolated from the medicinal plant Zanthoxylum rhetsa, an evergreen tree, native to subtropical areas [9]. Whereas the pharmacological properties of the plant extract and single constituents have been widely tested, we now show that all of the metabolites have anti-algal activities, all but 6 are antibacterial, and 6 and the reduction product 5 (derived from 4) are also antifungal. A detailed account on the biological activities of structurally diverse secondary metabolites from marine sponges having 2-aminoimidazole, glycociamidine, and/or 2-thiohydantoin ring functions has been analyzed by Kumar et al. [10].

4 Classification of Alkaloids

The alkaloids, as an important and enormously large conglomerate of naturally occurring nitrogen-containing plant substances having very specific as well as most diversified pharmacological properties, may be classified in a number of modes and means. Hegnauer [11] conveniently classified alkaloids into six important groups, corresponding to the six amino acids legitimately considered as the starting points for their biosynthesis, such as anthranilic acid, histidine, lysine, ornithine phenylalanine, and tryptophan. Price [12] further took a leading clue from the earlier observation and considered in details the alkaloids present in one of the families (Rutaceae) and logically placed them in the following *nine* chemical-structural categories, namely, acridines, amides, amines, benzylisoquinolines, canthinones, imidazoles, indolquinazolines, furoquinolines, and quinazolines. Another school of thought classifies alkaloids in the following *four* heads, namely:

(a) *Biosynthetic Classification* – In this particular instance, the significance solely lies to the precursor from which the alkaloids in question are produced in the plant biosynthetically. Therefore, it is quite convenient and also logical to group together all alkaloids having been derived from the same precursor but possessing different taxonomic distribution and pharmacological activities.

Examples

1. Indole alkaloids derived from tryptophan
2. Piperidine alkaloids derived from lysine
3. Pyrrolidine alkaloids derived from ornithine
4. Phenylethylamine alkaloids derived from tyrosine
5. Imidazole alkaloids derived from histidine

(b) *Chemical Classification* – It is probably the most widely accepted and common mode of classification of **alkaloids** for which the main criterion is the presence of the basic heterocyclic nucleus (i.e., the **chemical entity**).

Examples

1. Pyrrolidine alkaloids (e.g., hygrine)
2. Piperidine alkaloids (e.g., lobeline)
3. Pyrrolizidine alkaloids (e.g., senecionine)
4. Tropane alkaloids (e.g., atropine)
5. Quinoline alkaloids (e.g., quinine)
6. Isoquinoline alkaloids (e.g., morphine)
7. Aporphine alkaloids (e.g., boldine)
8. Indole alkaloids (e.g., ergometrine)
9. Imidazole alkaloids (e.g., pilocarpine)
10. Diazocin alkaloids (e.g., lupanine)
11. Purine alkaloids (e.g., caffeine)
12. Steroidal alkaloids (e.g., solanidine)
13. Amino alkaloids (e.g., ephedrine)
14. Diterpene alkaloids (e.g., aconitine)

(c) *Pharmacological Classification* – Interestingly, the **alkaloids** exhibit a broad range of pharmacological characteristics. This method is also used as a strong basis for the general classification of the wide spectrum of alkaloids derived from the plant kingdom, such as analgesics, cardiovascular drugs, CNS stimulants and depressants, dilation of pupil of eye, mydriatics, anticholinergics, sympathomimetics, antimalarials, and purgatives. However, such a classification is not quite common and broadly known.

Examples

1. Morphine as narcotic analgesic
2. Quinine as antimalarial
3. Strychnine as reflex excitability
4. Lobeline as respiratory stimulant
5. Boldine as choleretics and laxatives
6. Aconitine as neuralgia as an external agent in neuralgia and rheumatism
7. Pilocarpine as antiglaucoma agent and miotic
8. Ergonovine as oxytocic
9. Ephedrine as bronchodilator
10. Narceine as analgesic (narcotic) and antitussive

(d) *Taxonomic Classification* – This particular classification essentially deals with the "Taxon," i.e., the taxonomic category. The most common *taxa* are the genus, subgenus, species, subspecies, and variety. Therefore, the taxonomic classification encompasses the plethora of alkaloids exclusively based on their respective distribution in a variety of plant families, sometimes also referred to as the "natural order." A few typical examples of plant families and the various species associated with them are stated below, namely:

1. *Cannabinaceous Alkaloids:* e.g., *Cannabis sativa* Linn. (Hemp, Marijuana)
2. *Rubiaceous Alkaloids:* e.g., *Cinchona Sp*. (Quinine), *Mitragyna speciosa* Korth (Katum, Kratum, Kutum), *Pausinystalia johimbe* (K. Schum) (Yohimbe)
3. *Solanaceous Alkaloids:* e.g., *Atropa belladona* L. (Deadly Nightshade, Belladona), *Brunfelsia uniflorus* (Pohl) D. Don (Manaca, Manacan), *Capsicum annuum* L. (Sweet Peppers, Paprika), *Datura candida* (Pers.) Saff. (Borrachero, Floripondio), *Duboisia myoporoides* R. Br. (Corkwood Tree, Pituri), *Hyoscyamus niger* L. (Henbane, Henblain, Jusquaime), *Mandragora officinarum* L. (Mandrake, Loveapple), *Nicotiana glauca* R. Grah. (Tree Tobacco), *Seopolia carniolica* Jacq. (Scopolia), *Solanum dulcamara* L. (Bittersweet, Bitter Nightshade, Felonwood), *Withania somniferum* (L.) Dunal (Ashwagandha), etc.

Invariably, they are grouped together according to the name of the *genus* wherein they belong to, such as coca, cinchona, and ephedra. Some "phytochemists" have even gone a step further and classified the alkaloids based on their chemotaxonomic classification.

In the recent past, the alkaloids have been divided into *two* major categories based on the analogy that one contains a *non-heterocyclic nucleus* while the other has the *heterocyclic nucleus*. These two classes of alkaloids shall be discussed briefly as under:

(a) *Non-heterocyclic Alkaloids* – A few typical alkaloids having a non-heterocyclic nucleus are enumerated below with other related information:

S.No.	Basic ring structure	Alkaloid	Botanical origin	Family
1	Phenylethylamine 	Ephedrine	*Ephedra vulgaris*	Gnetaceae
		Hordenine	*Hordeum vulgare*	Graminae
		Capsaicin	*Capsicum annuum*	Solanaceae
		Mescaline	*Laphophora williamsii*	Cactaceae
		Narceine	*Papaver somniferum*	Papaveraceae

(b) *Heterocyclic Alkaloids* – A large number of specific alkaloids possessing heterocyclic nucleus are stated below with other related information

S.No.	Basic ring structure	Alkaloid	Botanical origin	Family
1	Pyrrolidine 	Hygrine	*Erythroxylon coca*	Erythroxylaceae
		Stachydrine	*Stachys tuberifera*	Labiatae
2	Pyridine 	Arecoline	*Areca catchu*	Palmaceae
		Ricinine	*Ricinus communis*	Euphorbiaceae
		Trigenelline	*Trigonella foenumgraecum*	Leguminosae
3	Piperidine 	Connine	*Conium maculatum*	Umbelliferae
		Lobeline	*Lobelia inflata*	Lobeliaceae
		Pelletierine	*Punica granatum*	Punicaceae
4	Tropane [piperidine-pyrrolidine(*N*-methyl)] 	Atropine	*Atropa belladona*	Solanaceae
		Cocaine	*Datura stramonium*	Solanaceae
		Hyoscyamine	*Erythroxylon coca*	Erythroxylaceae
			Atropa belladona	Solanaceae
5	Quinoline 	Quinine, Quinidine	*Cinchona officinalis*	Rubiaceae
		Cuspareine	*Cusparia trifoliata*	Rutaceae
6	Isoquinoline 	Papaverine	*Papaver somniferum*	Papaveraceae
		Berberine	*Hydrastis canadensis*	Berberidaceae
		Emetine	*Uragoga ipecacuanha*	Rubiaceae
		Corydaline	*Corydalis aurea*	Fumariaceae
			Corydalis solida	Fumariaceae
		Tubocurarine	*Chondodendron tomentosum*	Menispermaceae

(*continued*)

S.No.	Basic ring structure	Alkaloid	Botanical origin	Family
7	Aporphine Isoquinoline Phenanthrene  	Boldine	*Peumus boldus*	Monimiaceae
8	Norlupinane  	Sparteine	*Lupinus luteus*, *Lupinus niger*, *Cytisus scoparius*, *Anagyris foetida*	Leguminosae
		Lupinine	*Lupinus luteus*	Leguminosae

15	Pyrrolizidine 	Senecionine	*Senecio vulgaris*	Compositae
		Seneciphylline	*Senecio platyphyllus*	Compositae

It is pertinent to mention that the enormous volume of authentic information accumulated so far with regard to the isolation of alkaloids from a variety of plant species and their subsequent characterization by the help of latest analytical techniques they may be classified as follows:

(a) Alkaloids derived from amination reactions

1. Acetate-derived alkaloids
2. Phenylalanine-derived alkaloids
3. Terpenoid alkaloids
4. Steroidal alkaloids

(b) Alkaloids derived from anthranilic acid

1. Quinazoline alkaloids
2. Quinoline alkaloids
3. Acridine alkaloids

(c) Alkaloids derived from histidine

Imidazole alkaloids

(d) Alkaloids derived from lysine

1. Piperidine alkaloids
2. Quinolizidine alkaloids
3. Indolizidine alkaloids

(e) Alkaloids derived from nicotinic acid

Pyridine alkaloids

(f) Alkaloids derived from ornithine

1. Pyrrolidine alkaloids
2. Tropane alkaloids
3. Pyrrolizidine alkaloids

(g) Alkaloids derived from tyrosine

1. Phenylethylamine alkaloids
2. Simple tetrahydroisoquinoline alkaloids
3. Modified benzyl tetrahydroisoquinoline alkaloids

(h) Alkaloids derived from tryptophan

1. Simple indole alkaloids
2. Simple b-carboline alkaloids
3. Terpenoid indole alkaloids
4. Quinoline alkaloids
5. Pyrroloindole alkaloids
6. Ergot alkaloids (Table 15.1)

Table 15.1 Distribution of pathways according to alkaloids

S.No.	Pathway name	Alkaloids
1	Alkaloidal amines biosynthesis	Dopamine, colchicine, ephedrine, methaphetamine
2	Tropane alkaloid Biosynthesis	Scopolamine, nicotine, hygrine, calystegines B1, calystegines B2, spermidine, spermine, cocaine, tropinone, littorine, tropine
3	Quinoline alkaloid biosynthesis	Quinine, quinidine
4	Indole alkalod biosynthesis	Tryptamine, sarpagine, ajmaline, vinblastine, vindoline, catharanthine, serpentine, tetrahydro alstonine, ajmalicine
5	Quinolizidine alkaloid biosynthesis	Cadaverine, (+)-P- coumaroylepilupinine/lupinine, (−)-13a-tigloyloxymutiflorine/lupanine
6	Purine alkaloid biosynthesis	Xanthine, 1,3,7-trimethylxanthine(caffeine), 3,7-dimethylxanthine(theobromine), 1,3-dimethylxanthine (theophylline)
7	Steroidal alkaoid biosynthesis	Solanine, chaconine, solasodine
8	Isoquinoline alkaloid biosynthesis	Dopamine, sanguinarine, morphine, laudanine, berbamunine, guatteguaumerine, 2′-Norberbamunine, 10-hydroxychelerythrine, macarpine, (S)canadine, berberine, 7,8-dihydroberberine, thebaine, methopapaverberbine, macrantaline, narcotolinediol, narcotinediol, narcotoline, noscapine
9	Pyrrolizidine alkaloid biosynthesis	Senecionine *N*-oxide
10	Pyridine-piperidine alkaloid biosynthesis	Cadaverine, lupinate, L-pipecolate, *N*-methyl pelletierine, anapheline, anatabine, nicotine, nornicotine, *N*-formylnornicotine, nicotyrine, myosrnine, cotinine, tropinone, *N*-methyl pelletierine, anapheline, anatalline, anabasine

5 Biosynthesis of Alkaloids

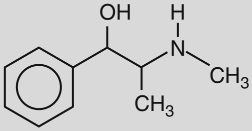
Alkaloids derived from tyrosine include phenylethylamine alkaloids, simple tetrahydroisoquinoline alkaloids, and modified benzyl tetrahydroisoquinoline alkaloids. The chemistry of Erythrina and related alkaloids from 1996 to mid-2009 has been reviewed, with a particular focus on the preparation of Erythrina alkaloids possessing an aromatic "D" ring [13].

Phenylethylamine Alkaloids

The important alkaloids belonging to this category are, namely, **ephedrine**, **hordenine**, **mescaline**, and **narceine**.

Ephedrine

It occurs in *Ephedra vulgaris* Hook. F. (*E. gerardiana* Wall), *Ephedra sinica* Stapf. (1–3 %), and *Ephedra equisetina* Bunge (2 %) belonging to the natural order *Gentaceae* and several other Ephedra species. Besides, it is also found in the roots of *Aconitum napellus* L. (*Ranunculaceae*) (Aconite, Monkshood, Blue Rocket); and *Ephedra nevadensis* S. Wats. (*Ephedraceae*) (Mormon Tea, Nevada Jointfir).

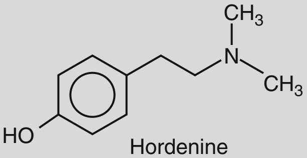


Ephedrine

α-[1-(Methylamino)-ethyl] benzene-methanol; ($C_{10}H_{15}NO$)

Hordenine

It is obtained from the plant of *Lophophora williamsii* (Lamaire) Coult. (*Catctaceae*) (Peyote) and *Selenicereus grandiflorus* Britt and Rose (*Coctaceae*) (Night Blooming Cereus).



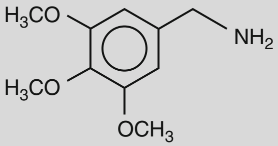
Hordenine

4-[2-Dimethylamino) ethyl] phenol; ($C_{10}H_{15}NO$)

It is very soluble in chloroform, ethanol, and ether; 7 g dissolves in 1 L of water; practically insoluble in petroleum ether; and sparingly soluble in benzene, xylene and toluene.

Mescaline

It is obtained from *Peyote* (Mescal Buttons) the flowering heads of *Lophophora williamsii* (Lemaire) Coult. (*Coctaceae*) and the cactus *Trichocereus pachanoi* Britton and Rose (*Cactaceae*) (Achuma, San Pedro Aguacolli).



Mescaline

3, 4, 5-Trimethoxybenzeneethanamine; ($C_{11}H_{17}NO_3$)

5.1 Pyrrolizidine Alkaloids

The system of pyrrolizidine alkaloids has proven to be a powerful system for studying the evolution of a biosynthetic pathway in plant secondary metabolism. Pyrrolizidine alkaloids are typical plant secondary products produced by the plant as a defense against herbivores. The first specific enzyme, homospermidine synthase, has been shown to have evolved by duplication of the gene encoding deoxyhypusine synthase, which is involved in primary metabolism. Despite the identical function of the homospermidine synthase for pyrrolizidine alkaloid biosynthesis in the various plant lineages, this gene duplication has occurred several times independently during angiosperm evolution. After duplication, these gene copies diverged with respect to gene function and regulation. In the diverse plant lineages producing pyrrolizidine alkaloids, homospermidine synthase has been shown to be expressed in a variety of tissues, suggesting that the regulatory elements were recruited individually after the duplication of the structural gene [14].

Pyrrolizidine alkaloids are one of the best-studied examples of a plant's defense system that has been recruited by several insect lineages for their own chemical defense. In each case, this recruitment requires sophisticated mechanisms of adaptations, e.g., efficient excretion, transport, suppression of toxification, or detoxification. Here, we briefly summarize the detoxification mechanism known for pyrrolizidine alkaloids and focus on pyrrolizidine alkaloid *N*-oxidation as one of the mechanisms allowing insects to accumulate the sequestered toxins in an inactivated protoxic form. Recent research into the evolution of pyrrolizidine alkaloid *N*-oxygenases of adapted arctiid moths (Lepidoptera) has shown that this enzyme originated by the duplication of a gene encoding a flavin-dependent monooxygenase of unknown function early in the arctiid lineage. The available data suggest several similarities in the molecular evolution of this adaptation strategy of insects to the mechanisms described previously for the evolution of the respective pathway in plants [15].

5.2 Isoquinoline Alkaloids

Isoquinoline alkaloids are tyrosine-derived plant alkaloids with an isoquinoline skeleton. Among them, benzylisoquinoline alkaloids form an important group with potent pharmacological activity, including analgesic compounds of morphine and codeine and antiinfective agents of berberine, palmatine, and magnoflorine. Biosynthesis of isoquinoline alkaloids proceeds via decarboxylation of tyrosine or DOPA to yield dopamine, which together with 4-hydroxyphenylacetaldehyde, an aldehyde derived from tyrosine, is converted to reticuline, an important precursor of various benzylisoquinoline alkaloids.

5.3 Isoquinoline Alkaloid Biosynthesis

Isoquinoline alkaloid biosynthesis is one of the well-characterized pathways in the secondary metabolism of plant cells which comprises some of the most important drugs for therapy and euphoria (e.g., morphine and its chemical derivatives, papaverine, berberine, dimeric bisbenzylisoquinolines).

The benzylisoquinoline alkaloid class includes several important medicinal compounds such as analgesic morphine, codeine, papaverine, berberine, tubocurarine, and antimicrobial sanguinarine. Enzymes involved in the biosynthesis of at least two tetrahydrobenzylisoquinoline alkaloids, the benzophenanthridine alkaloid sanguinarine and the bisbenzylisoquinoline alkaloid berbamunine, have been reported. The branch point that differentiates the biosynthetic pathway from that which leads to (S)-reticuline-derived benzylisoquinoline alkaloids is shown to be (S)-*N*-methylcoclaurine. All benzylisoquinoline alkaloids share a common biosynthetic origin beginning with a lattice of decarboxylations, ortho-hydroxylations, and deaminations that convert L-tyrosine into both dopamine and 4-hydroxyphenylacetaldehyde. Dopamine and 4-hydroxyphenylacetaldehyde condense to form the trihydroxylated (S)-reticuline which is a key branch-point intermediate in the biosynthesis of most benzylisoquinoline alkaloids, including those with a morphinan (e.g., morphine), benzophenanthridine (e.g., sanguinarine), or protoberberine (e.g., berberine) nucleus and are found mainly in species of the Papaveraceae, Monimiaceae, Ranunculaceae, Berberidaceae, and Menispermaceae. (S)-Reticuline is clearly one of the most versatile molecules in plant secondary metabolism. Five enzymes of alkaloid formation are reported: (R,S)-3-hydroxy-*N*-methylcoclaurine 4-*O*-methyltransferase central to the biosynthesis of tetrahydroisoquinoline-derived alkaloids, the berberine bridge enzyme of the sanguinarine pathway, (R,S)-reticuline 7-*O*-methyltransferase specific to laudanosine formation, and salutaridinol 7-*O*-acetyltransferase and codeinone reductase, which lead to morphine. The conversion of (S)-reticuline to (S)-scoulerine via the berberine bridge enzyme (BBE) represents the first committed step in benzophenanthridine and protoberberine alkaloid biosynthesis. Plant *O*-methyltransferases: molecular analysis, common signature and classification have been studied by Ibrahim et al. [16].

Morphine and codeine are members of the large and diverse group of benzylisoquinoline alkaloids, of which morphine and sanguinarine share a common biosynthetic pathway, beginning with the condensation of two L-Tyr derivatives to produce the central precursor (S)-norcoclaurine yields (S)-reticuline, the last common intermediate in the biosynthesis of both sanguinarine and morphine. Berberine bridge enzyme (BBE) catalyzes the conversion of (S)-reticuline to (S)-scoulerine, the first committed step in the sanguinarine pathway. Alternatively, (S)-reticuline can be isomerized to its (R)-epimer as the first step in the formation of morphine. Since the pathway from tyrosine to (S)-reticuline is also known at the enzyme level, the conversion of L-tyrosine to macarpine involves a total of 19 enzymes which are now at least partially characterized.

The isoquinoline pathway's enzyme orthologs in other plants showed that genes of methyltransferase family such as (R,S)-reticuline 7-*O*-methyltransferase, coclaurine 4′-*O*-methyltransferase, (S)-norcoclaurine 6-*O*-methyltrasferase, columbamine *O*-methyltransferase, coclaurine *N*-methyltransferase, putrescine *N*-methyltransferase responsible for the production of reticuline, coclaurine, norcoclaurine, columbaine have been reported from *Papaver somniferum, Coptis japonica, Thalictrum flavum, Thalictrum tuberosum, Coffea liberica, Coffea arabica, Coffea canephora, Nicotiana tabacum, Solanum tuberosum, Datura stramonium, Hyoscyamus niger*, and *Atropa belladonna*. Pathway contains information of about four alkaloids such as dopamine, colchicine, ephedrine, and methamphetamine and identified two missing links.

Eschscholzia californica produces various types of isoquinoline alkaloids. The structural diversity of these chemicals is often due to cytochrome P450 (P450) activities. Members of the CYP719A subfamily, which are found only in isoquinoline alkaloid-producing plant species, catalyze methylenedioxy bridge-forming reactions. In this study, four kinds of CYP719A genes from *E. californica* have been characterized. These four cDNAs encoded amino acid sequences that were highly homologous to *Coptis japonica* CYP719A1 and *E. californica* CYP719A2 and CYP719A3, which suggested that these gene products may be involved in isoquinoline alkaloid biosynthesis in *E. californica*, especially in methylenedioxy bridge-forming reactions. Expression analysis of these genes showed that two genes (CYP719A9 and CYP719A11) were preferentially expressed in plant leaf, where pavine-type alkaloids accumulate, whereas the other two showed higher expression in the root than in other tissues [17] (Fig. 15.3, Tables 15.2–15.5).

15	E15	*N*-methylcoclaurine 3′-monooxygenase	CYP, IMT, Hf1	*Eschscholzia californica*

6 Intermediates of Morphine Biosynthetic Pathway

Poppies (Papaver somniferum, Papaveraceae) have long been used as medicinal plants, food plants, and drugs of abuse. Morphine alkaloids are found in many members of the genus Papaver, but codeine and morphine are only found in *P. somniferum*. Another species, Papaver bracteatum contains thebaine. Morphine alkaloids are derived from (−)- or (R)-reticuline by series of reactions involving an oxidative coupling reaction. Radioactive labelling experiments have established the series of reactions from thebaine to codeine to morphine. The most important compound from a biosynthetic point of view is (+)-reticuline. This alkaloid is a precursor of several other groups of alkaloids. (+)- or (S)-reticuline is converted to (−)- or (R)-reticuline, which is, in turn, a major precursor of another alkaloid group. For morphinan alkaloid biosynthesis, (S)-reticuline undergoes an inversion of stereochemistry to (R)-reticuline (an isoquinoline alkaloid) catalyzed by (R,S)-reticuline 7-*O*-methyltransferase (OMT), a member of the short-chain dehydrogenase/reductase (SDR) protein family. (S)-reticuline formed in the poppy plant is converted by means of 1,2-dehydroreticuline to (R)-reticuline, which in turn is then transformed into morphine. cDNAs have been isolated for all of the enzymes leading to (S)-reticuline, as well as those involved in the conversion of (R)-reticuline to salutaridine-7-*O*-acetate. Recently, the short-chain dehydrogenase/reductase (SDR) implicated in morphine biosynthesis was cloned from Papaver somniferum. The biosynthetic pathways and the participating enzymes or cDNAs are characterized only for a few selected members, whereas the biosynthesis of the majority of the compounds is still largely unknown [18].

The benzylisoquinoline alkaloids (BIA) comprise a large and diverse group of nitrogen-containing secondary metabolites with about 2,500 compounds identified in plants. BIA biosynthesis begins with the condensation of the tyrosine-derived precursors dopamine and *p*-hydroxyphenylacetaldehyde to (S)-norcoclaurine. Subsequent regiospecific *O*- and *N*-methylations and aromatic ring hydroxylation lead to (S)-reticuline, which is the central intermediate for almost all BIAs. For morphinan alkaloid biosynthesis, (S)-reticuline undergoes an inversion of stereochemistry to (R)-reticuline, followed by C-C phenol coupling catalyzed by a unique cytochrome P450-dependent monooxygenase to yield salutaridine. The cDNA sequence of enzymes leading to (S)-reticuline, as well as those involved in the conversion of (R)-reticuline to salutaridine-7-*O*-acetate is already characterized. The inversion of (S)-reticuline to (R)-reticuline represent the important steps in morphine biosynthesis. Wound induced transcript accumulation in Papaver reveals a novel wound inducible EST (NCBI DbEST: GO238757) showing homology with (R,S)-reticuline 7-*O*-methyltransferase (ID:Q6WUC2) isolated from Papaver somniferum. Researchers compared the substrate binding homology of this novel wound inducible (R,S)-reticuline 7-*O*-methyltransferase (7-OMT) using template of P. somniferum (Q6WUC2; gb|AAQ01668) as experimental control. Homology modeling with 70 % identity and 85 % similarity with the catalytic site of template protein, i.e., (Q6WUC2) short-chain dehydrogenase/reductase (SDR), showed docking energy −69.9 and −75.8 kcal/mol with (S)-reticuline (CID:439653) and (R)-reticuline (CID:440586), respectively, which are comparable with experimental control binding site interaction energies. Docking of S- and R-reticuline into the active site revealed eight amino acids, namely, (F(5), E(18), W(24), C(47), F(44), P(45), C(46), and I(47), presumably responsible for the high substrate specificity of (R,S)-reticuline 7-*O*-methyltransferase.

The concept of phenolic oxidative coupling is a crucial theme in modifying the basic benzyltetrahydroisoquinoline skeleton to many other types of alkaloid. Tetrandrine and tubocurarine represent the coupling of two benzyltetrahydroisoquinoline molecules by ether bridges, but this form of coupling is perhaps less frequent than that involving carbon–carbon bonding between aromatic rings. The principal opium alkaloids **morphine**, **codeine**, and **thebaine** are derived from this type of coupling, though the subsequent reduction of one aromatic ring to some extent disguises their benzyltetrahydroisoquinoline origins. (*R*)-**Reticuline** is firmly established as the precursor of these morphinan alkaloids. (*R*)-Reticuline is the substrate for one-electron oxidations via the phenol group in each ring, giving the diradical. Coupling *ortho* to the phenol group in the tetrahydroisoquinoline, and *para* to the phenol in the benzyl substituent, then yields the dienone **salutaridine**, found as a minor alkaloid constituent in the opium poppy *Papaver somniferum* (Papaveraceae). The alkaloid **thebaine** is obtained by way of **salutaridinol**, formed from salutaridine by stereospecific reduction of the carbonyl group. Ring closure to form the ether linkage in thebaine would be the result of nucleophilic attack of the phenol group on to the dienol system and subsequent displacement of the hydroxyl. This cyclization step can be demonstrated chemically by treatment of salutaridinol with acid. Subsequent reactions involve conversion of thebaine into **morphine** by way of **codeine**, a process which modifies the oxidation state of the diene ring, but most significantly removes two *O*-methyl groups. One is present as an enol ether, removal generating **neopinone**, which gives **codeinone** and then codeine by allylic isomerization and reduction, respectively. The last step, demethylation of the phenol ether codeine to the phenol morphine, is the type of reaction only achievable in the laboratory by the use of powerful and reactive demethylating agents, e.g., HBr or BBr3. Because of the other functional groups present, chemical conversion of codeine into morphine is not usually a satisfactory process. However, the enzyme-mediated conversion in *P. somniferum* proceeds smoothly and efficiently. The enzymic demethylations of both the enol ether and the phenol ether probably involve initial hydroxylation followed by the loss of the methyl groups as formaldehyde.

The involvement of these *O*-demethylation reactions is rather unusual; secondary metabolic pathways tend to increase the complexity of the product by adding methyls rather than removing them. In this pathway, it is convenient to view the methyl groups in reticuline as protecting groups, which reduce the possible coupling modes available during the oxidative coupling process, and these groups are then removed towards the end of the synthetic sequence. There is also some evidence that the later stages of the pathway are modified in some strains of opium poppy. In such strains, thebaine is converted by way of **oripavine** and **morphinone**, this pathway removing the phenolic *O*-methyl before that of the enol ether, i.e., carrying out the same steps but in a different order. The enzymic transformation of thebaine into morphine and the conversion of (*R*)-reticuline into salutaridinol have also been observed in mammalian tissues, giving strong evidence that the trace amounts of morphine and related alkaloids which can sometimes be found in mammals are actually of endogenous origin rather than dietary. Detection of substrate binding motifs for morphine biosynthetic pathway intermediates has been done by Sonal Mishra et al. [19].

A minor constituent of *P. somniferum* is the aporphine alkaloid **isoboldine**. Other species of poppy, e.g., *Papaver orientale* and *P. pseudoorientale*, are known to synthesize aporphine alkaloids as principal constituents rather than morphinan structures. (*S*)-Isoboldine is readily appreciated to be the product of oxidative coupling of (*S*)-**reticuline**, coupling *ortho* to the phenol group in the tetrahydroisoquinoline and *para* to the phenol of the benzyl substituent. structures, e.g., **isothebaine** from *P. orientale*, are not as easily rationalized. (*S*)-**Orientaline** is a precursor of isothebaine (Fig. 15.4). This benzyltetrahydroisoquinoline, with a different methylation pattern to reticuline, is able to participate in oxidative coupling, but inspection of the structures indicates a phenol group is lost in the transformation. The pathway involves an unexpected rearrangement process, however. Thus, oxidative coupling *ortho–para* to the phenol groups gives a dienone **orientalinone** (compare the structure of salutaridine). After reduction of the carbonyl group, a rearrangement occurs, restoring aromaticity and expelling the hydroxyl (originally a phenol group) to produce **isothebaine**. This type of rearrangement, for which good chemical analogies are available, is a feature of many other alkaloid biosynthetic pathways and occurs because normal keto–enol tautomerism is not possible for rearomatization when coupling involves positions already substituted. The process is fully borne out by experimental evidence, including the subsequent isolation of orientalinone and orientalinol from *P. orientale*.

Stephanine from *Stephania* species (Menispermaceae) is analogous to isothebaine and shares a similar pathway, though from (*R*)-**orientaline**. The different substitution pattern in stephanine compared to isothebaine is a consequence of the intermediate dienol suffering migration of the alkyl rather than aryl group. **Aristolochic acid** is a novel modified aporphine containing a nitro group and is produced from stephanine by oxidative reactions leading to ring cleavage. Aristolochic acid is present in many species of *Aristolochia* (Aristolochiaceae) used in traditional medicine, e.g., snake root *A. serpentina*. However, because aristolochic acid is now known to be nephrotoxic and to cause acute kidney failure, the use of *Aristolochia* species in herbal medicines, especially Chinese remedies, has been banned in several countries.

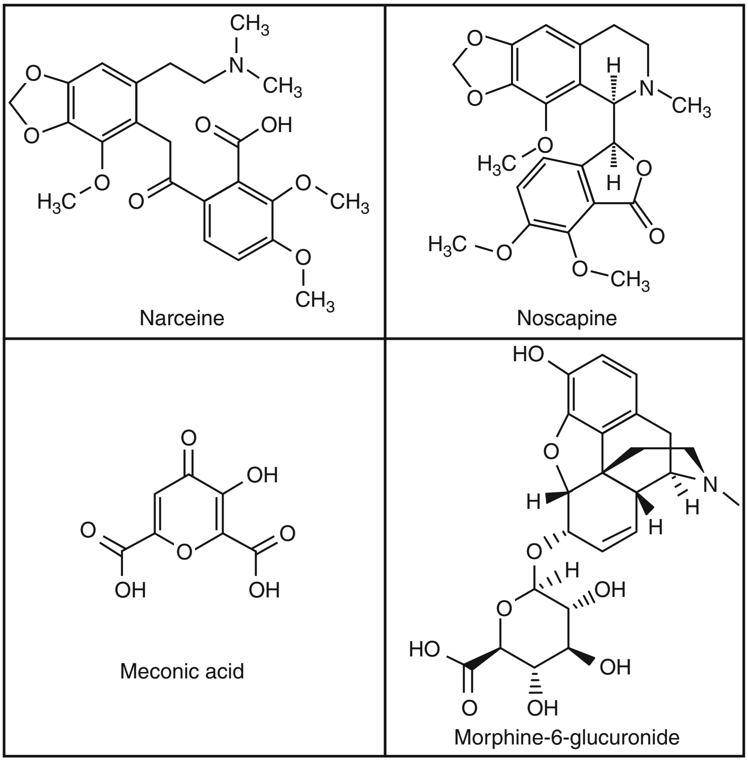

Fig. 15.5 Chemical structure of opium alkaloids

The alkaloid **berberine** is found in many members of the Berberidaceae (e.g., *Berberis*, *Mahonia*), the Ranunculaceae (e.g., *Hydrastis*), and other families. Berberine has antiamoebic, antibacterial, and antiinflammatory properties, and plants containing berberine have long been used in traditional medicine. Its tetracyclic skeleton is derived from a benzyltetrahydroisoquinoline system with the incorporation of an extra carbon atom, supplied from *S*-adenosylmethionine via an *N*-methyl group. This extraskeletal carbon is known as a "berberine bridge." Formation of the berberine bridge is readily rationalized as an oxidative process in which the *N*-methyl group is oxidized to an iminium ion, and a cyclization to the aromatic ring occurs by virtue of the phenolic group.

The oxidative cyclization process is analogous to the formation of a methylenedioxy group, while the mechanism of cyclization is exactly the same as that invoked in the formation of a tetrahydroisoquinoline ring, i.e., a Mannich-like reaction. The product from the enzymic transformation of (*S*)-**reticuline** is the protoberberine alkaloid (*S*)-**scoulerine**, the berberine bridge enzyme requiring molecular oxygen as oxidant and releasing H_2O_2 as by-product. Its role in the cyclization reaction completed, the phenol group in scoulerine is then methylated, and **tetrahydrocolumbamine** is oxidized further to give the quaternary isoquinoline system in **columbamine**. This appears to involve two separate oxidation steps, both requiring molecular oxygen, though H_2O_2 and H_2O are produced in the successive processes. The mechanistic sequence through an iminium ion has been suggested to account for these observations. Finally, **berberine** is produced by transformation of the *ortho*-methoxyphenol to a methylenedioxy group, via the O^2-, NADPH-, and cytochrome P450-dependent enzyme. The protoberberine skeleton of scoulerine may be subjected to further modifications. Cleavage of the heterocyclic ring systems adjacent to the nitrogen atom as shown give rise to new skeletal types: protopine, e.g., **protopine** from *Chelidonium majus* (Papaveraceae); phthalideisoquinoline, e.g., **hydrastine** from *Hydrastis canadensis* (Ranunculaceae); and benzophenanthridine, e.g., **chelidonine**, also from *Chelidonium majus*. The non-heterocyclic system seen in the opium alkaloid **narceine** from *Papaver somniferum* can be visualized as the result of cleavage of two of these bonds (Fig. 15.5). Some alkaloids of the phthalide type are medicinally important. **Noscapine** is one of the opium alkaloids, and although it lacks any analgesic activity, it is an effective cough suppressant (Fig. 15.5). **Hydrastine** is beneficial as a traditional remedy in the control of uterine bleeding. *Hydrastis* also contains berberine, indicating the close biosynthetic relationship of the two types of alkaloid. **Bicuculline** from species of *Corydalis* and *Dicentra* (Fumariaceae) and its quaternary methiodide have been identified as potent GABA (γ-aminobutyric acid) antagonists and have found widespread application as pharmacological probes for convulsants acting at GABA neuroreceptors. Figure 15.4 represents the branching points and links to different pathways in isoquinoline biosynthesis pathways.

6.1 The Opium Alkaloids

More than 12,000 alkaloids are known in plants, mostly used as medicine with a world market value of about 4 billion US$. Opium poppy, *Papaver somniferum*, is the most important economic source of morphinane alkaloids such as morphine, codeine, thebaine, narcotine, and papaverine that are exploited by the pharmaceutical industry as analgesics, antitussives, and antispasmodics. Opium is the air-dried milky exudates, or latex, obtained by incising the unripe capsules of the opium poppy *Papaver somniferum* (Papaveraceae). The plant is an annual herb with large solitary flowers, of white, pink, or dull red-purple color. For opium production, the ripening capsules, which are just changing color from blue-green to yellow, are carefully incised with a knife to open the latex tubes, but not to cut through to the interior of the capsule. These latex tubes open into one another, so it is not necessary to incise them all. Cuts are made transversely or longitudinally according to custom. The initially white milky latex quickly oozes out but rapidly turns brown and coagulates. This material, the raw opium, is then removed early the following morning, being scraped off and moulded into balls or blocks. Typically, these are wrapped in poppy leaves and shade-dried. The blocks may be dusted with various plant materials to prevent cohering. Fresh opium is pale to dark brown and plastic, but it becomes hard and brittle when stored. Crude opium has been used as an analgesic and sleep inducer (narcotic) and for the treatment of coughs. Opium has traditionally been smoked for pleasure, but habitual use develops a craving for the drug followed by addiction. An unpleasant abstinence syndrome is experienced if the drug is withdrawn [20].

The six opium alkaloids which occur naturally in the largest amounts are morphine, narcotine, codeine, thebaine, papaverine, and narceine. Of these, three are phenanthrene alkaloids and are under international control; these are morphine, codeine, and thebaine. They are all three used in the drug industry, thebaine usually for conversion into some derivative which is more useful medically. Of the other three, not under international control, narcotine and narceine have scarcely any medical or other uses. Consequently, the four economically significant alkaloids of opium are morphine, codeine, thebaine, and papaverine. About twenty other alkaloids exist in opium, but they have little or no significance medically or economically up to the present time. The relative proportions of the different alkaloids vary greatly, however, in different kinds of opium and certainly also in different varieties of the poppy. All varieties, however, belong to one species of poppy, *P. somniferum*. Figure 15.6 represents the biosynthesis of opium alkaloids.

In modern medicine, only the purified opium alkaloids and their derivatives are commonly employed. Although the ripe poppy capsule can contain up to 0.5 % total alkaloids, opium represents a much concentrated form and up to 25 % of its mass is composed of alkaloids. Of the many (>40) alkaloids identified, some six represent almost all of the total alkaloid content. Actual amounts vary widely, e.g., morphine (4–21 %), codeine (0.8–2.5 %), thebaine (0.5–2.0 %), papaverine (0.5–2.5 %), noscapine (narcotine) (4–8 %), and narceine (0.1–2 %). A typical commercial sample of opium would probably have a morphine content of about 12 %. Powdered opium is standardized to contain 10 % of anhydrous morphine, usually by dilution with an approved diluent, e.g., lactose or cocoa husk powder. The alkaloids are largely combined in salt form with meconic acid, opium containing some 3–5 % of this material. Meconic acid is invariably found in opium but, apart from its presence in other Papaver species, has not been detected elsewhere. It gives a deep red-colored complex with ferric chloride, and this has thus been used as a rapid and reasonably specific test for opium. Of the main opium alkaloids, only morphine and narceine display acidic properties, as well as the basic properties due to the tertiary amine. Narceine has a carboxylic acid function, while morphine is acidic due to its phenolic hydroxyl. This acidity can be exploited for the preferential extraction of these alkaloids (principally morphine) from an organic solvent by partitioning with aqueous base (Table 15.6).

6.1.1 Morphine

Morphine is the main alkaloid of opium both in amount and in medical importance (UNODC-Bulletin on Narcotics). The expression of the morphine content of opium as a percentage depends in part on the moisture content. When the government

purchases the opium as soon as practicable after it is collected, the moisture content is then usually about 30 percent (%). Commercial opium usually has around 15–10 % moisture. Opium apparently dry at ordinary temperatures still retains considerable moisture, usually about 6 % which can be driven off at about 103° centigrade. Normal, unadulterated opium of any type, in the air-dry condition, usually has between 8 and 19 % of morphine. The principal commercial opiums generally have approximately the following morphine contents: Yugoslavia 15 %, Turkey 13 %, Iran 11 %, and India 11 %. The quantity of morphine produced by poppy plants in the form of opium depends on two factors: the percentage of morphine in the opium and the quantity of opium produced. The latter factor in turn depends in part on whether each capsule is bled several times, or once only. In Turkey, Yugoslavia, Greece, and Bulgaria, it is customary to bleed each capsule only once, but in most other opium-producing

Table 15.6 Representation of chemical category and component of opium alkaloids

Chemical category	Opium components
Alkaloids	16-Hydroxythebaine, berberine, canadine, codamine, coptisine, coreximine, cycloartenol, cycloartenone, cyclolaudenol, dehydroreticuline, dihydrosanguinarine, glaucine, isoboldine, isocorypalmine, laudanidine, magnoflorine, narceine, narceinone, norlaudanosoline, norsanguinarine, oripavine, oxysanguinarine, palaudine, papaverrubine B (*O*-methyl-porphyroxine), papaverrubine C (epiporphyroxine), reticuline, salutaridine (sinoacutine), sanguinarine, scoulerine, somniferine, stepholidine
Morphine group (phenanthrenes, opioids)	Codeine, morphine, narcotoline, neopine, perparin, papaverrubine D (porphyroxine), pseudocodeine, pseudomorphine, thebaine
Isoquinolines	Cotarnine, eupaverine, hydrocotarnine, laudanosine, laudanine, noscapine (narcotine), papaverine, papaveraldine, xanthaline
Protopine group	α-Allocryptopine, α-fagarine, corycavamine, corycavine, cryptopine, protopine
Tetrahydroprotoberberine group	Corydaline, corybulbine, isocorybulbine, capaurine
Aporphine group	Dicentrine, glaucine, corytuberine, cularine, corydine, isocorydine, bulbocapnine
Phtalide-isoquinolines	Adulmine, bicuculline, bicucine, corlumine
α-Naphthaphenanthridines	Chelidonine, β-homochelidonoine, chelerythrine, sanguinarine
Other components	Meconic acid

countries, the capsules are incised repeatedly, often four or five times on different days, until they will yield no more latex.

The quantity of latex falls off rapidly with later incisions, and so does the morphine content, as was shown by Annett in India (1). Usually, all the opium so obtained is mixed together. This is probably the chief reason for the lower morphine content of Iranian and Indian opiums as compared with Turkish and Yugoslav opiums, although it must also be recognized that there are low-yielding and high-yielding strains of the poppy, one or the other of which may predominate in a given district. Samples of opium assaying some 15 % morphine from Japan, Indochina, and Afghanistan, as well as from Turkey, Greece, and Yugoslavia, have been examined by the Secretariat. Afghanistan at one time exported two grades of opium, one of about 15 % morphine and the other about 10 %. The morphine content of dry capsule-chaff is about 0.25–0.5 % when not washed out by rain. Here again there are low-yielding and high-yielding varieties, but proper agricultural selection of poppies for morphine production means taking into account not only the percentage yield of morphine but also the total weight of the capsule-chaff produced per hectare, the poppy seed production per hectare, and other factors. Morphine is used to manufacture apomorphine (not subject to the conventions), codeine, ethylmorphine, beta-4-morpholinylethylmorphine, benzylmorphine, diacetylmorphine, dihydromorphine, hydromorphone (dihydromorphinone), metopon, morphine-*N*-oxide, desomorphine (dihydrodesoxymorphine), and *N*-allyl-normorphine.

Pathway	Isoquinoline alkaloid biosynthesis (rn00950)

6.1.2 Codeine

The codeine content of opium is related inversely to the morphine content but only in a general way. The codeine content is closely related to the type of opium produced in a given district or even in some cases in an entire country. The opiums of the principal exporting countries have approximately the following percentages of codeine: Yugoslavia 1.25 %, Turkey 1.25 %, Iran 3.4 %, and India 3.0 %. The manufacturer's statistics do not ordinarily show all the codeine obtained from opium. Some of its coprecipitates with the morphine, and there is no necessity of purifying the morphine completely on its codeine content, especially if it is to be used to manufacture more codeine. Codeine is used to manufacture dihydrocodeine and acetyldihydrocodeine and may also be used to manufacture the drugs ordinarily made by conversion of thebaine.

KEGG reaction entry	R05124
Name	Codeine: NADP + oxidoreductase

	Enzyme	1.1.1.247; Codeinone reductase (NADPH); oxidoreductases; codeine-NADP + oxidoreductase
Pathway	Isoquinoline alkaloid biosynthesis (rn00950)

6.1.3 Thebaine

The Secretariat is currently engaged in a survey, the most extensive ever attempted in this field, of opium samples from different regions for their thebaine and papaverine percentages. As yet, it is premature for general conclusions. However, the highest thebaine percentages found (nearly 5 %) were in some samples from Indochina, which at the same time had virtually no papaverine. Both thebaine and papaverine have been higher in the most Iranian samples run. Papaverine is low in some Afghan and Indian opiums. Thebaine is the most poisonous opium alkaloid and is scarcely used medically. It is even omitted from some of the preparations of mixed opium alkaloids which are used as soluble substitutes for opium. However, it is converted into several other narcotics which have medical use: hydrocodone (dihydrocodeinone), acetyldihydrocodeinone, and oxycodone (dihydrohydroxy-codeinone). Papaverine has a considerable medical use, so much so that supplies available from opium have sometimes run short. It is then manufactured synthetically.

KEGG reaction entry	R04769
Definition	7-*O*-Acetylsalutaridinol < = > thebaine + acetate

6.2 Papaverine

Papaverine is a benzylisoquinoline alkaloid and is structurally very different from the morphine, codeine, and thebaine group of alkaloids (morphinans). It has little or no analgesic or hypnotic properties put possesses spasmolytic and vasodilator activity. It has been used in some expectorant preparations and in the treatment of gastrointestinal spasms, but its efficacy was not substantiated. It is sometimes used as an effective treatment for male impotence, being administered by direct injection to achieve an erection of the penis.

Papaverine is an opium alkaloid antispasmodic drug, used primarily in the treatment of visceral spasm, vasospasm (especially those involving the heart and the brain), and occasionally in the treatment of erectile dysfunction. While it is found in the opium poppy, papaverine differs in both structure and pharmacological action from the analgesic (morphine-related) opium alkaloids (opioids). Papaverine is approved to treat spasms of the gastrointestinal tract, bile ducts, and ureter and for use as a cerebral and coronary vasodilator in subarachnoid hemorrhage (combined with balloon angioplasty) and coronary artery bypass surgery. Papaverine may also be used as a smooth muscle relaxant in microsurgery where it is applied directly to blood vessels.

Papaverine is used as an erectile dysfunction drug. Papaverine, when injected in penile tissue, causes direct smooth muscle relaxation and consequent filling of the corpus cavernosum with blood, resulting in erection. It is also commonly used in cryopreservation of blood vessels along with the other glycosaminoglycans and protein suspensions. It functions as a vasodilator during cryopreservation when used in conjunction with verapamil, phentolamine, nifedipine, tolazoline, or nitroprusside. Papaverine is also being investigated as a topical growth factor in tissue expansion with some success.

6.2.1 Narceine

Narceine is an opium alkaloid produced by the *Papaver somniferum* (opium poppy) plant. It is a bitter, crystalline compound with narcotic effects and was formerly used as a substitute for morphine (Fig. 15.5).

6.2.2 Noscapine

Noscapine was first isolated and characterized in the chemical breakdown and properties in 1817 under the denomination of “Narcotine” by Pierre Robiquet, a French chemist in Paris. Noscapine’s antitussive effects appear to be primarily mediated by its sigma receptor agonist activity. Noscapine is currently under investigation for use in the treatment of several cancers and hypoxic ischemia in stroke patients. Noscapine can survive the manufacturing processes of heroin and can be found in street heroin.

Noscapine is a member of the phthalideisoquinoline alkaloids and provides a further structural variant in the opium alkaloids. Noscapine has good antitussive and cough suppressant activity comparable to that of codeine, but no analgesic or narcotic action. Its original name “narcotine” was changed to reflect this lack of narcotic action. Despite many years of use as a cough suppressant, the finding that noscapine may have teratogenic properties (i.e., may deform a fetus) has resulted in noscapine preparations being deleted. In recent studies, antitumour activity has been noted from noscapine, which binds to tubulin as do podophyllotoxin and colchicine, thus arresting cells in mitosis. The chemotherapeutic potential of this orally effective agent merits further evaluation. Noscapine (also known as narcotine, nectodon, nospen, anarcotine, and (archaic) opiane) is a benzylisoquinoline alkaloid from plants of the Papaveraceae family, without significant painkilling properties. This agent is primarily used for its antitussive (cough-suppressing) effects. It has also been shown to have anticancer activity (Fig. 15.5).

7 Other Compounds

7.1 Meconic Acid

Meconic acid, also known as acidum meconicum and poppy acid, is a chemical substance found in certain plants of the Papaveraceae family (poppy) such as Papaver somniferum (opium poppy) and Papaver bracteatum. Meconic acid constitutes about 5 % of opium and can be used as an analytical marker for the presence of opium. Meconic acid has erroneously been described as a mild narcotic, but it has little or no physiological activity, and is not used medicinally. Meconic acid forms salts with alkaloids and metals. These salts as well as meconic acid esters are called meconates. Meconic acid was first isolated by Friedrich Sertürner in 1805 (Fig. 15.5).

7.2 Morphine-6-Glucuronide

Morphine-6-glucuronide (M6G) is a major active metabolite of morphine and as such is the molecule responsible for much of the pain-relieving effects of morphine (and thus heroin). M6G is formed from morphine by the enzyme

UDP-glucuronosyltransferase-2B7 (UGT2B7). M6G can accumulate to toxic levels in kidney failure. The opioid receptor subtype 3 appears to be activated (agonized) by morphine-6β-glucuronide but not morphine itself. This finding is also true of certain heroin metabolites (6-MAM) but not morphine proper. This analgesic activity of M6G (in animals) was first noted by Yoshimura (Fig. 15.5).

7.3 Narcotoline

Narcotoline is an opiate alkaloid chemically related to noscapine. It binds to the same receptors in the brain as noscapine to act as an antitussive and has also been used in tissue culture media. It can be obtained from the opium poppy, Papaver somniferum. It is present at much higher levels in culinary strains (cultivars) of *P. somniferum* used for poppy seed production than in high-morphine pharmaceutical strains used for opium production.

KEGG reaction entry	R05211

Pathway	Isoquinoline alkaloid biosynthesis (rn00950)

7.4 Pseudomorphine

Pseudomorphine (also known as oxydimorphine or dehydromorphine) is a natural dimerization product of the morphine molecule in tandem and thus a common impurity in morphine concentrations. It was first described by Pelletier in 1835. This compound may be synthesized by the oxidative coupling of morphine by potassium ferricyanide.

7.5 Laudanosine

Laudanosine or *N*-methyltetrahydropapaverine is a recognized metabolite of atracurium and cisatracurium. Laudanosine decreases the seizure threshold, and thus, it can induce seizures if present at sufficient threshold concentrations; however, such concentrations are unlikely to be produced consequent to chemodegradable metabolism of clinically administered doses of cisatracurium or atracurium. Laudanosine also occurs naturally in minute amounts (0.1 %) in opium, from which it was first isolated in 1871. Partial dehydrogenation of laudanosine will lead to papaverine, the alkaloid found in the opium poppy plant (Papaver somniferum). Laudanosine is a benzyltetrahydroisoquinoline alkaloid. It has been shown to interact with GABA receptors, opioid receptors, and nicotinic acetylcholine receptors, but not benzodiazepinergic or muscarinic receptors which are also involved in epilepsy and other types of seizures.

7.6 Berberine

Berberine is a quaternary ammonium salt from the protoberberine group of isoquinoline alkaloids. It is found in such plants as Berberis (e.g., Berberis aquifolium (Oregon grape), Berberis vulgaris(Barberry), and Berberis aristata (Tree Turmeric)),Hydrastis canadensis (Goldenseal), Phellodendron amurense (Amur Cork Tree, Huang Bai, Huang Po, Po Mu) and Coptis chinensis (Chinese Goldthread, Huang-Lian, Huang-Lien), and Tinospora cordifolia, and to a smaller extent in Argemone mexicana (Prickly Poppy) and Eschscholzia californica (Californian Poppy). Berberine is usually found in the roots, rhizomes, stems, and bark. Berberine is strongly yellow colored, which is why in earlier times Berberis species were used to dye wool, leather, and wood. Wool is still today dyed with berberine in northern India. Under ultraviolet light, berberine shows a strong yellow fluorescence. Because of this, it is used in histology for staining heparin in mast cells. As a natural dye, berberine has a Colour Index (CI) of 75160.

As a traditional medicine or dietary supplement, berberine has shown some activity against fungal infections, Candida albicans, yeast, parasites, and bacterial/viral infections. Berberine seems to exert synergistic effects with fluconazole even in drug-resistant Candida albicans infections. Some research has been undertaken into possible use against MRSA infection. Berberine is considered antibiotic. When applied in vitro and in combination with methoxyhydnocarpin, an inhibitor of multidrug resistance pumps, berberine inhibits growth of Staphylococcus aureus and Microcystis aeruginosa, a toxic cyanobacterium. Berberine is a component of some eye drop formulations. There is some evidence it is useful in the treatment of trachoma, and it has been a standard treatment for leishmaniasis. Berberine prevents and suppresses proinflammatory cytokines, E-selectin, and genes, and increases adiponectin expression which partly explains its versatile health effects. Berberine is a nucleic acid-binding isoquinolone alkaloid with wide potential therapeutic properties. Berberine is produced by transformation of the *ortho*-methoxyphenol to a methylenedioxy group, via the O_2^-, NADPH$^-$, and cytochrome P450-dependent enzyme.

7.7 Sanguinarine

Sanguinarine is a quaternary ammonium salt from the group of benzylisoquinoline alkaloids. It is extracted from some plants, including bloodroot (Sanguinaria canadensis), Mexican prickly poppy Argemone mexicana, Chelidonium majus and Macleaya cordata. It is also found in the root, stem and leaves of the opium poppy but not in the capsule. Sanguinarine is a toxin that kills animal cells through its action on the Na^+-K^+ -ATPase transmembrane protein. Epidemic dropsy is a disease that results from ingesting sanguinarine. If applied to the skin, sanguinarine kills cells and may destroy tissue. In turn, the bleeding wound may produce a massive scab, called an eschar. For this reason, sanguinarine is termed an escharotic. In plants, sanguinarine is synthesized from dihydrosanguinarine through the action of dihydrobenzophenanthridine oxidase (EC 1.5.3.12).

7.8 Coptisine

Coptisine is an alkaloid found in Chinese goldthread (Coptis chinensis). Famous for the bitter taste that it produces, it is used in Chinese herbal medicine along with the related compound berberine for treating digestive disorders caused by bacterial infections. It is also found in Greater Celandine and has also been detected in opium. Coptisine has been found to reversibly inhibit Monoamine oxidase A in mice, pointing to a potential role as a natural antidepressant. However, this may also imply a hazard for those taking other medications or with a natural functional disorder in Monoamine oxidase A. Coptisine was found to be toxic to larval brine shrimp and a variety of human cell lines, potentially implying a therapeutic effect on cancer or alternatively a generally toxic character. The same authors illustrate a four-step process to produce Coptisine from Berberine.

7.9 Cycloartenol

Cycloartenol is an important type of stanol found in plants. The biosynthesis of cycloartenol starts from the triterpenoid squalene. It is the first precursor in the biosynthesis of other stanols and sterols, referred to as phytostanols and phytosterols in photosynthetic organisms and plants. The identities and distribution of phytostanols and phytosterols is characteristic of a plant species. One notable product of cycloartenol biosynthesis is the triterpenoid lanosterol.

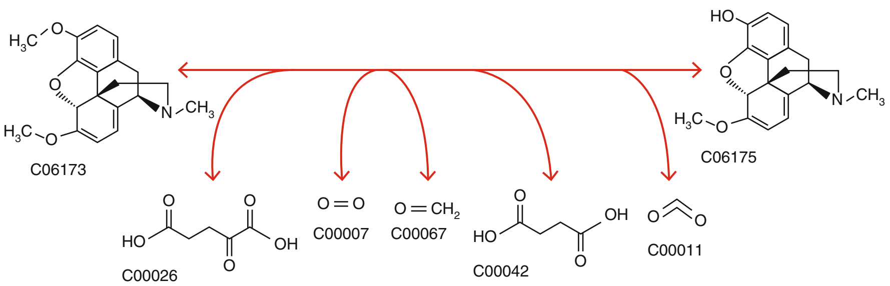
7.10 Glaucine

Glaucine is an alkaloid found in several different plant species such as Glaucium flavum, Glaucium oxylobum, Croton lechleri and Corydalis yanhusuo. It has bronchodilator and antiinflammatory effects, acting as a PDE4 inhibitor and calcium channel blocker, and is used medically as an antitussive in some countries. Glaucine may produce side effects such as sedation, fatigue, and a hallucinogenic effect characterized by colorful visual images, and has recently been detected as a novel recreational drug.

7.11 Oripavine

Oripavine is an opiate and the major metabolite of thebaine. It is the parent compound from which a series of semisynthetic opioids are derived, which includes the compounds etorphine and buprenorphine. Although its analgesic potency is comparable to morphine, it is not used clinically due to its severe toxicity and low therapeutic index. Oripavine possesses an analgesic potency comparable to morphine; however, it is not clinically useful due to severe toxicity and low therapeutic index. In both mice and rats, toxic doses caused tonic-clonic seizures followed by death, similar to thebaine. Oripavine has a potential for dependence which is significantly greater than that of thebaine but slightly less than that of morphine.

KEGG reaction entry	R05127
Name	thebaine,2-oxoglutarate:oxygen oxidoreductase (3-*O*-demethylating)
Definition	Thebaine + 2-oxoglutarate + oxygen < = > oripavine + formaldehyde + succinate + CO2
Equation	C06173 + C00026 + C00007 < = > C06175 + C00067 + C00042 + C00011



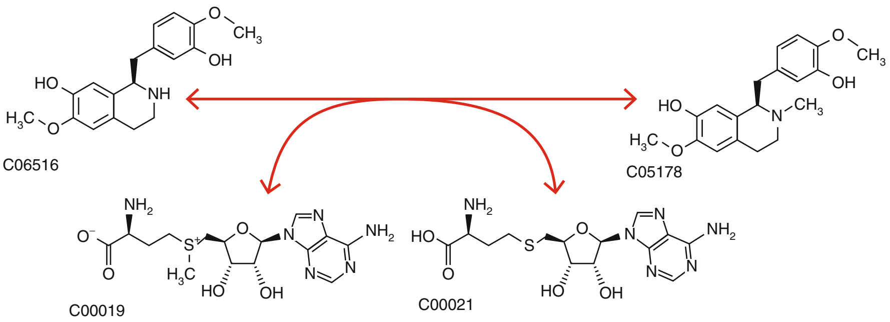
Enzyme	1.14.11.32; codeine 3-*O*-demethylase; codeine *O*-demethylase; CODM; oxidoreductases; codeine,2-oxoglutarate:oxygen oxidoreductase (3-*O*-demethylating)
Pathway	Isoquinoline alkaloid biosynthesis (rn00950)
KEGG Reaction Entry	R03698
Name	Oripavine,2-oxoglutarate:oxygen oxidoreductase (6-*O*-demethylating)
Definition	Oripavine + 2-oxoglutarate + oxygen < = > morphinone + formaldehyde + succinate + CO2

(*continued*)

Equation	C06175 + C00026 + C00007 < = > C01735 + C00067 + C00042 + C00011
	 C06175 C01735 C00026 C00007 C00067 C00042 C00011
Enzyme	1.14.11.31; thebaine 6-*O*-demethylase; T6ODM; oxidoreductases
Pathway	Isoquinoline alkaloid biosynthesis (rn00950)

7.12 Reticuline

Reticuline is a chemical compound that can be found in Lindera aggregata. It is also one of the alkaloids found in opium. Metabolism showed that 3′-hydroxy-*N*-methyl-(S)-coclaurine 4′-*O*-methyltransferase uses *S*-adenosyl methionine and 3′-hydroxy-*N*-methyl-(S)-coclaurine to produce S-adenosylhomocysteine and (S)-reticuline. Reticuline oxidase uses (S)-reticuline and O_2 to produce (S)-scoulerine and H_2O_2. Salutaridine synthase uses (R)-reticuline, NADPH, H^+, and O_2 to produce salutaridine, NADP$^+$, and H_2O. 1,2-dehydroreticulinium reductase (NADPH) uses (R)-reticuline and NADP + to produce 1,2-dehydroreticulinium, NADPH, and H^+.

KEGG Reaction Entry	R05216
Name	S-adenosyl-L-methionine:(RS)-1-benzyl-1,2,3,4-tetrahydroisoquinolie *N*-methyltransferase
Definition	S-adenosyl-L-methionine + (R)-Norreticuline < = > S-adenosyl-L-homocysteine + (R)-reticuline
Equation	C00019 + C06516 < = > C00021 + C05178
	


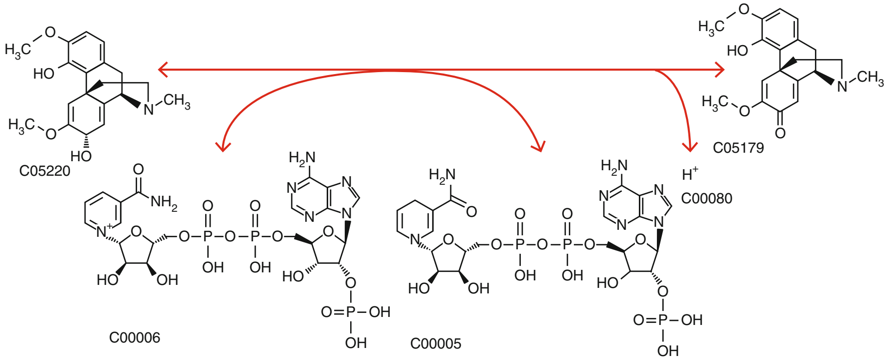
(*continued*)

Enzyme	2.1.1.115; (RS)-1-benzyl-1,2,3,4-tetrahydroisoquinoline N-methyltransferase; norreticuline N-methyltransferase; transferases
Pathway	Isoquinoline alkaloid biosynthesis (rn00950)

7.13 Salutaridine

Salutaridine is an alkaloid that is present in the morphinan alkaloid pathway of opium poppy. Its precursor is the alkaloid (R)-reticuline. (R)-reticuline is converted to salutaridine by the enzyme salutaridine synthase. Salutaridine is converted to salutaridinol by the enzyme salutaridine reductase (SalR), with the reduction of NADPH to NADP$^+$.

KEGG Reaction Entry	R04697
Name	Salutaridinol: NADP + 7-oxidoreductase
Definition	5,6,8,14-Tetradehydro-3,6-dimethoxy-17-methyl-morphinan-4,7-diol + NADP + < = > salutaridine + NADPH + H+
Equation	C05220 + C00006 < = > C05179 + C00005 + C00080



1.1.1.248; Salutaridine reductase (NADPH); oxidoreductases
Isoquinoline alkaloid biosynthesis (rn00950)
Salutaridine reductase (NADPH) [EC:1.1.1.248] (K13392)

7.14 Sanguinarine

Sanguinarine is a quaternary ammonium salt from the group of benzylisoquinoline alkaloids. It is extracted from some plants, including bloodroot (Sanguinaria canadensis), Mexican prickly poppy Argemone mexicana, Chelidonium majus, and Macleaya cordata. It is also found in the root, stem, and leaves of the opium poppy but not in the capsule. Sanguinarine is a toxin that kills animal cells through its action on the Na$^+$-K$^+$-ATPase transmembrane protein. Epidemic dropsy is a disease that results from ingesting sanguinarine. If applied to the skin, sanguinarine kills cells and may destroy tissue. In turn, the bleeding wound may produce a massive scab, called an eschar. For this reason, sanguinarine is termed an escharotic. In plants, sanguinarine is synthesized from dihydrosanguinarine through the action of Dihydrobenzophenanthridine oxidase (EC 1.5.3.12).

7.15 Scoulerine

Scoulerine, also known as discretamine and aequaline, is an alkaloid found in the opium poppy, Croton flavens, and certain plants in the Erythrina genus. Studies show that scoulerine is an antagonist at the α2-adrenoceptor, α1D-adrenoceptor, and 5-HT receptor. It has also been found to be a GABAA receptor agonist.

KEGG reaction entry	R03831
Name	(S)-reticuline:oxygen oxidoreductase (methylene-bridge-forming)
Definition	(S)-reticuline + oxygen < = > (S)-scoulerine + hydrogen peroxide
Equation	C02105 + C00007 < = > C02106 + C00027
	 OH O CH3 HO N CH3 H3C O C02105 O=O C00007 HO—OH C00027 O CH3 H OH HO N H3C O C02106
Enzyme	1.21.3.3; Reticuline oxidase; BBE; berberine bridge enzyme; berberine-bridge-forming enzyme; tetrahydroprotoberberine synthase; oxidoreductases
Pathway	Isoquinoline alkaloid biosynthesis (rn00950)
Orthology	Reticuline oxidase [EC:1.21.3.3]

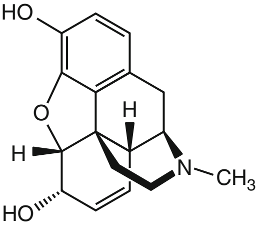
7.16 Stepholidine

(−)-Stepholidine is a naturally occurring chemical compound found in the herb Stephania intermedia. Stepholidine is a dual D2 receptor antagonist and D1 receptor agonist, and has shown antipsychotic activity in animal studies.

7.17 Structure and Properties of Alkaloids

The different types of alkaloids have different structures and thus have different properties. The structures and properties of alkaloids have been represented in Table 15.7 and 15.8

Table 15.7 Comparison of the properties of different opium alkaloids



Morphine

8 Use of Alkaloids in Medicine

Natural compounds, mostly from plants, have been the mainstay of traditional medicine for thousands of years [21]. They have also been the source of lead compounds for modern medicine, but the extent of mining of natural compounds for such leads decreased during the second half of the twentieth century. The advantage of natural compounds for the development of drugs derives from their innate affinity for biological receptors. Natural compounds have provided the best antimalarials known to date. Recent surveys have identified many extracts of various organisms (mostly plants) as having anti-plasmodial activity. Huge libraries of fractionated natural compounds have been screened with impressive hit rates. Importantly, many cases are known where the crude biological extract is more efficient pharmacologically than the most active purified compound from this extract. This could be due to synergism with other compounds present in the extract, which as such have no pharmacological activity. Indeed, such compounds are best screened by cell-based assay where all potential targets in the cell are probed and possible synergies identified. Traditional medicine uses crude extracts. These have often been shown to provide many concoctions that deal better with the overall disease condition than with the causative agent itself. Traditional medicines are used by ∼80 % of Africans as a first response to ailment. Many of the traditional medicines have demonstrable anti-plasmodial activities. It is suggested that rigorous evaluation of traditional medicines involving controlled clinical trials in

parallel with agronomical development for more reproducible levels of active compounds could improve the availability of drugs at an acceptable cost and a source of income in malaria endemic countries [21].

8.1 Antimalarial Properties of Alkaloids

Developing countries suffering from various infectious diseases like HIV, tuberculosis, and malaria. Among these diseases, malaria is the major killer of humans, and approximately 300–500 million clinical cases and one million deaths per year caused world wide due to malaria [22]. Four Plasmodium species (*P. vivax, P. ovale, P. malariae, and P. falciparum*) are responsible for human malaria. Out of these, *P. falciparum* species causes most fatal form of malaria. This parasite has a plastid-like organelle called as apicoplast. Resistance to known antimalarial and the lack of an effective vaccine has created an urgent need to discover new biologically active compounds.

Natural compounds as a source for antimalarial drugs. Research on natural compounds has already contributed to the discovery of new antimalarial drugs. Atovaquone, artemisinin, and its semisynthetic derivatives, as well as clindamycin, erythromycin, azithromycine, chlortetracycline, tetracycline, oxytetracycline, and doxycycline, are noteworthy examples of the varied contribution of natural products for the development of effective antimalarial drugs, particularly valuable for the treatment of chloroquine-resistant parasites. Several comprehensive reviews on the antimalarial potency of plant products derived from ethnic medicine were published in the last decade. The quality of the data used in these reviews differs, and in earlier reports the chemical structure of the purified compound was not known and toxicity tests were not performed. However, in many cases, good activity and selectivity were observed. Most importantly, several compounds containing unique structural composition have been isolated and characterized. It is therefore not surprising that natural compounds dominate the recent malaria patent literature [21]. Although many compounds cannot be further developed for reasons mentioned above, the discovered lead compounds provide valuable bioactive scaffolds which could be further adjusted by semisynthetic approaches to obtain effective antimalarials.

Living organisms, especially plants, provide an innumerable number of molecules with potential for the treatment of many serious diseases. The current chapter attempts to give an overview on the potential of such plant-derived natural products as antiprotozoal leads and/or drugs [23]. Many plant species are used in traditional medicines of malarious countries, and a relatively few number of these have been investigated for evaluation of their antimalarial effect. Still lower is the number of those that have had the active natural compounds isolated and the toxicity determined [24]. Indole alkaloids are one of the important class of marine-derived secondary metabolites, with wide occurrence among variety of marine sources such as sponges, tunicates, algae, worms, and microorganisms and have been extensively studied for their biological activities. Among this chemical family, a sponge-derived bis-indole alkaloid fascaplysin (1) exhibited broad range of bioactivities including antibacterial, antifungal, antiviral, anti-HIV-1-RTase, p56 tyrosine kinase inhibition, antimalarial, anti-angiogenic, antiproliferative activity against numerous cancer cell lines, specific inhibition of cyclin-dependent kinase-4 (IC(50) 350 nM) and action as a DNA intercalator [25].

The possible anti-plasmodial compounds from leaf, stem, root, and flower extracts of Ocimum canum (*O. canum*), *Ocimum sanctum* (*O. sanctum*), and *Ocimum basilicum* (*O. basilicum*) have been analyzed by Inbaneson et al. [35]. The leaf extract of O. sanctum showed excellent anti-plasmodial activity ($IC_{(50)}$ 35.58 μg/mL) followed by leaf extract of O. basilicum ($IC_{(50)}$ 43.81 μg/mL).

The in vitro anti-plasmodial activity might be due to the presence of alkaloids, glycosides, flavonoids, phenols, saponins, triterpenoids, proteins, resins, steroids, and tannins in the ethanolic extracts of tested plants. Thirty bioactive compounds belonging to a variety of chemical classes such as spermine and isoquinoline alkaloids, glycosylflavones, phenylethanoid glycosides, ecdysteroids, quercetin arabinofuranosides, clerodane-type diterpenoids, sipandinolid, galloylquercetin derivatives, gallates, oleamide, and mangiferin derivatives [26]. Bioassay-guided fractionation of the MeOH extract from the stem bark of Neonauclea purpurea used in traditional medicine resulted in the isolation of 2 indole alkaloids, cadambine (1) and alpha-dihydrocadambine (2), as well as a quinolic compound, 2,6-dimethoxy-1,4-benzoquinone (3). Antimalarial activity evaluation showed that compounds 2 and 3 exhibited mild in vitro antimalarial activity against *Plasmodium falciparum*, [27].

Two new indole alkaloids, bisnicalaterine D (1), consisting of an eburnane and a corynanthe type of skeletons, and nicalaterine A (2) were isolated from the bark of Hunteria zeylanica. Their structures were elucidated by various spectroscopic data such as NMR and CD spectra. A series of bisnicalaterines and nicalaterine A showed potent anti-plasmodial activity against *P. falciparum* 3D7 [28].

8.2 Anticancer Properties of Alkaloids

Several methods exist for the treatment of cancer in modern medicine. These include chemotherapy, radiotherapy, and surgery; most cancer chemotherapeutants severely affect the host normal cells. Hence, the use of natural products now has been contemplated of exceptional value in the control of cancer. Plant-derived natural products such as flavonoids, terpenes, and alkaloids have received considerable attention in recent years due to their diverse pharmacological properties including cytotoxic and cancer chemopreventive effects.

The antioxidant and anticancer evaluation of Scindapsus officinalis (Roxb.) Schott fruits has been attempted to investigate its antitumor activity [29]. The collection and authentication of the plant material, mainly fruits, and their various extractions were done. Identification of plant's active constituents by preliminary phytochemical screening was carried out. An *in vitro* cytotoxic assay using the brine shrimp lethality assay with brine shrimp eggs (Artemia salina) at a dose of 1–10 μg/ml with the fruit extract was performed.

Increasing recurrence of mammalian tumors and severe side effects of chemotherapeutic agents reduce the clinical efficacy of a large variety of anticancer agents that are currently being used. Vinca alkaloid and their derivatives, alone and in combination with therapeutic agents, have been used for a long time for the treatment of various types of cancers. Polyphenols form one of the most important and extensively used classes of plant-derived therapeutics for cancer prevention or chemotherapy. The present chapter highlights a plethora of studies focused on the antineoplastic properties of plant-derived chemicals, such as vinca alkaloids, saponins, and flavonoids [30].

Nature is the main source of compounds for pharmaceutical purposes, either by providing the natural organic chemical compounds of interest or as a source of inspiration for the design of new drugs. The known antiinflammatory and anticancer agents belong to a great diversity of structural skeletons since inflammatory and cancer processes involve many different biological targets. Their origins extend to plants, fungi, bacteria, and marine organisms, besides those produced by semisynthesis and total synthesis. The tasks of the organic chemist are the screening, the structure assignment, and the semi and total syntheses of active molecules. The active compounds are organized by their biosynthetic origins as terpenoids; macrolides, polyketides, and ansamycins; phenolics; alkaloids; peptides; glycoconjugates; other compounds; and food compounds [31]. The isolation of the vinca alkaloids, vinblastine, and vincristine. Paclitaxel (Taxol®, **3**) from the bark of the Pacific Yew, *Taxus brevifolia* Nutt. Camptothecin, isolated from the Chinese ornamental tree *Camptotheca acuminate* Decne (Nyssaceae), Topotecan and irinotecan are semisynthetic derivatives of camptothecin and are used for the treatment of ovarian and small cell lung cancers, and colo-rectal cancers, respectively [32]. Epipodophyllotoxin is an isomer of podophyllotoxin which was isolated as the active antitumor agent from the roots of *Podophyllum* species, *Podophyllum peltatum* Linnaeus and *Podophyllum emodi* Wallich (Berberidaceae) [33]. Etoposide and teniposide are two semisynthetic derivatives of epipodophyllotoxin and are used in the treatment of lymphomas and bronchial and testicular cancers [34]. Homoharringtonine, isolated from the Chinese tree *Cephalotaxus harringtonia* var. *drupacea* (Sieb and Zucc.).

9 Conclusion

In this chapter, we studied and analyzed the various biosynthetic routes involved in biosynthesis of alkaloids especially tyrosine-derived alkaloids. The plant alkaloids have been known to have important medicinal values and provided the medicines for the treatments of cancer, malaria, tuberculosis, etc. Keeping in mind the therapeutic importance, there is an urgent need to investigate their biosynthesis at the level of enzyme and gene.

Abstract

Alkaloids are one of the most important groups of secondary metabolites used since prehistoric age. It has been used as an anti-inflammatory agent for a long time. Besides, as a potential mitotic poison, colchicine is applied to produce polyploid and double haploid plants by the plant breeders. Colchicine is

a tricyclic proto-alkaloid, which has nitrogen atom in the side chain. Colchicine and its precursor autumnaline belong to phenethylisoquinoline group of alkaloids derived from tyrosine. Colchicine and its derivatives have been found in several genera such as *Colchicum*, *Gloriosa*, *Merendera*, *Androcymbium*, *Sandersonia*, etc. Biotic and abiotic factors are known to influence the production of secondary metabolites like colchicine in their natural ambience. Therefore, several biotechnological strategies like in vitro culture of colchicine-producing plants, media manipulation, precursor feeding, and application of elicitors have been practiced. After FDA approved colchicine as a drug in 2009, the demand of this high-value low-amount secondary metabolite increased significantly. So, to reduce the gap between demand and yield, the existing strategies should be improved, as well as new techniques can be applied to achieve the goal. The socioeconomic importance of colchicine is sure to encourage greater interest in near future.

Keywords

Alkaloid • anti-inflammatory agent • autumnaline • colchicine • *Colchicum* • double haploid • elicitors • in vitro culture • phenethylisoquinoline • polyploid

Abbreviations

2,4-D	2,4-dichlorophenoxyacetic acid
DH	Double haploid
GDP	Guanosine diphosphate
GTP	Guanosine triphosphate
IL	Interleukin
mM	Millimolar
MSU	Monosodium urate
NALP3	NACHT-LRR-PYD-containing protein-3
NSAIDs	Nonsteroidal anti-inflammatory drugs
RNAi	RNA interference
SAM	*S*-adenosyl methionine
US FDA	United states food and drug administration

1 Introduction

Plant-derived alkaloids are widely used in many purposes that include analgesics (morphine and codeine), stimulants (caffeine and nicotine), anticancer agents (vincristine, vinblastine, and camptothecin derivatives), gout suppressant (colchicine), muscle relaxant (C-tubocurarine, antiarrhythmic ajmaline), antibiotic (sanguinarine), and sedative (scopolamine) [1]. So, different biotechnological approaches are undertaken for the large-scale production of these compounds.

Biological precursors of most alkaloids are amino acids, such as ornithine, lysine, phenylalanine, tyrosine, tryptophan, histidine, nicotinic acid, anthranilic

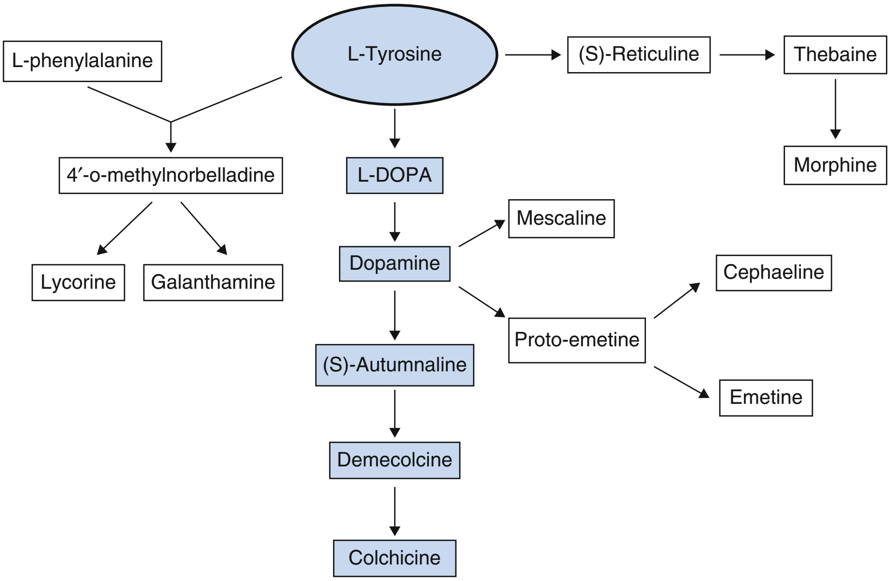

Fig. 16.1 Some important tyrosine-derived alkaloids

acid, and aspartic acid [2]. Numerous pathways are responsible for alkaloid biosynthesis and naturally cannot be easily classified. Tyrosine, as precursor, gives rise to chemically distinct five different groups of alkaloids like phenylethalamine and tetrahydroisoquinoline, benzyl tetrahydroisoquinoline, phenethylisoquinoline, terpenoid tetrahydroisoquinoline, and Amaryllidaceae alkaloids. Autumnaline and colchicine belong to phenethylisoquinoline group of compounds; autumnaline is an intermediate of colchicine biosynthetic pathway. Figure 16.1 shows some important tyrosine-derived alkaloids.

Colchicine was originally extracted from *Colchicum autumnale* (commonly known as autumn crocus or meadow saffron). Besides that, the presence of colchicine was also reported from *C. luteum*, *C. speciosum*, *C. hierosolymitanum*, *C. tunicatum*, *Gloriosa superba*, *Merendera* sp., etc. Colchicine is not a typical alkaloid in true sense, as the nitrogen atom it possesses is not involved in a heterocyclic ring; rather, the nitrogen atom is present in the side chain of tropalone nucleus. Thus, it is termed as non-heterocyclic alkaloids or proto-alkaloids [2]. Colchicine was first isolated in 1820 by Pelletier and Caventon. Since then, it has been used as therapeutic agent for many diseases. Due to its drastic side effects when used in high dose, it never got the approval until recently. After the approval of colchicine as drug for gout in 2009 by Food and Drug Administration (FDA, USA), there has been revival of interest in colchicine research and applications [3]. Colchicine is well known for its anti-inflammatory properties. Thus, it has been successfully used in gouty arthritis, inflammatory dermatitis, and familial Mediterranean fever since the past decade. Colchicine is also well known as “mitosis poison agent” as it binds to tubulin and inhibits its polymerization, which leads to blocking of chromosomal segregation [4]. By exploiting this property, many types of plants are generated commercially.

2 Occurrence

The term "colchicine" originated from the area known as "*Colchis*" near Black Sea. However, *C. autumnale* grows wild in Europe and Africa, while *Gloriosa* sp. is distributed in Africa and Asia including foothills of Himalayas, Burma, Indonesia, Malaya, etc. Table 16.1 gives a summary of the occurrence of colchicine reported since 1946.

3 Chemistry of Colchicine

3.1 General Properties

Pure colchicine is a fine, pale yellow powder. It darkens on exposure to light due to photoisomerization and formation of α-, β-, and γ-lumicolchicines [5, 6]. The optimum storage temperature for colchicine is −15°C to −25°C, in dark-colored bottles.

It is a neutral alkaloid and has been extracted from either acidic or alkaline solution by chloroform ($CHCl_3$). It is readily soluble in alcohol, chloroform, or cold water, but is less soluble in hot water or in cold benzene and is almost insoluble in ether [4].

3.2 Structure

Colchicine is a tricyclic alkaloid; the main features of which include a trimethoxyphenyl ring (A ring), a seven-membered ring (B ring) with an acetamide at the seventh position, and a tropolonic ring (C ring) (Fig. 16.2). Chemically, colchicine is (*S*)-*N*-(5,6,7,9-tetrahydro-1,2,3,10-tetramethoxy-9-oxobenzo(a)heptalen-7-yl) acetamide [7] with the molecular formula $C_{22}H_{25}NO_6$ (molecular weight 399.43; melting point 151–152°C).

(–)-Colchicine has only one stereogenic center, C_7. The designation of this carbon is *S*, according to the common Cahn-Ingold-Prelog rules. However, colchicine is also asymmetric due to axial chirality. The single bond between the A and C ring is rotationally restricted; this restriction adds a degree of asymmetry to the molecule. In 1933, Kuhn designated this type of stereoisomerism as atropisomerism (from Greek "a" meaning not and "tropos" meaning turn). The designation of this asymmetry is "a*S*" or "a*R*," according to the rules of molecular asymmetry, in which the "a" stands for axial chirality [8]. In colchicine, the C–C bond between the A and C rings is the chiral axis. In light of this molecular asymmetry, colchicine has four stereoisomers (Fig. 16.3). Each pair has either the *R* or *S* configuration at C_7 (–)-(a*S*, 7*S*)-. Colchicine, the natural isomer, can interconvert between the two conformational isomers a*R* and a*S*, given enough energy.

3.3 Tests for Identity

When colchicine solution is treated with a few drops of dilute mineral acid, an intense yellow-colored solution of colchiceine is obtained. However, colchicine can easily be distinguished from colchiceine by treating with ferric chloride ($FeCl_3$). Colchicine gives red color, whereas colchiceine produces olive green coloration (Fig. 16.4).

4 Biosynthesis

Several experiments have shown that the biosynthesis of colchicine involves the amino acids phenylalanine and tyrosine as precursors. When *Colchicum autumnale and C. byzantinum* were fed with radioactive tyrosine-2-C^{14} and phenylalanine-2-C^{14}, respectively, incorporation of radioactivity in the ring system of colchicine was observed. These labeling experiments suggested that tyrosine and phenylalanine both are required for colchicine biosynthesis. However, phenylalanine provides a C_6–C_3 unit rather than a C_6–C_2 fragment to form the intermediate (*S*)-autumnaline (Fig. 16.5). Further reports indicate that acetate is the precursor of the *N*-acetyl group; peripheral methyl groups were produced from methionine in *C. byzantium* and from methanol in *C. autumnale* [9]. The tropolone ring was demonstrated to be derived from tyrosine by ring expansion of a C_6–C_1 unit [10].

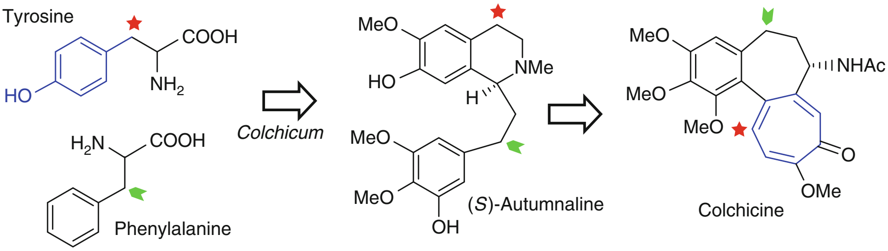

Fig. 16.5 Radioactive tracer experiment showing the formation of colchicine from the precursors

A para-para phenolic coupling reaction of isoquinoline (1*S*)-autumnaline catalyzed by isoandrocymbine cytochrome P-450 reductase produces the intermediate isoandrocymbine [11]. Then, *O*-methylandrocymbine methyltransferase catalyzes *O*-methylation of isoandrocymbine resulting in a key intermediate dienone *O*-methylan-drocymbine, where *S*-adenosyl methionine (SAM) acts as methyl group donor. Cleavage of cyclopropane ring of *O*-methylandrocymbine along with successive oxidation leads to the formation of *N*-formyldemecolcine, containing the seven member tropolone ring [12]. Hydrolysis of *N*-formyldemecolcine generates the demecolcine molecule, which undergoes oxidative demethylation that generates deacetylcolchicine. The molecule of colchicine appears finally after addition of acetyl coenzyme A to deacetylcolchicine by colchicine *N*-acetyltransferase [13, 14]. Figure 16.6 depicts colchicine biosynthesis steps.

5 Biotechnological Approaches

Like other alkaloids, supply of colchicine from traditional sources is limited either due to the gradual decreasing condition of plant sources or due to trace amounts of compounds present in the plants. Therefore, several alternative strategies have been adapted to increase the production of colchicine and colchicine derivatives.

Plant tissue culture represents a sustainable production system, which is constantly improving with respect to reliability and capacity. Commercial importance of the secondary metabolites greatly evolved in recent years, which caused great interest in secondary metabolism and particularly in the possibility to alter the production of bioactive plant metabolites by means of cell culture technology. Plant cell culture technologies were introduced at the end of the 1960s as a possible tool for both studying and producing plant secondary metabolites. The principle advantage of this technology is that it may provide continuous, renewable, reliable source of valuable medicinal compounds (plant pharmaceuticals), flavors, fragrances, and colorants, which cannot be produced by microbial cells or chemical synthesis. This system could be used for the large-scale culture of plant cells from which these metabolites can be extracted. Figure 16.7 shows some potential strategies for bio-production of secondary metabolites.

5.1 Optimization of Culture Media and Growth Condition

Standardization of medium is an important parameter in in vitro tissue culture technology since the composition of the culture media influences both the biomass yield as well as secondary metabolite production. Composition of the medium, culture conditions, and exogenous phytohormone combinations together influence the metabolite accumulation in the cell. Composition of macro- and micronutrients, nature and amount of carbon source, and level of total nitrogen has been found to play a vital role in the production of secondary metabolites.

C. autumnale is the first plant species exploited for the production of colchicine in vitro. Hunault [15] reported successful induction of callus culture of *C. autumnale* on Linsmaier-Skoog medium containing 2,4-dichlorophenoxyacetic acid (2,4-D) and kinetin. Growth and colchicine accumulation were increased in MS media supplemented with 20-mM ammonium and 40-mM nitrate. Addition of sulfate (SO_4^{2-}) also increased the accumulation of colchicine in *C. autumnale* [16].

5.2 Effect of Precursors

It has been observed that addition of precursors or related compounds (which are intermediate at the beginning of a secondary metabolite biosynthetic route) to the culture media sometimes stimulate secondary metabolite production. Phenylalanine and tyrosine play a central role for the production of colchicine. The lack of signal-inducing enzyme activity and biosynthetic precursors may act as a rate-limiting factor for the lower production of colchicine in vitro.

Feeding of some precursors, like phenylalanine and tyrosine, had no effect on in vitro colchicine formation in cell suspension cultures of *Colchicum autumnale*; however, *p*-coumaric acid, tyramine, and demecolcine feeding significantly increased colchicine production [17].

Callus culture of *G. superba* is an alternative source of colchicine. Feeding of tryptophan, phenylalanine, and tyrosine results in enhancement of colchicine content in callus culture of *G. superba* [18]. These results suggest that precursors are an important regulatory factor in colchicine accumulation in vitro. On the other hand, Ghosh et al. [19] reported enhanced colchicine production in root cultures of *G. superba* with the treatment of *p*-coumaric acid and tyramine.

5.3 Use of Elicitor Molecules in the Media

Plants show physiological and morphological responses to a range of physical and chemical factors known as "elicitors." These responses have been considered as defense reactions elicited by the plants' biochemical factory to ensure their survival, persistence, and competitiveness. The addition of trace amounts of elicitors in in vitro culture has been developed as one of the main strategies to improve the yield of secondary metabolites.

Elicitors trigger signals for the formation of secondary metabolites and are classified as abiotic or biotic elicitors. Elicitors of nonbiological origin are called abiotic elicitors, which predominantly consist of physical and chemical stresses such as UV radiation, extreme high or low temperatures, ethylene, fungicides, antibiotics, salts of heavy metals or high salt concentrations, etc. Biotic elicitors are substances with biological origin such as polysaccharides derived from plant cell walls (pectin or cellulose) or microorganism cell wall (chitin or glucans) and glycoproteins or intracellular proteins which activate or hinder a number of enzyme activities or ion channels. Biotic elicitors are categorized into two types based on their origin: exogenous (originated outside the cell) and endogenous elicitors (originated inside the cell). Elicitors reduce the processing time to attain high product concentrations. Application of elicitors to plant cell and organ cultures is useful for enhancing the biotechnological productivity of valuable secondary metabolites in vitro [20, 21]. An added biotechnological benefit is that they also promote release of the metabolites into the medium.

Various biotic and abiotic elicitors have been used to increase colchicine production. Application of methyl jasmonate as a biotic elicitor in the media showed increase in growth of the root cultures of *Gloriosa superba*. Higher concentration of methyl jasmonate decreased growth but enhanced intracellular colchicine content of the root cultures. However, such treatments with methyl jasmonate did not release colchicine into the medium [22].

Abiotic elicitors like cadmium chloride ($CdCl_2$), calcium chloride ($CaCl_2$), and aluminum chloride ($AlCl_3$) promoted many fold increase in biomass accumulation in root cultures of *G. superba*. However, casein hydrolysate, yeast extract, and silver nitrate had no significant effect on growth and colchicine accumulation in root cultures. The increase in $CdCl_2$ concentration in root cultures of *G. superba* facilitates intracellular colchicine accumulation as well as exudation into the medium. However, among the abiotic elicitors, $AlCl_3$ showed the most significant increase in colchicine production in root cultures of *G. superba* [22].

6 Biological Activities of Colchicine

6.1 Mechanism of "Mitotic Poisoning" by Colchicine

Colchicine has long been used as the potent chromosome-doubling agent. It induces chromosome doubling by inhibiting mitotic spindle of dividing cells. Mechanism of "mitotic poisoning" by colchicine has recently been elucidated. Colchicine has direct effect on microtubule assembly.

Microtubule consists of α- and β-tubulin proteins. Tubulin polymerizes end to end with the α-subunit of one tubulin dimer joining with the β-subunit of the next. The protofilament bundles are parallel to one another. Thus, in a microtubule, there is one end with only β-subunits exposed called (+) end, while the other end has only α-subunits exposed called (−) end. That is why a microtubule shows polarity. The (−) end is capped so elongation of the microtubule occurs from the (+) direction.

Microtubules are dynamic structures that lengthen or shrink by elongation at one end and dissolution at the other. Drugs like paclitaxel or docetaxel blocks dynamic instability by stabilizing GDP-bound tubulin in the microtubule. Thus, even when hydrolysis of GTP reaches the tip of the microtubule, there is no depolymerization and the microtubule does not shrink back. Colchicine does not enhance the rate of microtubule dissolution but inhibits the process of microtubule self-assembly in a substoichiometric fashion by binding α-tubulin with the formation of tubulin-colchicine complexes [23]. Addition of tubulin-colchicine complexes at the microtubule ends hampered normal polymerization of microtubulin. Thus, the spindle fiber formation during the cell division is hindered. In a recent study, it was found that colchicine analogues with modifications in the B ring bind to tubulin at the same site as colchicine. Thus, it is suggested that chemical specificity of the colchicine-binding site of tubulin is less stringent for the presence of the B ring than the A and C rings of colchicine [24].

6.2 Botanical Uses of Colchicine

6.2.1 Development of Double Haploid Lines

Anther culture followed by chromosome doubling generally gives rise to double haploid (DH) lines. Chromosome doubling may be spontaneous or induced by chemical agents (Fig. 16.8). The rate of spontaneous chromosome doubling in anther culture-derived haploid plants varies with species and even among varieties of the same species [25]. Charmet et al. [26] reported that about 10% of DH plants ($2n = 6x = 42$) of triticale show spontaneous chromosome doubling. The low rate of spontaneous doubling in many plants emphasizes the need of artificial chromosome doubling in order to enhance the number of DH lines. Probably, endomitosis (endoreduplication) explains the origin of spontaneous 2n and 4n embryos from microspore.

Colchicine is the most efficient and commonly used chromosome-doubling agent. It induces chromosome doubling by the inhibition of mitotic spindle of dividing cells. Inactivation of spindle inhibits the polar migration of chromosomes,

producing "restitution" nuclei, thus resulting in a cell with a doubled chromosome number (i.e., diploid instead of haploid, as gametes usually are). There have been some reports on in vitro colchicine treatment of anthers in wheat and in maize [27, 28] for chromosome doubling.

6.2.2 Production of Polyploid Plants

Generally, polyploidy is fatal to animal system, but in plant cells, it is well tolerated and frequently resulting to plants that differ from the diploid plants for larger size (of leaves, stems or roots, flowers, seeds, and fruits), faster growth, and their greater yield. For this reason, this type of genetic manipulation is frequent in commercial plant breeding. Thus, polyploid plants have enormous importance in agriculture. Colchicine is a well-known chemical agent that is largely used to alter ploidy level frequencies in cell populations, either in vivo or in vitro, to obtain tetraploid plants, starting with diploid material.

In addition, when such a tetraploid plant is crossed with a diploid plant, most of the time, it produces a sterile triploid offspring, which may be commercially useful in itself by requiring growers to buy seed from the supplier. Besides, these triploid offspring produces "seedless" fruits which have immense commercial value.

On the other hand, colchicine's ability to induce polyploidy can solve many important problems of plant breeding. Colchicine renders infertile hybrids fertile. For example, the maximum *Fuchsia* species are diploid or tetraploid. The cross between diploid and tetraploid results often in a triploid, which is mostly sterile because the process of meiosis requires the pairing of similar chromosomes and due to lack of mechanism to allow the alignment of three similar chromosomes. However, colchicine treatment produces fertile hexaploid plants. Breeding of triticale from wheat and rye shows similar problem: wheat is typically tetraploid and rye is diploid, with the triploid hybrid being infertile. Here also, treatment with colchicine results in fertile hexaploid triticale.

Colchicine treatment can also generate mixoploid cells which subsequently give rise to chimera plants consisting of diploid and tetraploid cells or tissues [25].

6.2.3 Callus Induction

Recently, an interesting effect of colchicine has been observed where it induced cell division. Positive effect of colchicine on pollen callus induction and plant regeneration on in vitro culture of *Triticum aestivum* and *Zea mays* is reported [29]. A similar effect has been observed on in vitro anther and isolated microspore cultures of *Brassica napus* where colchicine stimulated cell division and embryogenesis [30].

6.3 Therapeutic Uses of Colchicine

6.3.1 Colchicine for Treatment of Gout

Colchicine has long been known for the treatment of acute flare of gout from as early as 500 B.C. [31]. But surprisingly, it is only in July 2009 that the US FDA approved the use of it as a remedy to reduce pain in patients suffering from acute gout [3].

Gout is generally associated with hyperuricemia and is characterized by buildup of monosodium urate (MSU) crystals in the body, subsequently deposited within the joints. Consequently, it is considered as one of the most painful acute conditions a human being can experience. Gout management therapy mainly based on three aspects: treatment of acute gout flares, prophylaxis against acute gout flares, and urate-lowering therapy, which is considered as the long-term treatment of chronic gout [32]. Colchicine works by stopping inflammation and also prevents further attack. When the use of nonsteroidal anti-inflammatory drugs (NSAIDs) is unavailable, ineffective, or creating immunologic problems, colchicine is the best possible drug to be used for the patients with acute gouty arthritis [33].

Recently, the mechanisms of action of colchicine in crystal-associated arthropathies have been elucidated. It is found that at micromolar concentrations, it suppresses MSU crystal-induced NACHT-LRR-PYD-containing protein-3 (NALP3) inflammasome-driven caspase-1 activation, thereby inhibiting the processing and release of IL-1β [34]. At nanomolar concentrations, colchicine blocks neutrophils from entering the inflammation site. It does so by modulating the distribution of adhesion molecules on the endothelial cells and inhibiting crystal-derived chemotactic factor from neutrophil lysosomes as well as MSU crystal-induced production of superoxide anions [35].

6.3.2 Use of Colchicine in Familial Mediterranean Fever Treatment

Familial Mediterranean fever, an autosomal recessive disease, is characterized by short attacks of serositis (peritonitis, pleuritis, or arthritis) and fever. This genetic disorder is caused by a mutated protein pyrin, or marenostrin, encoded by the gene MEFV expressed in the cytoplasm of mature neutrophils and monocytes. Inflammatory mediators like interferon-γ and tumor necrosis factor are effective stimuli for expression of the gene which further suggest its role in neutrophil-mediated inflammation [36]. Since 1972, colchicine has been the first-line treatment for patients with familial Mediterranean fever. Colchicine does not stop an established attack; eventually, discontinuation may result in an attack within a few days.

In the clinical trials, it was found that colchicine prevents febrile attacks in 60 % of patients and significantly reduces the number of attacks in another 20–30 % [37]. In familial Mediterranean fever patients, death occurs mainly due to amyloidosis. However, treatment with colchicine greatly altered the prognosis by arresting amyloidosis and reversing proteinuria [38].

6.3.3 Colchicine and Dermatology

Colchicine with its microtubule-disrupting properties limits the chemotactic and phagocytic activity of polymorphonuclear lymphocytes. It also induces the release of prostaglandin E, a suppressor of leukocyte function by increasing the level of cyclic adenosine monophosphate [39]. Furthermore, the ability of colchicine in inhibition of IL-1 production and histamine release makes it an excellent drug for a number of dermatitis-related complexities like psoriasis, Behçet's syndrome, recurrent aphthous stomatitis, leukocytoclastic vasculitis and urticarial vasculitis, bullous disease, scleroderma, fibromatosis, Sweet's syndrome, amyloidosis, and many more [40].

6.3.4 Other Therapeutic Uses

Colchicine prevents recurrences of acute pericarditis in adults and children, thereby replacing prolonged administration of corticosteroids [41]. The Australian biotechnology company Giaconda has recently developed a combination therapy to treat constipation-predominant irritable bowel syndrome which combines colchicine with the anti-inflammatory drug olsalazine. The British drug development company Angiogene is developing a prodrug of a colchicine congener, ZD6126 (also known as ANG453), as a treatment for cancer.

6.3.5 Side Effects: The Dark Side of Colchicine

Colchicine was not shown to adversely affect reproductive potential in males or females. It crosses the placenta, but there is no evidence of fetal toxicity. Colchicine is excreted into breast milk and considered compatible with lactation.

The lowest reported lethal doses of oral colchicine are 7–26 mg. Colchicine overdose may lead to diarrhea, mild sore throat, nausea, stomach pain or cramping, vomiting, etc. It is also reported that due to colchicine poisoning, death may result from rapidly progressive multi-organ failure and sepsis. But most of the time, severity does not go that far; rather, recovery typically occurs within a few weeks of ingestion [42].

7 Future Prospects

Although the alkaloid field is a very old one, it is still in its infancy with regard to understanding its biosynthesis pathways: enzymology and their regulation. Exploitation of the biotechnological potential of alkaloid biosynthesis has only just begun.

We are still a long way from understanding how most alkaloids are produced in plants and how their biosynthesis is regulated. We also have much to learn about the chemical ecology of alkaloids so that we can better understand why these sophisticated and diverse structures evolved. It is evident that alkaloids as integral components of medicinal plants have enjoyed a long and important history in traditional medicine.

For the majority of secondary metabolism pathways, the proposed biosynthesis was mostly deduced from chemical considerations and feeding experiments, which need verification by identification of the corresponding enzymatic reactions. Thus, direct manipulations of the pathways are not possible due to the lack of enzymological background. In the past, enzymological knowledge related to secondary metabolism pathways has been drawn from the studies of cell suspension systems, but organ cultures and intact plants can also be excellent sources for study of such enzymes.

Identification and knowledge about the regulatory and rate-limiting enzymes was also very important to alter the flux of the particular secondary metabolites. Manipulation of these enzymes sometimes results in quantitative alteration of final product. It is also necessary to know whether the other biosynthetic enzymes are co-induced with the proposed regulatory enzyme or are present even in nonproducing cell cultures. Such knowledge helps to evaluate the possibility of specific manipulation of these secondary metabolism pathways to increase the yield of the desired product.

Different strategies, using in vitro systems, have been studied extensively with the objective of improving the production of colchicine, like media manipulation; establishment of cell culture, organ culture, and root culture of colchicine-producing plants; elicitation with biotic and abiotic elicitors; etc. Instead of these progresses, production of colchicine at commercial scale is yet not achieved.

Biosynthetic pathways of colchicine in plants as well as in in vitro cultures are not fully understood. The challenge remains to elucidate the complete biosynthetic pathways, thereby exploiting cell cultures more rationally for the production of this compound so much in need by the pharmaceutical industry. Whenever the detailed knowledge of the complete biosynthetic pathways will be available, genes controlling rate-limiting steps in the biosynthetic pathway can be overexpressed or synthesis of unwanted metabolites can be suppressed by various RNAi technologies. Moreover, colchicine has a potential of becoming a promising alkaloid for extensive study by the plant biotechnologists, which may lead to exciting opportunities to engineer colchicine metabolism in plants.

Abstract

Plants of the Amaryllidaceae family, including *ca.* 75 genera and about 1,100 species, are among the top 20 in the most widely considered medicinal plant families. A number of pharmacologically active compounds, such as phenols, alkaloids, lectins, peptides, etc., have been identified and characterized from this family. As primary constituents, up to 500 structurally diverse Amaryllidaceae

alkaloids have been isolated to date. These biogenetically related alkaloids are basically classified into 12 different skeleton types according to their ring systems. Representative structures for each type of Amaryllidaceae alkaloids are shown in this chapter. Biosynthetic pathways for each type of Amaryllidaceae alkaloids including those newly established subgroups are also discussed. In addition, recent reports on the occurrence and biological activity profiles of Amaryllidaceae alkaloids are summarized.

1 Introduction

The family Amaryllidaceae, its name taken from the genus *Amaryllis*, belongs to the monocot order Asparagales and is a class of herbaceous, perennial, and bulbous flowering plants [1, 2]. This family consisting of *ca.* 75 genera and 1,100 species in the 15 tribes is widely distributed in the tropics and warm temperate regions of the world. Geographically, distribution of the family Amaryllidaceae shows obviously regional endemism, with four main clades including the basically African, the Eurasian, the Australasian, and the American clades (Fig. 17.1). Based on modern molecular biology, phylogenetic evidence has indicated that the family evolved originally in Africa and subsequently dispersed to other continents, such as Eurasia, Australasia, and the New World, and South America is the center of secondary diversification [3].

The native habitats of the wild species of the family Amaryllidaceae varies greatly ranging from lowland to high mountain, including grassland, scrub, woods, river banks, and even rocky cliffs. They usually flower in late winter and spring with occasional exception in autumn. Most species have the large and showy and actinomorphic flowers. Shape of the flowers varies from star-like to trumpet-shaped or tubular, and colors range from red, orange, yellow, and pink to white, whereas bluish flowers are only found in the genera *Griffinia*, *Worsleya*, and *Lycoris*.

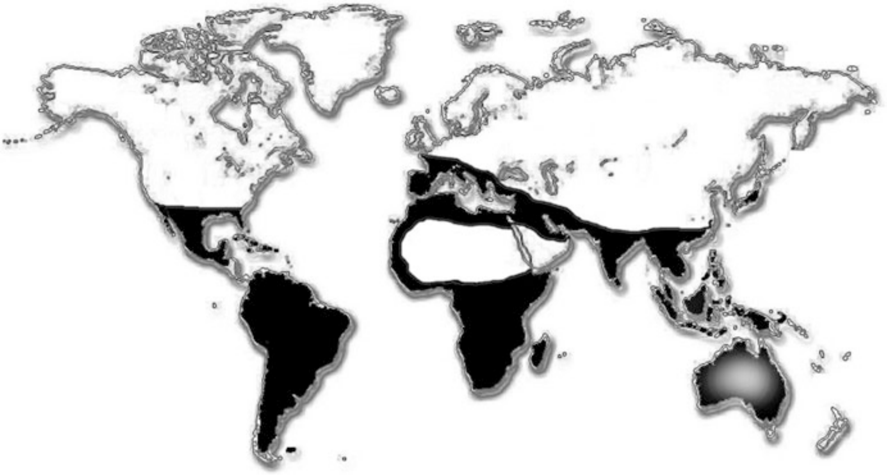

Fig. 17.1 Distribution of plants of the family Amaryllidaceae in the world

Moreover, the flowers often possess highly scented odor. As a result, plants of the family Amaryllidaceae, especially the genus *Narcissus* species (daffodils), have been horticulturally cultivated as ornamental plants for centuries.

For thousands of years, plants of the family Amaryllidaceae have been extensively identified as useful folk herbal remedies against various diseases in many countries and areas. Traditionally, Africans use the bulbs and leaves of this family as poultices and decoctions for treating sores and digestive disorders. With development of modern phytochemistry, a large number of natural chemical substances, such as alkaloids, phenolics, flavonoids, glycosides, etc., have been found to occur in the plants of this family over the past decades. Among them, structurally diverse alkaloids, termed as Amaryllidaceae alkaloids, are frequently associated with the significant pharmacological effects of the plants.

According to the most recent Angiosperm Phylogeny Group (APG) classification, APG III [4], the circumscription of the family Amaryllidaceae has been successively revised to a broader range. Therefore, the family was subdivided into three different subfamilies, one of which is the Amaryllidoideae (the old Amaryllidaceae family), the others being the Allioideae (the former Alliaceae family) and the Agapanthoideae (the former Agapanthaceae family). The subfamily Amaryllidoideae includes *ca.* 60 genera and approximately 800 species with a worldwide distribution (Table 17.1). The subfamily Allioideae was further divided into three tribes in the 16 genera, 13 of which are endemic to the temperate South America. The genus *Agapanthus* is the sole genus in the subfamily Agapanthoideae.

For their unique alkaloid chemistry and morphology, chemistry and biology of Amaryllidaceae alkaloids have been summarized on several occasions [5–19], and

Table 17.1 Wild species distribution of the family Amaryllidaceae

Plant genus	Location
Acis Salisb. (9 species)	Western and central Mediterranean region and Northern Africa
Amaryllis L. (2 species)	South Africa
Ammocharis Herb. (6 species)	Africa
Apodolirion Baker (6 species)	South Africa
Boophone Herb. (2 species)	Tropical and Southern Africa
Brunsvigia Heist. (*ca.* 20 species)	South Africa
Caliphruria Herb. (4 species)	Tropical regions of South America, mainly in Colombia
Calostemma R. Br. (3 species)	Australia
Chlidanthus Herb. (10 species)	Tropical South America, mostly native to the Andes
Clinanthus Herb. (22 species)	Ecuador to northwestern Argentina
Clivia Lindl. (5 species)	Native to Southern Africa
Crinum L. (*ca.* 180 species)	Tropical and subtropical areas worldwide
Crossyne Salisb. (2 species)	Southern Africa
Cryptostephanus Welw. ex Baker (2 species)	Southern Africa
Cyrtanthus Aiton (56 species)	Southern and Eastern Africa
Eucharis Planch & Linden (*ca.* 20 species)	Central America and South America from Guatemala south to Bolivia
Eucrosia Ker Gawl. (8 species)	Ecuador to Peru
Eustephia Cav. (6 species)	Peru
Galanthus L. (20 species)	Europe to Northern Iran
Gethyllis L. (30 species)	South Africa
Griffinia Ker Gawl. (21 species)	South America, Brazil
Griffiniopsis Dutilh & Meerow (1 species)	South America
Habranthus Herb. (74 species)	South America
Haemanthus L. (22 species)	South Africa, Namibia, and the kingdoms of Lesotho and Swaziland
Hannonia Braun-Blanq. & Maire (1 species)	Morocco
Hessea Herb. (13 species)	Southern Africa
Hieronymiella Pax. (8 species)	Southern Bolivia to northwestern Argentina
Hippeastrum Herb. (*ca.* 90 species)	South America from Argentina north to Mexico and the Caribbean
Hymenocallis Salisb. (63 species)	Southeastern USA, Mexico, and West Indies
Ismene Salisb. ex Herb (10 species)	Central Andean region
Lapiedra Lag. (1 species)	Western Mediterranean
Leptochiton Sealy (2 species)	Central Andean region
Leucojum L. (3 species)	Central and Southern Europe, from the Pyrenees to Romania and western Russia

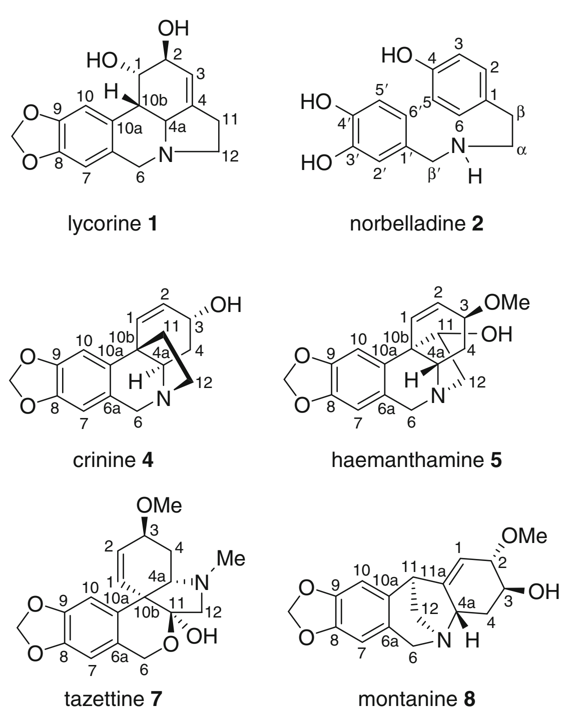
Table 17.1 (continued)

Plant genus	Location
Lycoris Herb. (22 species)	Eastern and Southern Asia including Japan, southern Korea, Eastern and Southern China, Northern Vietnam, Northern Laos, Northern Thailand, Northern Burma, Nepal, Northern Pakistan, Afghanistan, and Eastern Iran
Mathieua Klotzsch (1 species)	Peru
Namaquanula D.Müll.-Doblies & U.Müll.-Doblies (2 species)	Southern Africa
Narcissus L. (56 species)	Europe, North Africa, and Asia, from Macaronesia to Afghanistan, and Southeastern China to Japan
Nerine Herb. (23 species)	Southern Africa
Pamianthe Stapf (3 species)	Peru, Ecuador, and Bolivia
Pancratium L. (21 species)	South Africa to the Mediterranean and Asia
Paramongaia Velarde (2 species)	Peru, Ecuador, and Bolivia
Phaedranassa Herb. (9 species)	Colombia to Ecuador
Phycella Lyndl. (5 species)	South America
Placea Miers (6 species)	South America
Plagiolirion Baker (1 species)	Central America to Andean South America
Proiphys Herb. (4 species)	Malaysia, Indonesia, the Philippines, and Tropical Australia
Pyrolirion Herb. (6 species)	Peru to Northern Chile
Rauhia Traub (4 species)	Peru
Rhodophiala C. Presl (28 species)	South America
Scadoxus Raf. (9 species)	Tropical Africa
Sprekelia Heist. (2 species)	South America
Stenomesson Herb. (*ca.* 16 species)	Colombia to Northern Peru
Sternbergia Waldst. & kit. (8 species)	Central and Southern Europe to Central Asia
Strumaria Jacq. ex Willd. (24 species)	South Africa
Traubia Moldenke (1 species)	South America
Ungernia Bunge (10 species)	Central Asia
Urceolina Rchb. (5 species)	Colombia to Northern Peru
Vagaria Herb. (2 species)	Morocco to Lebanon and Israel
Worsleya Traub (1 species)	Brazil
Zephyranthes Herb. (94 species)	America

this topic is regularly reviewed by the journal *Natural Product Reports* of the Royal Society of Chemistry [20–26]. Due to the sufficiently structural particularity of Amaryllidaceae alkaloids, only the alkaloids isolated from the subfamily Amaryllidoideae, namely, the old Amaryllidaceae family, will be dealt with in this chapter.



lycorine 1
norbelladine 2
homolycorine 3
crinine 4
haemanthamine 5
narciclasine 6
tazettine 7
montanine 8
galanthamine 9

Scheme 17.1

2 Occurrence

A unique characteristic for plants of the family Amaryllidaceae is the production of a group of structurally diverse but biogenetically relative alkaloids. Since lycorine **1** was isolated as the first alkaloid from *Narcissus pseudonarcissus* in 1877, up to 500 alkaloids have been identified from plants of this family to date. Furthermore, the number remains increasing every year. At present, most genera of this family are validated to produce Amaryllidaceae alkaloids.

2.1 Classification of Amaryllidaceae Alkaloids

Although the structures of Amaryllidaceae alkaloids are greatly diverse, they are considered to be biogenetically related and have a common precursor alkaloid norbelladine **2**, which originally derived from the natural amino acids L-phenylalanine (Phe) and L-tyrosine (Tyr). Conventionally, according to molecule skeletons of the alkaloids, the large number of Amaryllidaceae alkaloids was classified mainly into nine different types, as represented by lycorine **1**,

norbelladine **2**, homolycorine **3**, crinine **4**, haemanthamine **5**, narciclasine **6**, tazettine **7**, montanine **8**, galanthamine **9** (Scheme 17.1) [9]. However, with continuous phytochemistry studies, some alkaloids owning new skeleton types have been isolated from plants of this family in recent years [8, 21, 22], which suggests that the classification of Amaryllidaceae alkaloids should be reconsidered and also their biosynthetic pathways.

On the basis of recent phytochemistry investigation about Amaryllidaceae alkaloids, a new 12-type classification, including (1) norbelladine type, (2) lycorine type, (3) homolycorine type, (4) crinine and haemanthamine types, (5) tazettine type, (6) montanine type, (7) plicamine type, (8) graciline type, (9) galanthindole type, (10) galanthamine type, (11) phenanthridone and phenanthridine types, and (12) other minor species populations, are deduced according to their ring systems. Representative structures for each type of Amaryllidaceae alkaloids are shown in Tables 17.2–17.13.

2.1.1 Norbelladine Type

This type of Amaryllidaceae alkaloids is derived initially from the condensation of tyramine and protocatechuic aldehyde or its derivatives in plants, and the intermediate Schiff's bases have been found to exist in nature (Table 17.2) [27, 28].

2.1.2 Lycorine Type

This type of Amaryllidaceae alkaloids owns an unique pyrrolo[*d*,*e*]phenanthridine skeleton and is one of the most common alkaloids in plants of the family Amaryllidaceae (Table 17.3). Usually, they have a *trans*-junction in the B/C ring, but a few alkaloids with *cis*-form unions of the B/C ring, such as fortucine **30** [30], amarbellisine **32** [31], etc., have been isolated recently. It is interesting to find that a part of this type of alkaloids has a completely unsaturated aromatic C ring and some possess an unusual quaternary nitrogen [32–35].

2.1.3 Homolycorine Type

The alkaloids of homolycorine type are biogenetically formed through a restructuring of lycorine-type alkaloids and have a common [3,4-*g*] benzopyranone ring due to the oxidation of the hydroxyl group at the C6 (Table 17.4). Almost all alkaloids of this type have a *cis*-form B/C ring junction with only an exception of poetinatine **73**. It is noteworthy that, alkaloids shown an oxygenated function at the C10b, such as pancratinine A **66** [36, 37], 10b-hydroxygalwesine **69**, and 10b-hydroxy-9-*O*-demethylgalwesine **70** [38], are very unusual, which is the probable precursor of alkaloids galasine **71** and hostasine **72**, incorporating a scarce spirolactone moiety.

2.1.4 Crinine and Haemanthamine Types

The crinine- and haemanthamine-type alkaloids, together with lycorine-type alkaloids, are the most abundant alkaloids in the plants of the family Amaryllidaceae. Both crinine-type and haemanthamine-type alkaloids have a 5,10b-ethano bridge moiety in their frameworks, a very significant taxonomic feature, and the configurations of the 5,10b-ethano bridge are opposite to each other (Table 17.5). Scarcely, haemanthamine-type alkaloids bujeine **132** owns an unusually modified bridge with a heteroatom between C11 and C12 and an acetoxymethyl substituent at the 11-*endo* position [39].

2.1.5 Tazettine Type

Alkaloids of this type, derived from the haemanthamine-type alkaloids, are characterized as a linkage between C6 and C11 by an oxygen atom to form a [3,4-*g*]benzopyran framework (Table 17.6) [40, 41]. Alkaloid obesine **149** is an only exception, which has a seven-member ring skeleton. The position on the C12 can be oxidized occasionally to produce an amide group, such as in 6-oxotazettine **147**.

2.1.6 Montanine Type

Montanine-type alkaloids constitute a limited group in Amaryllidaceae alkaloids and show a characteristic 5,11-methanomorphanthridine framework (Table 17.7). There are two classes of $C = C$ double bond substitution patterns in the C ring of alkaloid skeletons. Alkaloid nangustine **151** is the first member in this subgroup with a hydroxyl group at the C4 [42].

2.1.7 Plicamine Type

Alkaloids of this type are the first example of the dinitrogenous-type Amaryllidaceae alkaloids, where the oxygen atom at the C6 in the tazettine-type alkaloids is replaced by a nitrogen atom, substituted with a pendant

4-hydroxyphenethyl unit (Table 17.8) [40, 43]. In addition, all alkaloids of this minor subgroup have an amide group on the C12. So far, only four members **159–162** of this subgroup have been isolated from plants of this family.

2.1.8 Graciline Type

Alkaloids of this type belong to a newly established subgroup of Amaryllidaceae alkaloids and own a 10b,4a-ethanoiminodibenzo[*b*,*d*]pyrane skeleton (Table 17.9). To date, a total of five alkaloids including four monomeric alkaloids **163–166** and one dimeric alkaloid **167** have been isolated from plants of the family Amaryllidaceae [41, 44].

2.1.9 Galanthindole Type

Alkaloids of this type belong to another new subgroup isolated from the Amaryllidaceae family plants and own a 7-arylindole or 7-aryl-2,3-dihydroindole skeleton (Table 17.10). It is interesting that alkaloids of this type **171**–**174** recently isolated from the genus *Narcissus* cultivar show a rare axial chirality [45].

2.1.10 Galanthamine Type

Galanthamine-type alkaloids have a dibenzofuran nucleus and are the only group in the Amaryllidaceae alkaloids showing two *ortho* aromatic protons in ring A - (Table 17.11). Galanthamine **9** and lycoramine **192** are the two most abundant alkaloids in the family Amaryllidaceae plants, especially in the genera *Galanthus* and *Narcissus*.

2.1.11 Phenanthridone and Phenanthridine Types

Phenanthridone-type alkaloids have the highest oxygenated C ring in all Amaryllidaceae alkaloids, and they always show an amide group in ring B. On the contrary, alkaloids of the phenanthridine type often show completely aromatic ring system, occasionally with a methylation quaternary nitrogen atom, such as alkaloid bicolorine **214** (Table 17.12).

2.1.12 Miscellaneous

In addition to the abovementioned types of alkaloids, other minor subgroups have also been identified from plants of the family Amaryllidaceae (Table 17.13), including cherylline type, buflavine type, cripowelline type, augustamine type, gracilamine type, and so on. These scarce populations often show the unique skeleton in their molecular architectures. For instance, cripowellins A **222** and B **223** belong to structurally unique members of the Amaryllidaceae alkaloids with a 10-membered fused [5.3.2]bicyclic lactam core [46]. Furthermore, alkaloid gracilamine **227**, owning a unique pentacyclic core [47], represents the second dinitrogenous type in the Amaryllidaceae alkaloids besides plicamine-type alkaloids. Additionally, pallidiflorine **228** is the only bis-alkaloids formed directly from the junction of two different types of Amaryllidaceae alkaloids [48].

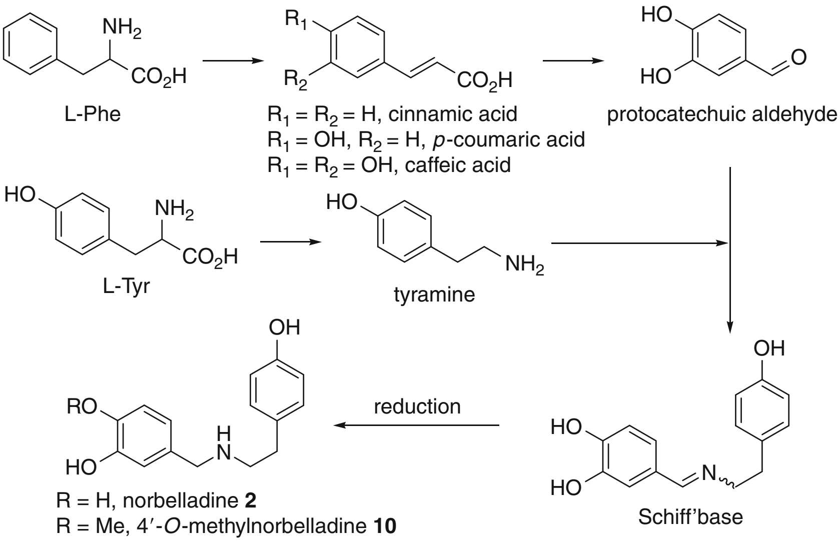
2.2 Occurrence of Amaryllidaceae Alkaloids

Recent examples for each type of Amaryllidaceae alkaloids isolated from the wild, cultivar, and intersectional hybrid species are summarized in Table 17.14.

3 Biosynthesis

Studies on the biosynthesis of Amaryllidaceae alkaloids initiated as early as the 1960s. In 1957, Barton and Cohen proposed for the first time that norbelladine **2** or its congener alkaloid was probably the original precursor of other structurally diverse Amaryllidaceae alkaloids [103]. The primary metabolic processes leading to the Amaryllidaceae alkaloids include mainly (a) intramolecular phenol



L-Phe
R1 = R2 = H, cinnamic acid
R1 = OH, R2 = H, p-coumaric acid
R1 = R2 = OH, caffeic acid
protocatechuic aldehyde
L-Tyr
tyramine

Scheme 17.2

oxidative coupling cyclization, (b) *O*- and *N*-methylation, (c) hydrogenation reduction of $C = O$ and $C = N$ double bonds, (d) oxidation of *C–O* and *C–H* bonds to $C = O$ and *C–OH* bond, and (e) enzyme-catalyzed epoxidation of $C = C$ double bond.

3.1 Norbelladine Type

In plants, norbelladine is produced from the condensation of protocatechuic aldehyde, and tyramine and the latter two metabolites arise from the naturally occurring L-Phe and L-Tyr, respectively (Scheme 17.2). Hydrogenation reduction of the resulting Schiff's base affords alkaloid norbelladine **2**, which is further converted into 4′-methylnorbelladine **10** after methylation on the 4′-*O* position. Generally, alkaloid 4′-methylnorbelladine **10** was considered as the key precursor for alkaloids of this family [104]. Alkaloid 4′-methylnorbelladine **10** can be converted into other structurally complicated alkaloids through three different oxidative coupling approaches: (1) *ortho–para′*, (2) *para–para′*, and (3) *para–ortho′* (Scheme 17.3).

3.2 Lycorine and Homolycorine Type

In the biosynthesis of lycorine **1**, alkaloid norpluviine **261** and its congener fortucine **30** were demonstrated as the first intermediate formed via *ortho–para′* phenol oxidative coupling of 4′-methylnorbelladine **10** based on the labeling

experiments (Scheme 17.4) [105–107]. The hydroxyl group at C2 in lycorine is incorporated via an epoxidation of $C = C$ double bond followed by a sequence of ring opening and allylic rearrangement [108–110]. In a similar manner, norpluviine **261** is converted into alkaloid galanthine **18** after 8-*O*-methylation. In addition, galanthine is considered the probable precursor of alkaloid narcissidine **28**, which is formed through an analogous epoxidation process [111]. The conversion of the *O*-methoxyphenol to the methylenedioxy group may occur late in the biosynthetic pathway [105].

The conversion of norpluviine **261** into homolycorine **3** has been validated via the benzylic oxidation at C6 position followed by B-ring opening to form an amino aldehyde with a free hydroxyl group, which gives alkaloid lycorenine **54** after *N,O*-methylation [112]. Finally, a subsequent oxidation produces homolycorine **3** (Scheme 17.5). Recently, the transformation from lycorine-type skeleton into homolycorine-type alkaloid has been experimentally demonstrated through a total synthesis of alkaloid clivonine **76** [113].

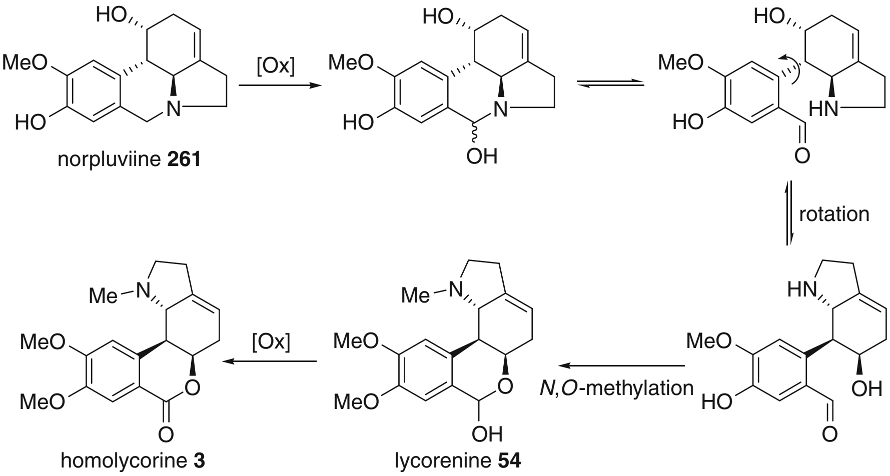
3.3 Crinine and Haemanthamine, Tazettine, Narciclasine, and Montanine Types

Crinine- and haemanthamine-type alkaloids are derived from norbelladine **10** through an intramolecular "*para–para′*" oxidative coupling sequence as shown in Scheme 17.3 [114, 115]. Additionally, the feeding labeling experiments showed that tazettine-, narciclasine-, and montanine-type alkaloids also originated from the crinine- and haemanthamine-type 5,10b-ethanophenthridine skeletons (Scheme 17.6). The biosynthetic conversion of haemanthamine **5** to tazettine-type alkaloids was demonstrated by feeding tritium-labeled alkaloids to the species *Sprekelia formosissima* [116]. In plant, haemanthamine **5** is converted to haemanthidine **111** by oxidation at C6 and subsequent to pretazettine **139** in



Scheme 17.5

an essentially irreversible manner. Phenanthridine alkaloid narciclasine **6** was proved to be derived from oxocrinine **78** by the loss of the two-carbon ethane bridge [117, 118]. Furthermore, oxocrinine **78** is also the probable precursor of alkaloid ismine **216** [119]. Based on labeling studies in the species *Rhodophiala bifida*, 11-hydroxyvittatine **108** was indicated as the intermediate in the biosynthetic pathway of alkaloid montanine **8** [115].

3.4 Galanthamine Type

Galanthamine-type alkaloids originated from the intramolecular *para-ortho′* oxidative coupling of 4′-*O*-methylnorbelladine **10** (Scheme 17.3). Initial studies showed that the intramolecular *para-ortho′* oxidative coupling does not proceed from 4′-*O*-methylnorbelladine **10** but from *N,O*-dimethylnorbelladine **264** [120], which has been isolated from the species *Pancratium maritimum* along with galanthamine **9** [121]. However, subsequent ^{13}C-labeled experiments in *Leucojum aestivum* demonstrated that the phenol oxidative coupling does proceed from 4′-*O*-methylnorbelladine **10** to form a postulated dienone, which gives alkaloid norgalanthamine **175** after reduction of $C = O$ double bond at C3 [122]. The final step of biosynthesis involves *N*-methylation of norgalanthamine **175** to galanthamine **9** [Scheme 17.7]. In addition, narwedine 185 is not the direct precursor of galanthamine **9** and could be possibly interconvertible with galanthamine in plants.

3.5 Miscellaneous

With continuous phytochemistry studies, some new skeleton-type alkaloids have been isolated from plants of this family in recent years and the biosynthesis of these alkaloids still remains unexploratory. Notwithstanding, their biosynthesis can be tentatively deduced from crinine- and haemanthamine-type alkaloids according to the structural characteristics (Scheme 17.8). The above-mentioned tentative biogenetic proposals for novel alkaloids should be further verified by feeding experiments with isotopically precursors as well as

synthetic studies. In fact, some recent synthetic examples have implicated the possible biosynthesis. For example, analogues of norbelladine could be readily converted into the tetrahydroisoquinoline skeleton of the cherylline-type Amaryllidaceae alkaloids via an oxidation–cyclization sequence [123].

4 Biological Activity

Alkaloids isolated from the plants of Amaryllidaceae family show diverse biological activities, such as antitumor, antibacterial, antifungal, antimalarial, antiviral, analgesic, and AChE inhibitory activities. Among them, the well-known galanthamine **9** has been commercialized as a selective and reversible AChE inhibitor for the treatment of Alzheimer's disease. Amaryllidaceae isocarbostyril derivatives, such as narciclasine, pancratistatin, and their congeners, are very promising antitumor agents. Recently, the anticancer potential of Amaryllidaceae alkaloids and their synthetic derivatives has been reviewed [124]. In addition, lycorine and its derivatives as novel lead compounds for anticancer drug design have also been summarized very recently [125]. The biological activities of alkaloids isolated from the genera *Pancratium* [5], *Crinum* [15, 18], and *Narcissus* [9, 14] have also been summarized in the previous reviews [17, 19]. Recent reports about the biological activities of Amaryllidaceae alkaloids are listed in Table 17.15.

Table 17.15 Biological activities of Amaryllidaceae alkaloids

Amaryllidaceae alkaloids	Biological activities	References
Lycorine type		
Amarbellisine **32**	Antiproliferative activity	[126]
2-*O*-acetyllycorine **22**	Apoptosis-inducing effect	[127]
Lycorine **1**	Apoptosis-inducing effect	[128–130]
	Antitumor activity	[131, 132]
	Antiviral activity	[133, 134]
	Anti-inflammatory effect	[135]
	Antifungal, antimicrobial	[136]
	Antimalarial effect	[137]
	AChE inhibitory activity	[138]
	Antiretroviral activity	[139]
Pratorinine **266**	Antimicrobial effect	[140]
1-*O*-acetyllycorine **267**	AChE inhibitory activity	[141, 142]
Ungeremine **44**	AChE inhibitory activity	[143]
3-*O*-acetylnarcissidine **27**	Antifeedant action	[144]
Homolycorine type		
Homolycorine **3**	Antitumor activity	[145]
	Antiretroviral activity	[139]
8-*O*-demethylhomolycorine **51**	Antitumor activity	[145]
	DNA-binding activity	[146]
Dubiusine **62**	Antitumor activity	[145]
	DNA-binding activity	[146]
Lycorenine **54**	Antitumor activity	[145]
	DNA-binding activity	[146]
Hippeastrine **49**	Antiviral activity	[147]
	Antifungal activity	[148]
Crinine and Haemanthamine type		
6-Methoxycrinamine **247**	Antifouling activity	[73]
Crinamine **246**		
Buphanisine **81**		
Buphanamine **101**	Inhibitory activity against the serotonin transporter	[75, 76]
Buphanidrine **251**		
Buphanisine **81**		
Distichamine **102**		
11-*O*-acetylambelline **88**	AChE inhibitory activity	[149]
Haemanthamine **5**	Antimalarial activity	[80, 137]
6-Hydroxyhaemanthamine **267**		
Crinine **4**	Apoptosis-inducing activity	[150–152]
Haemanthamine **5**		
Crinamine **246**		
Ambelline **89**		
Amabiline **105**		
Josephinine **106**

Table 17.15 (continued)

Hamayne **122**	AChE inhibitory activity	[138]
Haemanthamine **5**	Antiretroviral activity	[139]
Tazettine type		
Pretazettine **139**	Apoptosis-inducing activity	[127]
8α-Ethoxyprecriwelline **143**	affinity to the serotonin reuptake transport protein	[153]
N-demethyl-8α-ethoxypretazettine **141**		
N-demethyl-8β-ethoxypretazettine **142**		
Tazettine **7**	Weak antimalarial activity	[137]
Montanine type		
Montanine **8**	Antiproliferative activity	[154]
	AChE inhibitory activity	[155]
	Antimicrobial activity	[156]
	psychopharmacological activities including anxiolytic, antidepressive, and anticonvulsive effects	[157]
Galanthamine type		
3-*O*-acetylhabranthine **187**	AChE inhibitory activity	[95]
Norgalanthamine **175**	Promoting proliferation of dermal papilla	[158]
Galanthamine **9**	AChE inhibitory activity	[91, 159]
N-allylnorgalanthamine **188**	AChE inhibitory activity	[96]
N-(14-methylallyl) norgalanthamine **189**		
Phenanthridone and phenanthridine types		
Narciclasine **6**	Pleiotropic cytostatic effect	[160]
	Antiproliferation	[161]
	Antitumor effect	[162]
	Apoptosis-inducing cytotoxicity	[163]
	Antitumor, plant growth regulator activities	[164]
	Inhibitory activity on protein synthesis	[165]
Pancratistatin **202**	Antineoplastic activity	[166, 167]

5 Conclusion

So far, a great deal of the structurally diverse alkaloids have been isolated and identified from plants of the family Amaryllidaceae. However, given large numbers of the unexploratory plant species in this family, one can expect that more new alkaloids will be isolated from the plant species of this family in the future. In addition, although studies about biosynthesis of Amaryllidaceae alkaloids initiated as early as the 1960s, biosynthetic pathways of Amaryllidaceae alkaloids, especially those newly established scarce subgroups, are far away from complete comprehension to date. With continuous occurrence of new skeleton-type Amaryllidaceae alkaloids, considerable efforts aiming to explore the biogenetic origin of these alkaloids are still required.

In view of the significantly biological activities exhibited by Amaryllidaceae alkaloids, development of new phytomedicines derived from these natural products is of great importance. For instance, alkaloid galanthamine **9** has been launched into market for the treatment of Alzheimer's disease in Western countries in 2001 as a selective AChE inhibitor [168]. Besides, Amaryllidaceae isocarbostyril alkaloids, such as narciclasine **6**, pancratistatin **202**, and their hemisynthetic derivatives, are also in the preclinical development as very promising antitumor agents. Due to their superior pharmacological profiles as well as limited availability from nature, chemical synthetic approaches to these plant metabolites and related analogues represent an important vehicle for investigation of biological activity. Meanwhile, biotechnological approaches to these alkaloids also provide an inexpensive, efficient, and practical alternative [169].

Abstract

Studies on bioactive alkaloids have gained considerable importance in recent years and have been given prominent position in the field of medicine, both with respect to their biological activity and role played in the introduction of new pharmaceuticals. The biotechnological approach has further enhanced their industrial applications. Some specific groups of bioactive alkaloids have been ignored and not been given much attention because of various reasons, including their legal status. The tryptophan-based indole alkaloids, psilocybin and psilocin, are the best examples in this category which have been identified as most attractive bioactive alkaloids in large number of mushrooms, especially of the genus *Psilocybe*, but waiting since long for more control studies to ascertain

LSD	Lysergic acid diethylamide
OCD	Obsessive-compulsive disorders

1 Introduction

Alkaloids have occupied a unique and prominent position in both science and culture due to their diversified source of availability, biochemical properties, and applications. It represents one of the largest groups of natural products which almost all phyla are capable to synthesize at any stage of their life cycle. Fungi (mushrooms), in particular, are able in common along with the higher plants and bacteria to produce alkaloids. The indoleamines (four-substituted compounds) found in mushroom have a long history of investigation and research topic for various laboratories and institutions all over the world, and as a result, more than five decades back in 1958, Dr. Albert Hofmann, the discoverer of LSD, further reported two most fascinating bioactive alkaloids – Psilocybin and Psilocin – from mushroom *Psilocybe mexicana*. Both alkaloids are derived from L-tryptophan. Later, he also developed a synthesis technique for the production of psilocybin and psilocin [1, 2]. The chemical synthesis of psilocybin opened a new vista which ended with the introduction of first synthetically developed psilocybin under the brand name of "Indocybin" marketed by Sandoz for experimental and psychotherapeutic purposes in the 1960s. Psilocybin, also known as psilocybine, is classified as neurotropic or psychedelic indole alkaloid of the tryptamine family, with mushrooms of the genus *Psilocybe*, commonly known as hallucinogenic mushroom or magic mushroom [3] as the most common source. Various species of genus *Psilocybe* are found all over the world in most terrestrial (land) biomes, and more than 100 species have been so far identified and reported, but their potential to produce psilocybin is still to be determined because in some species the level of psilocybin and psilocin are reported as nondetectable. *Psilocybe cubensis* is considered as the most widely known species capable of producing psilocybin and psilocin in considerable quantity, though originally both alkaloids were isolated from *Psilocybe mexicana* [4]. The capability to produce psilocybin and psilocin varies among species on dry weight basis of mushroom and dependent upon various biochemical factors and the parts (mycelium or fruit bodies) of the mushroom used for processing and extraction. The fruit bodies have more alkaloid content than the mycelium. The rate limiting factors or the critical steps in the analysis of psilocybin and psilocin in mushrooms are the techniques used for the extraction, separation, and purification. The biotechnological approach and its utilization have greatly affected the production capacity of these alkaloids using submerged fermentation technology by manipulating media composition and growth parameters as well as with advanced extraction and purification techniques.

The chemistry of psilocybin and psilocin is not complex. Chemically, psilocybin is 4-phosphoryloxy-*N,N*-dimethyl-tryptamine, whereas psilocin is 4-Hydroxy-*N, N*-dimethyl-tryptamine. Psilocybin is regarded as prodrug which is finally converted into psilocin – the pharmacologically active form of the drug in the body by a dephosphorylation reaction and thus acts as a partial agonist at the serotonin receptor (5-HT$_{\mathbf{2A}}$), with high affinity in the brain where it mimics the effects of serotonin (5-HT). Based on this mechanism of action, psilocin is classified as a 5-HT$_{\mathbf{1A}}$, 5-HT$_{\mathbf{1D}}$, 5-HT$_{\mathbf{2A}}$, and 5-HT$_{\mathbf{2C}}$ agonist, and accordingly its psychotomimetic effect can be blocked by 5-HT$_{\mathbf{2A}}$ antagonists, such as ketanserin and risperidone in a dose-dependent pattern [4].

In view of its nature and classification as a neurotropic or psychedelic, psilocybin is capable of acting on CNS, crossing the blood–brain barrier and consequently altering perception, mood, consciousness, cognition, and behavior in a dose-dependent fashion. The use of *Psilocybe* (mushroom) and its two constituents, psilocybin and psilocin, remains very popular in the USA and Europe till the mid-1960s for its recreational and therapeutic purposes when finally in 1968 all three (mushroom and its two alkaloids) were declared illegal in the USA, and as a result psilocybin and psilocin were added to the new "Drug Abuse Prevention and Control Act of 1970" (commonly known as Controlled Substance Act), which came into force in 1971 and both listed in Schedule I drugs under the United Nations Convention on Psychotropic Substances. Despite all these, research actives continued till mid-1970s, and research activities continued to be halted throughout the 1980s and 1990s due to strict governmental control worldwide. The restrictions imposed worldwide during these periods have greatly affected the research activities on psilocybin and psilocin, preventing researchers to investigate the biological activities to ascertain biochemical and pharmacological properties of these two psychedelic indole alkaloids. So far, psilocybin has not been recognized as drug but has been extensively investigated in the treatment of various psychological disorders. However, findings of various investigations are not only highlighting the possible role and importance of psilocybin but also suggesting and demanding more organized and controlled studies to explore its role in the treatment of various mental conditions, including chronic cluster headaches and obsessive-compulsive disorders (OCD) and OCD-related clinical depression.

2 Occurrence

The archaeological evidences available throughout different cultures indicate history of psilocybin mushrooms as quite ancient. Though it is really difficult to correlate and extend any scientific note on such a diversified and scattered subject, yet the mushroom-shaped statuettes or mushroom-formed stones and several Mesolithic rock paintings reported at different archaeological sites, such as Guatemala, El Salvador, Mexico, and Tassili n'Ajjer (a prehistoric North African site identified with Caspian culture), and anthropological literatures further support the presence and history of traditional use of these mushrooms that dates back as far as 2000 BC [5, 6]. The period between fourteenth and sixteenth century remains much popular with respect to use of psilocybin mushrooms when Aztecs (ruler Moctezuma II) and Chichimecas (Nahua people of Mexico) were also reported as users of such mushrooms which they called "teonanacatl" (good mushrooms or flesh of the gods or wondrous mushroom, etc.). In the Western medical literature, the first scientific report appeared in 1799 when a critical article was published in London Medical and Physical Journal with the title "On a poisonous species of agaric." There is hardly any scientific study or report appeared between 1799 and 1899 on psilocybin mushrooms. Some activity was finally been reported by scientists working on psilocybin mushrooms in Harvard University, USA, during the end of the 1930s and 1940s [7] followed by the introduction of the word "magic mushrooms," appeared for the first time in Western literature in 1957 to describe the hallucinogenic property of psilocybin mushrooms [3]. The subsequent studies resulted finally in the discovery of both psilocybin and psilocin in 1958 [1].

Psilocybin mushrooms are quite diversified in nature and thus geographically have a wide range of distribution worldwide which covers both tropical and subtropical regions. These include Mexico, Cuba, Guatemala, Colombia, Bolivia, Brazil, Chile, Argentina, the USA (Florida, Vancouver, Washington, Oregon, California), Canada, England, Norway, Finland, the Netherlands, Germany, Austria, Spain, Thailand, Vietnam, India, Sri Lanka, Nepal, Cambodia, Indonesia, the Philippines, Japan, and Australia. Some species of Psilocybe are reported exclusively in Mexico and Guatemala. Mexico has the highest number of *Psilocybe* species (44 out of total 76 neurotropic fungal species), representing 39% of the total species reported worldwide [8–10]. Being classified as saprotrophs, psilocybin mushrooms can grow on various kinds of decaying organic matters in most biomes, with the exception of high deserts. Based on extensive work of various researchers and their findings reported elsewhere, presence of psilocybin has been reported in large number of species belonging to about 25 different genera [11–13]. These include *Agrocybe, Amanita, Conocybe, Copelandia, Coprinus, Entoloma,*

Table 18.1 Psilocybin and psilocin content of some major species of *Psilocybe*

[a] Average content and may vary in different regions due to environmental conditions and parts used

Galerina, Gerronema, Gymnopilus, Hygrocybe, Hypholoma, Inocybe, Marasmius, Mycena, Naematoloma, Panaeolina, Panaeolopsis, Panaeolus, Pholiota, Pluteus, Psathyra, Psathyrella, Psilocybe, Rickenella, and Stropharia. Out of 216 known species of neurotropic fungi reported elsewhere, most (116 species) fall in the genus *Psilocybe* [9], and out of 190 different mushrooms tested, 90 species have been identified to contain either psilocybin or psilocin or both with genus *Psilocybe*, showing the highest numbers (41 out of 55 species or varieties) in terms of psilocybin or psilocin content [14]. Few species of genus *Psilocybe* are quite prominent in producing psilocybin and psilocin, such as *P. azurescens, P. baeocystis, P. bohemica, P. cubensis, P. cyanescens, P. cyanofibrillosa, P. hoogshagenii, P. liniformans, P. pelliculosa, P. samuiensis, P. semilanceata, P. semperviva, P. subcubensis, P. stuntzii, P. tampanensis*, and *P. weilii* (Table 18.1).

Mushroom species with high psilocybin and psilocin content belonging to genera other than *Psilocybe* include *Agrocybe praecox, Conocybe cyanopus, Copelandia cambodginiensis, Gymnopilus purpuratus, Inocybe aeruginascens, Panaeolus subbalteatus*, and *Pluteus salicinus* (Table 18.2).

The quantity of psilocybin as mentioned in Tables 18.1 and 18.2 is quite variable (approximately 0.5–2.0% dry weight) and dependent on several factors, including age (mature mycelium contains more than the young one), growing and drying conditions (heat and light can affect alkaloidal content), and specific part of the mushroom used for estimation of psilocybin and other alkaloids. In some cases, variation in psilocybin content may be recorded up to 4x for species grown under controlled condition and as much as 10x for ones that are not.

Table 18.2 Psilocybin and psilocin content of some genera other than *Psilocybe*

[a] Average content and may vary in different regions due to environmental conditions and parts used

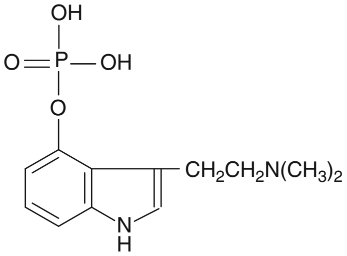
The word *Psilocybe* is derived from Greek roots – *psilos* and kube – which means "bald head" or "bare headed." *Psilocybe* is moderately large genus, with a variety of species. The characteristic macroscopic and microscopic features and taxonomy all are well documented elsewhere comprehensively [5, 6, 8–10, 15, 22, 30] and thus are beyond the scope of the present title for discussion. Precisely, the species of the genus *Psilocybe* are small brown to tan mushrooms with a primary distinguishable feature that they bruise blue when handled or injured. Though *Psilocybe* is placed taxonomically in the agaric (*Agaricales*) family *Strophariaceae* based upon spore and pileipellis morphology, yet the genus is quite complex in terms of classification and thus difficult to separate from genera *Stropharia* and *Hypholoma*, and all three are no doubt closely related. According to some authors, the relationship is close enough to combine these genera into one genus, *Psilocybe* [31]. It has long been suspected that the mushrooms in *Pholiota, Stropharia, Hypholoma, and Psilocybe* share a common ancestor. The current interpretation of DNA has resulted in a different way, suggesting *Psilocybe* comprising of two groups (one producing psilocybin and other does not) that are only distantly related to each other and both are distantly related to *Stropharia*. Presently, both groups are classified under *Psilocybe* but in fact resembling more to *Hypholoma* and *Pholiota* than to *Stropharia* [32, 33]. The DNA studies of mushrooms, no doubt, are revealing some new findings and relationships that were previously unsuspected, but the technology is still unable to answer a number of hidden questions which mycologist and molecular biologists may be interested to know to reach to final conclusion. The overall distribution of psilocybin among various genera has been reported as *Psilocybe* (116 species), *Gymnopilus* (14 species), *Panaeolus* (13 species), *Copelandia* (12 species), *Hypholoma* (6 species), *Pluteus* (6 species), *Inocybe* (6 species), *Conocybe* (4 species), *Panaeolina* (4 species), *Gerronema* (2 species), and *Agrocybe*, *Galerina*, and *Mycena* (1 species each) [9]. The mushroom caps contain more psilocybin or psilocin than the stem, while spores do not contain either psilocybin or psilocin [34, 35]. Most references cited elsewhere [10, 36–39] suggest that the distribution of psilocybin mushrooms may have their origin in southern hemisphere, mainly in South America and Australia and to some extent in South Africa because of the highly diversified geographical and climatic conditions in these regions.

The lower level of industrialization, smaller landmasses, and overall low population densities may have contributed well in the growth and propagation of enormous number of mushroom species in these regions. The historical findings also suggest the traditional users of psilocybin mushrooms among various ethnic groups located in Mexico and Colombia (South America), New Guinea (greater Indo-Australian Archipelago) and in Africa. From South America, it is believed to have further migrated to northern parts (North America, Canada, and Europe), while from Australia, it may have reached to Southeast Asia, South Asia, and other parts of Asia Pacific (Table 18.3).

3 Phytochemistry

The primary bioactive alkaloids reported in most *Psilocybe* mushrooms include psilocybin and psilocin and to a lesser extent baeocystin and norbaeocystin **(1–4)**.

Psilocybin: 4-phosphoryloxy-*N*,*N*-dimethyltryptamine;
3-[2-(dimethylamino)ethyl]-1 H-indol-4-ol-dihydrogen phosphate
Psilocin: 4-hydroxy-*N*,*N*-dimethyltryptamine;
3-[2-(dimethylamino)ethyl]-1-H-indol-4-ol
Baeocystin: 4-phosphoryloxy-N-methyltryptamine
Norbaeocystin: 4-phosphoryloxytryptamine.



Psilocybin

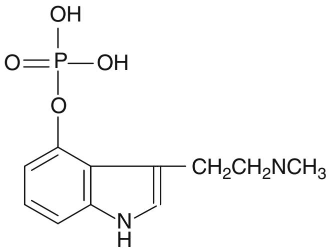
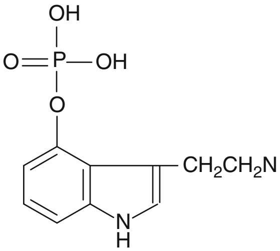
Psilocin
2



Baeocystin
3



Nor-baeocystin
4

Apart from these four bioactive indole alkaloids, *Psilocybe* mushrooms are capable of producing a number of indole derivatives (Table 18.4). Psilocybin has the molecular formula $C_{12}H_{17}N_2O_4P$ (mol. weight = 284.27). It is a prodrug that is

converted by the mechanism of dephosphorylation into psilocin (another pharmacologically active compound). Psilocin has the molecular formula $\mathbf{C_{12}H_{16}N_2O}$ (mol. weight = 204.27).

Psilocybin is regarded as tryptamine compound based on its biosynthesis route and precursor. Being a tryptamine compound, the chemical structure is derived from the amino acid tryptophan **(5)** which has a ring configuration, simply known as

Table 18.4 List of indole derivatives reported in various *Psilocybe* mushrooms

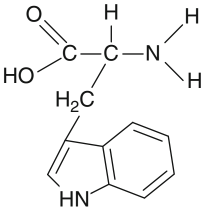
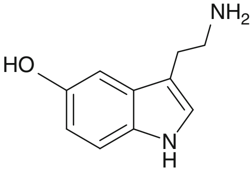
N,*N*-Dimethyltryptamine hydrogen-oxalate	Isatin
Bufotenine monooxalate	Gramine

[a]The list indicates addition compounds, apart from well-known alkaloids

indole (C_8H_7N), linked to an ethylamine substituent. Structurally, psilocybin has a close resemblance with a neurotransmitter serotonin or 5-HT (**6**). Tryptamines are one of the four categories of hallucinogenic indoles in more than 20 classes of indole compounds comprising approximately 600 alkaloids.



Tryptophan
5



Serotonin
6

Psilocybin is zwitterionic in nature (containing both positive and negative charges), insoluble in most organic solvents (such as chloroform, benzene, etc.,), slightly soluble in ethanol, moderately soluble in methanol (120 parts of boiling methanol), and soluble in water (20 parts of boiling water). Aqueous solution is highly unstable and rapidly oxidizes. This is an important factor and should be taken into consideration when psilocybin is used as an analytical standard [39]. Physically, psilocybin is white, needle-like crystalline structure with melting point between 185–195 °C [14] and 190–198 °C [95]. A 1% solution of psilocybin dissolved in 50% ethanol has a pH of 5.2 [2]. Scientific work carried out in

Japan with respect to large-scale chemical synthesis of psilocybin without chromatographic purification suggests use of 4-hydroxyindole to produce psilocybin from psilocin with a yield of 85% [95].

For presumptive analysis (color test) of psilocybin, both Ehrlich and Marquis tests can be applied. Care should be taken as some other C_2 unsubstituted indoles (such as DMT and LSD) may give similar colors with test reagent, thus making it mandatory for a confirmatory test before extending any final concluding remarks. With Ehrlich's reagent (1 g of p-dimethylaminobenzaldehyde in 10 ml methanol + 10 ml con. orthophosphoric acid), a violet to gray-violet color indicates the possible presence of psilocybin or psilocin. The detection limit of this method is approximately 1 μg. While with Marquis' reagent (solution A: 8–10 drops of 40% formaldehyde solution to 10 ml glacial acetic acid; solution B: con. H_2SO_4), an orange color indicates the possible presence of psilocybin and a green-brown color the presence of psilocin. The detection limit of this method is about 10 μg. Since the positive color reaction for psilocybin with Marquis' reagent is obscured by vegetable matter and as some other natural products present in mushrooms may develop a yellow color, therefore with sulfuric acid, this color test is not suitable for the detection of psilocybin or psilocin. Mandelin tests can also be applied to detect psilocybin. Application with Mandelin reagent (1 g of ammonium vanadate in 100 ml con. H_2SO_4) results in the development of green color, while DMACA reagent (0.5 g of p-dimethylaminocinnamaldehyde in 50 ml methanol + 10 ml con. HCl) can be sprayed to detect after chromatographic analysis [96, 97], or few drops can directly be added over the suspected material on a spot plate. Psilocybin gives gray-violet to violet color, whereas psilocin turns blue. The DMACA reagent is more sensitive than Ehrlich reagent and also reflects better color stability. The detection limit for DMACA reagent is about 20 ng for psilocybin and 10 ng for psilocin. Other techniques used to detect and quantify psilocybin include gas chromatography coupled to mass spectrometry [98], ion mobility spectrometry [26], capillary zone electrophoresis [99], ultraviolet spectroscopy [39], infrared spectroscopy [55], high-performance liquid chromatography (HPLC) with ultraviolet [39], fluorescence [100], and electrochemical [101] or electrospray mass spectrometric methods [102]. These chromatographic techniques can also be used to detect psilocin in the body fluids.

Solvent system does play very important role in the isolation and extraction of psilocybin. It is quite evident from the early phase of research activities that very polar solvent, such as methanol or mixtures of ethanol and water, is most suitable for the isolation of psilocybin. The polar properties of the phosphate group make psilocybin soluble in water and methanol (polar solvent), and as a result solubility decreases with the decrease in polarity, i.e., less soluble in polar solvent. In comparison, psilocin is less polar and thus readily soluble in polar solvent, such as 1-chlorobutane. For thin layer chromatography, solvent systems comprising of n-butanol + acetic acid + water (20:10:10) or methanol + con. ammonia solution (100:1.5) may be used to develop the plates, and visualization of the blue spots on fluorescent background can be made using ultraviolet (UV) light at 254 and 365 nm. The absorption characteristics of both psilocybin and psilocin in the UV region are quite prominent. Both exhibit native fluorescence and are electrochemically active.

Mushrooms of the genus *Psilocybe* generally have a brownish cap (pileus) when moist in fresh fruiting bodies but fade gradually in color during the process of drying. In addition, some species (typically the hallucinogenic species) have the tendency to change the color (a condition called blue staining reaction) when fruiting body is damaged. This is also described as blueing phenomenon. Some authors do conclude that the blueing phenomenon ultimately reflects and provides a reasonable correlation between psilocybin and other indole derivatives content present in that particular species [43, 103]. However, at the same time, others suggest not to use this phenomenon as a definite method for identification or determining the potency of a mushroom [6, 17]. The phenomenon that psilocybin has the tendency to form blue color in solution can further be linked to its conversion into psilocin (which is relatively unstable in solution due to its phenolic hydroxyl –OH group) by dephosphorylation in presence of enzyme phosphatase followed by oxidation of psilocin by cytochrome oxidase, or copper oxidase or Fe $^{2+}$ [104]. Animal module also supported and suggested a similar mechanism for the development of blue color by these mushrooms when psilocybin was incubated with the homogenates of rat kidney or other mammalian tissues. A rapid liberation of psilocin was observed through the action of alkaline phosphate which further undergoes oxidative degradation and forms a blue-colored product [105]. A mitochondrial enzyme (cytochrome oxidase) was found responsible in the oxidation of psilocin to a dark blue color by the tissue homogenates [106].

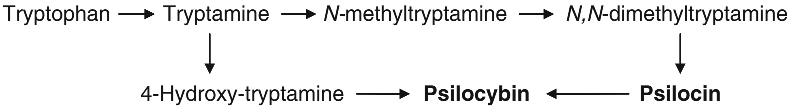
4 Biosynthesis

Studies on biosynthesis mechanism and the routes including enzymes involved in different steps are the best known toll in understanding the conversion or production of various biochemicals in living system. In case of psilocybin biosynthesis, though the experimental evidences are limited, but the overall mechanism can safely be discussed starting from chorismic acid, which is produced through shikimic acid pathway, a well-known pathway present in fungi which regulates the production of various biochemicals, including psilocybin and some other tryptamine-based psychedelic drugs, such as DMT and LSD.

The shikimic acid pathway leading to the production of chorismic acid is regulated in the cytosol of the fungal cells. Cytosol or intracellular fluid (cytoplasmic matrix) is a complex mixture of substances dissolved in water. These include ions (such as calcium, sodium, and potassium), macromolecules, and large complexes of enzymes that act together to carry out metabolic pathways. Production of chorismic acid in the cytosol is ultimately utilized in the synthesis of folate, ubiquinone, and amino acids, the most important of which is tryptophan which plays a major role in the biosynthesis of psilocybin.

The two starting materials of the shikimic acid pathway, phosphoenolpyruvate (a product of glycolysis) and erythrose 4-phosphate (a product of pentose phosphate pathway), act as phosphate donors. Glucose is phosphorylated by ATP, which loses a phosphoryl group to become ADP. The glucose 6-phosphate thus produced, enter into two different pathways, glycolysis and pentose phosphate pathway, to produce both the starting materials required to regulate shikimic acid pathway with the production of chorismic acid, a substrate to give anthranilic acid which is a precursor of tryptophan (Scheme 18.1). With a few minor exceptions, tryptophan and its decarboxylation product, tryptamine, give rise to the large class of indole alkaloids, including psilocybin [107, 108] (Scheme 18.2).

Earlier findings published in 1961 [107] suggested that psilocybin is finally been synthesize from tryptophan. The hypothesis was based on the results obtained from still cultures of *Psilocybe semperviva*. Subsequent studies on the subject carried out using *Psilocybe cubensis* under submerged cultural condition also supported this hypothesis that psilocybin may biosynthetically derive from tryptophan and tryptamine [108]. More details were then published to clarify the sequence of events which leads from tryptophan to psilocybin by incorporating H^{3}– and C^{14}- labeled hypothetical intermediates (such as DL-Tryptophan-^{3}H, Tryptamine-^{14}C, *N*-methyltryptamine-C^{14}-^{3}H, *N,N*-Dimethyltryptamine-^{14} C-^{3}H, 4-hydroxytryptamine-^{14} C-^{3}H, Psilocin-^{3}H, DL-4-OH-Tryptophan-^{3}H) into psilocybin in submerged cultures of *Psilocybe cubensis* [109, 110]. Other reports [111, 112] indicated no effect or influence of tryptophan on the biosynthesis of psilocybin when added in the culture medium during submerged fermentation of *Psilocybe cubensis* and *Psilocybe baeocystis*. It can be concluded from the results of most findings that tryptophan has to be modified by decarboxylation, methylation of the amino group, hydroxylation of the 4-position of the indole moiety, and phosphorylation of the 4-hydroxyindole moiety for the production of psilocybin with below sequence [108–110, 113].



However, this may not be the only route. The fungus still may have an alternate route to convert 4-hydroxytryptamine to psilocybin. This probably because phosphorylated intermediate baeocystin and norbaeocystin are also produced, in addition to psilocybin, which is most likely produced via one phosphorylase enzyme from psilocin.

The radioactive tryptamine is observed to function as a better precursor than the tryptophan and 4-hydroxytryptophan in submerged culture of *Psilocybe cubensis* [113]; it is reasonable to conclude that the decarboxylation of tryptophan to tryptamine is the most crucial step in the biosynthetic pathway. This step is highly sensitive to feedback inhibition due to allosteric enzymes. It is believed that as the concentration of psilocin increases in the culture media, it starts inhibiting further conversion of tryptophan to tryptamine, and as a result tryptophan will not be converted to tryptamine, and thus no psilocin or psilocybin is

PSILOCYBIN

Scheme 18.2 A proposed biosynthesis pathway of psilocybin biological activities formed. Further addition of tryptophan will have no impact on the formation of psilocybin. While conversion of tryptamine to N-methyltryptamine is not as sensitive to feedback inhibition; therefore, addition of tryptamine will increase the production of psilocin. Apart from this, all other steps are also not as sensitive to feedback inhibition either. There still exists some controversy among authors regarding biosynthetic route from tryptamine to psilocybin [114]. When *Psilocybe cubensis* (mini-cultures) grows under deuterium-labeled precursor solution, a wide range of tryptamine can readily be absorbed by mycelia and translocated into developing mushrooms. The deuterated tryptamine can be incorporated more efficiently into psilocin and psilocybin than were monomethyltryptamine and dimethyltryptamine, suggesting that though hydroxylation enzyme operates normally on tryptamine, but may be flexible enough to oxidize dimethyltryptamine or other natural compounds forced on it at a high concentration. As the hydroxylation of dimethyltryptamine to produce psilocin was noted to occur with NIH shift, therefore an intermediate compound (tryptamine-4,5-epoxide) is most probably present between tryptamine and psilocin.

It is really difficult to interpret and match the data obtained through submerged cultural condition with that of fruit bodies grown in wild to ascertain the biosynthesis mechanism. Some observations indicate that surface cultures of *Psilocybe semilanceata* have a high hydroxylation and phosphorylation capacity, although the ability to methylate tryptamine derivatives is low. These findings are in accordance with the earlier mentioned hypothesis that the fungus may have alternate route to convert 4-hydroxytryptamine to psilocybin.

5 Biological Acitivies

Despite the introduction of psilocybin more than five decades back by Sandoz, under the brand name of Indocybin, limited data are available for discussion. The original Indocybin tablets manufactured during 1958–1965 are still available in its original packaging (glass bottle with metal screw on lid, labeled: Sandoz Pharmaceuticals, 50 tablets, Psilocybin, each tablet contains 10 mg) in Bureau of Forensic Services Laboratory, Eureka, California. Traces of psilocin were still detectable by GC/MS in these tablets, but most peaks reflect tablet excipients. During the early mid-1960s (until it is classified as Schedule I in 1970 in the USA), psilocybin was used in psychiatric and psychological research as well as psychotherapy. Psilocybin mushrooms have had numerous medicinal and religious uses in dozens of cultures throughout history and have a drastically lower potential for abuse than other Schedule I drugs. Also, the UN's International Narcotics Control Board (INCB) has made it clear that *Psilocybe* mushrooms are not controlled by the UN [115, 116]. Research into the biological activity of psilocybin resumed in the mid-1990s, and currently a number of research institutes are working on biological activities of psilocybin to ascertain its clinical role in different disorders and syndromes. In view of highly scattered biological activities of psilocybin, it will be appropriate to discuss this topic under subheadings, such as Pharmacology (Pharmacodynamics and Pharmacokinetics); Physiological and Psychological Effects; Therapeutic Role (Advanced Stage Cancer, Cluster Headaches, Obsessive-Compulsive Disorders); and Toxicity (Side Effects and Risks).

5.1 Pharmacology (Pharmacodynamics and Pharmacokinetics)

After oral ingestion, psilocybin is rapidly dephosphorylated into psilocin which is structurally related to serotonin (5-HT) and lysergide (LSD-25). Psilocin has high affinity ($Ki = 6nM$) for 5-HT receptors, especially the 5-HT$_{\mathbf{2A}}$ in the brain (cerebral cortex) where it mimics the effects of serotonin and thus capable of altering perception, mood, consciousness, and cognition. It also has affinity (but binds less tightly, $Ki = 190$ nM) with other serotonergic receptors, such as 5-HT$_{\mathbf{1A}}$ (hippocampus), 5-HT$_{\mathbf{1D}}$ (cranial blood vessels), and 5-HT$_{\mathbf{2C}}$ (choroid plexus) and thus can also contribute to the subjective and behavioral effects. Psilocybin and psilocin have no affinity for dopamine $D_{\mathbf{2}}$ receptors [117]. The mode of action can precisely be explained in a way that psilocybin acts by altering the concentration of indoles, including serotonin, in the central nervous system and thus interfering with the transmission and processing of external stimuli. The psychotomimetic effects of psilocybin can be blocked in a dose-dependent manner by the 5-HT$_{\mathbf{2A}}$ antagonist drugs, such as ketanserin and risperidone [118].

Psilocybin and psilocin are stoichiometrically equivalent in potency. After dephosphorylation to psilocin, presumably via a first pass effect by hepatic metabolism, it is easily taken up by tissues. More than 50% of the psilocybin is absorbed through the lining of mouth, stomach, and intestine and is detectable as psilocin in the blood within 20–40 min. Distribution throughout the body is quite uniform, including the brain [119, 120]. The absolute bioavailability of psilocin after oral administration of psilocybin is recorded as 52.7 ± 20%. The average peak concentration of 8.2 ± 2.8 ng ml^{-1} ($C_{\mathbf{max}}$ ranging from 4 to 21 ng ml^{-1}) is usually achieved within 2 h (105 ± 37 min.) after oral administration of 10–20 mg psilocybin (0.224 ± 0.02 mg kg$^{\mathbf{-1}}$ body weight) and decline over the next 3–4 h. While after intravenous injection of 1 mg psilocybin, peak plasma concentration of 12.9 ± 5.6 ng ml^{-1} reaches within 1.9 ± 1.0 min. The average half-life ranges between 2.5 and 3 h [121–123], while quantification of psilocin can be made within 6–7 h after oral administration [121, 124]. Psilocin is excreted mainly as glucuronide and to some extent as unchanged psilocin as well in urine. According to one report, 65% of the absorbed psilocybin is excreted into urine and 15–20% into bile and feces within 24 h [125]. Other metabolites detected in quantities include 4-hydroxyindole-3-yl-acetaldehyde, 4-hydroxyindole-3-yl-acetic acid, and 4-hydroxytryptophol [121, 126–129]. A proposed metabolic route for psilocybin is suggested in Scheme 18.3.

5.2 Physiological and Psychological Effects

The effects of psilocybin are quite variable and usually dependent upon dose and duration of intake. This may also be linked with the individual brain chemistry and physiology which may have significant role in determining the response to psilocybin. Though the recreational dose ranges from 10 to 50 mg, yet only 4–10 mg is enough to induce hallucination [5, 6]. Some people may require relatively high dose to gain a low-dose effects of psilocybin. The mental and physical tolerance to psilocybin may build but dissipates quickly. So dose adjustment (especially for frequent users) may be required to avoid side effects. Cross-tolerance is also possible between psilocybin and LSD, as well as between psilocybin and phenylethylamine hallucinogens, such as mescaline and 2,5-dimethoxy-4-methylamphetamine [130–132].

The general features which are characteristic of the psychedelic reaction are same for psilocybin as well. The most common features include changes in perception (perceptual changes such as illusion, pseudohallucination, and hallucination) and changes in vision (objects, pictures, or patterns seem to come alive, shift, ripple, or become wavy). The psychological symptoms are greatly affected after psilocybin ingestions. Various trial reports published elsewhere [133–135] highlight these effects when psilocybin was given to healthy volunteers in decreasing order. The emotional alterations noted in 100% of the volunteers include disorders/alterations of consciousness in 91%, depersonalization in 84%, perceptual alterations in 75%, disorders/alteration of volition and psychomotor behavior in 34%, body image distortions in 25%, disorders/alteration of attention in 22%, disturbances in thought process in 22%, and disorders of memory in 19% of the volunteers.

5.3 Therapeutic Role (Advanced Stage Cancer, Cluster Headaches, Obsessive-Compulsive Disorders)

Results of various double-blind, placebo-controlled pilot studies carried out with psilocybin in the management of these conditions or reducing the severity of the various associated symptoms are highly encouraging. To reduce anxiety and improved quality of life in people with advanced stage of cancer, psilocybin has been observed as good alternate [136, 137]. In case of cluster headaches which has been recognized as one of the worst pain syndromes and difficult to control through presently available drugs, psilocybin has been reported to have promising effect in reducing the severity of the attack as well as to increase the attack-free periods in such patients [138–140]. A substantial reduction in symptoms in patients associated with obsessive-compulsive disorders (OCD) has also been noted with psilocybin therapy. The proposed mechanism and reason for this is the reduction in serotonin levels at 5-HT$_{2A}$ receptors due to psilocybin which ultimately suppresses the responsiveness to serotonin [141, 142]. In most cases, only sub-hallucinogenic dose of psilocybin is required to achieve the desired therapeutic effect without any major side effects.

5.4 Toxicity (Side Effects and Risks)

The therapeutic index of psilocybin as given by “The Registry of Toxic Effects of Chemical Substances” is quite high (therapeutic index = 641), in comparison to aspirin and nicotine for which the values are quite low (therapeutic index = 199 and 21, respectively), representing better a better safety profile [143]. Therapeutic index is the ratio of the dose that produces toxicity (TD$_{50}$) to the dose that produces a clinically desired or effective response (ED$_{50}$) in a population. The therapeutic index is a measure of a drug’s safety, because a larger value indicates a wide margin between doses that are effective and doses that are toxic. LD$_{50}$ in rats by oral route is 280 mg kg^{-1} while that of intravenous route in rabbit is 12.50 mg kg^{-1} [144]. The common side effects are very similar to those reported for other hallucinogens, such as ergoline and LSD. These include perception of time and space, derealization, depersonalization, dilated pupils, dizziness, fatigue, impaired concentration, unusual body sensations and thoughts, transient increase in blood pressure or heart rate, transient psychosis, change in mood, nausea, etc. These effects are mostly noted as acute which usually last for about 4–6 h [117, 145–148]. Oral intake of psilocybin appears to be at the lowest risk out of all other psychoactive drugs, while long-term toxicity studies in mice indicated no teratogenicity or mutagenicity [149, 150].

6 Biotechnological Approaches

The biotechnological approach has now occupied a prominent place while discussing topics in applied biology. However, the features and objects may vary based on scope of the study. In search of new drug molecules or to evaluate the existing therapeutically active molecules, especially from higher fungi, is increasing day by day. The higher fungi have tremendous capability to synthesize biologically active compounds, especially the alkaloids with diversified chemistry and pharmacological activity. However, unfortunately less attention has so far been given by the researchers to utilize biotechnological approach to produce tryptamines (e.g., psilocybin and psilocin), perhaps because of the legal status and their classification under Schedule I drug category in the USA which restricted such studies and funding as well. The Schedule I drugs deemed to have a high potential for abuse and are not recognized for medical use. In Canada, both psilocybin and psilocin are classified as restricted drugs and are listed in Schedule III of Canada's Food and Drugs Act [151]. However, with the change in scenario and after having some prominent results of psilocybin in the management of various disorders, the situation is thus demanding substantial quantity of such molecules for pilot study and commercialization. So the improvement in strains capability, media, and culture conditions as well as regulation of enzyme activity involved in different steps of the biosynthetic pathway of psilocybin require more attention. The function of enzymes is to effect the integration of overall metabolic pathway. The formation alkaloid relates to endogenous metabolism. Thus, the energy released during the process is utilized to maintain the viability and integrity of the cells. In the biosynthesis of psilocybin, tryptophan plays important role, both as a regulatory and a precursor. It will be worth to utilize biotechnological approach to study the enzyme tryptophan decarboxylase (responsible for the decarboxylation of tryptophan to form tryptamine) and its regulatory mechanism. This is the last major step in the pathway that is significantly inhibited by a self-feedback mechanism. Due to this, tryptophan decarboxylase stops converting tryptophan to tryptamine, and as a result less psilocybin is produced. No report available showing role of biotechnology in this direction or subject. The only reference available describes molecular cloning of enzymes (enzyme coded by cDNA) from the psilocybin biosynthesis pathway in *Psilocybe tampanensis* to determine enzymatic activities [152].

DNA-based approach (phylogenetic approach) has been reported by Canadian investigators for various species of psilocybin mushrooms which are quite helpful in the identification of species that contain the psychoactive compounds [153]. The method includes DNA amplification and sequencing of the internal transcribed spacer region of the rDNA (ITS-1) and a $5^{\prime}$portion of the nuclear large ribosomal subunit of rRNA (nLSU rRNA or 28 S). The method is quite useful in the identification of unknown fungal species with regard to presence or absence of psilocybin and psilocin. Genetic techniques based on polymerase chain reactions (PCR) of specific regions of the genomes can also be used to identify and differentiate between psilocybin and non-psilocybin-producing species and strains of various mushrooms. The submerged culture technique for the production psilocybin is still believed to be the best biotechnological approach. Though improvement can also be done through field cultivation of mushrooms, yet it will be quite laborious, expensive, time consuming, and will also depend upon several environmental factors not easily manageable.

7 Conclusion/Prospects

With the increasing number of psychotic patients worldwide, there is a definite need to explore and find new pathways of treatment by both discovering new molecules as well as utilizing known drugs by modifying the dimension of the research activities and protocols. The introduction of biotechnology will have significant impact to this approach. Both psilocybin and psilocin are excellent examples such actives to initiate research in a broader way to explore these two bioactive indole alkaloids not only to see the possibility of their use in psychiatry but to widen their application for the treatment of other disorders as well. Thus, further research studies on these psychedelic to examine their overall effect on cerebral nervous system are proposed. Apart from this, the clinical role of these novel alkaloids can further be explored by modifying the dosage form from immediate to modified (extended) release dosage form to establish more convenience in terms of dosage and to reduce side effects. Prospects are quite open but seem to be challenging.

Abstract

Over 140 beta-carboline (Harmala) alkaloids are detected in bacteria, algae, fungi, various plant groups, food products, alcoholic beverages, tobacco smoke, marine bryozoa, insects, and animal tissue including human. Some of these alkaloids and their derivatives are synthesized chemically. Several natural and chemically formed alkaloids are biologically active, and they can be used as potent pharmaceutical drug for anticancer therapy, angiogenesis, Alzheimer's, free radical scavenger, *Leishmania*, and viruses Herpes, Influenza, Polio, and HIV.

Keywords

Angiogenic • antitumor • β-carboline • harmala alkaloids • harmine

Abbreviations

CNS	Central nervous system
CNTs–GCE	Carbon nanotubes–modified glassy carbon electrodes
GABA	Gamma-Aminobutyric acid
GC	Gas chromatography
HPLC	High-performance liquid chromatography
HPTLC	High-performance thin-layer chromatography
LC	Liquid chromatography
MAO	Monoamine oxidase
MS	Mass spectroscopy
TLC	Thin-layer chromatography

1 Synonyms

Harman: aribine, colloturine, loturine, passiflorin, 2-methyl-β-carboline, 3-methyl-4-carboline; Harmaline: harmidine, Harmalol, methyl ether, *O*-methyl-harmalol, 3,4-dihydroharmine; Harmine: telepathine, leucoharmine, yageine, banisterine; Tetrahydroharmine: elaeagnine, calligonine, leptaflorin

2 Introduction

β-carboline alkaloids are heterocyclic amines with a 9-*H*-pyrido[3,4,b] indole structure derived from amino acid tryptophan. Initially, they have been isolated from plant *Peganum harmala* L. (Syrian Rue) and are also known as harmala alkaloids. They are active constituents in hallucinogenic plants and have a long tradition in ethnopharmacology. Since then, they have been reported in variety of plant groups, fungi, microorganisms, and in animal tissue including human beings [1–3]. More than 140 different types of β-carbolines are reported so far in plant and animal system [4, 5]. Norharman, harmane, and harmine are also known as mammalian indole alkaloids because they are endogenously produced in human and animal tissues as a product of secondary metabolism [6]. These compounds are also found in some medicinal plants [7]. During food production, processing, and storage, the chemical condensation between indoleamines and aldehydes or keto acids occurs naturally and results in formation of β-carbolines. Their presence is noted in well-cooked meat and fish and also in alcoholic beverages, tobacco smoke, and marijuana smoke [8]. They possess diverse biological properties due to their capability to bind to benzodiazepine or imidazoline receptors, such as hallucinogenic, tremorogenic, hypotensive or cardiovascular actions, and psychotropic properties.

3 Occurrence

β-carboline alkaloids are found mostly in plant system, but they also showed their presence in some animal tissue. In man, tetrahydro-beta-carboline (tetrahydronorharman), formed from tryptamine condensed with formaldehyde, occurs normally in plasma and is highly concentrated in platelets. After alcohol intake, its concentration is usually greatest at the time of hangover. These alkaloids may be found in particularly high concentrations (ng/g) in animal protein (i.e., meat). It is assumed that dietary sources were 50 times greater than endogenous sources [9]. Some β-carbolines, notably tryptoline and pinoline, are formed naturally in the human body [10].

β-carbolines are detected in bacteria, fungi, algae, and in plants belonging to bryophytes, pteridophytes, gymnosperm, angiosperms, and some specific marine organism (Table 19.1).

4 Phytochemistry

4.1 Physicochemical Characteristic

See Table 19.2.

4.2 Chemical Structures

See Fig. 19.1.

4.3 Extraction, Isolation, and Analysis

4.3.1 Extraction

Hundred grams of dried and powdered natural material (fruits, stem, or leaf) macerated with 250 ml of methanol at 50 °C in a water bath for 1 h., filter the extract with Whatman filter paper No. 1, and repeat the maceration of the material for four times. Combine the extract and evaporate to dryness. The residue was

dissolved in 20 ml HCl (2%) and filtered through 0.45 μ filter. Wash the residue with HCl (2%) till colorless filtrate is obtained. Combine the filtrate and extract three times with equal volume of petroleum ether. The aqueous acid layer is basified (pH > 10) with NH_4OH or NaOH and then extracts with equal volume of chloroform and repeat the extraction four times with chloroform. Wash the combine organic layer with water, dry the organic layer over anhydrous sodium sulfate, and remove the solvent under reduced pressure to get the residue. The residue can be used after dissolution in methanol for detection and quantification using TLC, HPTLC, or HPLC method or adsorb the entire residue on a column grade silica gel. Place it on a column of grade silica gel. Carry out the gradient elution with increasing polarities of chloroform–methanol mixture. Monitor the column fractions with TLC/HPLC/HPTLC.

4.3.2 Isolation

For purification and separation, the final residue obtained by above-mentioned method is mixed with 50 ml of 3% v/v acetic acid and allowed to stand for 24 h with occasional stirring. Repeat it for at least three times. Combine the acid extract containing acetates of alkaloids and treat with NaCl (10 gm/100 ml extract), allow to cool and conversion of alkaloidal acetates to alkaloidal hydrochlorides precipitate (ppt). Discard the supernatant. Repeat the process, dissolve the ppt in warm water (50–60 °C), and add ammonia carefully till harmine begins to crystallize, filter, and separate harmine crystals. Add ammonia to filtrate and allow to precipitate harmaline. Wash the crystals and subject to purification or recrystallization [41].

4.3.3 Analysis

Selective and sensitive detection of β-carbolines is possible using HPLC methods in combination with UV, chemiluminescence, and fluorometry. Besides this, LC-MS and GC-MS are the techniques predominantly used for identification, separation, and quantitation of β-carbolines and tetrahydro-β-carbolines [13, 42]. These alkaloids are detected in foods and beverages by HPLC with electrochemical detection at carbon nanotubes–modified glassy carbon electrodes (CNTs–GCE) [43]. In the seeds of *Peganum harmala* L., the alkaloids harmol, harmalol, harmine, and harmaline were separated using a Metasil ODS column by isocratic elution with isopropyl alcohol:acetonitrile:water: formic acid (100:100:300:0.3) (v/v/v/v pH adjusted 8.6 with triethylamine) and detected at 330 nm [13]. These alkaloids can be detected by HPTLC method [44].

Simultaneous quantification of 11 compounds found in ayahuasca (A popular Amazonian botanical medicine and religious sacrament) has been achieved using direct injection/liquid chromatography- electrospray ionization (ESI)-selected reaction monitoring (SRM) - tandem mass spectrometry procedure [45, 46].

5 Biosynthesis

The β-carboline alkaloids are heterocyclic amines, biosynthesized from combination of five- and six-ringed (i.e., cyclic) carbon structures, containing an amine group. β-carboline is made up of planar tricyclic ring structures derived from L-tryptophan (i.e., α-aminoindole-3-propinoic acid), a neutral heterocyclic amino acid containing essentially an indole ring system. The shikimic acid pathway converts the simple carbohydrate precursors phosphoenolpyruvate and erythrose-4-phosphate derived from glycolysis and pentose phosphate pathway, respectively, to aromatic amino acids (L-tryptophan). Decarboxylation of L-tryptophan yields tryptamine. The C-2 of indole nucleus is nucleophilic due to adjacent nitrogen atom which allows it to participate in a Mannich/Pictet–Spengler type reaction. These rearrangements enable a Schiff base derived from tryptamine to interact either with aldehyde or keto acid to yield β-carboline carboxylic acid which on oxidative decarboxylation gives rise to 1-methyl β-carboline. In formation of simple structures of β-carboline, keto acids are used, e.g., harman, harmaline, and elaeagnine. For formation of complex structures, the specific pathways used the aldehyde, e.g., ajmaline (terpenoid indole alkaloids). Hydroxylation followed by methylation of 1-methyl-β-carboline yields harmaline, while on reduction it yields elaeagnine, and upon mild oxidation produces harman. Oxidation of harmaline with loss of water molecule generates harmine while on reduction yield tetrahydroharmine. The demethylation of harmine gives rise to the alkaloid harmalol. Harmaline on condensation, oxidation, and decarboxylation yields to norharmine (Fig. 19.2).

6 Chemical Synthesis

Several beta-carboline alkaloids and their derivatives are chemically synthesized through the Pictet–Spengler reaction using tryptophan, its derivatives, and oxidation of $K_2Cr_2O_7$ by a sequential one-pot synthesis method [47]. There are some other methods reported for the chemical synthesis of β-carboline alkaloids [48–51].

$$\begin{array}{r}\beta\text{-phenyltryptamine} + \text{HCOOH} \rightarrow \text{N-formyl-}\beta\text{-phenyltryptamine}\\ \downarrow +\text{POCl}_3\\ \text{4-Phenyl-3, 4-dihydro-}\beta\text{-carboline}(5)(\text{monohydrate})\end{array}$$

7 Biological Activities

β-carboline alkaloids are widespread in plants and animals. Numerous reports investigated the effects of β-carboline alkaloids on the central nervous system (CNS). However, recent interest in this alkaloid and its derivatives has been focused on their potent antitumor, anticancer, antiviral, antimicrobial, antioxidant, antiparasitic, and several other biological activities [52]. The chemical analysis of plants *Banisteriopsis caapi* used in preparation of ancient drug "ayahuasca" showed that the active chemical constituent named telepathine was found to be identical to a chemical already isolated from *Peganum harmala* and was given the name harmaline. Later, it is well established that the β-carbolines are component of

some medicinal plants, such as *Peganum harmala* (Zygophyllaceae), *Passiflora incarnata* (Passifloraceae), and *Banisteriopsis caapi* (Malpighiaceae) (details are given in Table 19.1).

Beta carboline has biochemical, neurophysiological and the pharmacological effects in animals and man. They participate in several actions, including inhibition of MAO-A, 5-HT uptake, general inhibiton of Na^+ dependent transports, act as neuromodulators and some may have an endocrinological function [53].

7.1 Interaction with DNA and RNA

Some of the mutagenic and carcinogenic effects of β-carboline alkaloids have been studied in prokaryotic and eukaryotic cells related to their ability to intercalate into DNA [54, 55]. The β-carboline derivatives inhibit DNA topoisomerases and interfere with DNA synthesis. Harmine-, harmaline-, harman-, and norharman-inhibited DNA excisions repair directly or indirectly and lead to altered DNA replication fidelity and enzymatic activities in DNA-repair processes [56, 57]. These alkaloids consequently enhance UV or chemically induced mutagenesis [58]. Harman- and harmine-induced chromosome aberrations in Chinese hamster ovary cells after treatment with the clastogens mitomycin C and UV light [59] while in human neuroblastoma SH-SY5Y cells harman and norharman induced apoptosis as well as necrosis [60]. Aminophenylnorharman, a newly identified beta-carboline alkaloid induced sister chromatid exchange and chromosome aberrations in cultured Chinese hamster lung cells. The different types of β-carboline alkaloids showed variation in affinity to bind DNA, and it is in the order of harmine > harmalol > harmaline > harmane > tryptoline [61]. These alkaloids also bind with yeast RNA [62].

7.2 Interaction with Enzymatic Systems and Receptors

The activity of certain enzymes is inhibited in the presence of beta-carboline alkaloids. The alkaloids interact with neurotransmitter systems such as opiate, GABA, muscarinic, and cholinergic [59]. Inhibition of human DNA Topoisomerase I activity was observed with the seed extract of *Peganum harmala* L. in which harmine, harman, and harmaline are the dominating components [63]. Harmines were found as potent inhibitors of cyclin-dependent kinases [64, 65] and IkappaB kinase. Norharman acts as an inhibitor of the heme containing cytochrome (P450 CYP) related enzymes [66]. Different β-carboline alkaloids show bindings to several receptors like serotonin, benzodiazepines, 5-hydroxytryptamine, dopamine, and imidazoline [67, 68].

Recent results suggest that β-carboline alkaloids may exhibit antidepressant effects [69, 70], probably linked to its inhibitory actions on MAO [71, 72]. This might be the reason for psychopharmacological and toxicological effects of seed and root extracts of *P. harmala* containing β-carbolines and could be the basis for its purported antidepressant actions [73].

7.3 Neurotoxic Effects

Administration of β-carboline alkaloids to human being and a wide variety of laboratory animals produces an intense and generalized action tremor [74]. Harmane is a potent, tremor-producing β-carboline alkaloid and is used in epidemiological studies. It is one of the most abundant of all dietary heterocyclic amines, and human exposure to harmane through diet is greater than that of other heterocyclic amines [9, 67]. Due to its high-lipid solubility, harmane accumulates in brain tissue [75]. It provides the rationale for an in-depth scrutiny of their potential role in the etiology of essential tremor (ET), the most common tremor disorder [76]. β-carboline alkaloids are highly neurotoxic.

7.4 Antitumor Activities

β-carboline alkaloids synthesizing plants such as *P. harmala*, *Banisteriopsis caapi*, and *Passiflora incarnata* have been used as folk medicine in anticancer therapy. Recently, they have drawn attention because of their antitumor and anti-angiogenic activity. Angiogenesis is the physiological process responsible for vasculogenesis and formation of new blood vessels [77]. However, it is also a fundamental step in the transition of tumors from a dormant to a malignant state.

In vivo, anti-angiogenic activity on B16F-10 melanoma cells showed that harmine acts as strong angiogenic inhibitor which significantly decreased pro-angiogenic factors such as vascular endothelial growth factor, nitric oxide, and pro-inflammatory cytokines. At the same time, it increased antitumor factors [78]. β-carboline alkaloids (Callophycin A) show promising antitumor activity against a panel of mammalian cell lines [52, 79, 80]. Several β-carboline derivatives designed and chemically synthesized with various substituents on harmine to produce lower toxicity drug but effective against tumor. However, the structure–activity relationships (SAR) showed that the antitumor activity and acute toxicity as well as neurotoxic effect of β-carboline derivatives are substituent-dependant. Chemically synthesized 1-phenyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid and methyl 1-phenyl-β-carboline-3-carboxylate are potent compounds with better cytotoxicity against insect cultured Sf9 cell line [81].

7.5 Antiviral Activities

The β-carboline alkaloids and their derivatives are emerging as potent antiviral agents. Eudistomins C, D, E, H, I, K, L, N, and Q, manzamine A, and 8-hydroxymanzamine

A were effective against herpes simplex virus-1 (HSV-1and II) [82, 83]. Eudistomin K sulfoxide and eudistomin K have high activities against polio vaccine type-1 virus. Platinum (II) and palladium (II) complexes of harmaline, harmalol, harmine, and harman and (−)-Debromoeudistomin K were also observed to exhibit antiviral activities against influenza virus (A and B) and herpes virus [84]. Recently, harman and its derivatives were found to possess anti-HIV activities against human peripheral blood mononuclear (PBM) cells [85].

7.6 Antimicrobial Activities

Currently, Eudistomins and its derivatives showed antimicrobial activity against *Saccharomyces cerevisiae*, *Bacillus subtilis*, *Escherichia coli*, and *Candida albicans* [86, 87]. β-carboline alkaloids from marine bryozoan *Cribricellina cribraria* showed antimicrobial activities against *Pseudomonas aeruginosa* and *Escherichia coli*, *Bacillus subtilis* and fungi *Candida albicans*, *Trichophyton mentagrophytes*, and *Cladisporum resinae* [33]. The antimicrobial activity increased on application of β-carboline alkaloids as binary mixtures against *Proteus vulgaris*, *Bacillus subtilis*, and *Candida albicans* [88]. The antibacterial activity was higher with harmane as compared to harmaline, harmalol, and harmine [89].

7.7 Antiparasitic Activity

The most common β-carboline alkaloids harmine, harmane, and harmaline possess antiparasitic activities against *Leishmania mexicana* [90] and displayed antileishmanial activity toward the intracellular amastigote form of *Leishmania* [91]. Some β-carboline alkaloids are active against epimastigotes of *Trypanosoma* species [56, 92].

7.8 Antithrombotic Activity

The substituent on the β-carboline alkaloids changes the polarity, charge, molecular size, and spatial arrangement which might be the key factors in influencing their biological activity. Antithrombotic activity was detected in phenolic tetrahydro-β-carboline conjugates, perlolyrine, and its analogue [93, 94].

7.9 Antioxidant Activity

It has been reported that β-carbolines and tetrahydro-β-carbolines are potent antioxidants and may be useful for the prevention of diseases associated with oxidative damage [95]. Harmane, harmaline, harmalol, and their peptide conjugates designed and synthesized possess free radical scavenging activity [95, 96].

7.10 Antiplasmodial Activity

Harmine and harmaline showed a moderate in vitro antiplasmodial activity against *Plasmodium falciparum* [97].

7.11 Other Activities

β-carbolines also help in improving object recognition memory and stimulating insulin secretion [98]. They are useful in treatment of hypopigmentation-related disorders such as vitiligo as they induce cellular melanin biosynthesis [99]. Some of the chemically synthesized β-carboline showed better insecticidal activity. Harmine, harmaline, harmol, and harman showed good inhibitory activities against acetylcholinesterase inhibitors (AChE), therefore, they can form the basis of the newest drugs for the treatment of Alzheimer's disease [100]. Recently, it was reported that β-carbolines induce apoptosis by caspase-8 activation in carcinoma cells and function as an anti-inflammatory compound [101]. Pinoline formed naturally in the human body is implicated along with melatonin in the role of the pineal gland in regulating the sleep–wake cycle.

8 In Vitro Production

The alkaloids harmine, harmaline, harman, and harmalol have been detected in callus and cell culture of *Peganum harmala* [102] and *Tribulus terrestris* [23]. The hairy root induction was achieved in *P. harmala* with the help of *Agrobacterium rhizogene*. Harmine is the major alkaloid found in the normal root and hairy root culture. The alkaloids content were enhanced in hairy root culture of *P. harmala* by using the elicitor H_2O_2 and biosynthetic precursor, tryptophan [103]. The somatic embryoids of *Tribulus terrestris* are one of the best sources of Harmala alkaloids [23].

9 Conclusion

Certain β-carbolines are very toxic or precursors of mutagens while others are necessary to maintain normal metabolism or to recover from disorder. Human beings and animals are frequently exposed to beta-carboline alkaloids as they produced in well-cooked food, tobacco smoke, and hallucinogenic beverages. These metabolites are also synthesized endogenously in animal tissue. Some of the medicinal plants particularly *Peganum harmala*, *Passiflora incarnata*, and *Banisteriopsis caapi* are very rich sources of harmala alkaloids and are used in folk medicine for their antispasmodic, anti-jaundice, anti-lumbago, anti-inflammation agent, anticancer, antimalarial, and sedative properties and in the treatment of asthma. The world famous ayahuasca, a narcotic drug, is prepared using *Banisteriopsis* sp. and contains harmala alkaloids. These alkaloids are widely distributed in plants and animals. They are biosynthesized from tryptophan and pyruvate or acetate precursors. Some of these alkaloids and their derivatives are synthesized chemically. Enhanced production of some alkaloids occurs in cell and hairy root culture of *Peganum harmala* and somatic embryoids of *Tribulus terrestris*. Literature survey indicates that the beta-carboline alkaloid had extensive biochemical activities and multiple pharmacological effects. Taking all those reports together, it is revealed that some beta-carbolines and their derivatives from natural source and are chemically synthesized can be an important basis for the design and synthesis of potent pharmaceutical drug.

Abstract

L-Tryptophan is an indole ring containing aromatic amino acid derived via the shikimate pathway. The tryptophan-derived alkaloids are found in eight families, of which, Apocynaceae, Loganiaceae, Rubiaceae, and Nyssaceae are the best sources. The alkaloids under discussion are the *Catharanthus* alkaloids, namely, ajmalicine, tabersonine, catharanthine, vindoline, vinblastine, vincristine and vincamine as well as terpenoid alkaloids derived from other families, namely, yohimbine, reserpine, strychnine, brucine, and ellipticine. The above-mentioned alkaloids are pharmacologically very important and hence extremely valuable. This chapter describes various aspects of the tryptophan-derived alkaloids like occurrence, biological activity, phytochemistry, and commercial and biotechnological aspects.

Keywords

Catharanthus • TIA • Tryptophan-derived alkaloids

Abbreviations

16OMT	16-Hydroxytabersonine 16-O-methyltransferase
D4H	Desacetoxyvindoline-4-hydroxylase
DAT	Deacetylvindoline-4-O-acetyltransferase
STR	Strictosidine synthase
T16H	Tabersonine 16-hydroxylase
TDC	Tryptophan decarboxylase
TIA	Terpenoid indole alkaloids

1 Introduction: Tryptophan-Derived Alkaloids

L-Tryptophan is an aromatic amino acid derived via the shikimate pathway. Tryptophan is a precursor for well-known simple alkaloids, namely, melatonin, sumatriptan, eletriptan, and harmine, as well as complex alkaloids such as vinblastine, ajmalicine and serpentine [1] (Fig. 20.1).

Tryptophan decarboxylase (TDC; EC 4.1.1.27) catalyzes the formation of tryptamine from L-tryptophan. Tryptamine is a key precursor of a wide range of terpenoid-derived indole alkaloids in plants. The decarboxylation of L-tryptophan may be viewed as a branching point from primary into secondary metabolism. Tryptamine (indole moiety) condenses with terpenoid moiety provided by the secoiridoid secologanin, which is derived via the mevalonate/ isopentenyl diphosphate pathway. The alkaloids so derived are classified as terpenoid indole alkaloids (TIA) [2]. These pathways are regarded as the limiting branch for TIA biosynthesis in *C. roseus* cell and tissue cultures. Strictosidine synthase (STR: EC 4.3.3.2) is the first enzyme of the TIA pathway catalyzing the condensation of the amino acid-derived tryptamine and the terpenoid secologanin to form strictosidine. STR is the important enzyme leading to the production of either indole or ipecac alkaloids. Strictosidine is the universal

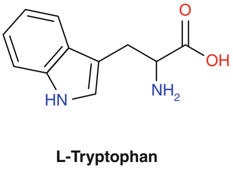

Fig. 20.1 Structure of L-tryptophan, the source of TIAs (Adapted from Ref. [153])

precursor for the therapeutically valuable TIAs, which are produced by four families, namely, Apocynaceae, Loganiaceae, Rubiaceae, and Nyssaceae [3]. Strictosidine occupies a central role in the biosynthesis of all major classes of monoterpenoid indole alkaloids of *C. roseus* as well as in the other members that produce these compounds [4]. Both TDC and STR could be viewed as the important regulatory enzymes, which regulate influx of metabolites into the TIA pathway.

Terpenoid indole alkaloids (TIA) produced via the TIA pathway are one of the largest groups of alkaloids with more than 3,000 representatives. The TIAs are classified as Corynanthe type (e.g., ajmalicine), the Aspidosperma type (e.g., tabersonine), and the Iboga type (e.g., catharanthine) (Fig. 20.2). Tryptophan is a precursor for a wide range of indole alkaloids which are subdivided into simple indole, simple β-carboline, terpenoid indole, quinoline, pyrroloindole, and ergot alkaloids. These pharmacologically important alkaloids are low in occurrence, without synthetic substitutes and therefore have an exorbitant market cost. Research is therefore focused to understand the basic architecture and regulation of biosynthesis of these TIAs in plant and its cultured tissues. *Catharanthus roseus* is a valuable and exclusive source of a number of terpenoid indole alkaloids therefore deserves a special mention in this chapter (Fig. 20.3).

Catharanthus roseus or periwinkle is a perennial subshrub indigenous to Madagascar and belongs to the family Apocynaceae (Fig. 20.2). *Catharanthus* has been used from time immemorial by traditional healers all over the world to treat many ailments. Till date, more than 130 bioactive terpenoid indole alkaloids (TIAs) have been identified. The production and storage of these alkaloids in plants is quite complex and multicellular in organization (at least four cell types involved: epidermis, internal phloem-associated parenchyma, laticifers, and idioblasts) and also involve spatiotemporal organization and is influenced by environmental factors [2, 5]. The TIA pathway is regulated mainly at four levels, inter- and intracellular compartmentation (chloroplast, vacuole, nucleus, endoplasmic reticulum and cytosol) of enzymes and substrates and interorganellar coordination and transport; transcriptional regulation of TIA biosynthetic genes; posttranslational regulation of enzymes and regulation by environment and culture conditions [2, 5] (Fig. 20.4).

The current research on the TIAs focuses on understanding six important aspects, namely, precise localization and expression of pathway enzymes (using modern in situ RNA hybridization tools), mechanisms of trafficking of pathway intermediates (both inter and intracellular), cloning and functional validation of genes belonging to the known or hitherto unknown pathway enzymes, global regulation mechanism of the pathway by transcription factors, control of metabolite flux and diversion at crucial branch points and strategized metabolic engineering approaches to improve the productivity of the desired TIAs in plant or corresponding cultured tissues [5].

2 Tryptophan-Derived *Catharanthus* Alkaloids

2.1 Occurrence

2.1.1 Ajmalicine

Ajmalicine is found in plants belonging to Apocynaceae, namely, *Catharanthus roseus*, *Rauwolfia serpentina*, and *Rauwolfia vomitoria*. Ajmalicine was first isolated from yohimbe bark and is one of the principal alkaloids of *Catharanthus roseus* and widely used to treat circulatory disorders [6] (Fig. 20.3). Ajmalicine is

extracted from the roots of *C. roseus*. Other sources for commercial extraction of ajmalicine are the roots of *Rauwolfia yunnanensis* Tsiang. I. [7], *C. trichophyllus* roots [8], and *Rauwolfia caffra* [9] (Fig. 20.5a).

2.1.2 Tabersonine

Tabersonine has been reportedly found in plants belonging to Apocynaceae, e.g., *Amsonia tabernaemontana*, *Amsonia sinensis*, *Voacanga thouarsii*, and *Melodinus reticulatus*, apart from *C. roseus*. Tabersonine is extracted from voacanga seeds for commercial purposes [10–12] (Fig. 20.5b).

2.1.3 Catharanthine

Catharanthine is produced in young developing leaves of *Catharanthus*. It accumulates entirely in the leaf wax exudates outside the leaf epidermis spatially separating it from vindoline [13] (Fig. 20.5c).

2.1.4 Vindoline

Vindoline is the main terpenoid indole alkaloid accumulated in leaves of *Catharanthus roseus* [14] (Fig. 20.5d).

2.1.5 Vinblastine and Vincristine

Vinblastine and vincristine are bisindole alkaloids obtained by the condensation of catharanthine and vindoline. The alkaloids are found exclusively in *Catharanthus* leaves and have great economic value [15] (Fig. 20.5e).

2.1.6 Vincamine

Vincamine is extracted from the leaves of *Vinca minor* belonging to Apocynaceae family, known as lesser periwinkle native to central and southern Europe. A closely related semisynthetic derivative of vincamine most widely used as medicine is known as ethyl-apovincaminate or vinpocetine [16–19] (Fig. 20.5f).

2.2 Phytochemistry

The alkaloid-related chemistry is summarized in Table 20.1.

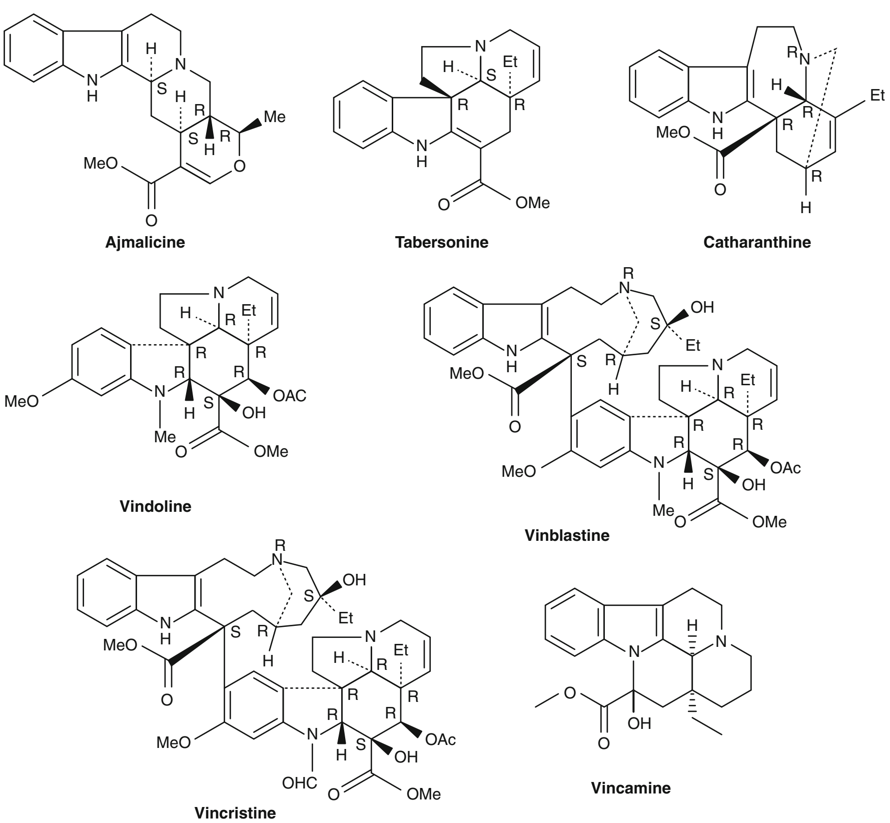

Fig. 20.5 *Catharanthus* alkaloids derived from tryptophan

2.3 Biosynthesis

Tryptophan is converted to tryptamine by tryptophan decarboxylase, encoded by a single gene in *Catharanthus roseus* which is regulated both developmental and inducible regulation. Secologanin biosynthesis is conversion of geraniol to 10-hydroxygeraniol mediated by geraniol 10-hydroxylase (G10H) which is a membrane-bound P450 monooxygenase, dependent on NADPH and O_2, and displays light-reversible CO inhibition. The conversion is also catalyzed by a P450-dependent enzyme. The level of G10H activity positively correlates with alkaloid accumulation indicating that the production of terpenoid precursors might play a regulatory role in TIA biosynthesis since the addition of secologanin or loganin to *C. roseus* cell cultures increases alkaloid accumulation. Strictosidine is produced by the condensation of tryptamine and secologanin which is the common precursor to all TIAs. STR is encoded by a single gene with

multiple isoforms due to glucosylations. STR cDNAs have been isolated from *Rauwolfia serpentina* and *C. roseus*. Strictosidine is deglycosylated by strictosidine-D-glucosidase (SGD) and reportedly exhibits high molecular mass, suggesting aggregation. The deglycosylated strictosidine is converted via several unstable intermediates to 4,21-dehydrogeissoschizine which is the source of many TIAs. The pathway enzymes for the TIAs so derived still remain obscure or uncharacterized. The conversion to catharanthine is largely unknown, and missing links to the synthesis of vindoline have to be yet resolved. Vindoline is ultimately coupled to catharanthine by a nonspecific peroxidase to yield vinblastine. The first of six steps involved in the conversion of tabersonine to vindoline involves hydroxylation at the C-16 position, 16-*O*-methylation, hydration of the 2,3-double bond, and *N*-methylation of the indole-ring nitrogen. The second-to-last step in vindoline biosynthesis is catalyzed by a 2-oxoglutarate-dependent dioxygenase that hydroxylates the C-4 position of desacetoxyvindoline. The last step in vindoline biosynthesis is catalyzed by acetylcoenzyme A: deacetylvindoline 4-*O*-acetyltransferase (Fig. 20.6a, b, c).

2.3.1 Ajmalicine

Ajmalicine is derived from tryptamine (partly from geraniol) via secologanin, strictosidine, and cathenamine. It has a Corynanthe skeleton from deglycosylated strictosidine [28]. Ajmalicine is synthesized in the cytosol by the action of cathenamine reductase on cathenamine facilitated by NADPH activity [32]. The biosynthesis of ajmalicine has been studied with reference to improving the content by various biotechnological approaches (Fig. 20.4). The regulation per se of ajmalicine production has not been explored in larger detail.

2.3.2 Tabersonine

Tabersonine is derived from strictosidine through a series of yet uncharacterized pathway via an intermediate cathenamine. The genes related to tabersonine biosynthesis as well have been an unexplored area [33].

2.3.3 Catharanthine

Catharanthine is synthesized via an uncharacterized pathway from strictosidine via intermediates, strictosidine aglycone, 4,21-didehydrogeissoschizine, and stemmedine [5].

2.3.4 Vindoline

Four genes and six steps are involved in the synthesis of vindoline in the leaves of *C. roseus*. Tabersonine 16-hydroxylase (T16H) anchored to the ER catalyzes the first step of vindoline biosynthesis. 16-Hydroxytabersonine 16-O-methyltransferase (16OMT) homodimers (excluded from nucleus) in the cytoplasm of aerial organ epidermis catalyzes the second step. Desacetoxyvindoline-4-hydroxylase (D4H) and deacetylvindoline-4-O-acetyltransferase (DAT), located in the nucleocytoplasmic compartment,

Fig. 20.6 (**a**) Terpenoid indole alkaloid biosynthesis in *C. roseus* (Courtesy Ref. [5]). 1 Geraniol-10-hydroxylase (G10H), 2 loganic acid methyltransferase (LAMT), 3 secologanin synthase (SLS), 4 tryptophan decarboxylase (TDC), 5 strictosidine synthase (STR), 6 strictosidine β-glucosidase (SGD), 7 geissoschizine dehydrogenase (GDH), 8 cathenamine reductase (CR), 9 tabersonine 16-hydroxylase (T16H), 10 16-hydroxytabersonine-16-O-methyltransferase (16OMT), 11 uncharacterized enzyme, 12 16-methoxy-2,3-dihydro-3-hydroxy-tabersonine N-methyltransferase (NMT), 13 deacetoxyvindoline 4-hydroxylase (D4H), 14 6-17-O-deacetylvindoline O-acetyltransferase (DAT), 15 class III basic peroxidase (PRX1), 16 tabersonine 6,7-epoxidase (T6,7E), 17 tabersonine 19 hydroxylase (T19H), 18 minovincinine-19-O-acetyltransferase (MAT) (**b** and **c**) Vindoline biosynthesis and its spatial and temporal regulation (Courtesy Refs. [13, 33])

are monomers following diffuses into nucleus. However, no interaction and therefore channeling of vindoline are detected between D4H and DAT. The understanding of spatial regulation in vindoline biosynthesis is still not complete [5]. Vindoline production in in vitro cultures like cell suspension culture is very less due to absence of chloroplasts.

2.3.5 Vinblastine and Vincristine

Vinblastine and vincristine are synthesized from monomers catharanthine and vindoline. Vinblastine and vincristine differ in the nature of the substituent group on the dihydroindole moiety, which is either a methyl group (vinblastine) or a formyl group (vincristine) [20].

2.3.6 Vincamine

Vincamine is an Aspidosperma type of alkaloid supposedly produced through two chemical reactions beginning with the catalytic reduction of tabersonine, an alkaloid extract of voacanga seeds. The resulting product, vincadiformine is oxidized forming vincamine [34].

2.4 Commercial Aspects

2.4.1 Ajmalicine

Each year, approximately 3,600 kg of ajmalicine is produced at a market price of about $2,000/kg [20]. Technically, naturally grown *C. roseus* has 50 % lower concentration of ajmalicine but would cost ca. $0.70/lb dry biomass ($619/kg ajmalicine). Alternatively, in vitro culture of *C. roseus* as cell culture yields far higher yields of ajmalicine, but the cost of production is estimated to be approximately $7.30/lb dry biomass ($3,215/kg ajmalicine). This is attributed to the slow specific product accumulation rate (0.26 mg/g/day) which has to be improved by a factor of 40 to make the process competitive [9].

2.4.2 Tabersonine

Tabersonine is available commercially at US$ 1,700 per kg [21]. One hundred grams of voacanga beans yields 1.7 g of pure tabersonine hydrochloride [22].

2.4.3 Catharanthine and Vindoline

Catharanthine and vindoline are per se not used as drugs but as precursors for vinblastine and vincristine. Biotechnological approaches at improving the yield in in vitro cultures have been largely varied.

2.4.4 Vinblastine and Vincristine

The yield of the dimeric alkaloids from *Catharanthus* plants is 0.0005 %. The dosage required per adult per injection is 1.4 mg/m^2 body surface. Currently, a single kilogram of vincristine costs around $US 20 million, making it one of the costliest drugs around [23]. Vinblastine, another anticancer drug from the same plant, is present at levels a thousand times higher than vincristine, and the cost is a third of vincristine.

2.4.5 Vincamine

Vincamine constitutes about 25–65 % of indole alkaloids extracted from *Vinca minor* [24].

2.5 Biological Activities

2.5.1 Ajmalicine

Ajmalicine is used to treat peripheral and cerebral vascular disorders. Ajmalicine acts as a selective alpha sympatholytic drug. It acts by depleting peripheral noradrenaline stores resulting in decrease of peripheral resistance and blood pressure. It is also known to deplete catecholamine and serotonin stores in the brain, heart, and many other organs. Many commercial formulations of ajmalicine are available in the market under the trade names, namely, Card-Lamuran^{TM}, Circolene^{TM}, Cristanyl^{TM}, Duxil^{TM}, Duxor^{TM}, Hydrosarpon^{TM}, Iskedyl^{TM}, Isosarpan^{TM}, Isquebral^{TM}, Lamuran^{TM}, Melanex^{TM}, Saltucin Co^{TM}, Salvalion^{TM}, and Srapan^{TM} [32].

2.5.2 Tabersonine

Tabersonine has wide applications as hypotensive, antitumor, hypoglycemic, and diuretic agent. It is used against the consequences of stroke, ischemic hypertensive encephalopathy, cerebrovascular disease caused by depression, anxiety, mood swings, and premature aging and is suitable to eliminate the symptoms of brain degeneration, such as dizziness, headache, memory loss, attention, aphasia, Meniere's syndrome, etc. It is also used during retinal hemorrhage, tachycardia, and other autonomic nerve dysfunction [21].

2.5.3 Catharanthine

Catharanthine is reported to stimulate the release of amylase from pancreatic fragments by causing an increase in cytoplasmic Ca^{2+} and cause extensive degranulation of pancreatic acinar cells with accumulation of membrane material in the Golgi region. Catharanthine is also reported to be the indole part of vinblastine and vincristine required for interaction to tubulin [35, 36].

2.5.4 Vindoline

Vindoline acts as an anchor for mediating the effects evident using vinblastine and vincristine. Catharanthine and vindoline are three times less effective than the dimeric alkaloids in bringing about the inhibition of tubulin self-assembly into microtubules [36].

2.5.5 Vinblastine and Vincristine

Vinblastine is used in treatment of Hodgkin's lymphoma, non-Hodgkin's lymphoma, breast cancer, uterine and cervical cancer, small cell bronchial cancer, rhabdomyosarcoma, and various sarcomas. Vincristine is used in the treatment of acute lymphoblastic leukemia (ALL) especially in children. Vinblastine and vincristine inhibit microtubule formation during mitosis and therefore prevent cells from reproducing which is more pronounced in cancer cells [15, 37].

2.5.6 Vincamine

Vincamine is effective in treating ailments related to central nervous system, cardiovascular system, and on the vessels of the brain. It is used to treat hypertension, vertigo, transient ischemic deficits, headache, and age-related neurodegenerative diseases such as Parkinson's, Alzheimer's, and Huntington's diseases, and improve memory, mental productivity, and concentration [38–45].

2.6 Biotechnological Approaches

The biotechnological approaches attempted have been summarized in Table 20.4 below. In brief, various approaches to improve the extraction from plants and increase the yield using various types of in vitro cultures like hairy root culture, cell culture, and callus culture have been attempted. The in vitro cultures have been optimized with respect to medium composition and culture conditions including the use of various biotic and abiotic elicitors. Strategic approaches to improve yield, namely, feeding of precursors with and without optimized culture conditions and elicitors, have been elaborately explored along with overexpression of homologous and heterologous genes. Genomic, proteomic, and metabolomic approaches have provided valuable insights. The current focus is on understanding the spatial and temporal regulation of the biosynthetic enzymes and products.

3 Other Tryptophan-Derived Alkaloids

3.1 Occurrence

3.1.1 Reserpine

The alkaloid reserpine is obtained naturally from the rhizome and roots of *Rauwolfia* spp. *Rauwolfia serpentina* is a small shrub belonging to Apocynaceae family and found in India, Burma, Java, and Thailand. *Rauwolfia vomitoria* is widely grown in Congo, Africa, and contains more than twice quantity of reserpine. Ninety percent of reserpine is present in the roots and only 10 % in the stem and leaves [107] (Fig. 20.7a).

3.1.2 Yohimbine

Yohimbine is obtained naturally in *Pausinystalia yohimbe, Rauwolfia serpentina,* and *Alchomia floribanda*. The tree is native to the coastal forests of Central Africa

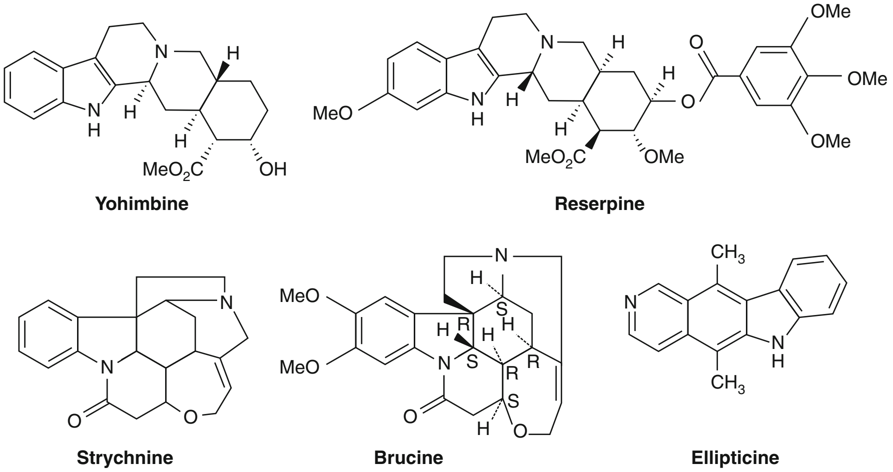

Fig. 20.7 Other tryptophan-derived alkaloids

and distributed from Southeast Nigeria to the Congolese Mayombe region. The commercial product is obtained from the dried bark of *Pausinystalia yohimbe* [108–111] (Fig. 20.7b).

3.1.3 Ellipticine

Ellipticine is isolated from species of the Apocynaceae family, including *Bleekeria vitensis, Aspidosperma subicanum, and Ochrosia* species. Ellipticine was first isolated from the leaf material of *Ochrosia elliptica* Labill by Goodwin et al. in 1959 [112]. It is a tropical evergreen tree belonging to the Apocynaceae family also contained several other alkaloids, including 9-methoxyellipticine. Ellipticine has since been isolated from several other plants of the Apocynaceae family (*Ochrosia vieillardii, Ochrosia acuminata, Ochrosia oppositifolia, and Ochrosia moorei*) [113–115] and from *Strychnos dinkagei* of the Loganiaceae family [115, 116]. *Ochrosia oppositifolia* is widely distributed on the coasts of the islands throughout Southeast Asia and the Pacific. In Africa, it is restricted to the Seychelles. Extracts of the roots of *Ochrosia acuminata* Val. (Apocynaceae) have been used by native people in Savu, Indonesia, to treat tumors and ectopic pregnancy (Fig. 20.7c).

3.1.4 Strychnine and Brucine

Strychnine and brucine are exclusively found abundantly in seeds of *Strychnos nux-vomica* and in varying quantities in roots, fruits, pulp, wood, leaves, and bark. *Strychnos nux-vomica* (Loganiaceae) is a tree 10–13 m high with a distribution including Ceylon, India, East Bengal, Burma, Thailand, Laos, Cambodia, and South Vietnam. These two alkaloids are present together or separately in other *Strychnos* species. This genus consists of around 196 species spread across the globe [117] (Fig. 20.7d, e) (Table 20.2).

3.2 Phytochemistry

It is noteworthy to mention that the synthesis of strychnine by Robert B. Woodward is one of the most famous syntheses in the history of organic chemistry. The structure of strychnine was first determined in 1946 by Sir Robert Robinson. Both chemists won the Nobel Prize (Robinson in 1947 and Woodward in 1965) [123]. Both brucine and strychnine are commonly used as agents for chiral resolution. Strychnine has developed to become a standard reference to NMR spectroscopy in organic chemistry as in this compound many typical structural features are present which cause spectrum to spread over entire chemical (Table 20.3).

3.3 Biosynthesis

The alkaloids under discussion share a common Corynanthe-type nucleus derived from secologanin. Yohimbine is a carbocyclic variant of ajmalicine, and the enzymes that convert deglycosylated strictosidine to yohimbine have not been identified [124, 125]. Strychnine and brucine are synthesized from the preakuammicine structure by hydrolysis, decarboxylation, and condensation reactions to aldehyde (Wieland-Gumlich), and subsequently reaction with acetyl-CoA to make a hemiacetal form of aldehyde (Wieland-Gumlich) and strychnine and brucine. Brucine is a dimethoxy form of strychnine. Ellipticine is a representative member of pyrido[4,3-b] carbozole alkaloid, and the formation of ellipticine is from ajmalicine (corynanthean skeleton) [126] (Fig. 20.8).

3.4 Commercial Aspects

3.4.1 Reserpine

Reserpine content was estimated 0.1 % of dry roots; the major problem in field grown plant is the variation in the compound yield. In 1976, the volume of reserpine sold in the USA for medical use was 440,000 lbs [127]. In 2009, reserpine was produced by seven companies, all in India [128]. Even though the chemical synthesis of reserpine is possible, it costs more than extracting it from natural resources [129].

3.4.2 Yohimbine

Bark may contain up to 6 % total alkaloids, of which 10–15 % is yohimbine [120]. Concentrations of yohimbine in commercial products ranged from less than 0.1 to 489 parts per million (ppm) compared with 7,089 ppm in the authentic material. The alkaloid yohimbine also is obtained from *Aspidosperma quebracho-blanco* and *Rauwolfia serpentina* [121]. Its interest outside the African continent was first recorded in Germany, where yohimbine, the main alkaloid of the drug and also known as aphrodine, quebrachine, or corynine, was isolated for the first time by Spiegel in 1896 [130]. Recent advancements in the development of yohimbe-based

Table 20.3 Phytochemistry of apocyanaceae alkaloids

Alkaloid	Chemical name/synonym	Molecular weight	Molecular formula	Appearance	Identification UV (max) specific optical rotation	References
Reserpine	(Methyl-11,17 –dimethoxy-18b-[(3,4,5-trimethoxybenzoyl) oxy] -3b,20q=yohimban-16b-carboxylate)	608.68 g/mol	$C_{33}H_{40}N_2O_9$	To off-white crystalline powder	220, 267, 292 nm (−)116-(−) 124° (Chloroform)	[119]
Yohimbine	17α-Hydroxy-yohimban-16α-carboxylic acid methyl ester	354.44 g/mol(base) 390.90 g/mol (hydrochloride)	$C_{21}H_{26}N_2O_3$	White crystalline powder; odorless	226, 280, 291 nm	[120, 121]
Ellipticine	5,11-Dimethyl-6 H-pyrido[4,3-b] carbazole	246.3	$C_{17}H_{14}N_2$	Bright yellow solid	239, 277, 286, 294, 332, 382, 400 nm	[122]
Strychnine		334.41 g mol^{-1}	$C_{21}H_{22}N_2O_2$	White, odorless, bitter crystalline powder	255, 280, 290 nm -139oc (Chloroform)	[118, 123]
Brucine		394.46 g mol^{-1}	$C_{23}H_{26}N_2O_4$		(Ethanol): 263, 301 nm D −127° (chloroform)	[118, 123]

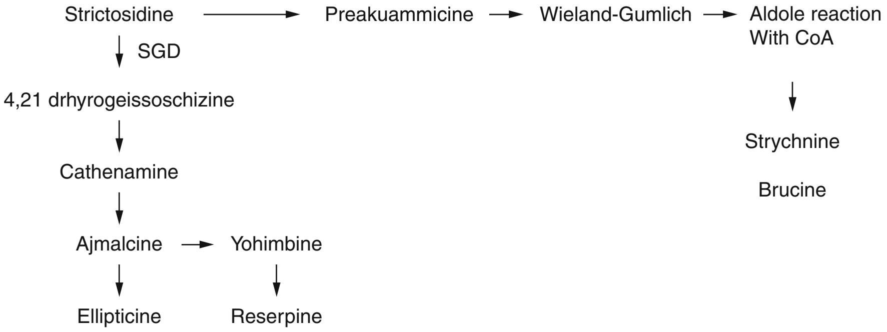

Fig. 20.8 Biosynthetic pathway for the synthesis of yohimbine, reserpine, ellipticine, strychnine, and brucine

remedies have led to an increased demand for the export market. Around 100 t of bark is annually supplied by Plantecam (Cameroon) to Europe [131]. The yohimbe tree presently grows abundantly, and there does not seem to be a problem of regeneration.

3.4.3 Ellipticine

Ellipticine isolated from *Ochrosia elliptica* costs US$ 240,000/kg [132].

3.4.4 Strychnine and Brucine

Strychnine and brucine are sourced from the seeds of the nux-vomica, a tree native to India. The seeds are powdered, blended with alkali, and extracted at ambient temperature with a hydrocarbon solvent. Seeds containing 2.5 % total alkaloids would yield on an average 7 kg each of strychnine and brucine per ton of seeds [151].

3.5 Biological Activities

3.5.1 Reserpine

For centuries, the natives of the Himalayan foothills have used the root of *Rauwolfia* for healing afflictions ranging from snake bites to insanity [133]. Reserpine is used for treatment of mild to moderate hypertension [134] as well as a tranquilizer and sedative in animal feed [127]. It has also been used as a radioprotective agent and contraceptive. Reserpine interferes with the Mg^{2+}– and ATP-dependent uptake of biogenic amines, thereby depleting norepinephrine, dopamine, and serotonin. The effect is universal and irreversible. Reserpine decreases both cardiac output and peripheral vessel resistance [133] by inhibiting normal sympathetic activity by decreasing the storage of catecholamines at the presynaptic, CNS, and peripheral neuron by binding to the storage vesicles which leads to leakage of catecholamine into synapse. Catecholamine when presynaptic neuron is stimulated and this affects

Table 20.4 Biotechnological approaches to improve other TIA content in Apocyanaceae

Compound	Condition /Treatment	Plant part used	References
Reserpine	MS+PABA(3 mg/l) +NAA(3 mg/l)	Callus from leaf	[145]
	MS + IBA (0.2 mg/ l) + NAA (0.2 mg/l)	Callus from shoot	[146]
	MS + IAA(2 mg/l) + Cu_2(5 uM)	Callus from leaf	[147]
	MS + 2,4-D(9 uM) + Tryptophan(50 mg/l)	Callus from leaf	[148]
	MS+2,4-D (9 uM)+NAA(3 uM)	Callus from leaf	[149]
	MS+1mg/l 2,4-D+200 μM MJ	Suspension culture from somatic embryo	[150]
Yohimbine	Ms+BA(1.0 ppm)+ NAA (0–1 ppm)	Callus	[151]

serotonin. This results in a reduction in both cardiac output and peripheral vascular resistance with long-term therapy [135].

3.5.2 Yohimbine

Yohimbine is an α2-adrenoceptor antagonist with potential clinical applications in erectile dysfunction [136]. Yohimbine reportedly may act by adrenergic blockade by increasing cholinergic activity. Yohimbine has a mild antidiuretic action, probably via stimulation of hypothalamic centers and release of posterior pituitary hormone. A more recent open-label study found yohimbine to be effective in managing anorgasmia (orgasmic dysfunction) [137]. Yohimbine is also used for weight loss (body fat) and xerostomia (dry mouth) and has been used in studies investigating autonomic failure and orthostatic hypotension [138].

3.5.3 Ellipticine

Ellipticine and its derivatives exhibit significant antitumor and anti-HIV activities, characterized by high efficiencies against several types of cancer and rather limited toxic side effects [139, 140]. Several mechanisms of their antitumor, mutagenic, and cytotoxic activities are (1) intercalation into DNA, (2) inhibition of DNA topoisomerase II activity, (3) selective inhibition of p53 protein phosphorylation, and (4) disruption of the energy balance of cells by coupling mitochondrial oxidative phosphorylation [141]. Recently, it has been shown that ellipticine also binds covalently to DNA in vitro and in vivo after being enzymatically activated with cytochrome P450 (CYP) or peroxidase, suggesting possible mechanism of action [142]. Ellipticine along with different and safer drug delivery using nanotechnology and gene therapies could significantly contribute to medical practice [143].

3.5.4 Strychnine

Strychnine isolated from *Strychnos nux-vomica* is a potent toxin affecting the nervous system and muscular system bringing about an extremely painful stop to the functioning of the above systems. Strychnine binds itself to receptor sites in the spinal cord and accommodates glycine. It has interesting pharmacological effects on several neurotransmitter receptors, including some members of the superfamily of ligand-gated ion channels. Strychnine today is used primarily as a pesticide, particularly to kill rats [143].

3.5.5 Brucine

Brucine is a dimethoxy form of strychnine and reported to possess antitumor and anti-angiogenic activities in vitro and in vivo [144]. Brucine causes paralysis of peripheral motor nerve without mediating the convulsive action characteristic of strychnine [118]. It is reportedly less toxic than strychnine.

3.6 Biotechnological Approaches

The rate of plant propagation and improvement of yield of tryptophan indole alkaloids through biotechnological technique is important for commercial cultivation to meet the pharmaceutical demand of the said alkaloids. There are scanty references or literature in this direction. Few of the literature surveys are highlighted in Table 20.4.

4 Conclusion and Prospects

Understanding the value and importance of the plant-derived TIAs has steered research in the direction of improving overall yield of the alkaloids. Though many attempts have improved yield of a specific alkaloid significantly, the overall understanding of the pathway, regulation, enzymes, and substrates is still far from complete. The understanding so far emphasizes the fact that TIA production should be viewed and understood from the plant-angle to bring about a revolution in the yield of the same.

Acknowledgments The authors would like to express their gratitude and acknowledge the support received from Novozymes South Asia Pvt Ltd. (Shilpa Ramani), Indian Institute of Science (Nandadevi Patil and Chelliah Jayabaskaran), and Bisco Seeds Pvt Ltd. (Suhas Balasaheb Nimbalkar).

Abstract

Cinchona alkaloids comprising quinine, quinidine, cinchonidine, and cinchonine as the major members constitute a unique class of quinoline alkaloids with tremendous impact on human civilization. The odyssey of Cinchona alkaloids began with the discovery of their antimalarial properties followed by the very successful application in stereochemistry and in asymmetric synthesis. Currently, the portfolio of applications of Cinchona alkaloids is much broader, involving chiral stationary phases for enantioselective chromatography, novel biological activities, and several useful transformation converting them into other modular and chiral building blocks, such as, for example, quincorine or quincoridine. Current pressure on a more intense exploration of sustainable products and easy access to diverse molecular architectures make Cinchona alkaloids of primary importance for synthetic catalytic and medicinal chemistry.

X	Halogen

1 Introduction

Among the many thousands of natural products isolated and characterized so far, Cinchona alkaloids with quinine as a major member occupy an exceptional position in human civilization [1–3]. *Cinchona* bark was originally used by South American Indian as anti-fever agent and has been introduced to Europe as early as in ca. 1640. The bark dominated in malaria therapy in Europe until 1820 when pure quinine was isolated and largely replaced the natural material. In this context, quinine can be regarded as the first, pure and genuinely active chemotherapeutic. Even today, despite small therapeutic window of quinine as well as increasing resistance of malaria vector *Plasmodium falciparum*, it can compete with newer antimalarial agents, remaining still an important drug for the severe malaria cases (see infra). Considering that quinine is perhaps the oldest drug known, it is not surprising that of all drugs introduced to the therapy, it has saved the largest number of human lives, according to some estimations [4]. However, besides pharmacology of antimalarial quinine and antiarrhythmic quinidine, a natural polygon of the wide exploration of Cinchona alkaloids was organic chemistry. Attempts to obtain quinine by chemical synthesis stimulated an intense research, both on chemical structure elucidation (initially by chemical methods) as well as on the total synthesis, engaging many famous chemists, such as Pasteur, Rabe, Woodward, and Prelog, to list only a few. Despite relative simplicity of the Cinchona alkaloid structure, the first total synthesis of quinine has not been completed until 2001 when Stork has demonstrated the first stereoselective variant, 150 years after quinine isolation [5]!

Perhaps even more important is the fact that Cinchona alkaloids and their derivatives gave foundations of the stereochemistry and consequently of the modern chiral technology. Cinchona alkaloids and their derivatives became popular resolving agents [6–8], catalysts and ligands [8–13], and recently also chiral selectors for enantioselective analytics [14, 15]. Again, it is worth to record the first resolution of a racemate carried out by L. Pasteur as early as in 1853 using cinchotoxine [16] and first examples of catalytic, stereoselective syntheses mediated by Cinchona alkaloids demonstrated by Bredig [17] at the beginning of the twentieth century and by Pracejus in the 1960s [18]. Currently, more than 50 types of highly enantioselective transformations can be efficiently promoted using Cinchona alkaloids or their simple derivatives, including oxidation and reduction and many C–C and C-heteroatom bond formation. The spectacular catalytic capabilities of Cinchona alkaloids and their derivatives resulted in classifying them as "*privileged class*" of chiral catalysts [19].

Last but not least, quinine has also two unique properties: a bitter taste and a strong fluorescence. The first is widely used in beverage and confectionary industry, which consumes ca. 25% of the world production of quinine [20], whereas fluorescence of quinine sulfate is routinely used in fluorescence spectroscopy as quantum yield standard [21, 22].

The highest demand for quinine (and to a lesser extent for other Cinchona alkaloids) has been observed in the nineteenth and in the first half of the twentieth century when quinine remained the only antimalarial drug available. In more recent times, introduction of the other alternative antimalarials resulted in the reduced but relatively stable annual production of quinine at the level of 500–700 t (perhaps the only alkaloid produced in a multiton scale!). Due to their relatively high abundance in the plant resources (*Cinchona* bark) and the well-developed isolation and purification technologies based on the extraction and crystallization, they are inexpensive natural products (ca. 200 € per 1 kg of quinine) with a high potential to be even more extensively explored in the future as green, sustainable, and chiral substrate.

The aim of this chapter is to provide a brief and up-to-date information and bibliography on all aspects of the chemistry and biology of Cinchona alkaloids with a special emphasis on their recent chemistry, applications, and perspectives. Former comprehensive reviews on this topic have been published mainly in the series of *The Alkaloids*, in 1989 by Verpoorte et al. in 1973 [23] by Uskokovic et al. and in 1953 [24] by Woodward et al. [25]. Specific subject such as the use of Cinchona alkaloids in stereoselective synthesis has been recently published in the monograph edited by Song [8] and in reviews by Hiemstra [9], Gawroński [10], Deng [11], Song [12], and Wynberg [13]. The efforts summarizing the progress of the total synthesis of quinine were subjects of the excellent accounts by Seeman [26], Kaufman [27, 28], and Smith [29]. The chemistry of Cinchona alkaloids with the emphasis on the mechanisms and unique reactivity of Cinchona moiety was a subject of authoritative reviews by Hoffmann et al. [30, 31]. Antimalarial activity of quinine has also been extensively reviewed [4, 32–35]. These well-reviewed subjects will be only briefly mentioned here. Similarly, it is not intended to provide the specific chemical and physical properties of Cinchona alkaloids; these data can be conveniently found in the electronic databases such as Reaxys or SciFinder. A good source of such characteristics is also the Dictionary of Alkaloids [36] and a review [23].

2 History

Quinine is deeply rooted in human civilization. This very desired good in the past has provoked a significant economical, political, and scientific ferment [1–3, 7, 37–39], and the science behind quinine had an enormous impact on the rapid development of the medicinal and organic chemistry of natural products.

Cinchona bark has been used as a medicine against fever by South American Quechua Indians who populated Peru long before the Europeans came to America [1, 37–39]. It is however difficult to assess precisely how the bark become popular in Europe. The legend (now historically disproved) [40] tells that this happened when the countess of Chinchon, the wife of a Peruvian viceroy, has been successfully cured in 1638 of malarial fever with the *Cinchona* bark. It is also believed that the name of the tree species and then name of the alkaloid class were derived from the misspelled name of Chinchon. The name quinine is probably derived from the original Quechua Indian word describing *Cinchona* tree bark – "*quina*" or "*quina-quina*" – which roughly means "*bark of bark*" or "*holy bark.*"

Cinchona bark was first become popular in England and has been officially introduced to the British Pharmacopoeia in 1677. Initially, its wider use was restricted in Europe, despite the widespread occurrence of malaria. Several years later, "*Jesuit's powder*" was popular also in Spain, again due to the Jesuits missions in South America. On the other hand, Jesuits activity as well as the successful therapies of aristocracy over Europe brought *Cinchona* bark popularity to the European countries.

The plant used for bark production was botanically indentified and characterized almost a hundred years later in 1735 by Joseph de Jussieu, a French botanist who accompanied the first non-Spanish expedition to South America. In the period ca. 1650–1850, *Cinchona* bark was the primary drug for a successful treatment of malaria. Monopoly of Spain and insufficient sources of *Cinchona* bark in South America and an increasing demand of quinine imposed pressure to break the Spanish hegemony by smuggling of *Cinchona* seeds and establishing of competitive plantations. The first plantations created by the British in India and Ceylon (*Cinchona pubescens*) and by the Dutch in Java (*Cinchona calisaya*) did not provide enough quinine. The situation changed dramatically when *Cinchona* *officinalis* "*ledgeriana*" seeds were smuggled from Bolivia and used by the Dutch in the plantations in Dutch East Indies (currently Indonesia). Extensive cultivation of these *Cinchona* species brought quickly domination of the Dutch in the quinine world market. At the beginning of the twentieth century, the majority of the world's supply of quinine was under the control of the Dutch "*kina bureau*" (quinine bureau) in Amsterdam. The Second World War did significantly change the quinine market. Java was occupied by the Japanese in 1942, resulting in the embargo for the supply of quinine to the Allies. As a partial solution of this problem, new plantations in South Africa have been established by the British, and the less important South American supplies were again more intensively explored. However, these plantations did not immediately satisfy the increasing demand, provoking the intensive research on the total synthesis of quinine. In 1944 Woodward and Doering have demonstrated a synthetic route to quinine, although critical studies recently published confirm that they did not prepare this alkaloid (showing rather a formal synthesis) [26–28, 41]. Although the synthetic quinine was too expensive to compete with the quinine isolated from *Cinchona* bark, the research resulted finally in the development of active and synthetically easily available antimalarials, for example, chloroquine, mefloquine, and primaquine.

3 Occurrence and Isolation

Cinchona alkaloids are characteristic and widely present in the genus *Cinchona* consisting of ca. 40 species which belong to the family *Rubiaceae* [42]. These plants are 15–30-m-high evergreen trees native to the eastern slopes of the Amazonian area of the Andes, growing from 1,500 to 3,000 m from Colombia to Bolivia (Costa Rica, Ecuador, Guatemala, Panama, Peru, Venezuela). They can also be found in the northern part of the Andes (on the eastern slopes of the central and western ranges).

Today, however, the most important *Cinchona* tree cultivators are Indonesia and India, together with Africa (in Zaire, Tanzania, and Kenya). South American countries such as Peru, Bolivia, and Ecuador where the *Cinchona* trees originated from become less important producers. Others plantations are also cultivated in Australia, Guinea, Papua New Guinea, and the Philippines [1–3].

For commercial purposes, three main *Cinchona* species, namely, *Cinchona succirubra* Pav. ex Klotsch (or *C. pubescens* Vahl, red *Cinchona*), *C. officinalis* "*ledgeriana*" (or *C. ledgeriana* Moens ex Trimen, yellow *Cinchona*), and *Cinchona calisaya* Wedd. together with their many varieties, hybrids, and grafts are usually cultivated due to the highest alkaloid content in the bark. For example, "red" bark of *C. succirubra* contains 5–7% of alkaloids, *C. calisaya* gives bark with an alkaloid content of 4–7%, whereas bark of *C. officinalis* "*ledgeriana*" may contain 5–14% of alkaloids. Selected *Cinchona* hybrids under the favorable cultivation condition could yield even more alkaloids, up to 17% in the bark. Analysis of the different types of *Cinchona* species bark shows that quinine is the most abundant alkaloid comprising usually 50–90% of the alkaloids sum [43–45].

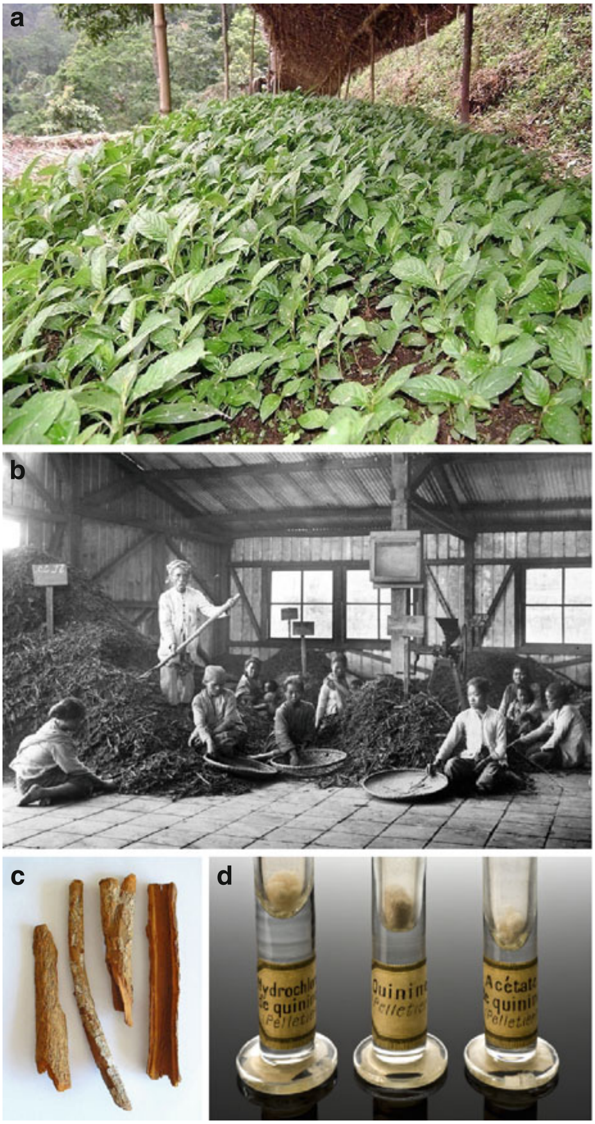

Fig. 21.1 (**a**) Current plantation of Cinchona tree in India (**b**) Workers sorting cinchona bark in Tjinjiroean (West Java, form the period 1915–1930, collection of Tropenmuseum of the Royal Tropical Institute (KIT), (**c**) cinchona bark samples, (**d**) authentic samples of cinchona alkaloids isolated by Pelletier and Caventou in 1834 roku (from www.sciencemuseum.org.uk)

Commercial product of *Cinchona* tree is *Cinchona* bark which is a dried bark from the stem and roots. The trees achieve harvestable bark usually within 6–10 years. The bark is then stripped and collected. The bark partially regenerates on the trees; therefore, a single tree can be explored a few times (depending on the species and cultivation technique) before it is uprooted and replaced by the new plants (Fig. 21.1).

Crude mixture of crystalline alkaloids from the bark has been first isolated by Gomes [46] in Portugal in 1810, and 10 years later, Pelletier and Caventou isolated

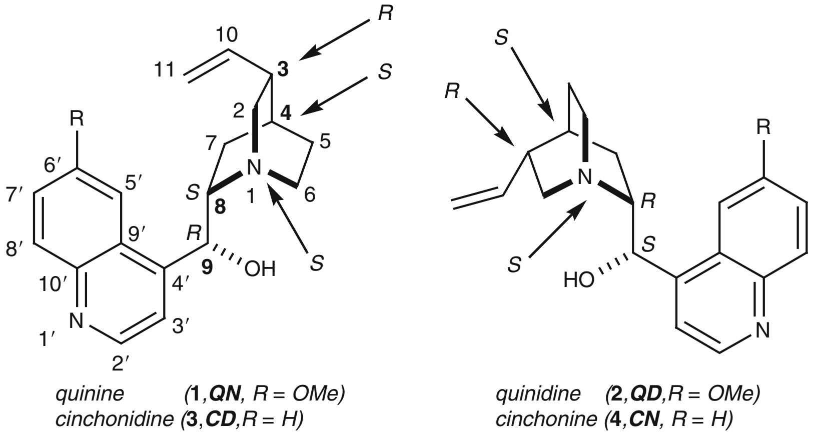

Fig. 21.2 Structure, common atom numbering and absolute configuration of four major Cinchona alkaloids

pure quinine and cinchonine [47–49]. In 1826 the researchers opened the first quinine factory processing annually ca. 150,000 kg of *Cinchona* bark and purifying ca. 3,500 kg of quinine. The two other major Cinchona alkaloids quinidine and cinchonidine were isolated by Delondre and Henry [50, 51] and Winckler [52], respectively. The structures of these four major Cinchona alkaloids which usually account for 30–90% of alkaloid content of the bark are given in Fig. 21.2.

Besides quinine (**1**), quinidine (**2**), cinchonidine (**3**), and cinchonine (**4**), a considerable number of their close derivatives have been found in the bark or in the leaves of *Cinchona* species (occasionally also in other species, see Table 21.2), differing mainly with the type of substituents (vinyl or ethyl group) at C-3 of quinuclidine moiety, methoxyl, hydroxyl, or hydrogen in the quinoline ring or in configuration at C-9 (Table 21.1) [23, 36].

Other minor quinoline alkaloids are those of quinicine (quinotoxine) class (**5**–**6**) [58, 59, 64, 67, 71, 72]. Besides quinoline alkaloids produced by *Cinchona* species, there are also a number of indole-type minor alkaloids classified as cinchonamines (**7**–**9**) [67, 72–76] or dimeric cinchophyllamine type (alternative name cinchophylline) (**10**) [76–81]. Other structures include quinamines (**11**) [61–63, 73, 76, 79, 82, 83], tetracyclic 3-isocorynantheol (**12**) [54, 84], or less typical for *Cinchona* species (*C. ledgeriana* and *C. pelleteriana*) pentacyclic aricine (**13**) [54, 79, 85, 86]. Their structures are given in Fig. 21.3.

A fraction of Cinchona alkaloids in the bark are present as the salts of quinic, cinchotannic, or other acids. Enzymatic oxidation of cinchotannic acid occurring during bark processing yields a red pigment, which gives a typical color especially of the “red” bark. Other minor, non-alkaloidal compounds found in *Cinchona* and *Guettarda* species are phenolic acids such as caffeic, chlorogenic, protocatechic and *p*-coumaric acid, epicatechin [87–89], phenylpropane-substituted flavane-3-oles – cinchonaines [87, 90], triterpene

quinovic acid and its glycoside quinovin [89, 91], and cincholic acids [89] as well as anthocyanosides (cyanidol-3-glucoside and cyanidol-3-rhamnoglucoside) [92], flavonoids (kaempferol, quercetin, avicularin, reynoutrin, delphinin) [87, 88, 93], and relatively high concentration of anthraquinones [23, 75, 94–96].

Investigation of the leaves of various *Cinchona* tree species showed that they differ remarkably in the alkaloid composition. For example, *C*. "*ledgeriana*" contains mainly indole type alkaloids (e.g., cinchophyllamines **10**, quinamine **11**a, and 3-epiquinamine **11**c) [76–79], in contrast to the samples of *C*. *succirubra*

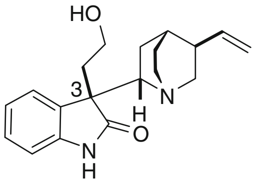
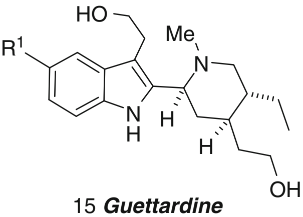
purposes in South America produce a number of typical quinoline alkaloids (Table 21.2) as well as more characteristic for this species – remijinine (**14**) [67, 68]. Guettardine (**15**) which is closely related to the dihydrocorynantheol is another example of the indole alkaloid present in the genus *Guettarda* [57]. Examples of the other species from which Cinchona-type alkaloids (**1**–**15**) have been isolated are given in Table 21.2.



14a ***Remijinine***
14a ***Epiremijinine***



15 ***Guettardine***

Some of the minor Cinchona alkaloids isolated from *Cinchona* or *Remijia* species reported in an old literature, for example, chairamidine, chairamine, cuscamidine, cusconidine, cusconine, javanine, and paricine [36], are up to now of unknown structure, and their identity needs confirmation.

Broad application of Cinchona alkaloids in medicine, food industry, as well as in academic research has stimulated very early the development of both qualitative and quantitative methods for their analysis. Currently, chromatographic TLC [98, 99], HPTLC [99, 100], HPLC [76, 101–104], and LC-MS [105, 106] and electrochromatographic methods [107] are preferred for *Cinchona* alkaloid separation, identification, and quantitative analysis. Older analytics from this field is the subject of a review [23].

4 Chemistry of Cinchona Alkaloids

Chemistry of Cinchona alkaloids has a very long history considering that purified quinine was available in Europe as early as in 1820. The seminal transformations of the Cinchona alkaloids, including, for example, the Pasteur's chinotoxine preparation by the treatment of quinine with a weak acid [108], were mainly directed toward the structure elucidation and remained very intuitive until the beginning of the twentieth century when P. Rabe solved the problem of quinine constitution [5, 26, 27, 29, 109, 110]. Nevertheless, a detailed stereochemistry of the Cinchona alkaloids was determined finally by Prelog et al. in 1950 [111]. The X-ray structures of major Cinchona alkaloids **1–4** have been published [112–116] as well, and their conformation was determined in past two decades by a combined NMR and/or computational approach [117–121].

Quinoline-type Cinchona alkaloids (**1–4**) consist of an aromatic quinoline (or 6′-methoxyquinoline) ring joined to the bulky bicyclic quinuclidine moiety by a carbinol linker C-9. Each Cinchona alkaloid contains five stereogenic centers at C-9, C-8, C-4, C-3, and N-1 (Fig. 21.2).

Although quinine and quinidine as well as cinchonidine and cinchonine are diastereoisomers, they are called often pseudoenantiomers because the crucial for the catalytic or chiral discrimination 1,2-aminoalcohol functionality remains enantiomeric in these pairs (however, diastereomeric rather than enantiomeric character is sometimes observed in various applications [8]).

The chemistry of the Cinchona alkaloids involves a typical reactivity of their fragments such as hydroxyl group at C-9 or vinyl group at C-3 and two basic nitrogen atoms incorporated into quinuclidine and quinoline as well as more specific transformation occurring with a rearrangement of their carbon skeleton.

The most popular way to modify alkaloids **1–4** is a derivatization of the alcohol or a replacement of hydroxyl group with retention or inversion of the absolute configuration at C-9 (Scheme 21.1; note quinine is given as a representative example, but most of the reaction could be also carried out with alkaloids **2–4** and the 9-epi series). Alkaloids could be easily transformed into the corresponding 9-*O*-ethers **16** [122–125], esters **17** [126, 127], and carbamates **18** [128, 129]

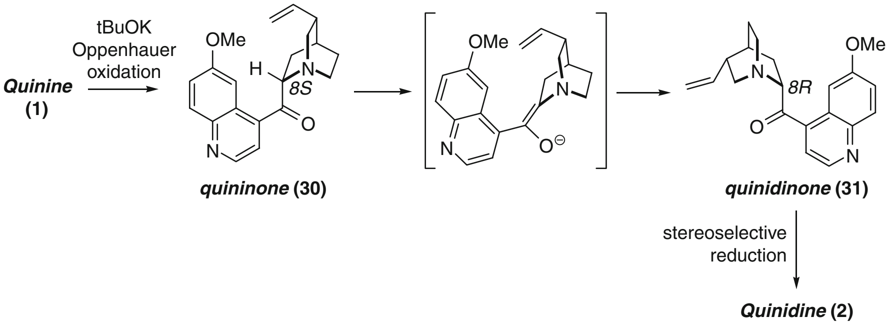
without affecting the configuration at C-9. Many of these derivatives are frequently used as catalysts in asymmetric synthesis or as chiral discriminating agents [8–12, 14, 130]. Substitution of the 9-hydroxyl group typically in Mitsunobu reaction or by intermediate 9-*O*-mesylates **19** of **1–4** [131] provides access to many useful derivatives, usually with a complete inversion of the configuration at C-9 (9-epimers are formed), such as 9-azides **21** [132] and the corresponding amines **22** [133]. Using this strategy, Skarżewski et al. obtained a library of Cinchona 9-thiols **23** and bis-cinchona disulphides, phenylsulphides, and phenylselenides as well as the corresponding sulfoxides [134–137]. Similarly, 9-epialkaloids **20** can be conveniently prepared in one step by aqueous hydrolysis of the corresponding 9-*O*-cinchona tosylates [138] or preferably 9-*O*-cinchona mesylates, as optimized by Hoffmann [139], or alternatively by Mitsunobu esterification/hydrolysis sequence [140]. 9-Epicinchona alkaloids **20** undergo many of the mentioned reactions giving in most cases access to 9-naturally configurated derivatives **21–23**. Cinchona 9-chlorides **24** can be favorably prepared by the treatment of alkaloids with $SOCl_2$ with inversion of configuration at C-9 [141, 142]. Cinchona derivatives **21–24** can further be transformed into a number of diverse compounds including



Scheme 21.2

9-aryl or vinyl substituted alkaloids **25** [143–145] as well as to 1,2,3-triazolo derivatives **26** synthesized by *click chemistry* [146]. Particularly important as powerful organocatalysts [147, 148] are currently 9-amino-9-epicinchona alkaloids **22** obtained by a one-pot procedure involving Mitsunobu azidation followed by Staudinger reduction [133]. They serve also as intermediates for the synthesis of thioureas **27** [149–151], amides **28** [152, 153], and imides **29** [154–156] which have found numerous applications in the asymmetric catalysis or chiral discrimination (for comprehensive reviews, see [8, 9]).

A reaction of commercial importance used for a large-scale manufacturing of quinidine (**2**) is the oxidation of hydroxyl group of quinine (**1**) leading to quininone **30** [157–159] (Scheme 21.2). Its epimerization via enol to quinidinone **31** [160] and subsequent reduction yield quinidine and quinine as well as their 9-epimers as unwanted by-products. The most convenient oxidation procedure was developed by Woodward who employed a modified Oppenauer-type oxidation and which was further optimized by Warnhoff [159]. Reduction of quinidinone by diisobutylaluminum hydride shows high stereoselectivity operating via complex formed with the aid of quinuclidine nitrogen. An elegant approach providing near-quantitative yield of quinidine by the reduction of quininone/quinidinone has been patented by Gignier and Bourelly. The strategy comprises of reduction of ketones **30–31** with diisobutylaluminum hydride in the presence of a stereoorienting agent such as pyridine and greatly avoids the formation of undesirable by-products such as quinine, epiquinine, and epiquinidine [161].

The vinyl group attached to the quinuclidine moiety is yet another site frequently used for a modification or immobilization of Cinchona alkaloids (Scheme 21.3). Diverse reactivity of the vinyl group of Cinchona alkaloids has been studied in details and is summarized by Hoffmann [30, 31]. Here the most typical or recent transformation is highlighted. The catalytic hydrogenation of the vinyl group leads to the corresponding 10,11-dihydroalkaloids **32** (often present up to ca. 10% in the isolated alkaloids) and can be completed both by using gaseous hydrogen in the presence of a heterogeneous catalyst, for example, palladium, platinum, or rhodium [162], or under transfer hydrogenation [163]. On the other hand, 10,11-didehydroalkaloids **33** bearing a terminal acetylene group instead of the

Scheme 21.3 Transformations of vinyl group of Cinchona alkaloids vinyl can be prepared by the bromination of the double bond followed by subsequent double elimination [164, 165]. These alkyne derivatives are more basic, as compared to the native Cinchona alkaloids, and are versatile substrates for a further elaboration. These include *click chemistry* approach for the synthesis of 11-(1,2,3-triazolo)-Cinchona alkaloids [166, 167] and a new Cinchona immobilization method via 1,2,3-triazole linker [168–170] as well as a number of diverse cross-coupling reactions [164, 171].

Radical addition of thiol or thiol-modified support to the vinyl group gives the respective thioether linkage **34** and represents one of the most convenient ways to immobilize Cinchona alkaloids [163, 172]. There are also few examples of platinum-catalyzed hydrosilylation of Cinchona alkaloids toward 11-silyl-substituted derivatives **35** with the use of monomeric silanes or polysiloxane polymers [173–175]. De Vries reported rhodium-catalyzed hydroformylation of the four main members of Cinchona alkaloids carried out on a hundred gram scale. Under optimized condition, linear aldehydes **36** were selectively obtained with the yield over 80% [176].

Oxidative cleavage of the vinyl group of quinine by $KMnO_4$ leads to the Cinchona C-10 acid (quitenine) or ester **37** with low yield [177, 178], whereas more efficient although longer route via hydroboration and subsequent oxidation gives primary alcohol **38** which can be oxidized to C-11 ester or aldehyde **39** [179, 180]. 10-Carbaldehyde **41** can be obtained from the easily accessible 10,11-cinchona diols **40** [180]. Last but not least, addition of HBr to the Cinchona alkaloids gives the corresponding diastereomeric bromides **42** [181] which could be eliminated to give a mixture of *E*/*Z* $\Delta^{3,10}$-isoalkaloids **43** (the so-called apocinchona alkaloids) [181, 182] (direct migration of the double bond has also been reported [182]). Apocinchona alkaloids **43** undergo an oxidative cleavage via the corresponding 1,2-diol, providing access to the ketones **44** (so-called rubanones), as demonstrated by Hoffmann [183].

Perhaps one of the most important transformations of the aromatic ring of quinine or quinidine is demethylation of the quinoline hydroxyl group, leading to cupreine **45** or cupreidine **46**, respectively. These alkaloids as well as their thiourea derivatives, for example, **47**, received recently wide attention as effective organocatalysts in the asymmetric synthesis [8, 9, 184, 185]. Their newer, more selective synthesis from quinine or quinidine involves deprotection mediated by thiolates [185]. The alkylation of cupreine to introduce a bulky alkyl group on the phenolic hydroxyl group in **45** or **46** leads to the corresponding ethers which after further elaboration can be used as efficient chiral selectors in enantioselective chromatography [14, 15, 186] (Scheme 21.4).

There are only a few reports on the nucleophilic substitution of the aromatic quinoline ring of Cinchona alkaloids. Typically, 2′-substituted products **48** are observed [187–190], but the sterically less demanding Grignard reagents add selectively to 4′-carbon. This leads to the loss of aromaticity and to unexpected formation of bicyclic *N*,*O*-acetals, for example, **49** [190]. An interesting variant of a selective functionalization of quinoline ring of quinine either in 2′ or in 3′ position

Scheme 21.4 Quinoline ring transformation in quinine

by metalation has recently been reported by the Knochel group. Typically, the metalation occurs at position 3′, but increasing the bulkiness of the C-9 hydroxyl group by formation of silyl ether selectively directs the metalation to position 2′. Quenching of the metalated quinine intermediate by various electrophiles gave access to the number of new quinine derivatives **50** with satisfactory yields [191]. Modification of the quinoline at 5′ involves a rare example of the direct nitration by HNO_3 yielding >90% of corresponding 5′-nitroquinine **51** which has been further converted into amino- and substituted urea derivatives, successfully employed in asymmetric catalysis [192]. Another specific example of the modification of 5′-position of cupreidine involves a direct amination, providing the atropisomeric derivatives **52** [193]. Quinoline ring can also be partially reduced, providing hexahydro derivatives **53** of unknown absolute configuration at the newly formed stereogenic center at C-4′ [194, 195]. These transformations are summarized in Scheme 21.4.

Last but not least, Cinchona alkaloids can be modified by using reactivity of their one or two basic nitrogen atoms. The quinuclidine moiety is a very strong base (pK_b 7.25) and could be preferentially quaternized by benzyl halides, as compared to the less basic quinoline nitrogen (pK_b 2.81). The comparison of the nitrogen reactivity was recently discussed on the basis of experiments and molecular modeling [196]. The simple quaternary salts of Cinchona alkaloids **54** were developed as efficient chiral phase-transfer catalysts in the 1980s, and their catalytic performance was constantly improved by a proper selection of the benzylic halide and the protecting group of 9-hydroxyl substituent (third-generation Cinchona quats **55** [197–199]). Their diversity and the application in asymmetric synthesis were reviewed in detail in [8–10]. Both Cinchona alkaloid nitrogen atoms can also be oxidized to the respective mono- (**56**-**57**) or *bis*-*N*,*N*-oxides **58** [200] (Scheme 21.5). *N*-Oxides of Cinchona alkaloids were not found in the plant sources but have been isolated as the metabolites of pathogenic fungi-colonized *Cinchona* species as well as Cinchona alkaloid metabolites in human and animals (*vide infra*).

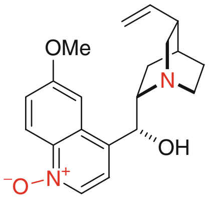
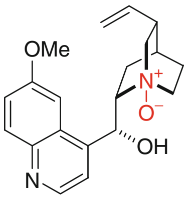
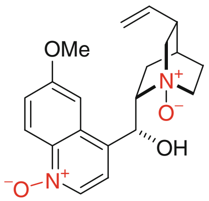
55



56



57



58

The multifunctional nature of Cinchona alkaloids makes them especially prone for a complex reactivity that occurs with a degradation or rearrangement of the carbon moiety, often controlled by the stereochemistry of the particular alkaloid. These characteristic for Cinchona alkaloid transformations include an acid-catalyzed formation of cinchotoxines **59** described as early as in 1853 by Pasteur [108] or synthesis of diverse cyclic ethers, for example, *β*-isoquinidine **60** or *β*-isocupreidine **61**, bearing oxazatwistane moiety [180, 201, 202] (Scheme 21.5). This can be used as an efficient catalyst of a stereoselective Baylis-Hillman reaction [8–10, 203, 204]. Hoffmann studied in detail the two distinct cage rearrangements

Scheme 21.5 Specific reactivity of Cinchona alkaloids of Cinchona 9-*O*-mesylates (**19**) or 9-halides (**24**) which provide an array of products, for example, **62-64** (depending on the condition and the alkaloid used) [30, 31]. The first "Cinchona rearrangement" leads to the cage-expanded [3.2.2] azabicyclic *α*-aminoethers **62**. The "second Cinchona rearrangement" affords *β*-functionalized [3.2.2] azabicyclic derivatives **63** and solvolysis products **64**. The latter reaction is favored for the so-called *cinch* bases (cinchonine and cinchonidine), and the rearranged products **63** can further be easily elaborated into several functionalized derivatives [205] (Scheme 21.5). Detailed explanations of the mechanisms of these rearrangements were discussed by Hoffmann [30, 31, 205].

An oxidative degradation of quinine or quinidine by a cleavage of C-9-4′ bond leads to quincorine **65** or quincoridine **66**, respectively, preserving the configuration at C-8 chiral center (methoxyquinoline **67** is a by-product of this reaction). This process has been developed by Hoffmann [30, 31, 206] and was further commercialized by Buchler GmbH, giving access to the large quantities of these versatile building blocks [207]. Similarly, degradation of quininone **30** provides meroquinene ester **68** utilized in the stereoselective synthesis of *cis*-isoquinolinone and *cis*-isoquinolinone derivatives **69** [208–210] or antihistaminic (+) mequitazine **70** [210] (Scheme 21.6). The older application of quinine in the synthesis of a number of indole alkaloids, for example, 10-mehoxydihydrocorynantheol **71** and dihydrohunterburnine **72**, has been reported by Sawa et al. [211–213].

5 Biosynthesis

Biogenetically, Cinchona alkaloids are terpenoid indole alkaloids synthesized from tryptophan (quinoline ring) and geraniol (quinuclidine moiety), as it was postulated by Goutarel et al. shortly after their full structure elucidation in 1950 [73]. This was supported later by a series of radioactive feeding experiments of Leete et al. [214] (reviewed in detail in [23, 24, 215]). The key intermediate in Cinchona alkaloid biosynthesis is 3α-(*S*)-strictosidine **73** (general precursor of indole alkaloids) forming in the Pictet-Spengler reaction of tryptamine and secologanin **74** [216]. A detailed mechanism of strictosidine synthase (EC 4.3.3.2) catalysis has been recently proposed, on the basis of both experimental and theoretical studies [217]. The early steps leading to the active hemiacetal form of strictosidine **75** are shown in Scheme 21.7.

Interesting correlation between distribution of the strictosidine synthase activity and alkaloid content in the 6-month *C*. "*ledgeriana*" plants was found by Aerts et al. The enzyme was active in the top of stems, in young leaflets, and in the roots, and these parts also contained the highest concentration of the alkaloids. Quinoline alkaloids were accumulated in the roots, whereas cinchophyllines in aerial part of plants [218]. Similarly high activity of strictosidine synthase in the germinating Cinchona seeds and cell cultures has been reported [219]. Four isoforms of strictosidine synthase have been isolated and purified from the suspension culture of *C. robusta* [220].

Scheme 21.6 Preparatively useful oxidative degradation of Cinchona alkaloids

Strictosidine after hydrolysis, subsequent decarboxylation step and removing one of the carbon atoms from the iridoid moiety is transforming to corynantheal **76**. This intermediate was shown to be effectively incorporated by plants in the feeding experiments giving alkaloids. The next steps involving the formation of the quinoline ring of alkaloids from the indole moiety are complex and not clear. It is generally accepted that cinchonaminal **75** formed from **76** by cleavage of the indole N-C bond is the key precursor; however, there is no experimental evidence until now. Another problem deals the hydroxylation of the aromatic quinoline ring and subsequent methylation of phenolic hydroxyl group. 5-Methoxytryptamine is not incorporated by *C. robusta* cells neither into the alkaloids nor into their precursors, as demonstrated by Verpoorte, giving the evidence that methoxylation is carried out

Scheme 21.7 Early steps of Cinchona alkaloids biosynthesis

in the latter steps of biosynthesis [106]. Not confirmed observation suggests that this may occur at or before formation of corynantheal **76** [23, 221]. The middle steps transforming the indole-type cinchonaminal **77** into the quinoline-type cinchonidinone (or quininone) **79** probably via aminoaldehyde **78** is a plausible mechanism again without experimental support. The final steps involving stereoselective reduction of ketones **79–80** to alkaloids **1–4** are catalyzed by specific oxidoreductases [221] which, on the basis of feeding experiments, were shown to be fully reversible [222]. NADPH-dependent cinchoninone oxidoreductase isolated from *C. ledgeriana* is present in two isoforms: I and II. Isoenzyme I is more specific toward cinchoninone (quinoline ring), whereas form II shows broader specificity acting on all of the Cinchona alkaloids bearing quinoline, 6′-methoxy, or

6′-hydroxyquinoline rings [221]. Scheme 21.8 shows the commonly accepted biosynthesis of Cinchona quinoline and indole alkaloids. It must be pointed out that this proposal is only partially verified experimentally (the early and the final steps) as only three specific enzymes of this pathway has been isolated and characterized so far.

6 Biological Activity

Most important activity of Cinchona alkaloids is antiprotozoal action of quinine used for more than 400 years for the treatment of malaria [1–4, 32–35]. Malaria is a vector-transmitted infectious disease caused by parasites of the genus *Plasmodium*. The life cycle of parasite requires two host organisms: female mosquitoes from the species *Anopheles* and humans (rarely other primates or mammals). Severe malaria is largely caused by *Plasmodium falciparum* (responsible for ca. 90% of deaths), while *P. vivax* or *P. ovale curtisi*, *P. ovale wallikeri*, and *P. malariae* give generally a milder disease with low fatality. Malaria remains a serious public problem in tropical and subtropical regions of Africa, Asia, and America involving more than 90 countries inhabited by approximately 2,400 million people (about 40% of the world population). Annual incidence of malaria is estimated at 250–500 million cases, causing between 1.5 and 2.7 million deaths per year (the highest mortality is observed in children under 5 years of age) mostly in sub-Saharan Africa, but also in Asia, Latin America, and the Middle East.

The economic burden of malaria is extremely high, according to the various estimations accounting for ca. 1.3% reduction of the annual economic growth rate in countries where the disease is endemic and costs as high as ca. 40% of whole public health expenditures. The problem of malaria is increasing yet due to the development of the resistance of plasmodia toward most of the synthetic antimalarial drugs used over last decades [4].

The mechanism of malaria is relatively well understood and involves infection of humans by biting by female mosquitoes who inject sporozoites (distinct morphological forms of parasites at mosquito stages) subcutaneously. They enter the bloodstream and migrate to the hepatocytes where they differentiate into merozoites. This form invades further erythrocytes to establish a blood-stage infection, where they appear initially as a ring stage, followed by a growing trophozoite, which develops into a dividing a sexual schizont. Some merozoites may also differentiate into male and female gametocytes (sexual forms) which, if taken up by a mosquito, will infect the insect and continue the life cycle. After complex process of the differentiation of parasite within the mosquito, new sporozoites migrate to the salivary glands and are ready for the infection of the next host organism. The detailed life cycle of *Plasmodium* is given [4, 223].

Among four major Cinchona alkaloids, quinidine and cinchonine were most active in the malaria therapy followed by quinine and cinchonidine. For example, quinidine is two- to threefold more active than quinine in both chloroquine-sensitive and chloroquine-resistant strains of *P. falciparum* [224]. Due to its cardiac

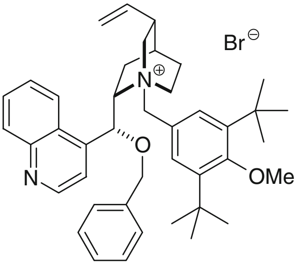
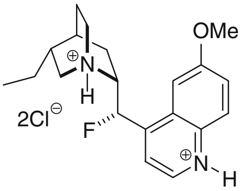
Scheme 21.8 Biosynthesis of Cinchona alkaloids activity, it cannot, however, be safely used as antimalarial; therefore, most abundant quinine historically continued to be a drug. 10,11-Dihydroanalogues of these alkaloids exhibit similar activity as compared with the parent compounds. Stereochemistry of 1,2-aminoalcohol moiety in alkaloids is crucial for their antiprotozoal action; e*rythro*-configurated natural bases are active, while 9-*epi*-configurated analogues (*threo* configuration) have no activity [224–226]. Detailed analysis of geometry and certain electronic properties of eight major Cinchona alkaloids were used for defining stereoelectronic features responsible for their antimalarial activity. This involves sufficiently acidic hydroxyl proton and an electronic feature of molecule pointing from quinuclidine nitrogen toward the quinoline ring [227]. Interestingly, quaternization of the four major Cinchona alkaloids by 4-methoxy-3,5-di-*tert*-butylbenzyl bromide and their further 9-*O*-etherification lead to antimalarial derivatives **81** comparable to parent alkaloids in in vitro tests [228]. Similarly, C-9-fluorinated quinine **82** showed high antiplasmodial activity reaching IC_{50} value as low as 267 nM for best compound (but below activity of parent alkaloids) [229]. This data may suggest that there is no single pharmacophore of Cinchona moiety responsible for its antimalarial activity.



81 *(from cinchonidine)*



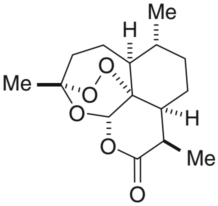
82 *(quinidine confg.)*

Despite newer antimalarial drugs, quinine continues to be important drug used for treatment of the multidrug-resistant malaria and severe malaria. It is also recommended as the only drug for treatment of malaria in the first trimester of pregnancy. Detailed recommendations, dosages, and comparison with other antimalarial drugs for the current medical practice are summarized in many works [4, 32–34]. Although there are some reports on the increasing local resistance of *P. falciparum* toward quinine, for example, in Southeast Asia, South America, and Africa, most of other studies confirm its high activity. In this context, efforts to find the genetic markers of *Plasmodium* indicative for its resistance against quinine have been undertaken [230].

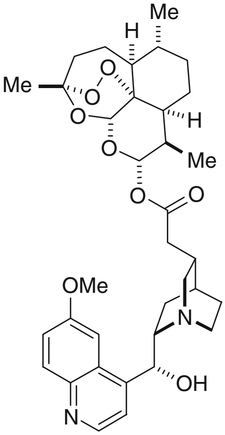
The mechanism of action of quinine is not perfectly understood. It is generally assumed, on the basis of several model studies [231, 232], that Cinchona alkaloids prevent the polymerization of the toxic hematin ([aquaFe(III)protoporphyrin IX]) formed by the degradation of hemoglobin in erythrocytes to hemozoin (β-hematin).

Blocking of this nonenzymatic detoxification process, developed by the parasites, results in a toxicity of the non-polymerized hematin [232, 233]. Other hypothetical scenarios explaining activity of quinine are discussed [232, 233].

Although quinine was the first efficient antimalarial drug, its limited supply, political instability in the past, as well as its narrow therapeutic window stimulated an intense research toward the synthetic quinine and other antimalarials. These efforts did not bring the economically viable synthesis of quinine but provided several synthetically more accessible analogues with antimalarial activity. Among them chloroquine, mefloquine, and primaquine were the most important compounds. These early-generation drugs are the subject of comprehensive reviews [223, 234]. Unfortunately, plasmodia strains acquired resistance to the most of these synthetic drugs (especially to the most popular chloroquine, used widely as an antimalarial prophylaxis) during the years of their constant use, resulting in refreshed interest in the quinine therapy. Newer class of drugs introduced to the antimalarial therapy in recent years include natural product artemisinin **83** and its semisynthetic derivatives artesunate, artemether, and arteether as well as synthetic 1,4-naphtoquinine-based atovaquone with combination of proguanil (Malarone) [4]. Artemisinin-based pharmaceuticals remain currently the first choice for the malaria treatment. Interestingly, synthetic quinine-artemisinin conjugate **84** obtained by Walsh exhibits high activity against the 3D7 and FcB1 (drug-resistant) strains of *P. falciparum* in culture. The synergic effect on the activity was observed, as compared with that of artemisinin or quinine alone and a 1:1 mixture of artemisinin and quinine [235].



83



84

The cardiological effects of Cinchona bark alkaloids have been recognized in an academic medicine at the end of the seventeenth century. Quinine was used at the beginning, but its pseudoenantiomer quinidine has been found to have more beneficial antiarrhythmic properties, thus becoming a standard medication until newer drugs were developed in the mid-twentieth century [236]. Quinidine inhibits fibrillation (uncoordinated contraction of muscle fibers in the heart) by blocking potassium channels [237, 238]. The major problem with the use of this alkaloid is its quick absorption by the gastrointestinal tract giving risk of overdosing. This may lead to diastolic arrest (ventricular arrhythmia) and death. Safety concerns resulted in the significant reduction of quinidine use in a therapy over years. However, recently renewed interest of the medical use of quinidine is observed; in particular, quinidine combination with verapamil has been reported to be safe and efficacious in the treatment of atrial fibrillation. Quinidine has also been used successfully to treat idiopathic ventricular fibrillation, Brugada, and short QT syndromes. Quinidine applications in the modern cardiology are subject of reviews [239, 240].

Muscle cramp is a recurrent and painful condition and a common complaint among elderly subjects and patients treated with hemodialysis. No specific cause of this syndrome was identified; therefore, therapy is mostly symptomatic. Over the years, quinine sulfate was claimed to be a medication relieving the muscle cramp symptoms, but safety issues declined its current use. Several detailed studies have been reported to clarify the controversy of quinine efficacy in this line [241, 242]. Meta-analysis of the different 23 trials with a total of 1,586 participants has been published with conclusion that quinine at the dosage typically 300 mg/day (range 200–500 mg), compared to placebo, significantly reduced cramp number over 2 weeks by 28%, cramp intensity by 10%, and cramp days by 20% but without affecting the cramp duration [241]. In another report, moderate quality evidence has been found confirming that quinine reduces cramp at similar dosage [242]. Typically, only minor side effects of quinine use were observed in patients, leading to the conclusion that this is a relatively safe drug. There are studies which claim beneficial effect of quinine for leg cramps treatment [243].

Quinine and cinchonine since two decades were also investigated in reversing of multidrug resistance (MDR) in cancer patients [24]. Phase I/II of clinical trials conducted for quinine shows that it could be used safely with a number of anticancer agents, for example, mitoxantrone, cytarabine, cyclophosphamide, or paclitaxel, improving the treatment of clinically resistant acute leukemias, breast cancer, or non-Hodgkin's lymphomas [244–246]. Continuation of trials in Phase III in patients with acute leukemia resulted unfortunately only in the modest success [247]. Other preclinical and Phase I studies in this line have shown that cinchonine is superior MDR agent as compared with quinine [248, 249]. Cinchonine combined with cyclophosphamide, doxorubicin, methylprednisolone, and vinblastine may be safely administrated in patients with malignant lymphoid disease, giving MDR reversing activity in every case [250]. Recently, dimeric quinine **85** linked by ester bond was shown to be highly active in MDR that completely reversed the *P*-glycoprotein (P-gp)-mediated paclitaxel resistance phenotype as well as inhibiting its transport in MCF-7/DX1 cell in vitro studies [251]. There are also reports on inhibitory action of quinine for microbial pathogen invasion on human skin [252].

Quinine bark is still popular as a herbal medicine. For example, in South America, besides being antimalarial drug, it is considered a tonic, digestive stimulant, and anti-fever. The bark is also used for anemia, indigestion, gastrointestinal disorders, general fatigue, fevers, and as an appetite stimulant. It is claimed that

Cinchona bark could also be used as a remedy for some types of cancer, amebic infections, heart problems, colds, diarrhea, lumbago, and other problems. These indications of the bark (besides malaria) have no until now strong evidence in the medical literature [253].

An interesting property of quinine (and quinidine) is their strong bitter taste (gin was originally added for the administration of quinine to make its bitter taste more acceptable) [20]. Thanks this quinine (in a form of water-soluble salts) is a valuable taste modifier in beverage (vermouth and tonic water) and occasionally also in confectionery industry. The typical concentration of quinine in beverages is up to 80 mg/L and could be considered as safe for consumers (however do not provide an effective antimalarial prophylaxis). Recent studies confirmed also that in contrast to some doubts, beverage level of quinine does not inhibit the cytochrome P450 (CYP2D6) which is involved in the metabolism of many drugs [254]. Although the receptors of quinine bitter taste have not been isolated until now, genetic studies carried out by Reed suggest that there is a gene cluster located on chromosome 12 responsible for coding of bitter receptors in the taste receptor cells and salivary proline-rich proteins. Significant genetic variation in this region is responsible also for an individual perception of bitterness of quinine [255].

There are also reports showing specific biological activity of minor Cinchona alkaloids, for example, cinchophyllamine **10** is active against Gram-positive bacteria [81] and cinchonaminone **9** is a monoaminoxidase inhibitor [72] (some older works regarding activity of Cinchona indole alkaloids are summarized in [23]). Dihydrocorynantheol has found to have antiparasitic and cytotoxic activity [256].

Recently, medicinal chemistry considers synthetic derivatives of Cinchona alkaloids as pool of diverse biological activity. For example, large library of Cinchona alkaloids and their quaternary salts have been tested toward cardiomyogenesis stimulators. Two members of screening set **86–87** exhibited very good activity in the test of cardiomyogenesis of transgenic murine embryonic stem [257]. Other quaternary salts derived from quinine and cinchonidine such as **88** were also shown to be inhibitors of butyrylcholinesterase exhibiting 250-fold selectivity increase as compared with acetylcholinesterase [258]. Cinchona alkaloid-AZT conjugates such as **89** linked by 1,2,3-triazole developed by Celewicz et al. showed marked cytotoxic activity in vitro [167].

89 *(quinine confg.)*

Last but not least, the ecological role of Cinchona alkaloids should be mentioned. The subject remains fuzzy because relatively few reports are available and most of them do not bring clear answer to the question why *Cinchona* species produce so much alkaloids. The seed germination and the level of the alkaloids in *Cinchona* seedlings were studied by Verpoorte et al. who suggested that initially high productivity of alkaloids has a deterrence of feeding of slugs [259]. In a laboratory experiment, the germination of *Ocimum*, *Spermacoce*, *Catharanthus*, and *Cinchona* itself was strongly inhibited by the alkaloids applied at concentrations higher than 0.3 mM. However, soil experiments with the living *Cinchona* plants showed that despite high concentration of the alkaloids in root (ca. 10 mM), their soil concentration was very low (ca. 0.02 mM); thus, no allelopathic plant-plant interaction was observed and probably they do not occur in the natural environment [260]. Another study by Verpoorte et al. has shown the toxic effect of the indole-type alkaloids (present in young leaves) on larvae *Spodoptera exigua* in contrast to quinoline alkaloids (mainly present in roots) [261]. Alkaloids from *Remijia peruviana* were found to have antifeedant activity on *Leptinotarsa decemlineata* [68].

7 Biotechnological Approaches

Biotechnological production of Cinchona alkaloids was considered as an attractive alternative to their isolation more than two decades ago. The major motivation for research in this field were difficulties with *Cinchona* plant harvesting, including high variation of alkaloid content in the bark, long time needed for achieving of tree maturity, and difficult access to the high-placed cultivating areas. Pathogen infection, for example, mold *Phytophthora cinnamomi* often destroying *Cinchona* plantations, is another problem. Several studies on the use of cell cultures for the bioproduction of alkaloids were carried using different strategies of cell cultivation and feeding. Unfortunately, despite intense research, generally low productivity (typically few mg/g of dry weight) was observed. Similarly, large-scale cultures, immobilization of the *Cinchona* cell, and microbial or genetic transformations did not bring the expected level of bioproduction of alkaloids [262–265]. Best results so far were achieved by the use of compact globular structures (CGS) which show a differentiation similar to that found in the *Cinchona* bark. In this case, however, higher levels of alkaloids exceeding 1% of dry weight were compromised by slow growth of CGS system that hampered the overall economy of the process [266]. The more detailed view of the biotechnology of *Cinchona* species was published [267, 268]. Currently, rather stable Cinchona alkaloid world market and relatively low prices of quinine make the biotechnological approach not competitive, at least until as the mentioned problems are solved. This is expected when the genetics of biosynthesis and its regulation in the cell lines become known and fully controllable.

Bioconversion of Cinchona alkaloids is relatively less explored as compared to other natural products. The reason for this is the fact that none of the Cinchona alkaloid precursors are available at lower prices than the final alkaloids. The only exception is tryptophan; however, it has no straightforward influence on the increasing production of alkaloids in cell cultures [267, 268].

A potentially attractive bioconversion involves a stereoselective enzymatic reduction of quinidinone to quinidine (this process is now carried out chemically, vide supra). Among about 450 microorganisms screened by Ray et al., yeast *Hansenula anomala* var. *schneggii* was found to provide quinidine (of unknown stereochemical purity) with 50% yield after 7 days of fermentation [269]. High-yielding transformation of Cinchona alkaloids **1–4** into the *N*-oxides by oxidation with endophytic fungi of *Xylaria* sp. isolated from young stems of *C. pubescens* Wahl. was published by Shibuya et al. [270]. Kieslich identified several fungal species metabolized Cinchona alkaloids **1–4** to quinine 1-*N*-oxide, 1’-*N*-oxide, and 3-hydroxyl derivative as well as 1-*N*-oxides of quinidine, dihydroquinidine, and cinchonidine. This latter alkaloid yielded 3-hydroxyl derivative when *Rhizopus arrhizus* ATTC 10260 was employed [271]. Fungal transformation of quinidine has been studied by Eckenrode who found that 3-hydroxyquinidine is a typical metabolite [272].

Metabolism and toxicology of Cinchona alkaloids in human received much attention since analytical methods became available. It was found that quinine is mainly transformed into (3 *S*)-3-hydroxyquinine **90** [273], but minor metabolites including 2′-oxoquininone **92** and (10 *S*/*R*)-11-dihydroxydihydroquinine **91** have also been identified [103, 274, 275]. Quinidine undergoes similar metabolic pathway giving (3 *S*)-3-hydroxyquinidine as a major metabolite and minor amounts of quinidine-*N*-oxide [276]. Important way to eliminate of quinine and quinidine is the formation of respective glucuronides. Stereoselective hydroxylation of quinine and quinidine is catalyzed by cytochrome type CYP3A4 [277, 278]. More detailed information regarding Cinchona alkaloids metabolism and toxicity in human is a subject of reviews [279, 280].

8 Perspectives

Among many thousands of natural products identified so far, Cinchona alkaloids provide a unique combination of properties, serving as a drugs, chiral catalysts and selectors, indicators, or bitter-taste agents. These multi-faced molecules remain still in a focus of life sciences despite their long history and intense research done over the last century. Currently, their use in catalytic asymmetric synthesis is the most explored area; nevertheless, renewed interest in seeking of novel biological activities is recently observed. This trend is supported by the development of reliable Cinchona alkaloid chemistry which provides diverse molecular architectures for screening.

Abstract

Quinoline alkaloid camptothecin (CPT) isolated in 1958 from Chinese tree *Camptotheca acuminata* is an important natural product serving as a lead compound for designing many more active and clinically useful anticancer drugs, such as approved topotecan and irinotecan. All camptothecins exhibit a unique mechanism of action involving inhibition of topoisomerase I which leads to the interruption of cell division processes. Current efforts in CPT research focus on construction of better drugs, prodrugs, and new forms of administration. Important area of clinical work involves testing of multidrug regimens of CPTs with conjunction of other anticancer drugs. This often resulted in an improved activity toward malignancies. Beside anticancer

activity, camptothecin and related compounds display also other activities such as antiviral or antiprotozoal. Insufficient natural supply of camptothecin led to significant improvement of camptothecins total synthesis as well as to attempts of its biotechnological production. The present chapter covering over 300 references is intended to provide a complete but condensed overview on camptothecins, with emphasis on the newest work in the field.

Me	Methyl
NMR	Nuclear magnetic resonance
NSCLC	Non-small-cell lung carcinoma
OR	Overall response ratio
Ph	Phenyl
SCLC	Small-cell lung cancer
X	Halogen

1 Introduction

Camptothecin (CPT, **1**, Fig. 22.1) is a quinoline pentacyclic alkaloid (classified as pyrrolo[3,4-*b*]quinoline) originally isolated from the Chinese tree *Camptotheca acuminata* Decne (*Nyssaceae*) in 1958 by Wall and Wani in the frame of NCI anticancer candidates screening program. In 1966 structure of camptothecin was determined by using combination of NMR and X-ray approach [1]. Camptothecin has shown to be very active antitumor compound both in vitro and in animals and quickly entered the clinical investigation. The wider use of camptothecin in the therapy was hampered by its low solubility in water and rapid inactivation due to the lactone ring opening at physiological pH (open hydroxyacid form **2** is produced) as well as considerable toxicity. Sodium salt of camptothecin **3** has been proposed as more soluble form of the drug. Unfortunately, further studies of Phase I and II showed its lesser efficacy and unpredictable severe side effects such as hemorrhagic cystitis and myelotoxicity. This eventually led to the discontinuation of trials in 1974 [2–4].

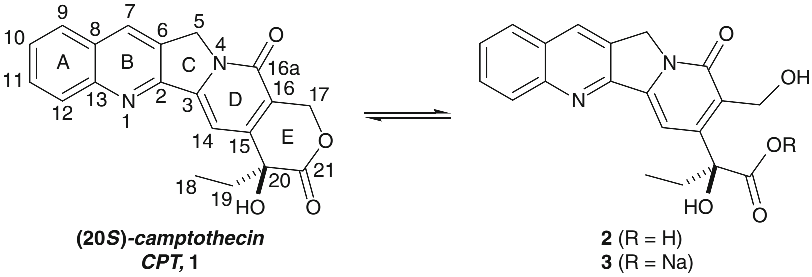

Fig. 22.1 Structure and atom numbering of camptothecin (CPT) and its open hydroxyacid form

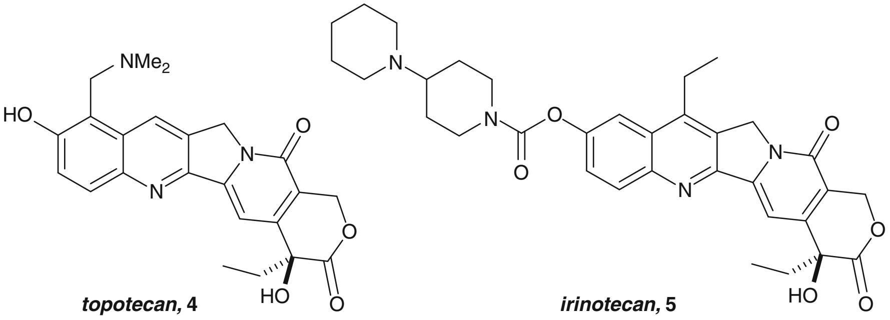

Fig. 22.2 Structure of topotecan and irinotecan

The renewed interest in camptothecin in the mid-1980s appeared after elucidation of its unique molecular mechanism of action which involves the inhibition of DNA topoisomerase I (topo I) [5, 6]. This discovery has stimulated a significant progress in camptothecin chemistry leading finally to the development of several more active and water-soluble derivatives in 1990s. Two of them have been already commercialized as topotecan (**4**, Hycamtin) [4] and irinotecan (**5**, Camptosar, CPT-11) [4] by GlaxoSmithKline and Pharmacia (currently Pfizer), respectively (Fig. 22.2). These drugs with combined annual sale over $600 million in 2010 [evaluatepharma.com] are currently important anticancer medicines in the treatment of metastatic colorectal, primary colon, and metastatic ovarian cancers [4, 7].

A number of other newer-generation camptothecin derivatives, such as belotecan **6** [8–11] gimatecan **7** [12–15], karenitecin **8** [16–19], rubitecan **9** [20–23], silatecan **10** [24, 25], SN-38 **11** [26], exatecan **12** [27], lurtotecan **13**, [28–30], homocamptothecin **14** [31–33], and diflomotecan **15** [34] (Fig. 22.3), are at various stages of clinical trials. Some of them exhibited high activity toward particular cancer types or better formulation/usage characteristics, but none left the clinical trial stage at present [4, 7] (vide infra). Another important area of the camptothecins research involves the design of new formulation of camptothecin and

its derivatives, providing the drugs with beneficial therapeutic profile, e.g., extended stability or higher solubility, better pharmacokinetics, or reduced side effects. Typical strategies employed to meet these goals include the use of the dedicated camptothecin carriers such as liposomes or microemulsion [28–30, 35, 36] or nano-sized biohybrids [37], particles [38–40], or drugs nanocrystals [41, 42]. Sophisticated prodrugs of camptothecin with drug covalently bound to the polymeric matrix resulted in the development few active systems, from which some entered into clinical investigation [43–46].

The early developments of CPT research are the subject of authoritative reviews by Wall and Wani [2, 47–51], Hutchinson [3, 52], and Oberlies et al. [53], whereas newer research, including total synthesis and chemical modifications is covered in reviews by Yang [54], Nessler [55], Hecht [56], Zu [57], Du [58], and Dallavalle et al. [59]. Clinical use of camptothecins is a subject of excellent reviews of Verweij [4], Simanek [60], Zunino [61], and a dedicated monograph [7]. Valuable source of chemical data of naturally occurring camptothecins is *Encyclopedia of Alkaloids* [62].

2 Occurrence and Isolation

CPT was initially isolated from the tree *Camptotheca acuminata* (Nyssaceae, common name *happy tree*) which is native of populated warm areas of southwestern provinces of China such as Szechwan, Yunnan, and Kwangsi. This plant is also cultivated in Taiwan, India, and California [50, 62–65]. CPT and related alkaloids comprising mainly simple hydroxylated or methoxylated derivatives or glucosides (Table 22.1) have been found in 12 other plant species belonging to unrelated orders of angiosperms. Among them only Indian *Nothapodytes foetida* Wight, Sleumer (formerly *Mappia foetida*, Miers) [66–71, 85], and *Nothapodytes nimmoniana* [72] constitute another important source of the alkaloid. Other species include *Ervatamia heyneana* (Apocynaceae) [73, 74], *Merrilliodendron megacarpum* [75], *Mostuea brunonis* Didr (Gelsemiaceae) [76], *Ophiorrhiza filistipula* [77], *O. liukiuensis* [78], *O. mungos* [79, 85]*, O. pumila* [80–82], *O. trichocarpon* [83] (Rubiaceae), and *Pyrenacantha klaineana* (Icacinaceae) [84]. Representative examples of camptothecins producing plants and their characteristics are given in Table 22.1.

Besides camptothecines, structurally related (having the same tetracyclic 11*H*-indolizino[1,2-b]quinoline-9-one core) alkaloids such as 18,19-dehydro-CPT **16**, mappicine **17** [86], nothapodytine, A and mappicine ketone **18** [87] (Fig. 22.4) and their hydroxylated or methoxylated derivatives and glucosides were isolated from *Nothapodytes foetida* (Icacinaceae) [65, 71, 76, 78, 81, 82].

Interestingly, CPT and its derivatives have recently been identified as metabolites of various entophytic fungi, e.g., *Fusarium solani* (from *Apodytes dimidiata*, E. Mey. ex Arn, Icacinaceae) [88], *Entrophospora infrequens* (from *Nothapodytes foetida*) [89], and others [90], providing an alternative to the plant cultures for their biotechnological production.

The isolation of CPT from plant material remains the major source of this alkaloid for the pharmaceutical industry (with estimated production ca. 1,000 kg annually) [91]. For this purpose *Camptotheca acuminata* is still in use. Typically,

seeds of this tree contain ca. 0.3% and bark 0.2%, whereas leaves yield up to 0.4% of CPT. The bark of *C. acuminata* contains also ca. 0.05% of 10-hydroxycamptothecin. Another important plant source of CPT is the bark and stem wood of *Nothapodytes foetida* (typical content of alkaloid 0.1–0.3% of dry plant material). Isolation of CPT involves the use of classical solvent extraction with nonpolar solvent for removal of fat material, followed by more polar solvent (ethyl acetate, acetone, methanol, or ethanol) for isolation of alkaloids. Typical yield of the solvent extraction lies in the range of 0.1% [92]. In order to improve the efficiency of the isolation (higher yield, lower solvent consumption, and time reduction), several other isolation techniques have been tested and critically compared by Fulzele [93]. Extraction of CPT and 9-methoxy-CPT from *Nothapodytes foetida* by employing either stirring or Soxhlet extraction, ultrasonic extraction, or microwave-assisted extraction (MAE) showed that the MAE gave the highest yield in the shortest time (typical time applied 3 min) [93]. Similarly, favorable results were reported by Yang et al. by using homogenate extraction technology for isolation of CPT and 10-hydroxy-CPT **32** from *Camptotheca acuminata* leaves [94]. Recently, imidazolium-based ionic liquids as extracting material in combination with MAE techniques were used for efficient and rapid isolation of CPT and 10-hydroxy-CPT from *Camptotheca acuminata* [95]. Analytical chemistry, isolation, and chromatographic determination of CPT and the corresponding semisynthetic drugs is a subject of a review by Aldaz et al. [96]. Chromatographic profiling of CPTs and their metabolites by combined techniques such as HPLC-ESI-MS/MS, UPLC-MS or HPLC-SPE-NMR have been reported recently [97, 98].

3 Chemistry of Camptothecin

Despite considerable activity and a unique mechanism of action, CPT exhibits several undesired properties which hampered its use in therapy. Firstly, CPT is very low water soluble complicating administration of the drug. Another problem associated with parent CPT is the α-hydroxylactone ring (ring E) opening under physiological condition, leading to the carboxylate open form **2** of CPT. The carboxylic acid **2** or its sodium salt **3**, although soluble, has much lower anticancer potency as compared with CPT. Moreover, this ionic form preferentially binds to the human serum albumin (HSA), lowering the concentration of the accessible drug. High toxicity of CPT and its sodium salt (which resulted in suspension of its trials in the 1970s) adds to the unfavorable profile of CPT [4, 7]. All of these drawbacks were addressed in an intense research activity for the last 30 years. This led eventually to deeper understanding of the structure–activity relationship (SAR), resulting in a development of two very active and soluble, semisynthetic anticancer drugs – topotecan (**4**) and irinotecan (**5**) – as well as several other being currently investigated (**6**–**15**). In line with SAR studies, chemistry of CPT, especially its transformation into related drugs **6**–**15** and the total synthesis, received much attention. These two aspects are briefly described here with the emphasis on the recent progress in the field. For more detailed view, see the reviews [56, 58, 59].

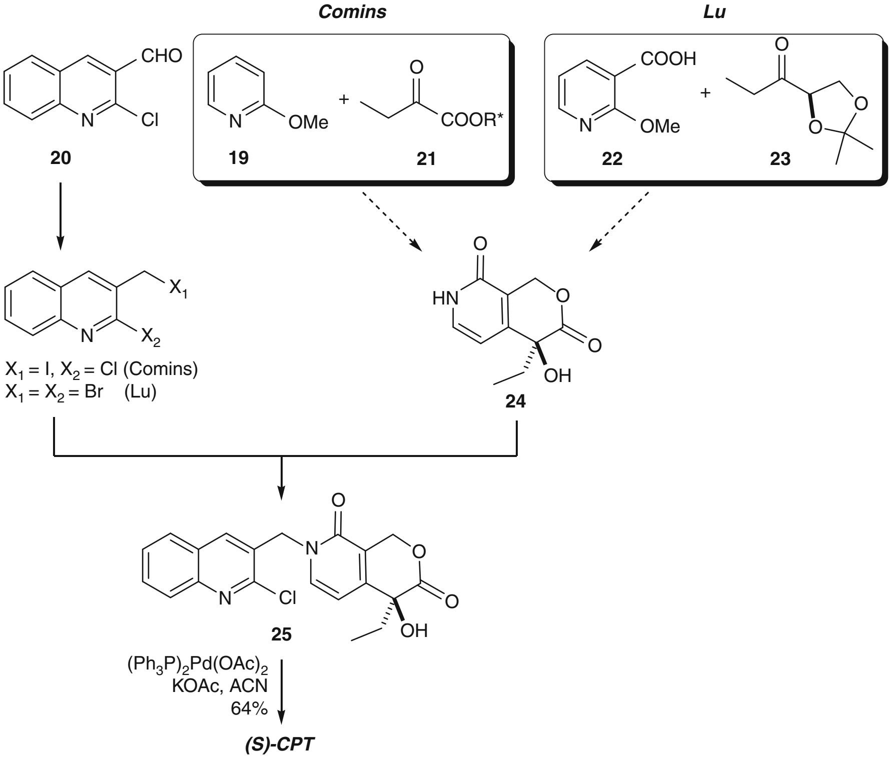
3.1 Total Synthesis of CPT and Semisynthesis of CPT-Related Drugs

Although isolation from plants still remains the major source of camptothecin, limited natural supply and environmental issues led to an enormous progress in its total synthesis since 1971 when the first syntheses of racemic CPT had been reported by Stork and Schultz [99] and Danishevsky [100]. Currently, this alkaloid as well as its derivatives can be efficiently synthesized in a highly stereoselective fashion from simple starting materials in the synthetic sequences typically not exceeding ten steps [58]. Generally, the most popular synthetic strategies are based on C-ring construction, providing CPT from various AB- and DE-ring precursors. The ring closure step usually involves the most broadly applied Friedlander condensation, cascade radical cyclization, Michael addition, or Diels–Alder cycloaddition, although palladium-catalyzed Heck-type reactions become recently very popular [101, 103].

Comins and Nolan adopted their six-step synthesis of racemic CPT [102] to the asymmetric synthesis of **1**, starting from the two commercially available heterocycles, namely, 2-methoxypyridine (**19**) and 2-chloroquinoline-3-carbaldehyde (**20**). The chirality is introduced in the addition of chiral ketoester **21** (esterified by commercially available *trans*-2-(α-cumyl)cyclohexanol which served as a chiral auxillary) to the lithiated pyridine **19**. Further one pot elaboration of the addition product gave key lactone **24** (DE-ring fragment) in 60% yield and 93% ee after recrystallization. Palladium-catalyzed (Heck reaction) intramolecular C-ring formation in **25** has been employed to complete the synthesis (Scheme 22.1). The yield of CPT starting from 2-methoxypyridine was ca. 12% [101]. Similarly, convenient asymmetric synthesis of CPT and SN-38 (**11**, 7-ethyl-10-hydroxy-CPT – active form of irinotecan metabolic activation in vivo) has been recently reported by Luo and Lu. In this case, however, nicotinic acid **22** and chiral glyceraldehyde (**23**) have been used as building blocks for the preparation of DE-ring synthon **24**. Again, Heck reaction has been used for the final C-ring closure of **25**. This synthesis furnished CPT in 14% yield (over 11 steps) and very high 99.9% ee (Scheme 22.1). Non-chromatographic purification of all intermediates is an additional advantage of this procedure [103].

More practical, catalytic asymmetric synthesis of key chiral DE-ring lactone **24** has been reported by Fang and coworkers from Glaxo by applying Sharpless asymmetric dihydroxylation reaction [104]. Other examples of catalytic enantioselective syntheses of CPTs are reviewed by Du in [58], whereas older approaches to racemic CPT are the subject of review by Hutchinson [52].

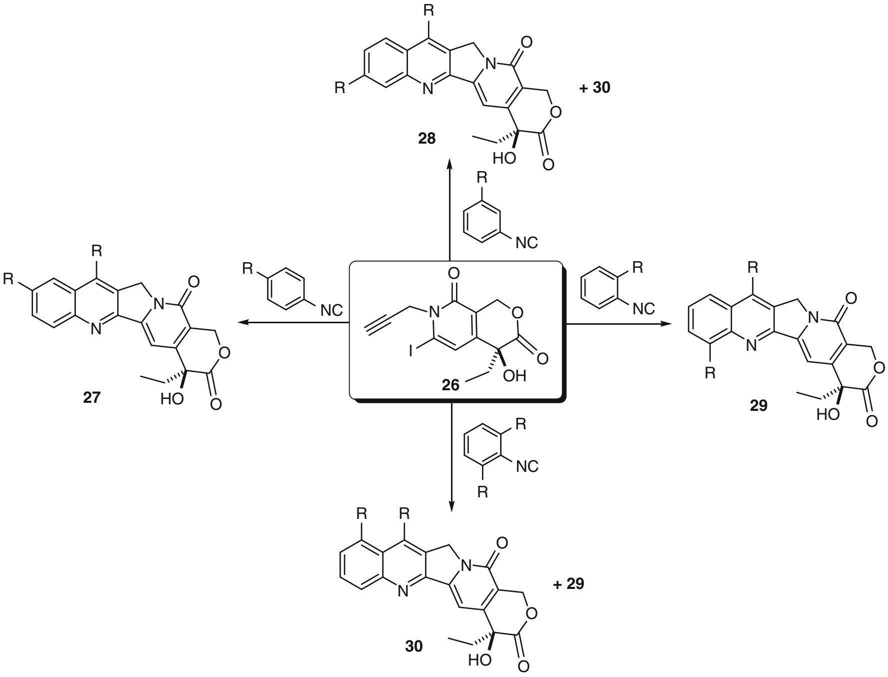
One of the most robust and versatile strategies for the synthesis of CPT and related alkaloids as well as their unnatural analogues has been developed by Curran et al. [105–107]. The synthesis is based on a cascade radical cyclization leading to the C and B rings through 4 + 1 radical annulation reaction of isonitriles (precursors of A ring) with D- or DE-ring precursors (preferentially *N*-propargyl-iodopyridone **26**, Scheme 22.2). This cascade radical annulation



Scheme 22.1 Shortest approach to asymmetric total synthesis of camptothecin by Comins and Lu

approach was applied initially to the synthesis of racemic CPT, followed by asymmetric total synthesis of CPT, (*S*)-mappicine **17**, and mappicine ketone **18** [106]. Furthermore, its generality has been demonstrated in the synthesis of a number of CPT analogues **27–30** difficult to synthesize by other method [107]. This strategy has also been extended by Curran to the parallel, combinatorial synthesis of 115-membered library of homosilatecans [108] and 560-membered library of mappicine ketone analogues [109]. One of homosilatecan library member – DB-67 (**10**) – has recently entered Phase I clinical trial for cancer chemotherapy [24].

Although total asymmetric syntheses of topotecan **4** and irinotecan **5** as well as homocamptothecin **14** have been reported [58], these drugs can be preferentially prepared by short semisynthetic routes starting from natural CPT. For example, SmithKline Beecham developed a synthesis of topotecan **4** from 10-hydroxy-CPT **32** [110]. This intermediate is obtained with 91% yield in two-step reduction–oxidation process involving an initial Pt-catalyzed partial hydrogenation to tetrahydroquinoline intermediate **31** and its subsequent oxidation with the use of PhI(OAc)$_2$ [110]. Condensation of 10-hydroxy-CPT with formaldehyde and



28

27

26

29

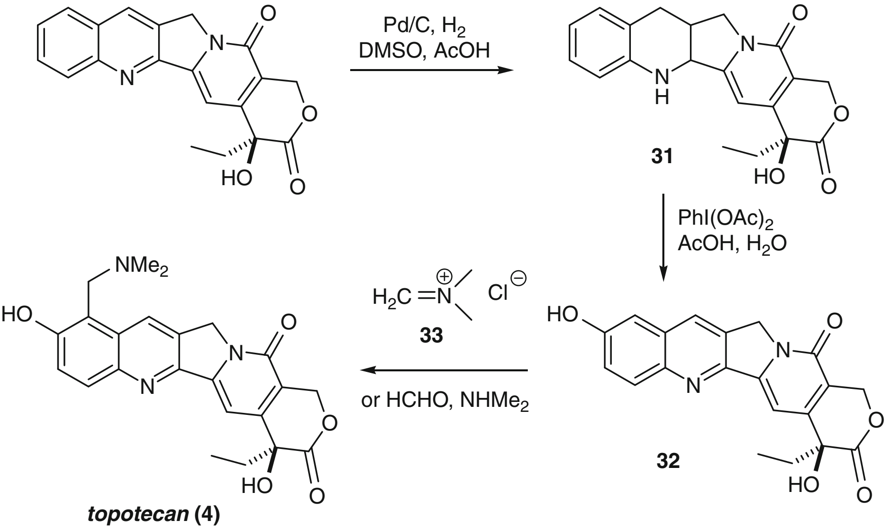
30

Scheme 22.2 Curran's modular strategy of CPTs synthesis

dimethylamine or more efficiently with *N,N*-dimetylmethyleneiminium chloride **33** (minimal formation of undesired 10-hydroxymethyl by-product) [111] gave topotecan **4** with good yield (Scheme 22.3).

Semisynthetic route to irinotecan **5** was developed by Sawada group in 1991 [112, 113]. The key step of this route is based on the addition of ethyl radical (generated in situ by the reaction of propanal, $FeSO_4$, and H_2O_2 in aqueous acidic medium) selectively in the 7-position of CPT. This represents a Minisci-type reaction [114] involving carbon radical addition to electron-deficient heteroaromatics such as pyridine and quinoline, which is especially useful in modification of position 7 in CPT. Subsequent oxidation of 7-ethyl-CPT **34** to the corresponding *N*-oxide **35** followed by photochemical hydroxylation led to 7-ethyl-10-hydroxyCPT **11** (SN-38) with overall yield 49%. Acylation of **11** with [1,4′] bipiperidinyl-1′-carbonyl chloride in pyridine or by 1,4′-bipiperidine/$COCl_2$ gave irinotecan **5** with 80% yield (Scheme 22.4) [112, 113, 115].

Other active derivatives of CPT such as silatecan (**10**), rubitecan (**9**), gimatecan (**7**), belotecan (**6**), and 9-aminocamptothecin (**36**) were also synthesized from CPT with the aid of rather simple chemistry which is summarized in Scheme 22.5. In the case of 7-position modification Minisci type reaction is typically applied with subsequent functional group modification such as in the synthesis of belotecan **6** or gimatecan **7** [116, 117]. A unique addition a silyl radical



Scheme 22.3 Semisynthesis of topotecan

to heteroaromatic ring of CPT served as a direct but rather low-yielding route to silatecan (**10**, yield 20%, in addition to 50–60% unreacted CPT) [118]. Rubitecan **9** and the corresponding 10-amino-CPT **37** as well as 10-hydroxy-9-nitro-CPT were prepared by nitration and reduction of the parent alkaloid or 10-hydroxy-CPT [119–123]. Semisynthetic approach to homocamptothecin **14** has also been reported as well as its total asymmetric synthesis [58, 124].

3.2 SAR Studies

Low solubility of camptothecin as well as instability of the hydroxylactone ring (which undergoes opening under physiological condition to the hydroxyacid **2**) [125, 126] was the main motivation for undertaking an extensive research focusing on the development of more soluble, stable and more active CPT derivatives. Large number of CPT derivatives and biological screening data allowed to identify the detailed SAR map of CPT (Fig. 22.5). This eventually led to the development of a number of clinically useful derivatives **4**–**15** mentioned above.

Generally, modification of A and B rings (quinoline moiety) at the C-7, C-9, and C-10 enhances anticancer activity. Depending of the character of substituents, water-soluble derivatives can be obtained by introduction of polar groups such as in topotecan **4**, irinotecan **5**, or lurtotecan **13**. On the other hand, the introduction of highly nonpolar group at C-7 such as alkylsilyl (e.g., silatecan **10**) resulted in retaining the desired biological activity and enhanced stability toward hydrolysis. These lipophilic derivatives can be preferentially incorporated into lipid bilayer vesicles, offering an additional way of administration. Substituents at C-11 and

C-12 are only rarely well tolerated [119, 127–130]. For example, seminal work of Wani et al. reported that among many modifications at these positions, only 11-fluoro and 11-cyano derivatives retained considerable activity. Interestingly, introduction of 10,11-(methylenedioxy) or 10,11-(ethylenedioxy) moiety gave derivatives displaying much higher activity compared to the parent CPT. In contrast, installation of two separate methoxy groups at C-10 and C-11 led to lowering of the activity. Similarly, linking positions 7 and 9 led to new hexacyclic ring which

in combination with small substituents at C-10 and C-11 (such as in exatecan **12** with Me and F at C-10 and C-11, respectively) resulted in superior antitumor activity exceeding the potency of topotecan **4** in some cancer types. Very favorable modification of CPT involves simultaneous introduction of two different groups in the positions C-7 or C-9 and C-10, such as in topotecan **4** or irinotecan **5** [131].

Biochemical studies provided an evidence that stabilization of topoisomerase I–DNA binary complex by CPT derivatives depends on the size of substituent at C-10 in CPT analogue. Small group shows little effect, whereas derivatives with larger group cannot efficiently stabilize the binary complex [130]. This observation contrasted with high activity of irinotecan having a large 4-(1-piperidyl)-1-piperidincarbamate group at C-10. Further studies led to the discovery that irinotecan serves only as a prodrug of 7-ethyl-10-hydroxy-CPT which is the actual active form of the drug [132].

Modifications of C and D ring of camptothecin by introduction of substituents in position C-5 (C ring) or C-14 (D ring) are limited due to difficult synthesis of these analogues. Nevertheless, existing studies clearly show the lack of useful activity of

such modified derivatives [133–136]. Some exceptions were reported when modification at C-5 was combined with introduction of hydroxy or nitro group in A ring [137]. There are only two reports demonstrating equal to CPT potency of 5-ethylidene-CPT **38** against P388 cells [138] and good in vitro activity of 2-fluoroethyl esters of CPT **39** [139]. Similarly, homologated C ring as well as C-nor-4,6-CPT (lack of C ring) is inactive, presumably due to the loss of planarity of such compounds [140, 141]. 4-Deaza analogue of CPT was found to be approximately 60-fold less efficient as topoisomerase I inhibitor [142]. Contrary, reasonable activity exhibited 14-azacamptothecin **40** [143].

The α-hydroxylactone ring E was for a long time considered as an essential part responsible for the activity of CPT while being concurrently an instable part of the molecule easily, undergoing of hydrolytic lactone ring opening [125, 126]. α-Hydroxyacid **2** as a product of this equilibration occurring under physiological condition retains about 10% of CPT activity. For this reason most of the performed studies were undertaken to identify the factors increasing the stability of hydroxylactone ring or providing its stable and active equivalents. Replacing the lactone with more hydrolytically stable lactam, thiolactam, carbinol lactam or imide functionality has been reported by Hertzberg. Unfortunately none of these derivatives showed any activity as topoisomerase I inhibitor [142, 144].

Much more successful approach based on homologation of E ring by replacing α-hydroxylactone with seven-membered *β*-hydroxylactone was first reported by Lavergne [145, 146]. So-called homocamptothecin **14** displayed high activity and enhanced stability toward ring opening, served as a lead compound for designing of series of promising drug candidates [31–34]. Among them 10,11-difluorohomocamptothecin (**15**, diflomotecan) entered Phase I clinical trials [34]. Lipophilic 7-*tert*-butyldimethylsilylhomocamptothecin (analogue of DB-67) developed by Curran exhibited high stability both in serum and in a buffer [118, 147].

Derivatization of 20-hydroxy group increases stability of the lactone ring in CPTs by elimination of intramolecular hydrogen bonding between the hydroxy and the lactone carbonyl groups [148] as well as by increasing of sterical hindrance of the carbonyl group. A number of CPT esters have been prepared by using structurally diverse acids. They show increasing stability of the lactone ring as expected and in some cases higher than CPT activity [149–152]. SAR studies of alkyl esters of CPT have also been published [153].

The *S* absolute configuration at C-20 is another prerequisite for keeping the bioactivity of all camptothecins, *R*-enantiomer is inactive and racemic CPT exhibits much lower potency [127]. Replacement of the 20-hydroxy group, with hydrogen, amino group or halogen atom resulted in significantly weaker activity although some inhibition of topoisomerase I in vitro has been observed for such derivatives [142, 144, 154, 155].

It is worth to note that there are some examples of CPT analogues with non-lactone E ring possessing appreciable cytotoxicity. Hertzberg prepared two CPT analogues **41**–**42** which exhibited remarkable cytotoxicity but were not inhibitors of topoisomerase I, suggesting an alternative mode of biological action in this case [144]. Contrary, luotonin A **43** is a structurally related alkaloid isolated from the Chinese herbal medicinal plant *Peganum nigellastrum*, and despite absence of lactone ring E, either exhibits cytotoxicity against the murine leukemia P-388 cell line and stabilizes the human DNA topoisomerase I–DNA covalent binary complex by way similar to the CPT [156]. Active non-lactone analogues of CPT were also obtained by Lavielle et al. [157].

43 (luotonin A)

Detailed discussion of SAR of camptothecin is a subject of reviews [153, 158–160]. Some computational approaches to quantitative structure–antitumor activity relationship (QSAR) have also been reported [161].

An important area of medicinal chemistry of CPT is design of its prodrugs and conjugates for enhancing solubility, lowering toxicity, and improvement of pharmacokinetics and bioavailability. Specific examples of such drugs and their characteristics are given in biological activity section. The conjugation of CPT is typically completed by installation (typically esterification) of a dedicated linker undergoing enzymatic hydrolysis. Preferential site for the covalent attachment of CPT is 20-hydroxyl group (this also providing an additional stability of lactone ring of conjugate). Less common site of conjugation involves the use of polar substituents present in the quinoline ring of CPT and its derivatives.

4 Biosynthesis of Camptothecin

All monoterpenoid indole alkaloids are synthesized from strictosidine **44**, which is a general biosynthetic intermediate formed by enzymatic condensation of tryptamine with secologanin [162]. Recently, cDNA coding strictosidine synthase (E.C. 4.3.3.2) was isolated from *O. pumila* and expressed further in *E. coli*. The enzyme has been characterized regarding its substrate specificity toward a number of tryptamines and activity regulation [163]. In another work distribution of strictosidine activity in *O. pumila*, tissues were shown to correlate with the pattern of respective mRNA expression [164].

Strictosidine **44** is a precursor of strictosamide **45** which has been proposed as a key precursor in biosynthesis of CPT in *C. acuminata* on the basis of experiments with the ^{14}C and ^{3}H-labeled substrates carried out in the late 1970s [165] (for details of the labeling experiments, see also a review [52]). Strictosamide is a product of intramolecular cyclization of strictosidine. It is not clear whether this is an enzymatic process (no specific enzyme was identified so far) since strictosamide can be formed easily nonenzymatically under basic conditions. For example, complete conversion of strictosidine into strictosamide has been observed at pH 11 within 10 min at room temperature [164]. Unfortunately, further steps of CPT biosynthesis remained speculative because no specific enzymes and all intermediates were isolated. Two of the key postulated metabolites of the final stage of CPT biosynthesis were not isolated until 1989 when Haginiwa found pumiloside **47** and deoxypumiloside **48** in *Ophiorrhiza pumila* [166]. The presence of pumiloside **47** in *Camptotheca acuminata* was also confirmed by Westley one year later using both X-ray and NMR techniques [167]. Another problem was associated with absolute configuration of deoxypumiloside **48**; the expected (3*S*)-enantiomer (the same configuration at C-3 as its precursors strictosidine and strictosamide) has not been found; instead (3*R*)-epimer of **48** has been identified in regenerated *O. pumila* callus culture [168].

Scheme 22.6 Biosynthesis of camptothecin

The plausible biosynthesis of camptothecin is outlined in Scheme 22.6. Strictosamide **45** may undergo oxidative cleavage of double bond giving diketo derivative **46** which provides pumiloside **47** after intramolecular aldol condensation (similar reaction sequence executed by chemical transformation was reported by Hutchinson [169]). Reduction of quinolone part in **47** afforded **48**, which forms CPT after double-bond rearrangement and hydrolytic cleavage of glucose.

This biosynthetic proposal became an indirect evidence by Brown et al. who demonstrated a biogenetically patterned synthesis of CPT and 20-deoxycamptothecin starting from strictosidine/vincoside. The complete route from **44** to racemic CPT has been completed by chemical transformation involving all of the postulated intermediates in the biosynthesis scheme [170]. Other biomimetic synthesis of CPT has also been reported [171].

Interesting studies on the early stages of CPT biosynthesis using in silico modeling (Atomic Reconstruction of Metabolism software) and in vivo tracer experiments with [1-^{13}C]glucose were conducted by Saito et al. The results have clearly shown that the monoterpene secologanin part is biosynthesized via 2C-methyl-D-erythritol-4-phosphate pathway but not via mevalonate route as postulated earlier. The quinoline part produced from tryptophan was suggested to be of shikimate origin [172].

The chemotaxonomical analysis of the distribution of CPT and their metabolites among plant genus suggests that the genes encoding the enzymes involved in CPT biosynthesis evolved early during evolution. The pool of the respective genes was probably not lost during evolution but might have not been expressed during a certain period of time and became active again at some later point. An interesting issue of self-resistance mechanism of CPT-producing plant was addressed by Saito. On the basis of observation that recombinant topoisomerase I from *O. pumila* expressed in yeast was resistant to CPT, he hypothesized that these plants may possess camptothecin-resistant topoisomerase I. In fact, aminoacid sequence analysis of *O. pumila* topoisomerase I revealed that a highly conserved residue adjacent to the catalytic part has been mutated [163, 173]. Similar mutations have been observed in all other CPT-producing plants as well as in CPT-resistant leukemia cancer in human [173]. Coevolution of CPT biosynthesis and self-resistance to CPT in plants were recently reviewed [174].

5 Biological Activity of Camptothecins

The most prominent activity of CPT and its derivatives is the inhibition of topoisomerase I which is a molecular basis of their anticancer properties. This specific mode of action of CPT has been proposed in the 1980s [5, 6, 175, 176], leading to reinvestigation of these alkaloids in medicinal and biological chemistry. DNA topoisomerases are essential enzymes present in all nucleated cells responsible for management of topology of DNA strands during replication, RNA transcription, recombination, repair, as well as chromatin assembly and remodeling [4, 177].

Topoisomerases were roughly classified as type I or type II depending of the type of DNA breakage mechanism. Type I breaks only one strand of duplex DNA giving 3′-phosphotyrosine intermediate **49** (so-called cleavable complex) in contrast to topoisomerases of type II which are able to break both strands of duplex DNA with the formation of a pair of 5′-phosphotyrosine covalent intermediates. In human topoisomerase I hydroxy group of Tyr^{723} residue is used for covalent modification of DNA. More specifically, the overall mechanism of enzymatic action involves four distinct steps: (1) DNA topoisomerase I binding; (2) breaking the single strand of DNA by reversible transesterification resulted in replacement of 5′-oxygen of phosphodiester bond for oxygen of enzyme Tyr^{723} (binary complex **49** formation); (3) DNA relaxation by single-strand passage around the unbroken strand; and (4) religation of cleaved DNA and concomitant release of the enzyme. The characteristics of human topoisomerase I and the details concerning its mechanism of action are given in a review [4, 177]. CPT non-covalently stabilizes the cleavable complex of DNA topoisomerase I, preventing the subsequent religation step (in this context the enzyme itself is a DNA-damaging agent). Stabilization of the cleavable complex **50** is not yet sufficient for the promotion of cell death mainly due to the complex reversibility. The lethal effect is a consequence of interaction between moving replication fork (or transcription process) and the CPT-stabilized cleavable complex **50**. This results in the formation of a double-strand break located at the fork and irreversible arrest of DNA replication in the S/G2 phase of cell cycle, leading to the apoptosis [178] (so-called fork-collision model). It is worth to note that cells in the S-phase division are up to 1,000-fold more sensitive to topoisomerase I inhibitors than in G1 or G2/M phases, so they are considered as S-phase-specific cytotoxic agents [179].

Interestingly, CPT does not bind to topoisomerase I and only weakly to B-DNA under physiological conditions [5], so both biomolecules and CPT are needed to form stable ternary complex **50**. Additional evidence supporting such mechanism comes from the observation of resistance of cell lines toward CPT which have specific mutations of enzyme [180–182] (for medical consequences of CPT resistance, see [4, 183]). Similarly, deletion of gene coding topoisomerase I from yeast (*Saccharomyces cerevisiae*) resulted in full resistance of viable cells to CPT, with restoration of sensitivity to CPT after expression of human or yeast topoisomerase I [184, 185]. The schematic mechanism of CPT action is given in Fig. 22.6.

Detailed mechanism of CPT stabilization of DNA–topoisomerase I complex is not perfectly understood and was a subject of three different proposals by Pommier [186, 187], Hol [188–190], and Kerrigan and Pilch [191]. Pommier suggested the intercalation of CPT in the binary complex in a manner capable of maximizing both stacking interaction and hydrogen bond formation to specific amino acids and DNA. Hol postulated stacking arrangement of CPT and +1 purine which flips out the DNA helix. Kerrigan and Pilch proposed a model of intercalation in which lactone E ring of CPT is located within minor groove interacting additionally via hydrogen bonding with binary complex. All of these proposals are summarized in a review [55–57].

Currently, the structure of the ternary complex received stronger experimental evidence by Staker et al. who reported X-ray crystal structure of human topoisomerase I covalently attached to duplex DNA and topotecan [192]. The drug intercalated into duplex DNA-enzyme complex and characteristic features are base-stacking interaction with both upstream and downstream base pairs and the use of only single Asp^{533} for hydrogen bonding with topotecan. Moreover, the quinoline part of the drug with C-7, C-9, and C-10 carbon atoms, located in the vicinity of the major groove of DNA, offers a space for accommodation of the substituents at these positions, which do not disrupt the activity of such modified CPT derivatives, in agreement with reported SAR studies. Interestingly, the report suggests also the possibility of intercalation of open carboxylate form of CPT in the pocket in the fashion similar to the lactone, although it was shown that carboxylate **2** does not bind to the binary complex **49** in solution [144].

Phase I clinical trial of CPT began in the 1970s, after demonstration of its high activity in preclinical studies. For this purpose, water-soluble sodium salt of CPT has been used intravenously. Although short-lasting remissions were observed in 5 out of 18 patients with primarily gastrointestinal cancers, further Phase I and Phase II trials in the USA did not confirm drug efficacy. In contrast, there was a single large trial in the People's Republic of China involving ca. 1,000 patients demonstrating a positive response (but caution is needed for its interpretation). (assumed to be the effect of poor solubility of drug) led to the discontinuation of trials [4, 193–195]. Almost 20 years later, water-soluble CPT derivatives topotecan and irinotecan were registered as anticancer drugs and approved for treatment of patients with cisplatin-refractory ovarian cancer and small-cell lung cancer (SCLC), after the failure of first-line chemotherapy (topotecan) and metastatic colorectal cancer (irinotecan) [4].

5.1 Irinotecan

Irinotecan (**5**) is a water-soluble derivative which is actually a prodrug of active 7-ethyl-10-hydroxycamptothecin (SN-38) formed by hydrolysis of dipiperidine carbamate residue at C-10. This active metabolite is ca. 100–1,000-fold more cytotoxic in vitro as compared with the irinotecan itself. Clinical use of irinotecan comprises typically the therapy of advanced or metastatic colorectal cancer [4, 7, 196–200] and gave in Phase II trial response rates of 10–35% independent of the applied schedule with median remission duration and median survival time 6–8 and 8–13 months, respectively. Further Phase III studies showed higher 1-year survival rate in patients refractory to previous treatment with 5-FU (36% vs. 14% of control group ($P < 0.01$)) [201] and similar survival advantage in patients with previously treated advanced colorectal cancer (1-year survival rates were 45% for irinotecan and 32% for 5-FU, respectively ($P < 0.05$)) [202]. Other Phase II trials with single-agent irinotecan encompassed small-cell lung, non-small-cell lung cancer (32–47% overall response rate), leukemia/lymphoma (17–38% response rate), as well as gastric, pancreatic, breast, and other cancer types (lowest efficacy) [203–206]. Apart from single use of irinotecan, there are a number of clinical studies showing beneficial effect of the use of irinotecan with combination of another anticancer drugs [207]. For example, first-line treatment of metastatic colorectal cancer by the combination of irinotecan, 5-fluorouracil (5-FU), and leucovorin (folinic acid) yielded a significantly higher remission rate, longer progression-free survival, and median survival [198, 208–210]. Similarly effective was a combination of irinotecan with bevacizumab which in the first-line regimen resulted in 67% of the overall response rate and median and overall survival of 12.3 and 23.7 months (95% CI), respectively [211].

Especially favorable irinotecan and platin-based drug combination often shows synergistic potency toward many tumors as it was demonstrated in many Phase II and III studies [212–220]. For example, in first-line chemotherapy of extensive SCLC, the improvement in the 1-year survival rate was 60% in comparison with conventional treatment with etoposide and cisplatin (40%) [221]. Other Phase III or II trials evaluated combination of irinotecan with etoposide [222–224], cetuximab [209, 225–229], docetaxel [230–233], mitomycin-C [234–238], and paclitaxel [239–241]. This topic has been reviewed in more detail in reviews [4, 7, 242, 243].

Pharmacology of irinotecan is very complex [4, 205, 244] depending on many enzymatic and protein systems, individual genetic factors, and being complicated by the fact that this drug exists in an equilibrium of the active lactone and an inactive carboxylate forms. SN-38 is detoxified in the liver by conjugation with glucuronide catalyzed by polymorphic enzyme uridine-diphosphate glucuronosyltransferase 1A1 (UGT1A1). Individual genetic profile of UGT1A1 was shown to be responsible for the disposition, efficacy, and toxicity of the drug [245–249].

5.2 Topotecan

Topotecan (9-[(dimethylamino)methyl]-10-hydroxy-CPT, **4**) is the second approved semisynthetic, water-soluble CPT derivative. Similarly to irinotecan, topotecan undergoes equilibration at physiological pH, giving only small fraction of active lactone form and most of the introduced dose as inactive carboxylate [250, 251] (tartaric acid is used in new parenteral formulation to prevent the lactone opening [252]).

Topotecan is currently approved in many countries for the second-line treatment of metastatic ovarian cancer after failure of initial or subsequent chemotherapy as well as for the treatment of patients with chemotherapy-sensitive SCLC after failure of first-line chemotherapy [4, 7, 253–258]. Other clinical use of topotecan as single drug in various schedules of administration has been evaluated in therapy of cervical, uterine, and brain cancers among others [259–261]. An advantage of topotecan is the possibility of its oral administration, which in Phase III trials was equally efficient in the treatment of SCLC in comparison to intravenous drug dosage [262]. Topotecan was also used in a combination with many other anticancer drugs such as cisplatin [263], carboplatin [264], taxol [265], amrubicin [266], or cyclophosphamide [267]. Despite a number of works evaluating such regimens, only few reported clear therapeutic benefits [265–268]; typically higher toxicity and lack of major improvement were observed. Topotecan pharmacology and toxicity are discussed in reviews [4, 205].

5.3 Other CPT-Related Anticancer Drugs

Belotecan ([7-(2-isopropylamino)ethyl]-CPT, Camtobell®, **6**) is a semisynthetic 7-substituted CPT approved in South Korea. Phase II clinical trials of single-agent belotecan against SCLC showed its remarkable efficacy (OR 24–42%) [8, 9]. Even more favorable results were reported for the treatment of SCLC and recurrent ovarian cancer by the combination of belotecan with cisplatin (OR 70%) and carboplatin, respectively (OR 57%) [10, 11].

The hexacyclic CPT analogue exatecan mesylate (DX-8951f, **12**) is a water-soluble, synthetic derivative with an additional six-membered ring with amino group and a methyl group and fluorine atom at C-10 and C-11, respectively. Exatecan showed superior and broader spectrum of antitumor activity in vitro and in vivo in comparison with other CPT analogues [269–271]. Disappointingly, clinical studies demonstrated only a modest activity against pancreatic, gastric, and metastatic breast cancers [272–275].

Gimatecan (ST1481, 7-*tert*-butoxyiminomethyl-CPT, **7**) is highly lipophilic rationally designed semisynthetic CPT derivative of potent antitumor activity (also against multidrug-resistant cancer), strong topoisomerase I inhibition, stable drug–target interactions, and favorable pharmacological profile [12–15, 276]. Very long biological half-life of 77 h and presence of only lactone form are additional advantages of this drug candidate. Gimatecan showed a high activity in large panel of human tumor xenografts model [12, 14] and entered currently to I and II Phase clinical trials against ovarian carcinoma and pediatric tumors [14, 15, 276].

Next two lipophilic drug candidates include silatecan (7-*tert*-butyldimethylsilyl-10-hydroxy-CPT, DB-67, **10**) [24, 25, 277] and karenitecin (7-[(2-trimethylsilyl)ethyl]-CPT, **8**) [16–19]. These newer generation camptothecin analogues contain trialkylsilyl group in position 7 (Fig. 22.3) and offer enhanced stability in blood and cell penetration, improved pharmacokinetics as well as increased lactone stability. Silatecan exhibited activity against the growth of in vivo-like histocultured human tumors and xenografted human tumors [25]. The results of clinical studies are not yet available. On the other hand, karenitecin was shown to be effective in Phase II trial for treatment of melanoma [16, 19], especially in combination with valproic acid [17] and in NSCLC [18].

Lurtotecan (GL147211C, 7-[(4-methylpiperazine)methyl]-10,11-(ethylenedioxy)-CPT, **13**) is another example of water-soluble, synthetic derivative of CPT bearing a dioxalane moiety between C-10 and C-11 [28–30, 278]. The antitumor activity of lurtotecan in Phase II trial was moderate in breast cancer patients and minimal in non-small-cell lung cancer patients, and no clear responses were obtained in colorectal patients [278]. Better results were observed with the use of liposomal lurtotecan formulation. Such prepared drug exhibited superior levels of activity and higher therapeutic index in preclinical models [279, 280]. Its clinical activity has also been confirmed in treatment of epithelial ovarian cancer [28].

Rubitecan (9-nitro-CPT, **9**) is a poorly water-soluble CPT analogue (formerly used for the preparation of 9-aminocamptothecin) which can be administrated orally, transdermally, or by inhalation with the use of liposomes as carriers [20–23]. It is not clear whether rubitecan acts itself as a drug or is a prodrug of 9-aminocamptothecin (which despite its considerable activity failed in clinical trials) [20]. Preclinical studies of rubitecan demonstrated its activity against broad spectrum of cancer types both in vitro and in vivo human tumor xenograft models. Unfortunately these favorable results were not usually observed in clinical trials [21].

Homocamptothecin (**14**) is an E-ring homologated camptothecin analogue (seven-membered E ring) that exhibited greater lactone stability in plasma compared with other topoisomerase I inhibitors and high activity in vitro studies [31]. Further SAR studies showed that even more potent are fluorinated derivatives of homocamptothecin [33], resulting a in development of diflomotecan

(10,11-difluoro-homocamptothecin, BN80915, **15**). **15** is a potent topoisomerase I inhibitor with enhanced plasma stability and superior preclinical antitumour activity as compared to irinotecan and topotecan [34, 281]. Diflomotecan is also the first homocamptothecin derivative which entered clinical studies. Phase I trial showed its better than other CPT-related drugs toxicity profile and highest oral bioavailability (ca. 70%) as compared with topotecan (30–44%) or lurtotecan (12–21%) [34, 281]. Reports from Phase II studies are not yet available. Several other homocamptothecin derivatives have also been prepared and screened as drug candidates [282–284].

Difficulties associated with CPTs administration, toxicity, and pharmacokinetics were a reason for the development of more favorable alternative forms of their delivery or prodrug systems [35–40]. Delivery of CPT and its derivatives was studied by using liposomes (see also lurtotecan). Examples of such lipid formulations of CPTs in clinical trials include CPX-1 (irinotecan-floxuridine liposome in Phase 1) from Celator Pharmaceuticals [285] and Brakiva® (Topotecan Optisome) liposomal formulation of topotecan from Hana Biosciences [286].

Micellar-drug formulation is another delivery system based on hydrophilic–hydrophobic block copolymers that self-assemble in aqueous solution into micellar particles with a hydrophobic core and a hydrophilic shell. NK012 is an example of micellar formulation of SN 38 (**11**) developed by Nippon Kayaku which is in Phase 1 clinical trial [287–289].

Newer delivery systems use the advantage of nanoscale and include CPT nanocrystals, nanoparticles, or nanobiohybrids. Most of these nano-sized formulations use CPT and were able to demonstrate their higher activity, cellular uptake, stability, and lower toxicity in vitro and in vivo tests as compared with CPT in solution [37–41]. For example, nanosuspension of CPT was compared with topotecan in vitro and in vivo cytostatic efficacy against MCF-7, HCT-8, and PC-3 cell lines using MTT assay and in antitumor activity in vivo against HCT-8 xenograft model. An about six times higher cytotoxicity against cell lines MCF-7 in vitro as compared with that of topotecan was reported, whereas similar level of antitumor potency was observed in vivo for both drugs. The lower toxicity of nano-sized CPT in comparison to that of topotecan was another advantage of this formulation [42]. Similarly, stable CPT nanocrystals were found to be more active in vitro toward MCF-7 cells as compared to CPT solution and exhibited significant suppression of tumor growth in MCF-7 xenografted BALB/c mice. Five times higher concentration of CPT at 24 h in the tumor was observed as compared with that obtained by using the drug salt solution [41].

Another important strategy used for the improvement of CPT delivery, distribution, stability, and lowering their toxicity is a construction of specific prodrugs which undergo a metabolitic activation, preferably at the place of requested action. Prodrugs of CPT are typically obtained by covalent modification of 20-hydroxy group, whereas semisynthetic CPTs are preferentially modified by using substituents located in AB (quinoline) moiety. Simplest types of CPT prodrugs were esters, amides, carbamates, and 20-*O*-carbonates of CPT [152], whereas newer attempts of their preparation involve rather the use of functionalized polymers as carriers,

typically poly(ethylene glycol) (PEG) or poly(*N*-(2-hydroxypropyl) methacrylamide) (PHPMA) [148, 290, 291]. Simple PEG-CPT conjugates gave better level of tumor regression in HT-29 xenografts and decreased toxicity relative to the parent CPT [152]. Dimeric CPT conjugate linked by PEG (**51**, Prothecan, Pegamotecan, Fig. 22.7) entered in Phase II clinical trial [292]. Other examples of PEG conjugates of CPT are presented in reviews [55–57]. Semisynthetic CPTs have also been used for the construction of prodrugs. For example, PEG–irinotecan conjugate NKTR-102 is a prodrug developed by Nektar Therapeutics and evaluated currently in Phase II clinical trial against solid tumor malignancies, including colorectal, breast, ovarian, and cervical cancers [293]. Another example is PEGylated SN38 (EZN-2208) from Enzon Pharmaceuticals. This drug is in Phase II trial for patients with metastatic colon cancer [294].

Polymeric nanoparticles comprised of cyclodextrin-poly(ethylene glycol) copolymer with the covalently attached CPT at 10–12 wt% loading (CRLX101, **52**, Fig. 22.8) which self-assemble in solution into nanoparticles have been developed by Svenson et al. The unique composition of **52** resulted in an apparent solubility increase of >1,000-fold as compared to the parent CPT as well as gave

superior preclinical pharmacokinetic results. CRLX101 was demonstrated to have significant antitumor activity superior to that of irinotecan across a broad range of xenograft models [45, 46] and is currently in Phase II clinical studies.

Another innovative product, XMT-1001 **53** from Mersana Therapeutics, is a CPT prodrug based on the carbohydrate-derived polyacetal matrix "Fleximer" (poly(1-hydroxymethylethylene hydroxymethylformal)). CPT is covalently linked to a hydrophilic and biodegradable polymer and releases CPT over an extended time period by dual-step activation comprising two major intermediates: CPT-20-*O*-(*N*-succinimidoglycinate) (**54**) and CPT-20-*O*-(*N*-succinamidoyl glycinate) (**55**). This mechanism was suggested to be responsible for broader therapeutic window of **53** compared with CPT and irinotecan in human tumor xenograft models and its lower toxicity. Currently, XMT-1001 is being evaluated in patients with advanced cancer in Phase 1 clinical trial [43, 44].

Conjugates of CPT with common anticancer drug paclitaxel were obtained by Lee. These compounds were found to be potent inhibitors of tumor cell replication with better activity relative to CPT. Specifically, selected conjugates such as **56** (Fig. 22.8) were more active against colon adenocarcinoma (HCT-8) cell replication as compared with simple mixture of paclitaxel and CPT. Interestingly, all of the conjugates were less potent than CPT as inhibitors of human topoisomerase I in vitro, suggesting their novel mechanism of action [295].

Chang et al. linked CPT and etoposide fragment (4b-amino-40-*O*-demethylepipodophyllotoxin). Rationale of this conjugation came from the observation that some CPT-resistant cell lines concurrently developed resistance toward etoposide which is topoisomerase II inhibitor. The bioconjugates **57** (Fig. 22.8) differing in a geometry of phenylenediamine linker were prepared, and their cytotoxic effects were reported to operate primarily through topoisomerase I inhibition. Interestingly, **57** was demonstrated to be more effective against human prostate cancer cells than either CPT or etoposide [296, 297]. Other examples of molecules conjugated with CPTs include 5-FU [298], somatostatin [299], bile acids [300], and glutathione [301].

Although the anticancer action of CPTs has received most attention both from academia and pharma community, wide biological screening of CPT and its derivatives resulted in finding several other potentially interesting activities. For example, antiviral efficacies of series CPT analogues on herpes simplex virus type 2 (HSV-2) in vitro were evaluated by Liu et al. [302]. It was found that several compounds exhibited high activity comparable or better than acyclovir (best compound $IC_{50} = 1.3\ \mu g\ mL^{-1}$). Preliminary biological tests suggested also that the intact E-lactone ring and 20-hydroxy group may not be a prerequisite for the antiviral activity [302]. Mappicine ketone **18** (Fig. 22.4) and its derivatives showed also antiviral action against herpes viruses (HSV) and human cytomegalovirus (HCMV) [303, 304].

In the 1990s inhibition of human immunodeficiency virus (HIV-1) replication in vitro by noncytotoxic doses of CPT has been demonstrated by Blair et al. [305]. On the other hand, Pardee et al. reported inhibition of Tat-mediated transactivation of HIV-1 by CPT [306]. These studies have not been continued until recently, when

Zheng et al. reported that 7-hydroxymethyl-CPT showed more potent anti-HIV activity compared with the parent CPT in vitro [307]. The anti-HIV activity has also been demonstrated for rubitecan [308].

CPTs exhibited also antitrypanosomal activity [309], and CPT itself was suggested to inhibit the biosynthesis of collagen [310].

Ecological role of CPT is not clear but indirect observations support the hypothesis that CPT may be a chemical defense system against insect pathogens [311, 312]. In fact, Liu observed that plantations of *C. acuminata* in the USA are relatively free of insect damages [311], and Cao et al. reported that leaves of the tree are toxic to goats [312]. Insecticidal activity of CPT and its derivatives received recently more attention [313–316]. Similarly, antifungal properties of CPT were studied in the context of the fungal diseases in *C. acuminata* that limit cultivation of the plants. Bioassays showed that pure CPT and flavonoids (trifolin and hyperoside) isolated from *Camptotheca* effectively control fungal pathogens of *Alternaria alternata*, *Epicoccum nigrum*, *Pestalotia guepinii*, *Drechslera* sp., and *Fusarium avenaceum* in vitro, although antifungal activity of these compounds in the plant is limited (full inhibition of mycelial growth was observed at 75–125 μg/mL CPT) [317].

6 Biotechnological Approaches

CPT bioproduction by plants has early been recognized as an attractive alternative to its isolation or total synthesis. In this context, since the 1970s CPT biosynthesis, its regulation and development of plant cell cultivation techniques were studied by several research groups. Unfortunately, most of initial efforts toward CPT bioproduction resulted in low alkaloid productivity, giving at best few milligrams for 100 g of dry weight of cultivated plant material or 1 L of liquid medium [318–320]. Further studies on optimization of the bioproduction of CPT involved the use of plant growth regulators and elicitors [321–324], metal ions [325], light, shading, and flooding [319, 326] as well as different cultivation techniques [327]. These efforts led eventually to the better control of the process and in many cases gave remarkable increase in the yield of CPT. For example, Roja et al. obtained by micropropagation *O. rugosa* plants which showed higher than natural plant CPT content, from 0.002% (roots) up to 0.09% (leaves) [322]. Similarly favorable results were reported by Madassery et al. who demonstrated that adventitious roots of *O. prostrata* exhibited stable level of CPT production in the range of 0.16–0.19% under optimized condition [323].

Saito et al. established a hairy root culture of *O. pumila* transformed by *Agrobacterium rhizogenes* strain 15834 characterizing by fast growth (16-fold during 5 weeks of cultivation) and high CPT productivity up to 0.1% per dry weight of the cells. Substantial amount of the alkaloid was excreted to the culture medium, especially in the presence of a polystyrene resin (Diaion HP-20) that absorbed CPT (with easy recovery of CPT from resin) [80]. The transformed hairy roots of *O. pumila* were later adapted to a larger-scale (3L bioreactor) culture affording

0.0085 % of CPT in the fresh wet tissue, and total amount of the alkaloid produced was 22 mg over 8 weeks culture [328].

10-Methoxy-CPT could be considered as a substrate in the semisynthesis of topotecan or irinotecan was produced in tissue culture of *O. liukiuensis* and *O. kuroiwai*, whereas hairy roots of these species gave predominantly CPT [324].

Endophytic fungi *Entrophospora infrequens* isolated form *N. foetida* were found to produce low amounts of CPT (maximal yield 0.5 mg/100 g of dry weight cell) when cultivated in bioreactor [329]. Similarly, low yield of CPT, 9-methoxy-CPT, and 10-hydroxy-CPT produced by some strains of *Fusarium solani* isolated from *Apodytes dimidiata* E. Mey. Ex Arn cultivated in broth medium was reported [88–90].

Genetic aspect of the biosynthesis of CPT and its regulation is a subject of a review [330].

7 Perspectives

The very successful story of camptothecin and related alkaloids confirms the importance of natural products chemistry as a major source of lead compounds for drug research. Although anticancer properties of CPTs focused most of the research attention, others, including antiviral, antiprotozoal, or insecticidal, are also considered in a research. Since CPT isolation in 1958 and first unsuccessful attempts in therapy, the dynamics of CPT research remains very high up to now, resulting in hundreds of published work each year. Although semisynthetic camptothecins such as topotecan and irinotecan hold their strong position in cancer chemotherapy, many other drug candidates were developed and are currently in various phases of the pre- or clinical testing. Recent works on CPTs involve also their new formulation (especially in a nanoscale) for the optimization of the drug delivery, stability and lowering their toxicity. Although substantial progress has also been observed in the total asymmetric syntheses of CPTs, further improvement is needed to provide cost-effective methods for their large-scale production. Biotechnological approaches to the CPT production are still inefficient and need more research to be competitive to the isolation of CPT from the plant material.

Abstract

Ergot alkaloids are secondary metabolites with significantly toxicological and pharmacological relevance and have been identified in different fungi of Ascomycota and several families of higher plants. Lysergic acid amides or peptides produced by the fungus *Claviceps purpurea* of the family Clavicipitaceae, e.g., ergometrine, ergotamine, or ergotoxine, and their semi-synthetic derivatives are widely used in modern medicine for treatment of diverse diseases. Large-scale productions of ergot alkaloids for pharmaceutical applications have been achieved by biotechnological processes including field cultivation of *Claviceps purpurea* on rye or in submerged cultures. Some members of the fungal family of Trichocomaceae such as *Aspergillus fumigatus* and *Penicillium commune* produce clavine-type ergot alkaloids. These substances consist merely of the ergoline ring system as a common structure of most ergot alkaloids and lack an amide or peptidyl moiety in comparison to ergoamides or ergopeptines. Diverse analytical methods were developed for detection and determination of ergot alkaloids as mycotoxins in foods, cereals, and livestock feeds. Significant progress has also been achieved on the molecular biological and biochemical investigations of ergot alkaloid biosynthesis in the last years. The reaction steps from prenylation of tryptophan to formation of the ergoline ring system have been studied in detail.

NRPS	Nonribosomal peptide synthetase

P. commune	*Penicillium commune*
SAM	*S*-adenosyl methionine
TLC	Thin-layer chromatography
TLR 4	Toll-like receptor 4

1 Introduction

Ergot alkaloids (EAs) are a complex family of naturally occurring secondary metabolites derived from the amino acid L-tryptophan **1** and dimethylallyl diphosphate (DMAPP) [1–5]. The tetracyclic ergoline ring **2** is the common structural feature of all EAs (Fig. 23.1). Based on their structures, EAs can be classified into clavine-type alkaloids (clavines), ergoamides **3** and ergopeptines **4** with **2** as the common structure [5]. Clavines consist merely of **2**, while **3** and **4** are D-lysergic acid **5** derivatives linked with an alkyl amine or tripeptide at the carboxyl group [2, 5].

The fungus *Claviceps purpurea* (*C. purpurea)* of the family Clavicipitaceae represents the most important EA producer, which parasitizes mainly on rye and forms the so-called sclerotium as resting structure during its life cycle. EAs were also detected in *Aspergillus fumigatus* (*A. fumigatus*) and *Penicillium commune* (*P. commune*) of the fungal family of Trichocomaceae as well as in plants of the families Convolvulaceae,

Poaceae, and Polygalaceae [1, 3, 5]. Recent investigation revealed however that the plant-associated fungi are responsible for EA production in plants [6, 7].

Due to their pharmacological and toxicological properties, EAs have attracted special attention as drugs in modern medicine, as mycotoxins in the food industry and ecological systems. In the middle ages, the consumption of rye bread contaminated with EAs led to severe epidemics, which have become known as ergotism or St. Anthony's fire. Ergotism can be distinguished in two forms dependent on observed symptoms. Ergotismus convulsivus is characterized by paranoia with hallucinations and ergotismus gangraenosus, which can lead to the loss of infected tissues [8]. The relationship between ergotism and infected rye was first recognized by Tulasne in 1853 [4]. Ergotism has been occasionally observed in livestock today [9]. Nowadays, EAs serve as important drugs in the modern medicine. They interact with serotonin, dopamine, and adrenergic receptors of the central nervous system and with adrenergic receptors of blood vessels. Natural and partial synthetic EAs are used in the treatment of postpartum hemorrhage, as antihypertensive drugs, in migraine therapy, in the treatment of Parkinson's disease, and in controlling the secretion of pituitary hormones such as prolactin [1, 4, 5, 10]. Infection of plants by endophytic fungi resulted in most cases in increased ecological fitness of the host. Infected plants show resistance to herbivores and extreme weather conditions such as drought. In addition, increased growth and mineral uptake is observed [11, 12].

First insights into the biosynthesis of EAs have been achieved by feeding experiments mainly carried out by the Gröger and Floss groups between the 1960s and 1990s [1, 3, 5, 13–15]. In 1999, the occurrence of EA biosynthetic gene cluster in *C. purpurea* has been proven by genome walking with the *dmaW* gene [16], which had been identified for the first pathway-specific enzyme dimethylallyl tryptophan synthase (DMATS) 4 years before [17]. The next important milestone in the research of EA biosynthesis was the identification of the biosynthetic gene cluster of fumigaclavine C **6** from the genome sequence of *A. fumigatus* Af293 by bioinformatic approaches [18, 19]. The identification of this cluster provided a convenient way to identify homologue genes in *C. purpurea* and *A. fumigatus* involved in the committed steps and different genes for specific steps in both pathways. Seven homologous genes were identified in both gene clusters and proposed for reactions from L-tryptophan to ergoline ring. In the last 7 years, the functions of most of these genes from both clusters were proven molecular biologically and biochemically.

2 Occurrence and Structures of Ergot Alkaloids

2.1 Ascomycota as Producers of Diverse Ergot Alkaloids

2.1.1 Fungi of the Family Trichocomaceae

Some members of the family Trichocomaceae, e.g., *A. fumigatus* [20] and *P. commune* [21], produce clavines as the main EAs. Festuclavine **8**, chanoclavine-I **9**, fumigaclavines A **10** or **11**, B **12** or **13**, and C **6** or **7** have been isolated from members of the Trichocomaceae [20]. The accumulated EAs have been observed to be present in or on conidia of *A. fumigatus*. No EAs were detected in the conidiation-deficient strains of *A. fumigatus* by disruption of the gene *brlA*. Complementation of the deficient strain with the wild-type allele of *brlA* by homologous recombination restored conidiation and EA production [19]. In *A. fumigatus*, **6** is the end product of EA biosynthesis, whereas in *P. commune*, the biosynthetic pathway ends with the formation of **10** [22]. **12** or **13** as a precursor for **10** or **11** was found in both *Aspergillus* and *Penicillium* strains [21, 23–25]. The stereochemistry of fumigaclavines was not given in the literature in most cases. Conversion of chanoclavine-I aldehyde **14** leads to the formation of **8** in *A. fumigatus* as predominant product (see below) [26], while *Penicillium* strains produce **8** as main and its stereoisomer pyroclavine **15** and agroclavine **16** as minor products [21, 27–29].

2.1.2 Fungi of the Family Clavicipitaceae

Fungi of the family Clavicipitaceae, e.g., *Claviceps fusiformis (C. fusiformis)*, *Claviceps paspali*, and *Claviceps hirtella*, were also reported to produce clavine-type EAs [2]. In comparison to *A. fumigatus* and *P. commune*, **14** is mainly converted to **16** in *Claviceps* species [30–34]. *Claviceps hirtella* produces clavines as major compounds and ergometrine **17** as minor component [35]. *C. fusiformis* is the sole exception of the family Clavicipitaceae, which produces clavines but no D-lysergic acid **5** derivatives such as **3** or **4** [31]. The most important **3** and **4** producing fungus of the family Clavicipitaceae is represented by *C. purpurea*. In this fungus, EAs are detected in the sclerotium [35]. In addition, *C. purpurea* strains differ from each other in the spectrum of EAs [35]. The strain P1 produces elymoclavine **18**, ergocryptine consisting of α-ergocryptine **19** and β-ergocryptine **20**, ergosine **21** and ergotamine **22** as major component [36]. In comparison, **22** and ergocristine **23** were found as major and **17** as minor EAs in the strain ECC93 [37, 38].

2.2 Accumulation of Ergot Alkaloids in Fungi-Associated Plants

It was assumed that not only fungi but also plants of the families Convolvulaceae, Poaceae, and Polygalaceae can produce EAs. These plants should have obtained the ability through a horizontal gene transfer from fungi during evolution [3, 6]. Investigations of four different EA-containing plants of the family Convolvulaceae demonstrated however that EAs were only detectable in the presence of the plant-associated fungi. Treatment of *Ipomoea asarifolia* (Convolvulaceae) with fungicides resulted in complete abolishment of EA production [39]. In conclusion plant-associated and mostly seed-transmitted fungi, not the plants themselves produced EAs [40]. Comparison of the ribosomal DNA and *dmaW*, encoding the first enzyme in the EA biosynthetic pathway, revealed that these clavicipitalean fungi are closely related but not identical [41]. Recently, two new plant-associated EA-producing fungi were described and named *Periglandula ipomoeae* and *Periglandula turbineae* [42]. In Poaceen plants, sexual endophytic fungi of the genus *Epichloë* and their asexual counterparts *Neotyphodium* as well as the genus *Balansia* are responsible for EA production [7]. Ergovaline **24** and simple lysergic acid amides have been identified in *Epichloë festucae*, which is determined to be symbiotic with many grasses [7].

2.3 Symbiotic Communities

Clavicipitalean fungi and higher plants of the family Convolvulaceae as well as grasses of the family Poaceae exhibit often symbiotic communities. The endophytic fungi benefit from its host by receiving nutrients, protection, and dissemination. Plants have also advantages by associating with endophytic fungi, including defense against herbivores, insects, and nematodes. Other benefits include increased growth of the plant, resistance to drought, and nutrient status [43]. The beneficial implications of EAs in endophyte-infected tall fescue have been analyzed by application of root extracts including polyphenolic fraction, EAs, and loline alkaloids to *Pratylenchus scribneri*, a nematode of tall fescue grasses. It has been shown that *P. scribneri* affects endophyte-infected tall fescue in very low amount, compared with noninfected tall fescue. The toxicological tests of EAs revealed that **19** and **24** were toxic to nematodes at concentrations of 5 and 50 µg ml^{-1}. Also **17** and ergocornine **25** showed nematistatic effects at most tested concentrations [44]. Another study revealed a putative biosynthetic gene cluster of **24** in *Neotyphodium lolii* (*N. lolii*) by cloning and analysis of a nonribosomal peptide synthetase (NRPS) gene. A monomodular NRPS and other genes have been identified, which are orthologous to *C. purpurea* and *A. fumigatus* genes. Endophyte-associated grasses expressed genes, which encode enzymes catalyzing the biosynthesis of **24**, whereas no formation of **24** was found in *N. lolii* mycelia from axenic culture. It was proposed that plants associated with endophytes induce the gene expression by special signal molecules [45]. EA occurrence was also analyzed in the symbiotic community of a clavicipitalean fungus and *Ipomoea asarifolia* (Convolvulaceae). The *dmaW* gene encoding the first EA biosynthesis specific step was identified in clavicipitalean fungus, but not in *Ipomoea asarifolia* [40]. This demonstrates that only the fungus possesses the genetic information for EA biosynthesis. Nevertheless, the produced EAs were only detectable in plants, while no alkaloids were measured in the associated epibiotic fungus. A transport system is supposed to be responsible for transferring EAs from fungus to its host [40]. In contrast, no observed benefits have been achieved by symbiosis of native grass populations and endophytes in a 4-year experiment. Neither advantages in growth nor seed production or reproductive effort under full herbivory were detected in comparison to grasses, which are not infected or infected but not producing EAs [46].

3 Cultivation, Extraction, Purification, and Analyses of Ergot Alkaloids

3.1 Cultivation of *Penicillium commune* as an Example for Ergot Alkaloid Production in Fungi

The optimal cultivation conditions for EA production in fungi vary enormously. For example, different conditions for EA production were described for *C. purpurea* strains (see Sects. 6.2 and 6.3) [31–33, 47–49]. Here, we will just demonstrate the principle for EA production in *P. commune* used in our laboratory. Glucose peptone with soy flour medium (GPS) and wheat grains liquid media were inoculated with 1×10^5 spores of *P. commune* per 100 ml medium and cultivated at 25 °C for 14 days in the dark without shaking.

3.2 Extraction and Purification of Ergot Alkaloids

EAs are natural bases, due to the N-6 of **2**. The solubility of EAs can be therefore influenced by changing the pH value of the solution. At low pH value (e.g., $\text{pH} < 6$), the N-6 will be protonated and easier soluble in water. EAs exist, at high pH value (e.g., pH 9), in their free base and therefore are soluble in organic solvents. Furthermore, the residues at C-8 of **2** contribute to the different polarities of EAs. These properties are usually used in the extraction and purification procedures of EAs [22, 26, 50]. Initially, halogenated organic solvents such as chloroform or dichloromethane were applied for extraction of EAs. Ethyl acetate and acetonitrile have been demonstrated later to be alternatives to halogenated solvents [51]. Nevertheless, dichloromethane was better in certain extraction procedures. Ammonium hydroxide or sodium hydroxide was often found as component in the extraction agents for EAs as free bases [52–54]. As aforementioned, EAs can be also extracted as EA salts by using polar solvents with acid, e.g., methanol and 0.25% concentrated phosphoric acid (40/60) [55], acetonitrile with phosphate-buffer pH 6.0 (60/40) [56], or 2-propanol, H_2O, and lactic acid (50/49/1, V/V). These systems were able to extract EAs with different polarities [57].

Purification of the EA-containing extracts was performed either by liquid-liquid extraction [53] or on solid-phase extraction using silica gel as normal phase or C18 as reverse phase [54, 58]. EAs with a wide range of polarities can be separated by reverse phase HPLC (high performance liquid chromatography) using gradient elution system beginning often with an aqueous solvent, e.g., 5% acetonitrile in 50 mM ammonium acetate to a nonpolar solvent, e.g., 75% acetonitrile in 50 mM ammonium acetate [1]. Cation exchangers are often used for purification after extraction of EAs with acids. Protonation of EAs at the N-6 enables them to adsorb at the negatively charged material. Elution of EAs is performed by deprotonating with basic solvents [51].

3.2.1 Extraction of Ergot Alkaloids from Liquid Cultures of *Penicillium commune*

The mycelia of *P. commune* are to be separated from media by filtration and the pH value of the filtrate is adjusted to 8–9 with ammonium hydroxide. The filtrate is subsequently extracted twice with equal volume of dichloromethane. The organic phases are combined and evaporated to dryness in vacuum.

3.2.2 Extraction of Ergot Alkaloids from Cultures of *Penicillium commune* on Wheat Grains

The solid cultures with wheat grains are suspended in 300 ml ethyl acetate and shaked at 25 °C for 4 h. The organic phase is obtained by filtration, subsequently dried over sodium sulfate and evaporated to dryness in vacuum.

3.3 Analyses of Ergot Alkaloids in the Extracts

3.3.1 Colorimetric Assay

EAs can be identified by various analytical methods. The most important colorimetric analysis is the reaction of EAs with van Urk's reagent, a mixture of *p*-dimethylaminobenzaldehyde, $FeCl_3$, and H_2SO_4. This reagent is also used for quantification of EAs by measurement of the absorbance at 580 nm of the reaction products [59, 60].

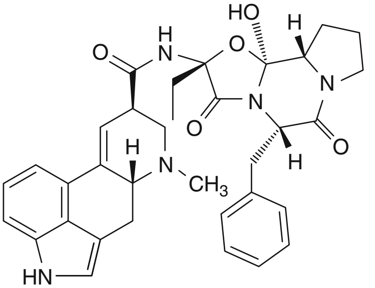
3.3.2 Thin Layer Chromatography (TLC)

TLC was performed on silica gel alone, impregnated with sodium hydroxide or formamide as well as aluminum oxide and used both for detection and separation of EAs [22, 49, 60–62].

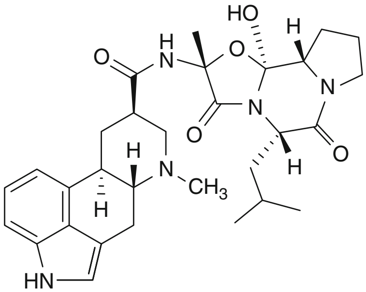
Detection of EAs on TLC was carried out by observation of their fluorescence or colors of reaction products with spray reagents. The presence of the double bond between C-9 and C-10 in EAs is prerequisite for a detection of their fluorescence under UV light. Clavine-type alkaloids show no auto-fluorescence due to the absence of the double bond in **2**. Various spray reagents are explored to detect clavine-type alkaloids or to distinguish between different EAs. Van Urk's reagent is also used as spray reagent to detect EAs [63]. To intensify the spots, TLC plates can be sprayed with sodium nitrite solution [64]. **22** was determined as a blue spot by using an acidic aqueous solution of 0.5% glyoxylic acid containing 0.05% ferric chloride. In case of ergoamides **3** additional heating of the sprayed plate at 110 °C is necessary for displaying spots [65]. Different colors of **22** can be achieved by spraying the TLC plates with π-acceptors such as 2, 3-dichloro-5, 6-dicyanobenzoquinone [66].

3.3.3 Enzyme-Linked Immunosorbent Assay (ELISA)

Specificity in the determination of EAs in immunoassays depends on the applied antibodies [63]. Most ELISA techniques were only able to detect certain EAs [51]. A competitive inhibition ELISA was developed for specific reaction of polyclonal antibodies with phenylalanine residues of EAs in **22**, **23**, and ergostine **26** [67]. Development of a monoclonal antibody permitted the detection of various EAs, e.g., **24** and clavine alkaloids [68]. Another competitive ELISA was used for measuring dihydroergosine **27** in grain and animal feed. **27** conjugated to bovine serum albumin was recognized by specific mouse monoclonal antibodies and rabbit polyclonal antibodies [69]. Furthermore, the semiquantitative competitive ELISA is applied for the determination of EAs in endophyte-infected plants by specific reaction of the monoclonal antibody with the lysergic acid moiety [70].



ergostine **26**



dihydroergosine **27**

3.3.4 High Performance Liquid Chromatography (HPLC)

HPLC was proven to be the most important instrumental analytical method for determination of EAs. Separation on HPLC and downstream detection by fluorescence detector or tandem mass spectrometer was performed. In the early 1970s, when the semisynthetic lysergic acid diethylamide **28** (LSD) became available in the drug scene, there was the need of a suitable analytical method for the detection of LSD. Since then, many HPLC analyses have been developed for the detection of EAs. Initially, normal phase HPLC was used for the determination of **4** with subsequent fluorescence detection. Today, reversed phase with C18 column materials is used more frequently for analysis of EAs [63, 71–73]. As mentioned before, EAs differ often in the position of the double bond in ring D of the **2**. Clavine-type EAs contain sometimes a double bond at C-8 and C-9, whereas **3** and **4** carry a double bond at C-9 and C-10 instead, which influences the chromophoric features and is therefore a key parameter for the choice of excitation and emission wavelength of fluorescence detection. Extract mixtures containing EAs with a double bond at different positions (C-8 and C-9 or C-9 and C-10) should be analyzed in two runs to ensure the detection and quantification of the complete EAs. Another possibility is to use two fluorescence detectors subsequently [74].

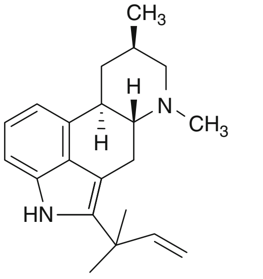
4 Versatile Biological Activities of Ergot Alkaloids

4.1 Therapeutically Significant Ergot Alkaloids and Those as Potential Pharmaceuticals

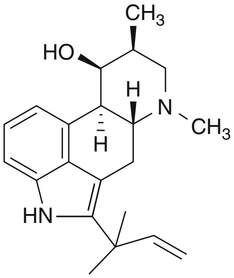
Comparison of the general ergoline structure of EAs with the neurotransmitters noradrenaline, dopamine, and serotonin display structural similarities [75] and accordingly explain their interaction with α-adrenergic receptors and serotonin receptors as agonists, partial agonists, and antagonists [76]. In addition, they act as agonists or partial agonists at dopamine receptors of the central nervous system. In the modern medicine, natural EAs and their semisynthetic derivatives are important therapeutic drugs. Due to the broad interaction with receptors and some adverse effects, pharmacologically used compounds are characterized as “dirty drugs.” To obtain desired affinity of EAs toward the various receptors, chemical modifications on the substituents linked to the carboxyl group of **5** were carried out [77].

4.1.1 Clavine-Type Alkaloids

An important compound with biological activity of clavines is represented by **6** as end product of EA biosynthesis in *A. fumigatus*. In animal experiments using rats, **6** exhibited vasorelaxant effects on isolated thoracic aortic rings independent of endothelial mediators. Several mechanisms are proposed for the vasorelaxant effect of **6**. These results indicate that **6** has potential capacity in vascular protection and may be used as therapeutic drug against cardiovascular diseases [78]. Treatment of mice with induced liver damage and colitis with **6** showed clear beneficial effects on these diseases [79, 80]. In addition, it has also been demonstrated that **6** exhibits potential relevance as an antiatherosclerotic agent. Inflammation processes like activation of toll-like receptor 4 (TLR 4) and nuclear factor κB (NFκB) have been shown to be responsible in the development of atherosclerosis. **6** interferes with the TLR 4/NFκB signaling pathway leading to a decrease of inflammatory factors [81]. Studies with other biologically active clavine-type alkaloids, e.g., **8**, **15**, **16**, and **18**, revealed that these compounds act as pure antagonists or partial agonists at $5HT_{2A}$ (5-hydroxytyptamine) receptors of rat tail artery and as antagonists at α_1-adrenoceptors of rat aorta [82]. It has been furthermore reported that clavines, e.g., 9-deacetoxyfumigaclavine C **29** and 9-deacetylfumigaclavine C **30** exhibit selective and potent cytotoxicity against human leukemia cells [83].



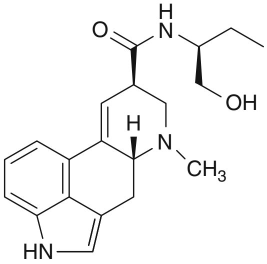
9-deacetoxyfumigaclavine C **29**



9-deacetylfumigaclavine C **30**

4.1.2 Ergoamides

17 and its semisynthetic derivative methylergometrine **31** are the main ergoamides used in modern medicine. **17** and **31** are assembled from **5** and amidated with 2-aminopropanol and 2-aminobutanol, respectively. Their pharmacological effects are based on the selective antagonistic interaction with 5-HT receptors on the smooth muscles and as partial agonists or antagonists to 5-HT receptors of the central nervous system. Additionally, they act on blood vessels as antagonists of dopaminergic receptors and partial agonists of α-adrenergic receptors. **17** and **31** are used due to the direct stimulatory effect on uterine contraction in obstetrics and for both prevention and treatment of postpartum hemorrhage [84]. **28** is also a semisynthetic ergoamide and it should be mentioned here. Due to the strong hallucinogenic side effects and abuse potential, **28** is no longer used for treatment of psychiatric disorders [85, 86].



methylergometrine **31**

4.1.3 Ergopeptines

Peptide alkaloids or ergopeptines **4** are composed of **5** with proline-containing tripeptidyl residues attached to the carboxyl group resulting in the formation of a tricyclic system. **22** is one of the therapeutically important peptide alkaloids. **22** interacts as partial agonist and antagonist with 5-HT- and α-adrenergic receptors in blood vessels and smooth muscles. The most significant effect of **22** is based on the agonistic effect at 5-$HT_{1B/1D}$ receptors at the blood

vessels in the central nervous system, where the constriction of intracranial blood vessels leads to reduction of neurogenic inflammation in the trigemino-vascular system. **22** is used for treatment of mild to severe migraine attacks and cluster headache [87, 88]. The hydration of the double bond at C-9 and C-10 of **22** results in the semisynthetic derivative dihydroergotamine **32**, which is also used in the therapy of migraine headache [89, 90] and furthermore in the therapy of orthostatic hypotension [91]. The ergopeptine alkaloids **19**, **20, 23**, and **25** are components of ergotoxine, which were initially thought to be a single compound. Dihydroergotoxine consisting of the semisynthetic derivatives dihydroergocornine **33**, dihydroergocristine **34**, α-dihydroergocryptine **35**, and β-dihydroergocryptine **36**, also named ergoloid, is used for treatment of age-related cerebral dysfunction like dementia [84, 92]. Furthermore **35** and bromocryptine **37**, a semisynthetic derivative of **19**, as well as pergolide **38** and cabergoline **39**, are used therapeutically for treatment of early-onset Parkinson's disease [93–95]. Their effects are based on their potent agonism on dopamine (D_2) receptors. Dopamine is a prolactin-inhibiting factor. The agonistic effect of **37** and **39** to dopaminergic receptors results also in inhibition on the release of the peptide hormone prolactin [96]. Therefore, they are also used in treatment of prolactin-related disorders such as galactorrhea, prolactin-dependent mammary carcinoma, amenorrhea, and acromegaly [97–99].

5 Biosynthesis of Ergot Alkaloids in Different Fungi

5.1 Biosynthesis of the Tetracyclic Ergoline as a General Structure of Ergot Alkaloids

Different approaches have been carried out to investigate the biosynthesis of EAs. Early feeding experiments with isotope-labeled precursors, e.g., [^{14}C]-L- tryptophan **1**, to rye ears infected with *C. purpurea* or to fermentation cultures of different *Claviceps* species proved its incorporation into **2** [100–102]. Further biochemical experiments with crude and purified enzyme extracts from producers revealed the determinant step in the biosynthesis of EAs by the key enzyme 4-dimethylallyltransferase (4-DMATS) [103, 104], i.e., the prenylation of **1** at C-4 position [17, 104, 105].

The gene *dmaW* encoding for the first pathway-specific DMATS was cloned firstly from *C. fusiformis* [17]. This was done by PCR amplification using degenerate primers deduced from partial amino acid sequences obtained from purified DMATS of *C. fusiformis* and cDNA (copy DNA) library from the same strain [17]. The identified nucleotide sequence of *dmaW* led later to detection of an EA gene cluster in *C. purpurea* containing 14 genes by chromosome walking (Fig. 23.2) [16]. This cluster was proven to be responsible for the biosynthesis of ergoamides,

Fig. 23.2 EA gene clusters of *C. purpurea*, *A. fumigatus*, and *P. commune*. The *black arrows* indicate the homologous genes of all clusters (Modified after [22, 35, 109])

e.g., **17** and ergopeptines, e.g., **22** [35, 38, 106]. Blasting the genome sequence of the first *Aspergillus* species, i.e., *A. fumigatus* Af293 [107] with *dmaW* sequence from *C. purpurea* revealed the presence of an EA gene cluster in *A. fumigatus* containing 11 genes on chromosome 2 [18] (Fig. 23.2). This cluster contains genes necessary for the biosynthesis of the clavine alkaloid **6** lacking an amide or a peptidyl moiety [5, 22]. To identify the biosynthetic gene cluster of **11**, a cosmid library with genomic DNA from *P. commune* NRRL2033 was constructed and screened with *fgaPT*, a homologous gene of *dmaW* from *P. commune* NRRL2033. Sequencing and analysis of three positive cosmids revealed a putative cluster consisting of nine genes for the biosynthesis of **11** (Fig. 23.2) [108].

Identification of the biosynthetic gene clusters for **6** and **11** as well as comparison of the EA biosynthetic genes in *C. purpurea*, *A. fumigatus*, and *P. commune* provided a convenient way to identify candidate genes for the formation of the common structure **2** and for the specific steps in the three fungi [5, 18, 22]. Comparison of the gene clusters from *C. purpurea, A. fumigatus*, and *P. commune* revealed the presence of seven orthologous/homologous genes (black arrows) in the three clusters (Fig. 23.2), which were speculated to be responsible for the formation of the ergoline scaffold **2** [5, 18, 22]. The NRPS genes *lpsA1, lpsA2, lpsB*, and *lpsC* from the cluster of *C. purpurea* P1 will be needed for the biosynthesis and attachment of the alcohol amine and peptidyl moiety to the carboxyl group of **5**. The presence of the putative acetyltransferase gene *fgaAT* in the cluster of **6** in *A. fumigatus* or $fgaAT_{Pc}$ in the cluster of **11** in *P. commune* would be used for the transfer of an acetyl group from acetyl-CoA to a hydroxyl group of **12** or **13**. The second prenyltransferase gene *fgaPT1* in the cluster of *A. fumigatus* could be assigned for the conversion of **10** to **6** [110]. This gene is absent in the cluster of *P. commune*, indicating that **11** instead **7** is the end product of the gene cluster. This was proven by isolation and identification of **11** as the main EA in *P. commune* NRRL 2033 [22, 108, 110].

Functional proof of genes was carried out by knock-out experiments and identification of the accumulated intermediates [111–115] or by biochemical approaches using purified recombinant enzymes [18, 26, 50, 110, 116–119].

The biosynthesis of **2** begins with the prenylation of **1** by the enzyme 4-DMATS (DmaW), e.g., FgaPT2 from *A. fumigatus* (Scheme 23.1). The essential role of *fgaPT2* for the biosynthesis of **6** in *A. fumigatus* has been proven by knock-out experiments [113]. Incubation of **1** with recombinant FgaPT2 from *Saccharomyces cerevisiae* in the presence of DMAPP and subsequent isolation and structure elucidation of the enzyme product proved unequivocally its conversion to 4-dimethylallyltryptophan (4-L-DMAT) **40** [18]. **40** was then converted to *N*-methyl-4-dimethylallyltryptophan (4-DMA-L-abrine) **41** by a methyltransferase, e.g., FgaMT from *A. fumigatus*, in the presence of *S*-adenosyl methionine, which was verified by using the purified recombinant FgaMT [117]. Conversion of **41** to the next detected intermediate **9** requires one decarboxylation and two oxidation steps. The first proposed oxidation starts with the formation of a diene by hydroxylation at C-9 resulting in formation of an unstable intermediate and subsequent spontaneous dehydration [3]. The gene *ccsA* (also termed *easE*) encodes a flavin adenine dinucleotide containing oxidoreductase, which plays an important role in the biosynthesis of **9**. Experiments with knock-out mutants of *C. purpurea* strain P1 lacking *ccsA* led to accumulation of **41** and traces of **40** [114]. In addition, the gene *easC* has been proven to encode a catalase and plays also an essential role in the biosynthesis of **9**. Disruption of *easC* in *A. fumigatus* by homologous recombination resulted in accumulation of **41** and abolishment of downstream EAs, similar to the results obtained from disruption mutants of *ccsA* mentioned above [111]. Feeding experiments with **9** to *easC* and *easE* mutants of *A. fumigatus* led to restoration of EA biosynthesis, which proved that the conversion of **41** to **9** required both EasC and EasE. Recombinant EasC from *Escherichia coli (E. coli)* showed catalase activity in the presence of H_2O_2. It was therefore speculated that two different classes of enzymes, a catalase and a flavin adenine dinucleotide-dependent oxidoreductase are together responsible for the formation of **9** (Scheme 23.1). Biochemical evidence for this hypothesis has to be provided in the future. The common biosynthetic pathway of EA-producing fungi, e.g., *Aspergillus*,

Scheme 23.1 EA biosynthesis in *A. fumigatus*, *P. commune*, and *C. purpurea* modified after [22, 26, 115, 124]

Penicillium, and *Claviceps*, ends with enzymatic formation of **14** (Scheme 23.1). Earlier experiments in the 1970s and 1980s by feeding *Claviceps* cultures with isotope-labeled precursors identified **14** as further intermediate in the conversion of **41** to **16** [13, 120]. Biochemical investigation showed that a short-chain dehydrogenase FgaDH from *A. fumigatus* catalyzed the conversion of **9** to **14** in the presence of nicotinamide adenine nucleotide (NAD^+) [50]. The orthologous EasD from *C. purpurea* and $FgaDH_{Pc}$ from *P. commune* are expected to catalyze the same reaction (Scheme 23.1).

14 was found to be the branch point in the biosynthesis of different EAs [112]. A lot of efforts have been made to investigate the conversion of **14** to downstream intermediates. *EasA* from *C. purpurea* and its homologous *fgaOx3* from *A. fumigatus* and *fgaOx3*$_{Pc}$ from *P. commune* belong to the old yellow enzyme family and encode for flavin adenine dinucleotide-dependent oxidoreductases. Investigations with purified recombinant proteins showed that in *A. fumigatus*, FgaOx3 catalyzed together with the festucalvine synthase the formation of **8** from **14** (Scheme 23.1) [26]. In the absence of FgaFS, FgaOx3 catalyzed the conversion of **14** to two shunt product isomers [121]. It has been proposed that conversion of **14** to **8** consist of two reduction steps. The double bond between C-8 and C-9 would be firstly reduced by FgaOx3 and the resulted dihydrochanoclavine-I aldehyde would undergo spontaneous cyclization to an iminium intermediate, which is subsequently reduced by FgaFS [26]. Similar to their orthologous FgaOx3 and FgaFS in *A. fumigatus*, $FgaOx3_{Pc}$ and $FgaFS_{Pc}$ from *P. commune* also catalyzed the conversion of **14** to **8** [22]. Interestingly, **15** was found as the second enzyme product in the incubation mixture of **14** with $FgaOx3_{Pc}$ and $FgaFS_{Pc}$. Incubation with different enzyme combinations proved that the second reduction catalyzed by FgaFS or $FgaFS_{Pc}$ controlled the stereochemistry of the product, i.e., those of **8** and **15** [22].

In contrast, EasA from *C. purpurea* was proven to be inactive and will be not involved in the conversion of **14** to **16** [22, 116]. The agroclavine synthase EasG in *C. purpurea* alone was responsible for conversion of **14** to **16**, via a nonenzymatic adduct with reduced glutathione (GSH) (Scheme 23.1). GSH was necessary for the isomerization of **14** to form isochanoclavine-I aldehyde, which would undergo spontaneous cyclization to an iminium intermediate. This imine is subsequently reduced by EasG, as in the case of FgaFS [116]. **8**, **15**, and **16** serve as precursors for **6** in *A. fumigatus*, **11** in *P. commune*, and lysergic acid **5** in *C. purpurea*, respectively.

5.2 Biosynthesis of Fumigaclavines

The first main tetracyclic intermediate with an ergoline **2** scaffold in the biosynthesis of fumigaclavines was detected as **8** in *A. fumigatus*, whereas another intermediate with tetracyclic scaffold was determined as **15** in *P. commune*. Both structures contain a saturated D-ring, which are different in their stereochemistry at C-8. In comparison, **8** and downstream enzymatic products of *A. fumigatus*, e.g., **6**, **10**, and **12** have *S*-configuration at C-8, while **15** and the subsequent enzymatic products, e.g., **11** and **13** have R-configuration at C-8 position. In addition, the biosynthetic pathway in *A. fumigatus* ends with the formation of **7**, whereas **11** is the last detectable product of *P. commune*. The difference of structural features of **6** and **11** depends on the additional gene *fgaPT1* encoding for a second prenyltransferase in *A. fumigatus* biosynthetic gene cluster, while the gene cluster of *P. commune* contains only one gene *fgaPT* encoding for a dimethylallyl tryptophan synthase [22]. The comparison of the structures **6** and **8**, which differ in an acetoxy group at position C-9 and a reverse prenyl moiety at position C-2 of **6**, indicates that three enzymatic reactions must be involved in the formation of **6** from **8**. These reactions must be hydroxylation, acetylation, and prenylation. Three genes in the cluster of *A. fumigatus*, *fgaP450-2*, *fgaAT*, and *fgaPT1*, encode a putative hydroxylase, acetyltransferase, and prenytransferase and are proposed to be responsible for the enzymatic synthesis of **6** from **8**. Two reactions, i.e., hydroxylation and acetylation, are needed in the biosynthesis of **11** from **15** in *P. commune*. It can be expected that the orthologous enzymes catalyze same reactions with different stereochemistry at C-9. Indeed, cloning of the putative genes *fgaAT* and *fgaPT1* from *A. fumigatus*, overexpression in *E. coli* and biochemical investigations revealed that FgaAT catalyzes the acetylation of **13** isolated from *P. commune* in the presence of acetyl-CoA, resulting in the formation of **11** [122]. FgaPT1 catalyzes the attachment of a prenyl moiety to C-2 of **11** isolated from *P. commune* in the presence of DMAPP [110]. Until now, the enzymatic conversion of **8** to **12** or **15** to **13** is not yet investigated. It is speculated that this reaction is catalyzed by a cytochrome P450 monooxygenase (Scheme 23.1).

5.3 Formation of D-Lysergic Acid

The conversion of **16** to **5**, as the acyl component of **3** and **4** in *C. purpurea*, requires two oxidation steps to form paspalic acid **42** via **18** and subsequent isomerization of **42** to **5**. Disruption of *cloA*, encoding a cytochrome P450 monooxygenase in the EA gene cluster of *C. purpurea*, resulted in the abolishment of **4** production, whereas the immediate precursor of **16**, **18**, and **42** accumulated in the *cloA* deficient mutant. Restoration of ergopeptine **4** biosynthesis was observed, on the one hand, by feeding the *cloA* deficient mutant with **5** and, on the other hand, by complementation of the mutant with intact *cloA* gene [123]. In addition, cross-complementation analyses of *cloA* between *C. pupurea* and *C. fusiformis* confirmed the function of CloA as elymoclavine oxidase. The EA biosynthesis in *C. purpurea* proceeds via **16**, **18**, and **42** to **5** and the ergopeptines **4**, while *C. fusiformis* is only able to produce **16** and **18**. Due to mutations and rearrangements of *cloA* in *C. fusiformis*, the biosynthetic pathway ends on the level of **18**. Integration of intact *cloA* from *C. purpurea* into *C. fusiformis* led to the production of **4**. In summary, these experiments showed the catalytic role of CloA bridging the biosynthesis of clavine alkaloids and D-lysergic acid-derived EAs in *C. purpurea* [115]. Until now, the conversion of **16** to **18** as well as **42** to **5** is not investigated biochemically. No information on the structural genes is available (Scheme 23.1).

5.4 Biosynthesis of Ergoamides and Ergopeptines

C. purpurea produces simple D-lysergic acid alkyl amides like **17** and ergopeptines **4**. The tripeptidyl moiety of **4** in *C. purpurea* contains in the first and second position variable unpolar amino acids and L-proline in the third position. Biochemical investigations revealed that biosynthesis of **4** are catalyzed by two interacting NRPSs. The biosynthetic gene cluster of EAs in *C. purpurea* includes four NRPS genes, *lpsA1*, *lpsA2*, *lpsB*, and *lpsC*. The lysergyl peptidyl synthetases LPSA1 and LPSA2, encoded by *lpsA1* and *lpsA2*, contain both trimodular domains ($A_1TC_1A_2TC_2A_3TC_3$). In contrast, LPSB and LPSC encoded by *lpsB* and *lpsC* contain only monomodular domains (ATC). In addition, LPSC includes a further domain termed as R-domain (reduction). The function of LPSA1 was investigated by deletion experiments in *C. purpurea* strain P1, which produces **19**, **20**, and **22**. **22**, with a tripeptide moiety of phenylalanine, alanine, and proline, was absent in the resulted deficient mutant, while **19** and **20**, with a tripeptide moiety of valine, proline, and leucine or isoleucine, were still produced by the mutant. These results prove that LPSA1 is involved in the formation of the tripeptide moiety of **22**, but not in the formation of the tripeptide moiety of **19** and **20**. In addition, these findings indicate that the formation of **4** with altered peptidyl residues is determined by NRPS specificity [37]. The second NRPS gene *lpsB* was investigated by several approaches. Analysis of the *lpsB* disruption mutant in *C. purpurea* P1 showed inability to produce any ergopeptines, whereas accumulation of **5** was observed. After heterologous expression of *lpsB* in *E. coli*, the purified enzyme LPSB was assayed with **5** and amino acids presented in the peptidyl moieties of **4**. LPSB was shown to be responsible only for **5** activation and incorporation into the ergopeptine skeleton. The connection of **5** with the tripeptidyl residue containing alanine, phenylalanine, and proline catalyzed by NRPSs is proposed to start with activation of **5** by the A-domain of the monomodular LPSB and subsequent transfer to the T-domain, which acts as peptidyl carrier protein binding D-lysergic acid as thioester. In comparison, the trimodular LPSA1 catalyzes the activation of alanine, phenylalanine, and proline by the A-domains and transfers them to the 4′-phosphopantetheinyl residues of the three T-domains. **5** is transferred to the trimodular LPSA1 and is then incorporated to the D-lysergyl mono-, di-, and tripeptides. It is presumed that the formation of the peptide bond between **5** and alanine is catalyzed by the C-domain of LPSB in a condensation reaction. The elongation to a tripeptide attaching phenylalanine and proline is then catalyzed by the C_1- and C_2-domain of LPSA1. The C_3-domain of LPSA1 releases the D-lysergyl tripeptide from the enzyme complex as lysergyl peptide lactam, after the cyclization between phenylalanine and proline. To obtain ergopeptine **4** as the end product one further heterocyclization is needed, which is catalyzed by a putative cytochrome P450 monooxygenase (Scheme 23.2).

6 Industrial Production of Ergot Alkaloids

6.1 Life Cycle of *Claviceps purpurea*

As aforementioned, *C. purpurea* is the most important fungus in the *Claviceps* genus. Approximately 400 species of grasses serve as hosts for the infection by *C. purpurea* [125, 126]. At the beginning of the life cycle, ascospores of *C. purpurea* infect unfertilized rye ovaries. Under unfavorable conditions, a sclerotium is formed as resting structure of the fungus. At springtime, fruiting bodies composing of perithecia with haploid ascospores are developed from the sclerotium. After releasing the ascospores from the tubular asci, they are transported by wind to flourishing rye ears and initiate the primary infection of the host. The spores attach to the stigmatic hairs of the ovary style and begin to germinate. Penetration of the hyphae into the host is probably enforced by the release of cell wall-dissolving enzymes [4]. The hyphae grow toward the ovary base and after reaching the base a massive colonization of the entire ovary occurs by extensive branching of the hyphae. Tissues below the base (rachilla) are not affected by fungal hyphae. Constriction of the hyphae leads to the formation of conidiospores which serve for vegetative propagation of the fungus before the sclerotium is formed again. Approximately one week after infection, a syrupy fluid is discarded, which is referred to as honeydew. The conidiospores are exuded into the honeydew. The sugary honeydew attracts insects to spread the spores to other unfertilized ovaries in a secondary infection [127–129]. After about 2 weeks, the production of honeydew stops and leads to the maturation of the horny black sclerotium containing hardened fungal mycelium [128, 130]. After 5 weeks, the maturation of sclerotium is complete. The sclerotium ensures the survival of the fungus at low temperatures in winter. Reaching of temperature to 20 °C in springtime, germination can occur beneath the soil surface [131].

6.2 Field Production of Ergot Alkaloids on Rye

Initially, EAs were produced on a large scale by field cultivation on infected rye or triticale. *C. purpurea, C. fusiformis*, and *Claviceps paspali* are generally applied as parasitic fungi to produce ergopeptines **4**, clavine alkaloids, and single lysergic acid derivatives as precursors for partial synthetic drugs, e.g., **22** [2, 77]. Chemical synthesis is time-consuming and expensive. Inoculation of hosts with parasitic cultures can be performed either with specific pricking machinery or by spraying conidial suspension initiating the primary infection cycle. Improvement of field

Scheme 23.2 Formation of Ergopeptines by LpsB, LpsA1, and LpsA2, respectively (Modified after [4]) cultivation technology results in higher yield of generated EAs [132]. Several cell lines of rye were interbred with each other to obtain a hybrid cell line with induced male-sterility. Due to prevented self-pollination the florets stay open longer increasing the probability of contact of the spore suspension with the stigmatic hairs of the ovary style [133]. The EAs are synthesized during the sexual life cycle of the parasitic fungi on their hosts. Mutants of *Claviceps* strains lead to increase of generated sclerotia from 400 to 1,000 kg per hectare [134]. Field cultivation on rye exhibits both advantages and disadvantages. The genetic variability of *Claviceps* strains leads to the production of a wide range of EAs. In addition, *Claviceps* strains used for cultivation on rye show genetic stability in comparison to submerged cultures. Furthermore, hybrid ryes with prolonged flowering time were used for field cultivation to ensure efficient infection by conidial suspension. However, the disadvantages of parasitic EA production are the dependency on environmental conditions such as weather, alternating quality of hybrid rye, and expensive purification processes [77].

6.3 Production of Ergot Alkaloids in Submerged Cultures

The submerged cultivation is also used for the production of EAs, e.g., **3**,**4**, and **5** [135]. The submerged cultivation requires a special media and is accomplished independently of the host organisms. The prerequisite for successful cultivation are suitable strains, which are capable to produce EAs in submerged cultures. To obtain appropriate fungi cultures, various *Claviceps* strains were isolated from its sclerotia modified by mutagenesis and selected according to desired properties. **5** serves as a starting compound for the production of partially synthetic drugs such as **31** or **39**. Only low concentrations of pure **5** can be obtained in cultivation processes [77]. Therefore, isomerization of **42** or hydrolysis of **3** or **4** to **5** was performed [136]. To assure a high quality of selected strains for EA production, storage in liquid nitrogen or freeze drying in a preservative solution consisting of sucrose and skimmed milk should be performed [137]. In nature, EA production is dependent on the formation of sclerotium during the life cycle of *Claviceps*. Mycelium at sphacelia stage is unable to synthesize EAs. The strains used in submerged cultures show different cell morphology [138]. The sclerotia-like cells possess the ability to produce EAs. Suitable medium for *Claviceps* cultivation in submerged culture contains characteristic components [139, 140]. Sucrose is used in a concentration of 300 g $L^{-\ 1}$ and glucose in concentration of 100 g L^{-1} [48]. An osmotic pressure of 10–20 bars is required to induce the formation of sclerotia-like cells, while the conidiation is inhibited at these conditions [141]. Furthermore, a noninhibitory, slowly metabolized carbon source such as mannitol, sorbitol, or sucrose is needed, which acts as nutrient for the fungus [142, 143]. Organic acids are used as carbon source for saturation of tricarboxylic acid cycle [48, 144] leading to increased synthesis of acetyl-CoA at glycolysis and citric acid cycle [145, 146]. Acetyl-CoA is the key substrate in the alkaloid and lipid synthesis [77]. Glyoxylate and pentose phosphate pathway supply the reducing agent which is provided for the mevalonate pathway and lipid biosynthesis [147]. Limitation of phosphate increases oxidative metabolism in cells of *Claviceps* strains and promotes the production of secondary metabolites such as EAs [147, 148].

6.4 Semisynthetic Modifications of Natural Ergot Alkaloids Yield Significant Pharmaceuticals

Dihydroergotamine **32** is produced by partial synthesis using the naturally occurring ergotamine **22**. Hydrogenation of the double bond at C-9 and C-10 of the **22** or amidation of dihydrolysergic acid with synthesized tripeptide results in the formation of **32** [149]. Dihydroergotoxine is a mixture consisting of **33**, **34**, **35**, and **36**. The peptidyl moieties of these compounds contain two identical amino acids, valine and proline, whereas the third amino acid differs from each other. Dihydroergotoxine is also obtained by hydrogenation of double bond between C-9 and C-10 of the natural EAs [76, 84]. Bromocryptine **37** is also an unnatural ergot alkaloid. It is maintained by brominating the C-2 of the α-ergocryptine indole ring [149].

7 Conclusion

The relevance of EAs for modern medicine, pharmaceutical and food industry, as well as for agriculture, leads to significant progresses in EA research. Identification of EA gene clusters in different Ascomycota facilitated the molecular biological and biochemical investigations of genes/enzymes in the EA biosynthesis. Based on the obtained genetic information, new EA-producing strains could be reconstructed by recombination of the biosynthetic genes and serve as sources for production of EAs with new structural features. The total yield could be improved by genetic manipulation. This field will be attractive for research on EAs in the near future.

natural distribution. Quinolin/ones and acridones undoubtedly occur in greatest abundance in plants from the Rutaceae family. The 2-alkylquinolin/4(1*H*)-ones are typical constituents of the Rutaceae but, surprisingly, they have also been isolated from some bacteria, mainly from *Pseudomanas*. Fungus *Penicillium* has yielded a novel class of quinolin/ones, which is based on the combination of amino acids L-valine and L-isoleucine, anthranilic acid, and acetic acid, or these amino acids and tryptamine. They constitute two small groups quinolactacins and quinocitrinines, which are alkaloid types at present unknown from any other source. Quinazoline derivatives are less common in Rutaceae, and a variety of them are produced by bacteria, fungi, and marine animals. In recent years, a number of these alkaloids have been found to possess real pharmacological activity, which is discussed.

Keywords
Acridone • Biological activity • Biosynthesis • *Penicillium* • *Pseudomonas* • Rutaceae • Quinoline • Quinazoline

Abbreviations

ACP	Acyl carrier protein
AMP	Adenosine monophosphate
Ant	Anthranilic acid
ATP	Adenosine triphosphate
AuaAE	Genes required for quinoline alkaloid aurachin synthesis
CF	Cystic fibrosis
CML	Chronic myelogenous leukemia
CoA	Coenzyme A as part of a thioester, e.g., acetyl-CoA $(CH_3COSCoA)$
CoASH	Coenzyme A
DMAPP	Dimethylallyl diphosphate
FPP	Farnesyl diphosphate
GC-MS	Gas chromatograph-mass spectrometry
Ger	Geranyl
Gln	Glutamine
INCA	Instituto Nacional do Cancer (Brazil – www.inca.gov.br)
L-Ala	L-alanine
L-Asp	Aspartic acid
L-Trp	L-tryptophan
$NADP^+$	Nicotinamide adenine dinucleotide phosphate
NADPH	Nicotinamide adenine dinucleotide phosphate (reduced)
NMR	Nuclear magnetic resonance spectroscopy

NRPS	Nonribosomal peptide synthetase
Phe	Phenylalanine
PKSs	Polyketide synthases
PPi	Inorganic diphosphate
PQS	Pseudomonas quinolone signal
pqsABCD	Genes required for PQS synthesis
pqsE	The function of the *pqsE* gene is not known but it is required for PQS synthesis
Pro	Proline
TNF	Tumor necrosis factor
Val	Valine

1 Introduction

The distribution, biogenesis, and biological activity of quinoline, quinazoline, and acridone alkaloids have been reviewed since 1953. Annual coverage has been provided by Openshaw (1953–1967), Snieckus (1972–195), Grundon (1976–1990), Michael (1991–2008), in Specialist Periodical Reports "The Alkaloids" (R. H. F. Manske and H. L. Holmes, ed; and The Chemical Society, Burlington House, London) and subsequently in "Natural Product Reports" [1–40]. In this chapter, some of the latest developments in the groups of natural products collectively known as the quinolin/one, quinazolin/one, and acridone alkaloids are presented. Emphasis is placed on their biogenesis, biological activities, and natural distribution.

In the context of this chapter, the term quinolin/one covers direct derivatives of anthranilic acid. The primary role of anthranilic acid in the formation of the quinoline nucleus has been substantiated by tracer experiments confirming the retention of the carbon atom of the carboxylic acid group and thereby eliminating the possibility of derivation via either the catabolism of tryptophan or some rearrangement analogous to that occurring in the biogenesis of quinine [41]. The term "pseudoquinoline" has been used to distinguish this group of alkaloids, and they were not included in this chapter.

Tables 24.1–24.31 list the different types of alkaloids indicated with their sources [1–162], and include research on quinolin/ones, quinazolin/one, and acridone alkaloids also listed in other reviews [1–42]. In order to bring up-to-data the distribution of these alkaloids the search was carried out in *Chemical Abstracts* (SciFinder) and Web of Science (to June, 2012). The biosynthesis of the alkaloids is discussed. In recent years, a number of these alkaloids have been found to possess real pharmacological activity, which will be discussed in the following sections.

Table 24.1 Occurrence of quinolin-2(1*H*)-one alkaloids in Rutaceae species

Table 24.1 (continued)

Alkaloids	Substituents	Occurrence
Casimiroine	1-Me, 4-OMe, 7-OCH_2O-8	*Casimiroa edulis* [42], *C. pubescena* [39], *Dictyoloma vandellianum* [23]
Halfordamine	4,6,8-triOMe	*Agathosma bisulca*, *A. capensis*, *A.* sp. nov. [21], *Halfordia scleroxyla* [44]
Swietenidine A	1-Me, 3,8-diOMe, 4-OH	*Chloroxylon swietenia* [44]
Ravenine	1-Me, 4-$OCH_2CH = CMe_2$	*Ravenia spectabilis* [42]
Atanine	3-$CH_2CH = CMe_2$, 4-OMe	*Afraegle paniculata* [44], *Euodia rutaecarpa* [29], *Haplophyllum canaliculatum* [47], *Ravenia spectabilis* [42], *Zanthoxylum xanthoxyloides* (*Fagara xanthoxyloides*) [42], *Z. integrifolium* [33]
–	1-Me, 3-$CH_2CH = CMe_2$, 4-OH	*Almeidea guyanensis* [44]
Ravenoline	1-Me, 3-CH(Me)C(=CH_2)Me, 4-OH	*Ravenia spectabilis* [42]
Paraensine	1-Me, 3-CH(Me)C(OH)Me_2, 4-OH	*Euxylophora paraensis* [17], *Ravenia spectabilis* [25]
Semecapifoline	3-CH_2OMe, 4,7-diOMe	*Melicope semecarpifolia* (= *M. confusa*, *Euodia merrillii*) [36]
Melisemine	3-CHO, 4,6,7-triOMe	*Melicope semecarpifolia* [37]
–	1-H, 3,4,8-triOMe	*Eriostemon gardineri* [29]
Haplobungine	1-H, 4,7,8-triOMe	*Haplophyllum bungei* [23]
–	1-Me, 4,7,8-triOMe	*Dictyoloma vandellianum* [23], *Spathelia sorbifolia* [44]
–		*Galipea officinalis* [35]
–		*Drummondita cálida* [48]
–		*Toddalia aculeata* (= *T asiatica*) [40]
–	1-Me, 4,7-diOMe, 3-$CH_2CH(OH)C(OH)Me_2$	*Toddalia aculeata* (= *T asiatica*) [40]

(*continued*)

Table 24.1 (continued)

Alkaloids	Substituents	Occurrence
N-Methylatanine	1-Me, 3-$CH_2CH = CMe_2$, 4-OMe	*Almeidea guyanensis* [44], *Citrus grandis* [17], *Drummondita calida* [48], *Esenbeckia alata* [49], *Glycosmis trichanthera* (*G. calcicola*) [33], *Melicope indica* [44], *Thamnosma africana* [33], *Zanthoxylum beecheyanum* (*Z. arnottianum*) [39]
Schinifoline	3-$CH_2CH = C(=CH_2)Me$, 4-OMe	*Glycosmis cyanocarpa* [28], *Zanthoxylum schinifolium* [27], *Z. simulans* [27]
N-Methylschinifoline	1-Me, 3-$CH_2CH = C(=CH_2)Me$, 4-OMe	*Zanthoxylum schinifolium* [27], *Z. simulans* [27]
Haplosamine	1-Me, 3-$CH_2CH(OH)C(OH)(CH_2OH)Me$, 4 OMe	*Hapophyllum perforatum* [30]
Glycocitlone-A	1-Me, 3-$CH = CHC(OH)Me_2$, 4-OMe	*Glycosmis citrifolia* [34]
Glycosolone	1-Me, 3-$CH_2CH = CMe_2$, 4-OMe, 8-OH	*Glycosmis citrifolia* [34], *G. pentaphylla* [44]
Glycocitlone-B	1-Me, 3-$CH = CHC(OH)Me_2$, 4-OMe, 8-OH	*Glycosmis citrifolia* [34]
Glycocitlone-C	1-Me, 3-$CH = CHC(OH)Me_2$, 4-OMe, 8-OMe	*Glycosmis arborea* [39], *G. citrifolia* [34]
Homo-glycosolone	1-Me, 3-$CH_2CH = CMe_2$, 4-OCH_2CH_3, 8-OH	*Glycosmis pentaphylla* [21]
Glycolone	1-Me, 3-$CH_2CH = CHMe_2$, 4-OCH_2CH_3, 8-OH	*Glycosmis pentaphylla* [23], *Zanthoxylum scandens* [27]
–	1-Me, 4-$OCH_2CH(OH)C(OH)Me_2$	*Euxylophora paraensis* [44]
O-Methylglycosolone	1-Me, 3-$CH_2CH = CMe_2$, 4,8-diOMe	*Glycosmis arborea* [33], *G. citrifolia* [18], *G. mauritiana* [44], *Zanthoxylum scandens* [27]
Zascanol epoxide	1-Me, 4,8-diOMe, 3–$CH_2\underbrace{CH-C}_{O}(CH_2OH)Me$	*Zanthoxylum scandens* [27]
Acutifolidin	3-$CH(OH)CH_2C(=CH_2)Me$, 4,8-diOMe	*Zanthoxylum acutifolium* [27]
Acutifolin	1-Me, 3-$CH(OH)CH_2C(=CH_2)Me$, 4,8-diOMe	*Glycosmis arborea* [39], *Zanthoxylum acutifolium* [27]

(*continued*)

Table 24.1 (continued)

Alkaloids	Substituents	Occurrence
(−)-*O*-Methylacutifolin	1-Me, 3-CH(OMe)$CH_2C(=CH_2)$Me, 4,8-diOMe	*Zanthoxylum acutifolium* [27]
Acutifolin palmitate	1-Me, 3-CH[OCO$(CH_2)_{14}$Me]$CH_2C(=CH_2)$ Me, 4,8-diOMe	*Zanthoxylum acutifolium* [27]
Glycophylone	1-Me, 3-$CH_2CH = CMe_2$, 4-OH, 8-OMe	*Glycosmis citrifolia* [34], *G. pentaphylla* [18]
–	3-$CH_2CH = CMe_2$, 4-OMe, 7-OCH_2O-8	*Ptelea trifoliata* [42]
Edulinine	1-Me, 3-$CH_2CH(OH)C(OH)Me_2$, 4-OMe	*Amyris diatrypa* [19], *Boronella pancheri* [28], *Casimiroa edulis* [44], *Citrus macroptera* [42], *Dutaillyea drupacea* [44], *Euodia gracilis* [23], *Haplophyllum foliosum* [15], *H. patavinum* [36], *Melicope semecarpifolia* [37], *Orixa japonica* [39], *Ruta graveolens* [42], *Teclea nobilis* [22], *T. simplicifolia* [22], *Zanthoxylum mayu* (*Fagara mayu*) [44], *Z. simulans* [16], *Z. usambarense* [30], *Z. williamsii* [44]
(−)-Acetoxyedulinine	1-Me, 3-$CH_2CH(OAc)C(OH)Me_2$, 4-OMe	*Skimmia laureola* [32]
(−)-Ptelefoliarine	1-Me, 3-$CH_2CH(OH)C(=CH_2)$Me, 4-OMe	*Skimmia laureola* [32]
(−)-Acetoxyptelefoliarine	1-Me, 3-$CH_2CH(OAc)C(=CH_2)$Me, 4-OMe	*Skimmia laureola* [32]
Orixiarine	1-Me, 3-$CH_2COCHMe_2$, 4-OMe	*Orixa japonica* [35], *Skimmia laureola* [32]
–	3-$CH_2CH = CMe_2$, 4-$OCH_2CH = CMe_2$	*Euodia roxbughiana* [30], *Haplophyllum bucharicum* [17], *H. tuberculatum* [42]
Pteleprenine	1-Me, 3-$CH_2CH = CMe_2$, 4-OMe, 7-OCH_2O-8	*Orixa japonica* [28], *Ptelea trifoliata* [44]
N-demethyllunidonine	3-$CH_2COCHMe_2$, 4-OMe, 7-OCH_2O-8	*Orixa japonica* [28], *Ptelea trifoliata* ssp. *pallida* var. *confinis* [44]

(*continued*)

Table 24.1 (continued)

Alkaloids	Substituents	Occurrence
Preskimmianine	3-$CH_2CH = CMe_2$, 4,7,8-triOMe	*Acronychia oligophylebia* [19], *Boronia bowmanii* [28], *B. pinnata* [35], *Citrus grandis* [17], *Dictaminus albus*, *D. angustifolius* [42], [44], *D. dasycarpus* [33], *Orixa japonica* [39]
Lunacridine	1-Me, 3-$CH_2CH(OH)CHMe_2$, 4,8-diOMe	*Lunasia amara*, *L. amara* var. *repanda*, *L. costulata* [42], *Zanthoxylum budrunga* [37]
Orixalone A	1-Me, 3-$CH_2COCHMe_2$, 4,8-diOMe	*Lunasia amara* [50], *Orixa japonica* [39]
Orixalone B	1-Me, 3-$CH_2COC(=CH_2)$ Me, 4,8-diOMe	*Orixa japonica* [39]
Orixalone C	3-$CH_2COC(=CH_2)$ Me, 4,8-diOMe	*Orixa japonica* [39]
Foliosidine	1-Me, 4-OMe, 8-$OCH_2CH(OH)C(OH)Me_2$	*Haplophyllum dubium*, *H. foliosum* [42], *H. perforatum* [44]
Foliphorin	1-Me, 4-OMe, 8-$OCH_2CH(OAc)C(OH)Me_2$	*Haplophyllum foliosum* [34]
Daurine	1-Me, 4-OMe, 8-$OCH_2CH = CMe_2$	*Haplophyllum dauricum* [17]
–	1-Me, 3,3-di$CH_2CH = CMe_2$ 1,2,3,4-tetrahydro, 4 = O	*Esenbeckia almawillia* [39], *E. flava* [44]
Buchapsine (Buchapine)	3-$CH_2CH = CMe_2$, 3-$C(Me)_2CH = CH_2$, 1,2,3,4-tetrahydro, 4 = O	*Euodia roxbughiana* [30], *Haplophyllum bucharicum* [17], *H. tuberculatum* [22]
rac-Haplotubinone	3-CH(1′,3-epoxide)CH [$C(OH)Me_2$] $CH_2CH = CMe_2$, 3,4-dihydro, 4 = O	*Haplophyllum tuberculatum* [35]
(−)-Pinolinone	1-Me, 3-$CH_2CH = CMe_2$, 3-α-OH, 4-β-OH, 3,4-dihydro	*Boronia pinnata* [35]
Sveribuxine	3,3-di$CH_2CH = C(Me)CH_2CH_2CH = CMe_2$, 6-OH	*Severinia* (= *Atalantia*) *buxifolia* [33]
–	1-Me, 3-$CH_2CH = CMe_2$, 4,6,8-triOMe, 3,4-dihydro	*Ptelea trifoliata* [44]
Ptelefolidine	1-Me, 3-$CH_2CH(OH)C(=CH_2)Me$, 4-OMe, 7-OCH_2O-8	*Ptelea trifoliata* [42], *P. trifoliata* ssp. *pallida* var. *confinis* [44]
Lunidonine	1-Me, 3-$CH_2COCHMe_2$, 4-OMe, 7-OCH_2O-8	*Lunasia amara* var. *repanda* [42], *Orixa japonica* [39], *Ptelea trifoliata*, *P. trifoliata* ssp. *pallida* var. [44]

(*continued*)

Oligophylicidine	**III**: 2′,3′,3′-triMe, 1-H, 7,8-diOMe	*Acrocychia oligophylebia* [19]

2 Biosynthesis and Biogenesis

2.1 Quinoline and Acridone Alkaloids

Alkaloids derived from anthranilic acid undoubtedly occur in greatest abundance in plants from the Rutaceae family. Particularly well represented are alkaloids based on quinoline and acridone skeletons. A more direct route to the quinoline ring system is by the combination of anthranilic acid and acetate/malonate. Anthranilic acid-specific enzymes involved in the biosynthesis of dihydrofuro- and dihydropyranoquinolin/one alkaloids have been detected in tissue cultures of *Choisya ternata* and *Ruta graveolens* [101]. The biosynthesis pathway illustrated in Scheme 24.1 is supported by tracer feeding experiments with *Skimmia japonica*, *Choisya ternata*, and *Ptelea trifoliata*, in which the alkaloids were formed by the initial condensation of anthraniloyl-CoA and a 2-carbon unit (malonyl-CoA) to give rise to the quinoline ring system, normally in the form of a quinolin-2-one (**1**). This may then be followed by addition to **1** of a 3,3-dimethylallyl unit at the highly activated C-3 position to yield the 3-(3,3-dimethylallyl)-4-hydroxyquinolin-2-one (**2**). Methylation of the 4-hydroxyl group then occurs preferentially and ensures that subsequent oxidative cyclization gives compounds with linear annelation. The cyclization of **2** between C-2-*O* and C-2′ [probably via initial epoxidation of the side-chain, (**3**)] to 2′-isopropyl-2′,3′-dihydrofuroquinolines (**4**) and then, by loss of the isopropyl moiety, to furoquinolines (**7**) is now well established [102–107]. The mechanism by which loss of the isopropyl substituent occurs has not, as yet, been satisfactorily established, however, the structures of some alkaloids isolated have provided substantial indirect evidence that oxidation at C-3′ may be involved, e.g., 2′-isopropyl-3′-hydroxy-2′,3′-dihydrofuroquinoline myrtopsine (**6**, R = Me) isolated from *Myrtopsis sellingii* [108].

Alkaloids	Substituents	Occurrence
(−)-Desmethoxychoisyne	**I**: 2″-C(OH)Me$_2$, 4-OMe	*Choisya ternata* [37]
Choisyne	**I**: 2″-CHMe$_2$, 4,7-diOMe	*Choisya arizonica*, *C. mollis*, *C. ternata* [42]
Medicosmine	**II**: 4-OMe	*Boronella koniambiensis* [40], *Medicosma cunninghamii* [42]
Acronydine	**II**: 4,7-diOMe	*Acronychia baueri* [42], *Melicope leptococca* [18], *Sarcomelicope dogniensis* [24], *S. leiocarpa* [19], *S. megistophylla* [29]
–	**II**: 4-OMe, 3″-α-OH, 4″-α-OH, 3″,4″-dihydro	*Boronella koniambiensis* [40]

(*continued*)

Table 24.7 (continued)

Alkaloids	Substituents	Occurrence
-(*Cis*)-	**II**: 4,7-diOMe, 3″-α-OH, 4″-α-OH, 3″,4″-dihydro	*Sarcomelicope dogniensis* [24]
-(*Trans*)-	**II**: 4,7-diOMe, 3″-α-OH, 4″-β-OH, 3″,4″-dihydro	*Sarcomelicope dogniensis* [24]
Dutadrupine	**III**: 4-OMe	*Almeidea coerulia* [32], *Comptonella sessilifoliola* [25], *Dutaillyea drupacea* [44], *Melicope erromangensis* [31], *M. semecarpifolia* [37]
Anhydroperforine	**III**: 4,8-diOMe, 5,6,7,8-tetrahydro, 3″,4″-dihydro	*Haplophyllum perforatum* [44]
Foliminine	**IV**: 3″,4″-dihydro, 4-OMe	*Haplophyllum foliosum* [44]
Isodutadrupine	**V**: 1-Me	*Almeidea coerulia* [32], *A. rubra* [39]
(+)-Semecarpine		*Melicope semecarpifolia* [37]
(−)-Sarcodifurine A		*Sarcomelicope folliculares* [39]
(+)-Sarcodifurine B		*Sarcomelicope folliculares* [39]

Dictamnine (**7**, R = Me) was a specific precursor of skimmianine (**7**, R = Me, 7,8-diOMe) and other furoquinoline alkaloids oxygenate in the aromatic ring in *Skimmia japonica* and *Choisya ternate* [41]; similar results were obtained with cell cultures of *Ruta graveolens* [104]. Dihydro- (**5**) and furoquinolin-4-ones (**8**) are also known.

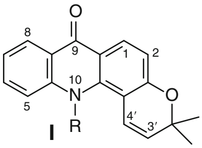
Table 24.16 Occurrence of pyranoacridone alkaloids in non-rutaceous species



I

Alkaloids	Substituents	Occurrence
7-Hydroxynoracronycine	1,7-diOH, 10-Me	*Rauvolfia verticillata* (Apocynaceae) [82]

The anellation of the three-ring system is generally linear, such as in dictamnine (**7**, R = Me), but a few representatives with angular anellation have been found, e.g., 2′,3′-dihydrofuroquinolin-2-one araliopsine (**9**, N-Me) isolated from *Araliopsis soyauxii* [44]. However, angular furoquinoline alkaloids are not known.

2′,2′-Dimethyl-3′-hydroxydihydropyranoquinolin/4-ones (**10**, **11**) have been obtained from several rutaceous species. Although tracer feeding experiments have not been reported, the co-occurrence of furoquinolin/one and these pyrano derivatives suggest that the biosynthesis of both groups involve oxidative cyclization of a common 3-(2,3-epoxy-3-methybutenyl)-4-hydroxyquinolin-2-one precursor.

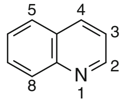
(±)-Neoacrimarine-B R_1, R_2 = H, R_3 = C(Me$_2$)CH = CH$_2$, 3′,4′-dehydro		*Citrus hybrids* [27]
(−)-Neoacrimarine-E R_1 = Me, R_2, R_3 = H,		*Citrus hybrids* [27]
(+)-Dioxinoacrimarine-A		*Citrus hybrid* "Yalaha" [29]
Neoacrimarine-K		*Citrus paradisi* [33]
Acrignine-A		*Citrus grandis* [27], *C. hybrid* *"Yalaha"* (*C. paradisi* x *C. tangerina*) [30], *C. yuko* [27]
(−)-Oriciacridone A R = H		*Oriciopsis glaberrima* [40]
(−)-Oriciacridone B R = OH		*Oriciopsis glaberrima* [40]

Table 24.18 Occurrence of quinoline alkaloids in the Rutaceae species



Alkaloid	Substituents	Occurrence
Quinoline		*Angostura trifoliata*[a] [1], *Citrus aurantium* [42], *Galipea officinalis*[a] [42]
3-Hydroxyquinoline (3-quinolol)	3-OH	*Ruta montana* [41]
Quinaldine	2-Me,	*Angostura trifoliata*[a] [1], *Galipea officinalis*[a] [44]
2-*n*-Propylquinoline	2-*n*-C_3H_7	*Galipea bracteata*[a] [41], *G. longiflora*[a] [41]
Chimanine B	2-(E) CH = $CHCH_3$	*Galipea longiflora*[a] [41]
Chimanine D		*Galipea longiflora*[a] [41]
2-*n*-Pentyl-quinoline (2-*n*-amylquinoline)	2-*n*-C_5H_{11}	*Angostura trifoliata*[a] [1], *Galipea bracteata*[a] [41], *G. longiflora*[a] [41], *G. officinalis*[a] [41]
2-(Pent-1-enyl)-quinoline	2-CH = CHC_3H_7	*Galipea bracteata*[a] [41]
4-Methoxyquinaldine	2-Me, 4-OMe	*Galipea officinalis*[a] [41], *Ruta montana* [41]
Chimanine A	2-*n*-C_3H_7, 4-OMe	*Galipea longiflora*[a] [41]
Chimanine C	2-(E) CH = $CHCH_3$, 4-OMe	*Galipea longiflora*[a] [41]
4-Methoxy-2-*n*-pentylquinoline (quinoleine)	2-*n*-C_5H_{11}, 4-OMe	*Angostura trifoliata*[a] [1], *Galipea longiflora*[a] [24, 41], *G. officinalis*[a] [41], *Zanthoxylum avicennae* [41]
4-Methoxy-2-*n*-heptylquinoline	2-*n*-C_7H_{15}, 4-OMe	*Zanthoxylum avicennae* [41]
4-Methoxy-2-(pent-1-enyl)quinoline	2-CH = CHC_3H_7, 4-OMe	*Galipea longiflora*[a] [24]
4-Methoxy-2-(1-ethylpropyl) quinolone	2-$CH(CH_2CH_3)CH_2CH_3$, 4-OMe	*Esenbeckia leiocarpa* [41]
4-Methoxy-2-(8-oxononyl)quinolone	2-$(CH_2)_7COCH_3$, 4-OMe	*Ruta montana* [41]
1-Methyl-2-propyl-1,2,3,4-tetrahydroquinoline	1-Me, 2-H, *n*-C_3H_7, 3-H,H, 4-H,H	*Galipea officinalis*[a] [41]

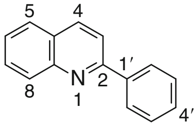
(*continued*)

Table 24.18 (continued)

Alkaloid	Substituents	Occurrence
2-*n*Pentyl-1,2,3,4-tetrahydroquinoline	1-H, 2-H, *n*-C_5H_{11}, 3-H,H, 4-H,H	*Galipea officinalis*[a] [41]
(−)-Angustureine	1-Me, 2-H, *n*-C_5H_{11}, 3-H,H, 4-H,H	*Galipea officinalis*[a] [41]
–	2-OCH_2O-3, 4,7-diOMe	*Acronychia laurifolia* (*A. pedunculata*) [34]
Montanine	2,4-diOMe	*Aegle marmelos* [38], *Hortia colombiana* [32], *Ruta montana* [24]
Isopteleprenine	2,4-diOMe, 7-OCH_2O-8, 3-$CH_2CH = CMe_2$,	*Orixa japonica* [28]
(−)-Preorixine	2,4-diOMe, 7-OCH_2O-8, 3−CH_2CH−C(Me)$_2$ 	*Orixa japonica* [27]
(+)-Isoptelefolidine	2,4-diOMe, 7-OCH_2O-8, 3-$CH_2CH(OH)C(=CH_2)Me$,	*Orixa japonica* [28]
Toddaquinoline		*Toddalia asiatica* [28], *Zanthoxylum beecheyanum* (*Z. arnottianum*) [39], *Z. nitidum* [34], *Z. simulans* [29]
Furoerioaustralasine		*Eriostemon australasius* subsp. *banskii* [28]
(−)-Folipidine		*Haplophyllum foliosum* [39], *H. pedicellatum* [39]

[a] *Angostura trifoliata* (syn., *Galipea officinalis*, see item III); *A. longiflora* (syn., *G. longiflora* K. Krause); *A. bracteata* (syn., *G. bracteata*); [41].

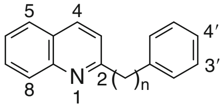
Table 24.19 Occurrence of 2-arylquinoline alkaloids in the Rutaceae species



Alkaloids	Substituents	Occurrence
2-Phenylquinoline		*Galipea longiflorae*[a] [41]
4-Methoxy-2-phenylquinoline	4-OMe,	*Lunasia amara* [2, 41], *Galipea longiflora*[a] [41]
Dubamine	3′-OCH_2O-4′	*Haplophyllum dubium* [3, 41], *H. latifolium* [59], *Dictamnus albus* [42]
Graveolinine	4-OMe, 3′-OCH_2O-4′	*Lunasia amara* [3, 41], *Ruta graveolens* [3, 41], *R. chalepensis* [41], *R. chalepensis* var. *latifolia* [41]

[a] *Angostura longiflora* (syn., *G. longiflora* K. Krause); [41].

Table 24.20 Occurrence of 2-alkylarylquinoline alkaloids in the Rutaceae species



Alkaloids	Substituents	Occurrence
2-(3,4-Dimethoxyphenylethyl) quinoline	n = 2, 3′-OMe, 4′-OMe	*Galipea longiflora*[a] [41], *G. officinalis*[a] [41]
Demethoxycusparine [2-(3,4-methylenedioxyphenylethyl) quinoline]	n = 2, 3′-OCH_2O-4′	*Galipea longiflora* [41], *G. bracteata*[a] [41], *G. officinalis*[a] [41]
2-(3-Hydroxy-4-methoxyphenylethyl)-4-methoxyquinoline or [(3-methoxy-4-hydroxyphenylethyl]-4-methoxyquinoline isomer	n = 2, 4-OMe, 3′-OH, 4′-OMe	*Galipea officinalis*[a] [41]
Cusparine	n = 2, 4-OMe, 3′-OCH_2O-4′	*Angostura trifoliata*[a] [1], *Galipea longiflora*[a] [41], *G. officinalis*[a] [41]
Galipoline	n = 2, 4-OH, 3′-OMe, 4′-OMe	*Angostura trifoliata*[a] [1], *Galipea officinalis*[a] [42]
Galipine	n = 2, 4-OMe, 3′-OMe, 4′-OMe	*Angostura trifoliata*[a] [1] *Galipea officinalis*[a] [41]
2-(3,4-Methylenedioxystyryl)-4-methoxyquinoline	n = CH = CH, 4-OMe, 3′-OCH_2O-4′	*Galipea longiflora*[a] [41]
2-(3,4-Dimethoxyphenylethyl)-1,2,3,4-tetrahydroquinoline	n = 2, 1-H, 2-H, 3-H,H, 4-H,H, 3′-OMe, 4′-OMe	*Galipea officinalis*[a] [41]

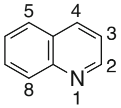
(*continued*)

Table 24.20 (continued)

Alkaloids	Substituents	Occurrence
2-(3,4-Methylenedioxyphenylethyl)-1,2,3,4-tetrahydroquinoline	n = 2, 1-H, 2-H, 3-H,H, 4-H,H, 3′-OCH_2O-4′	*Galipea officinalis*[a] [41]
(−)-Galipeine	n = 2, 1-Me, 2-H, 3-H, H, 4-H,H, 3′-OH, 4′-OMe	*Galipea officinalis*[a] [41]
3,4-Methylenedioxicuspareine or (−)-Galipinine (Allocuspareine)	n = 2, 1-Me, 2-H, 3-H, H, 4-H,H, 3′-OCH_2O-4′	*Galipea officinalis*[a] [41]
Cuspareine	n = 2, 1-Me, 2-H, 3-H, H, 4-H,H, 3′-OMe, 4′-OMe	*Angostura trifoliata* [1], *Galipea officinalis*[a] [41]
2-[6-(3,4-Methylenedioxyphenyl) hexyl]-4-methoxyquinoline	n = 6, 4-OMe, 3′-OCH_2O-4′	*Ruta chalepensis* [41]

[a] *Angostura trifoliata* (syn., *Galipea officinalis*, see item III); *A. longiflora* (syn., *G. longiflora* K. Krause); *A. bracteata* (syn., *G. bracteata*); [41].

Table 24.21 Occurrence of quinoline alkaloids in non-rutaceous species



Alkaloids	Substituents	Occurrence
Quinoline		*Peganum harmala* (Zygophyllaceae) [41]
Quinaldine	2-Me	*Peganum harmala* [41]
3-Phenylquinoline	3-Ph	*Peganum nigellastrum* [41]
3-(4-Hydroxyphenyl) quinoline	3-*p*-OH-Ph	*Peganum nigellastrum* [41]
Quinoline-3-carboxamide	3-$CONH_2$	*Peganum nigellastrum* [41]
–	2-OCH_2O-3, 4,8-diOMe	*Sebastiania corniculata* (Euphorbiaceae) [39]
–	2-OCH_2O-3, 4,7,8-triOMe	*Acanthosyris paulo-alvinii* (Santalaceae) [32], *Sebastiania corniculata* [39]
Echinorine	1-Me, 4-OMe	*Echinops sphaerocephalus* (Asteraceae) [89]
–	2-CH = CMe_2, 4,6-diMe, 7-OH	*Curcuma longa* (Zingiberaceae) [97]
3-(1*H*-Indol-3-yl)quinoline		*Peganum nigellastrum* [41]

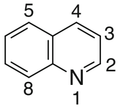
(*continued*)

Table 24.21 (continued)

Alkaloids	Substituents	Occurrence
–		*Aristotelia chilensis* (Elaeocarpaceae) [28]
Sibiridine		*Nitraria schoberi* [37], *N. sibirica* (Nitrareaceae) [37]
–		*Justicia betonica* (Acanthaceae) [98]
Cryptolepine		*Cryptolepis sanguinolenta* (Periplocaceae) [100], *Isatis indigotica* (Brassicaceae) [99]
NeoCryptolepine		*Cryptolepis sanguinolenta* (Periplocaceae) [100]
	Quinoline + Quinazoline	
Luotonin F		*Peganum nigellastrum* [41]

Thus, the isolation of (+)-(R)-isoplatydesmine and (−)-(S)-ribalinine from *Araliopsis soyauxii* suggests that the biosynthesis of these compounds via an 3-[(2-S)-2,3-epoxy-3-methybutenyl)-4-hydroxyquinolin-2-one occurs by cyclization with stereochemical inversion furnishing the dihydrofuroquinolin/4-one (**4**, **5**), and reaction at the tertiary carbon atom of the epoxide ring giving the dihydropyranoquinolin/4-one (**10**, **11**), without affecting the chiral center (Scheme 24.1).

Table 24.22 Occurrence of quinoline alkaloids in fungi, bacteria, marine organisms, and animal



Alkaloids	Substituents	Occurrence
Quinoline		*Oreophoetes peruana* (insect) [32]
Quinaldine	2-Me	*Copenatus mesoleucus* (skunk) [27]
2-Quinolinemethanethiol	2-CH_2SH	*Copenatus mesoleucus* (skunk) [27]
Jineol	3,8-diOH	*Scolopendra subspinipes mutilans* (centipede) [31]
–	2,8-diOH, 3,4-diOMe	*Scolopendra subspinipes mutilans* (centipede) [83]
Scolopendrine	2-OH, 3-OMe, 7-CH_2(3′-OMe, 4′-OH)Ph, 8-OSO_3^-	*Scolopendra subspinipes mutilans* (centipede) [36]
2-Pentyl-4-hydroxyquinoline	2-*n*-C_5H_{11}, 4-OH	*Alteromonas sp.*(marine bacterium), [41]
2-Heptyl-4-hydroxyquinoline	2-*n*-C_7H_{15}, 4-OH	*Alteromonas sp.*(marine bacterium), [41], *Pseudomonas aeruginosa* [41]
2-Nonyl-4-hydroxyquinoline	2-*n*-C_9H_{19}, 4-OH	*Pseudomonas aeruginosa* [41], *Pseudomonas* (strain 1531-E7 – associated with sponge *Homophymia* sp.) [41]
2-Undecyl-4-hydroxyquinoline	2-*n*-$C_{11}H_{23}$, 4-OH	*Pseudomonas aeruginosa* [41]
2-(Undec-1-enyl)-4-hydroxyquinoline	2-CH = CH$(CH_2)_8CH_3$, 4-OH	*Pseudomonas aeruginosa* [41]
Helquinoline	2-H, Me, 3-H_2, 4-H, OH, 8-CO_2H	*Janibacter limosus* [41]
Aurachin A (see Scheme 24.15)		*Stigmatella aurantiaca* (gram-negative bacterium) [41]
Aurachin B	1-O^-, 2-Me, 3-OH, 4-Frn	*Stigmatella aurantiaca* (gram-negative bacterium) [41]
Aurachin F – I, K, L, P (see Scheme 24.15)		*Stigmatella aurantiaca* (gram-negative bacterium) [41, 84]
2-Heptyl-4-hydroxyquinoline *N*-oxide	1-O^-, 2-*n*-C_7H_{15}, 4-OH	*Pseudomonas aeruginosa* [41]
2-Nonyl-4-hydroxyquinoline *N*-Oxide	1-O^-, 2-*n*-C_9H_{19}, 4-OH	*Pseudomonas* (strain 1531-E7 – associated with sponge *Homophymia* sp.) [41], *Pseudomonas aeruginosa* [41]
2-(Hept-1-enyl)-4-hydroxyquinoline *N*-oxide	1-O^-, 2-CH = CH$(CH_2)_4CH_3$, 4-OH	*Pseudomonas aeruginosa* [41]
2-(Non-1-enyl)-4-hydroxyquinoline *N*-oxide	1-O^-, 2-CH = CH$(CH_2)_6CH_3$, 4-OH	*Pseudomonas aeruginosa* [41]

(*continued*)

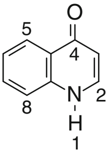
Table 24.22 (continued)

Alkaloids	Substituents	Occurrence
2-(Undec-1-enyl)-4-hydroxyquinoline *N*-oxide	1-O^-, 2-CH = $CH(CH_2)_8CH_3$, 4-OH	*Pseudomonas aeruginosa* [41]
–	6-OH, 8-COOH	*Cortinarius subtortus* [85]
–	4-NH_2, 6-OH, 8-COOH	*Cortinarius subtortus* [85]
Quinocitrinine A (see Scheme 24.23)		*Penicillium citrinum* (VKM FW-800), [41]
Quinocitrinine B (see Scheme 24.23)		*Penicillium citrinum* (VKM FW-800) [41]
(+)-Halitulin		*Haliclona tulearensis* (marine sponge) [33]

Frn Farnesyl group

However, 2′,2′-dimethyl-3′-hydroxydihydropyranoquinolin/4-ones and dihydrofuroquinolin/4-ones present in other rutaceous species do not have the same stereochemical relationship. Isoplatydesmine and ribalinine isolated from *A. tabouensis* had both R-configuration, 2′-R- and 3′-R, respectively. (+)-(R)-Balfourodine and (+)-(R)-isobalfourodine of *Balfourodendron riedelianun* are other examples, suggesting that the biosynthetic route given in Scheme 24.1 does not apply in these cases. The in vitro rearrangement of balfourodine to isobalfourodine in acetic anhydride and pyridine showed in Scheme 24.2 [41, 109] may well be a model for the biosynthetic process in the Rutaceae, rather than those showed in Scheme 24.1. However, a similar rearrangement of (+)-(R)-isoplatydesmine to (+)-(S)-ribalinine acetate, which was hydrolysed to (−)-(S)-ribalinine must occur by inversion of configuration at the chiral center [110]. A proposal is that a dual mechanism is involved, inversion of configuration predominating with isoplatydesmine and retention with balfourodine [41, 110, 111]. Few linear pyranoquinolines (**12**) have been found, only 4-methoxypyranoquinoline, 4,7,8-trimethoxypyranoquinoline isolated from *Euodia pilulifera* [24], and 4,8-dimethoxypyranoquinoline from *Dictamnus dasycarpus* [52] (Table 24.8). The formation of the pyrano ring can be explained by the loss of the hydroxyl substituent at C-3′ (Scheme 24.1). Linear pyranoquinolin-4(1*H*)-ones have not yet been detected in rutaceous species.

Table 24.23 Occurrence of Alkylquinolin-4(1*H*)-one alkaloids in the Rutaceae Species



Alkaloid	Substituents	Occurrence
1,2-Dimethylquinolin-4(1*H*)-one	1-Me, 2-Me	*Acronychia baueri* [42], *Glycosmis citrifolia* [30], *Platydesma campanulata* [41], *Ruta Montana* [41]
1-Acetoxymethyl-2-methylquinolin-4(1*H*)-one	1-CH_2OAc, 2-Me	*Boronia bowmanii* [41], *B. lanceolada* [41]
Leptomerine	1-Me, 2-*n*-C_3H_7	*Haplophyllum leptomerum* [41]
1-Acetoxymethyl-2-*n*-propylquinolin-4(1*H*)-one	1-CH_2OAc, 2-*n*-C_3H_7	*Boronia ternata* [41]
Schinifoline[a]	1-Me, 2-*n*-C_7H_{15}	*Zanthoxylum schinifolium* [41]
1-Methyl-2-*n*-nonylquinolin-4(1*H*)-one	1-Me, 2-*n*-C_9H_{19}	*Boronia bowmanii* [41], *Euodia rutaecarpa* [41], *E. sutchuenensis* [41], *Haplophyllum acutifolium* [41], *H. tuberculatum* [41], *Raulinoa echinata* [41], *Ruta graveolens* [12, 41]
1-Acetoxymethyl-2-*n*-nonylquinolin-4(1*H*)-one	1-CH_2OAc, 2-*n*-C_9H_{19}	*Boronia bowmanii* [41]
1-Methyl-2-(8-oxononyl)quinolin-4(1*H*)-one	1-Me, 2-$(CH_2)_7COCH_3$	*Ruta montana* [41]
1-Methyl-2-*n*-decylquinolin-4(1*H*)-one	1-Me, 2-*n*-$C_{10}H_{21}$	*Euodia rutaecarpa* [41], *Ruta graveolens* [41]
1-Methyl-2-(9-oxodecyl)quinolin-4(1*H*)-one	1-Me, 2-$(CH_2)_8COCH_3$	*Ruta montana* [41]
1-Methyl-2-(10-oxoundecyl)quinolin-4(1*H*)-one	1-Me, 2-$(CH_2)_9COCH_3$	*Euodia rutaecarpa* [86]
1-Methyl-2-*n*-undecylquinolin-4(1*H*)-one	1-Me, 2-*n*-$C_{11}H_{23}$	*Euodia rutaecarpa* [41], *Ruta graveolens* [41]

(*continued*)

Table 24.23 (continued)

Alkaloid	Substituents	Occurrence

Alkaloid	Substituents	Occurrence
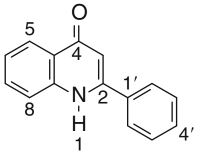
Dictyolomide A	3′-$(CH_2)_2CH = CHCH_2CH_3$ (Z)	*Dictyoloma peruviana* [41], *D. vandellianum* (syn. *D. incanescens* DC) [41]
Dictyolomide B	3′-$CHOH(CH_2)_4CH_3$	*Dictyoloma peruviana* [41]
(+)-6-Methoxydictyolomida A	3′-$(CH_2)_2CH = CHCH_2CH_3$ (Z), 6-OMe	*Dictyoloma vandellianum* (syn. *D. incanescens* DC) [41]

2′,2′-Dimethyldihydropyranoquinolin/4-ones (**13**, **14**) have also been obtained from rutaceous species, but they can be artifacts formed from 3-(3,3-dimethylallyl)-4-hydroxyquinolin-2-one (**2**) during isolation, by an electrophilic attack involving transfer of a proton to the alkene and the oxygen would be added to the more substituted carbon.

Angular pyranoquinolin-2(1*H*)-one are more widely distributed in the rutaceous species, however, the possible precursor angular 2′,2′-dimethyl-3′-hydroxydihydropyranoquinolin-2-one had not been reported until 2006. Thus, Grundon suggested that these alkaloids might be biogenetically derived from an alternative mechanism involving a quinone methide intermediate, as illustrated by a synthesis of *N*-methylflindersine in Scheme 24.3 [112].

Table 24.25 Occurrence of 2-arylquinolin-4(1*H*)-one alkaloids in the Rutaceae species



Alkaloids	Substituents	Occurrence

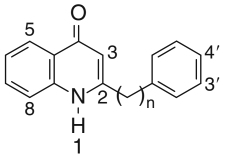
a: 1-Methyl-2-phenylquinolin-4(1*H*)-one; **b**: 1-Methyl-2-(3-methoxy-4,5-methylenedioxyphenyl) quinolin-4(1*H*)-one; **c**: 8-Methoxy-1-methyl-2-(3-methoxy-4,5-methylenedioxyphenyl)quinolin-4(1*H*)-one; **d**: 5-Hydroxy-1-methyl-2-phenylquinolin-4(1*H*)-one; **e**: 5,6-Dimethoxy-2-(3-methoxyphenyl)quinolin-4(1*H*)-one; **f**: 5,6-Dimethoxy-2-(3,4-dimethoxyphenyl)quinolin-4(1*H*)-one; **g**: 5,6-Dimethoxy-2-(2,3,6-trimethoxyphenyl)quinolin-4(1*H*)-one.

Table 24.26 Occurrence of 2-alkylarylquinolin-4(1*H*)-one alkaloids in the Rutaceae species



Alkaloids	Substituents	Occurrence
2-[4-(3,4-Methylenedioxyphenyl)butyl]quinolin-4(1*H*)-one (Rutaverine)	n = 4, 3′-OCH_2O-4′	*Ruta graveolens* [41]
2-[6-(3,4-Methylenedioxyphenyl)hexyl]quinolin-4(1*H*)-one	n = 6, 3′-OCH_2O-4′	*Ruta chalepensis* [41]
1-Methyl-2-[6-(3,4-methylenedioxyphenyl)hexyl]-] quinolin-4(1*H*)-one	n = 6, 1-Me, 3′-OCH_2O-4′	*Ruta graveolens* [41]

More recently, angular 2′,2′-dimethyl-3′-hydroxydihydropyranoquinolin-2-one (**15**) was isolated from *Skimmia laureolea* [69], which provided substantial indirect evidence that the loss of the hydroxyl substituent at C-3′ may be involved in the formation of pyranoquinolin-2-one (**16**, Scheme 24.1). This probably represents the natural process for all pyrano rings in quinoline alkaloids.

Quinoline alkaloid containing dihydrofuran ring with germinal dimethyl substituents have been found in Rutaceae, and one proposal for its biosynthesis involves Claisen rearrangement of the 4-(3,3-dimethylallyloxy)-quinolin-2-one giving 1,1-dimethylallyl derivative **17** (Scheme 24.4). This later can also suffer an abnormal Claisen rearrangement yielding 3-(1,2-dimethylprop-2-enyl)-4-hydroxyquinolin-2-one (**18**). Their cyclization products as 2′,3′,3′-trimethylquinolin-4-one (**19**) and 2′,2′,3′-trimethylquinolin-4-one (**20**) are also constituents of Rutaceae.

Vasicol	**IV**	*Adhotoda vasica* (Acanthaceae) [15], [23, correct structure]
Tryptanthrin	**V**	*Baphicacanthus cusia* (Acanthaceae) [19], *Calanthe aristurifera* (Orchidaceae) [33], *C. discolor* [33], *C. liukiuensis* [35], *C. reflexa* [33], *Isatis indigotica* (Brassicaceae) [35], *I. tinctoria* [28], *Polygonum tinctorium* (Polygonaceae), [58], *Strobilanthes cusia* (Acanthaceae) [14], *Wrightia tinctoria* (Apocynaceae) [31]
Candidine (Qingdainone)		*Baphicacanthus cusia* (Acanthaceae) [19, 24], *Isatis indigotica* (Brassicaceae) [31]

[a]Chang and coworkers showed that the structure of [a](+)-Hydrachine A was identical to (+)-Neodichroine [142].

The synthesis of ifflaiamine (**19**, R = Me) and lemobiline (**20**, R = Me) by means of the rearrangement reactions provided circumstantial support for the biogenetic pathway summarized in Scheme 24.4 [112].

The geranylquinoline alkaloids formed probably by normal and abnormal Claisen rearrangement are also common in Rutaceae, as bucharaminol (**23**) and bucharidine (**25**) (Scheme 24.5).

No data is available on the biosynthesis of dimeric quinoline alkaloids, which have been found in Rutaceae (Table 24.10); the proposed biogenetic pathway represents modes of Diels-Alder addition of prenyl dienes, as summarized for vepridimerine A (**26**, α-Ha) and B (**26**, β-Ha) in Scheme 24.6 [112]. These isomers suggest that dimerization of a quinoline diene takes place during isolation or that dimerization occurs nonenzymatically in the plant tissue.

Asperlicin		*Aspergillus alliaceus* [94]
Chaetominine		*Chaetomium* sp. [94]

A second type of quinoline dimer appears to be formed by acid-catalyzed reaction of the two alkaloids, as exemplified for pteledimerine (**27**, R = Me) in Scheme 24.7 [44].

Zanthoxyllum rhoifolium, *Metrodoria nigra*, and *Sarcomelicope megistophylla* yielded intriguing range of unprecedented *seco*-furoquinoline alkaloids dimethylrhoifolinate (**29**, R = Me, R_1 = H), furomegistine I (**29**, R = Me, R_1 = OMe) and furomegistine II (**30**, R = Me, R_1 = OMe) [26, 30, 35] formed from highly oxygenated quinolones by oxidative cleavage of ring A, (Scheme 24.8, Table 24.5).

Table 24.32 Biological activities of quinoline/one, quinazoline, and acridones alkaloids

Activity	Compounds
Antiprotozoal activity	
Leishmaniasis	1,5-Dihydroxy-2,3-dimethoxy-10-methyl-9-acridone, 2-phenylquinoline, 4-methoxy-2-phenylquinoline, 2-(3,4-methylenedioxyphenylethyl) quinoline, cusparine, 2-(3,4-dimethoxyphenylethyl)quinoline, 2-(pent-1-enyl)quinoline, 2-*n*-pentylquinoline, 2-*n*-propylquinoline, 5-hydroxynoracronycine, arborinine, chimanines A-D, dictyolomides A and B, melicopicine, N-nethyl-8-methoxyflindersine, normelicopicine, skimmianine [28, 30, 31, 38, 41, 45, 56].
Chagas	1,3,5-Trihydroxy-2,8-*bis*(3-methylbut-2-enyl)-10-methyl-9-acridone, 1,3,5-Trihydroxy-4-methoxy-10-methyl-2,8-*bis*(3-methylbut-2-enyl) acridin-9(10*H*)-one, 1,5-dihydroxy-2,3-dimethoxy-10-methyl-9-acridone, 2,3-Dihydro-4,9-dihydroxy-2-(2-hydroxypropan-2-yl)-11-methoxy-10-methylfuro[3,2-*b*]acridin-5(10*H*)-one, 3,4-Dihydro-3,5,8-trihydroxy-6-methoxy-2,2,7-trimethyl-2*H*-pyrano[2,3-*a*]acridin-12(7*H*)-one, 1-methyl-2-nonylquinolin-4(1*H*)-one, 2-(pent-1-enyl)quinoline, 2-nonylquinolin-4(1*H*)-one, 2-*n*-pentylquinoline, 2-*n*-propylquinoline, 5-hydroxynoracronycine, *bis*-5-hydroxynoracronycine, arborinine, citibrasine, citrusinine-I, citrusinine-II, chimanine B, chimanine D, glycocitrine IV, isodictamnine, iso-γ-fagarine, kokusagine, melicopicine, *N*-methylacridone, normelicopicine, pyranofoline, (7*R*,8*R*)-7-Acetoxy-8-[(*E*)-3-hydroxy-3-methylbut-1-enyl]-4,8-dimethoxy-5,6,7,8-tetrahydrofuro[2,3-*b*]quinoline, skimmianine [39, 41, 45, 56, 77].
Malaria	1,3,5-Trihydroxy-2,8-*bis*(3-methylbut-2-enyl)-10-methyl-9-acridone, 1,3,5-Trihydroxy-4-methoxy-10-methyl-2,8-*bis*(3-methylbut-2-enyl) acridin-9(10*H*)-one, 1,5-dihydroxy-2,3-dimethoxy-10-methyl-9-acridone, 2,3-Dihydro-4,9-dihydroxy-2-(2-hydroxypropan-2-yl)-11-methoxy-10-methylfuro[3,2-*b*]acridin-5(10*H*)-one, 3,4-Dihydro-3,5,8-trihydroxy-6-methoxy-2,2,7-trimethyl-2*H*-pyrano[2,3-*a*]acridin-12(7*H*)-one, 2-(3,4-methylenedioxyphenylethyl)quinoline, 2-*n*-nonylquinolin-4(1*H*)-one, 2-nonylquinolin-4-ol *N*-oxide, 2-[(1E)-undec-1-enyl]quinolin-4(1*H*)-one, 2-*n*-undecylquinolin-4(1*H*)-one, 2-pentylquinoline, 2-propylquinoline, 4-methoxy-2-phenylquinoline, 5-hydroxynoracronycine, *bis*-5-hydroxynoracronycine, acridone, acronycidine, acronycine, acronydine, acutine, angustureine, arborinine, artemisinin, atalaphyllinine, buxifoliadine-H, citibrasine, chimanines B, chimanines D, chloroquine, citrusinine-I, citrusinine-II, cryptolepine, cuspareine, γ-fagarine, febrifugine, flindersiamine, galipeine, galipinine, glycocitrine-IV, (−)-gravacridonediol, haplacutine E, haplopine, isofebrifugine, (−)-janoxepin, kokusaginine, mefloquine, melicopicine, *N*-methyl-2-nonylquinolin-4-one, neocryptolepine, normelicopicine, pyranofoline, quinazolin-4(3*H*)-one, quinine, (−)-rhodesiacridone, (−)-rutacridone, severifoline, skimmianine, tryptanthrin [23, 28, 30, 32, 34,36–38, 40, 41, 45, 56, 62, 66, 77, 87, 100, 153, 154].
Molluscicidal activity	2-(3,4-Methylenedioxyphenylethyl)quinoline, 2-*n*-pentylquinoline, 2-(pent-1-enyl)quinoline, 2-propylquinoline, cusculine [24, 27, 41].
Antimicrobial activity	1-Hydroxy-2-(non-2-enyl)-3-methylquinolin-4(1*H*)-one, 1-methyl-2-[(Z)-tridec-7-enyl]quinolin-4(1*H*)-one, 1-methyl-2-(1-hydroxygeranyl) quinolin-4(1*H*)-one, 1-methyl-2-(3-hydroxy-3,7-dimethyl-octa-1,6-dienyl)quinolin-4(1*H*)-one, 1-methyl-2-[(4Z)-tridec-4-enyl] quinolin-4-one, 1-methyl-2-[(4Z,7Z)-tridec-4,7-dienyl]quinolin-4(1*H*)-one,

Table 24.32 (continued)

Activity	Compounds
	3,4-epoxybutyl)-*N*-methylacridone, (−)-5-*N*-acetylardeemin, 2,3-dihydro-4,9-dihydroxy-2-(2-hydroxy-propan-2-yl)-11-methoxy-10-methylfuro[3,2-b]acridin-5(10*H*)-one, 5-dihydroxyacronycine, 1-hydroxy-3-methoxy-10-methyl-9-acridone, 1-hydroxy-2,3-dimethoxy-10-methyl-9-acridone, 3-hydroxy-1-methoxy-10-methyl-9-acridone, 5-hydroxy-*N*-methylseverifoline (*N*-methylatalaphyllinine), 1-methyl-2-undecyl-4-quinolone, 5-methoxymaculine, 6-(2′-Hydroxy-3′-chloroprenyloxy)-4,7-dimethoxyfuroquinoline, 7-hydroy-8-methoxydictamine, 7-Isopentenyloxy-γ-fagarine, 7-(2′-hydroxy-3′-chloroprenyloxy)-4,8-dimethoxyfuroquinoline, 9-hydroxynoracronycine, acronycine, arborinine, aspoquinolone A, aspoquinolone B, atalaphyllidine, atalaphyllinine, atanine, aurantiomide B, aurantiomide C, *bis*-5-hydroxyacronycine, casimiroine, chloroevellerine, citbrasine, des-*N*-methylnoracronycine, dihydroevocarpine, epoxievellerine, evocarpine, evodiamine, γ-fagarine, flindersiamine, flindersine, glyfoline, haplamine, haplopine, haplophytin-A (10-methoxy-2,2-dimethyl-2,6-dihydro-pyrano[3,2-c]quinolin-5-one), helebelicine B (3-Hydroxy-1,2-dimethoxy-10-methyl-9-acridone), isodictaminnine, iso-γ-fagarine, kokusagine, maculine, methylacridin-9(10H)-one, methylnkolbisine, orixalone A, orixinone, perfamine, preorixine, (−)-spiroquinazoline, rutaecarpine, skimmianine, tecleanatalesine B, tryptanthrin [23, 25, 27–29, 32–34, 39–41, 47, 51, 56, 61, 63, 74, 79, 82, 92, 155–157].
Toxicity in the brine shrimp	3-Hydroxy-1-methyl-3-(2-oxopropyl)quinoline-2,4(1*H*,3*H*)-dione, 4-hydroxy-3-methoxy-1-methyl-2(1*H*)-quinolinone, methyl 2-(3-hydroxy-1-methyl-2,4-dioxo-1,2,3,4-tetrahydroquinolin-3-yl)-acetate, 10*H*-Indolo[3,2-b]quinoline, asimicilone, (*Z*)-bogorin, dihydroevocarpine, evocarpine, kokusagainine, *N*-methylflindersine, *N*-methylswietenidine-B [27, 32, 33, 41, 46, 98].
Inhibitory effect on tumor necrosis factor (TNF) production	Quinolactacins A–C [41]
Nuclear Factor of Activated T Cells – NFAT inhibitor	1-Methyl-2-[(4Z,7Z)-tridec-4,7-dienyl]quinolin-4(1*H*)-one, 1-methyl-2-[(6Z,9Z)-pentadec-6,9-dienyl]quinolin-4(1*H*)-one, 1-methyl-2-*n*-nonylquinolin-4(1*H*)-one, 1-methyl-2-pentadecylquinolin-4(1*H*)-one, 1-methyl-2-tridecylquinolin-4(1*H*)-one, 1-methyl-2-undecylquinolin-4(1*H*)-one, 2-*n*-nonylquinolin-4(1*H*)-one , 2-n-undecylquinolin-4(1*H*)-one, dihydroevocarpine, evocarpine [38, 41].
Cytotoxic activity	1,3,5-Trihydroxy-2,8-*bis*(3-methylbut-2-enyl)-10-methyl-9-acridone, 1,3,5-Trihydroxy-4-methoxy-10-methyl-2,8-*bis*(3-methylbut-2-enyl) acridin-9(10*H*)-one, 1,5-dihydroxy-2,3-dimethoxy-10-methyl-9-acridone, 2,3-dihydro-4,9-dihydroxy-2-(2-hydroxy-propan-2-yl)-11-methoxy-10-methylfuro[3,2-b]acridin-5(10*H*)-one, 3,4-Dihydro-3,5,8-trihydroxy-6-methoxy-2,2,7-trimethyl-2*H*-pyrano[2,3-*a*]acridin-12(7*H*)-one, 3,4-Dihydro-3,5,8-trihydroxy-6-methoxy-2,2,7-trimethyl-2*H*-pyrano[2,3-a]acridin-12(7*H*)-one, 1-hydroxy-3-methoxy-10-methyl-9-acridone, 1-hydroxy-2,3-dimethoxy-10-methyl-9-acridone, 1-hydroxy-*N*-methylacridone, 1-methyl-2-[(Z)-pentadec-9-enyl]quinolin-4(1*H*)-one, 1-methyl-2-[(Z)-pentadec-10-enyl]quinolin-4(1*H*)-one, 2-hydroxy-4-methoxy-3-prenyl-quinoline, 2-(3,4-methylenedioxyphenyletyl) quinoline, 2-[2-(3,4-methylenedioxyphenyl)ethyl]quinol, 2-nonyl-4-
