Guaianolides are a large group of sesquiterpene lactones of chemotaxonomic as well as biological importance. The ability of the thapsigargins isolated from the genus *Thapsia*(Apiaceae) to inhibit an intracellular calcium pump and thereby inducing apoptosis has encouraged intensive research in order to develop a new drug, which at present is in clinical trial toward cancer diseases. Several other guaianolides have been investigated as chemotaxonomic markers. In particular, α-methylene guaianolides and guaianolides containing an α,β-unsaturated carbonyl moiety show biological activities.

Keywords

Guaianolide • SERCA inhibition • sesquiterpene lactones • thapsigargin

Abbreviations

DIBAL	Diisobutylaluminium hydride
DMAP	4-Dimethylaminopyridine
DMAPP	Dimethylallyl pyrophosphate
DXP	1-Deoxy-D-xylulose-5-phosphate
FPP	Farnesyl pyrophosphate
GGPP	Geranylgeranyl pyrophosphate
GPP	Geranyl pyrophosphate
HMG-CoA	(*S*)-3-hydroxy-3-methylglutaryl-CoA
HPMA	N-(2-hydroxypropyl) methacrylamide
IPP	Isopentenyl pyrophosphate
LDA	Lithium diisopropylamide
MEP	2-C-methyl-D-erythritol-4-phosphate
MVA	Mevalonate
PCC	Pyridinium chlorochromate
PMSA	Prostate membrane specific antigen
SERCA	Sarco/endoplasmic reticulum calcium ATPase
Ts	Paratoluenesulfonyl (tosyl)

1 Introduction

Biological properties and chemotaxonomic value of guaianolides have encouraged intensive studies. The best studied example is thapsigargin from *Thapsia garganica* L.

The skin irritating properties of the resin from this plant initiated studies that revealed the guaianolides thapsigargin and thapsigargicin as the active principles. The skin irritating effects might be related to the ability of these compounds to release histamine from mast cells [1]. In addition to thapsigargins, in particular, α-methyleneguaianolides and guaianolides possessing an α,β-unsaturated carbonyl moiety have been the focus of intensive studies as will be discussed in this chapter.

2 Definition

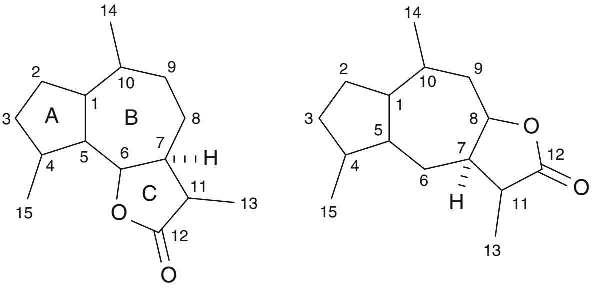
The guaianolide nucleus is defined as 3,6,9-trimethyldecahydroazuleno[4,5-b] furan-2(9bH)-one (**1**) or 3,5,8-trimethyldecahydroazuleno[6,5-b]furan-2(3H)-one (**2**) [2].

By definition, the tricyclic skeleton is depicted as shown in Fig. 98.1 with the A ring up to the left. This enables unambiguous definition of the stereochemistry of the compounds. The systematic names are seldom used; instead, the compounds are generally mentioned as 6,12-guaianolides (**1**) or 8,12-guaianolides (**2**) (Fig. 98.1). If C7, as shown, is substituted with hydrogen, this is α-disposed (Fig. 98.1). Pseudoguaianolides differ from guaianolides by the location of $CH_3$15, which in pseudoguaianolides is positioned at C5 instead of C4.

2.1 Occurrence and Use

A substructure search on all atoms in the database Reaxys using the above nuclei with zero, one, two, or three double bonds revealed that in mid-November 2011, more than 1,400 6,12-guaianolides and more than 170 8,12-guaianolides had been isolated from natural sources. The majority has been found within Asteraceae (composites) followed by Apiaceae (umbelliferous plants), but in addition, guaianolides have been reported from Lamiaceae, Porellaceae (liverwort), Magnoliaceae, and Thymelaeaceae. Furthermore, guaianolides have also been reported from marine organisms like *Pseudopterogorgia americana* (sea plume) and a *Placogorgia* species (a gorgonian). In conclusion, guaianolides are found in a diverse number of plants and other organisms, but mainly in Asteraceae and Apiaceae.

An interesting observation was made by Serkerov, suggesting that not all isolated guaianolides are produced by the organism itself but can be produced either by endophytic organisms or decay of the molding organism. Serkerov noticed that the two 8,12-guaianolides ferulidin and ferulin only occur in roots of *Ferula oopoda* (Apiaceae) that had become moldy by storage. These results could indicate that the 6,12-lactone ring is the endogenic isomer, whereas the 8,12-isomer ring in Apiaceae is formed as a result of molding. Thus, by either plant breakdown enzymes or enzymes of bacterial and/or fungal origin, badkhysin is transformed into ferulin, which is then hydroxylated into ferulidin [3]. This observation has not



1 2

Fig. 98.1 The structure of the two guaianolides. Annotations are illustrating numbering and labeling of carbons and rings

been examined further by others, and the observation that other 8,12-lactones have been found in other plant families as shown in Fig. 98.3 contradicts this suggestion.

Many of the guaianolides are reported to exhibit high antitumor, antischistosomal, anthelmintic, antimicrobial, contraceptive, root-growth stimulatory, root-growth, antifeedant, and germination inhibitory activities, just to mention a few of the reported properties [4, 5]. These diverse biological activities make guaianolides attractive compounds in the search for new drug leads, but due to their toxicity, no drug has come to the market at present [6, 7]. Lately though, the guaianolide thapsigargin (**11**) and prodrugs thereof have given new leads in the drug discovery process [8]. This again makes guaianolides interesting synthetic and biosynthetic targets since the natural source is often limited, preventing its use as a sustainable source for obtaining the compound in kilogram scale.

2.2 Configuration

Typical substituents on the nuclei of naturally occurring guaianolides are hydroxyl groups and esterified hydroxyl groups (Fig. 98.2). Often, one, two, three, or rarely more double bonds are found in the core skeleton of guaianolides, and all carbon atoms in the nuclei might be substituted. Apart from the general rule that if a C7 is substituted with hydrogen, it is α-disposed, no further simple rules for the stereochemistry exist. A Δ11,13 double bond (**4–9**) enables the molecule to undergo hetero-Michael additions, which might be of importance for the biological activity. Some guaianolides, in addition, possess α,β-unsaturated carbonyl groups at other positions in the molecule (**5**, **6, 12**). The substituents are not restricted to hydroxyl groups and esters of these. Epoxy groups occur frequently (**7**), chloride has been found (Fig. 98.3, **14**), and examples of guaianolides substituted with hydroperoxyl groups (**18**) or endoperoxide bridges (**13**) have been characterized along with glycosylations (**16**). The amino acid group in **15** can be explained by a hetero-Michael addition of proline to the α-methylene guaianolide, and the substituent with two thiophene rings in **17** probably has a polyacetylenic fatty acid as precursor. Compound **19** is an example of a guaianolide pigment found in deep sea gorgonian,

3 Chemistry of the Guaianolides

3.1 Azulene Formation

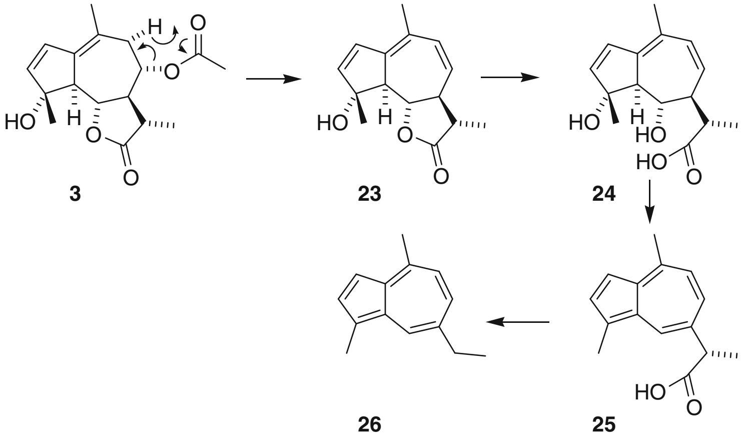
A characteristic of the essential oil of German chamomile is its blue color. During distillation, matricin (**3**) loses two molecules of water and eliminates acetic acid to give chamazulene carboxylic acid (Scheme 98.1, **25**), which decarboxylates into chamazulene (**26**). Chamazulene carboxylic acid (**25**) has been found in plasma after oral administration of **3** to healthy patients [10]. The structural similarities between **25** and ibuprofen and naproxen, both heavily used as anti-inflammatory, analgesic, and antipyretic drugs, have led to the hypothesis that the traditional use of German chamomile tea for treatment of inflammation might be rationalized by assuming that **3** is a prodrug for **25** [10]. Surprisingly, this fascinating hypothesis has not been investigated further.

In addition to **3**, also slovanolides like **27** and **28** can thermally be converted into chamazulenes. However, the presence of a hydroxyl group or an esterified hydroxyl group at C11 makes the reaction take different routes (Scheme 98.2).

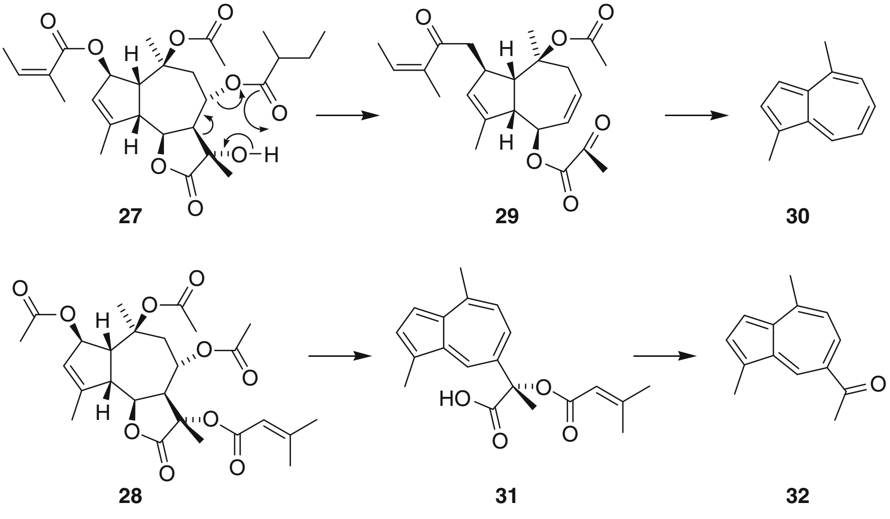
As appears from the reaction mechanism depicted in Scheme 98.2, the hydroxyl group at C11 of **27** is essential for the retro-Prince reaction affording **29**, which by elimination is converted into 1,4-dimethylazulene (**30**) [11]. The absence of the hydroxyl group in **28** prohibits the retro-Prince reaction, and instead, eliminations followed by decarbonylation afford 1,4-dimethyl-7-acetylazulene (**32**) [12].

3.2 Hetero-Michael Addition

α,β-Unsaturated carbonyl groups react by 1,4-addition with nucleophiles like thiol groups. The reaction is called Michael addition if the nucleophile is a carbanion and hetero-Michael addition if the nucleophile is a heteroatom. This type of reaction is illustrated in Scheme 98.3 using eupatundin (**33**) and cysteine as examples.

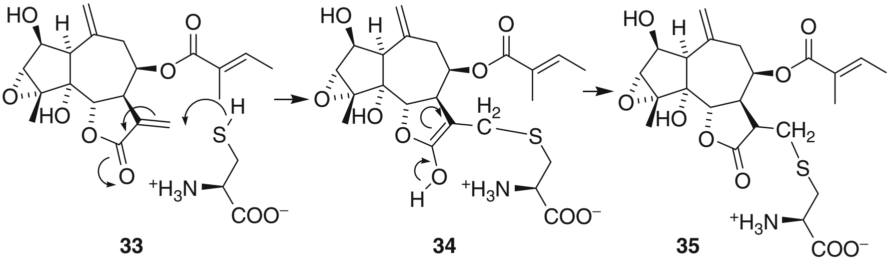


Scheme 98.1 Chamazulene (**26**) formation from matricin (**3**). Thermally, the reaction runs to **26**, whereas a reaction induced in artificial gastric or intestinal juice stops at **25**. Intermediates **23** and **24** are hypothetical.



Scheme 98.2 Formation of **30** from **27** occurs via a retro-Prince reaction that forms **29**, which eliminates three carboxylic acids to give **30**. In contrast, the absence of a hydroxyl group at C11 in **28** forces this reaction to proceed to 1,4-dimethyl-7-acetylazulene

Initially, this reaction was studied by Kupchan et al. to explain the cytotoxic activities of α-methylene sesquiterpene lactones [13]. By reaction of the guaianolide with an essential enzyme or receptor containing cysteine, a malfunctioning product might be formed that could kill the cell. In spite of several later studies, no drug based on this reaction has been registered until now,



Scheme 98.3 Hetero-Michael addition of cystein to eupatundin (**33**)

but a similar principle of action lies behind the molecular mechanism of a derivative of the α-methylene sesquiterpene lactone, dimethylaminoparthenolide, which at present is in clinical trials [14]. If two α,β-unsaturated carbonyl groups are present (e.g., **5** and **6**), a product in which two molecules of cysteine have reacted with the guaianolide can be formed. In general, however, α,β-unsaturated esters esterified with the sesquiterpene nucleus do not undergo hetero-Michael additions.

3.3 Selective Replacement of Ester Groups

The potent biological activity of thapsigargin (**11**) has led to intensive studies of the binding site in the sarco/endoplasmatic calcium ATPase (SERCA) [15]. An essential requirement for these studies was selective replacement of the acyl groups esterified to four of the oxygen atoms. This possibility was first obtained by removal of the butanoyl group by treatment with mild base like triethylamine in methanol (Scheme 98.4). An additional advantage of this procedure is that under these conditions no opening of the lactone ring occurs. The use of a stronger base affords ring opening, which again after addition of acid yields a mixture of **36** and **37**. The opening of the lactone ring is prevented by masking of O8 and O11 by forming the isopropylidene acetal (**38**). Treatment with strong base converts **38** into **39**. Reaction of **40** with an acid anhydride in the presence of an acid like paratoluenesulfonic acid under controlled conditions affords selective acylation of the secondary alcohol group to give **41**. In case R^2 is a methyl, acetate is formed; this reaction might advantageously be performed with 2-propylenyl acetate. Demasking the two hydroxyl groups again affords a secondary alcohol (**42**), which again can be selectively acylated at the secondary alcohol, whereby **43** is obtained. The use of appropriate acid anhydrides or acids enables selective replacement of the three acyl groups at O2, O8, and O10. The angeloyl group at O3 might be removed after treatment with osmium tetraoxide, permanganate, and periodate, whereby the angeloyl group is converted into a pyruvate, which selectively is removed after treatment with pyridine in methanol. The mentioned reaction sequence has been used for preparation of a prodrug of thapsigargin (**11**), which, at the present, is in clinical trial.

3.4 Synthesis of the Guaianolide Nucleus

Different procedures for the synthesis of guaianolides have been reviewed [16]. Some of these will be discussed in the following paragraph.

A early partial synthesis of the guaianolide nucleus was based on photochemical rearrangement of α-santonin (**44**) to give isophotosantonic lactone (**45**) [17] (Scheme 98.5). The stereochemistry of this reaction is remarkable. Irradiation of the santonin isomer, in which the C6–O6 bond is β disposed gives the C6–O6, C7–C11 *cis* isomer of **45** [18].

A total synthesis of a racemic guaianolide nucleus using the diketone **46** as starting material and compressenolide (**54**) as target molecule is described in Scheme 98.6. By taking advantage of the poorer reactivity of the α,β-unsaturated ketone, selective ketalization of the isolated carbonyl group is performed (**47**). Epoxidation affords a mixture of the two possible epoxides (**48a** and **48b**), which are separated by column chromatography. α−Alkylation of the ketone with isopentenyl bromide affords a mixture of the two epimers **49a** and **49b**, which can be separated using chromatography. The β-isomer is reduced with lithium in liquid ammonia to give selectively the α-diol **50**. The ketone group is then demasked by treatment with acetone and acid followed by a Wittig reaction that introduces the methylene group at C10 (**53**). Finally, the $CH_3$13 is introduced after masking of the two hydroxyl groups with trimethylsilyl chloride by alkylation using methyl iodide. Again, a mixture of epimers (**54a**, **54b**) is formed. Compressenolide is the isomer in which $CH_3$13 is α-disposed [19].

For the synthesis of **54**, the starting diketone **46** was obtained by photochemical addition of cyclopentenone (**55**) to 1,2-bis(trimethylsilyloxy)cyclopentene (**56**) as illustrated in Scheme 98.7.

A number of stereoselective syntheses of guaianolides have been based on the masked 3-hydroxycyclopentanecarboxylic acid (**64**) prepared from (*S*)-carvone (**59**) as illustrated in Scheme 98.8 [20].

The key step in this synthesis is the Favorskii ring contraction of the α-chlorocyclohexanone (**61**) to the cyclopentane via the intermediate cyclopropanone **63**.

The hydroxycyclopentanecarboxylic acid **64** has been used as starting material for enantiomeric pure guaianolides like (−)-estafiatin, thapsigargin (**11**) [20], and (+)-cladantholide (**65**, Scheme 98.9) [21]. Formation of the tricyclic ring

4 Biosynthesis of Guaianolides in Plants

In all living organisms, farnesyl synthases convert isopentenyl pyrophosphate (IPP) into farnesyl pyrophosphate (FPP) (**77**), the precursor of all sesquiterpene structures. The enzyme generating FPP, FPP synthase, has been extensively studied, and it was shown that the *E,E* conformation of FPP is the predominant product of farnesyl synthases and generally is the substrate for sesquiterpene synthases in eukaryotes [22].

From FPP, several possible cyclization reactions can occur, all of which generate substances that act as starting materials for the more than 300 cyclic sesquiterpene skeletons known. These cyclizations commence with an isomerization of *trans*-FPP (Scheme 98.10). This isomerization and the following ionization-dependent cyclization lead to a wide variety of cyclohexanoid, cyclodecanoid, cycloundecanoid, or bicyclohexanoid ring systems. Internal additions to the remaining double bonds of the initially formed carbocations also occur. Methyl migrations, Wagner-Meerwein rearrangements, and hydride shifts lead to the generation of the great variety of structures found in nature, among which sesquiterpene lactones, including the guaianolides, are found [23].

Of the sesquiterpene lactones identified so far, the one with the best described biosynthesis is the drug artemisinin, which is used in the treatment of malaria. A second well-studied sesquiterpene lactone is the germacranolide costunolide, which exhibits various cytotoxic effects. Both artemisinin and costunolide were identified in Asteraceae, and although these are not guaianolides, many of the reaction sequences generating these molecules are believed to be similar to those generating guaianolides.

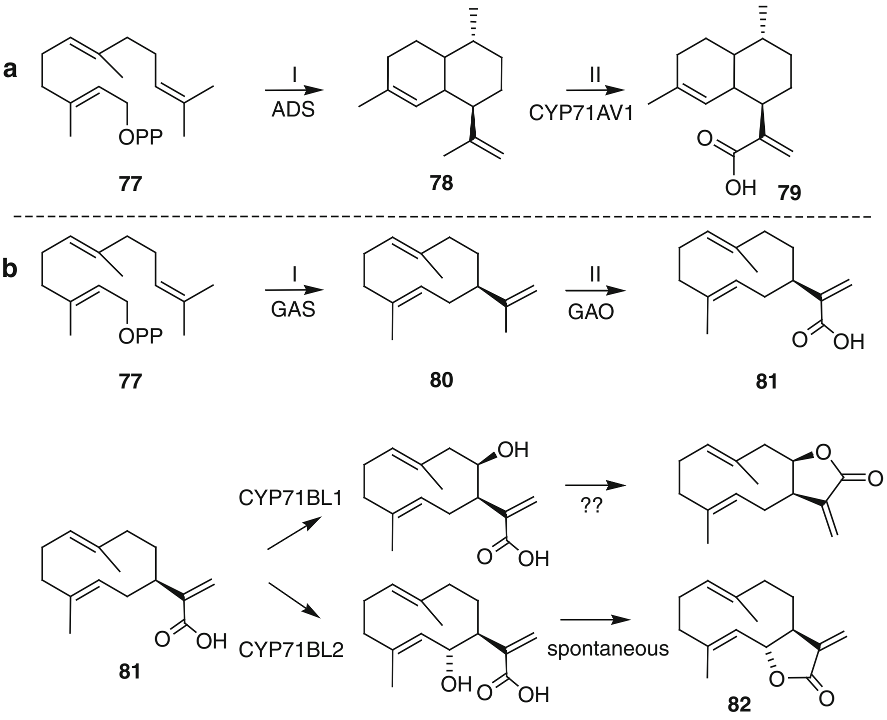
4.1 Guaianolide Biosynthesis in Asteraceae

The initial step of artemisinin biosynthesis is the formation of amorpha-4,11-diene (**78**) from FPP (**77**), a reaction catalyzed by amorphadiene synthase (Scheme 98.10, A). Germacrene A (**80**) was expected as an intermediate, but a single enzyme is able to facilitate the complete reaction to **78** [24]. Germacrene A synthases have been isolated from *Artemisia annua* and other asters [25]. From **78**, a multifunctional sesquiterpene oxidase, CYP71AV1, catalyzes the production of artemisinic acid (**79**) in yeast, whereas the *in planta* pathway goes to artemisinic aldehyde and



Scheme 98.10 Biosynthesis route to costunolide (**82**) in Asteraceae compared with artemisinic acid (**79**) that is spontaneously transformed in artemisinin [44, 48, 49]. *ADS* amorphadiene synthase, *GAS* germacrene A synthase, GAO germacrene A oxidase

through dihydroartemisinic acid to artemisin. The last steps in the biosynthesis responsible for converting dihydroartemisinic acid to artemisinin are less clear and are believed to occur spontaneously [24, 26].

In a series of articles from 1998 to 2002, Harro Bouwmeester and coworkers isolated several enzymes from chicory that are involved in the biosynthesis of the sesquiterpene lactone costunolide (**82**). This group recently described the formation of **80** from **77** and the subsequent conversion of **80–82** in chicory following a similar regime to that of artemisinin. This was confirmed in 2011 by Dae-Kyun Ro and coworkers with the isolation and characterization of the two enzymes CYP71BL1 and CYP71BL2 that hydroxylate C8 and C6, respectively (Scheme 98.10) [27, 28]. The formation of **82** is interesting in the context of guaianolide biosynthesis since the lactone ring has been formed before the 5- and 7-membered carbocyclic rings.

From **82**, it is hypothesized that guaianolides in chicory are generated via 4,5 epoxidation (Scheme 98.11, B) to give, e.g., parthenolide (**83**), which through opening of the epoxide by an intramolecular attack of the double bond affords the three-cyclic skeleton [27, 29, 30]. This reaction mechanism was already proposed

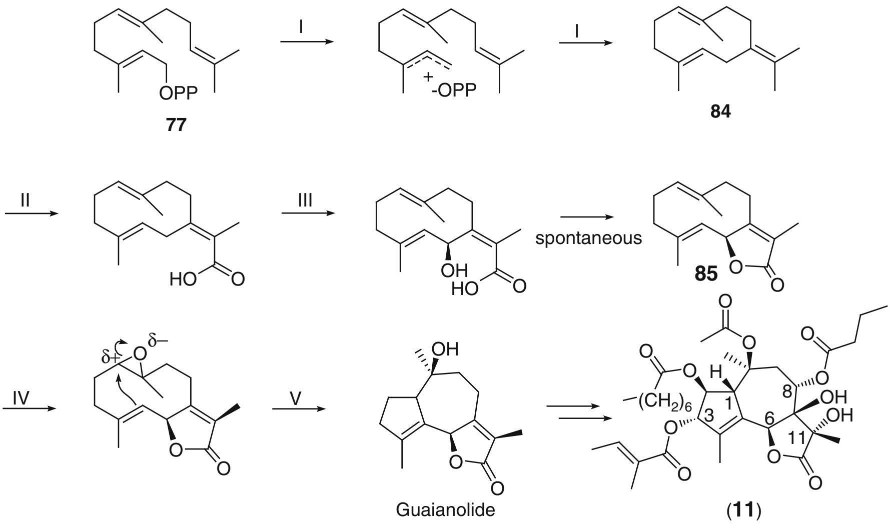
in 1995 [31]. The double bonds are formed by abstraction of a hydrogen ion attached to carbon atom neighboring the intermediate C10 carbocation. This abstraction will afford either Δ1-10, Δ9-10, or Δ10-14 double bonds. Alternatively, the carbocation might be quenched by reaction with a water molecule to give an alcohol at C10 (Scheme 98.11, B). Formation of other sesquiterpenes found in Asteraceae and Apiaceae is best explained by assuming a 1,10 epoxide as intermediate. A similar intramolecular attack as described above would afford a C4 carbocation from which isomers of Δ4-5, Δ3-4, or Δ4-15 double bonds or the equivalent alcohol at C4 may be formed (Scheme 98.11, A). Unfortunately, the enzymes involved in the last steps of guaianolide biosynthesis in Asteraceae have not been identified yet. However, studies in *Lactuca floridana* (Asteraceae) support the theory that **83** is the intermediate in guaianolide biosynthesis [32], and the isolation and characterization of the 6-hydroxylase (CYP71BL2) followed by spontaneous formation of **82** in *L. floridana* support this pathway in Asteraceae.

Notice that the suggested intermediate carbocations are tertiary carbocations but that the epoxides during the formations of guaianolides are attacked at the less substituted carbon atoms.

4.2 Guaianolide Biosynthesis in Apiaceae

No studies have yet been able to elucidate the biosynthetic pathway of guaianolides in Apiaceae. Even the biosynthesis of the otherwise well-studied compound thapsigargin (**11**) is unknown. Given the promising results against prostate cancer [33], an annual demand of one ton of thapsigargin might be expected, encouraging development of production protocols. One possibility would be biotechnological production in a genetically modified organism, an approach which, however, requires a detailed knowledge of the biosynthesis [34]. A biosynthetic pathway has been proposed (Scheme 98.12) [5]. The first step, **I**, is mediated by a germacrene B synthase. Germacrene B (**84**) has been identified in several Apiaceae species. This biosynthetic pathway could explain the stereochemistry at C1, which differs from that generally observed in guaianolides from Asteraceae [35, 36]. In steps **II** and **III**, the lactone ring is formed by enzymes similar to the Cytochromes P450 described in Scheme 98.10 followed by a spontaneous reaction, that has been shown to generate **82** (Scheme 98.10, B), and form the germacrenolide (**85**) shown in Scheme 98.12. The 1,10-epoxidation in step **IV** initiates the last step of the guaianolide formation, step **V**, in which an enzyme closes the guaianolide structure. This should, in the biosynthesis of thapsigargin (**11**), preferably proceed via 1,10-epoxidation in order to retain the Δ4-5 double bond that is present in thapsigargin, but it is likely that both 1,10 and 4,5 epoxidations can occur within plants belonging to the Apiaceae family, since the Δ4-5 double bond is not conserved within the family [5]. The final step also insures the conformations found in most guaianolides in Apiaceae, namely, 1βH, 10αCH_3, and 11βCH_3. Hydroxylation of C7 is only rarely found in guaianolides, and the 7β-hydroxyl group is unique to the thapsigargins. A likely explanation for the unique 7β-hydroxyl group is that a precursor possessing a Δ7-11 double bond is converted into an epoxide that is then opened into a trans-glycol [37].

The finding of guaiol and guaienes hydroxylated at positions C11 and C8 could suggest that the guaiene structure is formed prior to any secondary modifications. It has been observed in pine that sesquiterpene cyclases also perform these secondary modifications on the germacrene skeleton via hydride shifts, methyl migrations, and Wagner-Meerwein rearrangements [23]. It still needs to be seen whether this is also



Scheme 98.12 Proposed biosynthesis of guaianolides in Apiaceae, here depicted to afford thapsigargin (**11**) [5]. A 1,10-epoxide is suggested as an intermediate

true for enzymes found in Apiaceae, but this should be taken into consideration when elucidating the biosynthesis.

Since most of the enzymes involved in this pathway are cytochrome P450, sufficient oxygen and NADPH are crucial for the efficiency of the biosynthesis. Although the reactions catalyzed in Asteraceae by the proposed enzymes might seem similar to those observed in Apiaceae, differences in the stereochemistry of substrates and desired products might result in difficulties generating the pathway described. Attention has been called to the possibility that slight alterations in the substrate processed may alter the mechanism of the individual enzymes [38].

4.3 Stereochemical Differences Between Guaianolides from Apiaceae and Asteraceae

As observed with thapsigargin and other guaianolides, the presence of secondary modifications enhances the complexity of the stereochemistry, especially around the lactone ring. This is of particular interest with regard to the similarities and differences between Apiaceae and Asteraceae. Numerous sesquiterpene lactones have been isolated from both families [5, 39–41], but the guaianolides exhibit a peculiar difference between the two. In Apiaceae, the relative configuration of all 6,12 guaianolides identified so far differs from that of 6,12 guaianolides that have been identified in Asteraceae. In Apiaceae, the lactone ring is either 6β,7α or 6β,7β, whereas only examples of 6α,7β disposed lactones are known in Asteraceae. The difference in guaianolide structure between these two families might not seem to appear critical, but it causes dramatical changes in the conformation of the ring systems. Holub and Budesinsky proposed that these differences appear because of different substrate specificity of the enzymes involved. A possibility could be that the enzymes cyclize the *E*,*E*-FPP in different conformations [40]. Recently, an alternative route was presented based on the observation that (*E,E*)-germacradienes adopt several conformations of which ββ, βα, αβ, and αα are the most stable ones, where α and β refer to the orientation of the C14 and C15 methyl groups [42]. Thus, it was hypothesized that it is possible to transform a germacrene in the dominant αα-conformation (as observed in Asteraceae) into a ββ-conformation germacrene (as observed in Apiaceae) by adding a β-hydroxyl group at carbon C6. This would lead to steric hindrance of the αα-conformation and induce the flipping to the ββ-conformation. The conformation of either of these hypotheses would explain the biogenetic origin of guaianolides. The addition of the β-hydroxyl at C6 is likely to happen during the cyclization of FPP and would therefore lead to a germacrene-6-ol structure as the product of the terpene synthase.

4.4 Guaianolide Biosynthesis in Other Plant Families

In the plant family Lamiaceae, 8,12-lactones with a distinctive stereochemistry and lack of hydroxylation of the 11-12 bond have been isolated. Again, this indicates that different conformations of the substrates are favored by the involved enzymes.

5 Biological Activity

The presence of sesquiterpene lactones in a spectrum of plants suggests an ecological effect. A large number of sesquiterpene lactones, including some guaianolides, have been shown to be antifeedants to insects [43], and guaianolides often serve as defense compounds in the plants from which they are isolated. Conservations in structures in many parts of biomolecules occur all over the animal and plant kingdoms (privileged structures), thereby indicating that potent activity toward one kind of organism implies that other living organisms are affected as well. Plants containing guaianolides are often used to treat inflammatory disorders and related diseases [44]. Indeed, guaianolides possess a broad range of activities including cytotoxicity, antiprotozoal, antimicrobial, anti-inflammatory, and apoptotic activity [5]. In addition, some induce allergic contact dermatitis [45].

A common functional group in many guaianolides and other sesquiterpene lactones is the α-methylene-γ-lactone group and/or α,β-unsaturated cyclopentenone. Both residues react with thiol present in peptides and proteins and are of importance for the mechanism of action of guaianolides. Due to this feature, some guaianolides affect cell signaling, proliferation, apoptosis, and mitochondrial respiration [44]. It is generally thought that biological activity of sesquiterpene lactones possessing these functional residues is mediated by alkylation of nucleophiles (confer Sect. 5.2). The reaction of α,β-unsaturated carbonyl groups with peptides and enzymes has been studied by Schmidt et al. [44] and Kupchan et al. [7].

In many guaianolides, both alkylating groups are present (see Figs. 98.1, 98.2). Potential molecular targets for alkylation include 5-lipoxygenase and leukotriene C_4-synthase, both being enzymes of the leukotriene biosynthesis, glutathione, coenzyme A, papain, and nuclear transcription factors. An IC_{50} of 12 μM of helenalin on LT_4 synthase was determined to be borderline small to be of pharmacological importance for the anti-inflammatory effects [45].

In other cases, the activity is related to the presence of a pharmacophore in the molecule enabling complex formation with proteins without covalent binding. Examples of such guaianolides are the thapsigargins, which block a calcium pump in the cell and thereby induce apoptosis.

5.1 General Toxicity of Guaianolides

Guaianolides that have demonstrated potent cytotoxic activity against human leukemia cell lines have primarily been found in cell proliferation assay, and the inhibitory effects on cell aggregation are then probably caused by general toxic effects. It has been stated in several publications that the α-methylene-γ-lactone moiety of the guaianolides is crucial for the cytotoxic activity in agreement with the hypothesis of a cysteine alkylation [6, 46]. Cytotoxicity of sesquiterpene lactones, with two α,β-unsaturated carbonyl structural elements, has so far not been correlated with lipophilicity, in contrast to monofunctional sesquiterpene lactones whose activity increased with increasing log *P* [7]. A neighboring OH or O-acyl group has been found to enhance the rate of cysteine addition to the lactone. By using pseudoguaianolides as model compounds, it was observed that the cytotoxicity strongly depends on the number and type of alkylating centers. The conformation of the molecule and the number of H-bond acceptors, but not their position, are also deciding factors. The latter parameter indicates that noncovalent interactions of sesquiterpene lactones with proteins might bring the molecule in a position facilitating alkylation [47]. These studies underline that reactivity toward cysteine as well as interactions with further amino acids is of importance for their cytotoxic activity. Studies on the ability of the pseudoguaianolide helenalin to alkylate enzymes and peptides have revealed that a cyclopentenone residue in vitro is more reactive toward the thiol groups of cysteine than is the α-methylene lactone [44].

Also, synthetic derivatives of natural guaianolides have been found to be active against tumor cells. An example is the mono- and dihalohydrin analogues of repin showing significant antitumor potency. Repin itself was found to be potent against seven cancer cell lines. However, the monohalohydrins were generally less active than the parent diepoxide repin, an indication of a disruption of the active sites, namely, the α-methylene-γ-lactone moiety and possibly α,β-unsaturated carbonyls [7, 48]. It is known that the C13 side chain of the diterpenoid paclitaxel is crucial for its strong antitumor activity [49], and it was shown that esterification of repin with the side chain of paclitaxel led to increased potency in all tested cell lines. On the contrary, the presence of a diol rather than an epoxide on the cyclic skeleton of repin abolished activity. Likewise, guaianolides with an allyl hydroxy or diol in the side chain lost activity [48]. Again, these observations are in line with several other publications that have shown that decreasing the number of H-bond donors in the molecules also increased their potency [7, 47, 50–53]. The described cytotoxicity does not only apply to human cells but most likely to all eukaryotes.

5.2 Anti-inflammatory Activity of Guaianolides

In 1999, Irmgard Merfort and her group published a thorough study of sesquiterpene lactones and their NF-κB inhibitory activity [53, 54]. The term nuclear transcription factor (NF) applies to a family of highly homologous protein occurring ubiquitously in mammalian cells. NF-κB consists of two subunits of M_r 50 and 65 kDa. NF-κB is a genetic switch for many different genes encoding cytokines such as interleukins as well as inducible enzymes such as cyclooxygenase II and nitric oxide synthase. The most potent compounds in Merfort's study were pseudoguaianolides, guaianolides, germacrolides, heliangolides, melampolides, and 4,5-dihydrogermacranolides. In addition to an α-methylene-γ-lactone group, all the potent inhibitors had at least one further α,β- or α,β,γ,δ-unsaturated carbonyl group. The latter was concluded to serve as a bifunctional Michael acceptor (alkylant), with some of the structures having an additional α,β-unsaturated acyl side chain serving as a trifunctional Michael acceptor.

Additionally, Merfort concluded that sesquiterpene lactones that only have either a methylene lactone or a conjugated keto group are much less potent since they require inhibitory concentrations of about 100–200 μM. This lack of activity cannot be compensated by the presence of an α,β-unsaturated ester group. The guaianolide cumambrin A is an exception from this statement by showing a strong NF-κB inhibitory effect even significantly more active than the corresponding alcohol cumambrin B, which might be due to *O*-acetylation [54].

The mechanism of action is based on two cysteine residues, Cys37 and Cys120, in the p65 subunit of NF-κB with their free thiol groups located in a distance of 8 Å. This distance corresponds to the distance between C2 and C13 of helenalin, indicating that the pseudoguaianolide might bridge these two residues and thereby prevents the transcription factor from binding to the DNA-binding domain. A similar mechanism of action can be predicted for other bis-alkylating sesquiterpene lactones.

The same correlation between the esterified guaianolide and the free alcohol described for cumambrin has also been observed for 3β-O-(2-methylbutyryl)-moroccolide A, which showed a significantly higher inhibition of pro-inflammatory gene transcription than moroccolide A [55]. This effect may be related to acceptation of a hydrogen bond in the vicinity of the alkylating site. Such interactions, however, cannot sufficiently be explained with the present knowledge. Moreover, a more precise measurement of activity differences is needed to elucidate the structural factors that modulate the activity apart from alkylant functionality.

It has not yet been shown that the NF-κB inhibition by guaianolides is caused by alkylation at the mentioned cysteines in p65, but in many instances, the underlying chemical reaction has been shown to be correlated to the presences of low-molecular-weight thiols [47, 52, 56]. It is known that sesquiterpene lactone enzyme inhibitory activity is usually associated with the presence of free cysteine residues. Likewise, NF-κB inhibition by an alkylant of completely different structure has been demonstrated [57].

Guaianolides, unlike some other sesquiterpene lactones, have a rigid skeleton. Accordingly, the NF-κB inhibitory activity is not only correlated to the number of unsaturated carbonyl structures in the molecule but also to parameters that describe how the molecule fits into an active site. Additionally, it has been observed, as described, that an increasing number of free hydroxyl groups diminish the inhibitory activity [55]. A lower number of hydroxyl groups correlates with a higher lipophilicity followed by a better penetration through cell membranes. Whether lipophilicity, expressed as log *P*, significantly contributes to the inhibitory activity is still doubtful. Therefore, rather the position than the number of hydroxyl groups may be important for NF-κB inhibition.

Guaianolides have been shown to be favorable as starting materials for synthesis of NF-κB-inhibiting agents compared to other sesquiterpene lactones because of easier synthetic protocols [52]. The compound should possess two α,β-unsaturated carbonyl groups and an acyl moiety near the exocyclic methylene group. Moreover, it has to be considered that the QSAR studies published correlate nicely with the structure – activity requirements for cytotoxicity, making it unlikely to separate the wanted therapeutic effects from the unwanted side effects [52]. To avoid this problem, guaianolides could be either applied only externally or they could be designed as prodrugs that would be liberated at the location of inflammation for the treatment of chronic inflammatory diseases as seen with thapsigargin (Sect. 5.3).

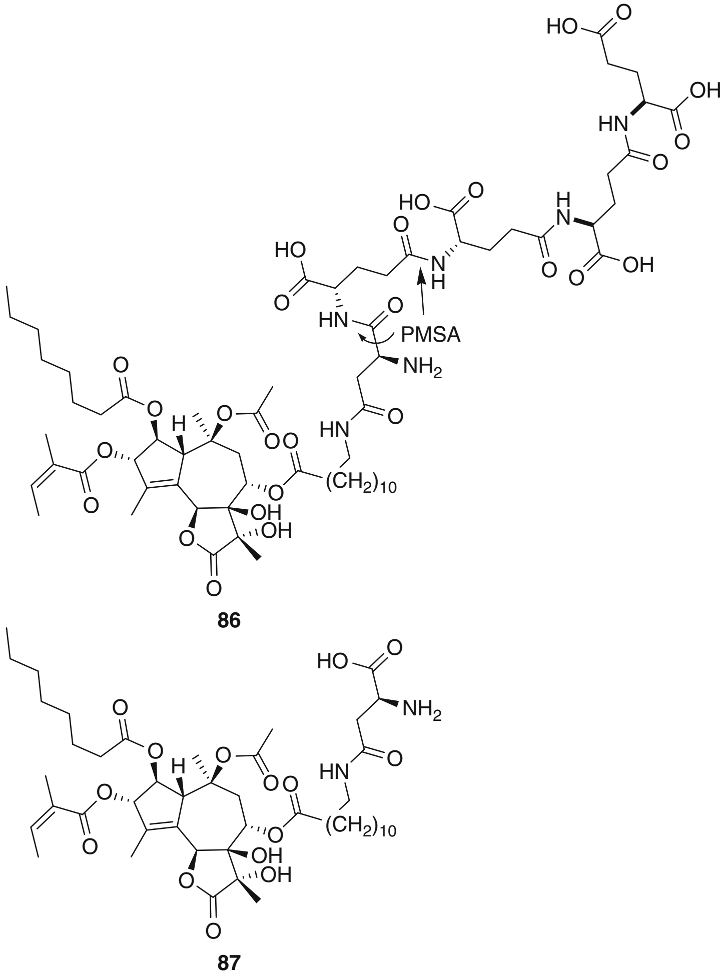
5.3 Thapsigargins: A Well-Studied Group of Guaianolides from Apiaceae

Thapsigargins are a structurally unique type of guaianolides: they are trans hydroxylated at C7 and C11 and possess a trans-annelated C7α-C6β γ-lactone ring (Fig. 98.2, **11**). Thapsigargins are known for their biological activity, despite the fact that they are lacking an unsaturated carbonyl moiety. Thapsigargin (**11**) originally was isolated as the skin irritant principle of the Mediterranean medicinal plant *Thapsia garganica*. The compound was found to be an extremely potent liberator of histamine from mast cells. Later studies revealed that the compound inhibited the calcium pump in the endo- and sarcoplasmic reticulum (SERCA) in subnanomolar concentrations. Prolonged inhibition of this pump results in an elevated cytoplasmic Ca^{2+} level, which eventually leads to the death of the cell. Thus, the anticancer activity of thapsigargins is mediated by a different mechanism than the one mentioned above. An X-ray structure of the thapsigargin-SERCA complex has enabled detailed studies of the binding site and the structural conformation of the binding complex, thereby also providing some clues used for later design of a targeted prodrug with thapsigargin as the active part [8]. Major contributions to the affinity of **11** to SERCA are lipophilic interactions of the angeloyl, the butanoyl, and the acetyl moieties with the backbone of the protein. In addition, the $CH_3$15 further assists in interaction with the pump. The importance of the different side chains has been confirmed by preparation of several analogues in which these side chains have been either removed or stereocenters had been inverted in order to prevent interaction of the appropriate side chain with SERCA. These studies revealed the importance of several of the residues present in thapsigargin (**11**). An interesting discovery was the dramatic effect caused as soon as stereochemistry at C8 changed. When changing the ester group from α to β configuration, the Ca^{2+}-ATPase inhibiting properties of the molecule decreased 3,000-fold [37]. X-ray analysis revealed that this residue was situated in a cavity between helices when bound to the SERCA protein, in which it would not fit with the alternative configuration. Equally, the results showed that removing the angeloyl group or simply changing the stereochemistry of C3 resulted in a significant decrease of the Ca^{2+}-ATPase inhibitory effect [8].

Replacement of the C10 acetoxy with a hydroxy moiety also decreased the biological activity of thapsigargin. Similarly, reversal of the stereochemistry at C3 severely decreased the affinity for the SERCA pump. These findings reveal that the localization of the side chain is of far more importance than the structure of the side chain, within certain limits [58]. The structure of the acyl group linked to the C8–O could be varied extensively if flexibility of the residue is maintained. These investigations laid the foundation of the subsequent design of thapsigargin analogues used for specific cell targeting (Fig. 98.5) [8].

A remarkable feature of thapsigargin is its ability to induce apoptosis in both slowly and rapidly dividing cells [59]. This contrasts usual chemotherapeutic agents, which mainly nonselectively target rapidly dividing cells and thus are unsuccessful in treatment of slowly developing cancer diseases. Per se, thapsigargin is unfit as a drug since it will kill all kinds of mammalian cells, irrespective of being benign or malignant. This drawback has been overcome by preparation of a prodrug. Prostate cancer cells in general proliferate slowly and are therefore not effectively treated with traditional chemotherapy. The neovascular tissue of prostate cancer tumors and many other solid tumors overexpresses the proteolytic enzyme prostate membrane specific antigen (PMSA). This enzyme is a serine protease that cleaves at specific amino acid motifs. Replacement of the 8-butanoyl-moiety in **11** with a specific peptide, including both a flexible region and the amino acid sequence recognized by PMSA, would result in a prodrug that would be activated in the proximity of cancer cells. The flexible region was determined by varying the length of the C8-positioned residue, and a candidate was chosen based on its preserved activity against prostate cancer cells (see Fig. 98.5) [60].

Preliminary trials showed that the prodrug (**86**) itself did not have any cytotoxic activity at 10 μM. However, the same dosage was able to completely inhibit the growth of a human prostate cancer cell line. Also, when tested in vivo in nude mice with xenografts from a human prostate cancer cell line, the level of cleaved active



86

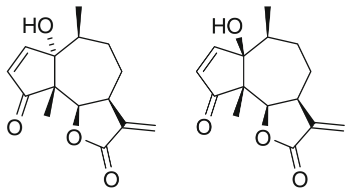
Fig. 98.5 The two *arrows* indicate the cleavage site for the enzyme PMSA. Compound **86** is at the time of writing in clinical trial 1 as a drug against a broad spectrum of cancer diseases. Compound **87** is the major drug formed by cleavage of the prodrug **86** in neovascular tissues in tumors [35]



88 **89**

Fig. 98.6 The pseudoguaianolides parthenin (**88**) and hymenin (**89**)

drug was much higher in tumor tissue than in the plasma or skeletal muscle of the mice, confirming effective drug targeting [61]. A prodrug based on thapsigargin is currently being developed by GenSpera, Inc. Further results have shown that the C2-positioned octanoyloxy moiety of thapsigargin does not bind to the SERCA pump. However, the residue has affinity for the inhibition of the pump, probably through binding to the lipids in the cell membrane.

5.3.1 SERCA Activity of Other Guaianolides in Apiaceae

Of the remaining guaianolides isolated from the plant family Apiaceae, most have only been isolated for elucidation of their structures. Additionally, many of them are only present in very small amount in the plants, making the biological examination very difficult.

A few of the identified compounds have, however, been tested in different assays. Among those were fegolide and three other structurally related guaianolides, but none of them showed significant activity as SERCA inhibitors [62]. The lack of inhibitory effect might be explained by the absence of a O8 residue in these compounds. Two of the tested structures have an acetoxy group at C3, but this is apparently insufficient to establish an effect. Anyhow, this suggests that several of the other guaianolides isolated from Apiaceae might have SERCA-inhibiting properties since many have an ester-bound residue at O8. However, quite a few also have substituents at C11, a substituent that will interfere with SERCA binding because of its proximity to one of the helices comprising the binding site. As mentioned, publications concerning the activity of sesquiterpene lactones focus on compounds with a methylene group at C11 on the lactone ring [5].

5.4 Antiprotozoal Activity of Guaianolides

Guaianolides have also been intensively examined toward protozoa like members of the genera *Trypanosoma* (sleeping sickness), *Leishmania* (leishmaniasis), and *Plasmodium* (malaria); only studies that also tested cytotoxic activity are considered here. In all cases, an antiprotozoal activity correlates positively with cytotoxicity, and the major determinants for activity are α,β-unsaturated carbonyl residues. Certain compounds are considerably more toxic against protozoa than against mammalian cells and vice versa. A comparative QSAR analysis has been undertaken, and both activities were found to depend mainly on the same structural elements and molecular properties. The observed variance in the biological data can maybe be explained by the positioning of the various molecules in the active site [63–65].

It appears therefore difficult to exploit the relative subtle structural differences responsible for differential activity with respect to lead structure optimization. While further QSAR models might reveal a clearer and more detailed relationship, the prodrug strategy chosen for thapsigargin might be useful for protozoa as well, especially with the several unique protozoal drug targets published in the recent years.

5.5 Allergic Contact Dermatitis

Allergy provoked by contact to plants belonging to Asteraceae is in most cases caused by sesquiterpene lactones. The type of immune response involved is delayed hypersensitivity, also termed type IV allergy. Also in this case, the sensitizing potential depends on the presence of alkylating groups. It is assumed that the allergy evolves because alkylation of proteins creates proteins unknown to the organism and therefore activates the immune response. The presence of an α-methylene-γ-lactone is the main requisite; however, the presence of this group is not sufficient since some sesquiterpene lactones possessing this structural unit are not sensitizing. The pseudoguaianolide parthenin (Fig. 98.6, **88**) is the allergenic principle of the plant *Parthenium hysterophorus*, also known as the scourge of India.

No simple correlation has been found in the structure-cross-sensitivity relationships, and hymenin (**89**) shows no cross sensitivity with the diastereomer parthenin.

5.6 Aromatase Inhibitors

Aromatases are key enzymes in the biosynthesis of estrogens, and inhibitors are used for treatment of hormone-dependent breast cancer. The aromatase inhibitor aminoglutethimide (Cytadren®) is presently used as a drug. The sesquiterpene lactone 10-epi-8-deoxycumambrin B (Scheme 98.13, **90**) has been shown to be a potent inhibitor of this enzyme, but hydrogenation of the 11,13-double bond afforded an even more potent inhibitor (**90**) inhibiting the aromatase in the same concentration range as aminoglutethimide [45, 66]. The guaianolides are believed to compete with testosterone for the binding site. A further advantage of removing the Δ11-13double bond was the significant lowering of the general cytotoxicity.

6 Conclusion

This chapter gives an overview of the chemistry, biochemistry, and pharmacology of guaianolides, mainly from the two plant families Asteraceae and Apiaceae. At present, the guaianolide most likely to become drugs are derivatives of thapsigargin, which is a very selective inhibitor of the SERCA pump. Nonetheless, the data presented here show the diverse range of guaianolides that are generated by different plants. Considering the number of guaianolides, the possibility that some of these might interact with new potential pharmacological targets enabling new principles of treatments, as did thapsigargin, should not be overlooked. With the increasing knowledge of the human genome, new and attractive targets might be revealed. In light of the interesting biological activities revealed by many of the guaianolides, a compelling argument is that the rest should also be investigated in depth.

Abstract

Artemisinin, a sesquiterpene lactone endoperoxide and isolated from aerial parts of *Artemisia annua* L. plants (family Asteraceae; commonly known as sweet wormwood), is popular as a potent, promising, highly effective, safe, and best therapeutic agent against drug-resistant strains of *Plasmodium* sp. The low yield of artemisinin content, is a serious limitation to its ability and affordablity to the most malaria sufferers. The chemically synthesized artemisinin is also costly due to low yield of the process. The World Health Organization (WHO) recommends the use of artemisinin-based combination therapies (ACTs), for the first-line treatment of malaria. To date, *A. annua* L.

is the only commercial source of artemisinin. Due to the urgent demand and short supply of this compound for the manufacture new antimalarial drugs (ACTs), efforts are being made worldwide to enhance its production by employing plant tissues culture and metabolic engineering of *A. annua* L. plants as well as microbes. So, in this chapter, we have discussed the various aspects of biotechnological approaches, including plant tissues culture and genetic engineering of *A. annua* L., *E. coli*, and *Saccharomyces cerevisiae*, to improve artemisinin production as reduce the cost of artemisinin based combination therapies (ACTs) to significantly below their current prices.

Keywords

Artemisia annua L. • artemisinin • malaria • metabolic engineering • plant tissue culture

Abbreviations

ACT	Artemisinin-based combination therapy
ADS	Amorpha-4, 11-diene synthase enzyme
ads	Amorpha-4, 11-diene synthase gene
Aldh1	Aldehyde dehydrogenase 1
cps	*β*-caryophyllene synthase gene
dbr2	double-bond reductase2 gene
DMAPP	Dimethylallyl diphosphate
ECS	Epi-cedrol synthase
FPP	Farnesyl diphosphate
fps	Farnesyl pyrophosphate synthase gene
fs	(E)-β-farnesene synthase gene
GPP	Geranyl diphosphate
gpps	Geranyl diphosphate synthase gene
GS	Germacrene A synthase
HMGR	Hydroxymethylglutaryl coenzyme A reductase
hmgr	hydroxymethylglutaryl coenzyme A gene
IPP	Isopentenyl diphosphate
RT-PCR	Reverse transcriptase polymerase chain reaction
sqs	squalene synthase gene

1 Introduction

Artemisinin (Qinghaosu) is a sesquiterpene lactone containing an endoperoxide bridge. It is popular as a potent, promising, safe, and best therapeutic agent against both drug-resistant and cerebral malaria causing strains of Plasmodium sp. [1]. It is a highly oxygenated sesquiterpene, containing a unique 1, 2, 4- trioxane ring structure, which is responsible for the antimalarial activity. Besides being its commercial use as antimalarial drug, it is also found to be effective for other infectious diseases such as schistosomiasis, HIV, hepatitis B, anti-leishmaniasis, and herbicidal [2–7]. Artemisinin has shown effectiveness against a variety of cancer cell lines, including breast cancer, human leukemia, colon cancer, and small cell–lung carcinomas [8, 9]. It was first isolated from the aerial parts of Traditional Chinese Medicinal herb *A. annua* L. plants by the Chinese Scientists [10]. The WHO in the year 2005 recommended the use of artemisinin derivatives in combination with other effective schizontocidal drugs, a treatment known as artemisinin-based combination therapy (ACT), for the first-line treatment of malaria [11]. The reported artemisinin contents in *A. annua* vary from 0.5 to 0.9 % (in India) and from 0.9 to 1.2 % globally [12]. There is a wide gap between the demand of artemisinin (40–50 t in India) and its supply (2 t in India). The cost of ACTs per dose at government public health clinics is around USD 1.00 and much higher at private pharmacies [13]. Due to its current use in artemisinin-based combination therapy (ACT), the global demand of artemisinin is continuously increasing. But the relatively low yield of artemisinin in *A. annua* L. plants (0.01–1.1 %) is a serious limitation to its commercialization [14, 15]. In recent years there have been large fluctuations in the price and availability of ACTs [16], and in 2007–2008 less than 15 % of children below the 5 years of age with fever received ACTs in 11 out of 13 countries surveyed [17]. So, there is an urgent need to increase the supply of artemisinin to both stabilize the price and increase the availability of ACTs in the developing world. Therefore, significant increase in the cultivation of *A. annua* L. plants would be needed to satisfy projected global demand. The chemical synthesis of artemisinin is not economically feasible, because of the complexity, low yield of the process, and lack of cost-effective, viable synthetic protocol [18]. To overcome this problem, efforts are being made worldwide to enhance its production employing various approaches such as conventional breeding and biochemical as well as physiological methods [19]. These approaches show potential for future development, but improvements delivered by them so far have not met the global demand. Therefore, the plant *A. annua* L. is still the only valid source of artemisinin.

2 Biosynthetic Pathway of Artemisinin in *Artemisia annua* L. Plant

Artemisinin biosynthesis takes place in the glandular trichomes of the plant. Different kinds of terpenoids in nature shared a common precursor, isopentenyl diphosphate (IPP); of course, artemisinin recognized as a sesquiterpene lactone is not an exception [20]. In artemisinin biosynthesis, there are two independent pathways producing IPP. One is the classical cytosolic mevalonate pathway (MVA) originating from acetyl Co-A and the other is the methylerythritol phosphate pathway (MEP) or 1-deoxy-D-xylulose-5-phosphate (DXP) localized in plastids, starting from pyruvate. The mevalonate pathway (MVA) has been discovered over half a century and the molecular genetics of MVA pathway has been elucidated. The genes involved in MVA pathway have been characterized by molecular genetics and biochemistry approaches. The cytosolic MVA pathway provided major part of the carbon skeleton for artemisinin biosynthesis (80.0 %) as compared to MEP/DXP pathway (14.0 %). Mevalonate (MVA) is the primary building block for isoprenoid biosynthesis in higher plants. It serves as a common precursor for the production of a number of compounds vital to normal plant growth and development, including carotenoids, the phytol tail of chlorophylls, plastoquinone, and ubiquinone, as well as the phytohormones viz abscisic acid (ABA), cytokinins, and gibberellins. Mevalonate also contributes to the formation of a wide variety of plant secondary metabolites such as phytoalexins, rubber, terpenoids, and indole alkaloids. Terpenoids are derived from two well-known common precursors, isopentenyl diphosphate (IPP) and its isomer dimethylallyl diphosphate (DMAPP).

In the MVA pathway, the acetyl-CoA C-acetyltransferase (AACT) catalyzes the first step, the condensation of three molecules of acetyl-CoA molecules to form acetoacetyl-CoA. 3-Hydroxy-3-methyl-CoA synthase (HMGS) catalyzed the condensation of acetyl-CoA with acetoacetyl-CoA to produce 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) and CoA. The 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) is used as intermediate for biosynthesis of various terpenes, viz., mono-, di-, tri-, and sesquiterpenes including artemisinin [21–23]. HMG-CoA is then reduced by the enzyme HMG-CoA reductase (HMGR) to yield mevalonic acid (MVA). HMGR is a rate-limiting enzyme that can be inhibited specifically by lovastatin and catalyzes the NADP-dependent synthesis of mevalonate from HMG-CoA, which is the most important committed step of the MVA biosynthetic pathway. The 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA), under the catalysis of mevalonate kinase, is converted to mevalonate 5-diphosphate, which is subsequently decarboxylated to yield IPP [24].

Besides the mevalonate pathway, a non-mevalonate pathway (MEP/DXP) operates in plastids. It also provides carbon for the synthesis of artemisinin. The DXP pathway was firstly discovered in plants in the year 1994 by Dr. Schwarz during his study on the biosynthesis of the ginkgolides in *Ginkgo biloba* [25]. Due to rapid development in bioinformatics and comparative genomics, that are revolutionizing the study of plant metabolism, the genes involved in the DXP pathway have been cloned and identified in different organisms. 1-Deoxy-D-xylulose-5-phosphate synthase (DXPS) catalyzes the thiamine pyrophosphate-dependent acyloin condensation between carbon atoms 2 and 3 of pyruvate and glyceraldehyde 3-phosphate to yield 1-deoxy-D-xylulose-5-phosphate. In the plants, DXPS is the first enzyme and a rate-limiting enzyme of the DXP pathway a potential target for metabolic engineering involved in the biosynthesis of isoprenoids plastids. It is 1-Deoxy-5-phosphate reductoisomerase (DXR) catalyzes the rearrangement and subsequent reduction of DXP to form 2-C-methyl-D-erythritol 4-phosphate (MEP), it is also the rate-limiting enzyme in this pathway [23]. 2-C-methyl-D-erythritol 4-phosphate cytidylytransferase (MCT) catalyzes the third step of the DXP pathway to form CDP-ME by conjugating CDP and MEP. 4-(Cytidine 5′-diphospho)-2-C-methyl-D-erythritol kinase (CMK) catalyzes the phosphorylation of CDP-ME to form CDP-MEP. 2-C-Methylerythritol 2, 4-cyclodiphosphate synthase (MECPS) catalyzes the conversion of CDP-MEP to 2-C methylerythritol 2, 4-cyclodiphosphate (ME-cPP). The final two steps on the DXP pathway include the formation of hydroxymethylbutenyl 4-diphosphate (HMBPP) from ME-cPP catalyzed by hydroxymethylbutenyl 4-diphosphate synthase (HDS) and the direct conversion of HMBPP in to a 5:1 mixture of isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP) by IPP/DMAPP synthase (IDS).

Upon the synthesis of IPP (C_5) and its isomer DMAPP (C_5) by either MVA or DXP pathways, the next step is chain elongation. The carbonium ion is a potent alkylating agent that can react with IPP (three molecules of IPP converted into one molecule of geranyl diphosphate (GPP) by condensation reaction catalyzed by enzyme geranyl diphosphate synthase), to yield geranyl diphosphate (GPP). Farnesyl pyrophosphate synthase (FPS) is the prenyltransferase that catalyzes 1′-4 condensation reactions of IPP with the allylic diphosphates, dimethylallyl diphosphate (DMAPP), to produce farnesyl pyrophosphate (FPP).

After FPP synthesis, the biochemical reactions and enzymes involved have not been fully understood and well characterized. Akhila et al. [21] proposed a complete biosynthetic pathway for artemisinin, starting from mevalonic acid and IPP. The pathway branches at FPP. FPP is converted in to squalene by the enzyme squalene synthase (SQS) and subsequently into sterol. SQS is the key enzyme catalyzing the first step of the sterol biosynthetic pathway, a pathway in competition with that of artemisinin biosynthesis [26].

The first committed step in artemisinin biosynthesis in *A. annua* L. is the conversion or cyclization of FPP to amorpha-4, 11-diene by the enzyme amorpha-4, 11-diene synthase (ADS) [27–30]. Amorpha-4, 11-diene is the direct precursor of artemisinin biosynthesis. In the following step, amorpha-4, 11-diene is hydroxylated to yield artemisinic alcohol. This reaction is catalyzed by a multifunctional cytochrome P450-dependent hydroxylase (*CYP71AV1*) capable of multiple oxidation of amorpha-4, 11-diene. This is followed by oxidation at C-11 of amorpha-4, 11-diene by the cytochrome P450-dependent hydroxylase (*CYP71AV1*) to give artemisinic alcohol. This enzyme can also oxidize the artemisinic alcohol to artemisinic aldehyde and then further on to artemisinic acid [31, 32]. It has long been assumed that artemisinic acid is a direct precursor of artemisinin. The pathway also branches at artemisinic aldehyde to give artemisinic acid by the action of cytochrome P450-dependent hydroxylase (*CYP71AV1*) [31, 32] or to give dihydroartemisinic aldehyde by the action of artemisinic aldehyde Δ11 reductase (Dbr2) [33] in which C11–C12 double bond of artemisinic aldehyde is reduced and subsequently oxidized into dihydroartemisinic acid catalyzed by aldehyde dehydrogenase 1 (Aldh1) [34]. The dihydroartemisinic aldehyde is reduced into dihydroartemisinic alcohol. This reaction is catalyzed by the enzyme dihydroartemisinic aldehyde reductase (*Red1*), but this enzyme does not convert artemisinic aldehyde into dihydroartemisinic alcohol despite its close similarity with grater chemical reactivity than dihydroartemisinic aldehyde [35]. Dihydroartemisinic alcohol appears to be a “dead-end product” that may be affecting the yield of artemisinin in a negative way (Fig. 99.1).

The conversion of dihydroartemisinic acid to artemisinin is believed to be a nonenzymatic spontaneous photooxidation or autoxidation reaction. The mechanism of this complex transformation is shown to involve four steps: first, initial reaction of the C11–C12 double bond of dihydroartemisinic acid with single molecular oxygen; second is the Hock cleavage of the resulting tertiary allylic hydroperoxide; third is the oxygenation of the enol product from Hock cleavage; and fourth is the cyclization of the resulting vicinal hydroperoxyl-aldehyde to the 1, 2, 4-trioxane system of artemisinin. The other pathway includes artemisinic acid converted to arteannuin B. Based on labeling studies, artemisinic acid and its derivatives, such as artemisinic acid hydroperoxide, arteannuin B, and artemisitene, have been suggested as precursors to artemisinin. Clearly, a more detailed knowledge of the biochemistry of C11 double-bond reduction during artemisinin formation is important in differentiating the proposed routes, which can be considered "early" and "late" reduction pathways [36].

3 Strategies to Enhance Artemisinin Production

There are a number of limitations to obtain plant-derived compounds. They may be restricted to one species or genus and might be formed only during a particular stage of growth or development or under specific seasonal, stress, or nutrient availability conditions [37, 38]. Chemists are trying to synthesize plant-derived compounds via organic chemistry. This is often hampered by the chemical complexity, the specific stereochemistry, and the economic feasibility. Metabolic engineering may offer prospects to overcome the lack of availability of such compounds, through the advancement of the molecular biology techniques, including cloning, recombinant DNA, and knowledge of the plant biosynthetic pathways.

3.1 Biotechnological Approaches to Enhance Artemisinin Production in *Artemisia annua* L. Plant

To date, cultivated *A. annua* L. plants are the only natural source of this antimalarial drug worldwide. However, the low yield of artemisinin in *A. annua* L. (0.30–1.00 % on dry weight) is a serious limitation to the commercialization in the form of ACTs. Chemical synthesis is economically not feasible and also not affordable to developing countries for treatment of malaria. In order to enhance artemisinin content in *A. annua* L., various efforts have been attempted globally. In last two decades, much progress has been made to elucidate the biosynthetic pathway of artemisinin in *A. annua* L. and cloning as well as characterization of the rate-limiting genes (enzymes) and a number of other genes that are involved in the biosynthesis of artemisinin in *A. annua* L. plants. This information offers the genetic manipulation of *A. annua* L. to increase the artemisinin content by overexpression of endogenous and heterologous rate-limiting genes and suppression of genes which encode the first enzymes of the competing branched pathways.

3.1.1 Metabolic Engineering

Metabolic engineering in plants involves the modification of biosynthetic pathways to increase the carbon flux toward, particular desired metabolites. It aims at three goals: overproduction of the desired compound, less production of the unwanted compounds, and the production of a novel compound (one which is produced in nature, but not in the host plant) [39]. Strategies, that are involved to increase the level of valuable target molecules, could be either increasing flux to the target molecule, overcoming rate limiting steps, reducing flux through competing pathways, overexpressing regulatory gene(S), or transcription factors to induce the pathways, inhibiting or limiting catabolism of the desired molecule. However, it needs to understand the regulation of the metabolic pathways involved at the levels of product formation. Specific enzymes and genes involved with other aspects such as intracellular transport and compartmentation of the desired molecule should also be taken into account to enhance its biosynthesis. Considerable work on engineering single step in the metabolic pathway has already been performed in *A. annua* L. plants. In our laboratory, we have however, engineered two steps that are very crucial in artemisinin biosynthesis [42, 43, 44].

3.1.2 Upregulating of Pathways (Overexpression of Endogenous and Heterologous Genes)

Overexpression of single or multiple genes through genetic engineering approach may lead to the increase in some rate-limiting enzymes involved in metabolism and consequently results in the accumulation of the target products. The cytokinin gene, isopentenyl transferase (IPT), catalyzes the condensation of isopentenyl diphosphate (IPP) with adenosine monophosphate to give isopentenyl AMP (iAMP) [40]. Sa et al. transferred the ipt gene isolated from A. *tumefaciens* into *A. annua*. In the transgenic plants obtained, the cytokinin (iPA and iP) content was elevated two- to threefold, the chlorophyll content increased by 20–60 %, and artemisinin content increased by 30–70 % compared to the control plants [41]. The 3-hydroxy-3-methylglutaryl-CoA reductase (HMGR) catalyzes the conversion of HMG-CoA to mevalonate, the first committed step in isoprenoid biosynthesis pathway in plants. In our laboratory, HMG-CoA reductase (*hmgr*) gene isolated from *Catharanthus roseus* L. was overexpressed in *A. annua* L. by using *Agrobacterium*-mediated gene transfer technology. Artemisinin content in one of the *A. annua* L. transgenic lines obtained was 38.9 % higher than that in non-transgenic plants, and HMGR enzyme activity in transgenic *A. annua* L. was also higher than that in the non-transgenic lines [42, 43] (Fig. 99.1). Recently, in our lab, HMGR gene from *C. roseus* L. along with amorpha-4, 11-dienesynthase (*ads*) from A. *annua* L. was also overexpressed in *A. annua* L. plants. Significant enhancement of artemisinin content (7.65-fold) was observed in one of the transgenic lines than non-transgenic plants [44]. Chen et al. previously reported that FPS (farnesyl diphosphate synthase) is a key regulatory enzyme in sesquiterpene biosynthesis [45]. *fps* gene was first cloned from *A. annua* by Matsushita et al. in the year 1996 [46] and 34.4 % artemisinin content and two- to threefold FPS activity were noticed in the transgenic lines than the transgenic plants developed by overexpressing the endogenous fps gene [2, 47]. Banyai et al. have overexpressed the endogenous *fps* gene in *A. annua* L. and studied its effect on biosynthesis of artemisinin content in transgenic A. *annua* L. plants. They showed 2.5–3.6-fold higher artemisinin content in transgenic lines than that of wild-type plants [48, 49]. Recently, 1.8-fold enhancement of artemisinin content was also reported in transgenic plants by co-overexpressing of two key regulatory genes (*hmgr* and *fps*) isolated from *A. annua* L. plants [49]. Further, overexpression of two key genes together, cytochrome P450 monooxygenase (*CYP71AV1*) and cytochrome P450 reductase (*CPR*), of artemisinin biosynthetic pathway had resulted in 2.4-fold higher artemisinin content than that in the control plant [50]. WRKY transcription factor study illustrates that WRKY proteins often act as repressors as well as activators and that members of the family play key roles in both the repression and repression of important plant processes. Majority of the artemisinin biosynthetic genes expressions were activated by transient expression of *AaWRKY1* cDNA. These results strongly suggest that *AaWRKY1* transcription factor participates in the regulation of artemisinin biosynthesis [51]. Besides engineering of isoprenoid synthetic pathway and artemisinin biosynthetic pathway, the overexpression of cyrptochrome 1 (CRY1) gene isolated from *Arabidopsis thaliana* was also led to achieve high artemisinin content (30–40 % higher) in transgenic *A. annua* L. plants when compared with the non-transgenic plants [52] (Fig. 99.1).

3.1.3 Downregulating the competing Pathways (Suppression of Squalene and Caryophyllene Synthase Genes)

In isoprenoid biosynthesis, FPP plays a central role as an intermediate precursor for synthesis of various sesquiterpene including β-caryophyllene [53], germacrene A [54], E-β-farmescene, *epi*-cedrol [55], squalene (first committed precursor of sterol biosynthesis) [26], and amorpha-4,11-diene (first committed precursor of artemisinin biosynthesis) [27–30]. All genes (full length cDNAs) responsible for encoding the enzymes associated with the synthesis of above sesquiterpene have been cloned and sequenced. Among the six above-mentioned sesquiterpene synthases, except *ADS*, all the other five sesquiterpene synthases compete for FPP with artemisinin biosynthesis. So, if the expression of gene encoding these sesquiterpene synthase(s) could be blocked by antisense technology or RNA interference, then the FPP contribution to artemisinin biosynthesis could possibly be increased and the biosynthesis of artemisinin could be enhanced. The antisense fragment of β-caryophyllene synthase cDNA (*asCPS*) was introduced into *A. annua* L. plants by an *Agrobacterium*-mediated transformation approach to assess the effects of inhibiting the competitive pathway on artemisinin biosynthesis by Chen et al. The artemisinin content of one of the transgenic lines was increased up to 54.9 % compared with the wild-type plants [56]. Similarly, sterol biosynthesis was also downregulated by suppressing the expression of squalene synthase gene (sqs) (Fig. 99.1) using hpRNA-mediated RNAi technology through *Agrobacterium*-mediated transformation method in *A. annua* L. plants. It resulted into increased artemisinin content (3.4-fold) rather than sterol production [57].

In one of the recent studies, five plant- and yeast-derived genes, involved in the mevalonate and artemisinin biosynthetic pathways, were cloned into a single mega-expression vector and introduced into *Nicotiana tabacum* resulting into the biosynthesis of artemisinin. Though the artemisinin levels in the transgenic tobacco plants were lower than that in *A. annua* L. plants naturally, the experimental platform developed may, in future, lead to the biosynthesis of various natural products in other heterologous plant systems [58].

3.1.4 Synthetic Biology

Due to the urgent demand and short supply of this antimalarial compound and till date, *A. annua* L. plants still the only source of artemisinin and its supply for the commercial production of ACTs [18] is a serious limitation to meet the global demand. Remarkable efforts have been made in the past towards structure modification of artemisinin and its analogue production. But, the chemical synthesis of artemisinin is not economically feasible due to the complexity and low yield of the process [59]. The semisynthesis of artemisinin following microbial production of a precursor molecule may however, be feasible [60]. So, microbial transformation serves as a valuable tool in the modification. Elucidation of biosynthetic pathway, including successful cloning, characterization, and expression of sesquiterpene synthase genes, provides an opportunity to manipulate the pathway in microbes other than plants. The reconstruction of the complete biosynthetic pathway towards artemisinin biosynthesis in transgenic yeast and bacteria has, however, not been achieved. The synthetic biology, therefore may be an alternative way to develop more potent antimalarial agents by production of artemisinin precursor with improved in vivo stability. Progress in production of artemisinin through metabolic engineering of genetically modified microbes is now being explored. The engineered microbial systems producing artemisinin or its precursor, which chemically can be converted to artemisinin, should facilitate the production of this by providing a cheap and environmentally benign alternative to extraction from the plant. For the production of appropriate precursors for artemisinin biosynthesis, the mevalonate pathway producing IPP along with synthetic amorpha-4, 11-diene synthase gene has been mobilized from yeast to *E. coli*, to produce amorphadiene [61] (Fig. 99.1). In recent years, efforts were also done to improve the production of amorphadiene through heterologous overexpression of mevalonate and, artemisinin biosynthetic genes from *A. annua* L. plants in yeast and yeast-conform variant to yield >40 g/L product. A chemical process was developed to convert amorpha-4, 11-diene to dihydroartemisinic acid, which could subsequently be converted to artemisinin [62, 63]. Similarly, the metabolic engineering of *S. cerevisiae* using engineered mevalonate pathway, and heterologous overexpression of amorphadiene synthase, as well as a novel cytochrome P450 monooxygenase (*CYP71AV1*) from *A. annua* that performs a three-step oxidation of amorpha-4, 11-diene, to produce high titers (up to 100 mg/l) of artemisinic acid is the next step hoping to semisynthesis of artemisinin [32, 64]. Artemisinic acid can also be reduced to dihydroartemisinic acid, which is auto-oxidized to artemisinin [65]. Artemisinic acid available from these transgenic microbes facilitates the subsequent partial synthesis of artemisinin by either chemical or biotransformational process, thereby providing an attractive strategy alternative to the direct extraction of artemisinin from *A. annua* L. The engineered microbes, capable of producing artemisinic acid at a significantly higher specific productivity than *A. annua* L. plants and, yield optimization as well as industrial scale-up, hence, will be required to raise artemisinic acid production to a level high enough to reduce the cost of artemisinin based combination therapies (ACTs).

3.2 Plant Tissue Culture

In principle, each plant cell, tissue, organ, or any part of the plant have the ability to divide and differentiate in to whole plants or organism in vitro under aseptic condition through a method known as micropropagation. This excellent whole process is known as "plant tissue culture." Plant cell culturing was initiated in the 1930s [66] and would offer alternatives to improve the production of the secondary metabolites, since natural harvest is sometimes bulky and not feasible from an economic point of view. The whole plants, plant organs, and even single cells can be used for the production of artemisinin and other secondary metabolites or pharmaceuticals. Various physiochemical factors such as quality of light [67, 68], temperature [68], carbon sources, nature of the nitrogen source and their relative amounts [69], water and salt stress [70] phosphate concentration [71], pH, ions concentrations, composition of various phytohormones of medium, and type of the explants influence the regeneration efficiency of plants, plant growth, as well as secondary metabolites including artemisinin [72, 73]. The main advantages of plant cell culturing are easy up-scaling, simple purification schemes due to product secretion, environmental friendliness, and amenability to strict control with regards to the FDA manufacturing standards [74]. Plant cell cultures are also not subjected to the changes in environmental conditions, thus the production of the desired compounds could take place at any location and season [75]. In order to enhance the artemisinin production in in vitro culture of *A. annua* L., the chemical composition of media was altered through addition of gibberellic acid or casein hydrolystate; by omitting plant growth regulators; by precursor feeding (mevalonic acid); by influencing the biosynthesis routing through inhibition of the sterol synthesis using miconazole, naftifine, or terbinafine; by altering the gene expression with 5-azacytidine or colchicine; and by elicitation, using cellulase, chitosan, glutathione, or nigeran. Casein hydrolysate, a source of amino acids and oligopeptides, at low concentration enhances artemisinin production in *A. annua* shoot cultures [76]. A combination of BA and kinetin was found to increase the yields of artemisinin in cultured shoots by 3.6- and 2.6-fold [77]. GA3, a plant hormone that can induce blooming, has been reported to improve growth and artemisinin biosynthesis in shoot cultures, root cultures, and plantlets of *A. annua* [78–81]. Recently, Banyai et al. [82] showed significant enhancement in artemisinin content at flower initiation stage in A. *annua* L. plants after exogenous GA_3-treatment plants in pot culture experiments as compared to the non-treated plants. Abscisic acid (ABA), defined as a stress hormone, plays a central role in responses to biotic and abiotic stresses [83]. It was also reported that ABA could stimulate the accumulation of some secondary metabolites [84]. Various concentrations of ABA evaluated to enhance artemisinin tested by treating *A. annua* L. plants. Significant enhancement of artemisinin content (65 % higher than that of control plant at 10-mM ABA) was observed in ABA-treated *A. annua* L. plants as compared to the non-treated plants [85]. Effects of various ratios and combinations of sugars on artemisinin biosynthesis were investigated in *A. annua* L. plants.

200 % enhancements of artemisinin content were observed in glucose-fed seedlings, while 80 % reduction were noticed in the seedling fed with 27 g/l sucrose + 3 g/l Palatinose [86, 87]. Most groups did not find artemisinin in root part of *A. annua* plant. However, artemisinin content in the shoot part of cultured plantlets was higher than that in the cultured shoots without roots [88, 89]. Enhancing the artemisinin production by precursor feeding was also investigated. Addition of artemisinin precursors to the tissue culture media of *A. annua* L. had resulted in a fourfold increase of artemisinin in the tissue and an 11-fold increase of artemisinin in the spent medium [90]. The feeding of mevalonic acid alone, however, did not induce in enhancement of artemisinin production [76]. But the addition of some compounds such as naphtiphine (an inhibitor of the enzyme squalene epoxidase) to the medium improved the artemisinin production. Other additions, such as 5-azacytidine (a gene regulator), colchicine (a gene regulator), miconazole (an inhibitor of sterol demethylase), and terbinaphine (an inhibitor of the enzyme squalene epoxidase), were too toxic for the cultures to induce an enhancement in the artemisinin production [76]. Kudakasseril et al., however, reported a concentration-dependent increase in the levels of artemisinin and growth of shoot cultures with miconazole [22]. Other sterol inhibitors, such as chlorocholine chloride, 2-isopropyl-4-(trimethylammonium chloride)-5-methylphenylpiperidine carboxylate, and 4- chloro-2-(2–diethylaminoethoxyphenyl)-2-(4-methylphenyl) benzene ethanol, increased both the incorporation of $_{14}$C-IPP into artemisinin by cell-free extracts and the production of artemisinin in shoot cultures of *A. annua*. Effect of triacontanol and chlormequat on growth, plant hormones, and artemisinin yield in *A. annua* L. plants was studied by Shuka et al. [91]. They found that statistically significant positive effect on artemisinin level as well as on plant height, leaf, and herbage was observed by applying triacontanol at 1.0 and 1.5 mg/l^{-1} on *A. annua* L. plants over control plants. Similarly, artemisinin level was also increased but the plant height was decreased at higher concentration of chlormequat (1,000 and 1,500 mg/l^{-1}) over non-treated plants.

3.2.1 Hairy Root and Cell Suspension Cultures

The word “hairy root” (HR) was initially given by Stewards et al. as far back as 1900 [92]. The unique symptom of HR disease is the formation of a hairlike mass of roots. A large number of small unlimited proliferative multibranched adventitious roots overhang as fine hairs directly from the infection site in response to *Agrobacterium rhizogenes* infection, a phenomenon that gave rise to the term “hairy root” [93]. The distinctiveness of the HR-causing organism remained uncertain for a long time. Riker et al. [94] later described and named the hairy-root-causing microorganism as *Phytomonas rhizogenes*, which was later renamed *Agrobacterium rhizogenes* [94]. *A. rhizogenes* is a Gram-negative soil pathogenic bacterium. They classified the genus *Agrobacterium* into two clusters: cluster 2 includes *A. rhizogenes* strains together with some *A. tumefaciens* strains. This conclusion has been accepted and given recognition by other authors [95]. Ackermann first prepared the hairy roots by transformation of higher plants with response to *A. rhizogenes* in the year 1973 [96]. Porter reported that more than 450 species of many different genera and families are known to be susceptible to the infection by *A. rhizogenes* [97] since then many more additions have been made to the list. The use of *A. rhizogenes* has been receiving attention in the past four decades in secondary metabolism research.

The employment of hairy root culture technology offers new opportunities for in vitro production of plant secondary metabolites. For the past two decades, most of the research efforts that use differentiated cultures instead of cell suspension cultures have focused on transformed (hairy) roots. The fast growth, genetic, and biochemical stability; low doubling time; ease of maintenance; and ability to synthesize a range of chemical compounds offer an additional advantage over other undifferentiated plant cell cultures. Hairy roots can synthesize more than a single metabolite and so prove economical for commercial production purpose [98]. It is true that some biosynthetic pathways are not expressed in roots, but in green plant parts such as leaves and shoots. However, hairy root cultures have been shown to accumulate those metabolites also that normally accumulate only in the aerial parts of an intact plant. Artemisinin was thought to accumulate only in the aerial part of the *A. annua* L. plants [99], but several reports have shown that hairy roots can also produce artemisinin [90, 100–102]. *A. annua* L. cell and tissue cultures have been explored for the production of artemisinin, although the yields obtained are not commercially attractive [103, 104]. Hairy root culture exhibited fast growth and high lateral branching on growth regulator-free MS medium. A comparative study in terms of yields from cell suspension culture and hairy root culture had been investigated by Sauerwein et al. [105].

Attempts were made to improve the artemisinin production by optimizing chemical and physical environmental factors. Wang and Tan [106] reported the influence of the ratio of NO_3/NH_4 and total initial nitrogen concentration on the artemisinin yield in hairy roots. With the ratio of NO_3/NH_4 at 5:1(w/w), the optimum concentration of total nitrogen for artemisinin production was 20 mM. Under this concentration, artemisinin production was 57 % higher than that in the standard MS medium [106]. Weathers' research group investigated the effects of media sterilization method and types of sugar on growth and artemisinin accumulation of *A. annua* hairy roots. They found that biomass from filter-sterilized medium was greater than that from autoclaved medium, but artemisinin accumulation from filter-sterilized medium was less than that from autoclaved medium. Growth of hairy roots in the medium with sucrose (3.99 g DW/l) was equivalent to the growth in the medium with fructose (3.75 g DW/l) and significantly better than in the medium with glucose (2.16 g DW/l), while the roots that grew in glucose showed a dramatic stimulation in artemisinin content, which is three- and twofold higher than that in medium with sucrose and fructose [107]. The effects of light irradiation on growth and production of artemisinin were studied in hairy root cultures of *A. annua* L. by Liu et al. [108]. They found that when the hairy roots were cultured under illumination of 3,000 lx for 16 h using several cool-white fluorescent lamps, the dry weight and artemisinin concentration reached 13.8 g/l and 244.5 mg/l, respectively [108]. Wang et al. [67]

investigated the dependence of biomass of hairy roots and artemisinin content on the light spectrum. They found that the highest biomass (5.73 g DW/l) and artemisinin content (31 mg/g) were obtained under red light at 660 nm which were 17 and 67 % higher than those obtained under white light, respectively [67]. Temperature in the range of 15–35 °C also affected growth and artemisinin biosynthesis in the cultured *A. annua* hairy roots. The maximum hairy root growth was found at 25 °C. However, the highest artemisinin content in the root cultures was observed at 30 °C [68]. Wang et al. studies the synergistic rolls of cerebrosides and nitric oxide on stimulation of artemisinin synthesis by applying cerebrosides and nitric oxide on *A. annua* L. hairy root culture. 2.3-fold increase of artemisinin was achieved at 20-day-old treated hairy roots as compared to the control [109]. Recently, Caretto et al. have established *A. annua* cell cultures that are able to produce artemisinin and to respond to the elicitor effect of methyl jasmonate (MeJA) [110]. Some artemisinin produced by these cultures was also observed in the culture medium. In order to improve the artemisinin biosynthesis in *A. annua* cell suspension culture, they investigate the roll of cyclodextrins on artemisinin biosynthesis. Cyclodextrins are nonreducing cyclic oligomers of 1, 4-α-D-linked glucose units, derived from starch by the action of microbial enzyme cyclodextrin glycosyltransferase. The most common CDs are α-, β-, and γ-CDs, which are formed by six, seven, and eight glucose units, respectively. Among the natural CDs, β-CDs, in particular, that are widely used in plant cell cultures to improve the production of various secondary metabolites have been described [111, 112]. The capability of cyclodextrins to form host–guest inclusion complexes with artemisinin has already been reported in several studies using pure artemisinin and various β-CDs. A synergistic effect of β-CDs and MeJA on resveratrol biosynthesis has also been reported. Native β-cyclodextrins, as well as the chemically modified heptakis (2, 6-di-O-methyl)-β-cyclodextrin (DIMEB) and 2-hydroxypropyl-β-cyclodextrins, were added to the culture medium of *A. annua* suspension cultures, and their effects on artemisinin production were analyzed. The synergistic effects of a cyclodextrin and methyl jasmonate treatment were also investigated. 55-mM DIMEB, as well as a combination of 50-mM DIMEB and 100-μM methyl jasmonate, was highly effective in increasing the artemisinin levels in the culture medium. The observed artemisinin level (27 μmol g^{-1} dry weight) was about 300-fold higher than that observed in untreated suspensions [113].

Further attempts were made to enhance yield of artemisinin content through development of hairy roots of high yielding transgenic strains of *A. annua* L. plants by *Agrobacterium rhizogenes*-mediated transformation [114, 107]. Several key genes involved in the biosynthesis of artemisinin have been introduced and overexpressed in *A. annua*. These genes encode enzymes involved in the biosynthesis, artemisinin viz farnesyl diphosphate synthase (FPS) [46], amorpha-4, 11-diene synthase (ADS) [27–30], and 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGR) [42–44, 47, 49, 115]. Hairy root cultures of *A. annua* L. that had also established genetic transformation by it via *A. rhizogenes* were transformed with fps from *G. aboreum*. The artemisinin content in the transgenic plants, which were regenerated from the hairy root cultures, was significantly higher than in the nontransgenic plant [116].

3.2.2 Environmental Regulation and Altered Physiology of Hairy Roots

Factors such as light, carbon source and its concentration, the ionic concentration of the medium, the pH of the medium, phytohormones, temperature and light quality [117], inoculum size, nature of the nitrogen source and their relative amounts [69], and phosphate concentration [71] are known to influence growth and secondary metabolism [72, 118]. Light, temperature, CO_2 and O_2 stress, as physical factors, play important role in controlling greening, growth, and secondary product formation in hairy root cultures.

3.2.3 Elicitation and Artemisinin Production

Plants and in vitro cultured plant cells show physiological and morphological responses to microbial, physical or chemical factors, which are known as "elicitors." They could also be defined as chemical substance which, when introduced in small concentration to a living cell system, initiate or improve the biosynthesis of specific compounds. Elicitation is induced or increased synthesis of secondary metabolites by the plants to ensure their survival, persistence, and competitiveness [119]. Elicitation at right stage of culture, concentration of elicitors, and appropriate combination of the medium and elicitor are also the regulating factors responsible for enhancement of secondary metabolites. Elicitor treatment at late log phase results in higher biomass yield as well as secondary metabolite production, whereas during early phase, if cultures are elicited, that leads to the immediate increase in secondary metabolite production only and lowering the biomass yield [120]. In order to choose the proper elicitor, it is also necessary to understand the signals involved in the process of elicitation. There is evidence that the use of elicitors has been an important strategy for improving the production of secondary metabolites in hairy roots. Elicitation is an interesting metabolic process, which has been used to investigate cell signaling pathways in secondary metabolite biosynthesis.

Oligogalacturonides (OGAs), the pectic fragments released from the plant cell walls, are the well-known oligosaccharides triggering a variety of defense responses in plants. OGA elicitor also exhibits highly specific activity of inducing secondary metabolite production. In early reports, pathogenic and endophyt fungal mycelia have been found to induce for artemisinin biosynthesis. OGA has also induced artemisinin biosynthesis in *A. annua* hairy root cultures. The different fractions of oligogalacturonides (OGA) from polygalacturonic acid hydrolysate had been partially purified using column chromatography. The isolated fraction, OGA2 was found to stimulate the accumulation of artemisinin in *A. annua* L. hairy roots. The isolated fraction, OGA2, was found to stimulate accumulation of artemisinin in *A. annua* L. hairy roots. The 16-day-old hairy root cultures, when exposed to the OGA elicitor (60 lg/mL) for 4 days, accumulated up to 11.3 mgL^{-1} artemisinin, which was 55.2 % higher than control plants. This increase in artemisinin production by hairy roots was due to OGA-induced reactive oxygen species (ROS) – in elicitation of artemisinin biosynthesis. Hydrogen peroxide and oxygen free radicals, which constitute ROS, could be the second messengers in accelerating the production of salicylic acid, jasmonate, and ethylene. These signaling molecules then switch on the expression of defense response genes leading to induced biosynthesis of artemisinin in hairy root cultures. Similar results were obtained by Putalun et al. [122], where they found that artemisinin production by hairy roots of *A. annua* L was increased to sixfold with the addition of 150 mgL^{-1} chitosan alone with MJ, 1.5-fold with the addition of chitosan and YE. On the other hand, Wang et al. studied the accumulation of artemisinin induced by fungal-derived cerebrosides. They observed that cerebrosides induced nitric oxide (NO) burst leading to enhanced artemisinin biosynthesis in the hairy roots [109, 122].

Jasmonic acid (JA), methyl jasmonate (MJ), and salicylic acid (SA) are naturally occurring phytohormones and known as "secondary messengers." They are capable of transducing normal developmental signals or adverse environmental stimuli to plant cells for initiating protective responses against oxidative stress through antioxidant defense enzymes and secondary metabolites [110, 125–135]. Baldi and Dixit have reported enhanced artemisinin production by the cell suspension culture of *A. annua* after the addition of MJ in the cell medium [138]. In previous studies, jasmonate and SA were reported to enhance artemisinin content in *A. annua* L. plants and in cell suspension culture [136, 137]. Further, the allene oxide synthase (AOS) was reported to catalyze the first committed step in jasmonate biosynthesis [138]. Very recently, a full-length cDNA of AOS gene named as AaAOS was cloned from *A. annua* L. and the magnitude of its expression was strongly correlated with the artemisinin content in *A. annua* L. plants treated with MeJ, ABA, and ethylene [139].

4 Conclusion

Malaria is a global health problem that affects more than three million peoples specially children annually. It is currently treated with artemisinin-based combination therapies (ACTs). Artemisinin is an endoperoxide sesquiterpene lactone, synthesized in aerial parts of *A. annua* L plants. Due to relatively low content of this compound (0.3–1.0 %) in *A. annua* L. [44] and the nonavailability of economically viable conventional synthetic processes, the ACTs become quite expensive and unaffordable, especially for economically disadvantaged people in developing countries, where malaria frequently occurs. In order to meet high demands and reducing the cost of ACTs, there is now an urgent need to improve the methods for artemisinin production. Various approaches are being explored worldwide to enhance the production of artemisinin both in vivo as well as in vitro. Metabolic engineering offers promising perspectives to improve artemisinin yields by either overexpressing genes encoding rate-limiting enzymes of isoprenoid and artemisinin biosynthesis pathways or suppressing the expression of genes encoding the rate-limiting enzymes of competing pathways. These include hmgr, ads, fps, CYP7AV, CRY1, red1, asCPS, and sqs [42–45, 47–52, 54, 56–58]. Recently, one yeast- and five plant-derived genes involved in MVA and artemisinin biosynthesis were overexpressed in tobacco to generate artemisinin [60] (Fig. 99.1). However, this novel work has not resulted in increased artemisinin accumulation in transgenic tobacco so as to meet the future demand. This approach had, however, opened a new window to genetically engineer the entire or partial secondary metabolic pathways in heterologous plants/organism for the production of valuable secondary metabolites including artemisinin. In addition to *A. annua* L., genetically modified microbes were also developed to produce intermediates of artemisinin biosynthesis [32] for semisynthesis of artemisinin. Similarly, the production of artemisinin in hairy roots and cell suspension cultures was demonstrated. These processes, however, need optimization and scaling up to produce artemisinin at commercial scale using bioreactors. Applied genomics, proteomics, and metabolomics are continuing to expand our knowledge of metabolic pathways, while advances in systems biology would help us to model the impact of different modifications more accurately. These, finally, will help in improving the yield of artemisinin and reducing the cost of ACTs [121, 123, 124].

Abstract

Nivalenol (NIV) belongs to the B-type trichothecene mycotoxins produced by *Fusarium* species. The occurrence of NIV contamination is limited to certain areas around the world, such as Japan, Korea, New Zealand, and a part of Europe, where it has had adverse effects on human and animal health. This chapter focuses on the mycology, occurrence, biosynthesis, toxicology, methods of analysis, and risk assessment of NIV.

Keywords

Analysis method • biosynthesis • exposure assessment • mycology • nivalenol • toxicity

Abbreviations

bw	Body weight
DON	Deoxynivalenol
ECEU	European Commission Union
EFSA	European Food Safety Authority
FHB	Head blight
FX	Fusarenon-X (4-acetyl NIV)
JECFA	Joint expert committee of food additives
$LD_{50:}5$	50% lethal dose
LOAEL	Low-observed-adverse-effect level
LPS	Lipopolysaccharide
NIV	Nivalenol
S9	S9 liver microsomal enzymes
SCF	Scientific Committee on Food
ZEN	Zearalenone

1 Introduction

Nivalenol (NIV) was discovered by Japanese scientists from the culture medium of *Fusarium nivale* strain Fn-2B obtained from *Fusarium* head blight-infected wheat, in Japan [1]. Subsequently, Fn-2B was reclassified as a new species, *F. kyushuense*

O'Donnell & T. Aoki [2] from molecular phylogenetic analyses. Other Japanese researchers identified the chemical structure of NIV, fusarenon-X (4-acetyl NIV), and deoxynivalenol (DON) [3–6].

Trichothecene mycotoxins are the main mycotoxins produced by *Fusarium* species. Although there are macrocyclic and non-macrocyclic mycotoxins, the latter primarily contaminate wheat, barley, and maize and are classified into two types: Type A, including T2 toxin and HT2 toxin, diacetoxyscirpenol, and neosolaniol and type B, including DON, NIV, and 4-acetyl NIV. T2 toxin is reportedly the causative agent of outbreaks of foodborne diseases that occurred in the Orenburg region of the USSR during the 1930s–1940s. This outbreak was termed alimentary toxic aleukia (ATA), and symptoms of this disease include nausea, emesis, diarrhea, leukopenia, hemorrhages, and shock-mediated death.

Although the outbreak caused by type B trichothecenes is less severe than ATA, acute human illnesses caused by the consumption of *Fusarium*-infected wheat and barley have been reported in Japan, India, and China [7–9]. In these outbreaks, DON, NIV, and zearalenone were commonly detected in food.

Concerning type B trichothecenes, chronic and acute adverse health effects are of considerable concern. DON and NIV have been reported to suppress the immune system, depending on the dose and frequency of exposure [10].

Compared to DON, the distribution of NIV-producing fungi is limited and lacks toxicological and exposure data. DON has been evaluated by the FAO/WHO Joint Expert Committee of Food Additives while NIV has not. In countries where NIV contaminates cereals, the adverse health effect induced by NIV is a serious problem, and NIV is considered to be one of the mycotoxins whose risk needs to be assessed and regulated. In Europe, a large-scale surveillance of trichothecenes in food from 2000 to 2002 revealed the occurrence of NIV contamination [11]. In Japan, as NIV-producing fungi also occur, the occurrence of DON and NIV were surveyed in food. Risk assessment has been completed by the Food Safety Commission (FSC) of Japan. The European Commission's (EC) (now the European Union, or EU) Scientific Committee on Food (SCF) evaluated and determined a provisional daily tolerable intake as 0.7 μg/kg of body weight (bw) [12], but the FSC of Japan concluded that this level should be 0.4 μg/kg of bw.

This chapter reviews the latest findings on the mycology, biosynthesis, occurrence, toxicology, analytical methods of analysis, and risk assessment of NIV.

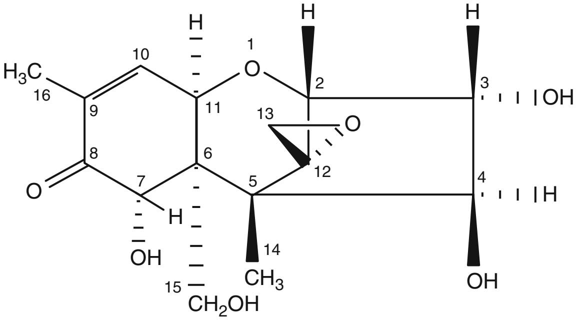
2 General Biology

2.1 Common/Systematic Name

CAS (No.23282-20-4)
3α, 4β, 7α, 15-tetrahydroxy-12, 13-epoxytrichothec-9-en-8-one, IUPAC
12, 13-epoxy-3α, 4β, 7α, 15-tetrahydroxytrichothec-9-en-8-one

2.2 Molecular Formula/Molecular Weight

$C_{15}H_{20}O_7$: 312. 32



Nivalenol

2.3 General Characteristics

Crystals from methanol; mp., 80–90 °C; dried in presence of P_2O_5 in reduced pressure; mp., 222–223 °C, tetraacetate; mp., 168–170 °C, $[\alpha]_D^{24}$+ 21.54° (c = 1.3, in EtOH)

2.4 Spectral Data

λ↓Max ↑MeOH 218 Nm (Ɛ = 7,500), Tetraacetate, 227 Nm (Ɛ = 7,900)

3 Mycology

Fusarium head blight (FHB) is a harmful disease that infects wheat, barley, and other cereals. This disease not only reduces grain yield and quality but also causes the contamination of trichothecene mycotoxins such as DON and NIV and other mycotoxins in the grain. The pathogens of FHB, *Fusarium* species, can be classified into two chemotaxonomic groups, the DON chemotype and the NIV chemotype [13–15]. Lee et al. [14] clarified that a single gene (*Tri13*) is responsible for the differential ability to produce DON or NIV. *Fusarium* DON chemotypes are found worldwide, while NIV chemotypes are found in more restricted regions, namely, limited areas of Asia, Africa, Europe, and North America [16, 17]. *F. kyushuense* and *F. graminearum* complex species (*F. asiaticum*, *F. culmorum*, *F. crookwellense*, *F. equiseti*, and *F. poae*) are also reported to produce NIV (Table 100.1).

The *F. graminearum* species complex [*F. graminearum* Schwabe; teleomorph: *Gibberella zeae* (Schwein.) Petch] is a species complex consisting of at least nine

Table 100.1 NIV-producing fungi

	Production of mycotoxins			
Fusarium species	DON	NIV	Commodity	Country/region
F. graminearum complex species	+	+	Wheat variety, rice, maize	Whole world
F. graminearum	+	-	Wheat variety, rice, maize	Temperate zone (cold zone of the northern hemisphere, especially): Japan (all), Korea, China
F. asiaticum	-	+	Wheat variety, rice	Temperate zone (especially warm temperature regions): Japan (Honshu and the south), Korea, China
F. vorosii	+	-	Wheat	Japan (Hokkaido), Hungary
F. culmorum	+	+	Wheat variety, maize	Temperate zone (especially cold regions): Europe, Asia, Africa, North and South America, Oceania
F. crookwellense	-	+	Wheat variety, maize	Temperate zone (especially cold region): Japan (Hokkaido)
F. equiseti	-	+	Wheat variety, maize	Subtropics, temperate zone
F. kyushuense	-	+	Wheat variety, rice	Japan (western Japan), China
F. poae	-	+	Wheat variety, maize	Temperate zone (especially cold regions): Japan (Hokkaido)
F. pseudograminearum	+	-	Wheat variety	Chiefly Australia

biogeographically structured lineages based on molecular phylogenetic analyses using worldwide collections. The lineages are as follows: lineage 1 is *F. austroamericanum*, lineage 2 is *F. meridionale*, lineage 3 is *F. boothii*, lineage 4 is *F. mesoamericanum*, lineage 5 is *F. acacia-mearnsii*, lineage 6 is *F. asiaticum*, lineage 7 is *F. graminearum* s. str., lineage 8 is *F. cortaderia*, while lineage 9 is *F. brasilicum*. On potato dextran agar (PDA), the *F. graminearum* species complex produces abundant white mycelia that become yellow to brownish or rose-colored as the cultures age (for 2 weeks); the color of the bottom surface of the colony is usually deep red. The undersurface is usually carmine red (Fig. 100.1). Macroconidia are usually long, slender, and slightly curved to straight, with five to six septa and a well-developed foot cell. Microconidia are absent; chlamydospores are rare but may form in macroconidia [18].

Trichothecene chemotypes of the *F. graminearum* species complex consist of three production groups according to strain differences: DON and 3-acetyl deoxynivalenol (3ADON), DON and 15-acetyl deoxynivalenol (15ADON), and NIV [13–15]. In the *F. graminearum* species complex, lineage classification is not well correlated with the trichothecene chemotype [19, 20].

Regional mycological studies discovered that geographic differences exist among these trichothecene chemotypes [21, 22]. The 3ADON productive group

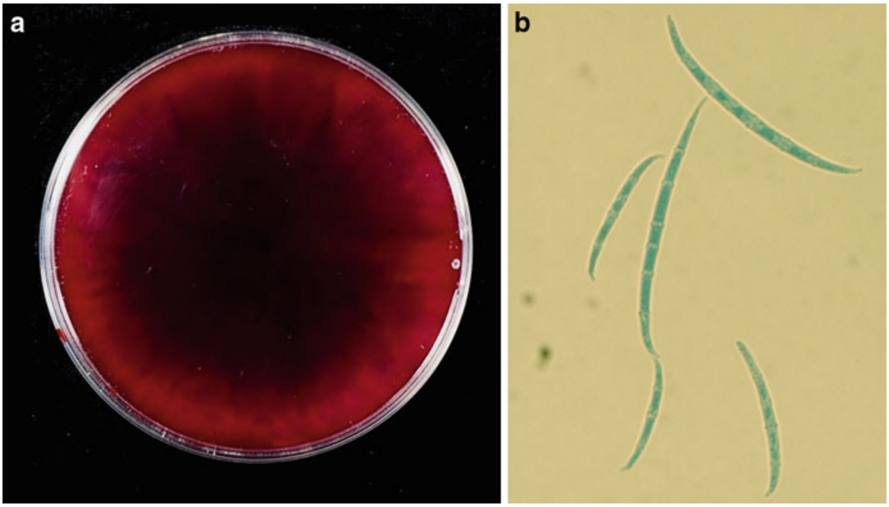


Fig. 100.1 *Fusarium graminearum.* (**a**): giant colony on PDA (*reverse side*) (**b**) Macroconidia

was not detected in 15 strains of *F. graminearum* s. str., and all 13 strains of *F. cortaderia* in New Zealand were of the NIV production group [23]. The NIV production group in *F. asiaticum* has been identified and is likely to represent about 25 % of the population of the *F. graminearum* species complex in Louisiana, USA [24]. In Japan, *F. graminearum* s. str. is predominant in the northernmost island (Hokkaido), while in southern areas, *F. asiaticum* is predominant [25].

In terms of pathogenicity, DON-producing strains are more aggressive and virulent than NIV producers [26, 27]. However, the NIV production group in *F. asiaticum* isolated from the western part of Japan was significantly more virulent than the most virulent DON chemotype *F. graminearum* s. str. strains [28].

Fusarium culmorum (W. G. Smith) Sacc. is the second most important FHB pathogen in wheat and strains of both DON and NIV producers exist. *F. culmorum* inhabits cooler areas such as North, Central, and Western Europe; North America; and Eastern Australia. Strains of both the DON and NIV production groups were isolated from England and Wales: in the south and west of England and Wales, NIV chemotypes are predominant, whereas in the north and east, DON chemotypes are predominant [29].

Fusarium poae (Peck) Wollenw. exists in Europe, North America, and Japan. It is one of the causative fungi causing FHB in small-grain cereals. In the northernmost area of Japan, the NIV production group in *F. poae* plays a role in the contamination of grains with NIV [30]. The NIV production group of *F. poae* was frequently found in Sweden, and NIV contamination has become a considerable concern in Scandinavia [31].

Fusarium crookwellense L.W. Burgess, P. E. Nelson & Toussoun was first isolated in Australia in 1971 as a new species [32]. It is another FHB pathogen found in small-grain cereals in Poland, New Zealand, China, Canada, Japan, and other countries [33]. *F. crookwellense* isolated from scabby wheat in the northernmost area of Japan produced NIV, 4-acety NIV, and zearalenone (ZEN) when cultured on rice-based medium [30].

4 Biosynthesis

4.1 History of Trichothecene Biosynthesis Studies

In earlier days, biosynthesis studies of trichothecenes were initiated using *Trichothecium roseum* as a model [34]. Having elucidated the scheme of biosynthesis from farnesyl pyrophosphate (FPP; **1**) (see Fig. 100.2), via a cyclized product trichodiene (TDN; **2**), to trichothecin [35, 36], researchers have moved to study *Fusarium* species that produce agriculturally important trichothecenes, such as T-2 toxin, DON, and NIV. Feeding experiments with TDN demonstrated its precursor role in DON biosynthesis [37], as was the case of *T. roseum*. Other postulated intermediates in the biosynthetic pathway were thereafter proven by blocked mutant analysis, precursor feeding experiments, and molecular genetic approaches using *Fusarium* species, including *F. culmorum*, *F. graminearum*, and/or *F. sporotrichioides* [38–40]. Compared to trichothecenes of other fungal genera, *Fusarium* trichothecenes are distinguished by the presence of a hydroxyl or *O*-acetyl at C-3.

4.2 Formation of 12, 13-Epoxytrichothec-9-ene Skeleton (Trichothecene Skeleton): Early Stage of Biosynthesis

In the biosynthesis of *Fusarium* trichothecenes, TDN is oxygenated by a cytochrome P450 monooxygenase (CYP) in the following order: 2α-hydroxylation, 12, 13-epoxidation, 11α-hydroxylation, and 3α-hydroxylation (Fig.100.2). The last oxygenation step proceeds only in *Fusarium* species, which makes *Fusarium* trichothecenes unique among all others (lacking a C-3 substituent) of non-*Fusarium* origin. Under acidic conditions, the resulting fully oxygenated intermediate, isotrichotriol (**3**), appears to undergo second cyclization nonenzymatically to give isotrichodermol (**4**) [41], the first trichothecene intermediate with a toxic 12,13-epoxytrichothec-9-ene skeleton (for a comprehensive review, see ref. [42]). Although isotrichodermol was not isolated as a natural product from wild-type *Fusarium* strains in the biosynthesis studies of many research groups, this may not be unreasonable in view of the importance of 3-*O*-acetylation in trichothecene biosynthesis; perhaps, isotrichodermol must readily be converted to isotrichodermin (ITD; **5**) (see Fig. 100.2) for self-protection of the trichothecene-producing fusaria [43]. ITD, a natural product isolated from a wild-type strain, is further metabolized to various important *Fusarium* trichothecenes [44].

Fig. 100.2 A common pathway to ITD in the biosynthesis of *Fusarium* trichothecenes. These early steps are conserved between type A (e.g., T-2 toxin) and type B (e.g., NIV) trichothecene producers. *Tri* genes that are responsible for these steps are indicated below the half-brackets in red letters. Functional groups highlighted in red indicate that they appeared as the results of expression of these *Tri* genes. Oxygen atom involved in intramolecular attack to C-11 in the nonenzymatic cyclization is shown in *blue*

4.3 Molecular and Genetic Studies of *F. sporotrichioides* as a Basis to Understand NIV Biosynthesis

In 1989, the first isolation and characterization of trichothecene biosynthetic gene was reported for T-2 toxin-producing *F. sporotrichioides* using an antibody raised against a purified enzyme [45]; this gene, designated *Tri5* (formerly *Tox5* in the literature), is responsible for the first committed step in the biosynthesis. Since cosmid clones containing *Tri5* complemented the *tri3*$^{-}$ and *tri4*$^{-}$ blocked mutants, but not the *tri1*$^{-}$ mutant, at least some of the trichothecene biosynthetic genes (*Tri* genes) proved to be clustered around *Tri5* [46]. On the basis of this finding, other *Tri* genes, including *Tri3* and *Tri4*, were identified on this core gene cluster. Three additional *Tri* genes necessary for T-2 toxin biosynthesis, *Tri101* alone and

Tri1 and *Tri16* adjacent to each other, occur separated from the core gene cluster (for reviews, see ref. [42, 47]). Roles of the *Tri* genes in T-2 toxin biosynthesis were examined by molecular genetic approaches, including targeted gene disruption and heterologous gene expression. The functions of *F. sporotrichioides* pathway *Tri* genes (*FsTri* genes) are summarized as follows (see Figs. 100.2 and 100.3):

1. *Tri5* (encoding trichodiene synthase). TRI5 catalyzes cyclization of all-*trans*-FPP via nerolidyl pyrophosphate to TDN [36, 45].
2. *Tri4* (encoding a multifunctional CYP responsible for conversion of TDN to isotrichotriol). *Fusarium* TRI4 [48], which is grouped into a CYP58 family, catalyzes four consecutive oxygenation steps from TDN to isotrichotriol as follows: TDN → 2α-hydroxytrichodiene → 12,13-epoxy-9,10-trichoene-2α-ol → isotrichodiol → isotrichotriol [49].
3. *Tri101* (encoding trichothecene 3-*O*-acetyltransferase). TRI101 catalyzes conversion of isotrichodermol to ITD [50]. Different from other pathway *Tri* genes, *Tri101* was first cloned from *F. graminearum* as a gene that confers resistance to T-2 toxin; subsequent analysis with *F. sporotrichioides* revealed its orthologue in the region of synteny [51]. In addition to isotrichodermol, many trichothecenes, including DON, T-2 toxin, and NIV, serve as good substrates of TRI101 [42]. In the amino acid sequence of TRI101, consensus sequences of acetyltransferases, HXXXDG and DFGWGKP, are found [50]. Apart from its role of self-protection against trichothecenes, C-3 acetyl is essential to serve as substrates of the enzymes in later steps in the biosynthesis.
4. *Tri11* (encoding ITD C-15 hydroxylase). TRI11, the first member of a new CYP family CYP65A1, catalyzes hydroxylation of ITD to give 15-deacetylcalonectrin (15-deCAL; **6**) [52].
5. *Tri3* (encoding 15-deCAL 15-*O*-acetyltransferase). TRI3 catalyzes 15-*O*-acetylation of 15-deCAL to give calonectrin (CAL; **7**) [53]. Other trichothecenes also serve as good substrates of TRI3. However, compared to 3-acetyltrichothecenes, 3-hydroxytrichothecenes are rather poor substrates [54]. The two consensus sequences of acetyltransferases described in the above section (3) were conserved in TRI3 as was the case with TRI101.
6. *FsTri13* (encoding 3-acetyltrichothecene C-4 hydroxylase). In T-2 toxin biosynthesis, FsTRI13 catalyzes hydroxylation at C-4 of CAL [55]. In addition to CAL, other trichothecenes with functional groups at C-8 (and also at C-7) serve as good substrates of FsTRI13.
7. *Tri7* (hypothesized to encode 3-acetyltrichothecene 4-*O*-acetyltransferase). TRI7 is involved in 4-*O*-acetylation of 3, 15-diacetoxyscirpenol (3, 15-DAS; **8**) and its derivatives in T-2 toxin biosynthesis [56]. However, different from TRI101 and TRI3, TRI7 does not possess the consensus sequences conserved among acetyltransferase family; TRI7 shows no amino acid sequence similarity to any other proteins reported so far. Attempts to prepare recombinant TRI7 were not successful, and its enzymatic function has not yet been rigorously proven.
8. *FsTri1* (encoding 3-acetyltrichothecene C-8 hydroxylase). FsTRI1 mainly catalyzes hydroxylation of 3, 4, 15-triacetoxyscirpenol (3, 4, 15-TAS; **9**)

Fig. 100.3 Biosynthetic steps to *F. sporotrichioides* T-2 toxin and *F. graminearum* NIV. Only major pathways to each trichothecene molecule are indicated, and minor pathways are not illustrated. *Tri* genes that are responsible for these steps are indicated in red letters. Functional groups highlighted in *red* indicate that they appeared as the results of expression of these *Tri* genes

(and to a lesser extent CAL) to give 3-acetylneosolaniol (3-ANEO; **10**) (and 8-hydroxycalonectrin) in T-2 toxin biosynthesis [57]. FsTRI1 shows broad substrate specificities and also accept ITD (**5**) and 3, 15-DAS as substrates. The broad substrate specificity of FsTRI1 and FsTRI13 allow branching of the biosynthetic pathway after CAL (**7**) in T-2 toxin biosynthesis (Fig. 100.3).

9. *FsTri16* (encoding an acyltransferase necessary for formation of ester side chain groups at C-8). FsTRI16 mainly catalyzes esterification at C-8 of 3-ANEO to give 3-acetyl T-2 toxin (**11**) [58].
10. *Tri8* (encoding trichothecene deacetylase). TRI8 removes an acetyl from C-8 of the trichothecene skeleton in T-2 toxin biosynthesis [59].

In addition to the pathway *Tri* genes, the core gene cluster contained two regulatory *Tri* genes and one transporter *Tri* gene, which are important for T-2 toxin production: *Tri6* encoding a zinc fingerlike transcription factor [60], *Tri10* encoding a novel protein with a role of other *Tri* gene activation [61, 62], and *FsTri12* encoding a trichothecene efflux pump [63]. *FsTri12* is indispensable for a high level production of T-2 toxin.

The structure of the core gene cluster and the function of the *Tri* genes were conserved between *F. sporotrichioides* and *F. graminearum* [14, 55, 56, 64, 65]. In this way, the identification of *FsTri* genes served as a useful tool for molecular biological analysis of *F. graminearum* that produce type B trichothecenes [66].

4.4 Biosynthesis of NIV

Compared to the structure of T-2 toxin, NIV is characterized by the presence of a keto at C-8 and a hydroxyl at C-7; also, C-4 and C-15 are not acetylated, and instead, hydroxyls are attached to these positions (see Fig. 100.3). To elucidate the biosynthetic pathway of NIV, *FgTri* genes in the core gene cluster were isolated on the basis of nucleotide sequence similarity, and their functions were characterized by the molecular approaches. As to the homologues of *FsTri1* and *FsTri16* that occur outside the core genes cluster, their sequences shared similarity only at the amino acid sequence level; *Tri1* is much more divergent between these *Fusarium* species (viz., 59 % identity between FsTRI1 and FgTRI1), and *Tri16* was found as a pseudogene adjacent to *FgTri1* [67]. The results of targeted gene disruption and heterologous gene expression suggested that most of the enzymes encoded by the *FgTri* genes show the same features as those of *F. sporotrichioides*. However, the following two enzymes exhibit significant differences in their activities depending on their origin:

1. Compared to FsTRI13, the substrates of FgTRI13 appear to be limited to a group of trichothecenes that have a hydroxyl at C-7 and/or a keto at C-8.
2. FgTRI1, but not FsTRI1, catalyzes oxygenation at both C-7 and C-8 of 4-deoxytrichothecenes [68].

Together with the analyses of other *FgTri* genes, a major biosynthetic pathway to NIV is hypothesized to proceed as illustrated in Fig. 100.3: ITD → 15-deCAL → CAL → 7,8-dihydroxycalonectrin (DHC, **12**) → 3,15-diacetyldeoxynivalenol

(3,15-diADON, **13**) → 3,15-diacetylnivalenol (3,15-diANIV, **14**) → 3,4,15-triacetylnivalenol (3,4,15-triANIV, **15**) → 4,15-diacetylnivalenol (4,15-diANIV, **16**) → 4-acetylnivalenol (4-ANIV, **17**) → NIV (**18**). In this scheme, all the biologically acetylatable position, namely, C-3, C-15, and C-4, are once acetylated in this order in the biosynthesis and then deacetylated at a later stage. Recently, a gene responsible for deacetylation at C-4 of 4-ANIV was identified and characterized. This gene, designated *Tri104*, is separated from all other known *Tri* genes in the genome of *F. graminearum* (our unpublished results).

5 Toxicology

5.1 Absorption, Distribution, Metabolites, and Excretion

NIV is mainly absorbed from the intestine, and 11–48 % of administered NIV remains in human bodies until 7.5 h post administration [69]. Acetyl NIV is immediately converted into NIV in serum after intravenous and oral administration. The bioavailability of acetyl NIV was 9.8 % and 19.5 % in broiler chickens and ducks, respectively [70].

In vivo examination using healthy swine showed that NIV was mainly absorbed from the ileum [71]. In vitro examination using a Caco-2 cell line (human intestinal epithelial cell line) showed that apical to basal transportation of NIV was simple diffusion depending on energy [72]. The maximum concentration of ^{3}H-labeled NIV and acetyl NIV was detected in serum after 60 min and 30 min in female ICR mice. The area under the curve of acetyl NIV was 10-fold higher than that of NIV. Acetyl NIV is metabolized in the liver and kidney [72].

NIV is converted by intestinal flora bacteria into less toxic de-epoxy NIV in the intestine as is DON. When NIV was anaerobically cultured with swine feces in vitro, NIV was converted into epoxy NIV. Swine that lacked de-epoxidation ability acquired this ability after their faeces with known de-epoxidation ability (containing as yet unclassified intestinal flora bacteria with de-epoxidation ability) were spread out in pens [73]. When NIV and stomach juice of bovine lumen were anaerobically cocultured in vitro, about 80 % of NIV was converted into de-epoxy NIV [73]. NIV and acetyl NIV are distributed in the serum, liver, kidney, and placenta [74]. Eighty percent of administered NIV was excreted in feces as de-epoxy NIV, while 1 % was excreted in urine as NIV in Wistar rats [75]. In chickens, trace levels of NIV were detected in liver and bile, while NIV and de-epoxy NIV were excreted through the feces in more than 10 % of administered NIV [76]. NIV and acetyl NIV were transmitted to milk in lactating mice [74].

As shown in Fig. 100.4, NIV is metabolized by intestinal flora into de-epoxy NIV and then excreted to urine and feces, while acetyl NIV is converted into NIV in serum and organs.

Table 100.2 LD_{50} of NIV after oral administration

Animal and strains	LD_{50} (mg/kg bw)	References
Mouse, ddY, male, 6 weeks old	38.9	[77]
Rat, F344, male, female, 5 weeks old	19.5	[78]

5.2 Acute Toxicity

Acute toxicity of NIV is shown in Table 100.2.

In 6-week-old male ddY mice, the 50 % lethal dose (LD_{50}) of NIV was 38.9 mg/kg of bw after oral administration, 7.4 mg/kg of bw after intraperitoneal injection, 7.2 mg/kg of bw after subcutaneous injection, and 7.3 mg/kg of bw after intravenous injection. Mice died within 3 days due to the effusion of blood and congestion in the intestine. In 5-week-old F344 rats, the LD_{50} of NIV was 19.5 mg/kg of bw/os and 0.9 mg/kg of bw after subcutaneous injection. Diarrhea and congestion in the gastrointestine were observed. In duck, vomiting was observed after 1.0 mg/kg of bw of NIV, and 0.4 mg/kg of bw of acetyl NIV was administered by subcutaneous injection [79].

5.3 Short-Term Studies of Toxicity

Short-term studies of toxicity were performed in mice, rats, pigs, and chickens, as summarized in Table 100.3.

5.3.1 Mice

C57BL/6 mice were given moldy rice containing at 0, 5, 10, and 30 mg/kg of NIV for 24 days. At 30 mg/kg of NIV, a significant reduction in red blood cell number was observed, but organ weight and the rate of weight gain did not change [80]. When using a diet containing NIV-contaminated rice at 0, 6, 12, and 30 mg/kg for 4 or 12 weeks, weight gain was inhibited in a dose-dependent manner. From these results, LOAEL was estimated to be 0.7 mg/kg of bw [82].

5.3.2 Rats

When Sprague-Dawley rats were treated with diets containing NIV at 0, 6, and 12 mg/kg for 2 or 4 weeks, a significant reduction in feed intake was observed after 1–2 weeks in the group given 0.6 mg/kg of NIV. However, rats recovered after 4 weeks. The low-observed-adverse-effect level (LOAEL) was estimated at 0.6 mg/kg of bw based on the reduction in organ weight [83]. Toxicity studies of single oral administrations using male and female F344 rats showed sedation, eyelid closure, staggering gait, diarrhea, and congestion of the lung and digestive tract. The oral LD_{50} value was estimated at 19.5 mg/kg in both sexes in a repeat oral test, purified NIV was given orally at daily doses of 0.4 and 2.0 mg/kg of bw for 30 days. Takahashi et al. reported subchronic toxicity using F344 rats fed

Table 100.3 Short-term studies of NIV

Study, strain, sex, age, group	Route of administration period	Dose		Critical effect	LOAEL (mg/kg bw/day)	NOAEL (mg/kg bw/day)	Notes	References

Table 100.3 (continued)

Study, strain, sex, age, group	Route of administration period	Dose		Critical effect	LOAEL (mg/kg bw/day)	NOAEL (mg/kg bw/day)	Notes	References
		(mg/kg of diet)	(mg/kg bw/day)					
				an increase of castration cells in the anterior pituitary, increase in the atretic follicle in feed with more than 1.5 kg/ml Male bw was reduced by a diet of more than 25 mg/kg Female white blood cell count was reduced by a diet of more than 6.25 mg/kg				
Pig, 51 days (6 males/ group)	Diet, contam. 21 days	0, 2.5, 5		Gastrointestinal erosion and renal disease in some Decrease in spleen cells in the feed of 5 mg/kg Time-dependent increase in the amount of IgA-producing feed more than 2.5 mg/kg	–	–	–	[86]
Chicken, 7 days (6 males/ group)	Diet, contam. 20 days	Experiment I: 0, 0.5, 2.5, 5, Experiment II: 0, 3, 6, 12		Experiment I: Increase in plasma uric acid concentration in the feed containing 5 and 2.5 mg/kg Experiment II: Feed efficiency and rate of weight gain and food consumption were reduced in the feed containing 6 and 12 mg/kg	–	–	–	[87]
Chicken, white leghorn, layer, 55 weeks	Diet, contam. 50 days	0, 1, 3, 5		Decreases in alkali phosphatase, total protein glucose in plasma in feed with 5 mg/kg Gastrointestinal erosion, duodenum internal bleeding, swollen cloaca, and oviducts with immature eggs in feed with 3 and 5 mg/kg Light, enlarged, and fragile livers at 1 mg/kg feed	–	–	–	[76]

[a] Corresponding value of EU Scientific Committee for Food
[b] Value corresponding to dose/day, three times a week
[c] Estimated intake amount by corresponding value of EU Scientific Committee for Food

a diet containing 0, 6.25, 25, or 100 ppm of pure NIV for 90 days. A decrease in bw and loose stools were observed at 100 ppm. In both sexes, bw was also reduced at 25 ppm in males from 6 weeks. In a hematological observation, the white blood cell count decreased after exposure to 100 ppm in males and to 6.25 ppm in females. Based on hematological data, the LOAEL of NIV was determined to be less than 6.25 ppm (corresponding to 0.4 mg/kg of bw/day for both males and females) [86].

5.3.3 Pigs

After pigs were exposed to purified NIV, no feed refusal, vomiting, or change in clinical appearance occurred, but a macroscopic examination showed gastrointestinal erosion and signs of nephropathy at low doses. Exposure to a high dose of NIV decreased the number of spleen cells. Histological data indicated that exposure of pigs to NIV in the diet caused pathological changes in the kidneys and gastrointestinal tract and reduced the number of splenocytes [87].

5.3.4 Chickens

When male broiler chickens were exposed to feed containing NIV, there was an increase in the uric acid concentration in serum, reduction in the rate of weight gain, gastrointestinal erosion, duodenum internal bleeding, swollen cloaca, and oviducts with immature eggs [76].

5.4 Chronic Studies and Carcinogenesis

Two long-term studies have been reported by the same Japanese group. In both studies, moldy rice powder containing NIV was used as the diet. This moldy rice was estimated to contain 3,147 mg/kg of NIV but no fusarenon-X. The first was a 1-year feeding study in which female C57BL/6CrSlc (SPF, 7-week-old mice) were given diets containing 0, 6, 12, and 30 mg/kg NIV; bw gain and feed efficiency showed a dose-dependent correlation. No changes were observed in the liver, thymus, spleen, kidneys, stomach, adrenal glands, pituitary gland, ovaries, sternum, bone marrow, lymph node, brain, and small intestines with or without Peyer's patch portion. Leukopenia was observed in the group administered 30 mg/kg NIV after 6 months and in all NIV-treated groups after 1 year. The LOAEL was determined to be 6 mg/kg of diet (corresponding to 0.68 mg/kg of bw) [77]. The other report was a 2-year feeding study in which the feeding conditions were identical to the 1-year feeding study. A reduction in bw gain was observed in all treated groups of animals. In the group given 30 mg/kg of NIV, leukopenia was observed, but it was not statistically significant. No tumors were found in any of the treated groups. Compared with the ratio of naturally occurring tumors, there was no difference between the treatment group and the control group. The LOAEL was 6 mg/kg feed (corresponding to 0.66 mg/kg of bw) [89] (Table 100.4).

Table 100.4 Long-term studies of toxicity

Study, strain, sex, age, group	Route of administration (solvent), period	Dose		Critical effect	LOAEL (mg/kg bw/day)	NOAEL (mg/kg bw/day)	Notes	References
		(mg/kg of diet)	(mg/kg bw/day)					
Mouse, C57BL/6CrS1c	Diet, contam. 1 year	0, 6, 12, 30	0, 0.68, 1.51, 3.84	Diet group after 6 months at 30 mg/kg, 1 year after NIV in all treatment groups, significant white corpuscle reduction, dose-dependent decrease in absolute weight, and increase in relative weight of liver, kidney, thymus	0.7		Used rice mold	[77]
				Histological abnormality was observed				
Mouse, C57BL/6CrS1c	Diet, contam. 2 years	0, 6, 12, 30	0, 0.66, 1.38, 3.49	Reduced bw gain in all treatment groups	0.7		Used rice mold	[88]
				Decrease in absolute kidney weight in the diet group of 30 and 12 mg/kg				
				Decrease in kidney weight, concentration in the serum of nonesterified fatty acid and alkaline phosphatase increased in the diet group of 12 mg/kg in a dose-dependent manner				
				Tumor could have caused by NIV was not observed				

Table 100.5 Genotoxicity studies of NIV

			Results		
Endpoint	Test system	Concentrations	Without a metabolic activation system	With a metabolic activation system	References
A: In vitro studies					
Sister chromatid exchange	Chinese hamster V79-E cells	5–50 μM/plate	Slightly pos.	Slightly pos.	[89]
Chromosome aberrations	Chinese hamster V79-E cells	5–50 μM/plate	Neg.	Slightly pos.[a]	[89]
Chromosome aberrations	Chinese hamster V79 cells	0.001–0.03 μg/mL	Pos. (3-fold)	N/a	[90]
Chromosome aberrations	Chinese hamster V79 cells	0.03 μg/mL	Pos. (3-fold)	N/a	[91]
Transformation	v-Ha-ras-transfected BALB/3 T3 mouse embryo cells	0.01–0.2 μg/mL	Neg.	N/a	[96]

N/a Not tested

5.5 Genotoxicity

Table 100.5 shows a summary of the results of genotoxicity studies of NIV. Some in vitro studies have been reported (Table 100.5A) using V79-E cells (a Chinese hamster lung-derived cell line), NIV induced cell cycle retardation. In the presence of metabolic activation (S9 mix), slight chromosomal aberrations were seen. These effects were nonspecific, suggesting that they were caused by inhibited protein synthesis [89].

In a chromosome aberration test using V79 cells, NIV purified from contaminated corn and barley induced, at 0.001–0.03 μg/mL and 0.03 μg/mL, respectively, a two to three-fold increase in chromosomal aberrations compared with the control [91, 92]. In a short-term transformation assay using v-Ha-Ras-transfected BALB/3 T3 cells, NIV showed no initiation or promotion activity [96]. A single-cell gel electrophoresis (comet) assay of NIV was conducted using CHO cells and ICR mice (4 males/group). At 50 and 100 μg/mL, NIV damaged the DNA of CHO cells in the absence of a metabolic activation system [92].

In an in vivo comet assay (Table 100.5B), oral treatment with NIV (20 mg/kg bw) resulted in DNA damage in the kidneys, bone marrow, stomach, jejunum, and colon. After intraperitoneal administration of NIV, no DNA damage was observed except in the colon [92].

5.6 Immunotoxicity

5.6.1 Effects on Immune Responses

As many scientists have indicated, NIV stimulates or suppresses the immune system depending on the dose as well as the presence of DON. Oral administration of 10 and 15 mg of NIV induced apoptosis in CD4(+) and CD8 (+) cells in thymus, Peyer's patch, and spleen in a dose-dependent manner [93, 94]. The effect of NIV on susceptibility against infectious diseases was shown by an in vivo infection experiment using BALB/c mice in which NIV at 6 mg/kg had no effect on survival rate against *Salmonella* infection [95]. However, in an in vitro experiment using RAW 264.7 cells, NIV inhibited the transcription activity and expression of inducible NO synthase (iNOS) by lipopolysaccharide (LPS) [96] (Sugiyama 2010).

5.6.2 Changes in Serum IgA Levels and IgA Nephropathy

Increasing IgA and induction of IgA nephropathy by NIV have been reported. These effects have been observed in mice but not in rats ([84], Table 100.6).

After C57BL/6 mice (ten males/group) were treated three times/week for 4 weeks by oral gavage with NIV (solvent: 5 % gum arabic water solution), the highest dose in that experiment (8.870 mg/kg bw) group showed a significant increase in plasma IgG but no changes in IgA [81], but 0.071 mg/kg bw/day and higher dose groups (0.355 mg/kg bw/day) showed a significant increase in plasma IgA [98]. When C3H/HeN, C3H/HeJ, and BALB/c mice (9–12 females/group) were treated for 4 or 8 weeks with feed containing 0, 6, or 12 mg/kg feed (corresponding to 0, 0.9, or 1.8 mg/kg bw/day, respectively) of purified NIV, the NIV-treated groups demonstrated an increase in IgA accumulation in glomeruli and increased serum IgA, particularly in the 12 mg/kg feed dose group at 8 weeks [99]. In a single oral administration study, Peyer's patches of BALB/c mice given NIV at 0 or 15 mg/kg bw showed a significant increase in all B cell subpopulations, particularly IgA + B cells, with the numbers of IgA + and IgM + B cells remaining higher than those of the control group [100] (#649).

Interestingly, an experiment using ovalbumin-TCR Tg (OVA-specific T cell receptor transgenic) mice (4 males/group) indicated that NIV significantly inhibited total IgE production and OVA-specific IgE, IgG1, and IgA production [101]. In F344 rats, NIV increased IgM level significantly but not IgG and IgA level even in the group given an oral dose of 6.9 mg/kg bw/day [84].

Table 100.6 Effect of NIV on IgA production

Study, strain, sex, age, group	Route of administration (solvent), period	Dose		Critical effect	LOAEL (mg/kg bw/day)	NOAEL (mg/kg bw/day)	Notes	References
		(mg/kg of diet)	(mg/kg bw/day)					
Mouse, C57BL/6, 6 weeks	Forced oral dosage 4 weeks in 3 days/week		0, 0.014, 0.071, 0.355, 1.774, 8.870 mg/kg bw, 3 times/week	Increase in plasma IgG administration group of 8.870 mg/kg bw No changes in IgA		3.8[a]		[81]
Mouse, C57BL/6, 6 weeks	Forced oral dosage 4 weeks in 3 days/week		0, 0.071, 0.355 mg/kg bw, 3 times/week	Increase in the plasma of IgA	0.03[a]			[98]
Mouse, C3H/HeN, C3H/HeJ, BALB/c, 6–8 weeks	Diet, contam. 4 or 8 weeks	0, 6, 12	0, 0.9, 1.8[b]	Increase of serum IgA (with the increase) immunopathological change of the kidney similar to IgA-induced renal damage	0.9[b]		Used rice mold	[99]
Mouse, BALB/c, 5 weeks	Single, oral route (10 % DMSO)		0, 15	Increasing IgA cell in Peyer's patch cells, decreasing pan-T cell, pan-B cell in lymph node	15			[101]
Egg albumen (ovalbumin)-specific T cell receptor αβ-Tg mouse, BALB/c, 8–13 weeks,	Drinking water, 2 or 4 weeks	0, 6	0, 0.9[b]	Inhibition of anti-OVA IgE, IgG1 and IgA antibody, Inhibition of IL-4 production, induction of IL-2 production in spleen	0.9[b]			[101]
Rat, F344, 5 weeks (10 males and females/group)	Diet, contam. 90 days	0, 6.25, 25, 100	0, 0.4, 1.5, 6.9	IgM increase in the treated group 6.9 mg/kg bw/day No change in IgA and IgG		6.9		[84]
Pig, 51 days (6 males/group)	Diet, contam. 21 days	0, 2.5, 5		IgA in plasma had no significant difference compared with control				[86]

[a] Value corresponding to dose/day three times/week
[b] Estimated intake amount by corresponding value of EU Scientific Committee for Food

In pigs fed with purified NIV at 0, 2.5, or 5 mg/mg in feed for 21 days, no significant differences were observed in plasma IgA levels between the control and treatment groups [87].

6 Other Toxicities

NIV inhibits protein and DNA synthesis but not RNA synthesis [102]. NIV inhibited protein synthesis in rabbit reticulocytes with an IC_{50} value of 6 μg/mL [103]. Cytotoxicity of NIV, 4-acetyl NIV, and de-epoxy NIV on 3 T3 cell growth was IC_{50} 1.19 ± 0.06 mM (373 ± 20 ng/mL), 0.72 ± 0.04 mM (255 ± 13 ng/mL), and 64.2 ± 3.14 mM (19030 ± 930 ng/mL), respectively [104].

7 Outbreaks Associated with NIV

Outbreaks linked with *Fusarium*-contaminated cereal-based foods occurred in Japan and Korea during the 1940s–1960s [9]. The symptoms reported were nausea, diarrhea, and emesis. In China, more than 30 gastroenteritis outbreaks from 1961 to 1981 were associated with the consumption of "scabby," i.e., *Fusarium*-infected wheat, barley, or maize [8]. Trichothecenes were predicted to be the causative agent. An outbreak of trichothecenes occurred in the Kashmir Valley, India, during June to September 1987 in which 50,000 people suffered from gastrointestinal disorders [105, 106]. The cause of the outbreak was assumed to be the consumption of bread made from mold-damaged wheat, evidenced by the presence of molds such as *Fusarium* sp. and *Aspergillus* sp. and varying quantities of trichothecene mycotoxins. The concentration of DON, acetyl DON, NIV, and T-2 toxin in causative wheat was 0.34–8.4, 0.6–2.4, 0.03–0.1, and 0.55–4 mg/kg, respectively [105, 106].

8 Analytical Methods

Since NIV occurs as a co-contaminant with other trichothecene mycotoxins, it is often analyzed simultaneously with the co-contaminants rather than alone. Analytical methods developed so far include thin layer chromatography (TLC); capillary gas chromatography (GC) with electron-capture detection (ECD), flame ionization detection (FID), or mass spectrometric detection (GC/MS); high-performance liquid chromatography (HPLC) with ultraviolet (UV), fluorescence, or mass spectrometric detection; supercritical fluid chromatography (SFC); and time-of-flight mass spectrometry (LC/TOF-MS).

Usually, to analyze trichothecenes in foods and feeds, solvent extraction is essential. Aqueous methanol and acetonitrile are commonly used for extraction. For applying GC–MS, HPLC, and LC–MS/MS, a sample needs to be cleaned up with a charcoal-alumina-celite, florisil, silica gel, or solid-phase extraction column. For laboratory experiments, TL is very useful because of its low cost and simplicity.

However, for surveillance studies, trichothecene mycotoxins coexist with other trichothecenes, and a simultaneous analytical method for the determination of some trichothecenes and *Fusarium* toxins is considered to be more practical than a single method. A decade ago, GC was very popular to analyze some trichothecene mycotoxins in food, but for GC analysis, various derivatives are needed that are sometimes troublesome.

GC is typically used conventionally for simultaneous analysis for trichothecene mycotoxins and ZEN but requires trimethylsilyl derivatization before analysis. GC–FID produced good results in a validation of the EU Standards, Measurements and Testing Programme [107]. However, the GC method requires a derivatization procedure, which generally causes a loss of time and recovery.

On the other hand, LC using UV requires no derivatization procedure [108–111]. HPLC–UV (220 nm) for the GC–MS determination of DON and NIV has been developed in Japan.

Over several years, many LC–MS and LC–MS/MS methods were reported for the simultaneous analysis of trichothecene mycotoxins, including DON and NIV. These methods have been applied to the hygienic control and surveillance of mycotoxins. However, LC–MS requires the use of expensive internal standards such as isotopically substituted compounds. Meanwhile, the precision of LC–UV has been valued, although its sensitivity is lower than that of LC–MS.

A selective analytical method based on HPLC, combined with atmospheric pressure photoionization (APPI) mass spectrometry, has been developed for the simultaneous determination of NIV and DON. A liquid chromatography/atmospheric pressure chemical ionization mass spectrometry (LC/APCI–MS) method based on time-of-flight MS (TOF/MS) with a real-time reference mass correction technique was also developed for the simultaneous determination of *Fusarium* mycotoxins (NIV, DON, fusarenon-X, 3-acetyldeoxynivalenol, 15-acetyldeoxynivalenol, HT-2 toxin, T-2 toxin, diacetoxyscirpenol, ZEN) and *Aspergillus* mycotoxins (aflatoxin B1, aflatoxin B2, aflatoxin G1, aflatoxin G2) in corn, wheat, cornflakes, and biscuits [112].

Sulyok et al. [113] reported the first validated method for the determination of 39 mycotoxins in wheat and maize by liquid chromatography with electrospray ionization–triple quadrupole mass spectrometry (LC/ESI–MS/MS) without the need for any cleanup. The 39 analytes included A and B trichothecenes (including deoxynivalenol-3-glucoside), ZEN and related derivatives, fumonisins, enniatins, ergot alkaloids, ochratoxins, aflatoxins, and moniliformin, and six trichothecene mycotoxins (NIV, DON, fusarenon-X, 15-acetyldeoxynivalenol, 3-acetyldeoxynivalenol, and T-2 toxin).

Taken together, these analytical methods should be chosen for any purpose. For surveillance, GC–MS and LC–MS/MS are efficient because of their sensitivity, and for enforcement of regulation, HPLC would be useful.

9 Exposure Assessment of NIV and Regulation

Exposure to mycotoxins depends on the contamination level in different foods and on the intake of those foods, which is influenced by the dietary culture of each country.

Table 100.7 Analytical methods for determination of NIV

Extraction	Cleanup column	Derivatization	Determination	Toxins analyzed	Detection limit (NIV)	Commodities	References
$CH_3CN—H_2O$ (85+15)	Charcoal-alumina-Ceite column	None	TLC $Alcl_3$ spray	DON, NIV, T-2, HT-2, DAS and two others	0.3–0.8 μg/g	Wheat, corn	[116]

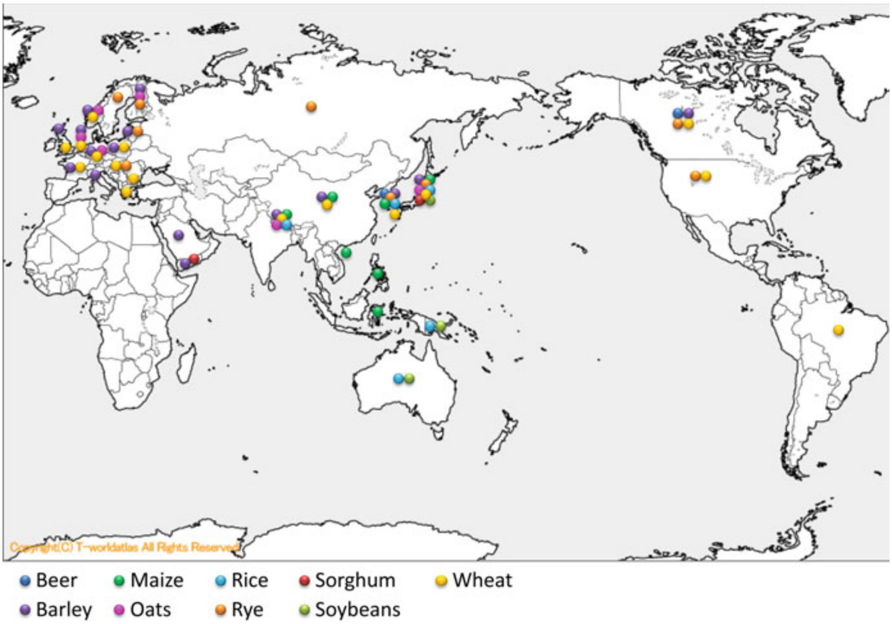

Fig. 100.5 Distribution of food contaminated with NIV (Modification cited by Ref. [120])

These data are based on established regulation levels of individuals or international institutes. For mycotoxins, it is ideal to correct the actual monitoring data over several years in raw and processed food. Especially, since exposure to trichothecenes and their toxicity are of concern in young children, it is important to assess the intake by age layers. FAO/WHO organized the Global Environment Monitoring System/Food Contamination Monitoring and Assessment Programme (GEMS/Food) and utilizes this information to assess the intake of mycotoxins (Table 100.7).

9.1 Occurrence of NIV in Food and Feed

Compared to the worldwide distribution of DON, NIV contamination is found only in limited areas. In Fig. 100.5, the commodities contaminated with NIV that have been reported are plotted [120]. Contamination of cereals (wheat, oats, barley, maize, rice, rye) has been frequently found in Far East Asia (China, Korea, Japan), Southeast Asia (the Philippines, Vietnam), Oceania (New Zealand, Australia) Europe (Germany, Poland, Norway, the Netherlands), and Eastern Europe (Lithuania). The contamination of soybeans (50 μg/kg of NIV) has also been reported in Australia [121].

From SCOOP data [11], food and food raw materials were shown to be contaminated by trichothecenes (DON, NIV, FX, T-2, and HT2 toxin, T-2 triol, diacetoxyscirpenol, neosolaniol, and verrucarol).

Table 100.8 NIV contamination in food in European Union member states

Commodities	% Positive	Mean (μg/kg)	Maximum (μg/kg)
Wheat	14	24	440
Maize	35	np	340
Barley	8	15	351
Oats	21	56	1,860
Rye	5	np	48

Adapted from Ref. [11]

Table 100.9 Occurrence of nivalenol in wheat in Eastern Asia (2002–2007)

Country	Commodities	Mean (μg/kg)	Maximum level (μg/kg)	References
Japan	Wheat	35	1,000	[122]
	Barley	172	3,000	
Korea	Maize	168	332	[123] [124]
	Barley	390	2,038	
	Rice (brown rice)	164	569	
China	Wheat	29	1,035	[125],
	Corn	18	1,400	

Table 100.8 shows NIV contamination in European countries. Among the cereals, mainly wheat, oats, wheat, barley, and rye are exposed to NIV. In Europe, the level and frequency of DON contamination are often higher than NIV contamination. Thus, it is generally believed that DON is more predominant than NIV and that their contamination levels shift in a parallel manner, i.e., when the DON level decreases, the NIV level also decreases. However, in the southern island of Japan (Kyushu), only the NIV-producing group strain exists (described in 1.3. mycology). Since commodities harvested from this area are contaminated with NIV, it has become a serious problem for human health.

Far East countries, including Japan, Korea, and China, are also suffering from NIV contamination of grain. In Japan, NIV concentration in barley was higher than that in wheat, while in Korea, barley was the most susceptible commodity contaminated with NIV. NIV contamination in rice has been reported in Korea but not in Japan. Since rice is the dietary staple in most Far East countries, even if the contamination level is low, it is of concern to human health (Table 100.9).

9.2 NIV Intake

The surveillance of NIV in food and estimated NIV intake were conducted in limited countries [22, 126]. Table 100.10 shows estimated NIV intake in the EU, UK, and Japan.

Table 100.10 Estimated NIV intake

Country	Age	Sex	NIV intake mean (95 % tile) ng/kg bw/day
Austria	Whole population		78 (274)
Denmark	Whole population		30 (72)
France	Adult		58 (99)
Finland	Adult		27 (np)
Norway	Adult	M	57 (110)
	Adult	F	50 (93)
Sweden	Adult		6 (13)
UK	Adult	M	25 (np)
	Adult	F	17 (np)
France	Children		94 (307)
Norway	1–6 years		113 (263)
UK	Infant		62 (np)
	1–4 years		64 (np)
	4–6 years		64 (np)
	7–10 years		50 (np)
	11–14 years		34 (np)
Japan	1–6 years		10 (330)
	7–14 years		10 (230)
	15–19 years		10 (180)
	>20 years		>10 (110)

Adapted from Refs. [11, 122]
np not provided

As shown in Table 100.10, viewing the entire population, the highest mean and 95th percentile of estimated NIV intake was shown in Austria. Among the exposed adults, in France, the estimated intake of NIV was highest compared to adults of other countries. However, the intake by children was higher than by adults. In young children, mean intake in the UK was 62–64 ng/kg bw/day, and these values were higher than in Japanese children.

9.3 International Evaluation

The FAO/WHO Joint Expert committee of Food Additives has not evaluated NIV contamination levels. The IARC has evaluated carcinogenesis of the toxins produced from *F. graminearum*, *F. culmorum*, and *F. crookwellense*, such as ZEN, DON, and acetyl NIV [127]. Their conclusion was that metabolites of these three *Fusarium* species should be placed in group 3, i.e., not classified as carcinogenic for humans.

The Scientific Committee for Food (EC) reported values for DON in 1999, for NIV in 2000, and for T-2 and HT-2 toxins in 2002[128]. According to their opinion, temporary tolerable daily intake (t-TDI) of NIV was estimated to be 0.7 μg/kg based on NOAEL and 0.7 mg/kg temporary bw based on the results of 1- and 2-year repeated dose studies reported by Ref. [77, 88].

In 2010, the FSC of Japan evaluated DON and NIV and concluded that the provisional maximum tolerable daily intake (PMTDI) of NIV was 0.4 μg/kg bw/day based on LOAEL (0.4 mg/kg bw/day) of subacute repeated dose toxicity studies using purified NIV [86]. As the PMTDI of DON was adopted to be 1.0 μg/kg bw, it had the same value as JECFA and EFSA.

9.4 Regulation

To date, no country has established a standard for NIV yet. However, regarding the risk assessment of NIV, Japan and EU lead the world. These countries have serious problems related to the management of NIV-producing fungi. The establishment of a regulation level for NIV is one of the effective means to prevent contamination of NIV in cereal grain.

10 Conclusion

Because NIV is a minor mycotoxin in the world, information for risk assessment is very poor. Of course, European countries and Japan have recognized the threat posed by NIV to human health and have started to evaluate this risk. In the risk assessment of NIV, it is recommended to take into account the effect of co-contamination with other trichothecene mycotoxins, namely, DON. As further studies, combination toxicology studies of NIV and DON are needed.

Abstract

Paclitaxel is a mitotic inhibitor used in cancer chemotherapy. It was discovered in the US National Cancer Institute program in 1967 when Monroe E. Wall and Mansukh C. Wani isolated it from the bark of the Pacific yew tree, *Taxus brevifolia*, and named it taxol. When it was developed commercially, the generic name was changed to paclitaxel.

Paclitaxel is now used to treat patients with ovarian, breast, and advanced forms of Kaposi's sarcoma. Paclitaxel stabilizes microtubules and, as a result, interferes with the normal breakdown of microtubules during cell division. Together with docetaxel, it forms the drug category of the taxanes.

While offering substantial improvement in patient care, paclitaxel has been a relatively controversial drug. There was originally concern because of the environmental impact of its original sourcing, no longer used, from the Pacific yew. So in recent years, extensive research has been done to find a way to produce it from alternative resources including related compounds and also to lessen the side effects of paclitaxel.

1 Introduction

Nature has been a source of medicinal agents for thousands of years. Compounds extracted from natural products have been used either as a new drug or a lead molecule to synthesize modern therapeutic agents in the treatment of variety of diseases for centuries. Pharmacologic activities have been found in different kinds of secondary metabolites such as alkaloids, terpenoids, coumarins, flavonoids, and lignans, all firstly isolated from plants.

During the last 60 years, unique classes of natural anticancer compounds have been isolated from plants. These plant products, represented by the *Vinca* and *Colchicum* alkaloids, as well as other plant-derived products such as paclitaxel (Taxol) and podophyllotoxin showed great promise for new drug discoveries based on nature.

The discovery of the novel diterpenoid anticancer agent taxol in 1971 by Monroe Wall and his collaborators ranks in retrospect as one of the most significant discoveries ever made in the field of naturally occurring anticancer agents. Although extensive researches have been done on natural anticancer agents, only a handful of plant-derived natural products have been found to show clinically useful activity, and taxol is clearly a member of this group.

This chapter is going to summarize the different aspects of discovery, analysis, semisynthesis, clinical application, side effects, and also related compounds of taxol as a valuable natural product in cancer therapy.

2 Taxol

2.1 Discovery of Taxol

After a strong interest about cancer in the United States in 1955, National Cancer Institute (NCI) organized a cancer drug screening program of plant extracts [1]. These studies led to a discovery that the stem bark extract of the Pacific yew tree, *Taxus brevifolia*, showed cytotoxicity in the preliminary screening against KB cells using MTT assay and also activity against carcinosarcoma in rats and leukemia in mice. At that time there were only a few methods available for separation, and of course, they were not so sophisticated. The method for taxol isolation began with ethanol extraction of 12 kg of Pacific yew bark followed by partitioning of the extract between chloroform and water. The chloroform phase was the active one, and further isolation was done to separate taxol from this fraction. It took about 2 years to isolate 0.5 g pure taxol from *T. brevifolia* bark in 1966. The molecular formula of $C_{47}H_{51}NO_{14}$ obviously indicated a complex structure. Some researchers claimed that the isolation of compounds belonged to the taxane family, but at that time only a few members had been elucidated.

The isolation of taxol was first presented at the American Chemical Society meeting in Florida in 1967 [2]. In the main paper published in 1971, the reported yield of taxol was 0.02 % from dried bark. It was also reported that taxol was present in other Taxus species including *T. baccata* and *T. cuspidate* [3].

2.2 Sources of Taxol

The only original source of taxol was the bark of the Pacific yew. Yews are small coniferous trees or shrubs in the Taxaceae family. They are relatively slow growing and can be very long-lived and reach heights of 1–40 m, with trunk diameters of up to 4 m. However, alternative sources range from the use of genetic engineering and tissue culture to partial and total syntheses. Other Taxus species such as *T. globosa, T. baccata, and T. wallichiana* also contain taxol or precursor of this compound.

Spjut reported as follows: The genus *Taxus* includes 24 species and 55 varieties distributed across the northern temperate and subtropical regions. The species are classified into three groups by differences in leaf epidermal (outer skin-like layer) and stomatal (donut-like cell) features. These are the *wallichiana* group with 11 species, occurring from central Himalayas to Indonesia; the *baccata* group with 9 species in temperate Eurasia, Northern Africa, and eastern North America; and the *sumatrana* group with 4 species overlapping in distribution with the *wallichiana* subgroup in Asia, but absent from North America. The *wallichiana* group is further divided into subgroups *wallichiana* and *chinensis*, and the *baccata* group is divided into the *baccata* and *cuspidata* species alliances [4].

From Taxaceae family, *Taxus brevifolia* has been firstly used as a good source of taxol and related taxoids.

2.3 Structure Elucidation

The structure of taxol (Figs. 101.1 and 101.2) was elucidated on the basis of the H-NMR spectrum (Fig. 101.3), in 1971 [3], but the full elucidation was done by X-ray crystallography. Although taxol was poorly soluble in various solvent systems and readily crystallized, the crystals were fine needles and unsuitable for X-ray. Today after almost 40 years, there is no any report of X-ray crystal structure of taxol. Mild methanolysis of taxol resulted in a methyl ester and a tetraol. The ester was characterized using X-ray crystallography as its p-bromobenzene derivative, and the tetraol was characterized as its bis diacetate. X-ray crystallography data, together with H-NMR data, gave the complete structure of taxol.

IUPAC recommended the numbering system for taxol and taxoids as shown in Fig. 101.1 [5].

Taxol is differentiated from most other taxane diterpenoids by its ester side chain at C-13 and by its oxetane ring D. It can be viewed as the *N*-benzoyl-β-phenylisoserine ester of baccatin III. The conventional planar representation of taxol can be misleading since its structure is best described as inverted cup shape as shown in Fig. 101.2.

The structure-activity relationship of taxol has been studied by a multitude of researchers. The molecule can divide into two parts: the side chain and the taxol skeleton. The side chain of taxol is critical for maintaining activity. The structure-activity of the side chain has revealed the following features:

- Protection of the C2′ hydroxyl group as an ester results in loss of activity in terms of microtubuline stabilization but not in cytotoxicity.
- The C3′ amide-acyl group is critical but may be aromatic or alkyl in nature.
- The C3′ bound nitrogen can be replaced by an oxygen atom without loss of activity.
- The C3′ aryl group is needed; replacement by a methyl group reduces the activity 19-fold.

Taxol consists of several rings including a four-membered ring, a six-membered ring, and an eight-membered ring and peripheral functionalities. Modification of the taxol skeleton and elucidation of its structure-activity have led to the following features:

- The oxetane ring is crucial for maintaining the activity; ring opening leads to a dramatic decrease in bioactivity.
- Contraction of the eight-membered ring to a seven-membered ring still provides the molecule with tublin depolymerization properties.
- Removal of the C-10 acetyl group does not have any effect on the activity.
- C2-*O*-benzoyl group removal causes a drastic reduction in its activity

The original discoverers of taxol reported a molecular ion at m/z 854, but later researchers only report fragment ion peaks under these conditions.

The mass spectrum of taxol shows good molecular ions at [M+H]+, [M+Na]+, and [M+K]+, and fragment ions are observed corresponding to loss of the protonated C-13 side chain and to the loss of acetic acid.

2.4 Isolation of Taxol

The need to carry out extensive surveys of Taxus species for their taxol content and to monitor taxol in clinical studies has spurred efforts to develop new analytical methods for taxol purification. Solvent extraction methods are always inexpensive and easy to handle. Different solvent systems started from very nonpolar solvents (e.g., n-hexane) [6]; semipolar system (chloroform and acetone or combination of dichloromethane: methanol) [7] and very polar system (methanol or ethanol alone or with H_2O) [7] have been employed for extraction of taxoids from bark or leaves of Taxus species. To date only chromatographic methods have been reported. Sadeghi-aliabadi et al. in their studies to find an optimized solvent for taxol extraction indicated that the solvent 100 % acetone is the best solvent to extract higher amount of taxol from *Taxus baccata* needles. They confirmed their results by HPLC, ESI-LCMS, and biological cytotoxic evaluations of extracted compounds [8].

2.4.1 TLC

Two TLC methods have been developed for detection of taxol in plant extracts. In one system a cyano-modified silica gel plate was used, with two-dimensional development using both normal phase (CH_2Cl_2:hexane:AcOH, 9:10:1) and reverse phase (H_2O:MeCN:MeOH:THF, 8:5:7:0.1) development.

The other system used a diphenyl-modified silica plate, with hexane:isopropyl alchol:acetone, 15:2:3, in the normal phase dimension and MeOH:H_2O, 7:3, in the reverse phase dimension. Both systems separated taxol and taxol B adequately and also separated several other compounds from *T. brevifolia* extract [9].

2.4.2 HPLC

HPLC methods were developed to separate taxol from cephalomannine, 10-deacetylcephalomannine, baccatin III, and 10-deacetylbaccatin III. Both isocratic and gradient reverse phase methods were tested, using cyano- and phenyl-bonded silica gel columns. Both columns gave adequate separations, but the cyano column required less organic solvent and thus tended to give higher back pressures and decreased column life. The optimum mobile phase for the phenyl column was a linear gradient starting with MeOH:H2O:MeCN (20:65:15) going to MeOH:H_2O: MeCN (20:45:35) in 20 min and ending with MeOH:H_2O:MeCN (20:25:55) in 30 min.

A similar system, but with slightly different solvent ratios, was used for the analysis of taxol and 10-deacetylbaccatin III in T*axus* species previously discussed. The analysis of *T. brevifolia* for taxol content previously noted was carried out using C18 columns and MeOH:H2O, 68:32, as the solvent. A method for analysis of taxol in *T. chinensis* has also been described. Very recently another method for the separation of taxol and cephalomannine has been published. This method uses a cyanopropyl column with hexane:iPrOH (2:1) and may be more amenable to preparative work than the reverse phase systems previously described [10–11].

HPLC has also used to determine taxol and related compounds in biological fluids [13]. After evaluating C8-, cyanopropyl-, and phenyl-bonded phases, Riley and his co-workers selected a C8-bonded phase column with a mobile phase of MeOH:NaOAc buffer (0.02 M, pH 4.5, 35:65 v/v) as their system for analysis of taxol in human plasma and urine.

A reverse phase HPLC assay was also used for analysis of taxol in human plasma and urine during the phase I trials of taxol; in this case a C18 column was used with a gradient of H_2O:MeCN, 65:35 to 0:100, as the mobile phase. Similarly, a reverse phase method was used for the analysis of taxol and its decomposition products in the cell culture media and in the rat bile [10–13].

2.4.3 LCMS

LCMS and LC-MS-MS have been developed as feasible and reliable techniques for detecting paclitaxel, 10-DABIII, baccatin III, cephalomannine, and other related taxanes. ESI in positive-ion mode and an MRM mode were utilized to optimize sensitivity and accuracy [8].

2.5 Mechanism of Biological Activity

Many of the important chemotherapeutic agents such as vinca alkaloids operate by destabilizing microtubules, while taxol appeared to work by microtubule stabilization. Microtubules are involved in many areas of cell physiology but essential in the cell division process. During cell division, they are the major structural components of the mitosis and mitotic spindle (the area of cell where the 2 sets of chromosomes align for separation). Taxol is believed to act as a mitotic spindle poison by binding to polymeric tubulin forming a highly stabilized microtubule. Inhibiting the release of monomeric tubulin from the ends of the microtubule polymer causes the inherently unstable assembly and disassembly process to be hampered, and therefore, cell division is suppressed [14].

2.6 Toxicology

The toxicology studies were performed on mice, Sprague-Dawley rats, and beagle dogs were quite problematic. Large single doses were toxic to the point of death when administered to beagle dogs, but tolerable on repeated smaller doses. The major toxicities assigned to taxol were myelosuppression, lymphoid depletion, emesis, diarrhea, mucosal ulcerations, and toxicity to male reproductive organs. These toxins were cumulative over a 5-day period which indicated a single injection schedule may be preferred. However, as a single injection schedule would require problematically large vehicle volumes, the clinical plan was to try a variety of administration schedules in the clinical trials [15].

2.7 Clinical Trials

Phase I of clinical trials of taxol began in 1983 and was aimed at determining the maximum tolerated dose in humans and any dose-limiting toxicities. At first, the drug caused some serious hypersensitivity reactions, but decreasing the rate of infusion or premedicating patients with antihistamines and steroids avoided such reactions. Studies in this phase showed efficacy of taxol against ovarian cancer.

In phase II, the activity of drug was tested on a large number of patients, and these trials are still being conducted. Some of the completed trials caused great excitement and were quiet encouraging. Some of them even showed a 30 % improvement among patients with advanced ovarian cancer.

The main problem in phase III studies was the large amounts of the drugs that were needed in this step. The CRADA (Cooperative Research and Development Agreement) was won by the Bristol-Myers Company, and they did an outstanding job of marketing supplies of taxol available and conducting the studies in cooperation with the NCI that led to the successful marketing approval in refractory ovarian cancer in 1992. The next major clinical development of taxol was the report of activity of taxol in primary metastatic breast cancer with a response rate of 56 %. It seems that breast and ovarian cancer are not the only taxol-treatable cancers [15].

2.8 Biosynthesis

Taxol biosynthesis consists of three distinct aspects:

(a) *Formation and functionalization of the diterpene moiety*

Terpenes share a biosynthetic pathway that forms isopentenyl pyrophosphate (IPP) from acetic acid. All the various classes of terpenes are then generated from IPP.

Diterpenes are produced from cyclization of geranylgeranyl pyrophosphate (GGPP), and the taxane ring system formation can be proposed to go by an electrophilic cyclization of GGPP, possibly from cembrane diterpenes or verticillin intermediates. The large number of functionalities present in taxol must be introduced into the diterpenoid ring system following the generation of the taxane ring system, and functionalization includes hydroxylation, acetylation of hydroxyl groups, oxidation to a ketone, and generation of the oxetane ring system.

(b) *Formation of the phenylisoserine side chain*

This part is usually made from phenylalanine.

(c) *Formation of taxol from its components*

The assumption would be that the terpene moiety is fully elaborated to the level of baccatin III and the C-13 side chain is attached last [16].

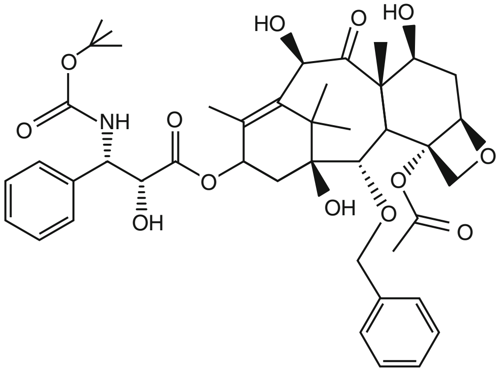

Fig. 101.4 Structure of docetaxel

3 Docetaxel (Taxotere)

Due to scarcity of paclitaxel, extensive research was carried out leading to the formulation of docetaxel (Fig. 101.4), an esterified product of 10-deacetyl baccatin III, which is extracted from the renewable and readily available leaves of European yew tree.

Docetaxel differs from paclitaxel at two positions in its chemical structure. It has a hydroxyl functional group on C-10 (see Fig. 101.1) whereas paclitaxel has an acetate ester, and a tert-butyl carbamate ester exists on the phenylpropionate side chain instead of the benzyl amide in paclitaxel. The C-10 functional group change causes docetaxel to be more water soluble than paclitaxel.

Docetaxel usually given to treat breast cancer, prostate cancer and non-small cell lung cancer either alone or incombination with other chemotherapeutic agents.

3.1 Mechanism of Biological Activity

The cytotoxic activity of docetaxel is exerted by promoting and stabilizing microtubule assembly, while preventing physiological microtubule depolymerization/disassembly in the absence of GTP. This leads to a significant decrease in free tubulin, needed for microtubule formation, and results in inhibition of mitotic cell division between metaphase and anaphase, preventing further cancer cell progeny.

Because microtubules do not disassemble in the presence of docetaxel, they accumulate inside the cell and cause initiation of apoptosis. Apoptosis is also encouraged by the blocking of apoptosis-blocking bcl-2 oncoprotein. Both in vitro and in vivo analyses show that antineoplastic activity of docetaxel against a wide range of known cancer cells would be greater than paclitaxel, possibly due to its more rapid intracellular uptake.

The main mode of therapeutic action of docetaxel is the suppression of microtubule dynamic assembly and disassembly, rather than microtubule bundling leading to apoptosis, or the blocking of bcl-2 [17].

3.2 Toxicology

Docetaxel is a chemotherapeutic agent and is a cytotoxic compound and so is effectively a biologically damaging drug. As with all chemotherapy, adverse effects are common and many varying side effects have been documented. Because docetaxel is a cell cycle specific agent, it is cytotoxic to all dividing cells in the body including tumor cells as well as hair follicles, bone marrow and other germ cells. For this reason, common chemotherapy side effects such as alopecia occur that sometimes can be permanent. However, the drug company Sanofi-Aventis claims that they do not routinely keep this data. Northwest France is conducting a survey to establish exactly how many patients are being disfigured in this way. Independent studies show it could be as high as 6.3 % which puts this ASE in the "common and frequent" classification.

Hematological adverse effects include neutropenia (95.5 %), anemia (90.4 %), febrile neutropenia (11.0 %), and thrombocytopenia (8.0 %). Deaths due to toxicity accounted for 1.7 % of the 2,045 patients, and incidence was increased (9.8 %) in patients with elevated baseline liver function tests (liver dysfunction) [18].

4 Natural Taxanes

The study of the secondary metabolites of the yew started in the nineteenth century, when a mixture of taxanes was obtained by a German pharmacist in 1856. These compounds were named as taxines, and also their structure characterization was extremely slow, due to the complexity of the structure and the need of modern spectroscopic instruments. Furthermore, the taxine obtained earlier had inconsistent physical properties (m.p.: 82–124) and later was shown to be a mixture of at least seven compounds. Seven years later, in 1963, the constitution of the taxane nucleus was elucidated for the first time as tricyclic esterified polyols with acids, such as taxinine whose stereochemistry was established 3 years later.

Systematic studies on the non-alkaloidal components of the yew tree were started in the late 1960s, and several new members of the taxane family were discovered. Incredible accomplishment shifted the attention of the scientists to paclitaxel and also attracted wide studies on various species of Taxus which led to the isolation of many new taxane family members. To date, over 100 taxanes have been isolated and structurally elucidated and divided into several structural subclasses:

4.1 Taxanes Having an Exocyclic Double Bond Between C-4 and C-20

This is the largest subclass of taxanes and including compounds with or without side chains at C-5; different oxidation states at C-1, C-13, and C-7; and ester functionalities at C-2, C-9, and C-10.

4.2 Taxanes Containing an Extra Bond Connecting Transannular Atoms

This class shares the common feature of a transannular bond, although the structure may look quite different. It is exemplified by taxinine K, taxinine L, and taxinine M. Change in the functional groups at C-1, C-2, C-5, C-7, C-9, C-10, and C-13 are also common, e.g., taxagifine.

4.3 Taxanes Having a C-4 Epoxide

This class contains relatively fewer compounds, including baccatin I, 1-hydroxy-baccatin I, C-5 isophenylalanine side chain derivatives, and some new derivatives having nicotinate substituent at C-9 [19].

4.4 Taxanes with an Exetane Ring at C-4 and C-5

This class of taxanes, such as paclitaxel as a characteristic compound, is usually found in quite small quantities in different parts of the yew tree, but they seem to be the most interesting class of taxanes having promising anticancer potential. Their key factor is a ketone group at C-9 and also a complex side chain at the C-13 position instead of C-5 position that is often observed in other classes of taxanes.

Baccatin III was the first compound of this class, isolated from the heartwood of *Taxus baccata* in 1966 by Chan et al., and its structure was elucidated [20]. Many compounds have been extracted from the bark of *Taxus baccata*, *Taxus wallichiana*, or *Taxus brevifolia* that differ only in the nature of the substituent at C-1, C-2, and C-4 positions.

An important biosynthetic precursor of paclitaxel, 10-deacetylbaccatin III, was also isolated in reasonably good yield from the leaves of *Taxus baccata* in 1981 and also from the bark of *Taxus brevifolia* in 1982. It serves as the starting material for the semisynthesis of paclitaxel through a coupling reaction with an appropriately protected side chain that can be prepared synthetically.

4.5 Miscellaneous Taxanes

Besides to the classes of taxanes discussed before, there are also some miscellaneous taxanes having a diversity of structural modifications in the tricyclic skeleton. Some examples include taxine A with a unique rearranged skeleton; brevifoliol (natural diterpene isolated from *Taxus baccata*) and taxchinine A (acetoxybrevifoliol) contain a five-membered A ring in place of the usual six-membered ring; hydroxylated analogs of the taxanes which have an exocyclic double bond between C-4 and C-20 (class A) and can also be viewed as the oxetane ring-opened compounds of the taxane class D [19].

New generation of taxoids with systematic modifications at the C-2, C-10, and C-3′positions was designed and led to the discovery of very promising candidates for future studies [21].

5 Conclusions

Paclitaxel and docetaxel, as very powerful anticancer drugs, proved to be a life saver for thousands of patients with various types of cancer. However, these drugs are expensive and difficult to synthesize and cause undesirable side effects as well as drug resistance, and their natural sources are limited. These mean that to remain taxol as an inexpensive drug in the pharmaceutical markets, separation of other biologically active compounds from renewable sources and new methods of synthesis or biotechnological cultivation techniques of plant cell and tissues to supply new generation of taxoids would be demanded.

Abstract

Diterpenes are a structurally diverse class of C_{20} natural compounds, widely distributed in nature and originating by condensation of four isoprene units derived from mevalonate or deoxyxylulose phosphate pathways. The latter, recently discovered, originates the diterpene compounds in plants. Diterpenes can be classified as linear, bicyclic, tricyclic or tetracyclic, pentacyclic, and macrocyclic diterpenes depending on their skeletal core. In nature, they are commonly found in a polyoxygenated form with keto and hydroxyl groups, these last often esterified by small-sized aliphatic or aromatic acids.

Diterpenes have attracted growing attention because of their interesting biological and pharmacological activities. Although thousands of diterpene compounds have been described in nature from terrestrial and marine organisms, only few of them became clinically effective. Overall, the anticancer drug taxol, used in therapy against ovarian, breast, and lung cancer, with its synthetic water-soluble analogue taxotere, is an example of unusual structure discovered from nature and used as medicine. Promising diterpenes are the ginkgolides showing potent and selective antagonistic activity toward platelet-activating factor increasing in conditions of shock, burns, ulceration, and inflammation skin diseases. Also used in therapy is the diterpene resiniferatoxin, an ultrapotent vanilloid, isolated from the *Euphorbia resinifera* latex, in clinical trials for bladder hyperiflexia and diabetic neuropathy. The diterpenes used in therapy will be described together with other promising bioactive diterpenes with particular attention to those isolated from plants.

1 Introduction

Diterpenes are a heterogeneous class of natural compounds based on 20 carbon atoms. They are widely distributed in nature, both in terrestrial and marine organisms, and originate by condensation of four isoprene units derived from mevalonate or deoxyxylulose phosphate [1] pathways, wherein the latter pathway was recently discovered taking place in the biosynthesis of diterpene compounds in plants [2]. As for other classes of natural compounds diterpenes have shown an importance as biomarker of certain species, thus contributing to their chemotaxonomy classification [3]. For example, macrocyclic diterpenes and their cyclization products have been isolated only from *Euphorbiae* plants of which they could be considered as biomarker [4]. Although thousands of diterpene compounds have been described in nature from terrestrial and marine organisms, only few of them became clinically effective [5]. Active compounds isolated from plants are used directly in therapy or as prototype of bioactive lead to develop more active and less toxic analogues. In this chapter, we describe the main structural type of diterpenes isolated from plants, their biosynthesis, biological activity, and therapeutic uses.

2 Chemical Structure

The most important diterpene skeletal types in terms of number and distribution are shown in Fig. 102.1, classified as bicyclic, tricyclic, tetracyclic and pentacyclic, and macrocyclic ring.

In nature, they are commonly found in a polyoxygenated form with keto and hydroxyl groups, the last free or esterified by small-sized aliphatic or aromatic acids.

2.1 Biosynthetic Origin

Diterpenes are formed by head (isopropylidene end) to tail (alcohol end) of four isoprene (C_5H_8) building blocks. The isoprene unit itself originates by the decomposition of natural cyclic hydrocarbons giving rise to the biochemically active isoprene units, identified as the pyrophosphate esters dimethylallyl diphosphate (DMAPP) and isopentenyl diphosphate (IPP) (Scheme 102.1).

The decomposition reaction proceeds in nature by two biosynthetic routes: the mevalonate pathway, via mevalonic acid (MVA) (Scheme 102.2), and the recently discovered mevalonate-independent pathway, via deoxyxylulose phosphate (DXP) (Scheme 102.3), the latter taking place in plants. In Scheme 102.2, a schematic representation of the mevalonate pathway is shown in which three molecules of acetyl-coenzyme A derived by carbohydrate, fat, or protein catabolism yield by aldol-type reaction β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA), which is irreversibly reduced to *R*-mevalonic acid (MVA), whose phosphorylation and elimination reaction afford IPP. This molecule is converted by an isomerase into an equilibrium mixture with DMAPP.

Scheme 102.3 reports the mevalonate-independent pathway, also named as deoxyxylulose (DXP) or methyl erythritol phosphate pathway. It starts from pyruvic acid and D-glyceraldehyde to form 1-deoxy-D-xylulose 5P (DXP) reduced to 2 C-methyl-D-erythritol 4P which by phosphorylation affords a cyclic intermediate 2 C-methyl-D-erythritol 2,4-cyclophosphate. This compound by elimination reaction followed by tautomerization gives IPP and DMAPP, the latter possibly formed either independently or by isomerization.

IPP and DMAPP react as shown in Scheme 102.4 to generate geranyl pyrophosphate (GPP), whose further reaction with IPP produce farnesyl pyrophosphate (FPP) that reacts with another molecule of IPP to afford geranylgeranyl pyrophosphate (GGPP), representing the linear diterpene C_{20} precursor.

2.2 Linear Diterpenes and their Cyclization

Linear diterpenes are less distributed in nature. Phytol (**1**), a reduced form of *geranylgeraniol*, is an example of linear diterpenes, constituting the side-chain of chlorophylls, for example, phylloquinone, the vitamin K$_1$ (**2**) and chlorophyll A (**3**).

Most abundant are instead cyclic diterpenoids that originate by cyclization reactions of GGPP from both sides of the molecule: tail (alcohol end) or head (isopropylidene end). Cyclization generally involves carbocations and proceeds by a concerted addition mechanism generating different cyclic systems, due to the folding of the acyclic substrate chain on the specific enzyme and originating rich and wide array of cyclic systems [6].

2.3 Bicyclic Diterpenes

The cyclization of GGPP is initiated by a proton attach, followed by a concerted cyclization sequence terminated with the loss of a proton from a methyl thus obtaining (−) copalyl PP or its enantiomer (+) copalyl, commonly known as labdadienyl PP (Scheme 102.5) depending on the enzyme surface.

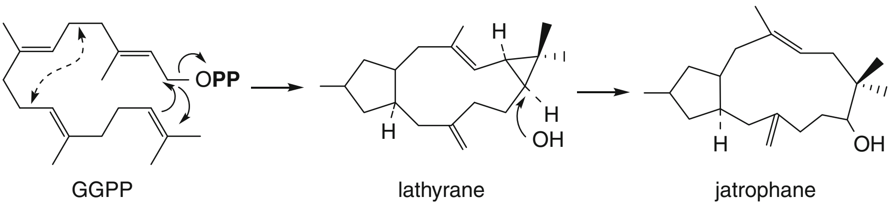
In Scheme 102.6b reports the key biosynthetic steps for the formation of atisane-type diterpenoids based on a tigliane tetracyclic skeleton whose consecutive oxidation affords phorbol that is esterified in nature giving rise to phorbol ester such as that shown in the Scheme, 12-O-myristoylphorbol 13-acetate.

2.6 Macrocyclic Diterpenes

Scheme 102.7 reports the formation of lathyrane and jatrophane skeletons starting from GGPP.

They are poly-oxygenated with keto groups and alcoholic function often esterified with small-sized aliphatic (acetic, propionic, butyric, iso-butyric)



Scheme 102.7 The cyclization of GGPP affords the macrocyclic lathyrane and jatrophane diterpenes

and aromatic (benzoic and nicotinic) acids. These compounds are less distributed in nature and are *Euphorbiaceae* plants. Their further cyclization affords the derivatives reported in Fig. 102.1.

2.7 Biological Activity and Therapeutic Uses

The biological significance of diterpenoids in plants is part of the general question concerning the role of secondary metabolites in the living organisms. It is unrealistic to expect a unique function for a class as a whole, composed as they are, of compounds of such varied and often restricted distribution, or to expect a biological role for each one of its members. A number of diterpenoids with insect growth regulatory activity [7], insect antifeedant [8], or insecticidal activity [9] have been isolated from higher plants. Insect chemistry has revealed the importance of several diterpenoids as pheromone [10] or defense chemicals [11]. Furthermore, several soft corals elaborate diterpenoids as highly toxic to fish [12].

Specifically, in the area of diterpenoids, a clear physiological role is found for gibberellins based on gibberellane skeleton (Fig. 102.1) as endogenous plant growth factor [13]. These diterpenoid acids were originally isolated from the fungus *Gibberella fujikuroi*, a pathogen which causes overgrowth of rice seedlings (tall straggly plants are obtained). The gibberellins are shown to be the causative agents of this syndrome, but they have been also isolated from many healthy plants. Indeed they seem to be ubiquitous plant hormones, responsible for increased growth, and induction of flowering. Phytol (Fig. 102.1) is an integrated part of chlorophyll constituting its lipophilic side chain necessary for the biological activity [14]. Retinol (Fig. 102.2), the vitamin A, originating by beta-carotene, is essential for mammalian growth. Retinol and related compounds are involved in the visual function of not only mammals, but also insects and fish [15].

Besides the above diterpenoids, which are basic to certain life processes, a number of diterpenoids with a variety of biological activities that may be essential for the welfare of the organism producing it have been isolated. These compounds differ from the earlier mentioned diterpenes in that their natural distribution is

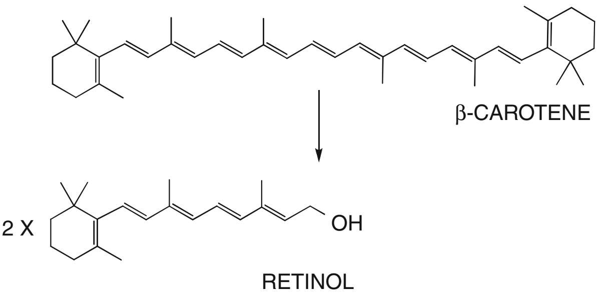


Fig. 102.2 Biosynthesis of retinol by the break of the central double bond of β-carotene

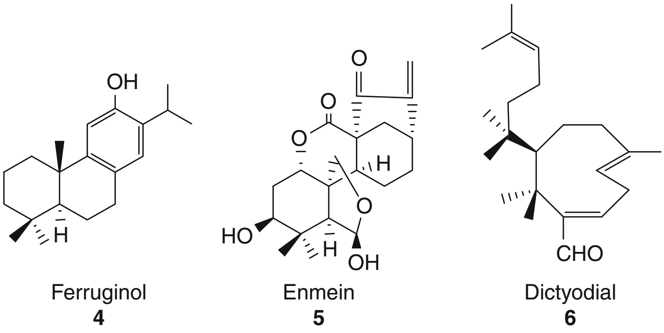

Fig. 102.3 Natural antibiotics from terrestrial and marine organisms

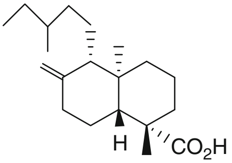
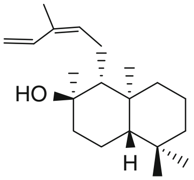
highly restricted. A number of diterpenes with plant growth regulatory activities have been described. Some kaurane (Scheme 102.6a) derivatives, for example, mimic gibberellin activity [16]. A number of diterpene antibiotics (Fig. 102.3) have been isolated from higher plants: ferruginol (**4**) [17] from *Podocarpus ferrugineus* resin and enmein (**5**) [18] from the leaves of *Isodon trichocarpus* have shown, respectively, antifungal and antibacterial activity. Likewise, several marine organisms are able to elaborate antibiotic compounds, for example, dictyodial (**6**) [19] from *Dictyota crenulata and D. flabellata.*

2.8 Bicyclic Diterpenes

Over a thousand of diterpenes based on a labdane and clerodane skeleton (Fig. 102.1) have been isolated from plants, marine organisms, fungi, and bacteria. Among them, those based on a labdane skeleton found in conifer plants (genus *Juniperus*, family Cupressaceae) and named communic acids (**7**) showed promising biological activities. In fact, antibacterial, antitumoral, hypolipidemic, relaxing smooth muscle activities have been reported and reviewed recently [20]. They were also used as building blocks for the semi-synthesis of other interesting bioactive compounds, such as quassinoids and antioxidant abietanes.



Communic acid
7



cis-abienol
8

The labdanoyl diterpene cis abienol (**8**) is a major component of the aromatic oleoresin of balsam fir, *Abies balsamea*, and it is used in the fragrance industry [21]. It is implicated in the biosynthesis of abietadiene/sandaracopimaradiene skeletons being an intermediate of the biosynthesis of these compounds in plants, used for fragrance production.

Also the clerodane class of diterpenes exhibited a wide range of biological activities. Of particular interest is asmarine A and B (**9**) [22] that showed antiproliferative activity against several human cancer cell lines and, clerocidin (**10**) [23], a naturally occurring antibiotic showing also anticancer and antimicrobial activities.

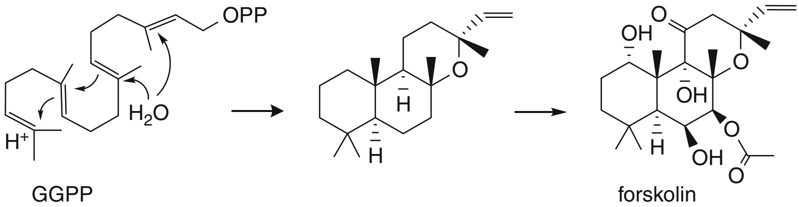
2.9 Tricyclic Diterpenes

Among these compounds, of particular interest is forskolin (Scheme 102.8) whose third ring is heterocyclic rather than carbocyclic. It has been isolated from *Coleus forskohlii* a plant used in Indian traditional medicine as hypothensive and in reducing spasm of the intestine. Forskolin (**11**), whose biosynthesis is



forskolin
11

Scheme 102.8 The biosynthesis of forskolin

showed in Scheme 102.8, is present in 0.1 % yields in the extract, is able to stimulate adenyl cyclase activity having effects on cardiovascular disease and possessing broncho-spasmolytic activity [24]. Its use is limited by the poor solubility in water and for this reason the research is aiming at developing analogues with increased solubility.

Totarol (**12**) is a compound isolated from totara tree together with several analogues. The compound was found to potentiate the antibiotic methycillin by reducing the minimum concentration against resistant *Staphylococcus aureus* [25].

Cyclization of copalyl PP affords (−)-acanthoic (**13**) acid that showed a potent anti-inflammatory property, whose synthesis was recently developed [26].

The tricyclic diterpene salvinorin A (**14**) is a trans-clerodane diterpenoid isolated from the Mexican plant *Salvia divinorum*. It acts as a kappa opioid receptor agonist and it is the first non-alkaloid compound acting on this receptor [27]. Salvinorin A is the most potent hallucinogen isolated from plants and it is also capable of inhibiting excess intestinal motility (e.g., diarrhea), through a combination of k-opioid and cannabinoid receptors.

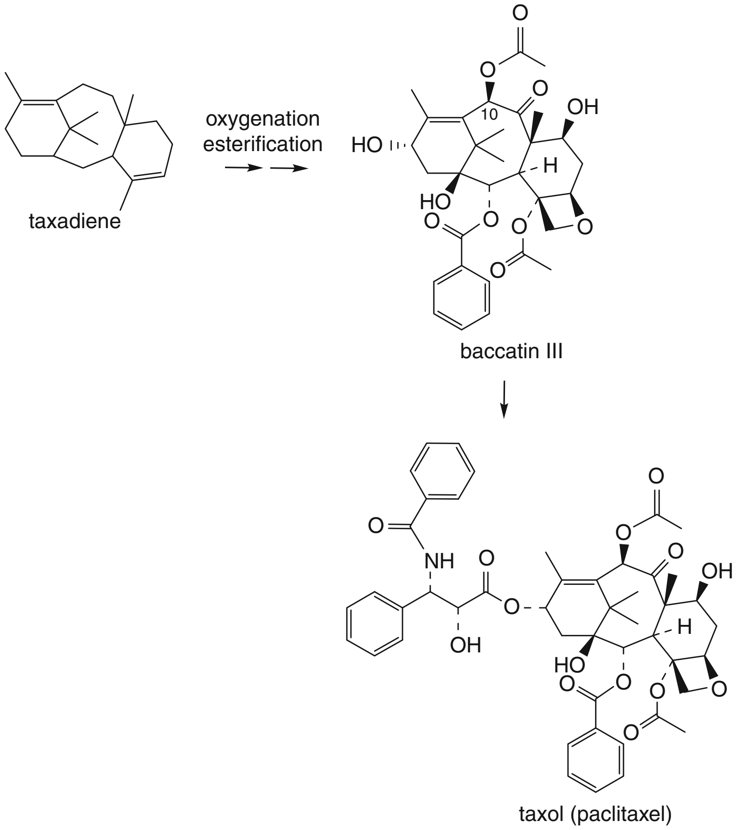
Scheme 102.10 The biosynthesis of ginkgolide

of members of this group of compounds are well studied. Among others, diterpenes from *Stevia* and from *Ginkgo* received particular attention from food industries. Stevioside (**15**), closely related to ent-kaurenoic acid and steviol (Scheme 102.9), is isolated from *Stevia rebaudiana* in large amounts (3–10 %) and it is 100–300 times as sweet as sucrose because of the presence of glucosyl ester and glucoside linkages in the molecule [28]. For this reason it has received increasing attention in the last years and it is now commercialized as sweetening agent.

Ginkgolides (**16**) have been isolated from *Ginkgo biloba* in high yields (0.1–0.25 %) [29]. The biosynthetic route for their formation is reported in Scheme 102.10. Extracts of the plant have been used traditionally to improve

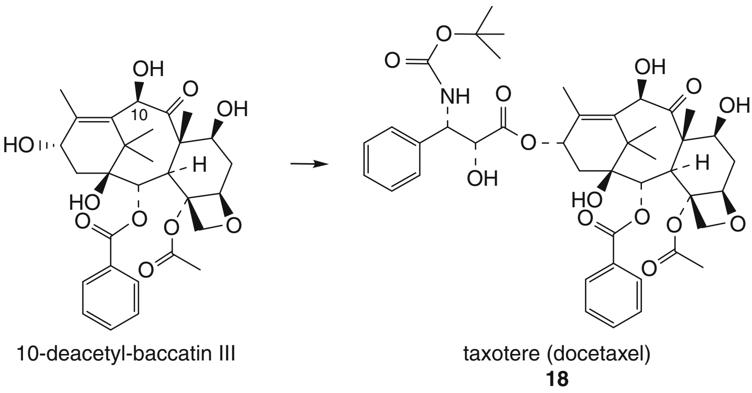


Scheme 102.11 The biosynthesis of taxol (paclitaxel)

peripheral and cerebrovascular diseases. For this reason, extracts are marketed against both cerebral and cerebrovascular circulation and the decline of cognitive function and memory processes of old age.

2.11 Macrocyclic Diterpenes and Derivatives

Among this class of compounds of great relevance is taxol (**17**), also named paclitaxel, based on taxane skeleton (Fig. 102.1), extracted on 1971 from the bark of the Pacific yew, *Taxus brevifolia* [30]. This compound has attracted growing attention because of its anticancer activity against several tumor cell lines not responding to other treatments, such as ovarian and breast cancers, non-small-cell and small-cell lung cancer, and cancers to the head and neck. Although, the drug is

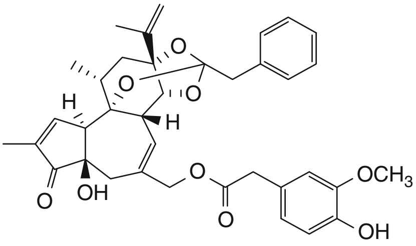


Scheme 102.12 The semi-synthesis of taxotere (docetaxel) from 10-deacetyl-baccatin III

used successfully in cancer therapy, a problem to be addressed is its supply because the 2 g necessary for one treatment is extracted from the barks of six plants which are 100 years old. Taxol derives biosynthetically from taxadiene whose oxygenation on the skeleton and esterification afford 10-deacetyl-baccalin III further esterified to taxol (Scheme 102.11). The problem of the taxol supply has been addressed by developing its semi-synthesis at increasing yields, starting from baccatin III e 10-deacetylbaccatin III, both present in *Taxus baccata*, the common yew, growing in Europe and the USA. The research in this field is also using microorganism, such as the fungi *Taxomyces adreanae* and *Pestalotiopsis microspora*, isolated from the inner bark of *T. brevifolia* and *T. wallichiana* respectively, which is able to produce taxol and taxanes at higher levels. More recently, a new taxol analogue, taxotere (docetaxel) (**18**), has been prepared by semi-synthetic route from 10-deacetyl-baccatin III (Scheme 102.12). The compound shows higher water solubility than taxol and possesses the same key pharmacophoric elements: the four-membered oxetane ring and the complex ester side chain in the structure. Taxol acts as antimitotic by binding the microtubules, promoting their assembly from tubulin, and stabilizing them against depolymerization during cell division. Thus, the abnormal microtubulin-tubule equilibrium disrupts the normal mitotic spindle apparatus and blocks cell proliferation. Taxol is also able to bind a second target, a protein which blocks the process of apoptosis, thus allowing apoptosis to proceed.

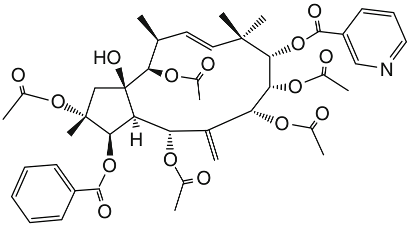
Resiniferatoxin, RTX, (**19**) is also an important drug isolated from the latex of *Euphorbia resinifera*, known since ancient times with the name *euphorbium* and used as purgatives, to remove warts and as a cathartic, in asthma and bronchial catarrh [30]. RTX is an ultrapotent vanilloid in clinical trials for bladder hyperiflexia and diabetic neuropathy [31].

The Euphorbiaceae plants are also called spurges, from the Latin word *expurgare* meaning to purge out, since these plants produce a toxic latex which can cause poisoning in humans and animals, skin dermatitis, cell proliferation, and tumor promotion (co-carcinogen activity). These severe irritant effects, especially on mucous membranes and the eye, are due to the diterpene esters, mainly esters of phorbol (Scheme 102.6) which activate protein kinase C, an important and widely distributed enzyme responsible for phosphorylating many biochemical entities. The permanent activation of protein kinase C is thought to lead to the uncontrolled cancerous growth.



resiniferatoxin
19

Recently, the discovery of interesting pharmacological properties of diterpenoids has opened new frontiers for research studies on *Euphorbia* genus. In fact, examination of other *Euphorbiaceae* yielded unusual diterpenoids, which make this plant family a prolific producer of jatrophanes [32] and of their cyclization products: lathyranes [33], pepluanes [34], paralianes [35], and segetanes [36]. These diterpenes showed antibacterial, anticancer, PGE_2-inhibitory, prolyl endopeptidase inhibitory, antifeedant, anti-HIV, analgesic, anti-inflammatory, and P-glycoprotein (PgP) inhibitory activity [37]. This protein is an interesting pharmacological target belonging to the class of ATP-binding proteins. It has been recognized as the biological factor responsible for the incoming of cross-resistance phenomena to drugs, known as multidrug resistance (MDR). MDR is particularly relevant in clinical practice: in fact some cancers (e.g., colon and kidney adenocarcinoma) are resistant to several chemiotherapeutic agents, while in others (e.g., leukemia and infantile neuroblastoma) after an initial success, a resistance to the pharmacological therapy appears. Among the tested diterpenes, pepluanin A (**20**) appears as the most promising drug having an activity two times higher than the drug cyclosporine A in reducing the resistance of cancerous cell lines to the cytotoxic drug daunomycin [38].



pepluanin A
20

3 Conclusion

The chapter describes the chemical structure and biological activities of the diterpenes isolated from nature. Particular attention is given to the biosynthetic routes affording a wide array of chemical diversity in this class of isoprenoids. The diversity in chemical structure of these compounds reflects also diversity in their distribution in the organisms, thus helping in chemotaxonomic classification. As the other classes of natural compounds, their role in the organisms has not yet been clarified [39]. However, they have attracted growing attention because of their interesting biological and pharmacological activities. Although thousands of diterpene compounds have been described from terrestrial and marine organisms, only few of them became clinically effective. Overall, the anticancer drug taxol, used in therapy against ovarian, breast, and lung cancer, with its synthetic water-soluble analogue taxotere, is an example of unusual structure discovered from nature and used as medicine. Other diterpenes used in therapy are the ginkgolides, forskolin, and resiniferatoxin.

Thus, diterpenes have shown a physiological role in the organisms (gibberellin, phytol, vitamin A, retinol), a specific taxonomic distribution (jatrophanes, lathyrane), a variety in their scaffold, inspiring chemists for the developing of parallel synthesis, and last but not least a huge array of therapeutic uses.

Abstract

Stevioside is an ent-kaurene type diterpenoid glycoside isolated from leaves of *Stevia rebaudiana* Bertoni. Leaves of this plant produce zero-calorie diterpene glycosides (stevioside and rebaudioside), a non-nutritive, high-potency sweetener. Stevioside content in leaves will vary in field grown plants and is also influenced by agroclimatic conditions. *Stevia* leaves are also in use for their medicinal benefits. In this chapter, natural distribution and cultivation of *Stevia*,

in vitro propagation, analysis of steviosides, purification of steviosides, their structural characteristics, biosynthesis, applications in food industry and health benefits are presented.

Keywords

HPLC • *Stevia* • steviosides

Abbreviations

4-PU	Cytokinin *N*-4-(Pyridyl)-*N*′-phenylurea
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A
IPP	Isopentenyl-diphosphate
LC-MS-ESI	Liquid chromatography mass spectrometry electrospray ionization
MEP	2-C-methyl-D-erythritol-4-phosphate
MVA	Mevalonic acid

1 Introduction

Stevia rebaudiana Bertoni is native to tropical and subtropical regions of North America and South America. There are nearly 240 species of *Stevia*. It is grown widely in countries like Brazil, Colombia, Paraguay, and Venezuela. *Stevia rebaudiana* Bertoni is a perennial herb of Asteraceae family [1]. *S. rebaudiana* (Bertoni) was rediscovered by Dr. M.S. *Bertoni* in 1888. Natural sweeteners are mainly plant constituents with over 75 sweet compounds reported. These sweet compounds fall mainly within the terpenoid, flavonoid, and protein compounds [2]. Among sweet compounds of plant origin, the most widely studied are steviol glycosides, that is, Stevioside and Rebaudioside A. It is a natural, noncaloric sweet-tasting plant used around the world for its intense sweet taste [3, 4]. The crop was initially established in Japan, subsequently in China. Standardized extract and pure stevioside was utilized commercially in Japan for sweetening and flavoring foods and beverage as a substitute for several synthetic sweeteners. *Stevia* is distinguished by the presence of the sweet diterpene glycosides: rebaudioside A, rebaudioside C, stevioside and dulcoside in its leaf tissue [5, 6]. Due to the high concentration of such sweet principles in the leaves of Stevia plants, these are known as honey leaf of sweet chrysanthemum or “sweet herb of Paraguay.” These sweeteners impart 250 times sweetness than sucrose. *Stevia* has been recognized as a crop of economic value and is now cultivated in India, China, Japan, Taiwan, Thailand, Korea, Brazil, Malaysia [7], some European countries, and all over South America [8]. Sweet extracts of *Stevia* are being used commercially in many countries for sweetening a variety of products including pickled vegetables, sea foods, soft drinks, soy sauce, and confectionary products [9]. Reportedly, *Stevia* extract represents more than 40 % of the high-intensity sweetener market in Japan.

In India, *Stevia* has been successfully cultivated in recent years in many areas of Indian states: Rajasthan, Maharashtra, Kerela, and Orissa. The increasing demands for natural sweeteners have driven the farmers in India toward large-scale *Stevia* cultivation.

2 Chemical Structure and Sweetness Property of Steviosides

Structurally, stevioside (13-[2-*O*-β-D-glucopyranosyl-X-glucopyran-osyl) oxy] kaur-16-en-19-oic-acid β-D-glucopyranosyl ester) is a glycoside with a glucosyl and a sophorosyl residue attached to the aglycone steviol, which has a cyclopentanon hydrophenanthrene skeleton. All of these isolated diterpenoid glycosides have the same chemical backbone structure (steviol) but differ in the residues of carbohydrate at positions C13 and C19 [10]. These eight glycosides consist of a diterpene backbone with a variety of substituent groups which include glucose, rhamnose, and/or xylose. The major components of the leaves are stevioside (5–10 % of total dry weight), rebaudioside A (2–4 %), rebaudioside C (1–2 %), and dulcoside A (0.4–0.7 %) [11]. The chemical structures of stevioside and its related compounds which include steviol, steviolbioside, stevioside, dulcoside A, B and rebaudioside A,B,D,E are shown in Fig. 103.1. The fold increase in sweetness of these glycosides shown in parenthesis compared to sucrose is dulcoside A (50–120), rebaudioside A (250–450), rebaudioside C (50–120), rebaudioside B (300–350), rebaudioside D (250–450), rebaudioside E (150–300), steviolbioside (100–125), and stevioside (300) [13]. Detailed studies with stevioside revealed that elongation of 13-*O*-glucosyl moiety up to a total number of four glucosyl units, accompanied by reduction of glucosylation at 19-*O*-glucosyl moiety, is associated with the enhancement of intensity of sweetness of the compound [14].

3 Analysis of Steviosides

High-performance liquid chromatography (HPLC), being more sensitive and accurate, has been adapted for the estimation of stevioside content in the samples [15–18]. The identity of stevioside and rebaudioside A was reportedly confirmed by LC–MS detection with electrospray ionization (ESI) in the negative ion mode [12]. For separation and quantification through HPLC analysis NH_2 column [19–21], C18 column [12, 16, 18], and carbohydrate columns [22] have been used. NH_2 columns have a high selectivity for all steviol glycosides. Detection by UV, mass spectrometry [23], and amperometry [24] has been reported. The separation of all eight of the known *S. rebaudiana* sweet glycosides, namely, Stevioside, Steviolbioside, Rebaudioside A–E, and Dulcoside-A has been reported [5]. Makapuguay et al. (1984) [19] reported on HPLC separation of the same compounds, using an NH_2 column with a linear gradient.

4 Stevioside Content in *Stevia rebaudiana* Bertoni

The leaves are found to contain a complex mixture of eight sweet diterpene glycosides, including stevioside, steviolbioside, rebaudiosides (A, B, D, E), and dulcoside A, B [25]. The most abundant among them are steviosides and rebaudiosides, depending on variety and growing conditions. Their amounts vary between 4 % and 20 %, depending on the plant cultivar and agroclimatic conditions like locations, latitude, altitude, topography, and rainfall [26–28]. The four most important steviol glycosides found in *Stevia* plant tissues are 5–10 % stevioside, 2–4 % rebaudioside A, 1–2 % rebaudioside C, and 0.5–1 % dulcoside A [29–31]. Rebaudioside B, D, and E may also be present in little quantities.

In India, the overall yield of stevioside was maximum from January harvest of second year crop (regenerated) (141.35 kg/hectare (ha)) in field grown plants and minimum in case of January harvest in the first year (27.74 kg/ha). In stem stevioside, yield was maximum in the regenerated crop harvested in September (60.71 kg/ha) followed by the regenerated crop harvested in January (48.02 kg/ha). Lowest stevioside yield in stem was obtained in the September harvest in the first year of the crop (14.75 kg/ha) [32]. Stevioside contents generally declined in the order leaves > shoots > roots > flowers. Steviosides proportion in leaves would change depending on the plant age and phase of development. The highest amount of the steviosides in leaves suggest both synthesis and primary accumulation of stevioside compounds occur in leaves [3]. Highest individual stevioside concentration in leaves from greenhouse plants was recorded for steviolbioside (64.80 g/kg dried plant).

5 Purification of Steviosides

Potential widespread use of steviosides requires an easy and effective extraction method. Enzymatic extraction of stevioside from *Stevia rebaudiana* leaves with cellulase, pectinase, and hemicellulase, using various parameters, such as concentration of enzyme, incubation time, and temperature, has been reported [33]. Purification is achieved through adsorption, column chromatography, and ion-exchange electrolytic technique for rebaudioside A, rebaudioside C, and dulcoside A [34]. An ultrafiltration (UF) process was reported for recovery of 45 % steviosides from an extract of leaves. Final purification was achieved by two consecutive mixed bed ion-exchange processes. The ion exchangers improved purity of the final product to 90 % [35].

6 In Vitro Propagation of *Stevia rebaudiana* Bertoni

The seeds of *Stevia* show a very low germination percentage [36], and propagation by seed does not allow the production of homogenous populations, resulting in great variability in important features like sweetening level and composition [37]. Micropropagation is commonly used to generate elite clonal plantlets in larger number in both economically important crops and ornamental plants. In vitro propagation of *S. rebaudiana* has been reported by a number of authors [37–39]. In vitro propagation of *Stevia* has been reported from nodal [1, 37, 40], leaf [41, 42], cell suspension cultures [43], and shoot apex [44–47]. The preferred method of developing uniform plant materials is through micropropagation adopting tissue culture methods. This provides consistent crop yield with fairly reproducible stevioside production. The induction of somatic embryogenesis from leaf explants on a medium supplemented with the cytokinin *N*-4-(Pyridyl)-*N*′-phenylurea (4-PU) has been reported [48]. Shootlets were regenerated from nodal explants of *Stevia rebaudiana* Bertoni through axillary shoot proliferation [49]. Mass propagation of shoots of *Stevia rebaudiana* using large-scale bioreactor has been reported [50]. Moreover, the influence of copper [51] and Fe-EDTA [52] in micropropagation and enhancement in biomass was reported in *Stevia rebaudina*. MS medium [53] supplemented with 3.0 mg/L Benzyl amino purine (BAP) was found to be optimum for shoot regeneration [54]. The influence of auxins and cytokinins in callus induction [55] and multiple shoot induction [56] from apical and nodal segments was also reported in S*tevia rebaudiana*. For the first time the production of stevioside in callus cultures of *S. rebaudiana* was reported [57]. Stevioside biosynthesis has been reported in callus, shoots, and rooted shoot cultures of *S. rebaudiana* [58].

7 Biosynthesis of Steviosides

Steviol glycosides are derived from the mevalonic acid pathway. The ent-kaurene skeleton of stevioside is formed *via* 2-C-methyl-D-erythritol-4-phosphate (MEP) pathway [59, 60]. High activity of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase in chloroplasts of *Stevia rebaudiana* has been reported [61]. Hence, the investigators anticipated mevalonic acid (MVA) as an intermediate of steviol biosynthetic route on the basis of the fact that HMG-CoA reductase is a key enzyme of the MVA route to isopentenyl-diphosphate (IPP).

8 Steviosides in Food Industry

Sweeteners are the most important ingredients in the food industry. Stevioside is an intense sweetener, and the extract of *Stevia* finds extensive use in Japan, China, Russia, Korea, Paraguay, Argentina, Indonesia, Malaysia, Australia, New Zealand, South America, and others, to sweeten local teas, medicines, food and beverages [62]. Being a low-calorie sweetener and dietary supplement for food, it was also approved decades ago and is commercially available as an alternative sweetener in foods and beverages [63]. It is estimated that about 30 million Indians are presently suffering from diabetes and by 2025 India’s contribution to the diabetic global population would be a whopping 89 million. The increasing consumption of sugar (sucrose) leads to excess calories, but also is not advisable for diabetic and obese patients. *Stevia* is likely to become a major source of high-potency sweetener for the growing natural food market in the future [64]. Therefore, low-caloric sweeteners have been investigated to substitute sugar [65]. Their organoleptic characteristics indicate that stevioside could be applied as a substitute for sucrose as sweetener in different products including pickled vegetables, seafoods, soft drinks, soy sauce, and confectionary products [66]. Stevioside levels in few foods have been shown in Table 103.1.

Table 103.1 Stevioside levels in foods

Food	Stevioside level (mg/kg)
Beverages (soft drinks, fruit drinks)	600
Breads	160
Biscuits	300
Cold confectionery	500
Desserts	500
Delicacies	1,000
Pickles	1,000
Sauces	1,000
Sweet corn	200
Yogurt	500

Adapted from The Joint Expert Committee on Food Additives (JECFA) at its 63rd, 68th, and 69th meeting [67]

At the present time, *Stevia rebaudiana* extract accounts for 40 % of the sweetener market in countries such as Japan, Korea, and Malaysia. *Stevia* extract and stevioside are officially approved as food additives in Brazil, Korea, Japan, and United States [68, 69]. Japan was the first country in Asia to market stevioside as a sweetener in food and drug industries.

9 Sensory Properties of Steviosides

Stevioside and rebaudioside A were tested for stability in carbonated beverages and found to be both heat and pH stable [22]. But, rebaudioside A was subject to degradation upon long-term exposure to sunlight. Several Japanese studies reveal that stevioside is highly stable [70]. Relative to other high-potency sweeteners, such as aspartame, bitterness tends to increase with concentration for both stevioside and rebaudioside A [71]. Both stevioside and rebaudioside A are synergistic in mixtures with other high-potency sweeteners such as aspartame and are good candidates for inclusion in blends [72].

10 Safety Evaluation of Steviosides

The toxicology and safety of stevioside used as a sweetener were studied by different investigators [73, 74]. Extensive safety and toxicological testing of stevioside have shown that it is safe for human consumption. Moreover, dental research suggests that the product may actually suppress the growth of oral microorganisms [75]. Nevertheless, in feeding experiments with rats and hamsters, stevioside was metabolized to steviol by the bacterial flora of the cecum [76]. Animal studies did not show any adverse effects or toxicity associated with stevioside consumption [77, 78]. Studies of acute toxicity, an LD_{50} of 8.2 g kg^{-1} for a refined stevioside extract, were cited by Katayama et al. [79]. The toxicology and safety of stevioside used as a sweetener were reviewed [80]. An acceptable daily intake (ADI) of 7.9 mg stevioside/kg body weight was suggested [81]. The safety of its use in food and beverages has been established and many regulatory boards around the world including the United States, Australia, New Zealand, and much of Asia and Latin America have permitted its usage for human consumption.

11 Standard Specifications of Steviosides in Various Countries

There are different views about standard specifications in different countries. In Japan and Korea its usage as a sweetener is permitted [69]. Initially the US government banned *Stevia* but in the year 2008, the extract of *Stevia* Rebaudioside-A was approved as food additive [81]. Today the number of countries permitting its usage is increasing. Governing bodies around the world have concluded that *Stevia* is safe for use as a general purpose sweetener. Specifically, in 2008 and 2009, the Food and Agriculture Organization/World Health Organization's Joint Expert Committee on Food Additives (JECFA), a global panel of food ingredient safety experts, and the United States Food and Drug Administration stated that the use of pure steviol glycosides (≥95 %) is safe for human consumption as a nonmedical ingredient up to 4 mg/kg of body weight/day. In 2011, the European Commission authorized the use of pure steviol glycosides (≥95 %) in foods and beverages across the European Union.

12 Health Benefits of Steviosides

The leaves of *Stevia* have insulin balancing properties [82]. Use of these sweetening compounds of *Stevia* has increased dramatically due to health concerns related to sucrose usage, such as dental caries, obesity, and diabetes. It is recommended for diabetes, has been extensively tested on animals, and also has been used by humans with no side effects. Several studies have reported the antihyperglycemic, insulinotropic, glucagonostatic, and antihypertensive effects of *Stevia* glycosides [83–85]. The sweet compounds pass through the digestive process without chemically breaking down, making it safe for diabetic and obese people, so there is no caloric intake [69]. These *Stevia* extracts have long been used in Southern Africa to treat diabetes [82]. Their ingestion causes a slight suppression of plasma glucose levels and significantly increased glucose tolerance in normal adult humans [82]. *Stevia* leaves are also in use for their medicinal benefits in hypertension, obesity, topical dressing for wounds, and other skin disorders [62]. Stevioside is reported to be beneficial for treating hypertension and hyperglycemia [83, 85]. Stevioside and related compounds are also reported to possess antitumor activity [86]. The anticancer efficacy of stevioside and six related compounds including the aglycones steviol and isosteviol were also evaluated [87]. Stevioside consumption and health effects have been shown in Table 103.2.

Table 103.2 Brief summary of published work on stevioside consumption and health effects

Stevioside consumption and health effects	Reference
Cardiovascular effects	[88]
Insulin balancing properties	[82]
Endocrine function	[89]
Topical dressing for wounds, and other skin disorders	[62]
Antitumor and anticancer activity	[86, 87]
Antihypertensive effects	[84]
Anti-inflammatory	[90]
Antidiarrheal activity	[91]

13 Conclusion

The demand for non-nutritive sweetener is ever increasing due to change in lifestyle, increased cases of diabetes and hypertensive patients, and enhanced longevity leading to geriatric-related problems. In this context, *Stevia* with its long history of usage as a source of sweetener is increasingly gaining attention. Already several countries have taken up its cultivation and processing for use as non-nutritive sweetener. Health benefits add value to the usage of steviosides or *Stevia* extracts. A number of different brands of *Stevia* products are available and are marketed internationally. However, regulations vary in different countries and need to be made uniform for acceptance. The global regulatory bodies have come to trust and accept *Stevia* as a safe food ingredient. Scientific validity of safety and creation of awareness is required for acceptance by populations. The available scientific evidences and extensive usage already in place make this crop and its metabolite stevioside as a potential non-nutritive sweetener which is here to study and benefit mankind.

Abstract

The aim of this chapter is to give the newest results on the chemistry and pharmacological properties of Polygalaceae saponins during the period

2005–2012. Around 60 new triterpene saponins were isolated and characterized, having mainly presenegenin, medicagenic acid, their 2-oxo or 11-oxo structural analogs, and bayogenin as aglycone. The sequence 3-O-(*β*-D-glucopyranosyl) presenegenin 28-{O-*β*-D-xylopyranosyl-(1→4)-α-L-rhamnopyranosyl-(1→2)-*β*-D-fucopyranosyl} ester often encountered in the genera *Polygala, Securidaca*, and *Atroxima* supported our previous conclusions that they may represent a chemotaxonomic marker for the Polygalaceae family. Additional glycosylations and acylations with 4-methoxy-, 3,4-dimethoxy-, or 3,4,5-trimethoxycinnamoyl groups contribute to the great chemical diversity of these saponins. The promising potential of the Polygalaceae saponins as immunoadjuvant, antiproliferative, anti-inflammatory, hypolipidemic, antidepressant, neuroprotective, and cognitive enhancer compounds has been highlighted.

Keywords

Biological activity • chemotaxonomy • Polygalaceae • presenegenin • triterpene saponins

1 Introduction

Many important reviews summarized different aspects related to triterpene and steroid saponins from a chemical and biological point of view [1–5]. Due to the enormous number of reports that appears worldwide, we have to set some limits. Interest on the Polygalaceae family, one of the four families of the Fabales order [6], has increased, specially due to its medicinal and taxonomic importance [7]. The most representative genus of Polygalaceae family is *Polygala*, comprising ca. 50 % of the 1,000 species of the family [6]. This genus consists of more than 500 species from all over the world of which 39 species are distributed in China. Some of these species have been used as traditional Chinese medicine for treating disturbances of the central nervous system (CNS) and inflammation [7]. Therefore, this review will highlight the newest phytochemical and biological achievements on the Polygalaceae saponins since our last review article dated from 2005 [8]. The main genera of Polygalaceae which have been reported in the literature during the period 2005–2012 are *Polygala*, *Carpolobia*, *Nylandtia*, *Securidaca*, and *Atroxima*, the genus *Polygala* being the most represented. They were reported to contain triterpene saponins, most of them having presenegenin as aglycone. The first part of this chapter will present the isolation and structures of the new and unusual saponins, whereas the second part is related to updated biological and pharmacological results.

2 Chemistry of the Polygalaceae

2.1 General Procedures

The extraction and isolation of the saponins from Polygalaceae is based on several methods, which were already reported and are still being used [8]. Briefly, after extraction with polar solvents (70 % aqueous MeOH or EtOH), the resulting crude extract is submitted to several chromatographic steps including column chromatography (CC), vacuum liquid chromatography (VLC), medium-pressure liquid chromatography (MPLC), and semi-preparative high-performance liquid chromatography (1/2 prep HPLC), resulting in the isolation of triterpene saponins, some of them being isolated as pairs of (*E*/*Z*) acylated isomers (Figs. 104.1–104.7). Various supports were used such as Sephadex LH-20, normal- and reversed-phase RP-18 silica gel, macroporous resin D-101, and reversed-phase YMC-Pack ODS-A. The structural determination of the saponins is based on 1D- and 2D-NMR experiments (COSY, TOCSY, NOESY, HSQC, HMBC) and mass spectrometry (ESI-HR-MS, FAB-MS) [8]. Recently, 18 saponins from *Polygala tenuifolia* were investigated by electrospray ionization ion trap multiple-stage mass spectrometry (ESI-ITMS) in positive- and negative-ion modes [9] in order to provide diagnostic key fragment ions important for the structural elucidation of saponins in this species.

Furthermore, analytical reliable studies have been developed in order to evaluate the quality of *Polygala japonica* Houtt, a traditional Chinese herbal medicine from different locations in China. An HPLC method using an evaporative light scattering detector (ELSD) has been developed allowing the simultaneous quantification of six triterpenoid saponins in the drug [10]. The separation has been achieved on a Discovery C-18 analytical column. The authors concluded that the total content of the six saponins could be used as chemical markers to assess the quality of *P. japonica*.

During the period 2005–2012, around 60 new triterpene saponins (**1**–**57**, Figs. 104.1–104.7) were isolated and characterized in several Chinese and African species such as *P. ruwenzoriensis, P. arenaria, P. japonica, P. tenuifolia, P. crotalarioides, P. micrantha, Carpolobia alba, Nylandtia spinosa, Securidaca longepedunculata, S. welwitschii, and Atroxima liberica*. They will be presented below according to the nature of their aglycone, presenegenin (**1**–**41**, Fig. 104.1) and its keto structural analogs at C-2 (**42**,**43**, Fig. 104.2) or C-11 (**44**, Fig. 104.3), medicagenic acid (**45**–**52**, Fig. 104.4) and its keto derivative at C-2 (**53**, Fig. 104.5), bayogenin (**54**–**56**, Fig. 104.6), and 3,23,27,29-tetrahydroxy-olean-12-en-oic acid (**57**, Fig. 104.7).

2.2 Presenegenin Glycosides

The first main group of saponins is represented by some forty presenegenin glycosides (Fig. 104.1) in *Polygala, Nylandtia, Carpolobia, Securidaca*, and *Atroxima* species, half of them (**1**–**22**) being isolated from *Polygala* genus.

From *Polygala ruwenzoriensis*, five new saponins (**1**–**5**), of which **1**–**4** as two pairs of (*E*/*Z*)-isomers, were isolated by successive MPLC [11]. They share the same sequence 3-O-(*β*-D-glucopyranosyl)presenegenin 28-{O-*β*-D-xylopyranosyl-(1→4)-O-α-L-rhamnopyranosyl-(1→2)-*β*-D-fucopyranosyl} ester (3-O-Glc-presenegenin-28-O-Fuc^2-Rha^4-Xyl) with additional substitutions of the position 4 of fucose moiety by either an (*E*)- and (*Z*)-4-methoxycinnamoyl (**1**,**2**) or an (*E*)- and (*Z*)-3,4-dimethoxycinnamoyl group (**3**,**4**). The position 4 of the xylopyranosyl (Xyl)

Fig. 104.1 Presenegenin glycosides

unit is substituted by a mono- or a disaccharide moiety. From *P. arenaria*, a new compound (**6**) without additional substitutions at Fuc-4 was isolated and characterized. The Xyl unit was substituted in a branched sequence by a *β*-D-glucopyranosyl (Glc) at C-3 and a *β*-D-galactopyranosyl (Gal) moiety at C-4 [11].

From *P. tenuifolia*, a plant which has been used in traditional Chinese medicine for thousands of years as an expectorant, tonic, tranquilizer, and to treat dementia, amnesia, and neurastenia, 11 saponins (**7**–**17**) were isolated. They share the same common sequence cited above (3-O-Glc-presenegenin-28-O-Fuc^2-Rha^4-Xyl) with additional substitutions at Fuc-3 either by a Rha (**7**, **13**–**16**) [12–15] or a Gal moiety (**11**) [13] or a (*Z*)-trimethoxycinnamoyl unit in the case of **9**, **10**, and **17** [13, 16]. In the compounds **7**, **8**, **11**–**14**, and **16**, an acylation was observed at Fuc-4 by either an (*E*)- or (*Z*)-4-methoxy- or an (*E*)-trimethoxycinnamoyl group [12, 13]. The originality of some compounds was observed by an unusual substitution at C-3 of Rha [13]. Namely, the presence of a *β*-D-apiofuranosyl (Api) unit which is acylated at C-5 by a glutaroyl moiety (**9**–**12**) is very rare in the family of Polygalaceae. Finally, the Xyl of the trisaccharide sequence at C-28 is free or substituted by a monosaccharide at C-3 or C-4.

Fig. 104.3 Glycoside of 11-oxo-olean-12-ene-2*β*,3*β*,27-trihydroxy-23,28-dioic acid

From the roots of *P. japonica* which have been used in Chinese folk herbal medicine as an expectorant, anti-inflammatory, antibacterial, and antidepressant agent, five presenegenin glycosides **18–22** were isolated [17, 18]. The originality of compounds **19–21** sharing the same above-mentioned common sequence at C-3 and C-28 of the presenegenin is due to the double substitution of Fuc at C-4 by an (*E*)-4-methoxycinnamoyl unit and at C-3 by an unusual substitution pattern of a Rha acylated at C-4 by a benzoyl unit (**19**, **20**) or by an acetyl group (**21**). The originality

of compound **22** is due to the unusual esterification at C-28 by a Glc^2-Rha^4-Xyl oligosaccharidic chain instead of a Fuc^2-Rha^4-Xyl chain.

The last derivatives of presenegenin **23–41** isolated from other genera than *Polygala*, particularly from *Carpolobia*, *Nylandtia*, *Securidaca*, and *Atroxima*, share the same sequence 3-O-Glc-presenegenin-28-O-Fuc^2-Rha^4-Xyl. In *Carpolobia alba* [11], one compound was isolated having an acetylation at Fuc-4 (**23**), whereas this position is free in the four new compounds from *Nylandtia spinosa* (**24–27**) [19]. This Fuc-4 position is acylated by an (*E*)-3,4,5-trimethoxycinnamoyl group in *Securidaca longepedunculata* (**28–31**) [20] and by a (*Z*)- or (*E*/*Z*)-3,4-dimethoxycinnamoyl group in *S. welwitschii* (**32–35**) [21] and

Fig. 104.7 Glycoside of 3*β*, 23,27,29-tetrahydroxy-olean-12-en-28-oic acid

	R	Source	Ref.
57	Glc-(1→2)-Glc	*P. japonica*	[17]

Atroxima liberica (**37–41**) [22]. The Fuc-3 position is either free (**24–28**, **31**, **36–38**) or glycosylated by a monosaccharide unit (Api) in *C. alba* (**23**), Gal or Glc in both *Securidaca* species (**30**, **32–35**), and by a dissacharide unit Xyl-(1→3)-Glc (**39–40**) in *A. liberica*. A branched trisaccharide at C-4 of Rha seems to be a common structural feature in *C. alba* and *N. spinosa*, whereas a linear disaccharide or a monosaccharide at this position is most common in the compounds from the two species of *Securidaca* and *A. liberica*. The C-3 position of Rha is mostly free or in some rare cases glycosylated by an Api (**24** in *N. spinosa*, **28–30** in *S. longepedunculata*) or acylated by an acetyl group (**34**, **35** in *S. welwitschii*).

2.3 2-Oxo-olean-12-ene-3*β*,27-dihydroxy-23,28-dioic Acid Glycosides

Two triterpene saponins (**42**, **43**, Fig. 104.2) having the unusual aglycone, 2-oxo-olean-12-ene-3*β*,27-dihydroxy-23,28-dioic acid, were isolated from *Polygala crotalarioides*, a well-known folk tonic medicine in Yunnan Wa (China) [23]. They possess the common substitutions at C-3 by a Glc and at C-28 by the sequence Fuc^{2}-Rha^{4}-Xyl which is substituted by a glucopyranosyl unit at Fuc-3 in the case of **43**.

2.4 11-Oxo-olean-12-ene-2*β*,3*β*,27-trihydroxy-23,28-dioic Acid Glycoside

One triterpene saponin (**44**, Fig. 104.4) having the unusual aglycone, 11-oxo-olean-12-ene-2*β*,3*β*,27-trihydroxy-23,28-dioic acid, was isolated from *Polygala japonica* [17]. On the common structural sequence found at C-28, Xyl is glycosylated by a disaccharide unit, Gal-(1→5)-Api.

2.5 Medicagenic Acid Glycosides

This aglycone is relatively rare in this family and has been encountered in few compounds (**45–52**, Fig. 104.4) isolated from three species *Polygala japonica* [24, 25], *P. micrantha* [26], and *Securidaca longepedunculata* [27]. The study of the aerial parts of *P. japonica* led to the isolation of three saponin derivatives of medicagenic acid (**45–47**) which possess the sequence Glc^{2}-Rha^{4}-Xyl at C-28 with additional substitution by an Api at Rha-3 in the case of **45** and **46**. The micranthosides A–C (**48–50**) isolated from *P. micrantha* possess the common sequence Fuc^{2}-Rha^{4}-Xyl with additional substitutions (Api, Gal, or Gal-Ac at different positions). Furthermore, the free position C-3 of the aglycone in the case of **46** and **47**, and its substitution by a branched triglucoside in the case of **50**, underlined the originality of these compounds. The study of *S. longepedunculata* led to the isolation of two medicagenic glycosides called securidacasides

A and B (**51**, **52**) having a common sequence at C-28 with an acylation at Fuc-4 by an (*E*)-4-methoxycinnamoyl (**51**) or by an (*E*)-3,4,5-trimethoxycinnamoyl (**52**) unit [27].

2.6 2-Oxo-olean-12-ene-23,28-dioic Acid Glycoside

Another new saponin (**53**, Fig. 104.5) isolated from *P. japonica* showed a very similar structure than compound **45** with the same sugar substitution pattern at C-3 and C-28, but differed only by the presence of a carbonyl group at C-2 of the aglycone instead of a secondary alcoholic function [24]. To the best of our knowledge, the 2-oxo-olean-12-ene-23,28-dioic acid as aglycone is encountered in this family for the first time.

2.7 Bayogenin Glycosides

Three derivatives of bayogenin (2*β*,3*β*,23-trihydroxyolean-12-en-28-oic acid) called polygalasaponins F, G, and J (**54**–**56**, Fig. 104.6) were isolated from *P. japonica* [25]. Two of them (**55**, **56**) were monodesmosidic C-28 oligosaccharide ester saponins. According to literature data [8] and updated reports, it seems that this plant is the unique source of bayogenin in the Polygalaceae family. As in compounds **45**–**47**, polygalasaponins F, G, and J possess the sequence Glc^2-Rha^4-Xyl at C-28 instead of the common sequence Fuc^2-Rha^4-Xyl. Furthermore, additional substitutions were observed (Api at Rha-3 in the case of **55**, Gal at Xyl-4 in the case of **56**).

2.8 3*β*,23,27,29-Tetrahydroxy-olean-12-en-28-oic Acid Glycoside

The study of *Polygala japonica* [17] led to the isolation of polygalasaponin XLVII (**57**, Fig. 104.7), having a free C-3 OH position and an unusual substitution pattern of the aglycone with the sugar chain attached to C-29 of the aglycone.

3 Pharmacological Studies on Polygalaceae

Plant saponins are a group of naturally occurring glycosides including a large number of biologically and pharmacologically active compounds [1, 28]. We will summarize below some of the recent advances on the Polygalaceae saponins with immunoadjuvant, antiproliferative, anti-inflammatory, and hypolipidemic properties as well as effects on the central nervous system (CNS). These studies will rationalize the traditional uses in folk medicine of some representative examples of Polygalaceae, belonging to the genus *Polygala*.

3.1 Immunoadjuvant Activity

If the quillaic acid derivatives and their analogs from *Quillaja saponaria* (Rosaceae) have been extensively studied for their immunoadjuvant properties and used as immunoadjuvants in commercial animal vaccines [29], few saponins from other sources have been reported to possess this property except some families including the Polygalaceae. Following encouraging results of earlier immunological studies on crude *P. senega* saponin extracts [30], eight pure triterpene saponins were isolated from this extract and their immunological activities evaluated [31]. Female CD-1 mice were immunized subcutaneously with ovalbumin (OVA) alone or mixed with *P. senega* saponins or *Quillaja* saponins as reference compounds (QS-18, QS-21). After a second immunization (day 10), the animals were killed (day 20) and serum samples were used for the measurement of anti-OVA immunoglobulin IgG and IgGa by enzyme-linked immunosorbent assay (ELISA). Onjisaponin A (**59**, Fig. 104.8) and onjisaponin B also called senegin III (**60**, Fig. 104.8) showed the most significant increase ($p < 0.01$), similar to QS-18 and QS-21 in anti-OVA IgG levels when compared with the control group of mice

	Nom	R^1	R^2	R^3	R^4	R^5	Source	Refs
58	PS1	Rha	Api	Rha-(1→4)-Gal(1→ 4)-Xyl	S^2	H	*P. senega*	[31]

Fig. 104.8 Some representative bioactive saponins from Polygalaceae

immunized with OVA alone. In the same way, three presenegenin saponins **58–60** (Fig. 104.8) were shown to enhance IgG2a antibody levels ($p < 0.05$), when compared with the control group. By using another strain of mice such as BALB/c mice, compounds **58–60** were found to promote higher level of IgG and IgG2a antibody production ($p < 0.1$ to $p < 0.01$) when compared with the control group. The effect of onjisaponin B (**60)** was similar to that observed with the reference compound QS-21 [31]. Furthermore, onjisaponin B (**60**), when administered with an antigen in BALB/c mice, significantly enhances production of interleukin-2 (Il-2) (similar to QS-21, $p < 0.05$) by spleen lymphocytes in response to OVA, thereby promoting a Th1-type immune response. Production of interferon-gamma (IFN-γ) in CD-1 and BALB/c mice did not appear to be significant for all saponins tested in comparison with the control group, although the concentration of IFN-γ was higher with some saponins than those of reference. This study confirmed that the adjuvant activity is not confined to *Q. saponaria* saponins but also characteristic of those isolated from *P. senega*. Since the presence of a dimeric fatty acid at C-4 of fucose in *Quillaja* saponins was reported to be a key factor in promoting a Th1-type immune response, the presence of a 4-methoxycinnamoyl group at C-4 of fucose in **58–60** might represent a structural feature important in the adjuvant activity. Furthermore, the carboxyl group at C-23 can form hydrogen bounds and thus be associated in adjuvant activity. In this work, it was shown that *P. senega* saponins may cause less toxic effects than *Quillaja* saponins that are presently used in commercial animal vaccine formulations.

3.2 Antiproliferative Activity

Uncontrolled angiogenesis is pathological and often associated with diseases such as atherosclerosis, arthritis, diabetic retinopathy, and cancer. Although several antiangiogenic agents have been approved for cancer chemotherapy, new lead compounds with novel action mechanisms and less side effects are still needed. Therefore, the antiangiogenic effects of senegasaponins have been recently studied [32]. The antiproliferative effect of senegasaponins from *P. senega* was evaluated against human umbilical vein endothelial cells (HUVECs) and various tumor cell lines, murine neuroblastoma cells (neuro 2A), human epidermoid carcinoma cells (KB3-1), human chronic myelogenous leukemia cells (K 562), and murine sarcoma cells (S 180) [32]. Senegin II, senegin III (**60**), senegin IV, and senegasaponins A (**61**) and B (**62**) exhibited antiproliferative activity against HUVECs with IC_{50} in the range 0.6–6.2 μM, with a selective index of 7–100-fold in comparison with those for several cancer cell lines, the most active being **60–62** (Fig. 104.8) (IC_{50} 0.59–1.1 μM). The 28-O-oligosaccharidic ester chain and the methoxycinnamoyl moiety were shown to be essential in this activity, since the deacyl mixture of senegasaponins and tenuifolin exhibited no antiproliferative activity against HUVECs and tumor cells. Some in vitro and in vivo assays were reported to see if the antiproliferative activity was based on inhibition of angiogenesis. Therefore, the effect of senegin III (**60**) was investigated on the migration and tubular formation of HUVECs stimulated by human recombinant vascular epithelium growth factor (VEGF) using a chemotaxicell chamber and an angiogenesis kit, respectively [32]. The results showed that the tubular network was prevented in a dose-dependent manner by senegin III in the 0.001–1.0 μM concentration range. These results suggested a possible antiangiogenic activity of senegin III, although its inhibitory effect for the VEGF-induced migration of HUVECs might not have a significant contribution to the antiangiogenic effect. Moreover, senegin III (2.5 mg/kg) suppressed tumor growth in the ddY mice sc-inoculated murine sarcoma S 180 cells, similar to cisplatin at 1 mg/kg. The formation of new vessels was assessed by using a Matrigel plug assay in mice [32]. The quantification of angiogenesis showed a significant decrease of 50 % and 60 % hemoglobin content in the groups treated with doses of 1.0 and 2.5 mg/kg of senegin III (**60**), respectively, proving its in vivo antiangiogenesis activity. The effects of **60** on VEGF-mediated signal transduction pathway in HUVECs showed that this compound would have a different mechanism of action from conventional antiangiogenic agents such as bevacizumab, sorafenib, and sunitinib. Another assay to elucidate the possible mechanism of antiangiogenic activity has shown that compound **60** induced pigment epithelium-derived factor (PEDF) protein expression in the cell lysate from 0.1 μM. All these observations showed that senegin III might have multiple targets to show the antiangiogenic effect.

3.3 Anti-inflammatory Activity

The use of *P. japonica* in traditional Chinese medicine (TCM) in the treatment of various inflammatory disorders suggests that active compounds from the plant might be potential anti-inflammatory agents. A bioguided fractionation led to the isolation of six pure triterpene saponins. Three of them, which are bayogenin derivatives [**54**, polygalasaponin V (3-O-(*β*-D-glucopyranosyl)bayogenin-28-{O-*β*-D-xylopyranosyl-(1→4)-[*β*-D-apiofuranosyl-(1→3)]-α-L-rhamnopyranosyl-(1→2)-*β*-D-glucopyranosyl}ester), and bayogenin-3-O-glucoside] showed significant anti-inflammatory activity in vivo [24, 33]. At the dose of 0.1 mg/kg, they significantly inhibited carrageenan-induced acute paw edema in mice. Furthermore, bayogenin-3-O-glucoside was shown to significantly inhibit the production of inflammatory mediators, nitrite oxide (NO), in LPS-stimulated RAW264.7 macrophages. These results support the wide use of *P. japonica* in TCM. It seems that the primary alcoholic function at C-4 of bayogenin and the carboxyl group at C-17 were crucial for an acute anti-inflammatory effect [24, 33].

3.4 Hypolipidemic Activity

The pathogenesis of atherosclerosis involves hyperlipidemia, endothelium dysfunction, infiltration of monocytes, activation of monocytes into macrophages, and smooth muscle cell proliferation [34]. The “oxidation theory” of atherosclerosis implies that agents that effectively inhibit low-density lipoprotein (LDL) oxidation and lesion development are potential antiatherogenic compounds. The roots of *Polygala aureocauda* Dunn (= *Polygala fallax* Hemsl) which is a Chinese medicinal herb, commonly used to treat infective inflammation and hypercholesterolemia, are reported to possess antivirus, hypolipidemic, and antioxidant activity [35]. A study examined the effects of the main constituent of the roots, a triterpene saponin named reinioside C (**63**, Fig. 104.8), on hyperlipidemic mice in vivo and on oxidative lesions induced by Ox-LDL in endothelium cells, macrophages, and smooth muscle cells in vitro. Mice were given a hyperlipidemic diet for 30 days and then administered reinioside C (4, 8, 16 mg/kg/day, *p.o.*) for 30 days. Then the serum lipid, superoxide dismutase (SOD), malonaldehyde (MDA), the total cholesterol (TC), and triglycerides (TG) in the liver extract were measured. The results showed that reinioside C (**63**) decreased serum and liver tissue lipid profiles in hyperlipidemic mice. In order to elucidate the mechanism of action, an in vitro study was achieved on HUVECs, peritoneal macrophages, and smooth muscle cells (SMCs) pre-incubated with reinioside C (**63**) and then cultured with oxidized low-density lipoprotein (Ox-LDL). It was shown that reinioside C protected the HUVECs against the Ox-LDL-induced LDH leakage and exerted a protective effect on oxidative lesions induced by Ox-LDL, inhibited cholesteryl ester accumulation in macrophages, and decreased [Ca^{2+}] and SMC proliferation in vitro. These results suggested that reinioside C (**63**) may be a promising hypolipidemic candidate [34]. A study of Bai et al. (2006) showed that reinioside C (**63**) at 1, 3, and 10 μM could inhibit the increased expression of lectin-like oxidized low-density lipoprotein receptor-1 (LOX-1) mRNA and LOX-1 protein induced by Ox-LDL in HUVECs [36]. Asymmetric dimethylarginine (ADMA), an endogenous nitric oxide synthase (NOS) inhibitor, has been implicated in vascular inflammation through induction of reactive oxygen species (ROS) and proinflammatory genes in endothelial cells, but few studies were made on monocytes, important cells throughout all stages of atherosclerosis [37]. A recent study showed that reinioside C (**60**) dose-dependently inhibited tumor necrosis factor-α (TNF-α) production, an important cytokine involved in the development of atherosclerosis induced by ADMA in cultured human monocytic (THP-1) cells. This effect was suggested to be promoted through inhibiting ROS/NF-kB signaling pathway, more precisely through inhibiting the ROS rise at the cellular level [37]. More recently, reinioside C (**63**) was suggested to attenuate the upregulated expression of adhesion molecules and the adherence of monocytes to endothelial cells by inhibiting NADPH oxidase/ROS/NF-kB pathway [38]. Other saponins such as ginsenosides were well documented as inhibitors of monocyte-endothelial cell adhesion [39]. Therefore, it was postulated that the sugar linkage position and the sugar residue number may play a role in the anti-atherosclerosis activity of reinioside C. However, further investigations need to be done to address structure-activity relationship.

3.5 Activity on the Central Nervous System

3.5.1 *Polygala japonica*

P. japonica has been used in a folk medicine as an antidepressant agent in the South of China. Among the saponins isolated from its aerial parts, the medicagenic acid derivatives polygalasaponin H (**46)** and E (**47**) (100 mg/kg orally, once daily, for 4 days) significantly reduce the immobility status of mice by 51.3 % and 58.1 %, respectively, in the forced swimming test [25]. These results suggested that these derivatives may be antidepressant constituents of *P. japonica*. A bayogenin glycoside, polygalasaponin G (**55**, Fig. 104.6), was shown to have a potent neurotrophic activity on pheochromocytoma (PC)-12 cells and cultured cortical neurons. This compound could promote neurite outgrowth of neurons cultured on the myelin substrates and inhibit the activation of proteins belonging to the family of Ras homologous A (RhoA) [40]. Such results might represent a therapeutic approach to improve axon regeneration after CNS injuries. Another study reported the neuroprotective effects of saponins which were evaluated in vitro using the MTT method, on a nerve cell injury model by incubating neuron-like PC-12 cells, in presence of amyloid-β peptides 25–35, $A\beta_{25\text{-}35}$, the major constituent of Alzheimer disease plaques [18]. In this model, two bayogenin derivatives, polygalasaponin II (3-O-(*β*-D-glucopyranosyl)bayogenin 28-{O-α-L-rhamnopyranosyl-(1→2)-*β*-D-glucopyranosyl} ester) [41] and F (**54**, Fig. 104.6) [25], showed moderate activity at 10 μM. Furthermore, polygalasaponin F (**54**) was shown to induce long-term potentiation in hippocampal dentate gyrus in anesthetized rats via N-methyl-D-aspartate (NMDA) receptor activation mediated by several signaling pathways [42]. This glutamate receptor is an important molecular device for controlling synaptic plasticity and memory function.

3.5.2 *Polygala tenuifolia*

P. tenuifolia has been widely used as a memory enhancer for people in Asian countries for many years [43] and is also included in many traditional prescriptions used for the treatment of amnesia and dementia. Recently, the ethanol extract of the dried roots of *P. tenuifolia* called BT-11 was shown to possess memory-enhancing effects in healthy [44] and elderly volunteers [45] with a randomized, double-blind, placebo-controlled study. The improvement of memory functions was evidenced in many animal models with learning and memory impairment induced chemically [46] or by stress [47]. This cognitive improvement by *P. tenuifolia* has been associated with polygalasaponins as its main constituents [46]. However, the toxicity of polygalasaponin fraction in animals seriously limit the application and development of an effective agent from *P. tenuifolia* for Alzheimer's disease (AD), a neurodegenerative disorder characterized by progressive memory loss and cognitive deterioration [48]. Therefore, the effect of the hydrolysate of polygalasaponins (HPS) with reduced toxicity was undertaken on cognitive improvement in amnesia C57BL/6J mice [49]. The effect was assessed by two behavioral tests (Morris water maze and step-through passive avoidance tests) on cognitive impairment induced by A$\beta_{25\text{-}35}$ injection into the hippocampus in comparison with the positive control galanthamine. In these assays, HPS (50 and 100 mg/kg) showed significant improvements [49]. Additionally, HPS increased the corresponding SOD activities (62.34 % and 22.09 %) and decreased MDA levels (28.21 % and 32.35 %) in both cortex and hippocampus as compared to model animals. These results showed that HPS may be a useful treatment against amnesia probably via its antioxidant properties. Another in vitro study showed that tenuigenin, mostly a mixture of onjisaponins extracted from *P. tenuifolia*, was shown to inhibit secretion of amyloid β-protein in transfected neuroblastoma (SH-SY5Y) cells [50]. This observation suggested that tenuigenin may be worthy of further in vivo studies as a possible anti-AD agent [50]. All these studies have been achieved with mixtures of saponins, but there are several pharmacological studies on pure constituents. Namely, polygalasaponin XXXII (**64**) [10, 13, 51] was shown to improve hippocampus-dependent learning and memory, possibly through improvement of synaptic transmission, activation of the mitogen-activated protein (MAP) kinase cascade, and enhancement of the level of brain-derived neurotrophic factor (BDNF) [52]. Therefore, this presenegenin derivative (**64**) might be considered as a potential cognition-enhancing therapeutic drug. The antagonistic effects of the saponins of *P. tenuifolia* were investigated on neurotoxicity induced by glutamate and serum deficiency in PC-12 cells by using the MTT method in vitro, with the nerve growth factor (NGF) as a positive control [13]. On the basis of this bioassay, the saponins of *P.* t*enuifolia* were considered to have neuroprotective effects at the concentration of 1×10^{-5} M. Six of them were the most active, onjisaponins Vg (**12**), Ng (**8**), J (**9**), L (**10**), B, and polygalasaponin XXXII (**64**) [9, 13]. The roots *P. tenuifolia* are used in folk medicine as a sedative-hypnotic drug. Therefore, the anxiolytic and sedative-hypnotic activities of polygalasaponins from *P. tenuifolia* (40, 80, 160 mg/kg, *p.o.*) were determined in mice using hole-board, elevated plus maze, open field, and sodium pentobarbital-induced hypnosis tests [53]. The results suggested that the polygalasaponins possessed evident anxiolytic and sedative-hypnotic activities with a relatively safe dose range, supporting the use of the roots in folk medicine.

4 Conclusion

Polygalaceae is a rich source of triterpene saponins, particularly in the genus *Polygala*. This chapter has summarized the newest achievements from a chemical and pharmacological point of view on Polygalaceae saponins, which were reported during 2005–2012. The family is reported to contain a diversity of complex triterpene glycosides, which have been classified into seven main classes according to the nature of the aglycone. Some 60 new saponins, triterpene saponins, having from three to seven sugar moieties were isolated and characterized from *Polygala*, *Carpolobia*, *Nylandtia*, *Securidaca*, and *Atroxima* genera, of which some 40 were derivatives of presenegenin (**1–41**). The other reported saponins have as aglycone structural analogs of presenegenin with a keto function at C-2 (**42,43**) or C-11 (**44**), medicagenic acid (**45-52**), its 2-oxo derivative (**53**), bayogenin (**54-56**), and 3*β*,23,27,29-tetrahydroxy-olean-12-en-28-oic acid (**57**). As we already observed [8], most saponins isolated from Polygalaceae shared the same sequence 3-O-(*β*-D-glucopyranosyl)presenegenin 28-{O-*β*-D-xylopyranosyl-(1→4)-α-L-rhamnopyranosyl-(1→2)-*β*-D-fucopyranosyl} ester, which represents a common structural feature in the family, and could be considered as a chemotaxonomic marker. Additionally, the above sequence is mostly completed by a glycosylation or acylation by an *E*-trimethoxycinnamoyl unit at the position 3 of fucose, whereas the position 4 of fucose is mainly acylated by either *E*/*Z*-4-methoxy-, or (*E*/*Z*)-3,4-dimethoxy-, or (*E*)-3,4,5-trimethoxycinnamoyl groups or by one acetyl group. The originality of some saponins is related to the presence of two apiofuranosyl units in the same oligosaccharidic chain which is very rare in the Polygalaceae family and was reported only in *Securidaca longepedunculata*. The results of the reported bioactivities have shown that some triterpene saponins mainly presenegenin glycosides from *Polygala* genus might be potent immunoadjuvant, antiangiogenic, hypolipidemic, anti-inflammatory, antidepressant, sedative, and neuroprotective agents. These observations indicate that the Polygalaceae saponins have multiple targets to show their pharmacological effects, deserving further additional studies to elucidate the mechanism of action and the structure-activity relationships.

Abstract

Saponins are a large and structurally diverse class of phytochemicals that consist of a nonpolar steroidal or triterpenoid skeleton that is glycosylated by varying numbers of sugar residues at different positions. Steroidal saponins exhibit a large range of biological activities, including cytotoxic, anti-inflammatory, hemolytic, antifungal, and antibacterial properties. Saponins possessing a steroidal skeleton are usually divided into two main structural categories, namely, spirostanol and furostanol saponins. However, the open-chain steroidal glycosides represent

a further structural class with numerous representatives, some of which possess potent cytotoxic activity. Different patterns of steroid oxygenation and glycosylation in furostanol, spirostanol, and open-chain steroidal saponins generate considerable structural diversity, which may account for their wide range of observed biological activities. The structures and stereochemistry of steroidal saponins are typically elucidated via a combination of multistage mass spectrometry, 1D and 2D NMR spectroscopy, and chemical degradation and synthesis.

1 Introduction

Saponins represent a large and structurally diverse class of plant terpenoids and are common chemical constituents of, for example, medicinal herbs. The term *saponin* is derived from the Latin word *sapo*, meaning soap, in reference to the stable, foamy lather that these compounds form when shaken in water. This derivation is also evident in the names of saponin-containing plants that historically have been used as natural detergents, for example, members of the *Sapindus* genus (commonly known as soapberries or soapnuts, family Sapindaceae), *Quillaja saponaria* Molina (soap bark tree, family Quillajaceae), and *Saponaria officinalis* L. (soapwort, family Caryophyllaceae). Structurally, saponins consist of either a steroidal (C_{27}) or triterpenoid (C_{30}) skeleton, referred to as the aglycone or sapogenin, which is substituted by varying numbers of sugar residues at different positions. (The suffix *genin* is used in the trivial nomenclature to denote an aglycone structure, as in diosgenin (**2**) and yamogenin (**10**).) In general, steroidal saponins are found in the monocotyledonous angiosperms, while triterpenoid saponins are common in dicotyledonous angiosperms [1]. Steroidal saponins are particularly abundant in the yam (Dioscoreaceae), asparagus (Asparagaceae), solanum (Solanaceae), lily (Liliaceae), and onion (Amaryllidaceae) families [1, 2]. Both steroidal and triterpenoid saponins are biosynthesized via the isoprenoid pathway through the cyclization of a 2,3-oxidosqualene precursor, before structural elaborations via, for example, hydroxylation or glycosylation. The steroidal aglycone typically has monosaccharide units or oligosaccharyl chains attached at one (monodesmoside), two (bisdesmoside) or, rarely, three (trisdesmoside) different positions. The sugar residues most commonly found in saponins are the hexoses D-glucose and D-galactose, the deoxyhexoses L-rhamnose and D-fucose, and the pentoses L-arabinose and D-xylose. Saponins have been reported to possess a large range of biological activities, doubtless owing in part to the high degree of structural diversity in this class of phytochemicals. The range of reported bioactivities, including cytotoxic, anti-inflammatory, hemolytic, antifungal, and antibacterial properties [3], has also led to considerable interest in the synthesis of these compounds and their analogs.

2 Structural Diversity of Steroidal Saponins

The majority of steroidal saponins isolated from terrestrial plants fall into two structural subfamilies: the pentacyclic furostanol saponins, characterized by a hemiacteal moiety at C-22 and a glycosidic linkage at C-26; and the spirostanol saponins, which instead possess six rings including a bicyclic acetal at C-22 (Fig. 105.1). A further class of plant saponins, which we have termed open-chain steroidal glycosides, are based upon a cholesterol-derived aglycone that lacks the additional ring(s) formed from the C-17 side chain that are characteristic of spirostanol and furostanol saponins. Within each of these three classes, structural diversity is generated through differences in stereochemistry and different patterns of oxygenation and glycosylation of the steroid nucleus.

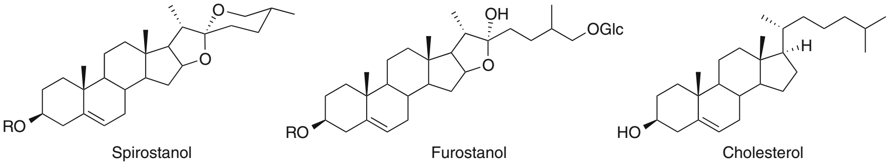

Fig. 105.1 Basic structures of spirostanol and furostanol saponins (*left* and *middle*, respectively) (R = sugar) and the structure of cholesterol (*right*)

2.1 Spirostanol and Furostanol Saponins

Spirostanol saponins are characterized by the presence of a bicyclic spiroacetal moiety at position C-22 involving the steroid E and F rings as seen in dioscin (**1**), a characteristic metabolite of *Dioscorea* species [2]. Dioscin, an archetypal spirostanol saponin, consists of a diosgenin aglycone (**2**) with a branched trisaccharide moiety composed of an inner β-D-glucose residue substituted by two α-L-rhamnose units (chacotrioside) linked at position C-3. Spirostanols are usually monodesmosidic (glycosylated at one position), having attachment of sugar units at position C-3 only. Although C-5 is sp^2 hybridized in **1**, the steroid A/B ring junction is also commonly found with either *cis* or *trans* fusion, while the B/C and C/D ring junctions are usually *trans* fused. The C-21 methyl group is always α-orientated, while the 25*R* or 25*S* absolute configuration gives rise to either equatorial or axial orientation of the C-27 methyl group, respectively. The steroidal F ring can also be further hydroxylated, for example, at position C-27.

In contrast to spirostanol saponins, furostanols, such as protodioscin (**3**), another saponin commonly found in *Dioscorea* plants [2], instead possess a hemiacetal moiety at position C-22. Cyclization of the steroid to form an F ring is prevented by glycosylation of position C-26, typically by a single β-D-glucose unit as in **3**. The structure of protodioscin (**3**) is otherwise identical to that of dioscin (**1**), as it possesses the same branched chacotrioside moiety linked at position C-3. As in spirostanol saponins, C-25 can possess either *R* or *S* absolute configuration in furostanols, while the C-22 hydroxyl moiety is mainly α orientated. Pentacyclic "furostanol" saponins may be further divided into those that possess either a hemiacetal (trivially designated 22-hydroxy) or methyl acetal (22-methoxy) moiety at C-22 and those that possess $\Delta^{20(22)}$-unsaturation. In most cases, 22-methoxy saponins are considered to be artifacts formed during methanolic extraction.

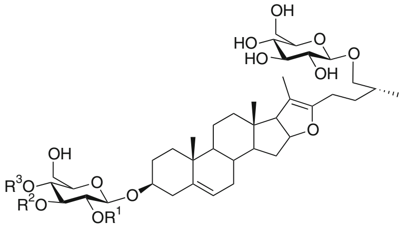
7 Protogracillin R^1 = α-L-Rha R^2 = β-D-Glc R^3 = R^4 = H
8 Methylprotogracillin R^1 = α-L-Rha R^2 = β-D-Glc R^3 = H R^4 = CH_3



5 Pseudoprotodioscin R^1 = R^3 = α-L-Rha R^2 = H
9 Pseudoprotogracillin R^1 = α-L-Rha R^2 = β-D-Glc R^3 = H

Many structurally analogous spirostanol/furostanol saponin “pairs” based on the same steroidal skeleton co-occur in the same plant species or genus, for example, dioscin (**1**) and protodioscin (**3**) are both found in *Dioscorea* [2]. The 22-methoxy and $\Delta^{20(22)}$-unsaturated analogs of protodioscin, methylprotodioscin (**4**) and pseudoprotodioscin (**5**) respectively, have also been reported from *Dioscorea* [2,4]. Another pair of structurally analogous saponins possessing the diosgenin aglycone are the spirostanol gracillin (**6**) and its corresponding furostanol protogracillin (**7**) [2]. Nicely illustrating the origins of structural diversity in saponins, these saponins differ from dioscin and protodioscin only in their glycosylation pattern; saponins **6** and **7** possess the gracillimatriose trisaccharide linked at position C-3 of the aglycone instead of the chacotrioside moiety. Again, the corresponding 22-methoxy (methylprotogracillin, (**8**)) and $\Delta^{20(22)}$-unsaturated (pseudoprotogracillin, (**9**)) saponins have been identified from *Dioscorea* [2]. A common point of difference in spirostanol and furostanol saponins is the stereochemistry of position C-25. Glycosides based on the 25*S* epimer of diosgenin, yamogenin (**10**), have also been isolated from the yam genus *Dioscorea*, as reflected in the trivial name of this aglycone [2]. The spirostanol saponin yamoscin (**11**) represents the 25*S* analog of dioscin (**1**) [5], while the corresponding furostanol protoneodioscin (**12**) bears the same relationship to protodioscin (**3**) [6]. In addition, methylprotoneodioscin (**13**) [7] and pseudoprotoneodioscin (**14**) [8] represent the 25*S* epimers of methylprotodioscin (**4**) and pseudoprotodioscin (**5**), respectively. The 25*S* glycosides that correspond to gracillin (**6**) and protogracillin (**7**) have also been characterized, as collettinside IV/zingiberenin B (**15**) [9] and protoneogracillin (**16**) [6], respectively.

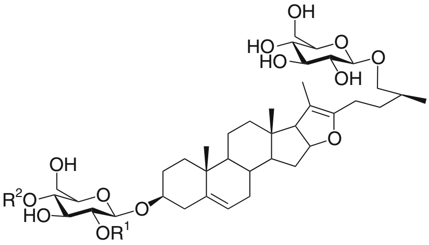
16 Protoneogracillin R^1 = α-L-Rha R^2 = β-D-Glc R^3 = R^4 = H



14 Pseudoprotoneodioscin R^1 = R^2 = α-L-Rha

As illustrated by consideration of **1-16**, a number of modifiers are commonly used in the trivial nomenclature of furostanol saponins. Where an analogous spirostanol glycsoide has been reported previously with a trivial name, the prefix *proto* can be added to give the name of the furostanol, for example protodioscin (**3**) derived from dioscin (**1**). The *methyl* prefix is used to indicate that the glycoside is a C-22 methyl acetal (22-methoxy) furostanol (as in methylprotodioscin, (**4**)), while *pseudo* indicates Δ$^{20(22)}$-unsaturation (pseudoprotodioscin, (**5**)). The *neo* modifier is used to indicate the 25*S* absolute configuration, for example in protoneodioscin (**12**) and protoneogracillin (**16**).

Though **1–16** all possess Δ$^{5(6)}$-unsaturation, spirostanol and furostanol saponins are also commonly found with either a *cis* (5β) or *trans* (5α) fused steroid A/B ring junction. For example, a number of glycosides have been reported with the 25*R* aglycone smilagenin (**17**) or its 25*S* analog sarsasapogenin (**18**), which differ from diosgenin (**2**) and yamogenin (**10**), respectively, only in possessing a *cis* (5β) A/B ring junction. Glycosides of smilagenin and sarsasapogenin are abundant in species of the *Smilax* (sarsaparilla) genus, again reflected in the trivial names of these aglycones and their glycosides. Smilagenin 3-*O*-β-D-glucopyranoside (**19**) isolated from *Smilax medica* Schltdl. & Cham (synonymous with *Smilax aristolochiifolia* Mill.) [10] is an example of a smilagenin-based spirostanol, while disporosides C and D (**20** and **21**) isolated from *Disporopsis pernyi* (Hua) Diels are examples of smilagenin furostanols [11]. Sarsasapogenin-based glycosides include the spirostanol parillin (**22**) and its corresponding 22-hydroxy and Δ$^{20(22)}$-unsaturated furostanols, sarsaparilloside (**23**), and Δ$^{20(22)}$-sarsaparilloside (**24**), respectively, first reported from *Smilax aristolochiifolia* Mill. [12–14]. The ^{1}H and ^{13}C NMR spectroscopic data for **22–24** were later reported along with the isolation of two additional sarsasapogenin-derived 22-hydroxy furostanols with different glycosylation patterns, sarsaparillosides B and C (**25** and **26**, respectively) [15]. Steroidal saponins having a *trans* (5α) A/B ring junction are also common in plants, for example, those based on the 25*R* tigogenin (**27**) or 25*S* neotigogenin (**28**) aglycones, which are otherwise analogous to diosgenin (**2**) and yamogenin (**10**), respectively.

24 $\Delta^{20(22)}$-sarsaparilloside R^1 = R^3 = β-D-Glc R^2 = α-L-Rha

Another source of structural variation in steroidal saponins is further hydroxylation of the steroidal aglycone, for example, the 1β-hydroxylation present in the

$\Delta^{5(6)}$-unsaturated aglycones ruscogenin (**29**) and neoruscogenin (**30**). There are many further examples of plant spirostanol and furostanol saponins based on aglycones having different oxygenation patterns, for example, the commonly occurring pennogenin (**31**), which possesses a 17α-hydroxyl group and hecogenin (**32**), which has a C-12 ketone moiety.

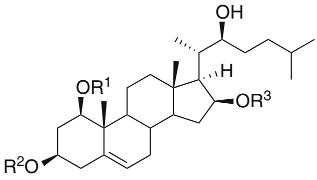
32 Hecogenin

The structural diversity of spirostanol and furostanol glycosides and their aglycones has been documented in a number of general reviews, for example, those of Vincken et al. [1] and Sahu et al. [16], as well as by Agrawal in his compilation of ^{1}H and ^{13}C NMR spectroscopic data for steroidal saponins and aglycones [17]. The saponins occurring in particular plant groups have also been cataloged, including those of *Dioscorea* [2, 18], *Tupistra* [19], *Ophiopogon* [20], *Tribulus terrestris* L. [21, 22], *Vernonia* [23], and the Agavaceae family [24], as well as the saponins found in plants of a particular geographical region, such as Brazil [25].

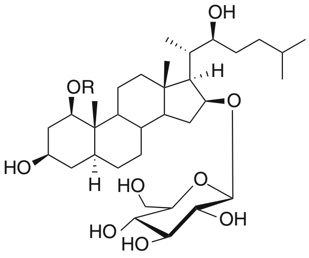
2.2 Open-Chain Steroidal Saponins

The open-chain steroidal saponins represent a further, less common structural class of steroidal glycosides. Like spirostanol and furostanol glycsoides, they possess a C_{27} aglycone, but they lack any additional ring(s) derived from the C-17 side chain. Saponins of this type, while abundant in marine organisms such as starfish, sponges, and cnidarians, appear to be less common in terrestrial plants. Open-chain steroidal glycosides are particularly prevalent in echinoderms, where they are the characteristic secondary metabolites of the classes Asteroidea (starfish) and Holothuroidea (sea cucumbers) [26]. While the structural diversity of open-chain steroidal saponins has been extensively cataloged in recent reviews of marine natural products [27–30], this class of glycoside has been largely overlooked in reviews of plant steroidal saponins, despite over 150 representatives having been reported to date. Plant open-chain steroidal glycosides are based upon a cholesterol-derived skeleton that possesses between three and five sites of oxygenation, typically at positions C-16 and C-22 as well as the C-3 oxygenation that is present as a consequence of their formation via the cyclization of 2,3-oxidosqualene. Plant open-chain saponins have been reported that possess one (monodesmosidic), two (bisdesmosidic), and three (trisdesmosidic) sites of sugar linkage with up to six attached sugar residues, most commonly β-D-glucose and α-L-rhamnose. Most open-chain steroidal saponins reported from terrestrial plants to date possess an aglycone with four sites of oxygenation, with a number of recurring oxygenation patterns emerging.

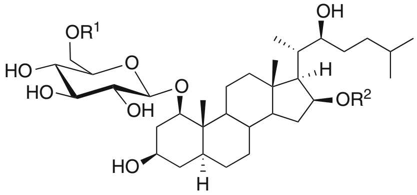
A significant proportion of the presently identified plant open-chain saponins are based on either the alliosterol aglycone, (22*S*)-1β,3β,16β,22-tetrahydroxy-cholest-5-ene (**33**), or a closely related skeleton having the same pattern of oxygenation. Alliosterol glycosides have been reported as natural products isolated from plants of the *Allium* (Amaryllidaceae), *Ruscus* (Asparagaceae), *Ornithogalum* (Asparagaceae), *Nolina* (Asparagaceae), *Reineckea* (Asparagaceae), *Tribulus* (Zygophyllaceae), and *Polianthes* (Asparagaceae) genera, with some saponins found in more than one genus. Alliosterol (**33**) was reported in 1991 as the aglycone of allosides A and B (**34** and **35**, respectively) from *Allium suworowii* Regel and *Allium stipitatum* Regel, from which the trivial names of this aglycone and its glycosides are derived [31]. The presence of a free hydroxyl group at position C-3 of the aglycone in **34** and **35**, while unusual in spirostanol and furostanol saponins, is common among glycosides of alliosterol. As in the spirostanol and furostanol saponins, differences in glycosylation pattern are a major source of structural diversity in open-chain steroidal glycosides. A total of 24 differently glycosylated alliosterol saponins have been reported to date, including monodesmosidic (**34**), bisdesmosidic (**35**), and trisdesmosidic (**36**) structures [31, 32]. Other common structural variations among open-chain steroidal glycosides are $\Delta^{5(6)}$-unsaturation or a *trans* A/B ring junction, and $\Delta^{24(25)}$-unsaturation. Interestingly, saponins based on aglycones that share the same oxygenation pattern as alliosterol uniformly possess the same 22*S* absolute configuration and β-orientation of the substituents at positions C-1, C-3, and C-16. A number of glycosides are based on aglycones that are structurally related to alliosterol but instead have *trans* (5α) A/B ring fusion (e.g., **37** and **38**) [33, 34], $\Delta^{24(25)}$-unsaturation (**39**) [35], or a C-22 ketone moiety (**40**) [36].



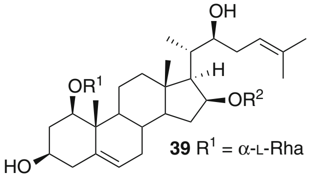
33 Alliosterol $R^1 = R^2 = R^3 = H$
34 Alloside A $R^1 = R^2 = H$ $R^3 = \beta$-D-Gal
35 Alloside B $R^1 = \beta$-D-Glc $R^2 = H$ $R^3 = \beta$-D-Gal
36 $R^1 = R^2 = \alpha$-L-Rha $R^3 = \beta$-D-Glc



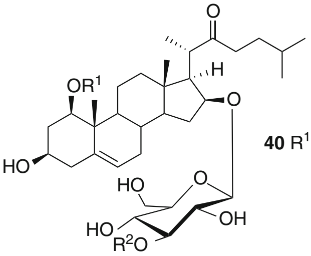
37 R = α-L-Rha



38 R^1 = 3,4,5-trimethoxybenzoyl $R^2 = \beta$-D-Glc



39 $R^1 = \alpha$-L-Rha $R^2 = \beta$-D-Glc



40 $R^1 = R^2 = \alpha$-L-Rha

Another recurring structural motif in open-chain steroidal glycosides is oxygenation of position C-26 as well the standard oxygenation of positions C-3, C-16, and C-22. This is seen in the 3β,16β,22,26-tetrahydroxy-cholest-5-ene skeleton (**41**) and its derivatives, which have been reported with varying stereochemistries at C-22 and C-25. The majority of glycosides derived from **41** or a structurally related aglycone are found in the *Solanum* (Solanaceae) and *Tribulus* (Zygophyllaceae) genera, though they have also been detected in *Trillium* (Asparagaceae) [37–39], *Chamaelirium* (Melanthiaceae) [40], *Dioscorea* (Dioscoreaceae) [41], and *Paris* species (Melanthiaceae) [42]. Again, structural diversity is generated among this family of steroidal saponins through differences in glycosylation pattern (e.g., in **42**–**44**) [38–40], *trans* A/B ring fusion as in pentandroside E (**45**) [43], and steroid oxidation states as in anguivioside XV (**46**) [44]. Abutilosides E and G (**47** and **48**) and their corresponding 5α glycosides abutilosides D and F (**49** and **50**, respectively) isolated from *Solanum abutiloides* (Griseb.) Bitter & Lillo are very unusual among the reported open-chain steroidal glycosides in possessing an α- rather than β-orientated C-16 hydroxyl group [45]. Glycosides such as **47–50** that possess both a C-22 ketone and a free C-16 hydroxyl group exist in an open-chain form because the α-orientation of the latter stereochemically prevents cyclization to form the five-membered E ring characteristic of furostanol and spirostanol saponins. In all of the reported saponins that instead possess a β-orientated C-16 hydroxyl group and a C-22 oxo moiety (e.g., **40**) cyclization is prevented by linkage of one or more sugar units at C-16 [36].

Another structural subfamily of open-chain steroidal glycosides is made up of OSW-1 or orsaponin (**51**) and related structures (e.g., **52** and **53**) derived from the 3β,16β,17α-trihydroxy-cholest-5-en-22-one aglycone [46]. So far, these have been found exclusively in species of *Ornithogalum* (Asparagaceae), specifically *Ornithogalum saundersiae* Baker [46–48], *Ornithogalum thyrsoides* Jacq. [49], and *Galtonia candicans* (Baker) Decne., which is synonymous with *Ornithogalum candicans* (Baker) J.C.Manning & Goldblatt [35]. This family of open-chain steroidal glycosides has generated particular interest because OSW-1 (**51**), as well as exhibiting potent inhibitory activity against cyclic AMP phosphodiesterase in the original literature report [46], has subsequently been shown to have potent cytotoxic activity against a number of malignant tumor cell lines [47, 48]. The potency and selectivity of **51** against a range of malignant tumor cell lines has led to considerable interest in the synthesis of this glycoside and its aglycone, as well as various derivatives [50–56].

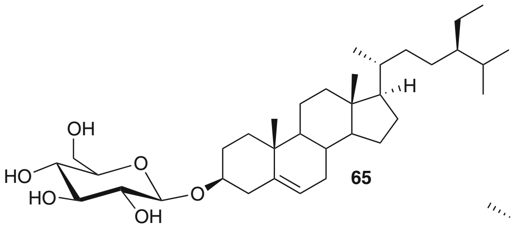
In addition to these three well-represented classes, many further structural types of open-chain steroidal glycoside have been detected in terrestrial plants. For example, glycosides based on the (22*S*)-3β,11,16β,22-tetrahydroxy-cholest-5-ene (**54**) aglycone, having characteristic oxygenation of position C-11, have been reported from *Ornithogalum* [57]. Closely related glycosides with hydroxylation of position C-26 are helosides A and B (**55** and **56**) isolated from *Chamaelirium luteum* (L.) A.Gray [58]. The majority of steroidal saponins isolated from *C. luteum*, chamaelirosides A–E (**57**–**61**) and 6-dehydrochamaelirosides A, B, and E (**62**–**64**), are based on comparatively highly oxygenated aglycones, with all possessing five sites of oxygenation (C-3, C-6, C-16, C-23, and C-24) of the steroidal aglycone [40].

2.3 Other Classes of Steroidal Saponins

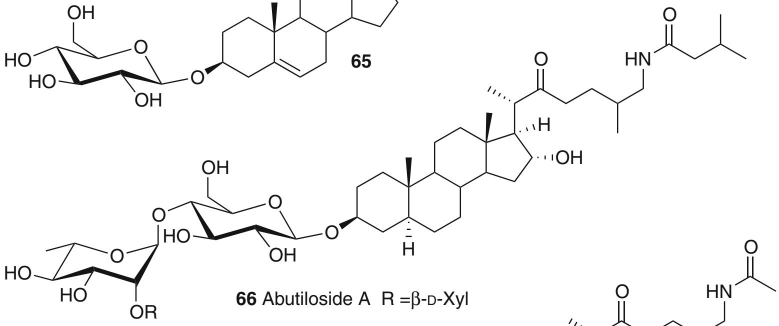
In addition to the well-represented classes of spirostanol, furostanol, and open-chain steroidal glycosides, the broad steroidal saponin family can also be considered to encompass structures derived from less common aglycones, such as cycloartane, lanostanol, sitosterol, stigmasterol, steroidal alkaloids ("glycosteroidalkaloids"), homocholestanes, and withanolides. These all share an early biosynthetic precursor, 2,3-oxidosqualene, whose alternative cyclizations and rearrangements give rise to the divergent triterpene and steroid biosynthetic pathways.

Glycosides of cycloartenol are common in the *Astragalus* genus of the Leguminosae family, for example, those detected in *Astragalus membranaceus* (Fisch.) Bunge (synonymous with *A. propinquus* Schischkin) [59]. Saponins derived from lanosterol are more unusual, with only a few reported from *Muscari paradoxum* (Fisch. & C.A. Mey.) K.Koch, which is synonymous with *Bellevalia paradoxa* (Fisch. & C.A. Mey.) Boiss. [60]. Sitosterol glucoside (**65**) and various derivatives have been reported as glycosides isolated from *Punica granatum* L. [61], *Mentha longifolia* (L.) L. [62], and *Paris formosana* Hayata (synonymous with *P. polyphylla* var. *chinensis* (Franch.) H.Hara) [63, 64]. Stigmasterol glycosides have also been reported from *Trichosanthes dioica* (Roxb.) [65], *Asparagus adscendens* Roxb. [66], and *Ambroma augustus* L.f. [67], and *P. formosana* Hayata (synonymous with *P. polyphylla* var. *chinensis* (Franch.) H.Hara) [63].

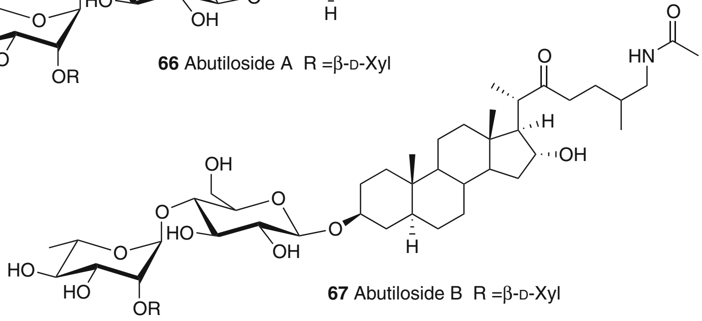
The basic cholesterol skeleton can also be modified by the incorporation of a nitrogen heteroatom as in the steroidal alkaloids. Two examples are abutilosides A and B (**66** and **67**) isolated from *S. abutiloides* [68–70], which are closely related to the open-chain steroidal glycosides abutilosides D-G (**47–50**) [45] discussed above. Glycosteroidalkaloids such as these are particularly abundant in the *Solanum* (Solanaceae) [68–70], *Lycopersicon* (Solanaceae) [71–73], and *Fritillaria* (Liliaceae) [74–76].



65



66 Abutiloside A R =β-D-Xyl



67 Abutiloside B R =β-D-Xyl

Additionally, several distinct classes of plant secondary metabolites also occur in glycosylated form and can be considered as saponins derived from a steroidal precursor, for example, glycosides of pregnane, androstane, homocholestane, the cardiac glycosides, and the withanolides. The triterpene biosynthetic pathway diverges from that of steroids at oxidosqualene and leads to the formation of glycosides based on the dammarane, tirucallane, lupane, hopane, oleanane, taraxasterane, ursanes, and cucurbitane aglycones, which have been cataloged by Vincken et al. [1].

3 Analytical Methods

Steroidal saponins are isolated from dried plant material including aerial parts, roots, and bark and are usually partitioned into a polar organic solvent before purification via reverse phase (RP) HPLC. The planar structure and stereochemistry of the isolated steroidal saponins is then typically determined using a combination of multistage mass spectrometry (MS^n), 1D and 2D NMR experiments, chemical degradation and derivatization, and enantioselective gas chromatography (GC).

3.1 Isolation and Purification

Steroidal saponins are typically extracted into aqueous methanol or acetonitrile or, less commonly, chloroform. The crude extract may then be partially purified via solid phase extraction (SPE) before further purification via RPHPLC. The general lack of a chromophore in steroidal saponins presents a challenge since UV detection cannot be used. Refractive index detection has been used in a number of recent reports of steroidal saponin isolation [77–81], but its application is limited since it cannot be used under a gradient elution regime. The utility of evaporative light scattering detection (ELSD) for steroidal saponins has been reviewed [82–84], making this now the preferred method of detection of steroidal saponins in gradient elution HPLC [15, 40, 58, 85–88]. Chromatographic separation of steroidal saponins can also be coupled with mass spectrometric analysis, for example, in HPLCESIMS^n. This can allow rapid dereplication since it provides information on the molecular weight of the saponin as well as the number and nature of attached sugar units. Given the wide range of biological activities of plant saponins and their potential application as pharmaceuticals or drug lead compounds, online or offline bioactivity-guided fractionation is also of interest. This method was employed in the isolation of the spirostanol orbiculatoside B from *Dioscorea deltoidea* var. *orbiculata* Prain & Burkhill (synonymous with *D. deltoidea* Wall. ex Griseb.), which showed antifungal and cytotoxic activities [89].

3.2 Multistage Mass Spectrometry: Preliminary Structural Information

Mass spectrometric data can provide important preliminary information about the structure of the steroidal aglycone and the number and type of attached sugar residues. Positive or negative electrospray ionization (ESI) is commonly used to detect steroidal saponins, since this “soft” ionization mode generates molecular ions that can be selected as precursor ions for further fragmentation in multistage mass spectrometry (MS^n). Other soft ionization modes such as fast atom bombardment (FAB) and matrix-assisted lazer desorption/ionization (MALDI) have also been used for the analysis of steroidal saponins [90, 91]. The MS^n experiment is now widely used as a powerful tool for structure elucidation of steroidal glycosides as well as identification of saponins present within a complex mixture [92–94]. The fragmentation of the intact saponin by stepwise dissociation of sugar residues from the aglycone, followed by examination of the fragment ion genealogy, indicates at once the number, nature, and linkage pattern (branched vs. linear) of attached monosaccharides. Analysis of the fragmentation cascade also enables predictions of aglycone structure by comparison with MS^n fragmentations of known compounds. The selective isolation of desired precursor ions also allows resolution of complex mixtures, even of compounds that co-elute in a coupled LC system.

3.3 NMR Spectroscopy: Determination of Planar Structure

The planar structure of steroidal saponins is routinely determined using 1D and 2D NMR experiments. Recent advances in instrumentation have meant that the acquisition of a complete set of 1D and 2D NMR spectra need not be prohibitively time or sample intensive. Further, structure elucidation may be performed on the intact glycoside, as opposed to the traditional, time-consuming procedure of degradation of the saponin into known structural elements.

A first step in the structure elucidation of a steroidal saponin is usually the acquisition of 1D ^{1}H and ^{13}C NMR spectra in either pyridine-d_5 or methanol-d_4 (solvents such as chloroform-d and dimethyl sulfoxide-d_6 are now used only rarely). Steroidal saponins are easily recognized by examination of their ^{1}H NMR spectrum, which usually displays characteristic signals for the steroidal methyl groups at positions C-18, C-19, C-21, and C-27, as well as a downfield region containing signals typical of the anomeric proton of a glycoside. The ^{13}C NMR spectrum of a steroidal saponin similarly displays the characteristic signals of the steroid methyl groups and sugar anomeric centers. In the spirostanol and furostanol saponins, the ^{13}C NMR spectrum additionally contains a hemiacetal/spiroacetal signal typically at around δ_C 110–114 ppm [17, 95]. In combination with MS data analysis, the ^{1}H and ^{13}C NMR chemical shifts of the isolated steroidal saponin can be compared with reference data, for example, those compiled by Agrawal et al. [17, 95], allowing rapid identification of known structures.

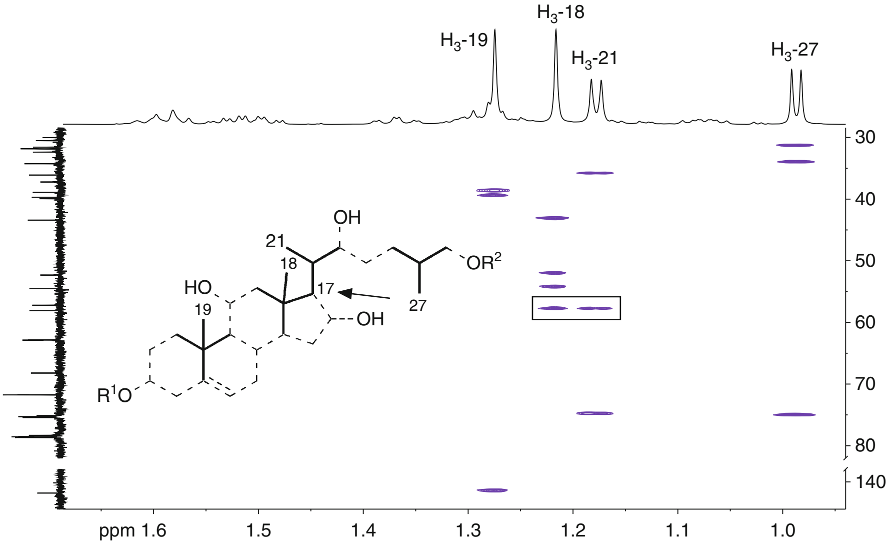


Fig. 105.2 Segment of the HMBC spectrum of heloside A (**55**) showing correlation of both H_3-18 and H_3-21 with C-17 ($R^1 = R^2 =$ β-D-glucose, pyridine-d_5, 500 MHz)

The structure determination of a new steroidal saponin usually requires the acquisition of a complete set of 1D and 2D NMR experiments including COSY, TOCSY, HSQC, HMBC, and ROESY spectra. A number of recent reviews provide information on the best choice of pulse sequences and post-acquisition processing strategies for the structure elucidation of natural products [96–98]. The examination of the long-range HMBC correlations of the characteristic steroid methyl group signals is a useful starting point for analysis. These correlations provide a means of rapid ^{1}H and ^{13}C NMR assignment of positions 18, 19, 21, and 27, since only those of H_3-18 and H_3-21 intersect (at position C-17) as illustrated in Fig. 105.2. The HMBC correlations of these methyl groups can then be used in combination with HSQC and COSY spectra to fully assign the steroidal aglycone. The gradient-selected HSQC experiment with spectral editing (i.e., CH and CH_3 up, CH_2 down) is particularly useful since it provides all short-range ^{13}C-^{1}H correlations and carbon multiplicity information, obviating the need for the separate acquisition of an edited DEPT spectrum.

The TOCSY experiment is invaluable for assignment of the saponin monosaccharide units as it allows the isolation of ^{1}H signals belonging to a single sugar from the original complex ^{1}H NMR spectrum. A 1D-selected TOCSY experiment is acquired by irradiation of a chosen, well-resolved signal followed by magnetization transfer throughout the mutually coupled spin system during the mixing period. Selective irradiation of a sugar anomeric doublet, for example, and acquisition of 1D TOCSY spectra with different mixing times, reveals the ^{1}H NMR signals of the entire sugar unit. Acquisition of a series of 1D TOCSY spectra with a range of mixing times allows the sequence of proton signals in a sugar to be assigned, which may be repeated for each attached sugar unit in a saponin and followed by assignment of ^{13}C NMR signals via HSQC. The 1D TOCSY experiment has two important advantages over 2D TOCSY; it provides improved resolution of ^{1}H signals, and the acquisition of a set of selected 1D experiments takes less time than acquisition of the corresponding 2D spectra. Correlations observed in an HMBC spectrum may then be used to map the sugar linkage pattern, greatly simplifying what was in the past a more onerous procedure involving permethylation followed by hydrolysis, with the non-methylated sites in the hydrolysis product revealing sites of sugar attachment.

3.4 Determination of Stereochemistry in Steroidal Saponins

Assignment of substituent and ring junction stereochemistry in a steroidal saponin is typically achieved through examination of through-space correlations in a 2D ROESY spectrum. The ROESY experiment is preferred over NOESY since the maximum observable nuclear Overhauser effect for compounds in the molecular weight range 750–2,000 Da (most steroidal saponins) is usually close to zero [96]. Again, the correlations of the steroidal angular methyl groups provide a helpful starting point for analysis, since they show through-space correlations with the nearby groups on the β (upper) face of the steroid. Along with correlations on the α (lower) face, these allow the unambiguous assignment of substituent and ring junction stereochemistry.

3.4.1 Determination of C-25 Absolute Configuration in Spirostanol and Furostanol Saponins

In spirostanols, the absolute configuration of C-25 can be determined via examination of the proton vicinal coupling constants for positions 24–26 as well as comparison of F ring ^{1}H and ^{13}C NMR chemical shifts with literature values [99, 100]. While stereochemistry is easily assigned within the rigid steroid ring system of spirostanols, it is more challenging in structures possessing a flexible side chain such as furostanols and open-chain glycsoides. A reliable but time-consuming method for the determination of C-25 stereochemistry in furostanol saponins is their conversion to the corresponding spirostanol, either through acid catalyzed hydrolysis or specific, enzymatic cleavage of the C-26 glucose residue to effect ring closure of the side chain [101]. The absolute configuration of C-25 in furostanols may also be more conveniently assigned by NMR spectroscopy. The geminal proton resonances of H_2-26 (δ_a and δ_b, $\Delta_{ab} = \delta_b - \delta_a$) are dependent on the configuration of C-25, being more resolved (greater Δ_{ab}) in 25*S* than 25*R* furostanols [102, 103]. Recently, the solvent dependency of this empirical rule has been highlighted; while 25*S* furostanols exhibit greater separation of the chemical shifts of H_2-26 in both pyridine-d_5 and methanol-d_4 (the two most commonly used solvents for acquisition of steroidal saponin NMR data), this behavior is less pronounced in methanol-d_4 [104]. The empirical rule proposed in the initial reports by Agrawal ($\Delta_{ab} \geq 0.57$ ppm for 25*S*; $\Delta_{ab} \leq 0.48$ ppm for 25*R*)

[102, 103] should be applied only when spectra are obtained in pyridine-d_5, while the revised rule ($\Delta_{ab} = 0.45–0.48$ ppm for 25*S*; $\Delta_{ab} = 0.33–0.35$ ppm for 25*R*) [104] should be used when spectra are acquired in methanol-d_4.

3.4.2 Side Chain Stereochemistry in Open-Chain Steroidal Saponins

The flexible nature of the steroidal side chain (C-20 to C-27) in open-chain glycosides hampers the assignment of stereochemistry via NMR spectroscopy. The absolute configurations of positions within the side chain of open-chain glycosides is often assigned via comparison of ^{1}H and ^{13}C NMR data with the literature, total synthesis, X-ray crystallography, or advanced Mosher ester analysis. For example, the (22*S*,25*R*) stereochemistry of helosides A and B (**55** and **56**) isolated from *C. luteum* was determined via X-ray crystallographic analysis of their aglycone helogenin [58]. For chamaelirosides A and B (**57** and **58**) isolated from the same plant, the stereochemistry of the vicinal C-23/C-24 diol was determined via total synthesis of the two *erythro* aglycone diastereomers with X-ray crystallographic analysis performed on an advanced synthetic intermediate (the aglycone acetonide) [88]. Comparison of the ^{1}H and ^{13}C NMR spectra of the two synthetic, diastereomeric aglycone acetonides with the acetonide derived from the natural aglycone of **57** and **58** revealed the (23*R*,24*S*) stereochemistry of the diol [88].

3.5 Determination of Sugar Absolute Configuration

The absolute configurations of attached monosaccharides in the saponin must be also be determined, as both D- or L- forms of some monosaccharides occur naturally. Methods reported for the determination of sugar absolute configuration in steroidal saponins typically involve acid hydrolysis of the saponin to yield free monosaccharide units, which are then subjected to either RPHPLC in line with refractive index/optical rotation detectors [34] or GC analysis of their trimethylsilyl thiazolidine derivatives from L-cysteine [44, 105]. An alternative procedure has been reported by König et al., in which methyl glycosides are generated via acid catalyzed methanolysis of the saponin before derivatization with TFAA and enantioselective GC analysis [106]. This method is preferred because the TFA-methyl glycosides give two or more peaks in enantioselective GC analysis (corresponding to formation of α- and β-anomers of the pyranoside/furanoside), allowing unambiguous identification of D- and L-enantiomers [106].

4 Biosynthesis of Plant Steroidal Saponins

The biosynthesis of plant sterols and saponins proceeds via the isoprene pathway with the cyclization and subsequent rearrangement of a C_{30} 2,3-oxidosqualene precursor, as discussed in reviews by Haralampidis et al. [107], Benveniste [108, 109], Kreis and Müller-Uri [110], and Osbourn et al. [111]. Following cyclization of 2,3-oxidosqualene (in the "chair-boat-chair" conformation), the resultant protosteryl carbocation is quenched in divergent pathways to yield either lanosterol (having $\Delta^{8(9)}$-unsaturation) or cycloartenol (having a cyclopropyl ring involving C-9, C-10, and C-19) [109, 110]. The C_{27} skeleton of plant sterols is then generated through the loss of three methyl groups mediated by sterol 4-demethylase and 14α-demethylase enzymes [109, 110]. The cycloartenol pathway of sterol biosynthesis appears to predominate in plants while the lanosterol pathway operates mainly in fungi and animals, although lanosterol glycosides have been reported from plants rarely (*vide supra*) [110]. Interestingly, the lanosterol synthases found in eudicots seem to have evolved independently of those found in fungi and animals, representing a catalytically unique class of lanosterol synthases [112]. The common plant metabolites sitosterol and stigmasterol are generated via C-24 alkylation of a steroidal precursor through the activity of sterol methyltransferases [113].

The basic C_{27} scaffold is elaborated through various enzymatic oxygenation and glycosylation reactions to generate the observed diversity of isolated steroidal saponins. The cholesterol aglycone is elaborated without further cyclizations in the case of open-chain steroidal glycosides, while one or two heterocyclic rings must be generated in furostanol and spirostanols, respectively. The 26-*O*-glycosylated furostanols are considered to be direct precursors to their spirostanol analogs, with specific cleavage of the 26-*O*-glucopyranose by a furostanol glycoside 26-*O*-β-glucosidase (F26G) leading to intramolecular spiroacetal formation [101]. It has been proposed that glycosylation of the steroidal nucleus can occur at various stages of saponin biosynthesis and it is known to be mediated by glycosyltransferases, such as the membrane-bound uridine 5′-diphosphate (UDP)-glucose: sterol glucosyltransferases [110]. There is some evidence that monosaccharide units are added successively to the aglycone substrate (as opposed to the attachment of a preformed polysaccharide) in triterpenoid saponin biosynthesis [114]; it remains to be seen whether this also applies in steroidal saponin biogenesis. Further structural diversity is generated by modifications such as specific acylation as seen in the OSW-1 family of glycosides (*vide supra*), perhaps carried out by a member of the BAHD family of acyltransferases [115]. (The BAHD family of acyltransferases is named for the first four members to be characterized: benzylalcohol *O*-acetyltransferase (BEAT); anthocyanin *O*-hydroxycinnamoyltransferase (AHCT); anthranilate *N*-hydroxycinnamoyl/benzoyltransferase (HCBT); and deacetylvindoline 4-*O*-acetyltransferase (DAT).)

5 Biological Activities of Plant Steroidal Saponins

Steroidal saponins isolated from plants have been reported to possess a wide range of biological activities. Early literature reports often describe steroidal saponins as having a bitter taste, perhaps reflecting an ecological function such as a protective effect against herbivory. A number of recent reviews have summarized the various bioactivities of steroidal and triterpenoid saponins, including cytotoxic/antitumor, hemolytic, hepatoprotective, antimicrobial, antibacterial, antifungal, and anti-inflammatory properties [3, 16, 116, 117]. Further, the therapeutic potential of saponins as anticancer agents has been brought into focus by reviews from Man et al. [118], Podolak et al. [119], Fuchs et al. [120], Bachran et al. [121], and Mimaki et al. [122].

As described in a review by Sautour et al. [2], a number of the above-discussed spirostanol and furostanol saponins isolated from *Dioscorea* species show cytotoxic activity against different human cancer cell lines. In particular, the cytotoxic activities of protodioscin (**3**) [123], methylprotodioscin (**4**) [124], gracillin (**6**) [125], methylprotogracillin (**8**) [126], protoneodioscin (**12**) [127], and methylprotoneodioscin (**13**) [128] were assessed against a panel of 60 human cancer cell lines as part of the National Cancer Institute anticancer drug screen. Compounds **3**, **8**, **12**, and **13** showed cytotoxic activity against most cell lines derived from leukemia and solid tumors [123, 126–128], while **4** was strongly cytotoxic against solid tumor cell lines and acted selectively against one colon cancer cell line and one breast cancer cell line [124]. Gracillin (**6**) was cytotoxic against most of the tested cancer cell lines, but displayed a lack of selectivity [125].

Among the open-chain steroidal glycosides, structures based on the 3β,16β,17α-trihydroxy-cholest-5-en-22-one aglycone, such as OSW-1 (**51**) and closely related saponins, exhibit potent bioactivities against a range of tumor cell lines. Compound **51** exhibits potent inhibitory activity against cyclic AMP phosphodiesterase [46] as well as cytotoxic activity against malignant tumor cell lines including leukemia HL-60, mouse mastrocarcinoma, human pulmonary adenocarcinoma, human pulmonary large cell carcinoma, and human pulmonary squamous cell carcinoma [47, 48]. A total of 20 glycosides have to date been reported to possess the 3β,16β,17α-trihydroxy-cholest-5-en-22-one aglycone. The evaluation of in vitro cytotoxic activity for this structurally related series of compounds allows their structure-activity relationships to be investigated; substitution of the C-16 diglycosyl unit by an aromatic ester group and the presence of a carbonyl group at C-22 appear to be required for cytotoxic activity [129].

6 Conclusions

Steroidal saponins, biosynthesized via the isoprene pathway, make up a large and structurally diverse class of plant natural product. Three main structural subfamilies of plant steroidal saponin exist: the spirostanol saponins, characterized by a bicyclic spiroacetal moiety at position C-22; the furostanol saponins, which instead possess a 22-hemiacetal, 22-methyl acetal, or $\Delta^{20(22)}$-unsaturation; and the open-chain steroidal glycosides, which lack the additional ring(s) present in spirostanol and furostanol saponins. The planar structure and stereochemistry of steroidal saponins is typically elucidated via a combination of multistage mass spectrometry (MS^n), 1D and 2D NMR spectroscopy, chemical degradation, and total synthesis. The observed structural diversity within this class of natural product is generated through differences in aglycone structure and glycosylation pattern, and is likely responsible for the wide range of reported biological activities for plant saponins.

Abstract

Carotenoids are C_{40}-compounds consisting of eight isopentenylpyrophosphate units. More than 750 structurally defined carotenoids are found in nature. They are synthesized by oxygenic phototrophs (land plants, algae, and cyanobacteria), anoxygenic phototrophs (purple bacteria, green sulfur bacteria, green filamentous bacteria, and heliobacteria), some eubacteria, some archaea, and some fungi. Most of animals also contain carotenoids, which they obtain from foods. The type of carotenoid present depends on variation in carotenogenesis pathways, different characteristics of carotenogenesis enzymes, and the

presence or absence of certain carotenogenesis genes. Some of the major carotenogenesis pathways have been elucidated, but some major and minor pathways remain unknown. These variations can be used for chemotaxonomical classifications of organisms. Here major carotenogenesis pathways, characteristics of enzymes and genes, and some biological functions of carotenoids are described.

1 Introduction

Phototrophic organisms including land plants, algae, cyanobacteria, and photosynthetic bacteria grow by photosynthesis, and necessarily contain (bacterio)chlorophylls (BChls/Chls) as well as carotenoids, whose main functions are light-harvesting and photoprotection. Furthermore, most non-phototrophic organisms including non-photosynthetic eubacteria, archaea, fungi, and animals contain carotenoids mainly for protection from harmful reactive oxygen species (Table 106.1). More than 750 structurally defined carotenoids are reported from nature [1]. Except for animals, these organisms can produce many types of carotenoids, which are synthesized in diverse carotenogenesis pathways. These carotenoids and carotenogenesis pathways can be used as chemotaxonomic makers [2–8]. Attempts have been made to cultivate single-cell algae and bacteria for a long time, but the numbers of single-cell algae and bacteria cultivated were limited. With the recent development of culture techniques, some single-cell species can be cultured, and their characteristics including their pigments can be studied. Algal and bacterial phylogenetics have been developed with the development of taxonomic technology involving DNA base sequences of 16S or 18S rRNA and some genes.

In addition, characteristics of carotenogenesis enzymes and genes have been investigated. Some carotenogenesis genes have high similarity from bacteria to land plants, but some differ greatly. Some homologous genes can be searched from complete genome sequences of many organisms at present, but some new carotenogenesis enzymes and genes for unique structures have yet to be identified.

Table 106.1 Distribution of characteristic carotenoids and carotenoid derivatives

		Characteristic carotenoids				Carotenoid derivatives

+ Means that there are species to have this carotenoid in the class

2 Distribution and Occurrence

Distributions of carotenoids can be used for chemotaxonomical classification (Tables 106.1, 106.2). Goodwin summarized the distribution of carotenoids in land plants, algae, and bacteria [2], and animals, especially invertebrates [3]. Rowan summarized the distribution in algae [4]. Recently, phytoplanktonic pigments have been summarized in a book by Roy et al. [9], and it compiles characteristics of algal carotenoids and Chls, including their structures, absorption spectra, and HPLC elution profiles [8].

Usually, "carotenoid" is used to indicate C_{40}-compounds consisting of eight isopentenylpyrophosphate (IPP) units. Some variations in carbon numbers of carotenoids are also observed (Table 106.1). C_{30}-carotenoids are synthesized by the combination of two farnesol instead of the usual geranylgeraniol unit. C_{45}- and C_{50}-carotenoids are synthesized by the addition of one and two IPP units to C_{40}-carotenoids, respectively. Unique carotenoid derivatives, such as carotenoid glycoside fatty acid esters and carotenoid sulfates, are also distributed in specific organisms (Table 106.1).

Land plants including moss, fern, gymnosperm, and angiosperm majorly contain the carotenoids, β-carotene **13**, violaxanthin **16**, 9′-*cis* neoxanthin **19**, and lutein **11** in chloroplasts for photosynthesis. Some unique carotenoids are found in specific organs, such as petals, fruits, and roots; these carotenoids are not involved in photosynthesis.

Algae are classified throughout many divisions (Table 106.2). Their sizes range from single cells of picoplankton to seaweeds. Some carotenoids are broadly distributed, and some are division specific. Allene (C=C=C), acetylene (C≡C), and acetyl (-O-CO-CH_3) groups are unique groups of carotenoids found in algae. Alloxanthin **66** is present only in Cryptophyta, fucoxanthin **75** is present mainly in Heterokontophyta, peridinin **72** and P457 **70** are present only in Dinophyta [10], and siphonaxanthin **63** is present in Chlorophyta [6, 7, 11].

Cyanobacteria are considered to originate from photosynthetic bacteria, and to have given rise to plant chloroplasts through evolution and symbiosis. The carotenoid structures and carotenogenesis pathways differ among photosynthetic bacteria, cyanobacteria, and chloroplasts, and accordingly, carotenoids seem to change discontinuously. It is interesting to speculate on how these different carotenogenesis pathways have evolved. Cyanobacteria produce unique ketocarotenoids and carotenoid glycosides (myxol glycoside **83** and oscillol diglycoside **87**) (Table 106.2) [12, 13].

Anoxygenic photosynthetic bacteria are classified into purple bacteria, green sulfur bacteria, green filamentous bacteria, and heliobacteria. Purple bacteria produce unique acyclic and tertiary methoxy carotenoids. Green sulfur and green filamentous bacteria mainly produce monocyclic carotenoids and its derivatives, and β-carotene **13**. Heliobacteria produce C_{30}-carotene 4,4′-dipaoneurosporene **81** and its derivatives [5, 14]. Carotenogenesis of purple and green sulfur bacteria are described later.

Archaea and eubacteria are divided into approximately 26 phyla, and at least 13 phyla contain carotenoids. Pigments in some species are identified as carotenoids, but those in many species have not been investigated. Consequently, the relation between the phylogenetic classification and presence of carotenoids is not known. These carotenoids may be photoprotective.

Usually carotenoids take all-*trans* forms. Some carotenoids take *cis* forms because of steric hindrance of some groups or for functions as indicated in the text.

3 Biosynthesis

3.1 Carotenogenesis Genes and Gene Clusters

In the 1980s, some carotenogenesis genes were cloned and functionally confirmed, and the characteristics of enzymes were investigated. Around 1990, carotenogenesis gene clusters were found in some eubacteria, such as *Rhodobacter capsulatus* [15] and *Pantoea ananatis* (previously *Erwinia uredovora*) [16]. Complete carotenogenesis pathways and the functions of each carotenogenesis gene involved in these pathways were investigated. All purple bacteria may have such a carotenogenesis gene cluster [14]. The aerobic photosynthetic bacterium *Bradyrhizobium* ORS278 has two sets of gene clusters for spirilloxanthin **35** and canthaxanthin **53** syntheses [17, 18]. Some eubacteria, such as *Paracoccus*, *Streptomyces*, and *Brevundimonas* contain carotenogenesis gene clusters. Furthermore, a part of the pathways was investigated in organisms lacking gene clusters, such as some eubacteria (including green sulfur bacteria, green filamentous bacteria, heliobacteria, and cyanobacteria), archaea, algae, land plants, and fungi.

3.2 IPP and Phytoene Synthesis

IPP, a C_5-compound, is the source of carotenoids, isoprenoids, terpenes, quinones, and phytol of BChls and Chls. There are two known independent pathways of IPP synthesis: the classical mevalonate (MVA) pathway and the alternative, non-mevalonate, 1-deoxy-D-xylulose-5-phosphate (DOXP) pathway [19, 20]. In the MVA pathway, acetyl-coenzyme A is converted to IPP through mevalonate. The enzymes and genes involved in this pathway are well studied [21]. The DOXP pathway was found in the 1990s, and in this pathway, pyruvate and glyceraldehyde are converted to IPP.

The distribution of these two pathways among prokaryotes follows no obvious pattern of taxonomic classification. The MVA pathways are found in some eubacteria including green filamentous bacteria, archaea, fungi, plant cytoplasm, and animals, whereas the DOXP pathway is found in some eubacteria (including purple bacteria, green sulfur bacteria, heliobacteria, and cyanobacteria) and the plastids of algae and land plants [19]. Carotenoids are synthesized from the nuclear genes in plastids. Exceptionally among algae, Euglenophyceae has only the MVA pathway, and Chlorophyceae has only the DOXP pathway [19].

Most carotenoids consist of eight IPP units. Farnesyl pyrophosphate **1** (C_{15}) is synthesized from three IPPs, and then one IPP is added to farnesyl pyrophosphate by geranylgeranyl pyrophosphate synthase (CrtE, GGPS) to yield geranylgeranyl pyrophosphate **2** (C_{20}). In a head-to-head condensation of the two C_{20}-compounds, the first carotene phytoene **3** (C_{40}) is formed by phytoene synthase (CrtB, Pys, Psy) using ATP [22, 23]. This pathway has been confirmed by cloning genes from two species of *Rhodobacter* (purple bacteria) and two species of *Pantoea* (previously *Erwinia*) [16, 22, 23]. *crtE* and *crtB* have high sequence similarity from bacteria to land plants, respectively.

3.3 Desaturation of Phytoene to Form Lycopene

Four desaturation steps are involved in the conversion of phytoene to lycopene (Fig. 106.1). Oxygenic phototrophs such as cyanobacteria, algae, and land plants require three enzymes: phytoene desaturase (CrtP, Pds), ζ-carotene desaturase (CrtQ, Zds), and *cis*-carotene isomerase (CrtH, CrtISO). CrtP catalyzes the first two desaturation steps from phytoene to ζ-carotene **5** through phytofluene **4**, and CrtQ catalyzes two additional desaturation steps from ζ-carotene to lycopene through neurosporene **6**. During desaturation by CrtQ, neurosporene and lycopene are isomerized to poly-*cis* forms such as 7,9,7′,9′-poly-*cis* lycopene **8**, and then CrtH isomerizes the poly-*cis* forms to all-*trans* forms. Light causes photoisomerization of *cis* forms of neurosporene and lycopene to all-*trans* forms [24–27]. The functions of these enzymes have been mainly confirmed in cyanobacteria, green algae, and land plants (Table 106.3). CrtP of *Synechococcus elongatus* PCC 7942 is stimulated by NAD(P) and oxygen as a possible final electron acceptor [28].

In contrast, eubacteria (including purple bacteria, green filamentous bacteria, and heliobacteria), archaea, and fungi use only one enzyme phytoene desaturase (CrtI) to convert phytoene **3** to lycopene **7**. Exceptionally, the primitive cyanobacterium *Gloeobacter violaceus* PCC 7421 uses this CrtI [29, 30]. *G. violaceus* is the first oxygenic phototroph that has been shown to use this enzyme (Table 106.3), whereas green sulfur bacteria use CrtP, CrtQ, and CrtH [14, 31].

Usually, almost all carotenoids in organisms are synthesized from lycopene **7**. Most carotenoids are dicyclic carotenoids, i.e., β-carotene **13**, α-carotene **10**, and their derivatives. Some eubacteria and some fungi produce the monocyclic carotenoids, γ-carotene **12**, and its derivatives. Acyclic carotenoids are mostly found in purple bacteria and some archaea [1–3].

3.4 β-Carotene and α-Carotene Synthesis by Lycopene Cyclization

All carotenoids in oxygenic phototrophs are dicyclic carotenoids, i.e., β-carotene, α-carotene, and their derivatives (Fig. 106.2, Table 106.2). Exceptionally, myxol

Fig. 106.1 Carotenogenesis pathway leading to conversion of phytoene to lycopene and functionally confirmed enzymes involved in this pathway. Oxygenic phototrophs require three enzymes (CrtP, CrtQ, and CrtH), whereas anoxygenic phototrophs, bacteria, and fungi use only CrtI. See the text and Table 106.3 for precise explanations

glycosides **83** and oscillol diglycosides **88** in cyanobacteria are monocyclic and acyclic carotenoids, respectively.

Lycopene **7** is cyclized into either β-carotene **13** through γ-carotene **12** or α-carotene **10** through δ-carotene **9**. Three distinct families of lycopene cyclases have been identified in carotenogenetic organisms (Table 106.3) [13, 32–34]. One large family contains CrtY in eubacteria except most cyanobacteria, and CrtL (CrtL-b, Lcy-b) in some cyanobacteria and land plants. Lycopene ε-cyclases (CrtL-e, Lcy-e) from land plants and lycopene β-monocyclases (CrtYm, CrtLm) from eubacteria are also included in this family. The amino acid sequences of these lycopene cyclases exhibit a significant five conserved regions [32, 33, 35, 36] and

have an NAD(P)/FAD-binding motif [37]. Maresca et al. [34] divided this family into two, CrtY and CrtL families.

Two cyanobacteria also contain these enzymes (Table 106.3). *Synechococcus elongatus* PCC 7942 contains a functional CrtL [38]. *Prochlorococcus marinus* MED4 contains two lycopene cyclases, CrtL-b and CrtL-e. CrtL-b exhibits lycopene β-cyclase activity, whereas CrtL-e is a bifunctional enzyme having both lycopene ε-cyclase and lycopene β-cyclase activities [39]. The combination of these two cyclases allows the production of β-carotene, α-carotene, and ε-carotene. Both enzymes might have originated from the duplication of a single gene. The characteristics of this CrtL-e are somewhat different from those observed in land plants [40].

The second family of lycopene cyclases, heterodimer (*crtYc* and *crtYd*) or monomer (*crtYc-Yd*), has been found in some eubacteria, archaea, and fungi [32, 33, 41–44], but not in phototrophs. CrtYc-CrtYd of some fungi is fused with CrtB and is named CrtYB (Table 106.3) [45].

A new third family of functional lycopene cyclase CruA has been found in the green sulfur bacterium *Chlorobaculum* (previously *Chlorobium*) *tepidum*, and the main product of CruA is γ-carotene **12** in *Escherichia coli* with a lycopene **7** background [34]. Homologous genes *cruA* and *cruP* have been found in the genome of *Synechococcus* sp. PCC 7002, and the main product of CruA and CruP is

β-carotene **13** and γ-carotene, respectively, in *E. coli* with a lycopene background (Table 106.3) [34]. In addition, the homologous genes of *cruA* and *cruP* are widely distributed in cyanobacteria such as *Synechocystis* sp. PCC 6803 and *Anabaena* sp. PCC 7120; however, these *cruA*- and *cruP*-like genes from both species did not show lycopene dicyclase or monocyclase activities [46]. *Synechococcus elongatus* PCC 6301 and PCC 7942 possess *crtL*-, *cruA*- and *cruP*-like genes; consequently, distributions of functional lycopene cyclases in cyanobacteria are unknown.

Because *Synechocystis* sp. PCC 6803 and *Anabaena* sp. PCC 7120 lack *crtL*-like genes and possess nonfunctional *cruA*-like genes, there is the possibility of a fourth new family of lycopene cyclases in these cyanobacteria. Further studies of functional lycopene cyclases (e.g., CrtL- and CruA-like) in cyanobacteria are needed.

Distribution of α-carotene **10** and its derivatives is limited in some algae classes and land plants (Table 106.2). CrtL-e and *crtL-e* have not yet been identified in algae. However, in some species of land plants, the characteristics of CrtL-e have been investigated [40, 47], and *crtL-e* has been shown to have sequence homology with *crtL-b*. Lycopene **7** is first converted to δ-carotene **9** by CrtL-e and then to α-carotene by CrtL-b. γ-Carotene **12** produced by CrtL-b is not a suitable substrate for CrtL-e (Fig. 106.2).

3.5 Carotenogenesis in Land Plants

Most of the carotenogenesis pathways and the functionally confirmed enzymes in land plants have been studied (Fig. 106.2, Table 106.3). Hydroxyl groups are introduced into β-carotene **13** by β-carotene hydroxylase (CrtR, CrtR-b, BCH) to produce zeaxanthin **14**. Epoxy groups are introduced into zeaxanthin by zeaxanthin epoxidase (Zep, NPQ) to produce violaxanthin **16** through antheraxanthin **15**. Under high light conditions, violaxanthin is converted to zeaxanthin by violaxanthin de-epoxidase (Vde) for dispersion of excess energy from excited Chls. These reactions catalyzed by Zep and Vde constitute the xanthophyll cycle [48]. One end group of violaxanthin is converted to an allene group of neoxanthin **18** by neoxanthin synthase (Nsy) [49, 50]. Because all neoxanthin in chloroplasts has the 9′-*cis* form of 9′-*cis* neoxanthin **19**, an unknown 9′-isomerase converting all-*trans* neoxanthin to 9′-*cis* neoxanthin and/or all-*trans* violaxanthin to 9-*cis* violaxanthin **17** should be present [51].

In *Arabidopsis thaliana*, β-carotene **13** is hydroxylated mainly by the non-heme di-iron enzymes, BCH1 and BCH2 (CrtR-b), to produce zeaxanthin **14**, whereas α-carotene **10** is mainly hydroxylated by the cytochrome P450 enzymes CYP97A3 for the β-end group and CYP97C1 for the β- and ε-end groups to produce lutein **11** [52, 53].

3.6 Carotenogenesis in Algae

Little is known about the carotenogenesis pathways among algae, but some are proposed based on the chemical structures of carotenoids (Fig. 106.3). Functionally confirmed enzymes are mainly reported in Chlorophyceae including *Chlorella*, *Chlamydomonas*, *Dunaliella*, and *Haematococcus* for CrtB, CrtP, CrtL-b, CrtR-b [54], Zep [55], Vde [56], and CrtW (Table 106.3) [6].

In the cell-free preparation of the Dinophyta *Amphidinium carterae*, ^{14}C-labellled zeaxanthin **14** was incorporated into neoxanthin **18**, and then into acetylenic diadinoxanthin **67** and C_{37} peridinin **72** (Fig. 106.3). In addition, the three carbon atoms (C-13′,14′,20′) of peridinin were eliminated from neoxanthin (C-13,14,20) [57, 58]. In organic chemistry, the C-7,8 double bond of zeaxanthin can be oxidized to the triple bond (acetylene group) of diatoxanthin **65** [59]. Enzymes for these reactions remain unknown.

Allenic carotenoids are very limited in algae (Table 106.2). From their chemical structures, all-*trans*-neoxanthin **18** might be converted to fucoxanthin **75**, dinoxanthin **74**, peridinin **72**, vaucheriaxanthin **69**, and diadinoxanthin **67**, but the pathways and enzymes remain unknown (Fig. 106.3) [6].

Both xanthophyll and diadinoxanthin cycles are active in algae (Fig. 106.3) [60]. Diatoxanthin **65** is converted to diadinoxanthin **67** by diatoxanthin epoxidase, and under high light conditions, diadinoxanthin is converted to diatoxanthin by diadinoxanthin de-epoxidase. The process is similar to the xanthophyll cycle in land plants, but the enzymes and genes involved have not yet been isolated.

Fig. 106.3 Carotenogenesis pathways in algae and functionally confirmed enzymes involved in these pathways. The pathways and enzymes vary with algal divisions and classes (Table 106.2) [6]

Under a stressful environment such as high light, UV irradiation, and nutrition stress, some Chlorophyceae such as *Haematococcus*, *Chlorella*, and *Scenedesmus*, accumulate the ketocarotenoids canthaxanthin **53** and astaxanthin **58**, which are synthesized by the combination of CrtR-b and β-carotene ketolase (CrtW, BKT) (Fig. 106.3, Table 106.3) [61–65]. Note that although β-carotene ketolase of *Haematococcus* and *Chlorella* were named CrtO at first [62, 63], they are CrtW-type not CrtO-type from amino acid sequences (Table 106.3).

Lutein **11** and its derivatives are found only in Rhodophyta (macrophytic type), Cryptophyta, Euglenophyta, Chlorarachniophyta, and Chlorophyta (Table 106.2), but nothing is known about α-carotene **10** hydroxylation. The chemical structures of siphonaxanthin **63** [66], loroxanthin **62**, prasinoxanthin **61**, and monadoxanthin **59** suggest that they are derived from lutein, but the pathways and enzymes remain unknown (Fig. 106.3) [6].

3.7 Carotenogenesis in Cyanobacteria

Cyanobacteria contain unique ketocarotenoids, such as echinenone **51** and 4-ketomyxol glycoside **84**, and carotenoid glycosides. Usually, the glycoside moieties are methylpentoses, fucose, rhamnose, and chinovose [13].

3.7.1 Zeaxanthin 14, Nostoxanthin 77, and Echinenone 51 Synthesis

Some cyanobacteria produce zeaxanthin, and some produce both zeaxanthin and nostoxanthin (Fig. 106.4, Table 106.3). First, the C-3 and C-3′ hydroxyl groups of zeaxanthin are introduced into β-carotene **13** by CrtR, and then the C-2 and C-2′

Fig. 106.4 Carotenogenesis pathways in cyanobacteria and functionally confirmed enzymes involved in these pathways. The pathways and enzymes vary with cyanobacterial species [6]

hydroxyl groups of nostoxanthin are introduced into zeaxanthin by 2,2′-β-hydroxylase (CrtG) [67].

CrtR from *Synechocystis* sp. PCC 6803 catalyzes the conversions of β-carotene **13** to zeaxanthin **14**, echinenone **51** to 3′-hydroxyechinenone **54**, and deoxymyxol 2′-dimethyl-fucoside **86** to myxol 2′-dimethyl-fucoside **83** (Fig. 106.4) [68, 69]. The CrtR activity for deoxymyxol 2′-fucoside from *Anabaena* sp. PCC 7120 and *Anabaena variabilis* ATCC 29413 is high, while that for β-carotene is very low, judging from trace or none of zeaxanthin present. Consequently, deoxymyxol **85** is a good substrate for CrtR in cyanobacteria because deoxymyxol is absent, while β-carotene is or is not a substrate, depending on the characteristics of CrtR in these species. On the other hand, β-carotene is a good substrate for CrtR in *Synechococcus* species, *Acaryochloris marina*, and *Prochlorococcus marinus* because of the presence of large amounts of zeaxanthin. Because CrtR in land plants and CrtZ in bacteria are known to catalyze the conversion of β-carotene to zeaxanthin, further studies of characteristics, including substrate specificities, functions, and amino acid sequence comparisons, are still needed for these enzymes [13].

Some cyanobacteria such as *Thermosynechococcus elongatus* and three *Synechococcus* species contain both caloxanthin **76** and nostoxanthin **77**, which have additional hydroxyl group(s) at C-2 and C-2′ of the β end group (Fig. 106.4, Table 106.3). CrtG has been found to catalyze C-2 hydroxylation of zeaxanthin **14** in three species of eubacteria *Brevundimonas* [44, 70], and recently also from *T. elongatus* [67]. In *T. elongatus*, CrtG also catalyzes the conversion of myxol

2′-fucoside **20** to 2-hydroxymyxol 2′-fucoside **23** [67]. Previously, hydroxymyxol 2′-glycosides were found in some cyanobacteria and named aphanizophyll, which were believed to be 4-hydroxymyxol 2′-glycosides **22**. A more definitive determination of 2-hydroxymyxol 2′-glycoside or 4-hydroxymyxol 2′-glycoside should be performed.

Echinenone **51** is a major carotenoid in some cyanobacteria, while canthaxanthin **53** is a minor one (Fig. 106.4). Echinenone might play a role in photosynthesis. CrtO and/or CrtW catalyze the introduction of the keto group as described below.

At present, with regard to enzymes involved in the above mentioned reaction, two distinct β-carotene ketolases, CrtO and CrtW, have been found, and only seven β-carotene ketolases have been functionally confirmed in four species of cyanobacteria (Fig. 106.4, Table 106.3). In *Synechocystis* sp. PCC 6803, CrtO catalyzes the conversion of β-carotene **13** to echinenone **51** [71], and 4-ketomyxol 2′-glycoside **84** is absent [72]. *Anabaena* sp. PCC 7120 has two functional enzymes: CrtO catalyzes the conversion of β-carotene to echinenone and CrtW catalyzes the conversion of myxol 2′-fucoside **20** to 4-ketomyxol 2′-fucoside **21** [73]. *Nostoc punctiforme* PCC 73102 has two CrtW-type enzymes, CrtW38 and CrtW148 [74], as well as echinenone and 4-ketomyxol 2′-fucoside [75]. Based on their substrate specificities, CrtW38 might catalyze the conversion of β-carotene to echinenone, and CrtW148 might catalyze the conversion of myxol 2′-fucoside to 4-ketomyxol 2′-fucoside [75]. In *Gloeobacter violaceus* PCC 7421, both CrtO and CrtW function to catalyze the conversion of β-carotene to echinenone. Oscillol 2,2′-di(α-L-fucoside) **88** is present but myxol 2′-glycoside **83** is absent [29, 30]. It is not known whether both or either gene function in the cells. In *Thermosynechococcus elongatus*, genes coding for ketocarotenoids, *crtO*- and *crtW*-like genes, are absent. In total, in cyanobacteria, the conversion of myxol 2′-glycoside to 4-ketomyxol 2′-glycoside is catalyzed by CrtW in two species, while that of β-carotene to echinenone is catalyzed by CrtO in three species and by CrtW in two species. The composition of the products, echinenone and canthaxanthin **53**, might depend on the characteristics of the enzyme. Consequently, two distinct β-carotene ketolases, CrtO and CrtW, are used in two pathways, β-carotene and myxol 2′-glycoside, depending on the species. It would be interesting to determine just how cyanobacteria obtain both or either β-carotene ketolases, and how they utilize them properly [13].

3.7.2 Myxol Glycoside Synthesis

Lycopene **7** is cyclized to γ-carotene **12** by one of lycopene cyclase (Fig. 106.4). The left half (β end group) of the γ-carotene is hydroxylated by CrtR. Its function has been confirmed by deletion mutants of *Synechocystis* sp. PCC 6803 [69] and *Anabaena* sp. PCC 7120 [46], which produce deoxymyxol 2′-glycosides **86** not myxol 2′-glycosides **83**. Because deoxymyxol **85** is almost absent in cyanobacteria, CrtR activity for deoxymyxol should be very high. Further, a keto group is introduced by the CrtW of *Anabaena* sp. PCC 7120 [73] and *Nostoc punctiforme* PCC 73102 [74] to form 4-ketomyxol 2′-glycoside **84**, and a 2-hydroxyl group is introduced by CrtG of *Thermosynechococcus elongatus* to form 2-hydroxymyxol

2′-fucoside **23** [67]. It is not known that whether 4-hydroxymyxol **22** is produced directly from myxol by hydroxylation or from 4-ketomyxol **21** by reduction, because the stereochemistry of 4-hydroxyl group from *Anabaena variabilis* ATCC 29413 is a mixture of (4*R*)- and (4*S*)-chiralities (Fig. 106.4) [76].

The right half (ψ end group) of myxol **82** has a very unique glycosidic linkage (Fig. 106.4). Although certain enzymes should be involved in myxol synthesis, little is known about this process. A deletion mutant of GDP-fucose synthase (WcaG) of *Anabaena* sp. PCC 7120 produces myxol 2′-rhamnoside, but not the usual myxol 2′-fucoside, and contains relatively little free myxol [46]. GDP-rhamnose could be the substrate for GDP-fucose transferase, which has yet to be identified, instead of the usual GDP-fucose. In contrast, the deletion mutant of GDP-fucose synthase of *Synechocystis* sp. PCC 6803 produces only free myxol, instead of the usual myxol 2′-dimethyl-fucoside **20** [46, 73]. This might be due to the absence of the substrate of GDP-fucose transferase. A *crtD* (3,4-dehydrogenase of *Rhodobacter*) homolog from a marine bacterium strain P99-3 (MBIC 03313; previously *Flavobacterium* sp.) [77], which produces free myxol, and *Deinococcus radiodurans* [78] are known to have a CrtD function, whereas this homolog from *Synechocystis* sp. PCC 6803 does not have CrtD functions [34, 79]. Furthermore, a *crtD* homolog in *Anabaena* sp. PCC 7120 (*all5123*) has no function in carotenogenesis [46]. In case of oscillol 2,2′-diglycoside **88**, enzymes involved in myxol synthesis catalyze both end groups of lycopene **7**, and this might be due to the characteristics of myxol-synthesizing enzymes and/or lycopene cyclase (Fig. 106.4, Table 106.3). Thus, further studies of myxol-synthesizing enzymes and associated genes are needed.

In *Anabaena variabilis* ATCC 29413, myxol glycosides are absent, while the free forms of myxol **82** and 4-hydroxymyxol are present [76]. Another strain of *A. variabilis* IAM M-3 produces myxol 2′-fucoside **20** and 4-ketomyxol 2′-fucoside **22** [75]. Thus, *A. variabilis* ATCC 29413 is the first cyanobacterium found to have free myxol and not myxol glycosides, and it seems to lack the gene for or activity of glycosyl transferase. It also has the GDP-fucose synthase homologous gene. Thus, this strain is considered to be of potential use in investigating the characteristics of myxol glycosides in cyanobacteria.

3.8 Carotenogenesis in Purple Bacteria

3.8.1 The Normal Spirilloxanthin Pathway

The biosynthesis of spirilloxanthin **35**, a final product of the normal spirilloxanthin pathway, is found in around half species of purple bacteria [5, 14]. Spirilloxanthin is a symmetrical compound containing the methoxy groups at C-1 and C-1′, and additional double bonds in the C-3,4 and C-3′,4′ positions. It has 13 conjugated double bonds (Fig. 106.5).

A sequence of the reactions leading from lycopene **7** to spirilloxanthin **35** has been confirmed (Fig. 106.5, Table 106.3). This sequence includes successive reactions of (1) hydration at C-1,2 by hydratase (CrtC); (2) desaturation at C-3,4

by desaturase (CrtD); and (3) methylation of the tertiary hydroxyl group at C-1 by methyltransferase (CrtF). These reactions occur initially on one half of the molecule to yield anhydrorhodovibrin **32**, and then on the other half. The major product is spirilloxanthin, and usually small amounts of all or a few of five intermediates (Fig. 106.5) are also found. These genes are found in the carotenogenesis gene clusters from *Rhodopseudomonas palustris* and *Rhodospirillum rubrum*. At present, the manner in which the successive reactions are controlled, with reactions first on one half of the carotenoid and then the other, has not been elucidated.

3.8.2 The Unusual Spirilloxanthin Pathway

When one enzyme of the normal spirilloxanthin pathway is lacking or is present with reduced activity, the carotenoid composition of the bacterium is expected to change (Fig. 106.5) [5, 14]. Indeed, some species have been reported to have such unusual compositions. Lycopene **7** is accumulated in *Rhabdochromatium marinum* and *Thiobaca trueperi*, and this may be due to low CrtC activity. Rhodopin **30** is the major carotenoid in some species: *Rhodopseudomonas palustris*, *Allochromatium vinosum*, *Thermochromatium tepidum*, and *Ectothiorhodospira marismortui* [5]. This may be due to low CrtD activity, and rhodopin may not be a suitable substrate for CrtF because of the single bond at C-3,4. On the other hand, 3,4,3′,4′-tetrahydrospirilloxanthin **40** is the major component in *Rhodospira trueperi*, *Thiocapsa pfennigii*, and *Thioflavicoccus mobilis* [5] probably because of lack of CrtD, but in these cases, rhodopin can be methylated by CrtF in spite of the single bond at C-3,4. The same carotenoid is also found in a *crtD* mutant of *Rhodospirillum rubrum* [80]. *Rhoseospira* accumulates 3,4-didehydrorhodopin **31** may be because of low CrtF activity [81].

3.8.3 The Spheroidene Pathway

Three genera *Rhodobacter*, *Rhodobaca*, and *Rhodovulum* produce spheroidene **26** and its derivatives [5, 14]. Spheroidene is an asymmetrical compound containing the same end group as spirilloxanthin **35** on one side and the 7,8-dihydro-ψ end group on the other side (Fig. 106.5, Table 106.3).

All seven carotenogenesis genes in *Rhodobacter capsulatus* [15] and *Rba. sphaeroides* [82] have been found to form a gene cluster. The characteristics of their products have been investigated. CrtI produces neurosporene **6** instead of lycopene **7** from phytoene **3**. Then, the sequence includes successive reactions of hydration at C-1,2 by CrtC to yield chloroxanthin **24**, desaturation at C-3,4 by CrtD to yield demethylspheroidene **25**, and methylation at the C-1 hydroxyl group by CrtF to yield spheroidene **26**. Further, CrtC can more or less hydrate at the 7′,8′-dihydro-ψ end group to yield OH-spheroidene **29** depending on species. Under semi-aerobic conditions, spheroidene monooxygenase (CrtA) introduces the keto group at C-2 to yield spheroidenone **27**. The 1′-hydroxy-7′,8′-dihydro-ψ end group cannot be modified further because of the single bond at C-7′,8′. The keto group of spheroidenone from *Roseobacter denitrificans* is the single bond *cis*-conformation around the conjugated double bond. Water is a substrate for CrtC in *Rba. sphaeroides*. The hydrogen acceptor of CrtD in *Rba. sphaeroides* is molecular oxygen. The methyl residue in the methoxy groups arises from *S*-adenosylmethionine in *Rba. sphaeroides* and *Rba. capsulatus*. The oxygen of the keto group at C-2 is derived directly from the atmosphere in *Rba. sphaeroides* [5].

Because *Rhodobaca bogoriensis* accumulates demethylspheroidene **25** and demethylspheroidenone **91**, CrtF activity in this bacterium may be low (Fig. 106.5).

Rubrivivax gelatinosus produces carotenoids using both the spheroidene and the spirilloxanthin pathways (Fig. 106.5). When *Rvi. gelatinosus crtI* is expressed in *Escherichia coli* with a phytoene **3** background, the products include approximately 90 % neurosporene **6** and 10 % lycopene **7** [83]. Accordingly, *Rvi. gelatinosus* produces spheroidene **26** and spirilloxanthin **35** from neurosporene and lycopene, respectively. Although the reaction of ketolation at C-2 of the ψ end group (CrtA) is usually involved in the spheroidene pathway and not in the normal spirilloxanthin pathway (Fig. 106.5), spirilloxanthin is also oxidized to 2,2′-diketospirilloxanthin **92** by CrtA in this bacterium.

Thus, the spheroidene pathway is a variant of the unusual spirilloxanthin pathway as a result of the different properties of CrtI and the additional enzyme CrtA [5, 14].

3.8.4 The Carotenal Pathway

Four types of cross-conjugated carotenals (Fig. 106.5) are found in 8 genera that include 12 species [5, 14]. Most species contain rhodopinal **36** as a major component, which has an aldehyde group at C-20 with the 13-*cis* form.

From the structure of these carotenals, Francis and Liaaen-Jensen [84] have postulated a branched pathway for each of the derivatives of cross-conjugated carotenals. To date, no other study supporting this postulate has been reported, and the partially modified carotenogenesis pathway is shown in Fig. 106.5. Rhodopin **30** and lycopene **7** are hydroxylated at C-20 to yield rhodopinol **78** and lycopenol **79**, and then the hydroxyl groups are oxidized to the aldehyde groups to yield rhodopinal **36** and lycopenal **80**, respectively. Because all of these carotenals have C-3,4 single bond, CrtD may be inactive. Furthermore, CrtF activity is absent or low. Additional enzymes for hydroxylation at C-20 and for oxidation to the aldehyde group may be involved in this pathway, whereas nothing is known about how the aldehyde group is introduced under anaerobic conditions. The position is necessarily at C-20 rather than C-20′ or C-19 and the 13-*cis* form, because it is more stable than the all-*trans* form as a result of the hydroxyl or aldehyde groups at C-20.

3.9 Carotenogenesis in Green Sulfur Bacteria

Green sulfur bacteria produce some types of carotenoids, β-carotene **13**, chlorobactene **46**, and their derivatives including their glucoside, and/or isorenieratene **50** (Fig. 106.6) [5, 14].

Carotenoids of *Chlorobaculum* (previously *Chlorobium*) *tepidum* have been precisely investigated [85], and some enzymes involved in the synthesis of these carotenoids have been functionally confirmed (Fig. 106.6, Table 106.3) [31, 34, 79].

Lycopene **7** is converted to γ-carotene **12** by a new lycopene cyclase (CruA). The β end group is changed to the ϕ end group by bifunctional desaturase/ methyltransferase (CrtU) to form chlorobactene **46**. γ-Carotene and chlorobactene are hydrated by CrtC. The hydroxyl group is glucosylated by glucosyltransferase (CruC), and then glucoside is esterified by lauroyltransferase (CruD). The enzyme that catalyzes 1′,2′-dihydrocarotene synthesis remains unknown. Both end groups of isorenieratene **50** are ϕ end groups.

3.10 Carotenogenesis in Non-phototrophic Bacteria

Pantoea ananatis (previously *Erwinia uredovora*) produces zeaxanthin diglucoside **89**. The complete carotenogenesis pathway has been determined, and the characteristics of enzymes and genes investigated, since it has a carotenogenesis gene cluster including *crtE, crtB, crtI, crtY, crtZ*, and *crtX* [16] (Table 106.3).

All or some of the genes in the gene cluster have been functionally confirmed, such as zeaxanthin diglucoside **89** in *Pantoea stewartii* (previously *Erwinia herbicola*) [86], two clusters for spirilloxanthin **35** and canthaxanthin **53** in *Bradyrhizobium* ORS278 [17, 18], astaxanthin **58** in *Paracoccus* sp. N81106 (previously *Agrobacterium aurantiacum*) [87], zeaxanthin **14** in *Paracoccus zeaxanthinifaciens* (previously *Flavobacterium* sp. R1534) [88], isorenieratene **50** in *Streptomyces griseus* [89] and *Brevibacterium linens* [33], and 2-hydroxyastaxanthn **90** in *Brevundimonas* sp. SD212 [70] (Table 106.3).

Some eubacteria and archaea do not possess carotenogenesis gene clusters. The genes for early steps can be found from homologous searches. Some genes and enzymes are found by molecular biological techniques (Table 106.3), but some genes for the final steps of complex carotenoids remain unknown.

Astaxanthin **58** synthesis has mainly been investigated using *Paracoccus* [87]. Lycopene **7** is cyclized to β-carotene **13**, and then by the combination of CrtW and CrtZ, keto and hydroxyl groups are introduced into β-carotene, respectively; usually, the intermediates are also found (Figs. 106.7, 106.8, Table 106.3). These enzymes are found in some bacteria and some algae, and their characteristics including activity and substrate specificity are somewhat different from each other. For high production of astaxanthin, pathway engineering including a combination of these enzymes from different organisms has been investigated [90]. Astaxanthin from these organisms has (3*S*,3′*S*)-chirality, while that from a red yeast, *Xanthophylomyces* shows the opposite (3*R*,3′*R*)-chirality. It is produced by one bifunctional enzyme astaxanthin synthase (ASY, CrtS), which has both β-carotene hydroxylase and β-carotene ketolase activities (Table 106.3) [91].

Two distinct β-carotene ketolases CrtO and CrtW are widely distributed in eubacteria, including cyanobacteria, and green algae [13, 63, 64, 70, 92]. Although the reactions catalyzed by both CrtO and CrtW involve the same β-carotene ketolation, the characteristics of these enzymes are different. CrtO is almost twice the size of CrtW, and does not share significant amino acid sequence homology with CrtW. CrtO acts only on compounds with the β end group (β-carotene **13** and

γ-carotene **12**) and mainly exhibits monoketolase activity. CrtW acts on compounds with the β end group (β-carotene) and 3-hydroxy-β end groups (zeaxanthin **14** and myxol **82**), and mainly exhibits diketolase activity. CrtO has six conserved regions including the FAD-binding motif [92], while CrtW has iron-binding motifs [74]. Two β-carotene ketolases might have evolved convergently from different ancestors to acquire the same functions, although further studies are needed to confirm this assumption [73].

4 Conclusion

Almost all organisms including plants, algae, bacteria, and animals contain various carotenoids (Tables 106.1, 106.2). Variation in carotenoids depends on the variation in carotenogenesis pathways, characteristics including substrate specificities of carotenogenesis enzymes, and presence or absence of certain carotenogenesis genes. These variations can be used for chemotaxonomical classification of organisms. Some of major carotenogenesis pathways have been elucidated, but some major and minor pathways remain unknown. Almost all animals may need carotenoids embedded in foods and may be able to modify them. Because some carotenoids are phylogenetically specific to certain groups, some carotenogenesis

genes might be lost and/or added. At present, some carotenogenesis genes have not been identified, the functional confirmed genes are limited, and only a few species have been examined (Table 106.3), although genome sequences have been determined in many organisms. Thus, further studies of carotenoids, characteristics of carotenogenesis enzymes and genes, and the carotenogenesis pathways are needed.

Abstract

Cosmetic products, including perfumes, are regulated by a single law concerning important aspects, such as composition or labeling, in order to protect public health. A revision on the regulatory aspects for fragrance chemicals in cosmetics and household products is exposed here.

Quality control of both, commercial perfumes and raw materials, is important for perfume manufacturers to assure that the finished perfume is the one that was formulated. On the other hand, analytical methods are necessary to assure, for safety purposes, that there are no undesired or banned compounds present in the finished product. Methods for perfume analysis are compiled and revised with special emphasis on the potentially allergenic fragrance-related substances and some other groups of substances such as musks and phthalates, being some of them restricted or forbidden.

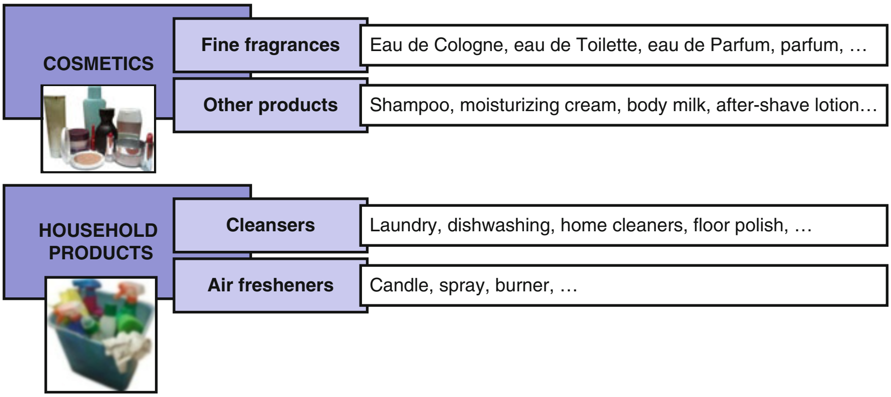
1 Introduction

"Scent is one of the most powerful of senses." This phrase can be read in the website of one of the more remarkable associations related to perfumes, the International Fragrance Association (IFRA), and we are all aware that this is true. Scent can alter mood, stress, or pain. We are not always aware of them, but odors are around us all the time and affect our daily life. People, food, plants, and everything have a particular odor, and we even add aromatic substances to many other things. Cosmetic products, such as shampoos, deodorants, soaps, and fine fragrances, or household products such as laundry detergents, cleaners, and bleaches contain perfumes (Fig. 107.1) which are responsible for their characteristic odors. Moreover, we sometimes scent the air with air fresheners or fragrance candles.

It is worth mentioning that the use of perfumes is not new, as they have been used for thousands of years since the Egyptian civilization, when they were used in religious rites. After the roman civilization, they became an oriental art, and it was not until the thirteenth century that all this knowledge arrived to Europe due to Arabic influences. Louis XV, in the eighteenth century, used it so much that his court was called *"le cour parfumee."* Nowadays, France is still the heart of the European perfume industry. Since then, the perfume market has become very important, with sales of billions of dollars.

Perfumes are composed of hundreds of aromatic chemicals, namely, fragrance chemicals, or just simply fragrances. Among these compounds, it is very common to find compounds with the characteristic five-carbon isoprene unit, giving them the names of terpenes, such as terpene aldehydes, monoterpene alcohols, sesquiterpene alcohols, terpene ketones, terpene esters, monoterpene hydrocarbons, or sesquiterpene hydrocarbons. In addition, other compounds, such as aldehydes, alcohols, ketones, esters, phenols, or lactones, are also very common.



COSMETICS
Fine fragrances
Eau de Cologne, eau de Toilette, eau de Parfum, parfum, …
Other products
Shampoo, moisturizing cream, body milk, after-shave lotion…
HOUSEHOLD PRODUCTS
Cleansers
Laundry, dishwashing, home cleaners, floor polish, …
Air fresheners
Candle, spray, burner, …

Fig. 107.1 Containing perfume products

Perfumes can be classified according to their nature, in *natural* or *synthetic*. *Natural perfumes* are obtained from plants (e.g., lavender, geranium) or from some of its parts, like flowers (e.g., jasmine, rose, gardenia), fruits (e.g., lemon, orange, vanilla), roots (e.g., vetiver, cistus, angelica), leaves (e.g., violet, patchouli, peppermint), wood (e.g., vetiver, sandalwood, cedarwood), bark (e.g., cinnamon, nutmeg), resin (e.g., benjui, tolu, galbanum), and seeds (e.g., angelica, celery, anis). Also, they may be obtained from animal glands and organs, for example, musk, which is obtained from the testicles of the musk deer; civet, which is a secretion from glands of the civet cat; ambergris, which is obtained from a secretion from the intestine of the sperm whale; and finally, castoreum, which is obtained from glands near the reproductive organs of the beaver. These natural perfumes, or essential oils, are extracted by several methods, which depend on the raw material and the chemical fragrances to be extracted [1].

Thus, *steam distillation* consists in passing water vapor through the raw material to perform the extraction. Once the steam condenses, the oil is easily separated from the water as it floats on the top. In *hydrodistillation*, the raw material is boiled in water, and the volatile essential oil is also obtained from the water vapor by condensation. In the case of *solvent extraction*, raw materials are submerged in organic solvents, such as hexane, ethanol, or petroleum ether. After extraction, the solvent is eliminated by distillation resulting in the extract known as “concrete.” The concrete can be further purified by a second extraction with ethanol. In this case, the resulting extract is known as “absolute.” When the extraction solvent is animal fat, the process is known as *enfleurage*. This is a very time-consuming and expensive way of extraction. *Maceration* is similar to enfleurage, but in this case, the raw material is immersed in warmed oil. In *rectification*, the raw materials are directly heated without a solvent. This method is used when a toasted scent is wanted. Another way of extraction is named *expression* and consists in manually or mechanically pressing the plants. This is very suitable for thermolabile compounds.

Finally, a more modern way of extraction is *supercritical fluid extraction*. In this process, carbon dioxide in supercritical conditions is used to extract the hydrophobic aromatic compounds from the raw material. It does not alter the nature of the aromatic compounds as it takes place at a low temperature and CO_2 vaporizes after depressurization. However, it is an expensive process and needs special instrumentation [2].

In the case of *synthetic perfumes*, they are obtained by mixing synthetic fragrance chemicals, which are synthesized in the laboratory, usually searching for a similar odor of a natural fragrance and sometimes searching for something new and original. In practice, this type of fragrances has many advantages, specially its lower cost compared to natural perfumes. The quantity and quality of natural source supplies are in many ways unpredictable, due to their dependence on crop quality or weather. Thus, synthetic perfumes do not have this inconvenience, but unfortunately, they have some others. For example, a natural essential oil is made up by hundreds or thousands of different compounds, which makes difficult to reproduce the desired perfume exactly by just mixing different synthetic fragrances. Moreover, all the compounds contribute with their characteristic odors, and then, not only the main components but also those minor components, including those at trace levels, can affect considerably the odor of the perfume. In addition, in those cases where two isomeric forms of a compound smell different, chiral synthesis is needed.

On the other hand, perfumes itself, and also the pure fragrance chemicals that compose the perfumes, are classified according to the note they provide, that is, according to the fragrance type. So, one can find different types, like floral, which reminds one of scents similar to jasmine, rose, heliotrope, etc.; citrus, which are aromas reminiscent of lemon, orange, lime, grapefruit, etc.; fruity, based on non-citrus fruity odors like peach, apple, banana, etc.; green, which creates the sensation of smelling recently cut grass and leaves; woody, which reminds one of dry wood and trees; oriental refers to those sweet strong fragrances reminiscent of vanilla, ambergris, etc.; spice, giving off a redolence coming from clove, cinnamon, thyme, pepper, etc.; animal refers to scents provided by musk, civet, and castoreum; and leather, which tries to reproduce the characteristic smell of leather, tobacco, smoke, etc.

It should be also emphasized that the perfume content depends of the product. Fine fragrances, which are hydroethanolic solutions of perfumes, are usually classified according to their perfume content in eau de cologne (1–5 %), eau de toilet (5–8 %), eau de parfum (8–15 %), and parfum (>15 %). Other cosmetic-products present lower perfume content. Moisturizing creams and body milks (0.1–0.5 %), aftershave (0.5–2 %), toothpastes (0.5–1 %), and hair care products (0.01–0.1 %) are just some examples. Regarding cleansing household products, nearly all, as, for example, laundry or dishwashing products and bathroom or furniture cleaners, contain perfume, in variable amounts, to make them smell clean and mask unpleasant odors from other components of the product.

Thus, perfumers rarely use pure fragrance chemicals, but they usually mix different raw materials, natural or synthetic, to create a perfume that fulfills the market expectations, that is, type of product to which it is to be added, product image, target consumer, originality, fashion, etc. For fine fragrances, high content of pungent and elegant perfumes are used, whereas more sweet and refreshing ones are found in eau de toilets and eau de colognes. For skin and hair care cosmetic products, sweet, tenuous, and refreshing perfumes are combined, whereas high refreshing notes are employed in toothpastes or mouthwashes. In the case of household products, detergents and softeners contain refreshing notes, while different home cleaners and air fresheners can be found with refreshing or on the contrary with pungent and elegant or sweet notes.

2 Regulatory Aspects for Fragrance Chemicals in Cosmetics and Household Products

The establishment of the single market in the European Union meant the free movement of goods in the member states. Cosmetic products were not an exception, but the great exposure of the population to these products enhanced the need of a single law concerning important aspects, such as cosmetic composition or labeling, in order to protect public health. As a result of many discussions between experts, Council Directive 76/768/EEC was adopted on the 27th of July of 1976. Since then, many amendments and adaptations have been made. Last recast of all these changes as one single text is Regulation 1223/2009 [3]. Among other aspects, this regulation controls and regulates the substances banned in cosmetics, as well as the maximum allowable amount of certain restricted substances according to their intended use. Moreover, there is also the so-called European Inventory of Cosmetic Ingredients [4] which lists the substances usually employed in cosmetic products. This inventory is divided into two sections where Sect. 2 deals with those ingredients used in perfume and aromatic raw materials.

Regarding the USA, cosmetics are regulated by the US Food and Drug Administration (FDA), but regulation is much more permissive [5].

A cosmetic product is defined by the European regulation as “any substance or mixture intended to be placed in contact with the external parts of the human body (epidermis, hair system, nails, lips and external genital organs) or with the teeth and the mucous membranes of the oral cavity with a view exclusively or mainly to cleaning them, perfuming them, changing their appearance, protecting them, keeping them in good condition or correcting body odors” and by the FDA as “an article intended to be applied to the human body for cleansing, beautifying, promoting attractiveness, or altering the appearance without affecting the body’s structure or functions.” Therefore, fragrances and perfumes are closely related to cosmetic products as, besides being a cosmetic product itself, they are many times an ingredient added to make the product smell nice or mask any undesirable odor of the product.

Both regulations specify that all ingredients of cosmetic products should be indicated on the label. In the case of perfumes, they are either elaborated by mixing different natural raw materials which could contain hundreds or thousands of different compounds or based on complexes synthetic formulations. This is why perfume components do not necessarily have to be specified, but they can be grouped and labeled under the word “perfume” or “aroma” in the EU or “fragrance” in the USA.

Nevertheless, in 2003, the 2003/15/EC Directive [6] listed 26 fragrances classified as potentially allergenic substances (PASs). Since then, any cosmetic product containing any of these 26 substances have to declare its presence in the label when present at a higher concentration than 10 μg mL^{-1} in those products to remain on the skin or 100 μg mL^{-1} in those intended to be rinsed off. This information should improve the diagnosis of contact allergies among consumers and should enable them to avoid the use of cosmetic products which they do not tolerate.

On the other hand, the European regulation also prohibits and restricts the amount used of more than 50 fragrance substances, like some extracts or synthetic musks, in cosmetic products. Other substances related to fragrances, such as phthalate esters, commonly known as phthalates, which have been used as solvents and vehicles for fragrance ingredients, are also restricted as a consequence of their undesirable side effects.

Regarding the US FDA’s list of prohibited ingredients, it bans only a few compounds, but none of them are used as fragrance ingredients. Nevertheless, the USA and other countries, such as Canada, will probably adopt the recommendations given in the EU regulation in the future [7].

The EU also regulates household products, and detergents are regulated by Regulation 648/2004 [8] where similar labeling to cosmetic products is required in the case of perfume content. A perfume or an essential oil shall be considered to be a single ingredient and will be labeled as “parfum” listing none of the substances that it contains. Additionally, as in the case of cosmetic products, there is an exception for those allergenic fragrance substances that appear on Annex III of the cosmetic regulation. If their concentrations exceed 0.01 % by weight, the allergenic fragrances must be labeled separately.

Despite the regulations in law in each country, the fragrance industry is in some way self-regulated by some independent entities. The Research Institute for Fragrance Materials (RIFM) evaluates and distributes scientific data on the safety assessment of fragrance substances found in cosmetics and other products. On the other hand, the aforementioned IFRA establishes usage guidelines for fragrance ingredients based on RIFM evaluation results. Recommendations to avoid many ingredients are given, although this organization has no legal authority, and therefore, the final decision is mostly conditioned on legislation [7].

3 Analytical Aspects of Fragrance-Related Compounds

Quality control of commercial perfumes and raw materials is very important for perfume manufacturers. This is the way to assure that the amount of perfume is the one that was initially formulated or that there are no undesired or banned compounds. In addition, characterizing an essential oil is also very interesting.

Different tests, depending on the instrumentation available, are performed in the industry. There are many easy and cheap quality control techniques that provide overall information about their quality, as measurements of physical (density, color, optical rotation, etc.) and chemical properties (acidity or carbonyl indexes). Spectrometric techniques, such as ultraviolet/visible or infrared spectrometry can also provide overall qualitative, or even quantitative, useful information for the quality control of a perfume, by comparing the obtained spectra with those previously recorded and kept in the databases. However, all these techniques do not provide information about each component separately, but overall information. For these purposes, more selective techniques are needed. As most of the perfume ingredients are volatile or semi-volatile compounds, gas chromatography (GC) is, by far, the technique of choice [9]. The identification of the individual compounds is then made by using the Kovats indexes and comparing them with those reported in the databases for the same chromatographic columns, although it can sometimes be a difficult task taking into account the high number of compounds that can be present in the perfume composition. In this sense, the mass spectrometry (MS) detector can be a useful tool since the identity of a compound can be elucidated from the MS spectra obtained.

The so-called electronic noses are also very useful. This device mimics human olfactory system and consists of a sample system in head space, a sensor array as detection system, and a computer for data treatment. It is not a separative mechanism; it just gives signal patterns for a particular odor. In a way, it measures smells. It is worth mentioning that an individual sensor is unspecific and could give exactly the same signal with two different odors. Thus, an array of sensors has to be used to reduce the probability of this happening [10]. In order to use an electronic nose, a database of reference has to be firstly built. To do so, a set of known samples would have to be analyzed and the data statistically treated, for example, with pattern recognition methods, such as principal component analysis (PCA), artificial neural network (ANN), or clusters. New samples could then be recognized by comparing them with the database. This technology is commonly used in the food and beverage industry [11]. It has also been used for medical or environmental applications and, of course, in the cosmetic and fragrance industry. In the last years, some works that use electronic nose in fragrance analysis have been published. For example, Carrasco et al. [12] discriminated between different families of Yves Saint Laurent perfumes by an electronic nose. Branca et al. [13] developed an electronic nose device combined with PCA and ANN to detect the presence of a perfume note called mangone in fragrances. Recently, Cano et al. [14] developed a PCA method to detect between original and counterfeit perfumes. Ye et al. [15] also used an electronic nose combined with PCA to discriminate between natural musk and adulterated. Although this is not an electronic nose, Chingin et al. [16] used extractive electrospray ionization mass spectrometry (EESI-MS) for the same purpose in a very simple and sample-preparation-free method which could be applied for quality control.

3.1 Determination of the Potentially Allergenic Fragrance-Related Substances

As mentioned before, 26 substances were declared as potentially allergenic substances (PASs) by the European regulation [6]. Of these 26 substances, listed in Table 107.1, 24 are chemically defined volatile compounds, whereas the other two are natural moss extracts, thus not defined chemicals, but a natural mixture of many of them.

Since this declaration took place in 2003, the determination of these skin-sensitizing ingredients has become a challenge. Literature deals separately with the determination of the 24 chemically defined PASs and the two natural moss extracts.

The group of the 24 chemically defined allergens belongs to very different classes of compounds. These diverse groups include alcohols (such as farnesol), carbonyl compounds (such as citral), esters (such as benzyl benzoate), lactones (such as coumarin), cyclic hydrocarbons (such as limonene), or phenols (such as eugenol). Their volatile characteristics make gas chromatography (GC) the better technique of analysis. Although universal detectors like flame ionization detector (FID) have been used, a more selective detector, like a mass spectrometer (MS), is also a necessity, as one of the biggest difficulties to face in their determination is the coelution between the target compounds and other of the many components of the perfume. The literature deals with these using different solutions, operating either in selected ion monitoring (SIM) or extracted ion chromatogram (EIC) mode, but it is difficult to completely eliminate false positives and negatives, due to coelution. Other solutions are the use of comprehensive GC or clean up steps before the determination to extract the target compounds [17].

Being aware of the problematic skin-sensitizing chemicals in perfumes, Rastogi proposed for the first time, even before the approval of the regulation, a solid-phase extraction (SPE) followed by GC method for the determination of 11 of these allergens [18]. GC-MS was used for previous identification, while GC-FID was chosen for quantification. Some years later, the author published another work [19] using the same GC-MS method, with some modifications, to survey the content of the 24 PASs in cleaning products and other consumer products such as cosmetics or toys. In this method, the sample treatment depended on the type of sample, but in summary, samples were shaken with methanol, and the lixiviated fraction was purified with a silica gel column before its injection into the GC port. Detection was performed in full scan (FS) and quantification in EIC mode. In the same way, Ellendt et al. [20] did also use GC-MS, FS mode for identification and SIM mode for quantification, for the determination of the 24 PASs in deodorants. However, coelution problems were encountered in complex fragrance mixtures.

Later, Chaintreau et al. [21] made a significant progress presenting a method to determine PASs in perfume concentrates, with direct injection of the samples. This work delves in the coelution problem between the target compounds and other components of the perfume. Four different columns were used to try to solve this problem. SIM mode of three different ions per compound (i.e., one ion

Table 107.1 List of the 26 potentially allergenic substances according to the European regulation

 Amyl cinnamal [CAS 122-40-7]	 Benzyl alcohol [CAS 100-51-6]	 Cinnamyl alcohol [CAS 104-54-1]
 Citral [CAS 5392-40-5]	 Eugenol [CAS 97-53-0]	 Hydroxycitronellal [CAS 107-75-5]
 Isoeugenol [CAS 97-54-1]	 Amylcinnamyl alcohol [CAS 101-85-9]	 Benzyl salicylate [CAS 118-58-1]
 Cinnamal [CAS 104-55-2]	 Coumarin [CAS 91-64-5]	 Geraniol [CAS 106-24-1]
 Hydroxyisohexyl 3-cyclohexene carboxaldehyde [CAS 31906-04-4]	 Anise alcohol [CAS 105-13-5]	 Benzyl cinnamate [CAS 103-41-3]
 Farnesol [4602-84-0]	 Butylphenyl methylpropional [80-54-6]	 Linalool [78-70-6]
 Benzyl benzoote [CAS 120-51-4]	 Citronellol [CAS 106-22-9]	 Hexyl cinnamal [CAS 101-86-0]
 Limonene [CAS 5989-27-5]	 Methyl 2-octynoate [CAS 111-12-6]	 Alpha-isomethyl ionona [CAS 127-51-5]
Oakmoss extract (*Evernia prunastri* extract) [CAS 90028-68-5]	Treemoss extract (Evernia furfuracea extract) [CAS 90028-67-4]	

for quantification and the other two as qualifiers) was also used and their relative abundances taken into account for correct identification, thus minimizing false positives and false negatives, by comparing the relative abundances with respect to those of the reference compound. Even though all this helped, false positives, due to coelution, still occurred. Moreover, false negatives can occur as a consequence of retention time shifts, that is, that a target compound shifts out of the acquisition SIM window. The work also claims ethanol is not a good candidate as solvent of the standard solutions since protic solvents react with some of the allergens. Thus, isooctane and o-fluorotoluene were chosen. This is an important fact which not all later works take into account. Lastly, in this paper, Chaintreau and coworkers highlighted the need for cleanup techniques as the nonvolatile parts of the cosmetic products remain in the injector disturbing future injections. It should be emphasized that this work was accepted as the official IFRA method for the quantification of potential fragrance allergens in fragrance compounds [22], with two recommendations: (1) in case of suspected coelutions, one of the qualifier ions should be used as quantization ion; (2) in case of retention time shifts, a qualitative FS run should be done before each sample in order to adjust the time windows. These recommendations were applied in a paper published some years later [23], which concluded that coelution problems could still occur and recommended to inject each sample in two different polarity columns as well as to monitor three ions per compounds to assure about the positive identification/quantification. A ring test was conducted using this strategy, and the results were published years later [24], in which the investigation of an automated data treatment procedure to aid the analyst during the interpretation of the analytical results was also proposed.

A similar strategy was followed by Leijs et al. [25] for the analysis of these 24 compounds in fragrance raw materials and perfume oils. These authors used a chromatograph with two injectors and connected each one to a different polarity column. Both columns were connected to a MS interface using a dual-hole ferrule, thus carrying out a sequential dual-column analysis for each sample. However, they preferred operating in FS mode and quantifying in EIC mode, to avoid additional acquisition in case of coelutions and to prevent false negatives as a result of retention time shift. Obviously, this mode of acquisition significantly increases the limit of quantification (LOQ).

Another work, from Mondello et al. [26], determined the PASs using fast GC-MS, by employing shorter and narrower columns besides high-speed MS detector. The MS operated in FS mode, and quantification was performed in EIC mode. The main novelty of the work basically consisted in a very short run time (less than 5 min). However, the same above-mentioned problems regarding coelutions are expected to occur.

Taking into account the Chaintreau and coworkers' recommendation dealing with cleanup steps to separate the target compound from the matrix and thus avoid dirtiness of the system, several works can be found in the literature describing cleanup steps before the determination of the 24 restricted allergens. For example, as mentioned before, Rastogi [19] used a silica gel column for purifying the extracts. Niederer et al. [27] proposed a cleanup step using size-exclusion chromatography prior to GC-MS for the determination of the 24 PAS in different cosmetic products, such as creams, body lotions, and oils. David et al. [28, 29] classified samples into four different groups based on matrix characteristics. Simple samples, with no presence of nonvolatile material, like fragrances, were diluted and injected.

This is not possible with dirtier matrixes, where a programmed temperature vaporizing (PTV) inlet with an automated liner exchange (ALEX) was proposed. Thus, fractioning of the target compounds from this nonvolatile matrix took place in the liner. When handling aqueous samples with the target compounds at very low concentrations, a stir bar sorptive extraction (SBSE) step was added before the PTV approach. Regarding cleanup steps, Chen et al. [30] used solid-phase microextraction (SPME) followed by GC-FID for the quantitative analysis of geraniol, a restricted allergen, and other flavor and perfume compounds in shampoo. Lamas et al. [31] proposed the use of solid-phase dispersion-pressurized liquid extraction (SPD-PLE) followed by GC-MS in EIC mode for the determination of the 24 regulated fragrance allergens and two other fragrance compounds in cosmetic products (creams and lotions). A year later, the same authors presented a method based on matrix solid-phase dispersion (MSPD) as concentration and cleanup step followed by GC-MS in SIM mode for PASs determination in cosmetic products [32] and a GC-MS method with no pretreatment of samples other than dilution for their determination among other fragrance-related components in perfumes [33].

Development in the field of comprehensive GC (GCxGC) also seems a good way to handle the coelution problem. In this sense, Chaintreau and coworkers [34] presented a GCxGC-FID method for the determination of the 24 regulated substances plus two other compounds. The method could not completely eliminate component overlap, leading to similar results than using 1D-GC coupled to MS. Later, the same authors [35] presented the first work dealing with the quantification of the PASs based on comprehensive GC coupled to a quadrupole MS (GCxGC-MS). As obviously expected, selectivity is improved compared to GC-MS and GCxGC-FID. Comprehensive GC can overcome coelution problems but is very time-consuming during the interpretation of the analytical results. The same authors published another paper [36] presenting a software prototype to reprocess the data which shortens this step. Leco [37] presented a method for allergens in perfumes using GCxGC-(TOF)MS (time-of-flight mass spectrometer). Identification was better achieved than using a simple quadrupole, but the equipment is too expensive to be used in routine analysis. Dunn et al. [38] compared two approaches for this analysis, GCxGC and multidimensional gas chromatography (MDGC), in which selected portions of the primary separation, rather than the whole sample, are transferred to a secondary column. MDGC seems to be a better option as data processing for the output is almost identical to a single column analysis, while the data of a GCxGC experiment is still relatively labor intense. Finally, Cordero et al. [39] published a work where determination by GCxGC-qMS and GCxGC-FID is accomplished.

Only two papers dealing with the determination of these compounds with a different technique than gas chromatography have been found. Villa et al. [40] propose the first work where liquid chromatography and UV detection (LC-UV) are used for the determination of the 24 suspected allergens in different cosmetic products. A C18 column and a gradient acetonitrile/water were used. Samples are basically weighted, diluted, sonicated, and filtered before injection. This can be a useful method for routine analysis in cosmetic industries where more expensive equipment is not available. However, coelution problems are present, not only between compounds but also for matrix components. In this sense, Furlanetto et al. [41] published a method for 18 of the 24 allergens by microemulsion electrokinetic chromatography (MEEKC) and UV detection. The method was applied to two rinse-off cosmetics, a shampoo, and a bath gel.

On the other hand, the number of publications regarding the determination of the two natural moss extracts restricted as potentially allergenic – treemoss and oakmoss – is rather scarce. The industrial processing varies considerably, but basically, harvested lichens, from oak trees in the case of oakmoss and pine and cedar trees in the case of treemoss, are extracted, usually with hexane or more polar solvents. Then, they are further diluted in ethanol and usually submitted to physical treatments intended to remove their original color. Taking into account their natural conditions and that industrial processing is not standardized, it is not surprising to find variability in the chemical composition of these extracts. Joulain et al. published two comprehensive reviews on the composition of these extracts. One hundred seventy constituents are identified in oakmoss extracts and 90 in the case of treemoss [42, 43].

The nature of these extracts makes them unsuitable to GC although Bernard et al. [44] searched for allergenic or sensitizing molecules in oakmoss using GC-MS after chemical fractionation of the extract by gel permeation chromatography (GPC). Some other works can be found in the literature dealing with the determination of some of the oakmoss components that show allergenic properties, like atranorin and chloroatranorin, a lichen depside, or atranol and chloroatranol, formed by transesterification and decarboxylation of atranorin and chloroatranorin during industrial processing. Hiserodt et al. [45] used LC-MS/MS to identify atranorin and some related potential allergens in oakmoss absolute. No quantification was performed in this work. Bossi et al. [46] used this method to quantify atranol and chloroatranol in perfumes. Rastogi et al. [47] also quantified the presence of these two allergenic compounds in different commercial perfumes based on this method. It is worth mentioning that these individually allergenic components of oakmoss are not listed by the European regulation, which only restricts total concentration of oakmoss and treemoss extracts.

3.2 Determination of Musks

Musk compounds have been widely used as fragrance chemicals in many consumer products such as cosmetics, detergents, food additives, or household products [48, 49]. They are valuable compounds not only for their unique odor but also for their fixative properties.

Natural musk, itself, was already used in ancient times and was obtained as a secretion produced by a gland of the musk deer. Traditionally, musk deer are killed to remove the musk gland, although musk can be extracted through the external orifice of the musk gland without the need of killing the animal. These facts and its difficult availability make this natural product very expensive [50].

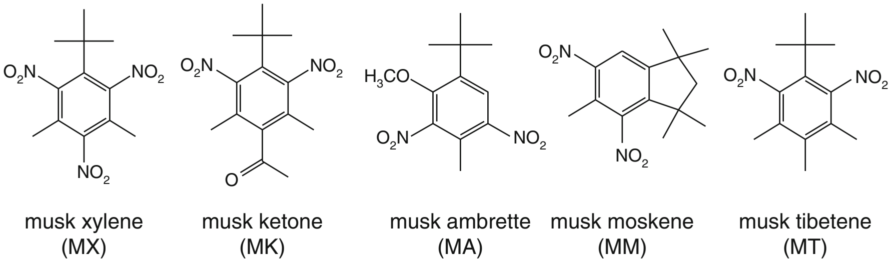


Fig. 107.2 Chemical structure of nitro musk compounds

On the other hand, the term musk also refers to other compounds, with totally different chemical structure but possessing musk-like odor properties. These are commonly named synthetic musks and appeared as a response to economical and ethical motives. Artificial musks have been generally divided in three subgroups: nitro musks, polycyclic musks, and macrocyclic musks.

The *nitro musks*, which are characterized by a nitro-aromatic moiety, were accidentally discovered by Baur in 1888 [51]. This group is basically formed by five compounds, that is, musk ambrette (MA), musk xylene (MX), musk moskene (MM), musk tibetene (MT), and musk ketone (MK). Figure 107.2 shows the chemical structure of these compounds.

Despite their pleasant aroma, nitro musks are believed to be persistent pollutants due to their strong tendency to bioaccumulate [52]. Many papers have been written about their health risks, showing they are related with different types of dermatitis, carcinogenic effects, and endocrine disruption [49, 53–58]. In fact, the use in cosmetic products of MA, MT, and MM is banned in the European Union, while the use of MX and MT is restricted. Nevertheless, its use is permitted in North America.

Regarding the *polycyclic musks*, these are composed of several cycles and do not have nitro substituents. Figure 107.3 shows the structure of some of the most commonly used polycyclic musks, such as 1,3,4,6,7,8-hexahydro-4,6,6,7,8,8-hexamethylcyclopenta(g)-2-benzopyran (HHCB) commonly known as galaxolide®, 6-acetyl-1,1,2,4,4,7-hexamethyltetralin (AHTN) commonly known as tonalide®, 5-acetyl-3-isopropyl-1,1,2,6-tetramethylindane (AITI) commonly known as traseolide®, and 1,1,2,3,3-pentamethyl-2,5,6,7-tetrahydroinden-4-one commonly known as cashmeran.

These musks were developed in 1950 and have slowly replaced the nitro musk compounds in Europe, since they are believed to have less harmful and toxic effects. However, in the later years, many studies show their bioaccumulation in the aquatic system and living beings [52, 59–61]. Nonpolycyclic musk is banned in the European Union, and only some of them are restricted. The rest can be freely used in cosmetic products. Thus, polycyclic musks are more used in Europe, while nitro musks are the common ones in North America [62].

Finally, *macrocyclic musks*, which are much larger compounds than the other two groups, have been developed in the recent years. Even though they have synthetic nature, they are synthesized trying to imitate the natural musk

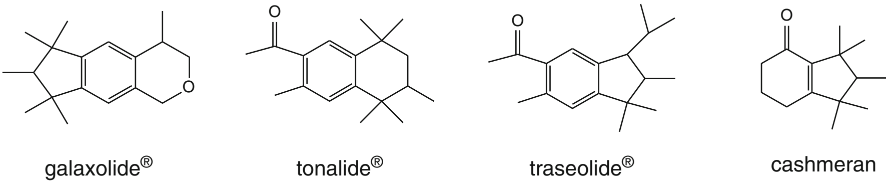

Fig. 107.3 Chemical structure of polycyclic musk compounds

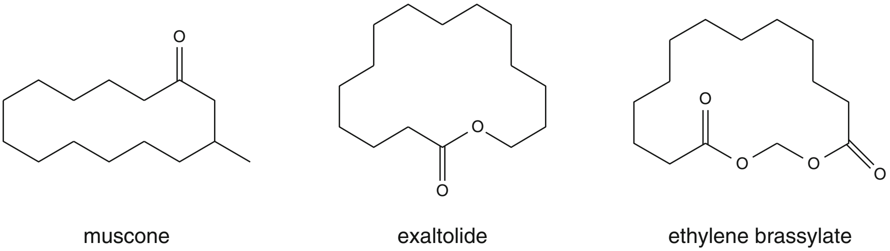

Fig. 107.4 Chemical structure of macrocyclic musk compounds

compounds. As these compounds are not restricted by law and seem not to have biodegradability problems, their use has increased considerably and is replacing the polycyclic musk compounds [50]. Some of the most important macrocyclic musks are shown in Fig. 107.4.

Many articles about the determination of artificial musks in different matrixes can be found in the literature. The most abundant are environmental samples such as air, water, and sediments [52, 59], but other matrixes such as biological fluids (blood [60, 63] or human milk [51]) or aquatic species [64, 65] are also available. However, the literature dealing with the determination of musks in cosmetic samples is rather scarce. The preferred technique is GC, with MS or electron capture detector (ECD) in the case of nitro musks.

Sommer [66] presented a method for quantification of nitro musks in cosmetics and detergents using GC with both, ECD and MS. Wineski et al. [67] determined MA in fragrance products with an internal standard addition technique by GC-ECD. The same author published another paper [68] some years later with a similar method to determine MA, MX, and MK. Struppe et al. [69] proposed a headspace solid-phase microextraction (HS-SPME) and GC with atomic-emission detection method for the determination of MX, MK, and MA in cosmetic samples. Four different commercially available fiber coatings were tested, and a 100-μm polydimethylsiloxane gave the best results. To the best of our knowledge, Eymann et al. [70] published the first paper where the determination of polycyclic musks in cosmetics was achieved, together with nitro musks. GC was used, with ECD in the case of nitro musks and MS for polycyclic musks. Some years later, Sommer and Juhl [71] proposed a GC with FID and MS detection to determine macrocyclic musks in alcohol-containing cosmetics.

More recently, several papers have been published on the determination of musks in cosmetic products. Roosens et al. [72] determined AHTN, HHCB, MX, and MK in 82 personal care products, 19 of them perfumes, with GC-MS and combined these results with the average usage to estimate exposure profiles through dermal application concluding that exposure to the polycyclic musks is much higher than to the nitro musk compounds. Ma et al. [73] proposed a SPE-isotope dilution-GC-MS/MS for the determination of MX in cosmetics. Martinez-Girón [74] achieved the enantiomeric separation of four chiral polycyclic musks using capillary electrophoresis (CE). The method was applied to determine these enantiomers in perfumes. Finally, as already mentioned before, Sanchez-Prado et al. [33] also developed a method that allows the simultaneous determination of many compounds, including nitro musks and polycyclic musks, in perfumes.

3.3 Determination of Phthalates

The term phthalate is used to designate the dialkyl or alkyl aryl esters of phthalic acid. These compounds are used in the cosmetic industry mainly as denaturants of the alcohols used in their manufacture, as fixatives or solvents for some fragrances (e.g., synthetic musks) and as film formers. Thus, it is usual to find them in nail polish, hairsprays, and perfumes [75]. Moreover, these substances are mainly used in the manufacture of plastics to increase their flexibility. Therefore, they can be found in different manufactured products, not only as part of its formulation but as a result of migration during manufacture or storage [1].

Phthalates have been proven to be harmful to living organisms [76–78]. These lipophilic compounds are rapidly metabolized by humans and biotransformed in their respective monoesters and other oxidative products, which are excreted in urine and feces [79]. Studies show that some phthalates and their metabolites are potentially toxic in animals due to endocrine-disruptive effects, which can cause adverse health effects, particularly for fertility and reproduction [80–82]. Moreover, some of them cause cancer in rats and mice [83]. Therefore, the presence of some phthalates is forbidden by the European legislation in some vulnerable products, such as toys [84] or personal care products [3]. Specifically, current European regulation of cosmetic products forbids the presence in cosmetic products of the phthalates shown in Table 107.2.

Other phthalates like diethyl phthalate (DEP), dimethyl phthalate (DMP), or di-n-octyl-phthalate (DNOP) are allowed in cosmetic products in Europe without any restriction, even though they are defined as pollutants by the US Environmental Protection Agency [85] and are also related to adverse health effects [86, 87].

Concerning the phthalate determination, the number of publications dealing with these compounds shows their great interest and their widespread presence in many consumer products and the environment. Specifically, in the case of the determination of phthalates in cosmetic products, several analytical methods for the identification and determination at the level of μg mL^{-1} and ng mL^{-1} have been published. The most commonly used techniques are liquid chromatography (LC)

Table 107.2 List of the forbidden phthalates in cosmetics by the European regulation

 dibutyl phthalate (DBP) [CAS 84-74-2]	 bis(2-ethylhexyl) phthalate (DEHP) [CAS 117-81-7]
 bis(2-methoyethyl) phthalate (DMEP) [CAS 117-82-8]	 1,2-benzenedicarboxylic acid, dipentylester, branched and linear (NPIPP) [CAS 84777-06-0]
 di-n-pentyl phthalate (DNPP) [CAS 131-18-0]	 diisopentylphthalate (DIPP) [CAS 605-50-5]
 benzyl butyl phthalate (BBP) [CAS 85-68-7]	 1,2-benzenedicarboxylic acid, di-$C_{7\text{-}11}$, branched and linear alkyl esters (DHNUP) [CAS 68515-42-4]

combined with UV-visible and gas chromatography (GC) with flame ionization detector (FID) or coupled to mass spectrometry (MS). Most of the publications deal with the determination of dibutyl phthalate (DBP), bis(2-ethylhexyl) phthalate (DEHP), benzyl butyl phthalate (BBP), and di-n-pentyl-phthalate (DNPP) within other non-prohibited phthalates. Less common are studies that include bis (2-methoxyethyl) phthalate (DMEP), the most polar prohibited phthalate. Finally, no analytical methods for the determination of all three isomers, DNPP, diisopentyl phthalate (DIPP), and n-pentyl-isopentylphthalate (NPIPP), or the mix of $C_{7–11}$ branched and linear alkyl esters have been found.

The determination of phthalates in cosmetic samples started many years ago, as shown in a work dated in 1973 where different phthalates were determined by GC-FID [88]. Some years later, Markovic et al. [89] published a work where the phthalate DMP and N,N-diethyl-m-toluamide, both used as insect repellent compounds, were determined in cosmetic samples by thin-layer chromatography (TLC) and UV scanning densitometry. Koo and Lee [90] estimated the median daily human exposure to phthalates by determining the presence of the phthalates DEHP, DEP, DBP, and BBP by HPLC in a hundred different cosmetic samples, like perfumes, deodorants, or nail polishes. Samples were weighted, dissolved in methanol, vortexed, and centrifuged before injection. A run time of 50 min in isocratic elution was needed. As expected, DEP, the non-banned phthalate, was found at high concentrations. Nevertheless, the other phthalates were also present in rather high concentrations in many samples.

Chen et al. [91] developed the first method for the determination of six phthalate esters, DMP, DEP, DBP, BBP, DEHP, and DNOP, in cosmetics by GC-FID. MS was also used but just to qualitatively confirm the presence of the target compounds. Sample pretreatment, similar to Koo and Lee's work, consisted in weighting the samples, dissolving them in methanol, sonicating, and centrifuging. Once water from the upper clean layer was eliminated with anhydrous sodium sulfate it was directly injected. Compared to the previous works, this method showed better sensitivity, with lower limits of detection (LOD). De Orsi et al. [92] continued with LC coupled to UV detection and presented a method where DMP, DEP, dipropyl phthalate (DPP), diisobutyl phthalate (DIBP), BBP, DBP, and DEHP were determined in nail cosmetics. This time, a gradient was used, and run time was reduced to 30 min. Shen et al. [93] studied the determination of seven phthalates and four parabens in different kinds of cosmetic samples, using both LC-UV and GC-MS in SIM mode. A cleanup step using C18 SPE was carried out, which improved the LOD. However, the method is time-consuming and uses high volumes of methanol, so it could not be considered a green method suitable for routine analysis. The IFRA has a phthalate quantification procedure, available in its website [94]. The determination is performed in a GC-MS in SIM mode, with both a quantifier and a qualifier ion per compound.

Regarding the sample pretreatment step, traditional extraction techniques that involve the use of high amounts of toxic solvents should be avoided. In this sense, Chingin et al. [95] presented a novel procedure based on extractive electrospray ionization mass spectrometry (EESI-MS) for the detection of DEP in perfumes with no need of sample pretreatment. Su et al. [96] determined DMP, DBP, dicyclohexyl phthalate (DCHP), and DNOP in perfumes and lacquer removers based on polymer monolith microextraction (PMME) and LC-UV. The conditions for extraction were optimized leading to a sensitive method.

Recently, Koniecki et al. [97] determined the phthalate levels in 252 cosmetic products from the Canadian market by GC-MS to estimate the dermal exposure. Sanchez-Prado et al. [33] also developed a method that allows the simultaneous determination of many compounds, including phthalates, in perfumes. The method consists in diluting the sample in ethyl acetate and injecting it directly into a GC-MS system.

All studies with real perfume samples agree that the presence of prohibited phthalates like DBP, BBP, and DEHP, even in several hundred parts per million, is very common. In this sense, the US Consumers Association [98] conducted a study with eight different brands of perfumes where basically all tested perfumes contained at least DEP and the prohibited phthalate DEHP. A Greenpeace study [75] of different commercial perfumes by GC-MS also found prohibited phthalates in the mg L^{-1} range. Cosmetic industry should try to avoid this issue using free phthalate plastics and solvents.

4 Conclusions

This work resumes the most important regulatory aspects for fragrance chemicals. Different legislations concerning cosmetic products or household products can be found all over the world. This should encourage analytical chemists to develop new methods that enable the determination of all the substances mentioned in these regulations. This would surely help manufacturers and authorities to perform quality control and to assure that no restricted substances are present in the product. Different methods for perfume analysis have been revised here, especially those on restricted or forbidden perfume-related substances, such as potentially allergenic fragrance-related substances, musks, and phthalates. All these works are a very good start, but much more work can be done in perfume analysis.

Abstract

Analytical techniques are very important for promoting the development of the research field of triterpenoid saponin. Although the traditional thin-layer chromatography and spectrophotometry lack sensitivity, resolution, and specificity, they are still widely used due to their high-throughput capacity, simplicity, and rapidity. The development of high-performance liquid chromatography and mass spectrometry, especially high-performance liquid chromatography coupled with hybrid mass spectrometry, has made it easy to comprehensively probe the triterpenoid saponins in matrix, as well as rapidly identify and simultaneously determine minor and multiple triterpenoid saponins from one sample. The type,

QQQ	Triple quadrupole
TOF	Time of flight

1 Introduction

Triterpenoid saponin exists widely in plants of Araliaceae, Campanulaceae, Polygalaceae, Leguminosae, Umbelliferae, etc. Triterpenoid saponin is consisted of triterpenoid sapogenins and saccharide chain. Tetracyclic and pentacyclic triterpenoid saponins are very common and showed extensive activity on immune system, cardiovascular system, even with antitumor effect. They have long been under study to elucidate their activity and mechanism, new structural compounds, and develop rapid and accurate analytical methods. The isolation of triterpenoid saponins is tedious due to their high polarity, and so is the structure identification due to the presence of more than three monosaccharides. New analytical tools and approaches have been developed for qualitative and quantitative analysis of triterpenoid saponins in food, medicinal plant and health care products. This chapter describes spectrophotometry, mass spectrometry, and chromatography coupled with different detector for triterpenoid saponin analysis in matrix.

2 Sample Preparation

The interference of the coexisting components is easily observed due to the weak ultraviolet absorbance and difficult volatility of triterpenoid saponins. The sample preparation is very important for analysis of triterpenoid saponins in matrix for high resolution, accuracy, and selectivity, regardless of the analytical techniques subsequently used. In general, the solid sample is dried and pulverized before extraction. Alcoholic solvents such as methanol, ethanol, and *n*-butanol are commonly used to extract triterpenoid saponins. For triterpenoid saponins with rich hydroxyl groups and strong hydrophobicity, water [1], *n*-butanol [2], and aqueous alcohol [3–19], such as 50 %, 70 %, and 80 %, showed good extract efficiency. However, for some triterpenoid acids and esters, chloroform [10–12, 20–24] and dichloromethane [25, 26] have good extract efficiency. Heat extraction [1, 3, 4, 6, 7, 9, 10, 12, 14, 19, 20, 26–28] and ultrasonic extraction [6, 8, 12, 13, 15–18, 22–25, 29] are typical extraction methods. Heat extraction involves extraction in a Soxhlet's extractor [3, 4, 26, 27] and under reflux [1, 6, 7, 9, 10, 12, 14, 19, 20, 28] at 50–80 °C.

Since coexisted lipophilic compounds decrease the resolution and efficiency for analysis of triterpenoid saponins, solid sample or extraction solution is usually defatted with lipophilic solvents such as petroleum ether [3, 9, 10, 20], ethyl acetate [11], and chloroform [2].

In order to further concentrate and separate target triterpenoid saponins and remove the bulk of the major co-extract compounds from extraction solution, the liquid–liquid extraction and chromatographic separation are attempted. For the most part, the extract of aqueous alcohol is filtered and then evaporated to dryness. The residue is dissolved in water, then extracted with *n*-butanol [9–11] or subjected to chromatographic column [1, 19, 27–29] such as macroporous resin column or to thin-layer chromatographic plate [25]. The *n*-butanol extraction solution and target eluents from chromatographic column or thin-layer chromatographic plate are collected and evaporated to dryness. The residue is dissolved in appropriate solvent for analysis.

For biological samples protein precipitation with acetonitrile [30] or methanol [5], liquid-liquid extraction [5, 31], and solid-phase extraction [32] are used to extract triterpenoid saponins from rat or human plasma. The extraction solution or collected eluents are evaporated and the residues are reconditioned by suitable solvent for analysis.

The optimum extraction conditions are obtained by experiments as follows: extraction solvent, the ratio of material to solvent (W/V), extraction temperature, extraction time, and elution or development solvents for chromatographic column or thin-layer chromatography. The sample preparation procedure, either one-step extraction or multiple-step extraction, needs to be carefully tried according to the analytical procedure subsequently used.

Accelerated solvent extraction is a new extraction technique and is performed at high temperature and high pressure. It demonstrates high efficiency, short extraction time, and low solvent usage. Diatomaceous earth was extracted on an accelerated solvent extraction extractor [33] and different solvents (dichloromethane, *n*-hexane, methanol, and ethanol/water (80:20)) are tested. The temperature

(5–130 °C) and number of extraction cycles are optimized. The extracts of each extraction cycle are evaporated separately. Prior to HPLC analysis, the dry residues resulting from different cycles are redissolved in ethyl acetate.

3 Analytical Method

3.1 UV–Vis Spectrophotometry

With unsaturated bond or 3-hydroxy and 3-carbonyl group, triterpenoid saponins can easily react with strong acids, such as glacial acetic acid, sulfuric acid, and perchloride acid, and form carbonium ion with visible color under anhydrous condition [34]. Carbonium ion can form stable visible color with vanillin by the nucleophilic addition reaction, so 5 % of vanillin-glacial acetic acid and perchloric acid are usually used as color-developing agents for the determination of triterpenoid saponin by ultraviolet visible (UV–vis) spectrophotometry [9, 11, 27]. The detection wavelength is set at 500–600 nm. In order to create the anhydrous reaction condition, the extract solution was evaporated to dryness and the residues were redissolved in anhydrous solvents. UV–Vis spectrophotometry can only be used to determine the total amount of triterpenoid saponins due to the lack of resolution and specificity. The total amount of triterpenoid saponins is calculated with the standard curves of reference compound. In order to improve the specificity and reduce the interference, the multiple-steps sample preparation is commonly performed to concentrate and separate target triterpenoid saponins.

3.2 Thin-Layer Chromatography

Thin-layer chromatography (TLC) is simple and fast, so it is still used as identification test for authentication of the medicinal plants containing triterpenoid saponins, such as Ginseng [2]. Silica gel thin-layer plate is usually employed and the lipophilic solvent is used as developing solvent. Ten percent of sulfuric acid in ethanol is color-developing reagent. With the development of thin-layer chromatogram scanner, TLC is used to determine triterpenoid saponins [20]. In order to avoid the noise and interference, two detection wavelengths are set, one for reference and the other for detection.

3.3 HPLC Coupled with UV and Evaporative Light Scattering Detector

High-performance liquid chromatography (HPLC) coupled with different types of detectors is often used to quantitatively determine or profile triterpenoid saponins. Most of triterpenoid saponins lack chromophores. Their ultraviolet absorbance depends on the degree of unsaturation. For triterpenoid saponins with independent double bonds, their ultraviolet absorbance is close to the 200–250 nm range with weak intensity [8, 14–16, 18, 21, 22, 25, 29, 31, 32, 35]. For ultraviolet detector, it is difficult to choose suitable mobile phase. For triterpenoid saponins with α,β-unsaturated carbonyl or conjugated diene bond, their ultraviolet absorbance is close to the 240–285 nm range [12, 24, 36]. Reversed phase C18 column seems more suitable to separate triterpenoid saponins than normal phase column [33]. Mobile phase for C18 column is consisted of water containing acids, such as phosphoric acid [14, 18, 22, 24, 31, 35, 36], phosphate [15, 16], acetic acid [21, 24], formic acid [17], and perchloric acid [24], and methanol or acetonitrile. Sometimes tetrahydrofuran [21] is added in mobile phase to improve chromatographic resolution. The gradient elution [8, 15–18, 22, 24, 25, 29, 31, 36–38] is often used for simultaneous determination of multiple triterpenoid saponin compounds in matrix [8, 15, 16, 18, 22, 25, 29, 31, 36, 38] or fingerprint analysis [17, 22, 24, 37] of triterpenoid saponins in medicinal plants. The limitation of detection and quantitation is in the range of 0.01–50 μg/mL.

Evaporative light scattering detection (ELSD) is an alternative technique for triterpenoid saponins with weak UV absorbance. In ELSD detector, the eluent from HPLC column is evaporated and the nonvolatile solute components as droplets are illuminated by laser. The scattered light of droplets is measured. Reversed-phase C18 column is commonly used and mobile phase consisted of water-containing volatile acids such as acetic acid, formic acid, trifluoroacetic acid, and methanol or acetonitrile containing above volatile acid is employed [3, 4, 6, 12, 13]. To improve chromatographic resolution, mobile phase is modified with tetrahydrofuran [3], isopropyl alcohol [3], and methyl tert-butyl ether [13]. The gradient elution is often used and the temperature of drift tube is set at 59–105 °C. The limitation of detection and quantitation seems better than that of ultraviolet detector. Evaporative light scattering detector can detect any compound that does not evaporate, so it lack of specificity as ultraviolet detector.

To get reliable quantization of triterpenoid saponins in extract solution, calibration curves for each target analyte must be generated, due to different signal responses. For determination of triterpenoid saponins in complex matrix with good accuracy and precision [25, 31], selection of internal standard (IS) is key. The ideal IS would be chemically similar to the target analytes. Calibration curve is constructed using the peak area ratios of analyte to IS versus the concentration of analyte.

3.4 HPLC Coupled with Mass Spectrometry

The high separation power of HPLC, together with excellent selectivity and sensitivity of mass spectrometry (HPLC-MS), overcame the above problem in the analysis of triterpenoid saponins. HPLC-MS [1, 5, 7, 10, 17, 19, 28–30, 37, 39–42] plays an important role in the analysis of triterpenoid saponins.

At present many mass analyzers are available, such as single quadrupole (Q), triple quadrupole (QQQ), ion trap (IT), time of flight (TOF), and fourier transform ion cyclotron resonance mass spectrometry (FTICRMS). In addition, new types of hybrid mass spectrometers, such as Q-TOF, IT-TOF, and LTQ-FTICRMS, provide the perfect connection between high-flow chromatography and mass spectrometry with high accuracy and resolution. The use of ion trap or quadrupole permits easy control and selection of the amounts of target parent or product ions sent to the mass spectrometry with high accuracy and resolution (TOF or FTICRMS). Mass data of target parent or product ions with good accuracy and resolution can be obtained to determine the elemental composition and to improve the resolution for the poor chromatographic separation. HPLC-TOF and HPLC-QTOF have been successfully applied for the identification of triterpenoid saponins in the complex constituents of crude herb extract [1, 5, 29, 42].

The multiple-stage MS, such as QQQ [41] and ion trap [1, 5, 10, 17, 19], can provide two-stage MS (MS/MS) analysis and multiple-stage MS (MS^n) analysis. The MS^n analysis is carried out automatically, by the selected data-dependent scan mode, that first-stage mass analyzer collects full scan mass data, then picks the parent or product ion of interest for fragmentation in collision cell by collision-induced dissociation (CID), and fragment ions are analyzed in second-stage mass analyzer. The cycle is repeated throughout the duration of the acquisition and provides a great deal of MS^n data, which is very useful for structure elucidation or confirmation of triterpenoid saponins [1, 5, 10, 19, 41]. Different aglycons have the characteristic fragmentation, and the aglycon structures of some triterpenoid saponins can be differentiated on the basis of diagnostic fragments [1, 5, 10, 19, 28, 29, 41, 42]. If the characteristic fragment ions of saccharide chain are obtained, glycosylation sites at aglycon, the sugar types, and the sequence of the sugar units can be determined [1, 5, 10, 19, 41, 42]. In order to get enough diagnostic fragment information, the mobile phase of HPLC is optimized and formic acid, acetic acid, and ammonium acetate are used to improve the mass signal response. The reference standards of the known triterpenoid saponins was primarily used to optimize mass parameters. The diagnostic fragment ions and fragmentation rules of known triterpenoid saponins are summarized. Based on the information of diagnostic fragment ions and fragmentation rules, the triterpenoid saponins in matrix, even the new triterpenoid saponins, might be identified. It is found that the positive ion mode is more sensitive than negative electrospray (ESI) mode for most of the triterpenoid saponins with TOFMS. The negative ESI mode of ITMS easily provided extensive fragmentation information by CID. Therefore, the positive ion mode of TOFMS [1, 5] and the negative mode of ITMS were selected to obtain the characteristic fragment ions and fragmentation rule which might differentiate isomers and determine the monosaccharide and the linkage of the saccharide chain.

3.5 Mass Spectrometry

Different kinds of tandem mass spectrometry techniques have been applied to different types of purified triterpenoid saponins from natural medicinal plants [23, 28, 29, 33, 39, 43–47]. ESI [23, 28, 29, 33, 39, 43, 44, 46, 47] and Matrix-assisted

Structural type A
Structural type B

Fig. 108.1 Structures of eight triterpene saponins [1–9]

Laser Desorption Ionization (MALDI) [45, 46] combined with hybrid types of mass spectrometers, such as ion trap [44], Q-LTQ [23], QTOF [28, 43], IT-TOF [46], TOF/TOF [46], and FTICRMS [47], are used to elucidate the fragmentation mechanism and rule of triterpenoid saponins and to discover diagnostic fragment ions for differentiating the aglycon and determine the substitute site, sequence, and linkage of saccharide chain. It is observed that the type of ionization method, either ESI or MALDI, does not influence the fragmentation of identical precursor ions in low-energy CID [46]. The energy of CID must be optimized so as to obtain useful structural information. The sugar linkage information resulting from cross-ring cleavage is easily available under low-energy CID. On the other hand the high-energy CID tends to yield diagnostic fragment information of the aglycon due to internal cleavage. We have developed the negative ESI-LTQ/FTICRMS method to analyze of triterpene saponins from *Ardisia crenata* Sims [47]. Eight isolated triterpene saponins belonging to two structural types A and B (Fig. 108.1) are analyzed using parent mass list-triggered data-dependent multiple-stage accurate mass analysis at a resolving power of 100,000. The accurate m/z values of precursor and product ions are obtained and used to calculate the chemical formulae (Tables 108.1–108.4). Characteristic mass fragmentation rules are summarized.

The triterpene saponins of structural type A undergo a sequential loss of sugar from the substituted saccharide chain at the C-3 position in the FTICR–MS^n experiment. The triterpene saponins of structural type B readily lose the substituted group at the C-30 position, with the subsequent loss of the terminal monosaccharide group from

the substituted saccharide chain at the C-3 position, which is similar to the tendency observed in the triterpene saponins of structural type A. On the basis of characteristic fragmentation rule and feature of fragment ions, two unknown traces of triterpene saponins were identified in the mixture 9 and 10.

3.6 Determination of the Absolute Configuration of Monosaccharides in Saccharide Chain and the Substituted Groups of Triterpenoid Sapogenins

The absolute configuration of monosaccharides in saccharide chain and the substituted groups of triterpenoid sapogenins is difficult to determine. Chemical analyses combined with chiral chromatographic method have been used to ascertain the absolute configuration. The absolute configuration of seven new pentacyclic triterpenoid saponins, named dianversicosides from the aerial parts of *Dianthus versicolor* is determined [48]. Isolated dianversicosides are hydrolyzed in 1 mol/L HCl at 80 °C. The reaction solutions were extracted with ethyl acetate. The water-soluble parts containing monosaccharides were neutralized and then concentrated to dryness. The dried residue was made to react with L-cysteine methyl ester hydrochloride and then trimethylchlorosilane. The reaction solutions were extracted with *n*-hexane. The supernatant was subjected to GC-MS analysis. The absolute configurations of the monosaccharide units were confirmed by comparison of the retention times with standard monosaccharide samples. A solution of $LiEt_3BH$ in dry tetrahydrofuran was added to solutions of isolated compounds in dry tetrahydrofuran, under an ice bath with an inflow of Argon for 30 min. H_2O was added to reaction mixture and 0.1 mol/L HCl was used to adjust the pH to 3. The reaction product lactones were extracted with ethyl acetate and analyzed by chiral HPLC. The retention times of isolated compounds were compared with those of (3S)- and (3R)-mevalonolactones standards, then the absolute configuration of the 3-hydroxyl-3-methylglutaryl group of some dianversicosides was elucidated as (3S)-3-hydroxy-3-methylglutaryate.

4 Conclusion

This chapter describes the different types of analytical methods in use for the analysis of triterpenoid saponins. HPLC coupled with mass spectrometry shows more merit than other analytical methods on selectivity, sensitivity, and resolution. The diversified HPLC-MS technique provides rich mass information to determine the type and sequence of monosaccharide in saccharide chain and structural type of some triterpenoid sapogenins. This technique is also of interest to develop the reliable and sensitive analytical method for minor triterpenoid saponins in complex matrix. However, due to the lack of standards, there are not many analytical methods for triterpenoid saponins in biological samples. Development of mass spectrometry–based method for triterpenoid saponins in biological samples is necessary to understand the effect and mechanism of triterpenoid saponins.

Abstract

Forskolin is a well-known activator of adenylyl cyclase, obtained from the roots of *Coleus forskohlii*. Several methods were reported for the isolation of pure forskolin from the roots of *C. forskohlii*. The various methods of isolation, the purity, and yield of isolated forskolin are described. The methods included column chromatography, vacuum liquid chromatography, charcoal

column chromatography, immunoaffinity column chromatography, hydrotropic extraction, and adsorption on a selective adsorptive ligand designed by molecular simulation. Forskolin with a maximum purity of 98 % w/w was obtained through adsorption on a selective adsorptive ligand designed by molecular simulation. Similarly, several analytical techniques like, TLC, HPTLC, HPLC, GLC, and ELISA are described for the quantitative determination of forskolin in standardized crude extracts and pharmaceutical formulations. Among the analytical methods, HPLC and HPTLC appear to be more popular and widely used in the industry and academia. Analysis of forskolin by ELISA appears to be highly sensitive than other techniques.

Keywords

Analytical techniques • Charcoal column chromatography • Chromatography • *Coleus forskohlii* • Forskolin • ELISA • GLC • HPLC • HPTLC • Hydrotropic extraction • Immunoaffinity chromatography • Microwave-assisted extraction • Molecular simulation • TLC

Abbreviations

BSA	Bovine serum albumin
cAMP	Cyclic adenosine monophosphate
CNBr	Activated Sepharose 4B – Cyanogen bromide-activated-Sepharose 4B
ELISA	Enzyme-linked immunosorbent assay
GC	Gas chromatography
GLC	Gas liquid chromatography
HAS	Human serum albumin
HPLC	High performance liquid chromatography
HPTLC	High performance thin layer chromatography
IgG	Immunoglobulin G
LC-MS	Liquid chromatography mass spectrometry
MAb	Monoclonal antibody
NaCl	Sodium chloride
$NaHCO_3$	Sodium bicarbonate
PBS	Phosphate buffered saline
TLC	Thin layer chromatography
UV	Ultraviolet

1 Introduction

Coleus forskohlii Briq. (Lamiaceae) is a perennial herb, occurs naturally in Indian subcontinent and is also distributed in Egypt, Arabia, Ethiopia, tropical East Africa, and Brazil [1, 2]. In traditional medicine, *C. forskohlii* is commonly used in different countries for various disorders. In Egypt and Africa, the leaf is used as an expectorant, emmenagogue, and diuretic [1]. In Brazil, it is used as a stomach

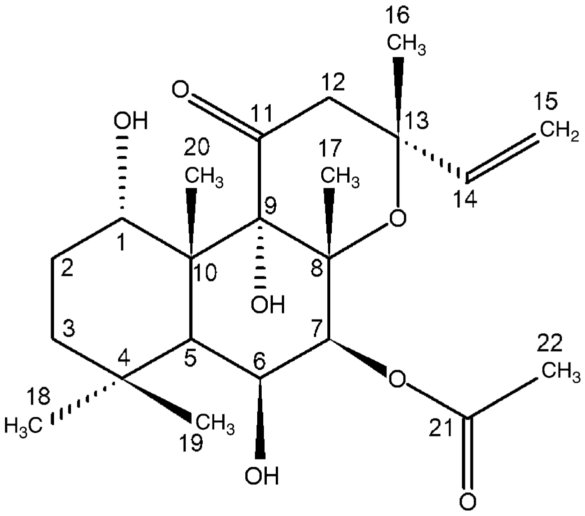

Fig. 109.1 Structure of forskolin

aid, for treating intestinal disorders and to interrupt pregnancy [1, 3]. In India, it is used as a condiment and the root tubers are prepared as pickle and eaten. In traditional Ayurvedic systems of medicine, *C. forskohlii* has been used for treating heart diseases, abdominal colic, respiratory disorder, insomnia, convulsions, asthma, bronchitis, intestinal disorders, burning sensation, constipation, epilepsy, and angina [4]. The root tubers are employed in the treatment of worms and to reduce burning sensation in festering boils. The root paste is applied to treat eczema and other skin infections after mixing with mustard oil. The plant is also used for veterinary disorders [5]. The root tubers of *C. forskohlii* are included in various Ayurvedic formulations and listed in Ayurvedic Pharmacopoeia of India as *Gandira* [6].

Forskolin is a bioactive compound obtained mainly from the tuberous roots of *C. forskohlii*. Recently, stem of *C. forskohlii* was also found to contain appreciable quantities of forskolin [7]. *C. forskohlii* roots have long been used in Ayurvedic medicine for treating heart and lung disease, intestinal spasms, insomnia, and convulsions [4]. Forskolin (Fig. 109.1), a labdane diterpene, has exhibited positive effects in asthma, glaucoma, hypertension, cancer, heart disease, diabetes, and obesity [4]. Forskolin was isolated during 1970s by Indian researchers and initially referred to as coleonol and later changed to forskolin [8–10]. Its structure and stereochemistry were established by several studies [8, 10–13]. Forskolin occurs exclusively in *C. forskohlii* and could not be detected in other *Coleus* species [14]. Forskolin's major pharmacological mechanism of action is linked to its action on adenylyl cyclase enzyme. Forskolin activates various isoforms of adenylyl cyclase, which results in the increase in intracellular cAMP. Forskolin is used in many biochemical and pharmacological experiments as an activator of adenylyl cyclase [15].

The roots contain approximately 0.15–1.5 % w/w of forskolin. The content of forskolin in stems was found to be around 0.02 % w/w [7]. Apart from the

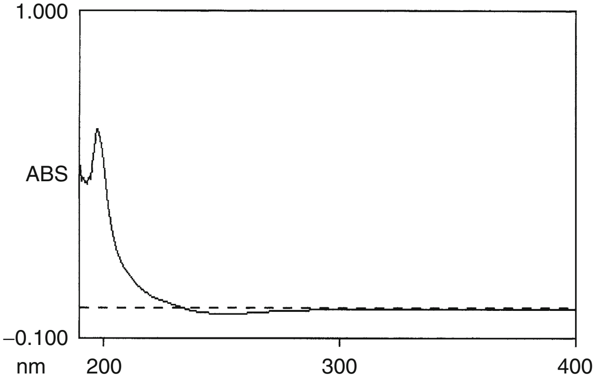

Fig. 109.2 UV spectrum of pure forskolin isolated from *C. forskohlii* roots [17]

Ayurvedic formulations which contain *C. forskohlii* as one of the ingredients, standardized extracts of *C. forskohlii* have been marketed in the recent days as nutraceutical supplements mainly for weight loss. Several analytical methods were developed for the quantitation of forskolin in crude extracts as well as in formulations. There is one clinical study in obese men indicating the efficacy of forskolin in inducing weight loss, promoting lean body mass, bone mass, and increasing serum free testosterone levels [16].

1.1 Physicochemical Properties of Forskolin

Forskolin is relatively a nonpolar compound, thus sparingly soluble in water. However, it is also insoluble in petroleum ether and xylene. Thus, it is soluble in solvents like toluene, chloroform, ethanol, and methanol. This property is exploited in the fractionation and isolation of forskolin. Also, forskolin is not very much UV sensitive. Its UV absorption maximum is around 200 nm (Fig. 109.2). Hence, during isolation process, monitoring of the fractions is done usually by TLC. However, TLC is cumbersome, as it involves spraying with either anisaldehyde-sulfuric acid reagent or vanillin-sulfuric acid reagent and heating [7, 17].

2 Isolation by Column Chromatography

Column chromatography was used extensively for the isolation of forskolin during 1970s–2000s. Forskolin was isolated by using column chromatography on silica gel from methanolic extract of root powder by Bhat et al. and other researchers [8, 9, 18, 19]. The crude extract was chromatographed several times before pure forskolin was obtained. The mobile phase system consisted of eluting with nonpolar solvents first to remove impurities, followed by gradually increasing the polarity of solvents [7].

3 Isolation by Vacuum Liquid Chromatography

Vacuum liquid chromatography was employed to separate the forskolin-rich fractions from the crude extract [Unpublished reports]. This vacuum liquid chromatographic method was a modification of the published method for the flash chromatography [20]. The crude extract was obtained by extracting the root powder with toluene or chloroform. Here, the polar solvents like ethanol and methanol were avoided to reduce the extractable impurities. The crude extract, after the solvent removed, was subjected to vacuum liquid chromatography in a sintered glass Buchner funnel, which was connected to a Buchner flask. Silica gel (230–400 mesh) was used as an adsorbent. The vacuum (100–200 mmHg) was applied to suck the eluate. The mobile phase was selected based on the TLC profile of crude extract. The TLC method of crude extract was optimized to have forskolin's R_f value around 0.30. For TLC, aluminum-backed silica gel GF_{254} was used as the stationary phase and anisaldehyde-sulfuric acid reagent was used as the spray reagent. The mobile phase which gave the forskolin's R_f value around 0.30 was a combination of toluene and ethyl acetate (80:20 % v/v). Instead of toluene, *n*-hexane also can be used. Elution was carried out first with 100 % v/v of low-polar solvent (toluene or *n*-hexane) to elute the impurities out. Then, exhaustive elution was carried out with the selected mobile phase. After monitoring by TLC, similar fractions were combined and the solvent was evaporated. The residue obtained thus was brownish yellow in color. This crude forskolin was repeatedly crystallized in a mixture of *n*-hexane and ethyl acetate (75:25 % v/v) to obtain white or off-white crystals of pure forskolin [Unpublished reports].

4 Isolation by Charcoal Column Chromatography

Activated charcoal, a nonpolar adsorbent, has been extensively used for the separation and purification of organic compounds for its easy regeneration, low cost, high adsorption capacity. It is mainly used in the fractionation of monosaccharide-oligosaccharide mixtures and in the isolation of sugars and their polar derivatives using aqueous solvents. The adsorbent surface consists mainly of carbon, which enables adsorption to take place on the principle of dispersion forces [21]. Adsorption on charcoal is largely governed by the molecular size of the sample. Charcoal more strongly adsorbs higher molecular weight dissolved organic molecules than lower molecular weight molecules and nonpolar molecules than polar molecules [22]. Recently, several applications of charcoal column chromatography to separate low-polar compounds with nonaqueous solvents have been reported [17, 23, 24].

Charcoal column chromatography was used to purify forskolin [17]. Activated charcoal used in this study was untreated, granular carbon prepared from chemically activated wood with a particle size of less than 75 μm (80–90 %) (100–400 mesh). One hundred grams of powdered root material was extracted with toluene. The toluene extract was concentrated to 15 ml under reduced pressure at 40 °C. To this extract, 150 ml of *n*-hexane was added slowly under continuous stirring to obtain crude forskolin (brown solid precipitate) in powder form (1.6 g). This crude forskolin was placed on a column (7.5 cm × 1.7 cm i.d.), packed with activated charcoal (6 g), placed on a Buchner flask of suitable size connected to a vacuum source (100–200 mmHg), eluted with methanol and acetonitrile:methanol (50:50, v/v). Forskolin was detected by TLC as a major spot in the eluates obtained with acetonitrile:methanol (50:50, v/v) and as a minor spot in the eluates obtained with methanol. Hence, the yellowish brown colored eluates obtained with acetonitrile:methanol (50:50, v/v) were combined and concentrated under vacuum at 40 °C to obtain a residue (500 mg). This residue was stirred with *n*-hexane to remove *n*-hexane soluble impurities, and *n*-hexane was removed by filtration. After drying the residue, it was dissolved in 5 ml of chloroform. To this solution, 50 ml of *n*-hexane was added with continuous stirring to remove most of the coloring matter and crude forskolin was obtained as a pale yellow precipitate. This precipitate was crystallized in ethyl acetate:light petroleum (b.p. 40–60 °C) mixture (25:75, v/v) to obtain the forskolin. This crystallization step was repeated once to get forskolin as off-white color precipitate. This precipitate was again crystallized with diethyl ether:*n*-hexane (1:15, v/v) to obtain pure forskolin (yield – 0.0971 % w/w with respect to the weight of dried root powder; purity – 96.9 % w/w) [17].

5 Isolation by Immunoaffinity Column Chromatography

Yanagihara et al. developed an immunoaffinity column chromatography method to isolate forskolin from the roots of *C. forskohlii*, by using the anti-forskolin monoclonal antibody [25]. Anti-forskolin monoclonal antibody was prepared by injecting the forskolin-bovine serum albumin conjugate into BALB/c mice followed by cell culture techniques. Purified IgG in phosphate buffered saline (PBS) solution was added to the slurry of CNBr-activated Sepharose 4B in coupling buffer (0.1 M $NaHCO_3$ containing 0.5 M NaCl), and used as the affinity gel. The dried powder of tuberous root was extracted with diethyl ether. After evaporation of solvent, the residue was dissolved in PBS containing 6 % methanol and subjected to the immunoaffinity column separation. Elution was carried out with PBS containing 45 % methanol. The forskolin content was estimated by ELISA. The recovery of forskolin was found to be 95.6 % w/w. However, forskolin purified in this way by the immunoaffinity column was still contaminated by a small amount of 7-deacetyl forskolin because this compound has cross-reactivity against anti-forskolin monoclonal antibody. Therefore, the mixture was treated with pyridine and acetic anhydride at 4 °C for 2 h to give pure forskolin [25].

6 Isolation by Hydrotropic Extraction

Hydrotropes are highly water-soluble small molecular weight organic salts (e.g., sodium salicylate and sodium cumene sulfonate). They possess ability to dissolve other organic compounds in aqueous solutions in a concentration-dependent manner. Hydrotropes exhibit their solubilization capacity for organic compounds above a characteristic minimum hydrotrope concentration (MHC). Hydrotropic solubilization technique is one of the methods used to enhance the aqueous solubility of insoluble or slightly soluble bioactive compounds. Hydrotropes dissolve well the organic compounds above their MHC in aqueous solution. Hence, if the hydrotrope solution containing organic compound is diluted below its MHC, then the solubility of that organic compound in aqueous solution decreases and the organic compound may separate out [26–29]. Gaikar et al. employed this technique to isolate piperine [30], boswellic acids [31], diosgenin [32], and andrographolide [33]. This technique was successfully employed to isolate forskolin by Mishra et al. [34].

Pulverized roots of *C. forskohlii* were suspended in aqueous hydrotrope solution of sodium cumene sulfonate and agitated vigorously. After the extraction, the solution was subsequently filtered under vacuum. A clear brown color solution was obtained as filtrate, while the insoluble sticky solid portion was collected as residue. The filtrate was diluted with water to the respective minimum hydrotrope concentration (MHC) of the hydrotrope. Solid brown color crystals of forskolin that precipitated out from the hydrotrope solutions were isolated by centrifugation or filtration. The purity of isolated forskolin was 85 % w/w with maximum extraction of 70 % w/w [34].

7 Isolation by Microwave-Assisted Extraction

Microwave is used to irradiate the plant material during the extraction process. Microwave irradiation is reported to cause rupture of cells, thereby facilitating the action of solvents on the cells [35]. The usage of microwave irradiation was employed for the isolation of curcumin from turmeric [36–39], piperine from *Piper nigrum* [40], solanesol from tobacco leaves [41], and artemisin from *Artemisia annua* [42].

Microwave irradiation was employed to extract forskolin from the roots of *C. forskohlii* by Devendra et al. [35]. The raw material was soaked in water before subjecting it to microwave irradiation and it was irradiated with microwave, after it was evenly and thinly spread over a Petri dish, in a microwave oven. After the irradiation, the material was extracted by suspending it in 150 ml of methanol with vigorous agitation. The methanolic extract was concentrated by evaporating methanol up to 80 % of its original volume. Crude forskolin was crystallized from the concentrated solutions by simultaneous addition of petroleum ether and water in a 1:1 volumetric ratio. Forskolin crystallized from the above process was a free-flowing and brown colored powder with 30–35 % w/w purity. The crude forskolin was dissolved in acetonitrile and further decolorized by adsorption on an alumina column. When forskolin extract in acetonitrile was passed over an alumina bed, all brown colored organic impurities of the crude extract were strongly retained by the column. The light yellow eluate from the column contained 78 % (w/w) forskolin, 15 % (w/w) of 7-deacetylforskolin, and 6 % (w/w) of

1,9-dideoxyforskolin. No separation of forskolin and its analogues was, however, achieved with the alumina column, but the product contained no other impurities. This fraction was further purified to isolate forskolin by using a chloromethylated polystyrene polymer loaded with diethanolamine [35].

8 Isolation by Using Selective Adsorbent Designed by Molecular Simulation

Devendra et al. reported the usage of selective adsorbent designed by the molecular simulation technique to isolate forskolin and its analogues based on the interaction between the adsorbent and the target molecules [35].

Diethanolamine was loaded on chloromethylated polystyrene matrix by chemical synthesis. Diethanolamine was selected as a ligand for interacting with the target molecules based on the hypothesis that the hydroxyl groups of diethanolamine would form hydrogen bonding with the hydroxyl groups of forskolin and its analogues in a differential manner because of relative spatial positions of different hydroxyl groups on the structures of interacting molecules. This hypothesis was tested in silico by using a computer modeling software, Material Studio 3.2 (MS, Acclerys, USA). Each solute and two units of the amine-loaded polystyrene were allowed to interact in different solvent environments. In the case of interaction studies in the solvated state in acetonitrile, none of the functional groups of forskolin showed any interaction with the amine-loaded polymer, whereas in the case of 7-deacetylforskolin, all the four hydroxyl groups interact with the hydroxyl groups of the amine-loaded polymer. In the case of 1,9-dideoxyforskolin, the acetyl group at seventh position interacts with the hydroxyl groups of the amine-loaded polymer. These theoretical calculations indicated the possibility of separating forskolin from its analogues by selective adsorption of the latter on a diethanolamine-loaded polystyrene matrix from acetonitrile solutions.

Devendra et al. performed the experimental work to confirm the predictions of in silico molecular simulation. The methanolic extract of the root was concentrated by evaporating methanol up to 80 % of its original volume. Crude forskolin was crystallized from the concentrated solutions by simultaneous addition of petroleum ether and water in a 1:1 volumetric ratio. Forskolin crystallized from the above process was a free-flowing and brown colored powder with 30–35 % w/w purity. The crude forskolin was dissolved in acetonitrile and further decolorized by adsorption on an alumina column. The eluate obtained after decolorization of the crude forskolin extract through an alumina column mainly contained forskolin and its analogues and, therefore, was used as a feed solution for adsorption on the amine-loaded polymer, loaded in a column to investigate their adsorption behavior. The uptake by the polymer from the acetonitrile solution was found to be maximum for 1,9-dideoxyforskolin (91 %), intermediate for 7-deacetylforskolin (37 %), and minimum for forskolin (12.2 %) until five bed volumes. These differential uptakes validated the hypothesis from molecular simulation that analogues shall be adsorbed more preferentially than forskolin on the polymer. Almost 90 % w/w of forskolin was recovered from this technique and the purity of forskolin was 94 % w/w.

In another study, Devendra et al. [43] used different selective polymers designed by molecular simulation to have interaction with forskolin to isolate forskolin. *N*-propinoyl aspartic acid (NPAA), phenyl glycine-*o*-carboxylic acid (PGOCA), and phenyl glycine-*p*-sulfonic acid (PGPSA) were used as the ligands for selective adsorption of forskolin. Extraction and decolorization processes of crude extract were carried out as per the previous report [35]. The ligands were synthesized and loaded on chloromethylated polystyrene matrix cross-linked with divinylbenzene in dimethyl sulfoxide (DMSO) solutions. The ligand-loaded polymer was packed in a glass column. The decolorized extract solution was pumped through the packed adsorption bed by a peristaltic pump. Samples were collected at regular time intervals at the exit of the column. The PGPSA-loaded polymer gave almost 98 % w/w pure forskolin during desorption, with the yield of 16 % w/w. About 95 % w/w pure forskolin was achieved with 46.54 % w/w recovery with PGOCA-loaded polymer.

9 Extraction by Three-Phase Partitioning

Three-phase partitioning (TPP) is a bioseparation technique useful for the fractionation and concentration of proteins from plant materials and microorganisms. It involves the partitioning of hydrophilic constituents, proteins, and hydrophobic constituents in three phases comprising of water, ammonium sulfate, and organic solvent [44, 45]. TPP was utilized for extraction of forskolin from *C. forskohlii* roots. Aqueous slurry was prepared by mixing 5 g of *C. forskohlii* root powder in 50-ml distilled water by mild stirring with a magnetic stirrer. Calculated quantities of ammonium sulfate was added to the aqueous slurry prepared, followed by addition of known amount of *t*-butanol. The extraction was carried out for 1 h by gentle stirring with magnetic stirrer. The mixture was allowed to stand for 1 h for the formation of three phases. The three phases so formed were separated by centrifugation. The upper organic layer was collected and the solvent (*t*-butanol) was evaporated to dryness. Forskolin content was estimated in the extract thus obtained by HPLC. A maximum of 30.83 % recovery of forskolin was obtained under the optimized conditions. Ultrasonication and enzyme pretreatment with commercial enzyme preparations of Stargen® 002 (contains *Aspergillus kawachi* alpha-amylase expressed in *Trichoderma reesei* and a glucoamylase from *T. reesei* that work synergistically to hydrolyze granular starch substrate to glucose) and Accellerase® 1500 (mixture of cellulase and glucosidase that works synergistically to hydrolyze cellulosic substrate to glucose) followed by TPP gave 79.95 % and 83.85 % recovery (when compared to conventional soxhlet extraction which is taken as 100 %), when used individually within 4 h [46]. This study only described extraction procedure for the extraction of crude extract which contains forskolin and not the isolation of pure forskolin from *C. forskohlii* roots [46]. The summary of all isolation procedures is given in Table 109.1.

Table 109.1 Overview of isolation of forskolin by several methods

Isolation method	Principle of separation/isolation	Yield from plant roots	Purity	Reference
Column chromatography	Adsorption	0.103 % w/w [7]	b	[7–9, 18, 19]
Vacuum liquid chromatography	Adsorption	a	b	[Unpublished reports]
Charcoal column chromatography	Adsorption	0.0971 % w/w	96.9 % w/w	[17]
Immunoaffinity column chromatography	Antigen-antibody interaction	a	b	[25]
Hydrotropic extraction	Solubility	a	85 % w/w	[34]
Microwave-assisted extraction	Solubility/partition/ adsorption	a	b	[35]
Selective adsorbent designed by molecular simulation	Adsorption	a	94 % w/w [35], 98 % w/w [43]	[35, 43]

a – yield not stated in the literature; b – purity not stated in the literature

10 TLC Analysis of Forskolin

Generally, TLC method is used to monitor the presence of forskolin during the isolation process. However, it can also be used to determine the quantity of forskolin present in the crude extract as well as in formulations. Inamdar et al. described a TLC method for the quantification of forskolin in pharmaceutical preparations [47]. In this method, forskolin was detected by using vanillin in acetic acid and perchloric acid as the detection agent. Forskolin gave violet color spot and the intensity of violet color was quantitatively estimated.

A validated TLC method was reported by Ahmad et al. [48]. This method was developed on TLC aluminum plates precoated with silica gel $60F_{254}$ using solvent system benzene:methanol (9:1, v/v), which gave compact spot of forskolin (R_f value 0.25 ± 0.02). Densitometric analysis of forskolin was carried out in the absorbance mode at 545 nm after spraying with anisaldehyde-sulfuric acid visualization reagent. After spraying with anisaldehyde-sulfuric acid regent, the TLC plate was dried and heated to 110–120 °C. Forskolin was detected as a dark violet or purple color spot. This method was applied for determination of forskolin in *C. forskohlii* root and in capsule dosage forms, which showed 0.18 % and 0.57 % w/w of forskolin [48]. In a stability test, forskolin was subjected to acid and alkali hydrolysis, oxidation, photodegradation, and heat degradation. It was observed that the drug was susceptible to acid, base hydrolysis, oxidation, photo-oxidation, and heat degradation. This TLC method effectively resolved the forskolin from components of *C. forskohlii* root, from excipients of capsule as well as the degradation products of forskolin [48].

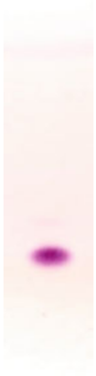

Fig. 109.3 Thin layer chromatogram of pure forskolin

Another TLC method was reported by our group, which was mainly used as a qualitative identification method [7, 17]. TLC was performed with precoated plates of silica gel $60F_{254}$ (Merck, Darmstadt, Germany) in toluene:ethyl acetate (80:20, v/v) as mobile phase. Anisaldehyde-sulfuric acid was used as the spraying reagent (1 ml concentrated H_2SO_4 was added to 0.5-ml anisaldehyde in 50-ml acetic acid). After developing the plate, the plate was dried and heated to 110–120 °C for 5–10 min in a hot air oven with careful and periodical monitoring to avoid excessive heating and subsequent charring of the plate. After the plates were taken out from the hot air oven, the plates were allowed to cool to room temperature and scanned immediately in a digital photoscanner and the scanned image was stored in a computer. Furthermore, the plate was preserved by wrapping with cellophane tape. It was observed that if the plates were left exposed to air, the spots disappeared after few days. R_f value of 0.27 was obtained for forskolin as a single, compact dark violet/purple spot (Fig. 109.3). Similar TLC method was reported by Selima et al. [49] but with a different R_f value of forskolin (0.48).

There is a monograph available in Indian Pharmacopoeia Commission (IPC) website (http://www.ipc.gov.in) for the characterization of *Coleus* dry extract [50]. A TLC method is described in that monograph. The procedure consisted of coating the plate with silica gel GF_{254} and developing in a mobile phase consisting of a mixture of 40 volumes of ethyl acetate and 60 volumes of hexane. Test solution was prepared by dissolving about 500 mg of the extract under examination with 10-ml methanol and filtered. Reference solution was prepared by making a 0.1 % w/v solution of forskolin RS in methanol; 10 μl of each solution was applied to the plate as bands of 10 mm by 2 mm. The mobile phase was allowed to rise up to 8 cm. The plate was air dried and sprayed with anisaldehyde-sulfuric acid reagent solution. The plate was heated at 110 °C for 10 min and examined under 365 nm and under day light. The chromatogram obtained with the test solution showed a band corresponding to the band obtained by using reference solution, indicating the presence of forskolin.

11 HPTLC Analysis of Forskolin

HPTLC analysis of crude extracts for the quantitation of marker compounds has gained wider acceptance by the industrial scientists in the recent days for the relative ease of the technique and its capability to analyze multiple samples at the same time in a single plate [51]. An automated multiple development HPTLC method for the separation of several forskolin derivatives was developed and validated. The HPTLC development used a 25-step gradient with a polarity range of methylene chloride–methanol to hexane and detection by chlorosulfonic acid reagent [52].

Pushpa et al. described a HPTLC method in which benzene extract of *C. forskohlii* roots was applied to HPTLC plate. Benzene: ethyl acetate (80:20 v/v) was used as the mobile phase and anisaldehyde-sulfuric acid was used as the spray reagent. After developing and spraying, the plate was dried at 100–105 °C. Forskolin gave violet colored spot with R_f value of 0.45 [53].

Vijay et al. described a HPTLC method for estimation of forskolin in ophthalmic preparations. A stock solution of forskolin (marker compound) equivalent to 1 mg ml^{-1} was prepared and different quantities of this solution, namely, 1, 2, 3, 4, 5 μl, were spotted onto precoated silica gel GF plates (10 × 10 cm size) using automatic sample syringe (Linomat IV Application mode) of the CAMAG-HPTLC equipment in order to develop calibration between 1 and 4 μg drug concentrations. The plate was placed in the twin-trough development chamber, which was presaturated with the mobile phase consisting either of a mixture of toluene:ethyl acetate (7:3) or chloroform:methanol (8:2) separately. The plate was developed for about 20 min and dried with a current of hot air. The plate was then scanned at 292 nm in the densitometer, and the area under the curve (AUC), of each concentration, was determined. Calibration curve was developed by plotting a graph between the concentration and the area under the curve [54]. Several other HPTLC methods were also reported in the literature [55–58]. An overview of HPTLC parameters for the analysis of forskolin is given in Table 109.2.

12 HPLC Analysis of Forskolin

HPLC analysis of forskolin has gained wider acceptance among academic and industrial researchers due to its high accuracy and repeatability. It is used for the quantitative estimation of forskolin in *C. forskohlii* root crude extracts and in formulations. Inamdar et al. described a HPLC method for the determination of forskolin in crude extracts and in pharmaceutical formulations [47].

A rapid method was developed for the evaluation of forskolin in the root and stem of dried *C. forskohlii* and in 17 market products by reversed-phase high performance liquid chromatography (RP-HPLC) with a photodiode array detector at 210 nm. The temperature was held constant at 30 °C, and the retention time of forskolin was approximately 6.8 min. The samples were extracted with acetonitrile by sonication.

Table 109.2 Overview of HPTLC conditions for the analysis of forskolin

Mobile phase	Stationary phase	Detection/scanning wavelength	R_f value of forskolin	Reference
Benzene: Ethyl acetate (80:20 v/v)	HPTLC plate	anisaldehyde-sulfuric acid/ 560 nm	0.45	[53]
Toluene:ethyl acetate (7:3) or chloroform: methanol (8:2)	Precoated silica gel GF plates	292 nm	a	[54]
Benzene:ethyl Acetate (85:15)	Silica gel $60F_{254}$	Vanillin-sulfuric acid/550 nm	a	[59]
Toluene:methanol (18:1.5, v/v)	Silica gel $60F_{254}$	Anisaldehyde sulfuric acid/ 545 nm	0.27 ± 0.02	[60]
Benzene:ethyl acetate (75:25, v/v)	Precoated plates	200 nm	0.49 ± 0.01	[58]

a – R_f value not stated in the literature

The method was found to be precise and accurate. The response was linear through zero from 6.3 to 630 μg ml^{-1} with a correlation coefficient (R^2) of 0.9998. Identity of the marker compound was confirmed by a LC-MS experiment [61].

Another rapid reverse-phase HPLC method with evaporative light scattering detection (ELSD) was reported for the determination of forskolin in weight-loss multi-herbals products. The analysis was performed by water-acetonitrile gradient elution at a flow rate of 1.0 ml min^{-1}. The evaporator tube temperature of ELSD was set at 35 °C, and with the nebulizing gas flow rate (pressure) of 3.0 bar. Good linear relationships were obtained with correlation coefficients exceeding 0.9995. The average recovery of forskolin ranged from 99.4 % to 100.4 % with RSDs below 3 %. The percent relative standard deviations (% RSD) of intra- and inter-day precision varied by less than 2.1 %. LOD and LOQ were 0.95 and 3.21 μg ml^{-1}, respectively. The method was found to be accurate, precise, and repeatable [62]. Several other similar HPLC methods were also reported in literature especially for the analysis of forskolin in tissue culture studies and in formulations [63–72].

A HPLC method was used by our group to quantify the purity of isolated forskolin. Actually, this method was adapted from a previously reported method [61]. In this method, C18 (250 × 4 mm i.d., 5 μ) column was used with a mobile phase consisting of water (A):acetonitrile (B) (50:50, v/v) at a flow rate of 1.0 ml min^{-1}. The gradient elution was 50A/50B to 43A/57B in 10 min. The UV detection was carried out at 210 nm. The retention time of forskolin was found to be 10.3 min [17]. An overview of various HPLC methods is given in Table 109.3.

13 GC Analysis of Forskolin

Usually gas chromatographic (GC) analysis requires an analyte to be volatile. Forskolin is not naturally volatile. Hence, it needs to be converted into its volatile

Table 109.3 HPLC conditions for the analysis of forskolin

Stationary phase	Mobile Phase	Flow rate	Detection	Reference
C18	water-acetonitrile gradient elution	1.0 ml min^{-1}	ELSD evaporator tube temperature at 35 °C, nebulizing gas flow rate (pressure) of 3.0 bar	[62]
C18 (150 × 4.6 mm i.d., 5 μ)	Water (A): Acetonitrile (B) (50:50, v/v); The gradient elution was 50A/50B to 43A/57B in 10 min.	1.0 ml min^{-1}	210 nm	[61]
C18 (250 × 4.6 mm i.d., 5 μ)	Acetonitrile:water (50:50, v/v)	1.6 ml min^{-1}	220 nm	[59]
C18 (250 × 4.6 mm i.d., 5 μ)	Acetonitrile:methanol (80:20, v/v)	1.0 ml min^{-1}	254 nm	[58]
C18 (250 × 4.6 mm i.d., 5 μ)	Acetonitrile:water (45:55, v/v)	1.0 ml min^{-1}	220 nm	[67]
C18 (250 × 4 mm i.., 5 μ)	Water (A): Acetonitrile (B) (50:50, v/v); The gradient elution was 50A/50B to 43A/57B in 10 min.	1.0 ml min^{-1}	210 nm	[17]
C18 (300 × 3.9 mm i.d.)	Acetonitrile:water (65:35, v/v) at pH 2.5 by adding orthophosphoric acid	1.0 ml min^{-1}	202 nm	[73]

derivatives. Since, this is a limiting factor especially for the analysis of crude extracts, only one gas chromatographic method was reported in literature. A GLC method was reported by Inamdar et al. for the quantitative estimation of forskolin in crude extracts and in pharmaceutical formulations [74].

14 Analysis of Forskolin by ELISA

Immunoassay systems using monoclonal antibody (MAb) against natural products have become an important tool for studies on receptor binding analysis, enzyme assay, and quantitative and/or qualitative analytical techniques in animals or plants [75]. Immunogenic forskolin-bovine serum albumin (BSA) conjugate was synthesized via 7-deacetyl-7-hemisuccinyl forskolin. BALB/c male mice were injected intraperitoneally with forskolin-BSA conjugate emulsified with Freund's complete adjuvant. Splenocytes were isolated from the hyperimmunized BALB/c mice and fused with the P3-X63-Ag8-U1 myeloma cells. Six hybridomas producing monoclonal antibodies (MAbs) reactive to forskolin were obtained.

One of the original clones secreted anti-forskolin antibody which was purified by protein A affinity column chromatography and its purity was confirmed by MALDI mass spectrometry. The MAb was bound to polystyrene microtitration plates precoated with a forskolin-human serum albumin (HAS). The full measuring range of the assay extended from 6 ng to 200 ng ml^{-1} of forskolin [68, 76]. The ELISA system established in this study was more sensitive compared to TLC [47], GLC [74] or HPLC [47, 77].

15 Hyphenated Techniques

Hyphenated techniques like GC-MS and LC-MS techniques are mainly used for identification of the compound and confirmation of its structure and stereochemistry. A LC-MS technique was employed for the identification of forskolin in crude extracts and in marketed formulations. A C18 column (150 × 4.6 mm, 5 μm) was used at ambient temperature. The mobile phase consisted of water (A) and acetonitrile (B). At a flow rate of 0.5 ml min^{-1}, the gradient elution was programmed to change from 50A/50B to 43A/57B in 10 min and to remain constant at 43A/57B for next 10 min. The detection wavelength was 210 nm, and the injection volume was 5 μl. Best results were obtained in positive electrospray ionization (ESI) mode, with ionization voltage set to 25 V, source voltage to 3.0 kV, and probe temperature to 350 °C [61].

16 Conclusion

Several diversified techniques are summarized for the isolation of forskolin from the tuberous roots of *C. forskohlii*. However, the purity of the isolated forskolin remains a matter of concern for the biologists, since forskolin with high purity is required in biological tests. Higher the purity of a bioactive compound, lesser would be the effect of the impurities present and the observed pharmacological effect can be safely attributed to the major compound. Only few techniques like charcoal column chromatography, selective adsorption using phenyl glycine-*p*-sulfonic acid–loaded polymer, and selective adsorption using phenyl glycine-*o*-carboxylic acid–loaded polymer could achieve purity greater than 95 % w/w. Even though hydrotropic extraction process seems to be simple to perform, the purity of forskolin was only 85 % w/w, thus disabling its potential application. Further research is required to identify processes which will yield high purity forskolin in less amount of time in an environment-friendly manner. One of those approaches may focus on using molecular simulation technique to identify a suitable hydrotrope or adsorbent for separating forskolin from its structurally similar analogues.

Standardized crude extract of *C. forskohlii* and forskolin are marketed as weight-loss products. Several analytical techniques were reported in the literature for the quantification of forskolin from crude extracts as well as in formulations.

Among them, many were HPLC methods. In addition, HPTLC technique was also reported in many papers. These indicate the popularity of HPLC and HPTLC techniques in the analysis of forskolin. The analysis of forskolin by ELISA technique appears to be more sensitive than other methods and may be further explored for regular utilization.

1 Introduction

Natural products play a dominant role in pharmaceutical industry, and systematic investigation of natural resources for the discovery of new drug molecules is the primary objective for bioprospection programs [1]. The profound knowledge of herbal remedies in traditional culture has been developed through trial and error over many centuries based on the verbal knowledge transferred from one generation to the next. Majority of bioactive constituents isolated from plants fall into the category of secondary metabolites and can be divided into three chemically distinct groups – terpenoids, phenolics, and nitrogen-containing compounds.

Quassinoids are degraded triterpenes, reported from the members of the Simarouboidaea subfamily of Simaroubaceae. Legend states that a man named “Quassi” treated fever using the bitter extracts derived from the bark of these trees and hence named “quassin” [2]. Quassinoids have received attention due to their antiplasmodial, anticancer, and anti-HIV properties. Its efficacy as combinatorial drug coupled with the structure–activity analysis has reclaimed novel structural leads for new drug development.

Chromatographic techniques such as paper chromatography (PC), thin layer chromatography (TLC), gas chromatography (GC), and high-performance liquid chromatography (HPLC) are utilized to isolate and quantify secondary metabolites.

These techniques when coupled with detectors, the most popular being the UV–Vis detector for HPLC, may detect a separated compound, by matching the retention time to that of a known standard compound and pattern of UV–Vis scan. In addition to univariate identification, e.g., retention time in chromatography, and wavelength/frequency in spectrometry, the use of mass spectrometry is an excellent tool to define the chemical identification.

This present entry reviews the structure, structure–activity relationship, and methods of isolation, detection, and characterization of quassinoids. Recent LCMS/MS-based techniques could effectively provide more lead molecules which would act in synergism with other compounds.

2 Structure: Quassinoids

Quassinoids are categorized into five distinct groups according to their basic skeleton, viz., C-18, C-19, C-20, C-22, and C-25 (Fig. 110.1). The C-19 and C-20 quassinoids have received particular attention in view of their bioactive properties in vitro and in vivo. The majority of isolated quassinoids have a C-20 skeleton and are δ-lactones, while the few C-19 skeletal-type quassinoids that have been isolated are γ-lactones with the lactonic linkage either at C-12 or at C-7 [3].

In the 1940s, it was reported that compounds extracted from the barks of plants belonging to the Simaroubaceae are effective against malaria [4], and subsequently, a strong antimalarial activity of many derivatives has been demonstrated. C-20 compounds are associated with antiplasmodial activity and are of two types, tetracyclic (without oxygenation at C-20) and pentacyclic (with additional oxygenation at C-20 allowing the formation of an additional ring). An α-, β-unsaturated ketone in ring one and an oxymethyl bridge are associated with providing the antimicrobial activity [5]. Quassin (**1**) and neoquassin (**2**) are the first of the quassinoids to be isolated and characterized, and all the other compounds isolated later from the members of the Simaroubaceae family are chemically related to quassin (Table 110.1).

Quassinoids have attracted much attention due to the wide spectrum of biological activities that they display, viz., antimalarial, antifeedant, anti-inflammatory, antiulcer, antipyretic, antifertility, antileukemic, cytotoxic activities, and induction of murine stem cell differentiation which have been widely reported [54–59]. We have demonstrated that quassin is a potent immunomodulatory tool that efficiently controls the establishment of leishmanial parasite within the host macrophages [60]. Our contention was that quassin could be used as a potential immunomodulator to generate the required immunity not only for the treatment of leishmaniasis but also for the treatment of other chronic infectious diseases. Subsequently, we had shown that both quassin and neoquassin can be used along with artesunate (a derivative of artemisinin) as combinatorial therapy against malaria [61].

Several novel quassinoids are being reported every year with bioactive properties, keeping the possibility of obtaining a lead molecule within the realm of possibility. Recently, six new bioactive quassinoids have been reported [62];

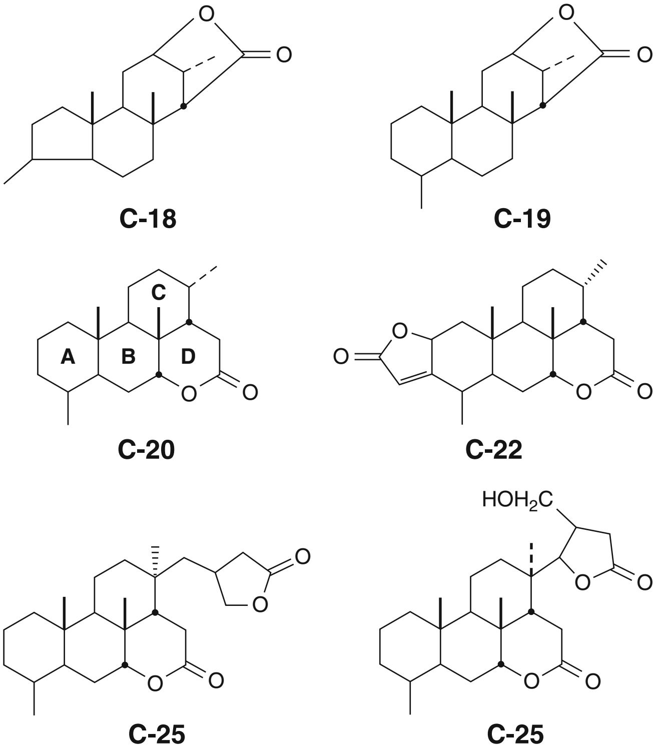

Fig. 110.1 Structural representation of C-18, C-19, C-20, C-22, and C-25 quassinoids

among these, five have unusual structure with a 2,3-seco A-ring. A new quassinoid picrasin K (**3**) was isolated from *Quassia amara* leaves with low activity on *Plasmodium falciparum* and on human cancerous cell line [41]. A compound simalikalactone E (**4**) was reported to be less cytotoxic than simalikalactone D (**5**) [63]. Two new quassinoids, javanicolide E and javanicolide F, have been isolated from the seeds of *Brucea javanica* with potential antitobacco mosaic virus activity [64]. Delaumonones A and B isolated from *Laumoniera bruceadelpha* show antimalarial activity [65].

3 Structure–Activity Relationship

In spite of rapid advances in isolation and characterization of natural compounds that have been the mainstay of traditional medicine for centuries, only a few of the thousands of potent bioactive compounds make it to the stage of clinical trials. This has led to a decline in mining of potent bioactive compounds in the latter half of the twentieth century [66]. Although natural products have provided the best antimalarial compounds known till date, the activity of the isolated compound at several

Table 110.2 Analysis of structure activity relationship in quassinoids

Activity	SAR analysis	Reference
Antileukemic	Inhibition of protein synthesis by binding to ribosome	[67]
Inactivation of rabbit reticulocyte ribosomes	Double bonds in the A-ring and lactone ring	[68]
Inhibitors of induced inflammation and arthritis in rodents	3-Hydroxy-delta 3-2-oxo moiety and C-15 ester-bearing delta-lactone ring in brusatol, 1-hydroxy-delta 3-2-oxo moiety in brucein-D, C-11 and C-12 free hydroxyl groups	[69]
Inhibitory effect on Epstein–Barr virus activation	Methyleneoxy bridge and side chain enhance activity, sugar moiety-reduced activity	[70]
Herbicide	Oxymethyl bridge	[71]
Antimalarial activity	Ring A functionality, oxygenation at C-2	[56]
Eukaryotic protein synthesis	Nature of C-15 side chain, nature of A-ring modifications, presence or absence of sugar moiety, the presence of an epoxymethano bridge	[51]
Antitrypanosomal activity	Presence of a diosphenol moiety in ring A, the nature of the C-15 side chain	[72]
Antimalarial activity	Unsaturated lactone on ring A, oxymethyl bridge between C-8 and C-11	[63]

instances do not account on their own for the activity of the crude extract [66]. Structure–activity relationship (SAR) analysis enables the determination of chemical groups responsible for evoking a particular biological effect and as such is immensely important in understanding its potency. Recently, the method has been refined as quantitative structure–activity relationship (QSAR), which provides a mathematical relationship between the chemical structure and biological activity.

Several SAR studies have been conducted on the wide range of activities attributed to quassinoids (Table 110.2) and is discussed in detail in recent review articles [55, 56]. A strong correlation between the potent antileukemic activity and the ability to inhibit protein synthesis by bruceantin (**9**) has also been reported [67]. For the potent use of quassinoids as herbicides, the oxymethyl bridge is reported to be required by computer modeling [71]. SAR analysis reveal that quassinoids affect eukaryotic protein synthesis depending on the nature of C-15 side chain, nature of A-ring modifications, presence or absence of sugar moiety, and the presence of an epoxymethano bridge [51]. Enhancement of biological activity is reported to be due to the free hydroxyl at C-1 or C-3 because of the intramolecular hydrogen bonding between the hydroxyl and oxygen of the enone which further activated it toward a nucleophilic attack [71, 73]. Several workers have addressed the SAR in C-, D-, and E-rings (Fig. 110.2) of C-20 quassinoids whereby oxygenation pattern and integrity of the D-ring and E-ring are essential for antitumor activity [74–79]. It has also been suggested that the C-ring is flattened due to the E-ring which holds the quassinoid in a stable, biologically active confirmation.

In addition, several extensions of the SAR studies by multilinear regression, artificial neuron network, regression through origin, etc. have enabled better understanding of the mechanism of binding bioactive compounds to potential targets [80]. The utilization of techniques such as QESAR (quantitative electronic structure–activity relationship) has facilitated the designing of novel derivatives [81, 82]. The mode of action of quassinoids on the GABA receptor for potential nematocidal activity has been evaluated by comparative molecular field analysis, a method of three-dimensional quantitative structure–activity relationship analysis [83]. Several potent antitumor and anti-HIV drug candidates based on natural compounds have been developed employing bioactivity and mechanism of action-directed isolation and characterization coupled with rational drug design-based modification and analogue synthesis [84, 85]. Chemical modification of quassin into γ-lactone is reported to enhance its antiplasmodial activity with a derivative 15α-hydroxy,16-O-m-chlorobenzoyl analogue showing 506-fold enhanced activity [3]. Quassinoids are potent molecules against cancer and is known to downregulate c-Myc, a transcription factor that regulates induction of differentiation and controls apoptotic pathways [86, 87]. In view of above findings, quassinoid derivatives have a fresh lease of life as bioactive natural products. Although the effectiveness of several quassinoids is unquestionable, some are too toxic to be used without any modification and synthesis of suitable analogues. About 65% of the novel small molecule drugs introduced from 1981 to 2006 are either natural products or their derivatives.

4 Isolation, Detection, and Characterization

4.1 Isolation Methods

Crude plant extracts contain several hundreds of secondary metabolites of varying chemical nature and spectroscopic parameters. Several of these compounds are also

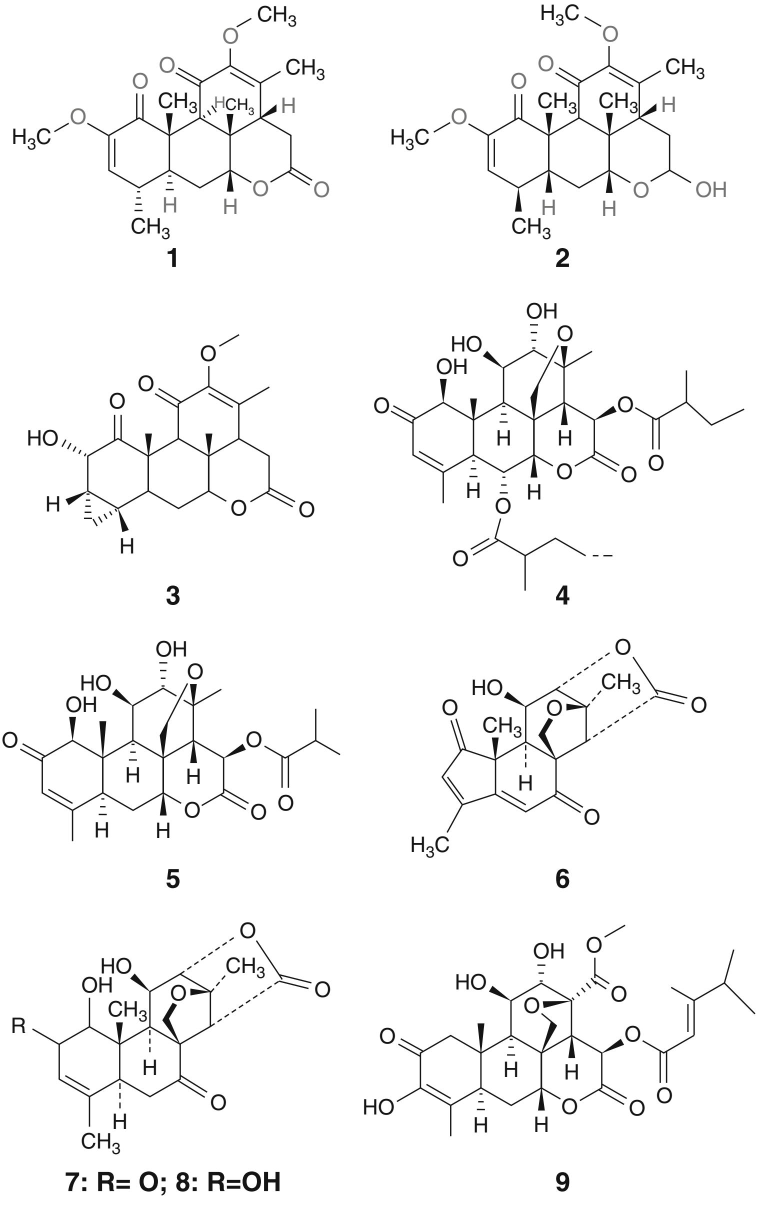

Fig. 110.2 Quassinoids. *1*. Quassin, *2*. neoquassin, *3*. picrasin K, *4*. simalikalactone E, *5*. simalikalactone D, *6*. samaderin A, *7*. samaderin C, *8*. samaderin B, *9*. bruceantin

present as conjugates within the cell and are difficult to separate from the tissue matrix. Extraction, chromatographic purification, or isolation is thus important for the detection, identification, and quantification of such compounds. Several chromatographic methods such as paper chromatography (PC), thin layer

Extract containing concentrated quasinoids.

Scheme 110.1 Protocol for isolation of simalikalactone from *Quassia amara*

chromatography (TLC), high-performance liquid chromatography (HPLC), and gas chromatography (GC) have been standardized for the purpose of isolation and quantification of secondary metabolites.

Optimization of extraction methods for bioactive compounds from plants often encounters several challenges in effectively isolating it from the complex matrix. Extraction rate expressed as the amount of a compound isolated from a given amount of raw material provides an indication of the suitability of the method in the recovery of said phytochemical. Quassinoids are generally extracted in alcoholic solvents or in a combination of methanol–water and methanol–chloroform at different ratio. Extraction of plant material with hexane and several times with boiling water followed by subsequent extraction in chloroform is used in some extraction protocols. Using several solvents sequentially for removing the interfering compounds have also been followed for some of the quassinoids. In *P. amarus* [88], extraction of the plant material is performed in 50% methanol for 72 h followed by rinsing with extraction solvent (1:10) for another 72 h prior to filtration. The supernatant is concentrated and extracted three times with hexane and the residual water extract utilized for analysis of quassinoids. During the extraction step with hexane, chlorophyll is removed by liquid-phase extraction. The crude extract is generally freeze dried. However, several modifications are reported for various quassinoids, and purification of the aqueous decoction [63] is now routinely done (Scheme 110.1) with the advent of highly sophisticated detection techniques.

4.2 Separation/Purification Techniques

Chromatographic techniques are routinely used for separation and also when coupled to spectrographic detectors for identification of components in a complex mixture of extracted compounds. Components of the crude/partially purified extract are carried through stationary phase by the mobile phase and separations based on the differences in migration rates between the sample components.

4.2.1 Thin Layer Chromatography (TLC)

TLC is a simple, inexpensive technique that can be effectively used for the analysis of natural products including quassinoids. In addition to being used as an analytical tool, TLC is also used to partially purify and isolate quassinoids as in column chromatography. The effectiveness of the separation depends on the extract, choice of mobile phase, and absorption layer such as silica gel, alumina, cellulose powder, polyamides, and ion-exchangers supported on glass or metal plate. R_f values or the retention factor is commonly used to describe chromatographic behavior and is defined as distance moved of a particular spot divided by the distance moved by the solvent front. Comparative R_f values can be utilized to analyze extracts both qualitatively and quantitatively. Quassinoids give red color on TLC plate when sprayed with concentrated sulfuric acid and brown when heated. Various stationary and mobile phases have been utilized in the separation of quassinoids, viz.:

- Whatman linear-K preparative plate with methylene chloride–methanol–acetic acid (65:10:1) as the mobile phase [23]
- Silica gel with toluene–ethyl acetate as solvent phase (4:1) and detection by a radiochromatoscanner [89]
- Silica gel eluted with toluene–acetone-acetic acid (70:30:0.05) or n-butanol–acetic acid–water (65:15:25) and spots identified under short-wave UV light and sprayed further with iodoplatinate and anisaldehyde–sulfuric acid reagent [90]
- Silica gel with diethyl ether–methanol (9:1), detection under UV light and after spraying subsequently with 5% phosphomolybdic acid and 60% sulfuric acid in methanol, followed by heating at 120 °C for 10 min

4.2.2 High-Performance Liquid Chromatography

With the advent of HPLC techniques, the separation and detection of natural products with better resolution is possible. HPLC techniques for quassinoids were developed in the early 1980s [91, 92] and thereafter have been extensively used (Table 110.3). Several protocols are available for the HPLC separation of quassinoids employing different columns and mobile phases for a specific set of compounds. HPLC technique requires the comparative profile of the standard for identification which is generally based on UV–Vis detection but with the advent of mass spectrometers coupled to the LC system that has given a definite edge to this popular technique over the others. Both isocratic and complex gradient programs have been used for the separation of quassinoids.

Although RP HPLC provides the most efficient separation of biological samples, a survey of available literature indicates that most commonly used solvent systems involving acetonitrile/methanol–water give unsatisfactory resolution of quassinoids necessitating addition of n-heptane and sulfonic acid in gradient flow [101]. Such solvents also hinder further processing of the eluted compounds for mass spectrometry confirmation. HPLC method for analysis and purification of quassinoids from *Q. amara* dates back to the early 1980s [102]. Solid-phase extraction method on a phenyl sorbent was used for the extraction of quassin from spirits and quantitative determination carried out using HPLC on a RP-18 column with acetonitrile as a mobile phase and detection using UV and fluorescence [92]. A linear gradient of methanol–water–ammonium acetate–acetonitrile in a Microsorb phenyl column was used to separate quassinoids [11] with neoquassin eluting at 27 min and 28 min and quassin at 30 min with a total run time of 55 min. Separation of neoquassin and quassin is reported in a Waters RP Nova-Pak C18 column using acetonitrile–water (65/35) with neoquassin eluting at 6.0 and 6.4 min and quassin at a very short interval of 6.8 min [94]. Although the solvent system is compatible to LC–MS, collection of compound fractions was very difficult. Also, the resolution of the peaks could not be improved using methanol. Another protocol was developed to separate quassin from *P. crenata* extract with linearity for quassin in the range 13.13–100 μg/mL [97]. The aqueous extract showed linear response within the range 0.978–6.520 mg/mL. Recently, an isocratic protocol has been reported with a simple gradient run of 40–100% methanol–water in a Phenomenex Luna RP C18 column with well-separated peaks of quassin eluted at 14 min and isomers of neoquassin eluted at 21 and 23 min [61]. The separated compounds can be directly applied for mass analysis. Methanol is less toxic as compared to acetonitrile and is the preferred solvent in RP HPLC [103].

4.3 Structure Determination

Classical methods of structure determination including UV and IR spectroscopy, optical rotatory dispersion and circular dichroism, and later on NMR spectroscopy were instrumental in the structure elucidation of natural products including quassinoids. Early in the application of NMR spectroscopy, chemical shift and multiplicity of signals on chemical changes provide useful methods for assigning signals and interrelating protons. As many terpenoid compounds differ only in the number of the hydroxyl group or esters, the changes in spectra associated with changes in functionality provide means for establishing structures [104].

Novel mass spectrometric techniques are increasingly being used for the identification of quassinoids. These techniques have the advantage as they can be coupled to chromatographic techniques and allow comparative analysis with a database or library of previously reported structures. In 1958, the first application of mass spectrometry to the analysis of biomolecules was reported [105]. Mass spectrometry (MS) is an excellent analytical tool to measure the mass-to-charge (m/z) ratio of charged particles [106]. Many ionization methods are available, viz., atmospheric-pressure chemical ionization (APCI), electron impact ionization (EI), chemical ionization (CI), thermospray ionization (TSP), field desorption ionization (FDI), fast atom bombardment (FAB), electrospray ionization (ESI), and matrix-assisted laser desorption ionization (MALDI). The ionization procedure is involved in the formation of molecular ions; both positively and negatively charged ions are generated by depending on the proton affinity of the sample.

With the development of sensitive LC/MS methods, it has been possible to differentiate and make comparative studies as demonstrated in a study with Jamaica quassia (*Quassia excels*) and quassia extract (*P. quassioides*) whereby the main constituents isolated were quassin and two isomers of neoquassin; however, there was a difference in the minor components. This finding is of significance to evaluate the quality and suitability of the extracts when used as food additives. An ultraperformance liquid chromatography–time-of-flight mass spectrometry (UPLC–TOFMS) protocol for multiresidue determination of the sum of quassin and neoquassin in strawberry has been developed [107].

A combination of column chromatography, ODS HPLC, IR, ^{1}H and ^{13}C NMR, ESI-MS (neg.), and HR-ESI-TOF-MS (pos.) was utilized in isolation two novel quassinoids, delaumonones A (HR-ESI-MS [*m/z* 531.187 $(M + Na)^{+}$]) and B (HR-ESI-MS [*m/z* 523.2180, $(M + Na)^{+}$]) from *Laumoniera bruceadelpha* [108]. LC ESI-MS/MS has been utilized in the determination of quassin and neoquassin in fruits and vegetables [98] of *Q. amara*. Limit of determination (LOD) and limit of quantification (LOQ) for both quassinoids were 0.5 and 1 μg/kg, respectively, while for picrasinoside B, they were 5 and 10 μg/kg. This study demonstrated that multiple reaction transitions of precursor ions can be used for analytical purposes, and it is possible to detect and quantify quassinoids at trace levels.

Three LC–MS/MS hybrid systems (QTof, TripleTof, and QTrap) have been used to profile small metabolites (*m/z* 100–1,000) and to detect quassinoids along with alkaloids, triterpene, and biphenylneolignans from the aqueous extracts of *Eurycoma longifolia* collected from two different geographical terrains – Pahang and Perak [99]. The use of LC–MS/MS hybrid system enabled the simultaneous detection of 38 quassinoids (particularly eurycomanone and its derivatives) that were present in higher concentration compared to other group of metabolites. It was also possible to tag particular quassinoid to a particular geographical location, e.g., 3,4ε-dihydroeurycomanone was detected only in the Pahang extract, whereas canthin-6-one-3N-oxide was detected only in the Perak extract. Another study on the same plant compares electrospray ionization (ESI) and atmospheric-pressure chemical ionization (APCI) mass spectrometry using automated flow injection analysis (FIA) to the determination of eurycomanone, 13α (21)-epoxyeurycomanone, eurycomanol, eurycomanol-2-*O*-*β*-D-glucopyranoside, and 13,21-dihydroeurycomanone [100]. The detection limits (LODs) determined in isolation mode (selected ion monitoring, SIM) ranged between 0.03 and 0.1 μg mL^{-1}, while the intraday and interday precisions were less than 5.72% and 4.82%, respectively. Mass spectrometric techniques provide a robust and high-throughput method for the detection of quassinoids in minute compounds.

5 Conclusion

The importance of quassinoids as anticancer and anti-HIV compounds has revived with the isolation and characterization of new bioactive compounds. Its efficacy as combinatorial drug coupled with the structure activity analysis has provided novel structural leads for drug development. The present methods of detection including LC–MS/MS techniques could effectively provide more lead molecules which might act in synergism with other compounds. Rigorous evaluation of traditional medicines involving controlled clinical trials in parallel with agronomical development for enhanced in vivo production of active compounds could alleviate availability of phytochemicals at an acceptable cost that would ameliorate disease control and would also serve as a source of income generation.

Abstract

Carotenoids have received much attention because of their various functions. They are natural pigments synthesized by plants and some microorganisms. Carotenoids exhibit yellow, orange, and red colors but when they are bound to proteins, they acquire green, purple, or blue colors. They are found in a large number of natural products, such as fruits, vegetables, and sea products.

1 Introduction

Carotenoids have been of great interest, and their importance in food coloration has been reviewed by some researchers [1–5]. Carotenoids are notable for their wide distribution, structural diversity, and various functions. More than 600 carotenoids, not including cis and trans isomers, have been isolated and characterized from natural sources, including the enormous array of carotenoids in algae, bacteria, yeast, and fungi [6].

Hydrocarbon carotenoids (e.g., β-carotene, lycopene) are known as carotenes, and oxygenated derivatives are called xanthophylls. Common oxygen substituents are the hydroxy (as in β-cryptoxanthin), keto (as in canthaxanthin), epoxy (as in violaxanthin), and aldehyde (as in β-citraurin) groups. Carotenoids can be acyclic (e.g., lycopene), monocyclic (e.g., γ-carotene), or dicyclic (e.g., α- and β-carotene). In nature, carotenoids exist primarily in the more stable all-trans (or all E) form, but small amounts of cis (or Z) isomers do occur.

Because plants are able to synthesize carotenoids de novo, the carotenoid composition of plant is enriched by low levels of biosynthetic precursors and derivatives of the main components. Carotenoids are not as widely distributed in animals and are present at much lower levels. Animals are incapable of carotenoid biosynthesis and hence depend on dietary carotenoids, which are selectively or unselectively absorbed, converted to vitamin A, and deposited as such or slightly altered to form carotenoids typical of animal species.

Figure 111.1 shows the principal carotenoids found in natural products, together with zeaxanthin, which is not as ubiquitous. β-Carotene, α-carotene, β-cryptoxanthin, lutein, and lycopene are also the carotenoids most commonly found in human plasma. These carotenoids, together with zeaxanthin, have been shown to have health-promoting effects.

β-Carotene, α-carotene, and β-cryptoxanthin are provitamins A. Structurally, vitamin A (retinol) is essentially one-half of the β-carotene molecule. Consequently, β-carotene is the most potent provitamin A; it is also the most widespread [7, 8]. The minimum requirement for a carotenoid to have vitamin A activity is an unsubstituted β-ring with an 11-carbon polyene chain. Thus, α-carotene and β-cryptoxanthin exhibit about 50% of the vitamin A activity of β-carotene.

Carotenoids, whether provitamins A or not, have been credited with other beneficial effects on human health: enhancement of the immune response and reduction of the risk of degenerative diseases such as cancer, cardiovascular diseases, cataract, and macular degeneration [9–19]. The action of carotenoids against diseases has been attributed to an antioxidant property, specifically, their ability to quench singlet oxygen and interact with free radicals [20]. However, other mechanisms have been reported: modulation of carcinogen metabolism, inhibition of cell proliferation, enhancement of cell differentiation, stimulation of cell to cell communication, and filtering of blue light [15, 21].

The ability of carotenoids to quench singlet oxygen has been linked to the conjugated double bond system, the maximum efficiency being shown by carotenoids with nine or more conjugated double bonds [22]. The acyclic carotenoid lycopene was found to be more efficient than the dicyclic β-carotene [23], despite both compounds possessing 11 conjugated double bonds. The effects of lycopene on human health have drawn considerable interest in recent years [24–33], the current evidence being stronger for lycopene protection against lung, stomach, and prostate cancer.

Recently, food processors and technologists have shown a great interest in the extraction, identification, and purification of natural colorants, including carotenoids. This unit describes a practical way of extracting, isolating, and purifying

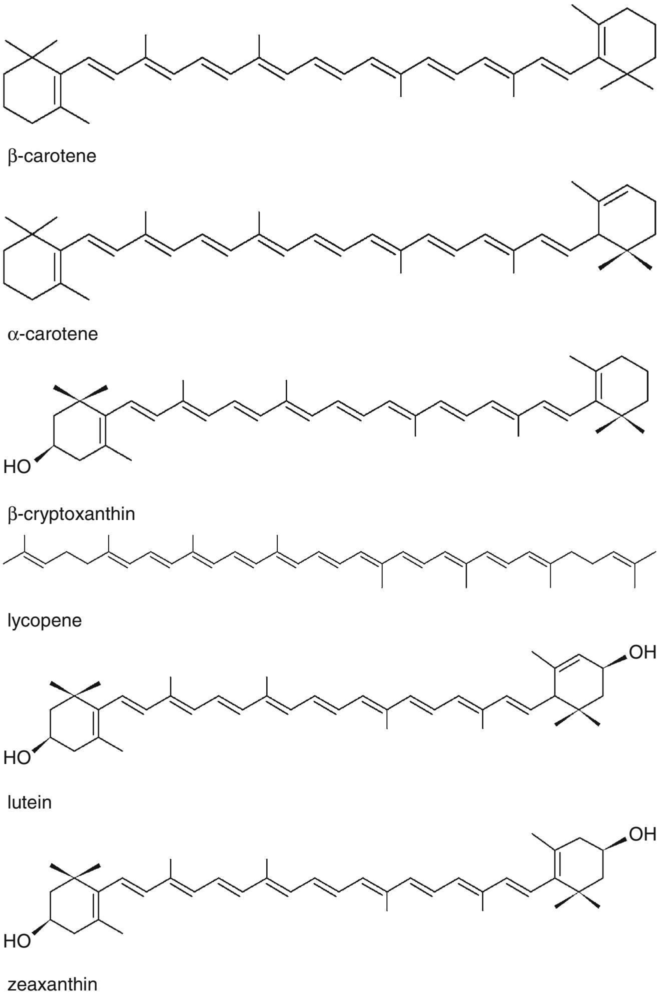

Fig. 111.1 Stuctures of the principal carotenoids in natural products and zeaxanthin

carotenoids from plant materials. The method is based mainly on the natural form in which the carotenoids are found (esterified or free) and to some extent on their polarity and/or solubility in the solvents used. Common and readily available solvents and laboratory equipment are suggested.

The extraction and isolation of three groups of carotenoids of different polarities are described in Sect. 2. A method for prepurifying carotenoids using crystallization is described in Sect. 3. Carotenoids may be purified further by chromatographic techniques and characterized (Sect. 4). The preparation of the sample before extraction is described in Sect. 2.1.2. This process consists mainly of removing water from the sample, followed by sample grinding or homogenizing.

In this chapter, extraction is carried out using solvents. Other methods for extracting carotenoids are available. Supercritical fluid extraction (SFE) has been used for extracting and isolating carotenoids from natural product samples since this technique shows several advantages, for example, more speed in extraction, the evaporation step is not required, and carbon dioxide, the fluid most used in SFE, is nontoxic, its cost is low, it is non-flammable, and it is environmentally acceptable [34]. In addition, carbon dioxide has a low critical temperature (31°C), making it ideal for extraction of thermally labile compounds. Nevertheless, carbon dioxide presents a low polarity and makes the extraction of polar compounds very difficult. This limitation can be solved by adding an organic modifier such as methanol or ethanol in order to increase its solvation power [35]. The use of supercritical carbon dioxide is described by Spanos et al. [36], Mendes et al. [37], de Franc et al. [38], Cadoni et al. [39], Canela et al. [40], Rozzi et al. [41], Machmudah et al. [42–44], Macias-Sanchez et al. [45], Prado et al. [46], and Ruen-ngam et al. [47]. The SFE conditions are summarized in Table 111.1.

Enzymes may also be used to help digest plant material and then facilitate carotenoid extraction by physical or chemical means [53–55]. Ultrasound may also be used to aid the extraction process; it is used in laboratory and industrial work for extracting carotenoids and other compounds [56, 57]. Vegetable oil may be used as an extractant and carotenoid carrier [44, 58, 59]. However, using oils for extraction produces low carotenoid concentrates. By introducing organic solvents, pigments are more easily solubilized, and extracts of high purity may be obtained.

2 Solvent Extraction and Isolation of Carotenoids

This section begins with the extraction of a dehydrated sample. It continues with a saponification procedure to initiate the isolation of the carotenoid mixture. During saponification, the esters are hydrolyzed and the free pigments released. Then, to continue the isolation, open-column chromatography (OCC) is suggested as a simple and fast means of separating the three main groups of carotenoids based on their different polarities.

2.1 Carotenoids Extraction

Numerous organic solvents such as acetone [60–64], tetrahydrofuran (THF) [65, 66], n-hexane [67, 68], pentane [51], ethanol [69, 70], methanol [71, 72], and chloroform [41], as well as solvent mixtures such as dichloromethane:methanol (6:1, v/v) [73], acetone:petroleum ether (50:50, v/v) [74], THF:methanol (1:1, v/v) [75, 76], n-hexane:toluene (5:4, v/v) [77], *n*-hexane:acetone (6:4, v/v) [78], 2-propanol:dichloromethane (2:1, v/v) [79], *n*-hexane:ethyl acetate (85:15, v/v) [80] and *n*-hexane:acetone:ethanol (50:25:25, v/v/v) [81] have been widely used. Thus, Taungbodhitham et al. [82] evaluated six different solvent combinations: acetone:hexane (4:6, v/v), ethanol:hexane (4:3, v/v), chloroform:methanol (2:1, v/v), dichloromethane:methanol (2:1, v/v), hexane:isopropanol (3:2, v/v),

Table 111.1 Example of supercritical fluid extraction conditions employed in carotenoid analysis

Sample	Carotenoid	Supercritical fluid	SFE conditions (temperature, pressure, flow rate)	References
Tomato	All-trans-lycopene	CO_2 without modifier	T = 40°C Pressure: 281 bar Flow rate: 4 ml/min	[48]
Tomato seeds and skins	Lycopene, β-carotene, α-carotene, α-tocopherol, γ-tocopherol, δ-tocopherol	CO_2 without modifier	T = 86°C Pressure: 345 bar Flow rate: 2.5 ml/min	[41]
Algae *Dunaliella bardawil*	Geometrical isomers of β-carotene	CO_2 without modifier	T = 40°C Pressure: 448 bar Flow rate: 0.5 − 1 ml/min	[49]
Tomato paste waste	Lycopene, β-carotene	CO_2 and 5% ethanol as modifier	T = 55°C (lycopene), 65°C (β-carotene) Pressure: 300 bar Flow rate: 4 kg/h	[50]
Vegetables (carrots, collard, turnip greens, kale, mustard greens, broccoli flowerets, zucchini, yellow squash)	α- and β-carotene	CO_2 and ethanol as modifier	T = 40°C Pressure: 342 bar Flow rate: 1.5 ml/min	[51]
Spirulina pacifica algae	β-Carotene, β-cryptoxanthin, zeaxanthin	CO_2 and 15% ethanol as modifier	T = 80°C (zeaxanthin), 76°C (β-cryptoxanthin), 60°C (β-carotene) Pressure: 342 bar Flow rate: 1.5 ml/min	[35]
Carrots (*Daucus carota* L. var. Caro Pride)	α- and β-carotene	CO_2 and 5% chloroform as modifier	T = 40°C Pressure: 606 bar Flow rate: 1 ml/min	[52]
Haematococcus pluvialis algae	Astaxanthin	CO_2 and ethanol as modifier	T = 40–80°C Pressure: 200–550 bar Flow rate: 2–4 ml/min	[42]
Rose hip fruit	Lycopene, β-carotene, lutein	CO_2 without modifier	T = 40–80°C Pressure: 150–450 bar Flow rate: 2–4 ml/min	[43]
Tomato peel waste	Lycopene, β-carotene	CO_2 and tomato seed oil as modifier	T = 70−90°C Pressure: 200−400 bar Flow rate: 2−4 ml/min	[44]

and acetone:petroleum ether (50:50, v/v) to extract lycopene and α- and β-carotene from canned tomato juice, and the best recoveries were obtained with the ethanol: hexane mixture. Deli et al. [83] used methanol followed by diethyl ether to extract carotenoids from fruits of pepper (Capsicum annuum var. lycopersiciforme rubrum). Gandul-Rojas et al. [67] extracted chlorophylls and free and monoesterified xanthophylls with dimethylformamide and carotenoids with hexane from olive fruits.

A good extraction procedure should release all the carotenoids from the natural products matrix and bring them into solution, without altering them. Because carotenoids are found in a variety of natural products, the extraction procedure should be adapted to suit the plant being analyzed. The solvent chosen should efficiently extract all carotenoids present in the sample. Because the solvents used in extraction will ultimately be removed or at least reduced by evaporation, solvents with low boiling points should be chosen to avoid prolonged heating.

The solvent used for extraction must be chosen according to the polarity of the pigments presumably present. If this characteristic is unknown, an acetone/hexane (1:1, v/v) mixture is suitable [84]. When it is known that the carotenoids in the sample are nonpolar or are in the ester form, hexane is a good choice for extraction. Ethanol will extract polar carotenoids, and a nonpolar solvent like hexane will promote crystallization. Simple procedure for extraction of carotenoids is describe here.

2.1.1 Extraction Procedure

1. Place dried/dehydrated plant material (see Sect. 2.1.2) and filter paper in a 500-ml extraction vessel.
2. Add 3 vol (v/w) solvent (1:1 (v/v) hexane/acetone or hexane alone) and mix for 15 min using an explosion-proof shaft mixer to suspend paste in solvent.

   Solvent is 1:1 (v/v) hexane/acetone or hexane alone.

   The type of solvent should be chosen based on the carotenoids of interest. No heating is necessary.
3. Vacuum filter mixture using Whatman no. 42 filter paper. Save filtrate.
4. Separate filtrant cleanly from filter paper, if possible, and extract a second time using 2 vol solvent. Continue extractions using smaller volumes of solvent until no appreciable color is observed in filtrate. Save and pool all filtrates.

   Note:

   If filtrant cannot be separated from paper; both should be placed in the extraction vessel.

   At this point, concentrated filtrate from the sample preparation (see Sect. "Removal of Water from Carotenoid-Containing Samples Using Alcohol," step 8) may be pooled with the filtrates.
5. Concentrate extracts to ~40 ml in a rotary evaporator attached to a vacuum pump at ≤55°C.
6. Add 3 ml saponifying solution and stir for 45 min at 56°C.
   - This is the temperature recommended for hot saponification of pigments by the AOAC [85].
   - Saponifying solution: 40% (w/v) KOH in methanol (cool to room temperature before bringing up to volume)

7. Transfer saponified extract to a 125-ml separatory funnel and add 1 vol salting-out solution.
    - Salting-out solution: 10% (w/v) Na_2SO_4
8. Remove bottom layer and wash upper layer three times with 10 ml water.
9. Add 3 g anhydrous Na_2SO_4 and filter using Whatman no. 42 filter paper.

2.1.2 Sample Preparation

For extraction, water content is considered an important factor. It has been found that working with low-moisture samples simplifies the extraction process. Industrial extraction normally is done with dry material, which reduces complications arising from the solvents used for processing and their recovery.

The plant material as prepared in sections "Removal of Water from Carotenoid-Containing Samples Using a Vacuum Oven and "Removal of Water from Carotenoid-Containing Samples Using Alcohol," is ready for extraction. It may contain some water (≤10%), which will not affect extraction. Freeze-drying may be another way of eliminating water with little pigment damage and may be an acceptable alternative to drying in a vacuum oven as long as the moisture content is taken to an appropriate level for efficient extraction. Freeze-drying is not adequate if sugar or other water-soluble compounds must be eliminated by physical separation (e.g., by filtration or centrifugation).

Removal of Water from Carotenoid-Containing Samples Using a Vacuum Oven

Plant tissues contain variable amounts of water, which is easily eliminated in order to facilitate extraction with organic solvents. Using a low-temperature vacuum oven is a good way of removing water from materials that are easily pulverized. This is true for many vegetables [86]. The procedure for removing water from materials is described below.

Procedure:

1. Weigh plant tissue of interest and record weight.
    Note:
    The initial wet weight is important as, in many cases, extraction and purification of carotenoids are done to quantify pigment concentrations, which must be related to the fresh material.
    The amount of tissue used is dependent on the expected pigment concentration. Usually 100–500 g is appropriate.
2. Place sample inside a vacuum oven at 60°C. Maintain set temperature.
3. Turn on and control the vacuum between 12 and 20 in.Hg (305–508 mmHg).
4. Open oven door occasionally during drying and stir material to obtain uniform dehydration.
5. Dry to ~8% moisture content.
    Note:
    Overdrying can damage the carotenoids present in the sample.

A moisture balance calibrated to indicate an 8% moisture content can be used to monitor weight loss and may be useful until experience is gained. The calibration can be performed as a gravimetric determination on a sample analyzed in parallel. This measurement can also be used to estimate an 8% moisture content relative to the initial sample weight.

6. Grind material to an appropriate size (≤30 mesh) with a laboratory mill.
7. Weigh powder for extraction.

   The weight will also be indicative of residual moisture if the initial amount is known.

Removal of Water from Carotenoid-Containing Samples Using Alcohol

This procedure is a practical way of removing water from plant tissues when water is needed for homogenization or when the dry material cannot be ground to a powder due to the presence of lipids, waxes, or sugars [86].

Procedure:

1. Weigh plant tissue of interest and record weight.
2. Mix plant tissue to a paste with an explosion-proof shaft mixer. If the material does not lend itself to mixing, add sufficient water to homogenize sample.
3. Add 2 vol of 95% ethanol to homogenate, and mix thoroughly for 5 min.
4. Vacuum filter homogenized sample using Whatman no. 41 filter paper. Save filtrate.
5. If filtrate is cloudy, repeat steps 3 and 4 using 1 vol of 95% ethanol. If filtrate is clear, continue with step 6.

   Note:

   A cloudy filtrate is an indication that additional alcohol is needed.
6. Remove and save filtrant along with the filter paper. Store ≤24 h at −20°C.
7. Pool filtrates in a separatory funnel. Add 1 vol hexane.

   Note:

   Some of the more polar pigments are usually carried into the filtrate and must be recovered by extraction.
8. Remove bottom layer and concentrate upper layer containing the lipophilic carotenoids in a rotary evaporator attached to a vacuum pump at ≤55°C. Store ≤24 h at −20°C.

2.2 Carotenoid Isolation

Carotenoid isolation is carried out in open-column chromatography (OCC). OCC should be carried out under a fume hood to protect the analyst from inhaling solvent vapor. Breathing hexane, for example, should be avoided due to neurotoxicity of some of its oxidative metabolites [87]. The isolation procedure is as follows.

Procedure

1. Plug the bottom of a 600 × 40-mm chromatography column with glass wool. Mount the column on a vacuum filtration device using a 1-l filtration flask as a receiving vessel.

2. Add adsorbent to obtain a 20-cm layer while applying vacuum.
   Note:
   Adsorbent: Mix equivalent weights of silica gel 60 GF_{254} (Merck) and diatomaceous earth (Hyflo Super-Cel; Celite, World Minerals) in a mechanical blender or in a large plastic bag for 2 h. Store $\leq$3 months in a sealed container at room temperature [85].
3. Level the surface of the adsorbent and place a firm 2-cm layer of anhydrous Na_2SO_4 on top.
4. Pour carotene eluant into column until eluant wets all of the adsorbent.
   Note:
   Carotene eluant: 4% (v/v) acetone in hexane.
5. Replace receiving vessel with a clean flask and pour filtrate (2.1.1 step 9) into column.
6. Allow all the sample to penetrate into the adsorbent and then add carotene eluant until the first carotenoid band that separates is completely collected in the flask.
   - The carotenes and esters present in the sample are contained in this fraction. Other carotenoids remain on the column.
   - The chromatography process is monitored visually. The exact volume of eluant added to the column will vary depending on sample concentration and composition.
7. Elute monohydroxy pigments with monohydroxy pigment (MHP) eluant and dihydroxy pigments and more polar pigments with dihydroxy pigment (DHP) eluant using a clean receiving flask for each. If necessary, store pigments $\leq$24 h at 0–5°C and protect from light.
   Eluates should be processed as soon as possible.
   Note:
   - MHP eluant: 1:9 (v/v) acetone/hexane
   - DHP eluant: 1:8 (v/v) acetone/hexane

3 Prepurification of Carotenoids by Crystallization

Once the carotenoids have been isolated as described in Sect. 2.2, they can generally be crystallized as an initial step to purification. Actually, what is most likely to happen is a co-crystallization. When working with a nonpolar fraction, α- and β-carotene may co-crystallize. In the same way, a polar fraction may yield lutein – zeaxanthin crystals. A pure carotenoid product may be obtained by crystallization of a fraction derived from a preparatory chromatographic procedure, which can be done using TLC, HPLC (Sect. 4), or in some cases column chromatography [84]. The crystallization procedure is shown here.

Procedure:

1. Place isolated carotenoid eluate (Sect. 2.2, steps 6 and 7) in a 50- or 125-ml pear-shaped flask and concentrate eluate to near saturation in a rotary evaporator attached to a vacuum pump under a stream of nitrogen from a nitrogen gas tank.

Note:

- Only one carotenoid eluate (carotenes, MHPs, or DHPs) should be prepurified at a time.
- The flask size will depend on the volume of eluate to be concentrated.

2. Add precipitating solvent drop by drop until the solution starts turning cloudy, indicating that precipitation has begun.
   Note:
   - A solvent mixture should be selected for crystallization that will easily solubilize the carotenoid of interest and also, when added in small quantities, will force the carotenoid out of solution and start crystallization. The extractants from Sect. 2.1.1 (hexane/acetone or hexane alone) are appropriate.
   - Precipitating solvent: 1:1 (v/v) hexane/acetone or hexane alone, room temperature and cold (0–5^{o}C)
3. Refrigerate (0–5°C) solution overnight.
   Crystallization can be accelerated by placing solution at −20 to 0^{o}C for 3 or 4 h. Usually better crystals are produced by a slow crystallization.
4. Vacuum filter crystals using Whatman no. 42 filter paper. Wash crystals with cold (0–5°C) precipitating solvent.
5. *Optional*: Repeat crystallization sequence to obtain crystals of higher purity, beginning with a saturated solution of crystals (step 4) in acetone and continuing with step 2.
6. Dry crystals in a vacuum oven at 40°C, flushing drying chamber occasionally with nitrogen.
7. Pack crystals under nitrogen and store for ≤6 months at −20°C if further purification work is anticipated.

4 Analytical Method of Carotenoids

This section includes identification and measurement of carotenoids by UV/visible spectrophotometry and column chromatography. The UV/visible absorption and the chromatographic behavior spectrum provide the first clues for the identification of carotenoids. Both the wavelengths of maximum absorption (λ_{max}) and the shape of the spectrum (spectral fine structures) are characteristics of the conjugated unsaturated part of the carotenoid molecule containing delocalized π-electrons called the “chromophore.” The λ_{max} values of the carotenoids commonly found in natural products in various solvents are listed in Table 111.2.

Most carotenoids absorb maximally at three wavelengths, resulting in a three-peak spectrum. As the number of conjugated double bonds increases, the λ_{max} shifts to longer wavelengths. Thus, the most unsaturated acyclic carotenoid, lycopene, with 11 conjugated double bonds, is red and absorbs at the longest wavelengths (λ_{max} at 444, 470, 502 nm in petroleum ether) (Fig. 111.2). The dicyclic molecule β-carotene, despite possessing the same number of conjugated double bonds as lycopene, is yellow-orange and exhibits absorption peaks at 450 and 477 nm and a mere shoulder at 425 nm (Fig. 111.2). Monocyclic γ-carotene is red-orange and exhibits a spectrum

Table 111.2 UV-Visible absorption data for common natural product carotenoids

Carotenoid	Solvent	λ_{max} (nm)			%III/II
α-Carotene	Acetone	424	448	476	55

Refs. [84, 88–90]

Parentheses indicate a shoulder. %III/II is the ratio of the height of the longest-wavelength absorption peak, designated III, to that of the middle absorption peak, designated II, taking the minimum between the two peaks as the baseline, multiplied by 100

intermediate to those of lycopene and β-carotene, in both λ_{max} and shape, reflecting a structure that is intermediate with respect to the other two carotenoids. α-Carotene is light yellow, and its absorption spectrum is slightly better defined with λ_{maxs} at slightly shorter wavelengths (422, 445, 473 nm) compared with the spectrum of β-carotene.

The absorption spectra of carotenoids are markedly solvent dependent (Table 111.2). This characteristic of carotenoids must be remembered when analyzing spectra recorded by the photodiode-array detector in HPLC because such spectra are taken in mixed solvents in isocratic elution and in varying mixed solvents in gradient elution.

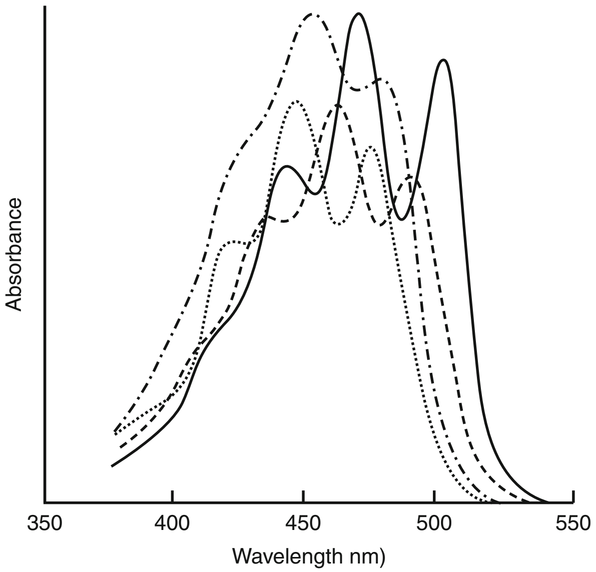

Fig. 111.2 Visible absorption spectra of lycopene (———), γ-carotene (- - - -), β-carotene (—·—·), and α-carotene (·······) in petroleum ether [88]

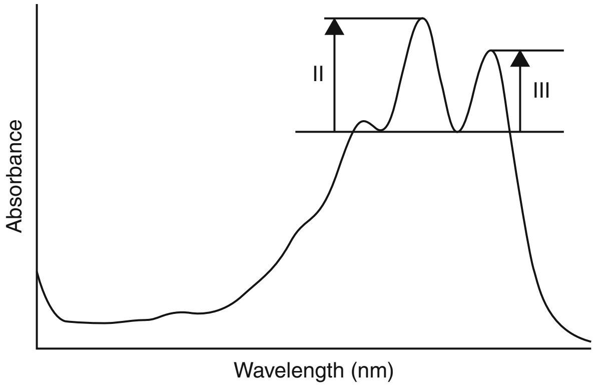

Fig. 111.3 Calculation of % III/II (III/II × 100) as an indicator of spectral fine structure [84, 88]

The λ_{max} values of carotenoids in hexane or petroleum ether are practically the same as in diethyl ether, methanol, ethanol, and acetonitrile and higher by 2–6 nm in acetone, 10–20 nm in chloroform, 10–20 nm in dichloromethane, and 18–24 nm in toluene [89].

To obtain the absorption spectral fine structure, the %III/II (Fig. 111.3) can be presented, along with the λ_{max} values. The %III/II is the ratio of the height of the longest-wavelength absorption peak, designated III, and that of the middle absorption peak, designated II, taking the minimum between the two peaks as the baseline, multiplied by 100 [89].

The chromatographic behavior of carotenoids bears a definite relationship with their structures; however, carotenoids cannot be identified based on chromatographic data alone. Nevertheless, these data serve as useful complementary information.

4.1 Analysis of Carotenoids by UV-Visible Spectrophotometry

The majority of carotenoids exhibit absorption in the visible region of the spectrum between 400 nm and 500 nm. Carotenoids in solution obey the Beer-Lambert law, where absorbance (A) equals concentration multiplied by absorption coefficient ($A^{1\%}$), where the absorption coefficient ($A^{1\%}$) is defined as the absorbance of a 1% (10 g/l) solution of carotenoid, in a defined solvent, in a 1-cm path-length cuvette, at a specific wavelength (λ). This information can be used to quantify the concentration of a pure (standard) carotenoid (see Sect. 4.1.1) or to "estimate" the total carotenoid concentration in a mixture or extract of carotenoids in a sample (see Sect. 4.1.2). The absorption coefficient may also be expressed in terms of molarity.

The absorption coefficient values of selected carotenoids in certain solvent are presented in Table 111.3. The values may contain significant levels and error or uncertainty [89], and some discrepancies can be noted in Table 111.3. Given that different authors choose different coefficients for some carotenoids (in the same solvents), this alone can account for a good part of the variations in analytical results.

As seen in Table 111.3, a 1% solution (10 g/l) of β-carotene in hexane has an absorbance of 2,592 AU and a molecular weight of 537 g/mol (i.e., 1 mM = 0.537 g/l); therefore, the absorbance expected for a 1 mM solution is (0.537 g/l)/(l0 g/l) × (2,592 AU) = 139 AU/1 mM β-carotene. Using this ratio, if a β-carotene solution has an absorbance of 5, then the concentration is given as (5 AU)/(139 AU/mM) = 0.036 mM. It is important to note that due to the inherent difficulties in procedures for accurate determination of absorption coefficients, there may be a significant level of uncertainty in some published values. Small variations (e.g., 2–3 nm) may also occur in published data of absorption maxima. Whenever possible, the spectrum of a compound under investigation should be compared directly with an authentic pure standard. The spectra of the unknown and the standard should be identical for both the λ_{max} and the fine structure (%III/II).

4.1.1 Quantification and Calibration of Individual Carotenoid Standards

In this section, commercially purchased carotenoid standards are dissolved in a suitable solvent and the absorbance measured at its maximum wavelength (λ_{max}). Using published absorption coefficients (Table 111.2) and taking into consideration the dilution factor, the concentration of the standard carotenoid is calculated. The spectrum is also scanned in order to evaluate the fine structure.

Table 111.3 Absorption coefficients ($A^{1\%}$) of selected carotenoids

Carotenoids	MW	Solvent	λ_{max} (nm)	$A^{1\%}$	$\varepsilon^{1\ mM}$

Refs. [84, 88, 89]

The carotenoid solution should ideally be assayed by HPLC as described in Sect. 4.2 to establish chromatographic purity and thus correct the calculated concentration. Procedure for quantification of individual carotenoids sample/standard is described below.

Procedure:

1. Dissolve carotenoid (e.g., ~1–5 mg) in a suitable solvent (see Table 111.2). Make to an accurate volume (e.g., 10–50 ml) in a volumetric flask.
   Note:
   A larger volume may be used if desired.
   It is essential that the carotenoid be completely dissolved. With crystalline samples, dissolution can be aided by initial addition of a small amount of a more effective solvent (e.g., dichloromethane) prior to making to volume for

spectrophotometric measurement (for most commonly assayed carotenoids, no more than 10% of the total volume should be required; however, lycopene may require up to 100%). Where a carotenoid is supplied in a sealed ampule, dissolution can be conveniently achieved by adding successive small aliquots of the more effective solvent to the ampule, and transferring to a volumetric flask. It is not easy to assess complete dissolution visually; therefore, it is advisable to filter the solution through a suitable solvent-compatible 0.45-μm filter.

Stock solutions that have been stored (e.g., in a refrigerator), should be allowed to warm up to room temperature, refiltered, and a "new" concentration calculated prior to preparing a new working solution, which should be checked for chromatographic purity.

2. Dilute the solution (e.g., 1:50) in desired solvent if necessary to give ~0.3–0.7 AU as measured on a spectrophotometer at λ_{max}.

   Note:

   It is recommended that at least two independent dilutions be made to ensure confidence in the measurement.

   If a larger final volume is used (see step 1) reduce the dilution accordingly.
3. Warm up the spectrophotometer per manufacturer's instructions.
4. Zero the spectrophotometer with solvent in a cuvette.

   Note:

   - It is not necessary to completely fill the cuvettes, ~$^2/_3$ full is normally sufficient. This helps to avoid accidental spillage.
   - Cuvettes must be kept scrupulously clean; avoid handling the surfaces of the cells.
5. Place a cuvette containing the carotenoid solution into the sample cell holder of the spectrophotometer.

   Note:

   Before placing the cells in the cell holder, the optical faces can, if necessary, be polished carefully (avoiding any spillage) with a fine tissue.
6. Measure the absorbance at λ_{max}. Take reading immediately.

   Note:

   Spectrophotometric readings should be carried out immediately after the solution has been placed in the cuvette to avoid evaporation of the solvent or degradation.
7. Scan to allow measurement of the fine structure (see Table 111.1).
8. Calculate the concentration of carotenoid as shown in the example below for all-*trans* β-carotene:

$$\frac{A \times V_1}{A^{1\%}} \times C^{1\%} = \frac{0.5\text{AU} \times 50}{2,592\text{AU}} \times 10\frac{\text{mg}}{\text{ml}} = 96.5\mu\text{g/ml} \qquad (111.1)$$

Where A is the absorbance reading of the diluted sample (0.5 AU), V_1 is the dilution factor (50×), $A^{1\%}$ is the absorbance of a 1% solution (i.e., the absorption coefficient; 2,592 AU), and $C^{1\%}$ is the concentration of a 1% solution (10 mg/ml). Using this formula, the concentration of the original solution in this example is = 96.5 μg/ml.

9. Subsequent to measurement of the carotenoid concentration, the solution should be assayed by HPLC to establish the chromatographic purity (see Sect. 4.2).

   For example, assuming the same values as (Eq. 111.1), if the total chromatographic area is 10,000, and the area of all-trans β-carotene peak is 9,500, then the chromatographic purity is 9,500/10,000 × 100 or 95%, and the actual concentration of β-carotene is 96.5 μg/ml × 95/100 or 91.7 μg/ml.

4.1.2 Measurement of Total Carotenoid Concentration in Food Colorants, Pharmaceuticals, and Natural Extracts

The same principle as described above can be used for the "estimation" of the carotenoid content of extracts of food colorants, pharmaceuticals, foods, biological samples, or chromatographic fractions. This procedure employs calculations used for individual carotenoids of high purity and thus will estimate the "total carotenoids" present in a food, biological, or natural extract, where a mixture of carotenoids would be expected. Greater accuracy can be obtained as extracts are purified to contain single components. A spectrum scan is not employed in this procedure as the fine structure of a mix of carotenoids can only be identified after HPLC separation and identification.

Procedure:

1. Prepare the sample as detailed in Sect. 2.1.2. Dilute the sample appropriately using a suitable solvent.

   Samples containing esterified carotenoids, chlorophyll, or high levels of fat may require saponification (Sect. 2.1).
2. Warm up spectrophotometer per manufacturer's instructions.
3. Zero the spectrophotometer with solvent in a cuvette.
4. Place a cuvette containing a suitably diluted (i.e., ~0.3–0.7 AU) extract of pharmaceutical, food, biological, or natural material into the sample cell holder of the spectrophotometer.
5. Measure absorbance at selected λ_{max} (Tables 111.2 and 111.3). Read immediately.
6. Estimate the total carotenoid concentration of the sample (see Sect. 4.1.1 procedures, step 9, and Eq. 111.1).

   With the exception of individual food colorants and single carotenoid pharmaceutical products, it is unlikely that the extract will be composed of only one predominant carotenoid; therefore, a specific λ_{max} or absorption coefficient (Table 111.3) cannot be used. In this case it is convenient to use a λ_{max} of 450 nm and a typical $A^{1\%}$ value of 2,500. Alternative values and other considerations are discussed below.

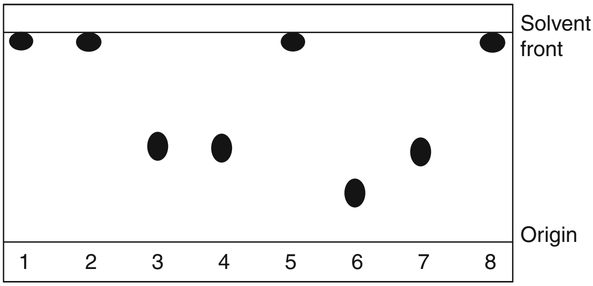

Fig. 111.4 TLC silica gel chromatogram of carotenoids and reaction products, developed with 5% methanol in toluene. *1* β-carotene, *2* lycopene, *3* β-cryptoxanthin, *4* β-cryptoxanthin methylated with acidic methanol – negative response, *5* β-cryptoxanthin acetylated with acetic anhydride, *6* lutein, *7* lutein methylated with acidic methanol, and *8* lutein acetylated with acetic anhydride [88]

4.2 Chromatographic Methods for Separation and Analysis of Carotenoids

Natural product samples typically contain both the nonpolar carotenes and the more polar xanthophylls. Whatever the method used, the chromatographic process should be able to cope with this polarity range.

Chromatography in descending, gravity-flow (often with slight pressure provided by a water aspirator) columns, known as open-column chromatography (OCC), is the classical method for separating carotenoids for quantitative analysis. It is also useful in isolating (See Sect. 2.2) and purifying carotenoids to be utilized as standards for HPLC. Separation of the carotenoid pigments is followed visually. Low pressure may also be applied at the top of the column (e.g., with N_2 gas); this technique is called flash column chromatography.

Thin-layer chromatography (TLC), although efficient in monitoring the progress of chemical tests for identification purposes, is not adequate for quantitative analysis because of the danger of degradation and isomerization on a highly exposed plate [91–93]. Carotenoids are particularly prone to oxidation by air when adsorbed on TLC plates. Additionally, it is not easy to quantitatively apply the sample on the plate and quantitatively recover the separated carotenoids from the plate for measurement. For qualitative purposes, TLC can separate the presence of oxygen substituents in carotenoids. This is demonstrated in a silica thin layer developed with 3% methanol in benzene or 5% methanol in toluene, in which all carotenes elute with the solvent front, whereas the xanthophylls are distributed along the plate according to the number and type of substituents present (Fig. 111.4). The hydroxyl group greatly influences absorption behavior. For instance, in the TLC chromatogram in Fig. 111.4, the hydroxycarotenoid appears near the origin, whereas the monohydroxycarotenoid appears near the middle of the chromatogram. The effect of more than one oxygen substituent is not always additive; a second substituent in the same end group tends to have less influence than the first.

In OCC, the column has to be packed for each analysis. A definite advantage of HPLC over OCC is that reproducible separations can be performed by using a reusable column under controlled conditions without undue exposure to air or light.

Reversed-phase HPLC on C18 columns has been the preferred mode for separating carotenoids for quantitative analysis. The popularity of the C18 column derives from its weak hydrophobic interactions with the analytes (which should make it less destructive than the polar forces in normal-phase OCC), compatibility with most carotenoid solvents and with the polarity range of carotenoids, and wide commercial availability. Many different C18 reversed-phase materials are available from different manufacturers, varying in the degree of carbon loading, end capping, and the nature of the bonded phase (i.e., monomeric or polymeric).

The majority of carotenoid separation has been carried out with 5 μm C18 spherical particles packed in a 250 × 4.6-mm column. However, shorter and narrower (narrow bore) columns, smaller particles, and C30 stationary phases are increasingly used.

Monomeric phases are simpler to use and more reproducible. Polymeric C18 phases have been found to have excellent selectivity for structurally similar carotenoids such as the geometric isomers of β-carotene [94, 95] and lutein and zeaxanthin [96]. However, the total carbon load is lower in the wide-pore polymeric phases, resulting in weak retention of carotenoids [97]. Additionally, compared with monomeric columns, the peaks tend to be broader, and columns from different production lots are more variable.

Guard columns, which should be changed frequently, are used for pigment samples to prevent particulate material and impurities from entering the analytical column, thus prolonging the column's life. Guard columns can, however, cause band broadening and could potentially retain carotenoids.

The most important properties to be considered in selecting the mobile phase are polarity, viscosity, volatility, and toxicity. In addition, it must be inert with respect to the carotenoids. Many solvent systems have been suggested as mobile phases for carotenoids, but the primary solvents are acetonitrile and methanol, with most systems being slight modifications of some basic combinations [97]. Acetonitrile has been widely used because of its lower viscosity and slightly better selectivity for xanthophylls when a monomeric C18 column is used [98]. Epler et al. [96] reported, however, that methanol-based solvents gave higher recoveries of carotenoids than acetonitrile-based solvents in almost all of 65 columns tested. Methanol is also more available, less expensive, and less toxic than acetonitrile. Addition of triethylamine to acetonitrile-based solvents was found to enhance carotenoid recovery [99].

Small amounts of other solvents are added to obtain the desired retention, increase solubility, and improve resolution. Chlorinated solvents (e.g., chloroform, dichloromethane) are frequently used for this purpose on account of their good solvent properties and effects on selectivity, although these solvents can be contaminated with traces of HCl. Other solvents used as modifiers are THF, ethyl acetate, hexane, acetone, and water. In some cases, methanol has been added to an acetonitrile-based mobile phase. Craft [100] investigated nine solvent modifiers and found THF to be the most beneficial modifier of methanol. Analysts tend to use mixtures of three or more solvents; however, Craft [100] cautioned against this practice because it can complicate the method, enhance demixing, and result in different evaporation rates, causing variation in the retention times during the course of the day.

Gradient elution should only be employed when the analysis cannot be done isocratically. Isocratic separation is rapid, can be performed with simple equipment (a single high-pressure pump and premixed solvent), and results in a stable baseline and more reproducible retention times. It is usually sufficient for the determination of provitamin A carotenoids or the principal carotenoids of natural samples.

Gradient elution has the advantages of greater resolving power, improved sensitivity, and elution of strongly retained compounds. It is more likely to resolve the whole range of carotenoids found in a given natural product. However, it has several disadvantages: (1) increased complexity, (2) requirement for more sophisticated and expensive equipment, (3) need for column reequilibration between runs, (4) greater differential detector response (i.e., different detector signals for the same concentration of different compounds), and (5) often poor reproducibility. The column must be brought back to the starting solvent and equilibrated for 10–30 min in this solvent before a new run is commenced. Good solvent miscibility is required to prevent baseline disturbance due to outgassing and refractive index effects [100].

Because *cis* isomers have different biological potencies than their *trans* counterpart, it is necessary to separate and quantify *cis* isomers when they are present in appreciable amounts. This level of detail, however, makes the analysis even more complicated. The polymeric C30 column was developed specifically for this purpose [101, 102]. This column, with an isocratic solvent system consisting of methanol:methyl-tert-butyl ether (89:11), was used for the quantification of *cis-trans* isomers of provitamin A carotenoids in fresh and processed fruits and vegetables [103].

The injection solvent must be compatible with the HPLC mobile phase. If the carotenoids are much more soluble in the injection solvent than in the mobile phase, the carotenoids will precipitate on injection, leading to peak tailing, or they will remain in the injection solvent while passing though the column, resulting in broad bands and doubled peaks [100]. These problems are particularly pronounced if the carotenoid solution is nearly saturated. The carotenoids will not dissolve completely if the solvent is too weak. Samples can be injected in the mobile phase to avoid this incompatibility problem. However, because of the solubility range of carotenoids in food samples, another solvent may be preferred for solubilization and injection.

Temperature regulation is recommended to maintain within-day and day-to-day reproducibility. Variations in column temperature result in substantial fluctuation of the carotenoid retention times. Temperature may also influence selectivity.

This section describes several liquid chromatographic methods for separating and analyzing carotenoids. The first procedure incorporates a reversed-phase separation using a wide-pore, polymerically synthesized C18 column with visible detection at 450 nm (see Sect. 4.2.1). The first alternate procedure is also isocratic C18 reversed phase but permits simultaneous analysis of retinol, tocopherols, and carotenoids using both a programmable UV–Vis detector and fluorescence detector, or a single diode-array detector (see Sect. 4.2.2). The second alternate procedure is oriented toward more detailed carotenoid analysis of geometric isomers (see Sect. 4.2.3); it incorporates a unique C30 "carotenoid" column with gradient separation and visible detection at 450 nm. The final basic protocol described in this unit is a normal-phase separation, permitting more complete quantitation of xanthophylls and their isomers (see Sect. 4.2.4). The detail preparation of standards for generating a calibration curve was described in Sect. "Standards Preparation and Calibration," while the guidelines for sample preparation based on knowledge of the sample matrix were performed in Sect. "Sample Preparation."

4.2.1 Isocratic Carotenoid Analysis Using Wide-Spore, Polymeric C18

This method requires the least sophisticated equipment and relies heavily on the unique characteristics of the column to separate the carotenoids [95, 96]. It incorporates the use of a polymeric C18 column, which has been shown to offer unique selectivity for structurally similar compounds such as geometric isomers. The addition of a second detector or use of a diode-array detector permits the simultaneous analysis of tocopherols, but not retinol. If the method is modified to incorporate a solvent gradient, retinol can be measured also [104].

HPLC system:

- Column: Vydac 201TP or 218TP C18 column, 5 µm, 250-mm × 4.6-mm (Vydac/Separations Group), Bakerbond WP C18 (J.T. Baker), or HiPore RP 318 (Bio-Rad Laboratories) and guard column containing similar packing material
- Pump: isocratic
- Detector: fixed, variable, programmable, or diode-array (DAD) UV–Vis detector
- Injector: manual

Procedure:

1. Prepare mobile phase by mixing 900 ml HPLC grade methanol, 100-ml HPLC grade acetonitrile, and 1 ml of HPLC grade triethylamine (TEA).
   Note: Triethylamine serves as a modifier to prevent both nonspecific adsorption and oxidation.
2. Degas the mobile phase via vacuum filtration, ultrasonic agitation, or inline vacuum degasser.
3. Set the HPLC pump flow rate at 1.0 ml/min.
4. Set UV–Vis detector at 450 nm (436 nm if using filter photometer).
5. Inject individual standards and the standard mixtures, including any optional internal standard, as described to generate a standard curve (see Sect. "Standards Preparation and Calibration").
6. Inject 10–50 µl of sample (see Sect. "Sample Preparation") and any optional internal standard dissolved in a solvent miscible with the mobile phase (e.g., ethanol, methanol, acetonitrile).

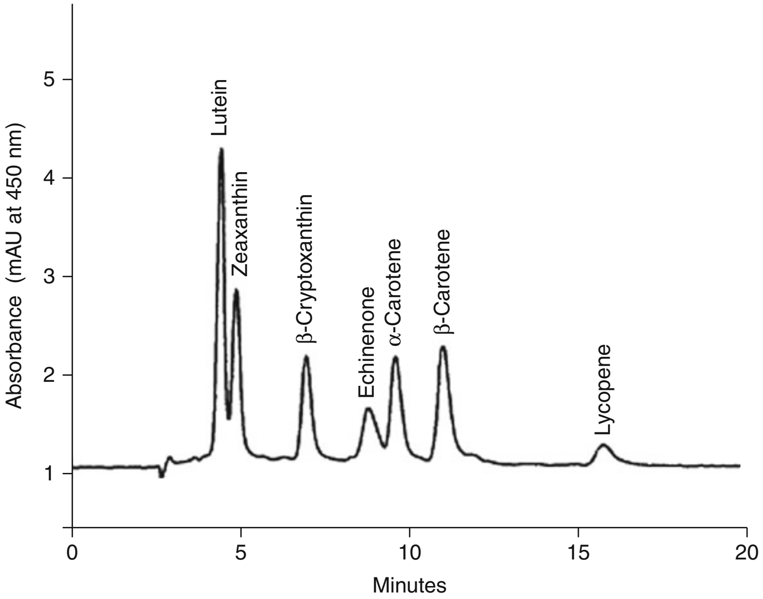

Fig. 111.5 Isocratic HPLC analysis of carotenoid standards. Condition: 5-μm × 250-mm × 4.6-mm Vydac 201TP column, 90:10 methanol/acetonitrile mobile phase, 1.0 ml/min flow rate, visible detection at 450 nm, and column temperature 25°C [84]

Note:

The complete separation from lutein to lycopene requires ~20 min. Figure 111.5 illustrates the separation of carotenoid standards using this system. The elution order using this method (i.e., lutein, zeaxanthin, β-cryptoxanthin, echinenone, α-carotene, β-carotene, lycopene) differs from many other methods.

Carotenoid retention and separation are influenced by column temperature; at temperatures above 20–25°C, lutein and zeaxanthin may not be well separated. Tocopherols can be measured simultaneously by using a diode array detector, a second UV detector set at 280–300 nm, or a fluorescence detector set at 296 nm excitation and 336 nm emission.

7. Calculate the final concentrations of carotenoids in samples by multiplying the peak areas of analytes by the calibration response factors. Apply sample weight and dilution factors to arrive at the concentration of carotenoids in the original sample (i.e., initial concentration).

   Note: The response factor is the ratio of the analyte concentration to the peak area (or height) produced under the defined set of conditions during calibration (e.g., wavelength, solvent composition, column). Typically, data systems will generate response factors for each analyte from calibration data. For example, to calculate the initial concentration, where the sample weight (W_1) is 0.5 g, the initial dilution (D_1) is 25 ml, and the dilution factor for injection (D_2) is 10×.

The final concentration of the injected sample (F_c) equals the response factor (R_f) multiplied by the peak area (P_a or height). The initial concentration (I_c) equals the final concentration multiplied by the initial dilution multiplied by the dilution factor for injection divided by the sample weight ($I_c = [F_c \times D_1 \times D_2]/W_1 = (5.0\ \mu g/ml \times 25\ ml \times I0)/0.5\ g = 2.5\ mg/g$, where $F_c = P_a \times R_f = 25{,}000$ units $\times\ 0.002 = 5.0\ \mu g/ml$).

Standards Preparation and Calibration

Analytical methods are only as good as the initial calibration; therefore, it is essential that the calibration for the accompanying HPLC methods be performed carefully. Carotenoids are labile compounds that are seldom obtained in pure form and degrade readily upon exposure to oxygen and light. Precautions should be taken to minimize standard and sample exposure to UV light and air. Given the above considerations, it is never recommended that carotenoid calibrants be prepared gravimetrically without verification using a spectrophotometer. This can lead to serious errors in quantitation [105]. Many impurities contribute mass but not color to the standards. In addition, carotenoids tend to dissolve slowly in many solvents. Thus, accuracy can be significantly improved by applying absorptivities ($A^{1\%}$) and Beer's Law to filtered solutions of carotenoids to obtain concentration. The value assigned can be further refined by correcting for peak purity. This is accomplished by injecting individual standard solutions into the HPLC column while monitoring the wavelength maximum of each standard. Once the standard solution concentrations have been established, the individual carotenoid standard solutions can be mixed to form calibration solutions. The general procedure is provided below.

Procedure:

1. Dissolve ~1–2 mg lutein, zeaxanthin, β-cryptoxanthin, and other xanthophylls directly in 100 ml reagent alcohol containing 30 ppm butylated hydroxytoluene (BHT). Dissolve ~1–2 mg lycopene, α-carotene, and β-carotene in 10 ml HPLC grade THF stabilized with 250 ppm BHT and then dilute to 100 ml with reagent alcohol.
   Note:
   For normal-phase separations, solutions should be prepared using hexane.
   Crystalline carotenoid standards are available from Sigma, Indofine Chemical, Atomergic Chemetals, Fluka Chemical, Kemin Industries, Wako, and others.
2. Vacuum filter stock solutions through a 0.45-μm membrane to remove any undissolved material.
3. Measure the absorbance of the solutions at the wavelength maximum, as described in Table 111.4, against an appropriate blank (i.e., reagent alcohol) on a spectrophotometer. Dilute appropriately with reagent alcohol to measure between 0.5 AU and 1.0 AU.
4. Inject each standard individually into the appropriate HPLC column (see Sects. 4.2.1 to 4.2.4), monitoring its wavelength maximum to determine the necessary purity correction.

Table 111.4 Commonly used absorptivity values for carotenoids and their corresponding wavelength maxima

Analyte	Wavelength (nm)	Absorptivity ($A^{1\%}$)[a]
α-Carotene	444	2,800
β-Carotene	452	2,592
δ-Carotene	456	3,290
α-Cryptoxanthin	445	2,636
β-Cryptoxanthin	452	2,386
Lutein	445	2,550
Lycopene	472	3,450
Neoxanthin	439	2,243
Phytoene	285	1,250
Phytofluene	347	1,577
Violaxanthin	443	2,250
Zeaxanthin	452	2,350

[a] Ref. [84]. For some carotenoids, $A^{1\%}$ is provided in petroleum ether or hexane and is not significantly different from those in ethanol

For example, if the area of the analyte peak constitutes 90% of the total peak areas, then the concentration calculated using spectrophotometric absorbance is adjusted to 90%.

5. (Optional) Inject the internal standard(s) to determine if there are any degradation products or impurities that may co-elute and absorb at the wavelength of the analytes and to determine the purity correction of the internal standard.
   Note: An internal standard is a compound that is not present in the sample, but is chemically and physically similar to the analytes of interest. A fixed quantity is incorporated into the calibration solutions. The same concentration of internal standard is added to the samples during extraction to compensate for analyte recovery and injection variability. As seen in Fig. 111.5, Echinenone, which is not typically found in natural products, is used as the internal standard. Unfortunately, compounds which may be used as internal standards for carotenoid analysis are not readily available commercially.
6. Mix standards in the range expected for each analyte in the sample matrix (see Table 111.5), optionally adding a fixed amount of internal standard. Dilute to a known volume (usually 5 ml) with ethanol to provide the desired final concentration.
   Note: A minimum of three concentrations should be prepared although five concentrations weighted toward the lower end are preferred. Total carotenoids in any single solution should not exceed 20 μg/ml. For normal-phase separations use hexane rather than ethanol for dilution.
7. Inject mixture (volume as recommended in the procedures for the particular column and conditions; see Sects. 4.2.1 to 4.2.4) and generate calibration curves.
   Note:
   Most HPLC instruments include computer data systems which automatically plot peak response versus concentration to generate response factors; however;

Table 111.5 Calibration range for carotenoids

Analyte	Range (μg/ml)[a]
α-Carotene	0.05–5.0
β-Carotene	0.05–10.0
β-Cryptoxanthin	0.05–5.0
Lutein	0.05–10.0
Lycopene	0.05–10.0
Zeaxanthin	0.05–5.0

[a] Ref. [84]

if using an older system, the standard curve can be plotted manually. The calibration curves should be linear with a correlation coefficient of >0.98 and intersect very near the origin.

Sample Preparation

Natural materials are variable and complex matrices. Knowledge of the sample matrix is critical for accurate carotenoid quantification. The type and chemical form of carotenoids and the composition of the natural products matrix are critical to the amount of sample preparation that is necessary prior to sample analysis. Many factors regarding the natural products matrix must be considered for efficient carotenoid extraction. For instance, the relative content of lipid to carotenoid in the natural products matrix influences the method of sample preparation. If both the lipid and carotenoid content are high, it may be possible to dilute the sample in an organic solvent that is miscible with the HPLC mobile phase for direct injection; however, when the lipid content of the sample is high and the carotenoid content is low, saponification is useful to separate the lipid (primarily triglycerides) from the carotenoids. Another factor is the form of the carotenoid that is present in the sample. Carotenes (hydrocarbon carotenoids) do not form ester linkages and can be directly extracted by homogenizing in the presence of lipophilic solvents (e.g., hexane, ethyl acetate, and toluene); however, the xanthophylls frequently form esters which will readily extract into lipophilic solvents. The xanthophylls are more easily quantified in the free form, which requires hydrolysis. Saponification (alkaline hydrolysis) is necessary to remove chlorophylls that are present in many foods because they can interfere with the detection of carotenoids. In other words, there is not one given sample preparation that will apply to all natural products; therefore, to provide general guidelines, sample preparation has been broken into the following three categories: (1) oil-based natural product samples containing only hydrocarbon carotenoids or nonesterified xanthophylls that are visibly yellow to red in color (e.g., palm oil), (2) direct extraction for natural product samples that do not contain xanthophyll esters or chlorophylls and have a low lipid and high carotenoid content (e.g., carrots), and (3) saponification for natural product samples containing xanthophyll esters, chlorophylls, or high lipid and low carotenoid content (e.g., spinach).

Procedure:

For oil-based natural products samples containing only hydrocarbon carotenoids or nonesterified xanthophylls that are visibly yellow to red in color (e.g., palm oil)

1a. Weigh 0.5–5.0 g of sample.

2a. Dissolve in 25 ml of HPLC grade THF stabilized with 250 ppm BHT and then dilute to volume in a 50-ml volumetric flask. Dilute the sample further with reagent alcohol until the carotenoid concentration is ~5–10 mg/l.

Note: The carotenoid concentration is approximated by diluting and measuring the absorbance at 450 nm on a spectrophotometer where 1 AU = ~4 mg/l

3a. (Optional) Filter through 0.45-μm filter prior to injection.

Note: If the sample is free of particulate, it may be directly injected into the HPLC column for analysis.

For direct extraction of natural products samples that do not contain xanthophyll esters or chlorophylls, and have a low lipid and high carotenoid content (e.g., carrots)

1b. Homogenize ~5 g of ground sample with 10% (w/w) magnesium carbonate and 25 ml of 50:50 HPLC grade methanol/THF.

Note: Lyophilized and dry samples should be reconstituted with water prior to extraction. They may require saponification if the samples contain chlorophylls or xanthophyll esters. Beadlet materials should be suspended in hot water, saponified, or enzymatically hydrolyzed before extraction. Follow the manufacturer's recommendations before analyzing by HPLC.

2b. Centrifuge in a swinging bucket rotor for 10 min at 6,000 × g, 4°C and remove the supernatant.

3b. Repeat steps lb and 2b until the extracting solvent is colorless.

4b. Combine the extracts and vacuum filter through Whatman paper no. 42 to remove particles.

5b. Dilute to a known volume with reagent alcohol so that the THF represents <10% of the total solution (e.g., if total volume is 90 ml dilute to 500 ml).

6b. (Optional) Filter through 0.45-μm filter prior to injection.

For saponification of natural products samples containing xanthophyll esters, chlorophylls, or high lipid and low carotenoid content (e.g., spinach)

1c. Proceed with a direct sample extraction as instructed in steps 1b–5b.

2c. Transfer a 5-ml aliquot to a 30–50-ml capped tube for saponification.

3c. Add 1 ml of 10% (w/v) pyrogallol in reagent alcohol.

4c. Add 2 ml of 40% (w/v) KOH in methanol.

Note: The final concentration of reagents in the mixed solution should be ~5–10% KOH and >1% pyrogallol.

5c. Flush the tubes with nitrogen gas and cap.

6c. Saponify the samples at 60°C for 1 h in a shaking water bath or 30 min in an ultrasonic bath.

7c. After saponification, dilute the samples with 8 ml of saturated NaCl solution.

8c. Extract by vigorous mixing with 10 ml 75:25 hexane/THF.

Note: Free xanthophylls, both endogenous and present in the saponified samples, are more polar and extract less eficiently into lipophilic solvents.

Frequently, the addition of a polar organic solvent (tetrahydrofuran, methylene chloride, diethyl ether) is required to thoroughly extract them from the sample matrix and aqueous phase.

9c. Remove the upper phase.

10c. Repeat the extraction step until the upper phase is colorless.
Note: For some samples the phases will not separate on standing and may require centrifugation to break emulsions.

11c. Wash the combined extract with water to remove traces of KOH and pyrogallol that may have been co-extracted.

12c. Place 3-in. solid sodium sulfate in the bottom of a 1.5 × 12-in. glass column plugged with sintered glass frit or plugged with glass wool. After removing the water, pass the extract through the sodium sulfate to remove any traces of water remaining.

13c. Remove the solvent from the extract using a solvent evaporation apparatus.

14c. Dissolve residue in a known volume of reagent alcohol to yield 5–20 mg/l (an absorbance of 1.5–5.0 AU at 450 nm).
Note: Samples extracted into strong organic solvents (hexane, ether, petroleum ether, ethyl acetate, etc.) must be transferred into a solvent miscible with the mobile phase. A small volume (e.g., 1 ml) of the organic extract should be evaporated under N_2 gas and dissolved in reagent alcohol. Further dilutions with alcohol may be necessary to obtain 5–10 mg/l concentration before HPLC injection.

15c. (Optional) Filter through 0.45-μm filter prior to injection.
Note: If this sample is free of particulate, it may be directly injected into the HPLC column for analysis.

4.2.2 Isocratic Carotenoid Analysis Capable of Simultaneous Separation of Retinol and Tocopherol Using Spherisorb ODS2

This method is the simplest approach for simultaneous carotenoid, retinol, and tocopherol analysis. Both the column and mobile phase have been chosen to provide efficiency and selectivity for the analysis of these components without the use of a gradient. The method uses the Spherisorb ODS2 column, in which the C18 chain is monomerically bound to the silica particles (i.e., the C18 chain binds at one site to the silica particles).

HPLC system (see Sect. 4.2.1):

- Column: 3-μm × 150-mm × 4.6-mm Spherisorb ODS2 (ES Industries, Phenomenex, or Waters) and guard column containing similar packing material

Procedure:

1. Prepare mobile-phase solution:
   - Dissolve 0.385 g ammonium acetate in 50 ml methanol.
   - Mix 830 ml acetonitrile, 130 ml *p*-dioxane, and 1 ml triethylamine (TEA).
     Note: TEA serves as a modifier to prevent both nonspecsific adsorption and oxidation.

- While stirring, slowly add 40 ml methanol/ammonium acetate solution prepared in step 1.
- Vacuum filter through 0.45-μm PTFE or polypropylene membrane.

2. Set the HPLC pump flow rate at 1.5 ml/min.
3. Set UV–Vis detector at 450 nm (436 nm if using filter photometer).
4. Inject 10–30 μl individual standards and the standard mixtures, including any optional internal standard, as described to generate a standard curve (see Sect. "Standards Preparation and Calibration").

   Column temperature should be maintained at a fixed temperature between 22°C and 29°C in either a room with well regulated temperature, or a column oven for above ambient temperatures.

   If the injection solvent is of comparable solvent strength to that of the mobile phase, up to 30 μl may be used as the sample injection volume; however, if the injection solvent is more lipophilic than the mobile phase, the injection volume is limited to 10 μl.
5. Inject 10–30 μl standard or sample dissolved in a solvent miscible with the mobile phase (e.g., methanol, acetonitrile).

   The complete separation from retinol to β-carotene requires ~15 min. Figure 111.6 illustrates the separation of vitamins and carotenoids in the mixed natural products extract using this liquid chromatography (LC) system. The elution order using this method is: lutein, zeaxanthin, β−cryptoxanthin, lycopene, α−carotene, and β−carotene.
6. Detection:
   (a) For carotenoids: Monitor 450 nm.
   (b) For retinol and carotenoids: Monitor 325 nm for 3.2 min, then program the detector to change the wavelength to 450 nm.
   (c) For tocopherols (optional): Place fluorescence detector after UV–Vis detector and monitor excitation at 296 nm and emission at 336 nm.
   (d) For diode array detectors (optional): monitor 296 nm for tocopherols, 325 nm for retinol, and 450 nm for carotenoids.
   7. Calculate the final concentrations as described above (see 4.2.1).

4.2.3 Gradient HPLC Analysis Using C30 Carotenoid Column

This method requires the most sophisticated equipment and yields the most detailed results by utilizing the C30 column that was created specifically for carotenoid separation. The C30 column is polymerically bonded, yielding selectivity similar to the polymeric C18. The column has an intermediate pore diameter (200 Å) and a 30 carbon alkyl chain, which results in higher carbon content and therefore stronger retention of the carotenoids. Due to the strong retention of carotenoids on this column, a gradient must be employed unless the sample is previously fractionated or only contains a specific group of carotenoids. It is possible to separate a wide polarity range of carotenoids and their isomers.

HPLC system:

- Pump: ternary gradient
- Column: 3-μm × 250-mm × 4.6-mm C30 with 3-μm guard column (water)

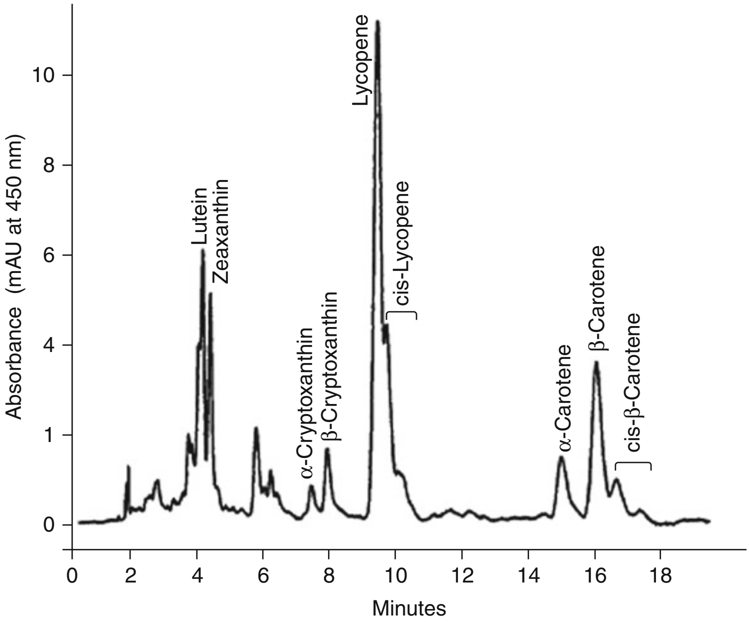

Fig. 111.6 Isocratic HPLC analysis of the natural material carotenoids using procedure 4.2.2. Conditions: Spherisorb 3-μm × 150-mm × 4.6-mm ODS2 column, 83:13:4:0.1 acetonitrile/dioxane/150 mM ammonium acetate in methanol/TEA mobile phase, 1.5 ml/min flow rate, visible detection at 450 nm, and column temperature 29°C [84]

- Column oven: 35°C
- Mobile phase:
  - Solvent A: 0.05% TEA and 50 mM ammonium acetate in methanol
  - Solvent B: 0.05% TEA in isopropyl alcohol
  - Solvent C: 0.05% TEA in HPLC grade THF stabilized with 250 ppm BHT

Procedure:

1. Set the HPLC pump flow rate at 1.0 ml/min.
2. Set UV–Vis detector at 450 nm (436 nm if using filter photometer).
3. Inject 10–50 μl individual standards and the standard mixtures, including any optional internal standard as described to generate a standard curve (see Sect. "Standards Preparation and Calibration").
4. Inject 10–50 μl sample (see Sect. "Sample Preparation") dissolved in a solvent miscible with the mobile phase (e.g., ethanol, 90% ethanol/10% isopropanol). Note: The complete separation from lutein to lycopene requires ~40 min with an additional 15 min to equilibrate the column back to the initial mobile phase. Figure 111.7 illustrates the separation of carotenoid in the mixed natural products extract using this LC system. The elution order using this method difers from many other methods: lutein, zeaxanthin, β-cryptoxanthin,

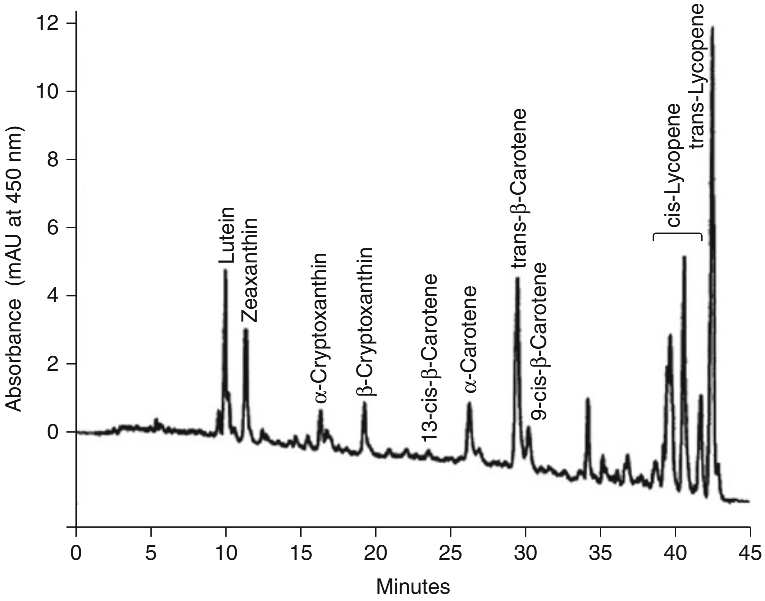

Fig. 111.7 Gradient HPLC analysis of the natural products reference material carotenoids using procedure 4.2.3. Conditions: 3-μm × 250-mm × 4.6-mm waters C30 column, 1.0 ml/min flow rate, visible detection at 450 nm, column temperature 35°C, solvent A = 50 mM ammonium acetate in methanol, B = isopropyl alcohol, and C = THF (all solvent contain 0.1% TEA). Flow program: 90% A/10% B linear gradient, 54% A/35% B/11% C over 24 min, linear gradient to 30% A/35% B/35% C over 11 min, hold for 8 min, and then return to initial conditions over 10 min [84]

15-*cis*-β-carotene, 13-*cis*-β-carotene, αcarotene, *trans* β−carotene, 9-*cis*-β-carotene, *cis*-lycopene, and *trans*-lycopene.

5. Prepare gradient:

   Starting with 90% solvent A/10% solvent B, establish a linear gradient over 24 min to 54% solvent A/35% solvent B/11% solvent C, followed by a second linear gradient over 11 min to 30% solvent A/35% solvent B/35% solvent C. Hold 5 min, return to initial conditions over 10 min. Hold 5 min before next injection.

   Note: Triethylamine in the solvent serves as a modifier to prevent both non-specific adsorption and oxidation.

6. Detection:
   - For carotenoids: Monitor 450 nm.
   - For tocopherols (optional): Place fluorescence detector after UV–Vis detector and monitor excitation at 296 nm and emission at 336 nm.
   - For a diode array detector (optional): Monitor 296 nm for tocopherols, 325 nm for retinol, and 450 nm for carotenoids.

7. Calculate the final concentrations as described above (see Sect. 4.2.1, step 7).

4.2.4 Normal-Phase Analysis of Xanthophylls

In normal-phase chromatography, polar components are more strongly retained than nonpolar components. Thus, hydrocarbon carotenes elute quickly while xanthophylls are retained and separated. This approach provides a more complete separation of polar carotenoids and their geometric isomers. This procedure is useful to the analyst that is specifically interested in the xanthophyll fraction of a sample.

HPLC system (see Sect. 4.2.1)

- Column: 5-μm × 250-mm × 4.6-mm Lichrosorb Si column (ES Industries, Phenomenex, or EM Science) and guard column containing similar packing material

Procedure:

1. Prepare mobile phase by mixing 800 ml hexane, 200 ml dioxane, 15 ml indole-3-propionic acid (IPA), and 2.0 ml TEA.
   Note: TEA serves as a modifier to prevent both nonspecific adsorption and oxidation.
2. Degas the mobile phase via vacuum filtration, ultrasonic agitation, or inline vacuum degasser.
3. Set the HPLC pump flow rate at 1.0 ml/min.
4. Set UV–Vis detector at 450 nm (436 nm if using filter photometer).
5. Inject 10–100 μl individual standards and the standard mixtures, including any optional internal standard as described to generate a standard curve (see Sect. "Standards Preparation and Calibration").
6. Inject 10–100 μl of standard (see Sect. "Standards Preparation and Calibration") or sample, including any optional internal standard, (see Sect. "Sample Preparation") dissolved in hexane.
   Note: The complete separation from β-carotene to violaxanthin requires ~35 min. Figure 111.8 illustrates the separation of carotenoids in a mixed natural products extract using this LC system. The hydrocarbon carotenes (β-carotene, α-carotene, lycopene) elute together at the solvent front. The elution order is: β-cryptoxanthin, α-cryptoxanthin, lutein, *cis*-lutein, zeaxanthin, *cis*-zeaxanthin, neoxanthin, and violaxanthin.
7. Calculate the final concentrations as described above (see Sect. 4.2.1, step 7).

4.3 Mass Spectrometry of Carotenoids

The high sensitivity and selectivity of mass spectrometry (MS) facilitates the identification and structural analysis of small quantities of carotenoids that are typically obtained from natural product samples such as plants, animals, or human serum and tissue. Structural information from the abundant fragmentation is provided by classical ionization methods, such as electron impact (EI; see Sect. 4.3.1) and chemical ionization (CI; see Sect. 4.3.1), but molecular ions are not always observed. Recent advances in soft ionization techniques, such as fast

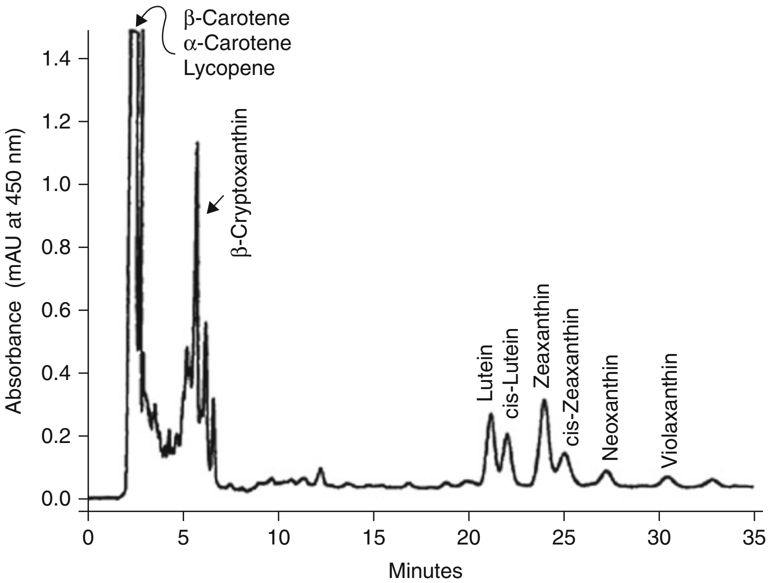

Fig. 111.8 Isocratic HPLC analysis of the natural products reference material carotenoids using procedure 4.2.4. Conditions: Lichosorb Si60, 5-μm × 250-mm × 4.6-mm column, hexane/dioxane/IPA/TEA (80:20:0.15:0.02) mobile phase, 1.0 ml/min flow rate, and visible detector at 450 nm [84]

atom bombardment (FAB; see Sect. 4.3.2), matrix-assisted laser desorption/ionization (MALDI; see Sect. 4.3.3), electrospray ionization (ESI; see Sect. 4.3.4), and atmospheric pressure chemical ionization (APCI; see Sect. 4.3.5), have facilitated the molecular weight determination of carotenoids by minimizing fragmentation that is typical of EI and CI. Once the molecular weight of a carotenoid has been established using one of these ionization techniques, collision-induced dissociation (CID) and tandem mass spectrometry (MS/MS) can be used to augment fragmentation and obtain structurally significant fragment ions that may aid in the differentiation of structural isomers, such as differentiation of lutein from zeaxanthin or of α-carotene from β-carotene and lycopene. CID and MS/MS parameters are independent of the ionization step so that no modifications of the sample preparation and ionization procedures are needed. Although CID and MS/MS can be used with any ionization technique, the application of this approach is illustrated using FAB ionization in Sect. 4.3.2.

MS can be coupled to high-performance liquid chromatography (HPLC) to obtain separation of isomeric carotenoids or to remove interfering contaminants prior to ionization and detection. Except for MALDI, every ionization method discussed in this unit has been utilized during liquid chromatography MS (LC/MS; see Sects. 4.3.1–4.3.2 and Sect. 4.3.5). However, LC-APCI-MS is now the preferred approach due to its widespread availability and ease of use. Although LC/MS and LC/MS/MS (see Sect. 4.3.2) are routinely carried out, gas chromatography MS (GC/MS) is rarely used because carotenoids typically decompose when exposed to the high temperatures of the GC process. Reviews of LC/MS and MS of carotenoids have been published by van Breemen [106, 107]. A general introduction to mass spectrometry is given in Watson [108].

4.3.1 Electron Impact and Chemical Ionization Mass Spectrometry of Carotenoids

Most of the original structural elucidation studies of the >600 known carotenoids used El and CI [109]. Electron impact (EI) and chemical ionization (CI) MS have been used for carotenoid analysis for more than 30 years. Therefore, mass spectra of unknown carotenoids can be compared to a large number of published mass spectra to aid in identification. Unlike the newer "soft" ionization techniques in MS, EI and CI produce considerable fragmentation, and molecular ions are not always observed. Therefore, these techniques are most useful for obtaining fingerprints, or characteristic fragmentation patterns, instead of confirming or determining molecular weights of carotenoids. Alternatively, direct exposure EI (DEI) and/or direct exposure CI (DCI) MS can be used.

EI/CI-MS system:

- Reagent gas: methane or isobutane (for CI only)
- Mass spectrometer equipped with direct insertion probe and EI and/or CI ionization

Procedure:

1. Using a microsyringe, load 1 μl carotenoid sample onto a direct insertion probe of a mass spectrometer.
   Note: Carotenoid sample (1–100 mg/l; 2–200 μM) is dissolved in volatile organic solvent (e.g., hexane, THF, methyl-tert-butyl ether, acetone), stored in an airtight glass vial.
2. Let solvent evaporate and then insert probe into the ion source of the mass spectrometer.
3. Introduce reagent gas (for CI only) and then turn on the electron beam (typically 70 eV for EI and 200 eV for CI).
4. Heat probe to vaporize carotenoid.
5. Record mass spectrum over the range m/z (mass-to-charge ratio) 50–800 for EI and m/z 100–800 for CI.
   Note: All known carotenoids and their major fragment ions should be included in this range. By beginning the scan at m/z 100 during CI, reagent-gas ions can be avoided.

4.3.2 Fast Atom Bombardment, Liquid Secondary Ion Mass Spectrometry, and Continuous-Flow Fast Atom Bombardment of Carotenoids

Fast atom bombardment MS (FAB-MS) and liquid secondary ion MS (LSIMS) are matrix-mediated desorption techniques that use energetic particle bombardment to simultaneously ionize samples such as carotenoids and transfer them to the gas

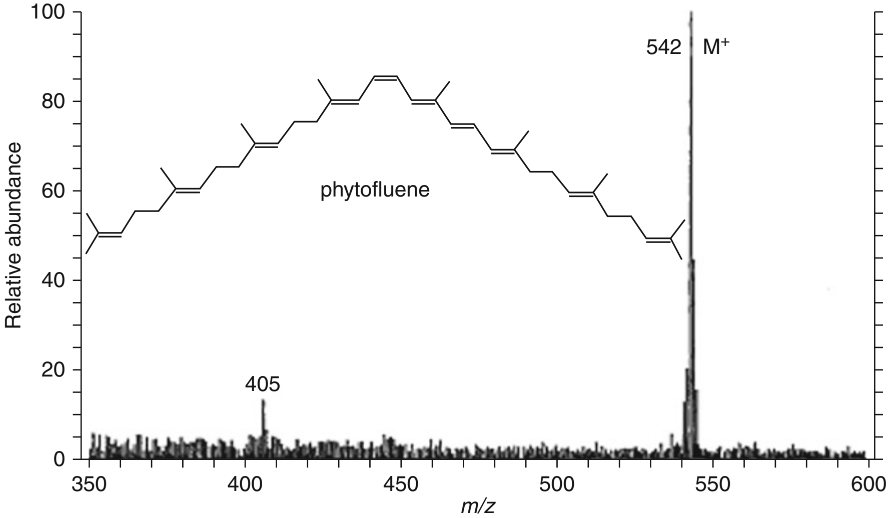

Fig. 111.9 Positive ion fast atom bombardment (FAB-MS) mass spectrum of phytofluene isolated from blueberries. The base peak of m/z 542 corresponds to the molecular ion. Characteristic of FAB-MS, background signals are observed at every m/z value. The mass spectrum was obtained during continuous-flow FAB-MS LC/MS using a magnetic sector mass spectrometer. Although the 16-*cis* isomer of phytofluene is shown, the FAB mass spectra of all-trans and other cis isomers are indistinguishable [84]

phase for mass spectrometric analysis. Unlike with the EI and CI techniques, molecular ions are usually abundant and fragmentation is minimal. Figure 111.9 shows the positive ion FAB-MS mass spectrum of carotene phytofluene. The base peak of m/z 542 corresponds to the molecular ion.

FAB-MS system:

- Mass spectrometer or tandem mass spectrometer equipped for fast atom bombardment (FAB)-MS or liquid secondary ion (LSI)-MS, with direct insertion probe and with continuous-flow ionization source (as needed)
- Syringe pump or HPLC pump capable of delivering flow rates of 1–10 μl/min (for continuous-flow only)
- Reversed-phase HPLC (typically C18 or C30) column (for continuous-flow FAB-MS or LSIMS)

Procedure:

For probe analysis:

1a. Load 1 μl of 3-nitrobenzyl alcohol onto a direct insertion probe and then use a microsyringe to load 1 μl carotenoid sample onto the surface of the liquid matrix. Note: Carotenoid sample (1–100 mg/l; 2–200 μM) is dissolved in volatile organic solvent (e.g., hexane, THF, methyl-tert-butyl ether, acetone), stored in an airtight glass vial.

2a. Let solvent evaporate and then insert probe through the vacuum interlock into the ion source of a mass spectrometer or tandem mass spectrometer.

3a. Turn on FAB-MS or LSIMS beam and record the positive ion mass spectrum over the range m/z (mass-to-charge ratio) 50–900.

Note: If desired, the peaks at m/z 154 and m/z 307 for the protonated monomer and dimer of the matrix, 3-nitrobenzyl alcohol, can be eliminated by scanning from m/z 310–900.

For continuous-flow analysis:

1b. Set up a syringe pump or an HPLC pump and equilibrate a reversed-phase HPLC column with appropriate eluents such as methanol and methyl-tert-butyl ether (e.g., 70:30, v/v).

Note: A reversed-phase HPLC column (typically C18 or C30) is required for HPLC separations. Because the flow rate into the continuous-flow FAB-MS or LSIMS source must be 10 μl/min, either a capillary column must be used or else the flow must be split postcolumn. For narrow-bore HPLC columns operated at 200 μl/min, the split ratio would be 30:1. Isocratic or gradient analysis may be used. A syringe pump is usually necessary for capillary columns, but standard HPLC pumps are suficient for applications using narrowbore columns.

2b. Add the matrix, ~0.1% (v/v) 3-nitrobenzyl alcohol prepared in appropriate mobile phase, postcolumn at a flow rate of ~1–3 μl/min.

3b. Interface the continuous-flow probe to a mass spectrometer. Tune the continuous-flow FAB-MS or LSIMS ion source on the 3-nitrobenzyl alcohol dimer ion at m/z 307.

4b. Inject a carotenoid sample onto the HPLC column, turn on the FAB-MS or LSIMS beam, and record the positive ion mass spectrum over the range m/z 300–1,000.

Note: An injection volume of 15 μl is typical for narrow-bore columns.

4.3.3 Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry of Carotenoids

A matrix-mediated ionization technique, matrix-assisted laser desorption/ionization time-of-flight (MALDI/TOF) MS, uses an intense flash of laser light to vaporize a solid matrix containing the sample. Although usually regarded as an ionization method reserved for high-mass compounds such as proteins and polymers, MALDI has shown remarkable promise for the analysis of carotenoids. In particular, MALDI has been effective in the ionization of intact esterified carotenoids that would fragment too extensively using other ionization methods. Figure 111.10 shows the mass spectrum profile of nonpolar carotenoids extract from Tangela ripe tomato fruit. The spectrum revealed a collection of m/z ranged from 536 to 545. Although overlap between the isotopic species occurs, the monoisotopic peaks correspond to pro-lycopene ($C_{40}H_{56}$; m/z detection, 536.426; theoretical, 536.438), neurosporene ($C_{40}H_{58}$; m/z detection, 538.447; theoretical,

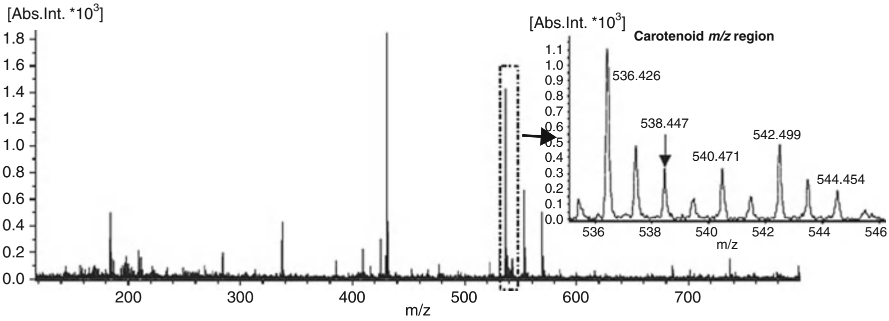

Fig. 111.10 Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI/TOF-MS) profiles of nonpolar extracts in ethyl acetate (1 mg/ml) from Tangella ripe tomato fruit. MALDI/TOF-MS spectra was acquired with a Bruker MALDI/TOF-MS reflex III operated in the positive reflectron mode. A nitrogen laser emitting 337 nm was used to generate ions. A source voltage of 25 kV was used, and 20.7-kV extraction voltage and no ion suppression were employed. Scans were extended to 3,000 m/z [110]

538.453), ζ-carotene ($C_{40}H_{60}$; m/z detection, 540.471; theoretical, 540.469), phytofluene ($C_{40}H_{62}$; m/z detection, 542.499; theoretical, 542.485), and phytoene ($C_{40}H_{64}$; m/z detection, 544.454; theoretical, 544.500).

MALDI/TOF-MS system:

- Matrix-assisted laser desorption ionization time-of-flight (MALDI/TOF) mass spectrometer with UV laser (i.e., 337-nm nitrogen laser), MALDI probe, and optional delayed extraction and postsource decay

Procedure:

1. Mix 20 µl carotenoid sample with 10 µl acetone saturated with 2,5-dihydroxybenzoic acid as sample matrix.
2. Using a microsyringe, load 5–10 µ1 carotenoid/matrix sample onto the target of a MALDI probe.
3. Let solvent evaporate (only a few seconds are required) and then insert probe through the vacuum interlock into the ion source of a MALDI/TOF mass spectrometer.
4. Record MALDI/TOF mass spectra in positive ion mode. Look for molecules ions and protonated molecules in the range m/z 300–1,000.

4.3.4 Electrospray Ionization Liquid Chromatography/Mass Spectrometry of Carotenoids

Unlike other LC/MS techniques in which removal of the mobile phase and sample ionization are discrete steps, electrospray is both an ionization method and an interface between an HPLC system and a mass spectrometer. Electrospray is also one of the most universal ionization techniques for MS, as virtually every class of compound has been analyzed using this technique, including carotenoids.

For flow-injection analysis of carotenoids, ~1 μl of a 0.1–100 μM carotenoid sample can be injected into a solvent stream and carried into the electrospray source without chromatography. This approach is particularly useful for high-throughput analysis of pure samples and for tuning and optimizing the parameters of the electrospray source. The sample should be dissolved in a volatile organic solvent (e.g., hexane, THF, methyl-tert-butyl ether, acetone, methanol) but may contain water. The sample should be stored in an airtight glass vial. A narrow scan range (e.g., m/z 520–620 for compounds such as β-carotene and lutein) or selected ion monitoring of the molecular ions (e.g., m/z 536 and 568 for β-carotene and lutein, respectively) is usually used during flow-injection analysis.

When HPLC is used as part of the analysis, the mobile phase is typically a mixture of methanol and methyl-tert-butyl ether (i.e., 50:50, v/v), although other HPLC solvents for LC/MS using electrospray (e.g., water, THF) can be used. It is important to note that entirely organic solvent systems might pose a fire hazard for some home-built ion sources and some older commercial instruments if air leaks into the ionization chamber. Therefore, water or a halogenated solvent should be added to the mobile-phase postcolumn to suppress ignition. The electrospray source must always be vented outside the laboratory. The scan range is typically m/z 300–1,000 in order to include known carotenoids and this esters.

When tuning the electrospray source of a mass spectrometer or tandem mass spectrometer, optimum sensitivity for carotenoids will be obtained using the highest possible voltage on the electrospray needle before corona discharge occurs. For example, an electrospray needle voltage of −5,100 V provided excellent sensitivity in one published report [111]. Because not all electrospray ion sources support voltages this high, the sensitivity might be lower in other systems. A reversed-phase HPLC C18 or C30 column is typically used for LC/MS with electrospray ionization (ESI). The flow rate into the mass spectrometer, as controlled by a syringe pump or HPLC pump, should be matched to the design of the system, but in most current commercial systems, the flow rate can be varied between 1 μl/min and 1,000 μl/min. Microbore, narrow-bore, or analytical-scale columns at flow rates from 1 μl/min to 1,000 μl/min are compatible with most LC/MS electrospray interfaces.

2,2,3,4,4,4-Heptafluoro-1-butanol can be added postcolumn to give a final concentration of 0.1% (v/v) to enhance ionization efficiency during electrospray. Typically, a 2% (v/v) solution in mobile phase is added at 50 μl/min to the HPLC column effluent at 1 ml/min. Addition of this reagent is optional.

Because of the efficiency of the solvent removal in the LCMS interface and the flexibility of the ESI process, ESI is compatible with a wide range of HPLC flow rates (from 0.1 ml/min to 1 ml/min) and with a variety of mobile phases including the methanol/methyl-*tert*-butyl ether solvent system that is ideal for analysis using C30 carotenoid columns. A potential limitation of ESI for quantitation is its relatively narrow dynamic range (approximately two orders of magnitude). Aside from this narrow range of linear response during quantitative analysis, ESI shows excellent sensitivity and is compatible with HPLC using a wide range of solvents and flow rates. An example of the positive ion LC-ESI-MS analysis of carotenes in an extract of human plasma is shown in Fig. 111.11.

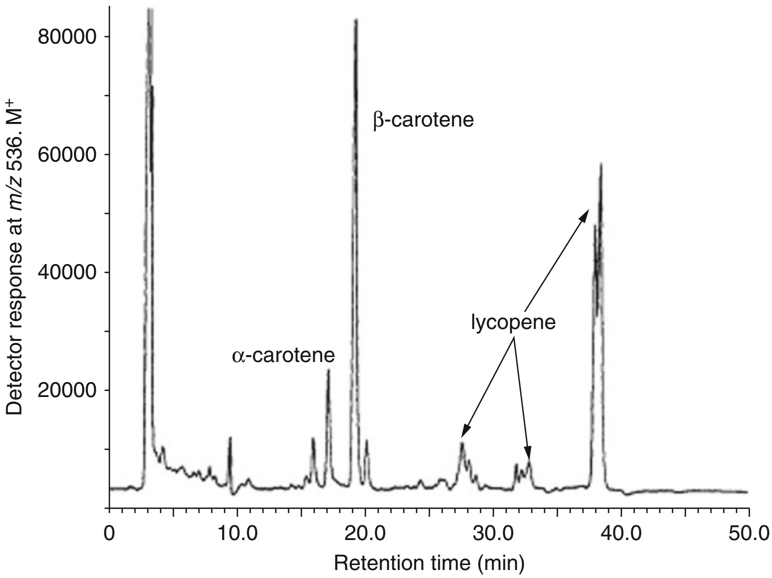

Fig. 111.11 Liquid chromatography/mass spectrometry (LC/MS) analysis of isomeric carotenes in a hexane extract from 0.5 ml human serum. Positive ion ESI-MS was used on a quadrupole mass spectrometer with selected ion monitoring to record the molecular ions of lycopene, β-carotene, and α-carotene at m/z (mass-to-charge ratio) 536. A C30 HPLC column was used for separation with a gradient from methanol to methyl-tert-butyl ether. The all-trans isomer of lycopene was detected at a retention time of 38.1 min, and various cis isomers of lycopene eluted between 27 min and 39 min. The all-trans isomers of α-carotene and β-carotene were detected at 17.3 min and 19.3 min, respectively [84]

4.3.5 Atmospheric Pressure Chemical Ionization Liquid Chromatography/Mass Spectrometry of Carotenoids

Most mass spectrometers equipped for electrospray ionization can be converted to atmospheric pressure chemical ionization (APCI), and many commercial LC-APCI-MS instruments are equipped with both ionization techniques. During APCI, ionization takes place in an atmospheric pressure chamber when the sample molecules collide with solvent ions formed in a continuous corona discharge. Unlike electrospray, the needle used to spray the HPLC effluent is not at high voltage.

For flow-injection analysis of carotenoids, ~1–5 μl of a 0.1–100 μM carotenoid sample, which may contain water, can be injected into a solvent stream and carried into the APCI source without chromatography. This approach is particularly useful for high-throughput analysis of pure samples and for tuning and optimizing the parameters of the APCI source. The sample should be dissolved in a volatile organic solvent (e.g., hexane, THF, methyl-tert-butyl ether, acetone, methanol) but may contain water. The sample should be stored in an airtight glass vial. A narrow scan range of m/z 520–620 is appropriate for most carotenoids such as

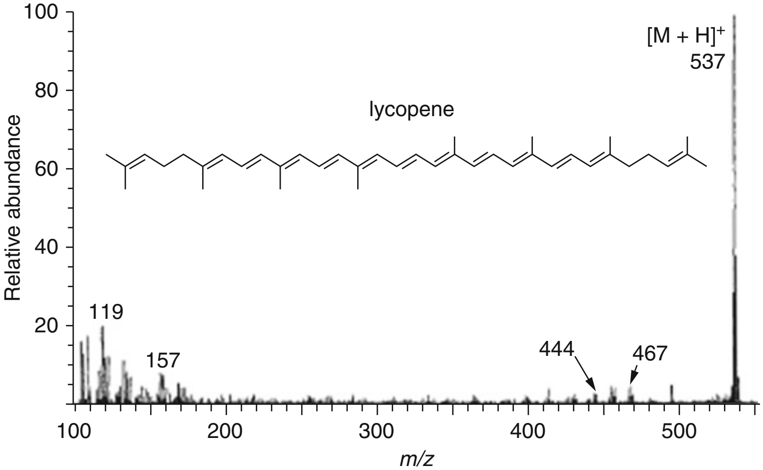

Fig. 111.12 Flow-injection positive ion atmospheric pressure chemical ionization (APCI) mass spectrum of −1 pmol lycopene. The carrier solvent for flow-injection analysis consisted of methanol/methyl-tert-butyl ether (5,050; v/v) at a flow rate of 200 μl/min. The lycopene standard was isolated from tomatoes. The all-trans isomer of lycopene is shown, which is the most abundant isomer found in the tomato. This carotene is the familiar red pigment of the tomato [112]

β-carotene and lutein. Alternatively, selected in monitoring of the molecular ions or protonated or deprotonated molucules may be used.

When HPLC is used as part of the analysis, the mobile phase is typically a mixture of methanol and methyl-tert-butyl ether (i.e., 50:50, v/v), although other HPLC solvents for LC/MS using APCI (e.g., water, THF) can be used. It is important to note that if combustible nonaqueous solvent systems are used, water or a halogenated solvent such as methylene chloride or chloroform should be added to the mobile-phase postcolumn to suppress ignition in the ion source. In addition, the APCI source must be vented outside the laboratory and should not allow air into the ionization chamber. A scan range of m/z 300–1,000 will include the known carotenoids and their most common esters.

A reversed-phase HPLC C18 or C30 narrow-bore column is typically used for LC/MS with APCI. For most APCI systems, the optimum flow rate into a mass spectrometer or tandem mass spectrometer equipped with APCI, as controlled by a syringe pump or HPLC pump, is usually between 100 μl/min and 300 μl/min, which is ideal for narrow-bore HPLC columns. Larger diameter columns should be used with a flow splitter postcolumn to reduce the solvent flow into the mass spectrometer. For example, if a 4.6-mm i.d. column was used at a flow rate of 1.0 ml/min, then the flow must be split postcolumn ~5:1 so that only 200 μl/min enters the mass spectrometer.

Carotenoids form both molecular ions and protonated molecules during positive ion APCI and molecular ions and deprotonated molecules during negative ion analysis. The relative abundances of molecular ions and protonated or deprotonated molecules vary with the mobile-phase composition [112]. For example, polar

Table 111.6 Elemental composition and exact masses[a] of common carotenoids [109]

Carotenoid	Elemental composition	Exact mass
β-Apo-8′-carotenal	$C_{30}H_{40}O$	416.3079
3-Hydroxy-β-apo-8′-carotenal	$C_{30}H_{40}O_2$	432.3028
α-Carotene	$C_{40}H_{56}$	536.4382
β-Carotene	$C_{40}H_{56}$	536.4382
γ-Carotene	$C_{40}H_{56}$	536.4382
Lycopene	$C_{40}H_{56}$	536.4382
Neurosporene	$C_{40}H_{58}$	538.4539
ζ-Carotene	$C_{40}H_{60}$	540.4695
Phytofluene	$C_{40}H_{62}$	542.4852
Phytoene	$C_{40}H_{64}$	544.5008
2′,3′-Anhydrolutein	$C_{40}H_{54}O$	550.4175
Echinenone	$C_{40}H_{54}O$	550.4175
α-Cryptoxanthin	$C_{40}H_{56}O$	552.4331
β-Cryptoxanthin	$C_{40}H_{56}O$	552.4331
Alloxanthin	$C_{40}H_{52}O_2$	564.3967
Cantaxanthin	$C_{40}H_{52}O_2$	564.3967
Diatoxanthin	$C_{40}H_{54}O_2$	566.4124
Lutein	$C_{40}H_{56}O_2$	568.4280
Isozeaxanthin	$C_{40}H_{56}O_2$	568.4280
Zeaxanthin	$C_{40}H_{56}O_2$	568.4280
Lycopene-16,16′-diol	$C_{40}H_{56}O_2$	568.4280
4-Ketoalloxanthin	$C_{40}H_{50}O_4$	578.3760
Pectenolone	$C_{40}H_{52}O_3$	580.3916
Phoenicoxanthin	$C_{40}H_{52}O_3$	580.3916
4-Ketozeaxanthin	$C_{40}H_{54}O_3$	582.4073
Antheraxanthin	$C_{40}H_{56}O_3$	584.4229
Lutein epoxide	$C_{40}H_{56}O_3$	584.4229
7,8,7′,8′-Tetradehydroastaxanthin	$C_{40}H_{48}O_4$	592.3553
7,8-Didehydroastaxanthin	$C_{40}H_{50}O_4$	594.3709
Astaxanthin	$C_{40}H_{52}O_4$	596.3866
Neoxanthin	$C_{40}H_{56}O_4$	600.4179
Isozeaxanthin bispelargonate	$C_{58}H_{88}O_4$	848.6683

[a] Exact mass is defined as the monoisotopic molecular weight of a molecule and is calculated using the mass of the most abundant isotope of each element

solvents such as alcohols lead to an increased abundance of protonated carotenoids, and nonpolar solvents such as methyl-tert-butyl ether facilitate the formation of molecular ions. Even though APCI tends to produce more fragmentation in the ion source than either ESI or FAB-MS, these fragment ions are often not abundant. For example, the positive ion APCI mass spectrum of lycopene is shown in Fig. 111.12. If additional fragmentation is desired for structure confirmation, then CID with MS/MS would be required. The elemental composition and exact mass of many common carotenoids is shown in Table 111.6.

5 Conclusions

A practical way of extracting, isolating, and purifying carotenoids from plant materials is described in this chapter. The method is based mainly on the natural form in which carotenoids are found (esterified or free) and to some extent on their polarity and/or solubility in the solvents used. Common and readily available solvents and laboratory equipment are suggested. Preparation and determination of carotenoids are described. Moreover, an advanced extraction and analytical technique of carotenoids is also explained.

Abstract

Cannabinoids, a class of meroterpenoids derived from the alkylation of an olivetol-like alkyl resorcinol with a monoterpene unit, are the most typical constituents of *Cannabis*. This class includes over a hundred members belonging to several structural types, mainly differing by the constitution of their terpenoid moiety. The biomedical relevance of cannabinoids transcends the psychotropic properties of Δ^9-THC since, because of their anti-inflammatory, analgesic, and antibacterial activity, they show potential in various fields of medicine, addressing unmet needs like the symptomatic mitigation of multiple sclerosis and the treatment of MRSA infections. Research on cannabinoid activities has yielded to the discovery of an entire new class of human receptors, called cannabinoid (CB) receptors, and of their endogenous agonists, collectively named endocannabinoids (EC). Since its discovery in the early 1990s, the EC system has increasingly emerged as a key signaling system involved in a plethora of physiological and pathological functions in mammals. This chapter will provide an overview on this multi-faceted class of natural products.

Keywords

Cannabinoids • Endocannabinoids • Δ^9-THC • Psychotropic effects • Pain treatment

Abbreviations

CB receptor	Cannabinoid receptor
CBC	Cannabichromene
CBD	Cannabidiol
CBE	Cannabielsoin

SAR	Structure-activity relationship
THC	Tetrahydrocannabinol
TRPV1	Vanilloid receptor type 1

1 Introduction

Cannabinoids are a large class of meroterpenoids (prenylated polyketides) isolated from *Cannabis sativa* L. (Cannabaceae). These secondary metabolites are accumulated in the epidermal resinous glands in the leaves and flowerheads of the plant, and are characterized by very specific and potent pharmacological activities, as exemplified by the well-known activity of Δ^9-tetrahydrocannabinol (Δ^9-THC) on central nervous system (CNS). At least two *Cannabis* chemical phenotypes can be identified: (a) a fiber-type *Cannabis*, rich in cannabidiol (CBD) and almost devoid of Δ^9-THC (generally $< 0.2\ \%$ dry weight), also called hemp and used for textile or seed oil purposes, and (b) the drug type *Cannabis*, a psychotropic, Δ^9-THC-rich plant (concentration up to 20 %), whose flowers and subtending leaves and stalks are known as marijuana and are used to obtain hashish. With the exception of cannabigerol (CBG), which also occurs in an African *Helichrysum* species [1], the different varieties of *C. sativa* represent the sole natural source of these compounds.

C. sativa and cannabinoids constitute one of the most paradigmatic examples of the deep impact that natural products can have on biochemistry, pharmacology, and toxicology. This plant has been domesticated thousands of years ago, and it is one of the oldest medicinal plants, already used in China about 6,000 years ago. Modern science has discovered a wealth of pharmacological activities for the secondary metabolites of this venerable plant: in addition to the psychotropic activity of Δ^9-THC, cannabinoids have been reported to possess pharmacological potential in several other fields of medicine, including analgesic, neuroprotective, anti-inflammatory, and antibacterial activities. Most importantly, some cannabinoids have shown the capacity to address unmet needs like the relief of nausea [2] and anorexia [3], especially those associated to radio- and chemotherapy, and very significantly to mediate a mitigation of multiple sclerosis symptoms [4]. Investigation on these activities has yielded to the discovery of an entire new class of human receptors, called cannabinoid (CB) receptors, and many of the potential therapeutic uses of cannabinoids seem to be related to interaction with these receptors. However, a number of activities, like the antibacterial or the antitumor properties, are largely independent of the interaction with CB receptors and, therefore, they could be potentially dissected from the mind-altering effects of *Cannabis*. The intense research activity on CB receptors resulted also in the discovery of their endogenous agonists (collectively called endocannabinoids, EC) and, since its discovery in the early 1990s, the EC system has increasingly emerged as a key signaling system involved in a plethora of physiological and pathological functions in mammals.

The Δ^9-THC-rich chemotype of *C. sativa* constitutes nowadays the most widely utilized illicit recreational drug in the world, and the cultivation and use of psychotropic *Cannabis*, even for medicinal purposes, is illegal in many countries due to the potentially harmful acute and short-lasting effects of this drug. Many interesting comments on the impact of *C. sativa* and cannabinoids on society, on criminology, and even on art (e.g., the "Club des Hashischins" of the French artistic community [5]) could be done, but they are beyond the scope of this chapter.

2 Structural Classification of Cannabinoids

The phytochemical diversity of *C. sativa* is well illustrated by more than 500 compounds isolated from this plant, encompassing all major classes of phytochemicals (polyketides, terpenoids, alkaloids, flavonoids, stilbenoids, oxylipins). Undoubtedly, the most important and peculiar secondary metabolites of *C. sativa* are cannabinoids, a class of mono- to tetracyclic C_{21} (or C_{22}) meroterpenoids encompassing more than 100 members. These compounds are synthesized in secretory cells of glandular trichomes, most concentrated in unfertilized female cannabis flowers prior to senescence. A number of detailed accounts on the cannabinoid chemistry have been reported in the literature [6–8], also recently by Appendino et al. [9]. In this paragraph, we will provide an updated, although not comprehensive, account of the chemistry of this fascinating class of secondary metabolites.

As shown in Scheme 112.1, cannabinoids are secondary metabolites of mixed biogenesis, derived from the assembly of a resorcinyl-type polyketide moiety (commonly C_{12}, starting from hexanoylCoA, elongated with three malonylCoA units and then cyclized) and a monoterpene moiety (geranyl pyrophosphate, GPP), in turn derived from the deoxyxylulose phosphate/methylerythritol phosphate pathway. The linking of these two moieties gives rise to the formation of cannabigerolic acid (CBGA), which should be considered as the parent compound of the entire class. All the other cannabinoids differ from CBGA for an extensive rearrangement of the terpene moiety which can give rise to the formation of up to three additional rings (Fig. 112.1). It has also been demonstrated that many rearranged cannabinoids derive directly from CBG through the intervention of a single enzyme. In this context, the case of Δ^9-THC, for which an FAD-dependent enzyme (THCA synthase) has been isolated [10], is emblematic.

CBGA and the products of its rearrangement are normally isolated in small amounts and they are commonly obtained as decarboxylated analogs. This decarboxylation step is, most likely, nonenzymatic and it should occur spontaneously during either storage or extraction/purification of the compounds. Light, temperature, and cofactors are believed to facilitate the decarboxylation of the 2-hydroxybenzoic moiety. Interestingly, the carboxylated version of Δ^9-THC is not psychoactive.

An important subfamily of cannabinoids differs from the major compounds for a shorter linear alkyl chain attached to the phenyl ring. The most frequently

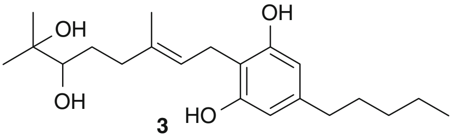
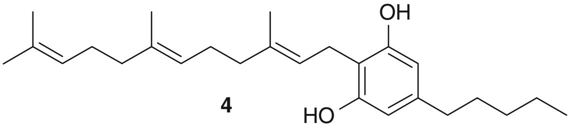
encountered are the C_3 counterparts (named cannabivarins) of the standard C_5 cannabinoids, believed to derive from a shorter starter unit (butanoylCoA) for the ketide homologation. For simplicity, in the next paragraphs, we will no longer mention cannabinoid acids and cannabivarins, but the reader should consider that practically for all the major cannabinoids also the corresponding acids and the corresponding cannabivarin analogs have been isolated. Figure 112.1 summarizes the structural variability of cannabinoids, starting from the structure of CBGA.

2.1 Monocyclic Cannabinoids: CBG-Type

A few analogs of CBG have been obtained and they differ in oxidation of either the side chain or the ring moiety, for example, carmagerol (**3**) [11]. Some quinone derivatives of cannabigerol have been recently reported from a high-potency Δ^9-THC-rich variety of *C. sativa* [12].



3



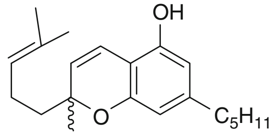
4

We have very recently reported the isolation of sesquicannabigerol (**4**) [13], the farnesyl prenylogue of CBG and the first example of cannabinoid including a terpene unit of the sesquiterpene (C_{15}) type. This molecule could be the result of a loss in the substrate specificity of the prenyltransferase-synthesizing CBG, which could occasionally accept farnesylPP in addition to the standard substrate geranylPP. Since CBG is the precursor of all the series of rearranged cannabinoids described in the next paragraphs, prenylogues of all major cannabinoids could be assumed to exist in Cannabis.

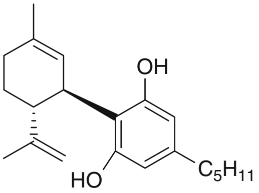
2.2 Bicyclic Cannabinoids: CBC-, CBD-, CBM-Types

An oxidative intramolecular cyclization on the CBG skeleton affords cannabichromene (CBC, **5**), found as the racemate and well represented in both psychotropic and fiber-type varieties of *C. sativa* [14]. Cannabidiol (CBD, **6**), characterized by the formation of a carbon-carbon linkage between C-1 and C-6 of the prenyl unit, is the main constituent of the non-psychotropic (fiber-type) varieties of *C. sativa*. The aromatized analog of CBD is named cannabinodiol (**7**) [15], and it is likely an artifact, since it has been observed that its concentration increases with the age of the stored plant.

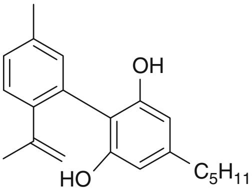
Cannabimovone (CBM, **8**), isolated from a non-psychotropic variety of *C. sativa* (Carma) [16], is characterized by an unprecedented *abeo*-menthane terpenoid structure, which can be rationalized in terms of dihydroxylation of the endocyclic double bond of CBD, followed by oxidative cleavage of the glycol system and then aldolization of the resulting dicarbonyl. Attempts to mimic this pathway led only to the crotonized analog of the natural product.



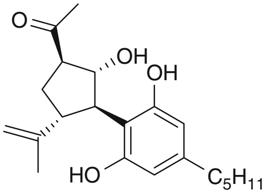
5



6



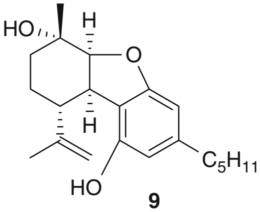
7



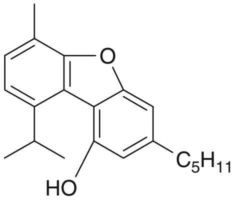
8

2.3 Tricyclic Cannabinoids: CBE- and CBF-Types

Cannabielsoin (CBE, **9**)-type compounds formally derive from attachment of one of the two phenolic oxygen atoms to the endocyclic double bond of the CBD monoterpene unit, thus generating a dihydrofuran-type ring [17]. Interestingly, compounds of the CBE class have also been detected during studies of the mammalian metabolism of CBD [18]. An aromatized analog of CBE, cannabifuran (CBF, **10**) [19], is characterized by a dibenzofuran skeleton.



9



10

2.4 Tricyclic Cannabinoids: THC-Type

This is the structural class of Δ^9-THC (**11**), the most important cannabinoid and the main bioactive component of the psychotropic varieties of *C. sativa*. Δ^9-THC (**11**) is commonly accompanied by minor amounts of the isomer Δ^8-THC (**12**) and by the completely aromatized analog cannabinol (CBN, **13**). Similar to cannabinodiol, CBN is thought to be an artifact and the Δ^9-THC/CBN ratio is used as an indication of the duration for which the marijuana samples are stored.

Cannabiripsol (**14**) is the dihydroxylated analog of Δ^9-THC [20], while cannabitriol (**15**) [21] shows a double bond at the junction between the two nonaromatic rings. Cannabitetrol (**16**) [22] is a trihydroxylated analog of Δ^9-THC. The configuration at the three stereogenic carbons of this metabolite has never been investigated.

Most recently, ElSohly and coworkers [23] have reported the isolation of a Δ^9-THC dimer, called cannabisol (**17**) from high-potency marijuana samples. Authors hypothesized that the methylene bridge connecting the two THC units could derive from a Claisen-type reaction between two THCA units followed by decarboxylation and enzymatic reduction of the resulting ketone. A dicumarol-type biogenesis involving the reaction of two molecules of THC with one formaldehyde-equivalent seems also plausible. Unfortunately, the impact on the activity of this dimerization has not been reported.

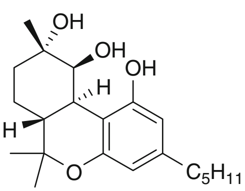
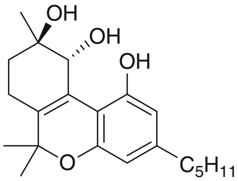
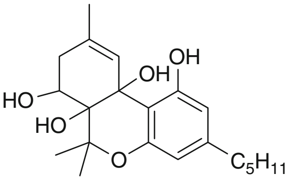
13



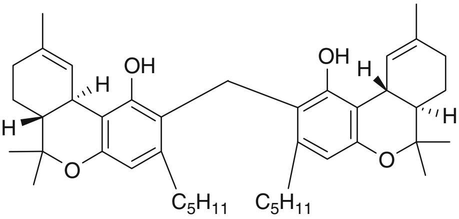
14



15



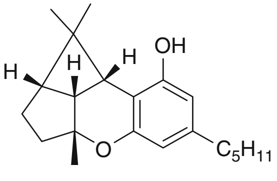
16



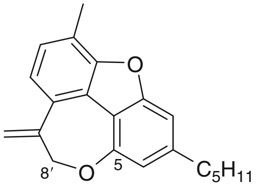
17

2.5 Tetracyclic Cannabinoids: CBL- and CBX-Types

The tetracyclic system of cannabicyclol (CBL, **18**) [24] seems to derive from a [2 + 2] intramolecular cycloaddition of CBC (**5**). It is still not clear whether the formation of CBL is the result of natural irradiation on the plant or this metabolite is an artifact formed during the extraction process. Cannabioxepane (CBX, **19**) is a novel bis-oxygen bridged diphenyl-type cannabinoid obtained by Pagani et al. [25] from the same Italian fiber hemp (cultivar Carmagnola) which yielded also CBM (**8**, see below). The skeleton of CBX bears some similarities with CBF (**10**), but it is the first cannabinoid to show a linkage between the oxygen atom at C-5 and C-8′, thus giving rise to an unprecedented seven-membered ring.



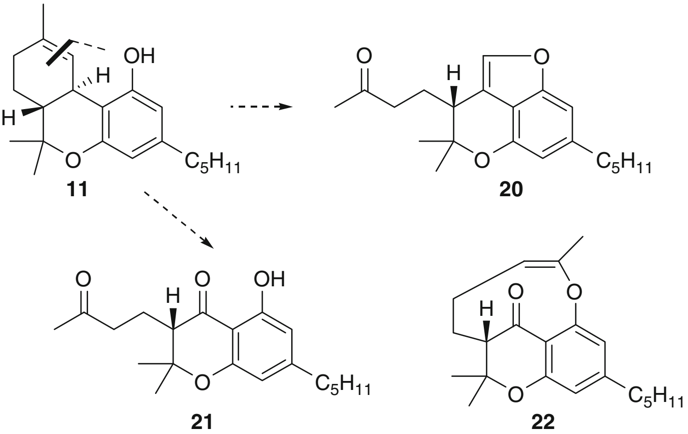
18



19

2.6 Rearranged Cannabinoids

A family of rearranged cannabinoids formally derive from Δ^9-THC through the cleavage of the tri-substituted Δ^9 double bond. In the case of cannabicoumaronone (**20**), this cleavage should be followed by hemiacetalization/dehydration yielding to the furan ring [26]. A further oxidative cleavage is the likely biogenetic origin of cannabichromanone (**21**), for which a series of derivatives, including the cyclized analog **22**, have been reported [27].



3 The Cannabinoid (CB) Receptors and Endocannabinoids (EC)

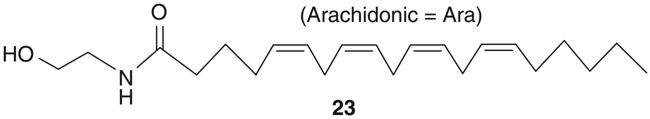
Although the psychotropic properties of Δ^9-THC were known since the middle of last century (Δ^9-THC was isolated in the pure form in 1964), investigations on the mechanism of this activity resulted in the discovery of the CB receptor family only in 1988 and their cloning in early 1990s [28].

Two cannabinoid (CB) receptors with about 40 % homology have been identified and cloned to date, namely CB_1 and CB_2. These receptors belong to the superfamily of G-protein coupled membrane receptors [29] and consequently they show a typical heptahelical structure. Interaction with cannabinoid receptors stimulates a cascade of signal transduction pathways, including interaction with potassium and calcium channels (for CB_1) and several kinases (e.g., MAP kinase). Since a number of cannabinoid-like effects persist in CB_1/CB_2 knockout mice, the existence of other cannabinoid receptors different from CB_1 and CB_2 has been suggested (e.g., GPR55) [[30], [31]], but their effective role still awaits to be clearly defined.

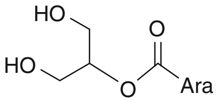
CB_1 is expressed in the brain but also in liver, kidneys, and in many other organs, while CB_2 is mainly localized on cells of the immune system (macrophages, T- and B-cells), hematopoietic cells but also on peripheral nerve terminals. The cannabinoid system has been identified as one of the most ubiquitous and pleiotropic pro-homeostatic system, whose role should be to help cells and organs to reestablish the physiological steady state after acute or chronic perturbations of their homeostasis [32]. Thus, cannabinoids participate in the regulation of practically all the biological and physiological systems of the organism.

The presence of CB receptors implies the existence of endogenous ligands. The first member of this family of neuromodulator lipids, collectively indicated as endocannabinoids, has been discovered in 1992 by Mechoulam and Devane [33], identified as *N*-arachidonylethanolamine and called anandamide (**23**). Endocannabinoids are amide (e.g., anandamide), ester (e.g., 2-arachidonoyl glycerol, **24**) [34], or ether (e.g., noladin) derivatives of arachidonic acid with small molecules, such as ethanolamine or glycerol.

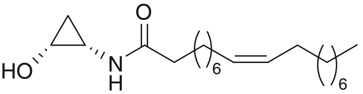
Other endogenous fatty acid amides (such as palmitoylethanolamide, PEA) do not activate CB_1 and CB_2 receptors, but they exhibit anti-inflammatory and analgesic properties [35], due to the interaction with peroxisome proliferator-activated receptor alpha (PPAR-α) and possibly also with the postulated new cannabinoid receptors GPR55 and GPR119 [36].



23



24



25

PEA has been demonstrated to potentiate the effects of classical endocannabinoids as anandamide or arachidonoyl glycerol, and this has been called "entourage effect" [37]. We have recently shown [38] that introduction of a methylene lock on the ethanolamide head to generate a cyclopropane ring is able to trigger strong CB_1 affinity in oleoylethanolamide, as in compound **25**, but not in PEA.

The enzymes that degrade the endocannabinoids, such as fatty acid amide hydrolase (FAAH) or monoacylglycerol (MAG) lipase, are an obvious pharmacological target to modulate the effects of cannabinoid receptors (illustrated in the next paragraph). In particular, targeting FAAH activity has been identified as a promising new therapeutic strategy for the treatment of pain and other neurological-related or inflammatory disorders. FAAH belongs to the superfamily of serine hydrolases characterized by a Ser-Ser-Lys catalytic triad. Most of the FAAH inhibitors disclosed so far act through a covalent modification of the catalytic serine in the active site, but recently the first noncovalent inhibitor of FAAH, characterized by a keto-benzimidazole structure, has been reported [39].

4 CB-Mediated Effects of Cannabinoids

Given their ubiquitous distribution, CB receptors are involved in the regulation of many biological and physiological systems of the organism. However, the most important pharmacological effects triggered by stimulation of CB receptors can be identified as the: (a) *psychotropic effects*, (b) *analgesic effects*, (c) *immunomodulatory effects*, and (d) *cardiovascular effects*.

4.1 Psychotropic Effects

The psychoactive effects of cannabinoids are mediated by interaction with central CB_1 receptors [40]. Δ^9-THC shows the highest affinity to CB receptors (K_i ab. 40 nM for both CB_1 and CB_2) [41], while CBD and other non-psychoactive cannabinoids show a very low affinity for CB receptors, but some of them act as inverse agonist for CB_1 [42].

The euphoric feelings associated with *Cannabis* use are thus ascribable to the interaction of Δ^9-THC with CB_1 receptors on presynaptic nerve terminals. However, CB receptors are also present in other areas of CNS, and thus, the same cannabinoids also cause impairment of cognition and memory (hippocampus) [43], involuntary movements and partial loss of motor control (basal ganglia and cerebellum) [44], and a beneficial and potential therapeutically useful inhibition of emesis [45], especially of the chemotherapy-induced emesis. It is still unclear whether the CB receptors are responsible for all of the centrally mediated actions of the cannabinoids.

4.2 Analgesic Effects

CB_1 receptors play an important role in the transmission of the nociceptive information in several key tissues, and the interaction of some cannabinoids with CB_1

confers them a powerful analgesic effect. It has been estimated that Δ^9-THC is as potent as morphine in blocking nociceptive stimuli in many animal models [46], and, moreover, it can act synergistically with opioid-receptor agonists.

The analgesic effect of cannabinoids could be partly due also to the binding of PPAR-γ and of some thermo-TRPs, ion-channels characterized by an intracellular ligand-binding domain and co-involved in pain and inflammation [47].

4.3 Immunomodulation

The immunomodulatory properties of Δ^9-THC [48] are likely due to the interaction with CB_2 receptors, highly expressed in cells of the immune system (T-cells, B-cells, macrophages). The effect on the immune system of cannabinoid administration appears to be hormesic, and related to the dosage. Indeed, high doses of cannabinoids suppress immune responses, while more physiologically relevant concentrations of cannabinoids result in metabolic stimulation of lymphocytes and in an increase in pro-inflammatory cytokine production rather than immunosuppression. It has been proposed that the immunosuppressive properties of cannabinoids can find application in the treatment of multiple sclerosis.

4.4 Cardiovascular Effects

Δ^9-THC has a well-known effect on blood pressure (prolonged hypotension) and heart rate (initial bradycardic response) through interaction with CB_1 receptor [49], but also with TRPV1. FAAH inhibitors have revealed the antihypertensive effects of endogenously elevated anandamide levels and have been proposed as a strategy to prevent complications of cardiomyopathies.

5 Structure-Activity Relationships of Cannabinoids

Δ^9-THC is the single most potent natural cannabinoid interacting with CB receptors, and the isolation of analogs, coupled to the synthesis of several derivatives, have highlighted the most important pharmacophoric portions of this molecule.

The presence of an alkyl side chain on the aromatic ring is required for activity. The affinity for the CB receptor decreases in cannabivarins (C_3 alkyl chain) [50], while it has been demonstrated to increase for synthetic C_7 or C_8 chains. Synthetic cannabinoids with methyl branching at one or both the first two carbons of the side chain (or showing double or triple bonds at these positions) have also shown a greater affinity for both CB receptors [51]. For example, compound **26** (Fig. 112.2) showed high affinities for both CB_1 and CB_2 (ab. 0.4 nM).

The free hydroxyl group on the aromatic ring A is required for activity on CB_1 presumably due to the formation of hydrogen bonding with Lys12 in transmembrane helix 3 [52].

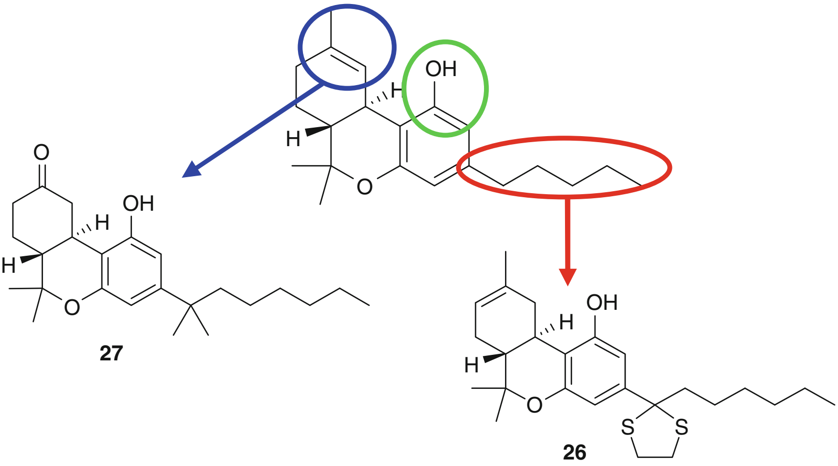


Fig. 112.2 Main sites of modification on the scaffold of Δ^9-THC

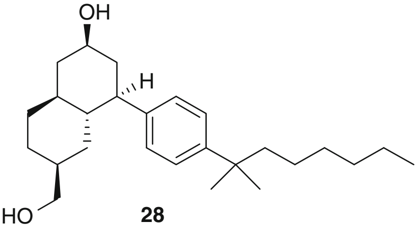
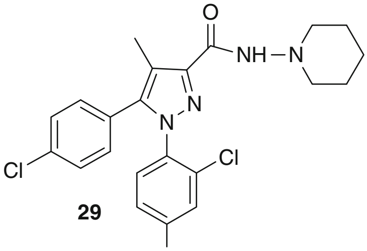
Hydroxylation or oxidative cleavage of the allylic methyl group present on the carbocyclic nonaromatic ring increases affinity for both CB receptors, as exemplified by the structure of nabilone (**27**), which has been introduced into the market as antiemetic agent for cancer supporting care and has also recently been approved in USA for the treatment of neuropathic pain [53]. The position of the double bond seems to be not crucial, indeed Δ^8-THC is almost equipotent with Δ^9-THC; however, aromatization of this ring, as occurs in CBN, causes a marked decrease in affinity.

A number of synthetic compounds, showing only vague similarities with Δ^9-THC and other natural cannabinoids, have been described. These compounds show potent affinity for both CB_1 and CB_2 in the one-digit nanomolar range (e.g., CP-55,244, **28**) [54]. The synthesis of some of these compounds is simple and has fueled the development of an illegal market for cannabinoid analogs, as exemplified by the infamous *spice* [55]. Interestingly, β-caryophyllene, a very common sesquiterpenoid also present in cannabis, has been found to be a selective full agonist of CB_2 [56], qualifying as the first phytocannabinoid of wide distribution in plants.

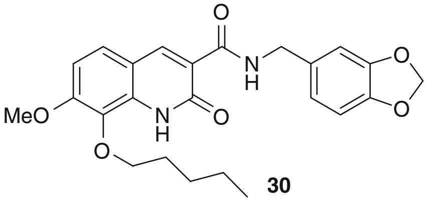
A number of synthetic compounds, completely unrelated to the structure of natural cannabinoids have been found to act as CB_1 and/or CB_2 antagonist/inverse agonist. The most important member of this class of compounds is rimonabant (**29**), a diarylpyrazole derivative [57], approved for the treatment of obesity and as an aid in the cessation of cigarette smoking, but later withdrawn from the market because of the severe depression it could induce in sensitive patients. A number of structural motifs significantly different from the pyrazole system have been proposed for CB_2 selective antagonists, as exemplified by the quinoline derivative **30**.



28



29



30

6 Other Biological Activities of Cannabinoids

Owing to the presence of high concentrations of Δ^9-THC, biomedical attention on *C. sativa* has so far mainly focused on the psychotropic varieties of this plant, while the pharmacological potential of fiber hemp has been largely overlooked. However, certain biological properties of THC are shared also by non-psychotropic cannabinoids, and thus, some pharmacologically useful activities of *C. sativa*, such as antibacterial and anti-inflammatory actions, could be dissected from its psychotropic potential and an easier therapeutic application found [58].

6.1 Neuroprotective Effect

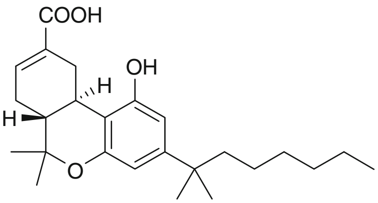
The neuroprotection exhibited by Δ^9-THC and CBD is likely a multicomponent effect, mediated by interaction with CB, PPAR-α [59], 5-HT$_1$a, and other receptors which are involved in a very complex neural web and whose manipulation is difficult to predict in terms of in vivo effects. Δ^9-THC likely acts mainly by activating CB$_1$ receptors on presynaptic terminals of glutamatergic and GABAergic synapses and suppressing the presynaptic release of these neurotransmitters [60], while CBD likely acts by interacting with 5-HT$_1$a receptors leading to an increased cerebral blood flow and neuroprotective effect [61].

Cannabinoids, particularly CBD, have been proposed for treatment of spasticity and pain symptoms associated with multiple sclerosis and amyotrophic lateral sclerosis, and some CBD analogs have been proposed for neuroprotection in glaucoma to delay the progressive damage of the optic nerve [62].

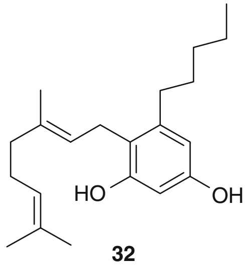
6.2 Anti-inflammatory and Anticancer Activity

Since non-psychoactive cannabinoids, such as CBD and CBN, are able to induce a marked decrease in the levels of interferons, pro-inflammatory cytokines, and chemokines after stimulation with LPS [63], this activity is unlikely to be mediated by interaction with CB receptors, while the involvement of the adenosine signaling has, rather, been postulated [64]. CBD and CBG have also demonstrated a non-CB-mediated inhibition of the proliferation of human keratinocytes, supporting a potential role for cannabinoids in the treatment of psoriasis [65]. A synthetic cannabinoid, ajulemic acid (**31**), has been proposed for treatment of arthritis and for the management of pain and inflammation in multiple sclerosis patients [66].

Owing to the connections existing between inflammation and cancer, it is not surprising that some cannabinoids have been associated with a reduction of the cancer proliferation. Δ^9-THC retards the growth of lung adenocarcinoma [67] and induces apoptosis in C6 glioma cells through activation of mitogen-activated protein (MAP) kinases and interaction with ERK-dependent pathways. CBD (or its quinone derivative) seems to act through an apoptotic mechanism and activation of caspase-3 [68, 69]. CBD has also been shown to reverse insensitivity of cancer cells to vinblastine by reducing expression of Pgp [70] and to inhibit BCRP and MRP1, the two additional transporters involved in chemoresistance [71, 72].



31

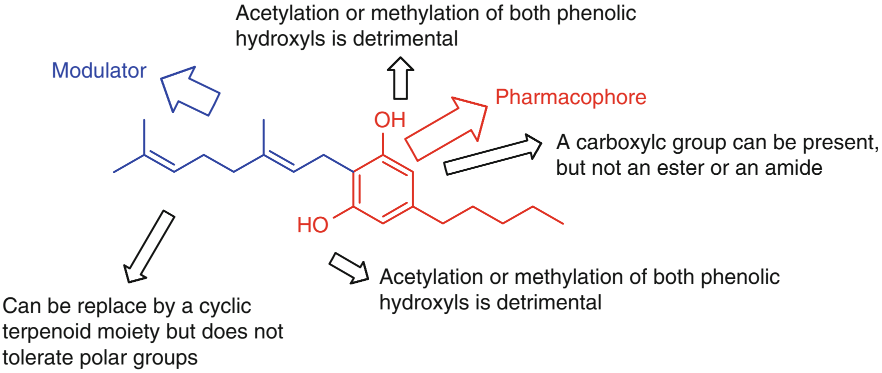


32

In this context, it should be remarked that *Cannabis* contains also non-cannabinoid phenolics (cannaflavins, canniprene, cannabispirenone), endowed with potent inhibitory activity against some pro-inflammatory enzymes like COX [73, 74], with the potential to complement the activity of cannabinoids in terms of anti-inflammatory action.

6.3 Antibacterial Activity

Since cannabinoids are phenolics, their antibacterial activity is not surprising; however, their potency and the activity against multidrug-resistant bacterial strains are remarkable. Data on the antibiotic activity of CBC [75], CBG [76], CBD [77], and Δ^9-THC [77] have been obtained, and *C. sativa* preparations have been investigated as topical antiseptic agents. More recently, the potential of the major cannabinoids to address antibiotic resistance to methicillin-resistant



Acetylation or methylation of both phenolic hydroxyls is detrimental
Modulator

Fig. 112.3 Structure-activity relationships for the antibacterial activity of cannabinoids

Staphylococcus aureus (MRSA) has been investigated [78]. MRSA infections are responsible for over 10 % of cases of septicemia cases, and CBD, CBC, CBG, Δ^9-THC, and CBN showed potent activity against a variety of MRSA strains of current clinical relevance (MIC values in the 0.5–2 μg/mL range), outperforming antibiotics currently used for the management of these infections.

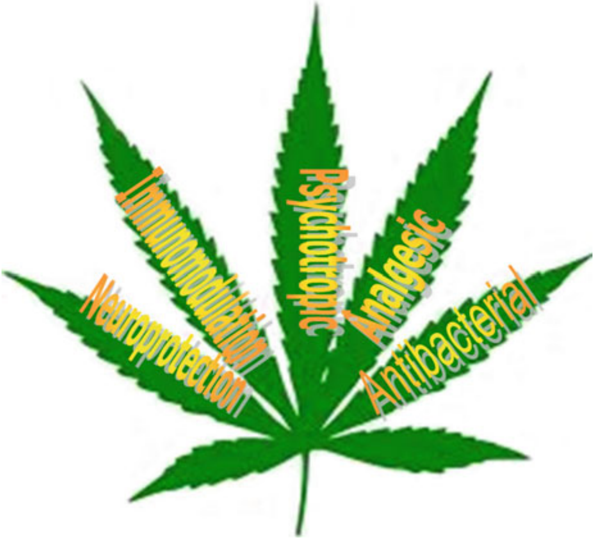
Structure-activity studies on the non-psychotropic CBD and CBG showed that the antibacterial activity was remarkably tolerant toward the nature of the prenyl moiety, its relative position compared to the *n*-pentyl moiety (abnormal cannabinoids, e.g., **32**), and toward carboxylation of the resorcinyl moiety (cannabinoid acids). Conversely, decrease in the polarity, obtained through derivatization of the phenolic hydroxyls, or introduction of a second prenyl moiety is proved to be detrimental for antibacterial activity. SAR for the antibacterial activity is summarized in Fig. 112.3.

It has been proposed that some monoterpenoid constituents of *Cannabis*, such as α-pinene or limonene, may synergize the antibacterial action of CBD, CBG, and CBN [79]. Interestingly, a potentiating effect of mono- or sesquiterpenoids present in *Cannabis* has been postulated also for other activities, and this observation supports arguments that whole plants and their complex preparations are better drugs than individual components isolated from them.

7 Conclusions

Cannabinoids and endocannabinoids are a hot topic of chemical and biomedical research, and more than one thousand research articles and a host of well-documented reviews have been written in the last three decades on this class of compounds. The debacle of the CB_1 inverse agonist rimonabant well exemplifies the difficulties of working with these pleiotropic compounds, while the successful development of Sativex^{TM} – a combination of natural cannabinoids approved in Canada, UK, and Spain for the symptomatic treatment of multiple sclerosis – is encouraging.

Fig. 112.4 A pictorial view of the most important pharmacological activities associated to cannabinoids



In Fig. 112.4, we have pictorially indicated the most important pharmacologic activities associated to cannabinoids; the contribution of novel researches in this area will, hopefully, foster the optimal exploitation of this ancient but still largely unexplored plant.

Abstract

Phytosterols (PS) are plant sterols and stanols widely distributed in plant sources that resemble cholesterol in terms of structure and physiological functions. The cholesterol-lowering capacity of PS is well documented in animal and human studies. However, recent studies suggest that the beneficial effects of PS are not only limited to their hypocholesterolemic capacity as they can also act as immunomodulatory, anti-inflammatory, and antidiabetic agents. Further, there is a growing body of evidence which supports that they play an important role in the prevention of other diseases such as cancer and atherosclerosis. Nevertheless, the mechanisms by which PS exert their beneficial functions, the physiological relevance of PS, and their potential adverse effects are not yet fully understood. Therefore, the main aim of this chapter is to provide a contemporaneous overview of the beneficial properties of PS, their mechanism of action, and safety.

anticancer • antidiabetic • cardiovascular diseases • cholesterol • immunomodulation • inflammation • molecular mechanism • phytostanols • phytosterols • side effects

Abbreviations

ABC	ATP-binding cassette transporter
ACAT	Acyl-CoA: cholesterol *O*-acyltransferase
CHD	Cardiovascular heart disease
GST	Glutathione-*S*-transferase(s)
HDL	High-density lipoprotein
HMG-CoA	3-Hydroxy-3-methyl-glutaryl-coenzyme A
hs-CRP	High-sensitive C-reactive protein
IDL	Intermediate-density lipoprotein
IL	Interleukin
LDL	Low-density lipoprotein
LDL-c	Low-density lipoprotein cholesterol
LTB_4	Leukotriene B4
LXR	Liver X receptor
NPC1L1	Niemann-Pick C1-like 1 protein
PS	Phytosterol(s)
PSO	Phytosterol oxide(s)
TICE	Transintestinal cholesterol efflux
TNF-α	Tumor necrosis factor alpha
VLDL	Very-low-density lipoprotein

1 Introduction

Phytosterols (PS) are plant sterols or stanols found in plants. Plant sterols belong to the triterpene family and differ from cholesterol by having a methyl or ethyl group in C24. Plant stanols, on the other hand, are the saturated form of the plant sterols (Fig. 113.1). PS are present in free or conjugated form as fatty-acyl esters, hydroxycinnamate steryl esters, steryl glycosides, or acylated steryl glycosides. The main function of plant sterols/stanols is to stabilize plant membranes and serve as precursors in the synthesis of steroidal saponins, alkaloids, and other steroids [1].

PS are widely distributed in plants and plant-containing foods. The most abundant of which are β-sitosterol, campesterol, and stigmasterol [2]. Table 113.1 shows the most common sources of PS. Vegetable oils are considered to be the major sources of PS and their esters [2]. Other good dietary sources include legumes, plant seeds, cereals, and cereal-milling products [3–6]. It is estimated that the dietary intake of PS ranges between 150 mg day^{-1} in western-style diets to 500 mg day^{-1} in diets rich in vegetable dietary habits [7, 8].

The capacity of both plant sterols and stanols to reduce blood cholesterol is well documented [10–12]. However, their precise mechanism of action is not yet fully defined. Current research is providing new insights on the mechanisms of action of PS as well as potential new roles in other physiological benefits. In addition, the safety of these products when they are used at high doses has recently been challenged. Therefore, the main objective of the present review is to discuss current evidences regarding not only the bioactive properties of PS and their mechanism of action but also their potential undesirable effects.

2 Metabolism and Physiological Effects

A large number of studies have provided consistent evidence on the beneficial physiological effects of PS, especially their hypocholesterolemic capacity [10, 13–15]. Thus, the use of PS as functional food components or dietary supplements has become of great interest and led to the development of a wide variety of functional foods and nutraceutical products [16, 17].

2.1 Phytosterol Bioavailability

Like cholesterol, PS are absorbed in the proximal part of the small intestine after being incorporated into mixed micelles. Compared to cholesterol, the intestinal absorption of PS is low. While 40–60% of dietary cholesterol is absorbed, only about 5% of the PS are absorbed [18]. In addition, the efficiency of PS absorption is critically dependent on the structure of both sterol nucleus and side chain. For instance, the rate of plant sterol absorption was investigated in a human study

using deuterium-labeled PS. The absorption rates of the different plant sterols were 1.9% and 0.5% for campesterol and β-sitosterol, respectively, whereas that of stanols were 0.16% for campestanol and 0.04% for sitostanol [19]. Plasma concentrations of PS are normally very low due to the low absorption of these compounds but it can be very variable among populations mainly due to the differences in dietary habits. Plasma concentrations of campesterol range from 6.9 to 27.9 μmol L^{-1}, whereas those of sitosterol range from 2.8 to 16.0 μmol L^{-1} [20].

2.2 Hypocholesterolemic Effect

An elevated concentration of plasma cholesterol is considered one of the most important risk factors for the development of coronary heart disease (CHD) [21]. The hypocholesterolemic effect of PS was first demonstrated in the 1950s [22]. Since then, the capacity of both plant sterols and stanols to reduce blood cholesterol has been well documented [10–12]. Moreover, a large number of clinical studies has confirmed their efficiency as cholesterol-lowering agents in humans (see Ref. [15] and [23] for exhaustive summary of clinical trials).

The beneficial effects of PS on cholesterol levels are usually shown after a period as short as 2–3 weeks of intervention and remain stable for at least 1 year of continuous treatment [15]. In humans, the absorption of cholesterol can be reduced by 30–40% after consumption of 1.5–2.0 g day^{-1} [15, 24]. Doses of 0.8–4.0 g of PS day^{-1} have been efficient in reducing LDL-cholesterol (LDL-c) concentration by 10–15% [10]. However, a dose of 2.0 g day^{-1}, which can result in a reduction of plasma LDL-c of 10%, has been proposed as optimal [25]. Higher doses than 2.0 g day^{-1} are in general not recommended as they do not show additional reductions in cholesterol levels and may lead to undesirable side effects [16], although this aspect remains controversial [26]. In addition, it has been suggested that in some cases, PS exert beneficial effects on other lipid variables, such as increasing HDL-cholesterol, decreasing triglycerides levels, and decreasing the ratio of apolipoprotein B/apolipoprotein A1 [27].

It is still a matter of controversy whether plant sterols and stanols are equally efficient in reducing cholesterol levels [28]. Some studies have shown that despite their different bioavailability, there is no clinical relevance with regard to their effect on total cholesterol, LDL-c, HDL-cholesterol, or triglyceride levels [25, 29]. Nevertheless, other authors have suggested that the differences in efficacy between plant sterols and plant stanols remain in the long-term interventions rather than in the short-term studies [30]. For instance, in a recent meta-analysis of randomized placebo-controlled trials, decreases in LDL-c concentrations were dose-dependent for plant stanols but not for sterols. Similarly, intakes of plant stanols higher than 2 g day^{-1} have been associated with additional and dose-dependent reductions in LDL-c [26]. Yet, this effect remains questionable [29]. It has been proposed that the difference in efficiency between these two compounds may be explained by the fact that plant stanols may reside longer in the intestine due to their lower absorption [31].

Several factors can influence the overall effect of plant sterols and stanols. Naumann et al. [32] reported that men are slightly more sensitive to PS intake than women, although the responsible mechanism for this difference is unknown. Another factor that may influence the efficiency of PS involves the baseline levels of plasma lipids [25, 32, 33]. For example, subjects with high and very high baseline levels showed stronger reductions in LDL-c levels than subjects with levels near optimal clinical concentrations [25, 33]. However, these effects could not be reproduced by other authors [34]. Similarly, controversial effects are seen on the improvement of other lipid parameters as HDL-cholesterol concentration increases in subjects with low baseline levels and decreases in those subjects with initially high levels [32]. These differences suggest that people with an unfavorable ratio of total to HDL-cholesterol would especially benefit from PS consumption.

Another beneficial effect of PS is based on their ability to decrease serum concentrations of triacylglycerols especially in people with high serum concentrations [32]. This effect may be attributed to a reduction in the synthesis of very-low-density lipoproteins (VLDL), which are the main transporters of this type of lipids [35].

2.3 Combination with Other Therapies

In order to increase the effectiveness of PS in the reduction of CHD-associated factors, PS can be used in combination with other drugs or bioactive substances [23]. For instance, PS have been used in combined therapies with statins (3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) inhibitors) [36], with

Table 113.2 Summary of intervention studies of PS combined with other therapies

Combined therapy	Study design	Time[a]	Conclusions	References
Stable statin treatment + plant sterols (2.0 g day^{-1})	Double-blind, randomized trial (55 patients on stable statin treatment)	6 weeks	No further cholesterol reduction observed	[40]
Stable statin treatment + plant sterols or plant stanol (2.5 g day^{-1} each)	Double-blind, randomized trial (54 patients on stable statin treatment)	85 weeks	Increased reduction of LDL-c for both plant sterols (8.7%) and plant stanols (13.1%) compared to statin treatment alone	[41]
Ezetimibe (10 mg day^{-1}) + phytosterols (2.0 g day^{-1})	Double-blind, randomized trial (40 mildly hypercholesterolemic subjects)	4 weeks	No therapeutic benefit over ezetimibe	[42]
Ezetimibe (10 mg day^{1}) + phytosterols (2.5 g day^{-1})	Double-blind, randomized, placebo-controlled, triple crossover study (21 mildly hypercholesterolemic subjects)	3 weeks	Enhanced reduction of LDL-c from 16% (ezetimibe alone) to 22% (combined therapy)	[43]
Saturated-fat dairy and whole wheat cereal diet + diet containing viscous fibers (5–10 g day^{-1}), soy foods (25 g soy protein day^{-1}), and almonds (estimated total PS intake of 1–3 g day^{-1})	Randomized crossover trial (34 hypercholesterolemic subjects)	4 weeks	LDL-c reduction of 29%, which was similar to that of statins	[44]
Omega-3 polyunsaturated fatty acids provided as sunola (1.4 g day^{-1}) or fish oils (1.4 g day^{-1}) + plant sterols (1.4 g day^{-1})	Randomized, double-blind, 2 × 2 factorial design (60 hyperlipidemic subjects)	3 weeks	Reduction of inflammatory markers: hs-CRP, TNF-α, IL-6, and LTB_4. Increased levels of adiponectin. Higher CHD risk reduction	[38]
Fish oil (2.0 g day^{-1}) + plant sterols (2.0 g day^{-1})	Randomized, double-blind, 2 × 2 factorial design (200 hypercholesterolemic subjects)	4 weeks	The combination lowered triglycerides by 15% compared to control but no significant interaction between PS and n-3 on plasma cholesterol	[45]

ezetimibe (inhibitor of cholesterol transporter of Niemann-Pick C1-like 1 (NPC1L1) that blocks the intestinal absorption of both biliary and dietary cholesterol) [37], with n-3 polyunsaturated fatty acids [38], and with different fibers [39], among others. A summary of clinical studies is shown in Table 113.2.

The combination of n-3 polyunsaturated fatty acids with PS is having an emerging interest; it has been reported that it is effective in reducing the levels of inflammation markers [38, 46] and cardiovascular risk factors including total cholesterol and triglyceride concentrations, pro-aggregatory factors, eicosanoid, and thromboxane A2 levels [47]. Moreover, Micallef et al. [38] estimated that sunola or fish oils (4.0 g day^{-1}), which are rich in n-3 fatty acids, were more efficient in reducing cancer risk when administered in combination with 2.0 g day^{-1} of PS than when administered alone.

Nevertheless, despite that the use of PS with other therapies seems promising, clinical evidence remains scarce and far from being conclusive.

3 Mechanism of Action

The cholesterol-lowering activity of PS has been attributed to several mechanisms which are mainly ascribed to their structural similarities with cholesterol. Traditionally, the main mechanism accounted for the cholesterol-lowering capacity of PS has been attributed to the competitive solubilization into mixed micelles between cholesterol and PS at the intestinal level [48]. However, several studies have provided evidence to support that the cholesterol-lowering activity is also related to mechanisms other than interference with cholesterol incorporation into micelles [15, 28, 49, 50]. Although the physiological relevance of all these mechanisms is not clear, the metabolic effects of PS are commonly attributed to lower absorption of cholesterol and changes in intestinal cholesterol efflux and lipoprotein homeostasis. These mechanisms are summarized in Scheme 113.1.

3.1 Competitive Incorporation into Mixed Micelles

Intestinal cholesterol absorption begins with the incorporation of both dietary and biliary cholesterol into mixed micelles. A large number of studies have demonstrated the competition between cholesterol and PS for solubilization into micelles [48, 51–54], wherein the incorporation of PS into mixed micelles seems to be more favorable than that of cholesterol [48, 54]. However, it remains questionable whether sterols and stanols can compete for micellar incorporation differently. In vitro studies using micelle preparations have shown that cholesterol can be substituted in a similar extent by the most abundant phytosterols: campesterol, sitosterol, and sitostanol [54]. On the contrary, the effect of minor plant sterols (i.e., stigmasterol) is not clear. While some authors have reported that minor sterols have lower ability to decrease cholesterol solubility [53], others have not detected such differences [52]. Differences in the micellar system used may well be responsible for the discrepancies between studies.

3.2 Effect of PS at Intestinal Level

Once cholesterol is incorporated into the micelles, its uptake by enterocytes is actively mediated by transporters, mainly NPC1L1 protein, which is located in the brush border membrane [55, 56]. Cholesterol is then esterified with fatty acids by acyl-CoA: cholesterol *O*-acyltransferase 2 (ACAT-2), incorporated into chylomicrons and then secreted to the lymph through the basolateral membrane of the enterocyte [57]. Unesterified cholesterol can be secreted back to the intestinal lumen by ATP-binding cassette transporters G5 and G8 (ABCG5/ABCG8) in direct opposition to NPC1L1 [58]. Moreover, ABCA1 can mediate the incorporation of sterols into nascent high-density lipoproteins (HDL) which lead to their secretion into the lymph [59]. Alternatively, emerging evidence suggests that the proximal part of the small intestine is able to secrete cholesterol actively, a pathway called transintestinal cholesterol efflux (TICE), although its molecular mechanism has not yet been elucidated [60].

Therefore, cholesterol absorption is a complex process that involves different molecular targets. Recent studies have proposed that PS can play an important role in this process [49, 50], although the mechanisms are not yet fully understood and further investigation is necessary. It has been postulated that LXR induction could explain the hypocholesterolemic action of PS [51, 61]. However, this hypothesis is still controversial [62]. For instance, although some authors have reported that PS can act as LXR ligands [51, 61] and regulate the expression of NPC1L1 and ABC transporters [58, 63], others could not confirm this role [49, 50]. Moreover, it has been reported that dietary PS decrease intestinal cholesterol absorption independently of changes in gene expression of intestinal NPC1L1 and ABC transporters [64, 65]. These observations do not rule out the possibility that the activity of these transporters could be altered by PS through posttranscriptional mechanism. Thus, several studies have used genetically engineered mice to examine the involvement of these transporters [66, 67]. However, these studies have shown that the reduction in cholesterol induced by PS is not influenced by the absence of the heterodimer ABCG5/G8 [66] and ABCA1 transporter [67].

Other mechanisms independent to LXR have also been proposed [49]. For instance, it is plausible that PS could reduce plasma cholesterol levels by competing with cholesterol for esterification in the enterocyte by ACAT-2 enzyme, thus reducing its incorporation into chylomicrons [68]. In addition, in vitro experiments with CaCo-2 cells have demonstrated that PS can reduce endogenous cholesterol synthesis by inhibiting the expression of HMG-CoA, a rate-limiting enzyme in the synthesis of cholesterol [69]. However, other reports have reported contradictory results [70, 71]. Although its functional importance is less clear, it has been hypothesized that PS can also interfere with the expression of other mucosa proteins from the ANX family, such as ANXA2, which are involved in cholesteryl ester transport [49, 72]. Since ANXA2 mediates the internalization of cholesteryl esters from caveolae to internal membranes of the brush border [73], it has been postulated that PS may reduce cholesterol transport [49]. Nevertheless, there is yet no clinical evidence to confirm this hypothesis. Finally, it has been recently reported that PS can also increase cholesterol excretion via TICE [50], although further research is necessary to elucidate the molecular mechanisms.

In conclusion, although recent insights into the intestinal absorption of cholesterol have also provided new evidence regarding the potential action of PS, the molecular mechanisms of PS are still a field of debate and further research is necessary.

3.3 Effect of PS on the Liver

It is well known that the liver plays a critical role in cholesterol homeostasis. Hepatic cholesterol concentrations are a balance of its intestinal absorption, its synthesis, its degradation to bile acids, and its excretion with the bile or as VLDL [74]. Reduced cholesterol absorption results in multiple changes in lipid homeostasis in the liver.

Firstly, a decrease in hepatic cholesterol concentrations leads to an upregulation of LDL-receptor expression, ultimately leading to a decrease in plasma LDL-cholesterol [28]. In addition, lower hepatic cholesterol may lead to reduced liver secretion of VLDL [75, 76]. Like in the intestine, ABCG5 and ABCG8 transporters can also be upregulated by PS, which favors hepatic secretion of cholesterol into the intestinal lumen [49].

Finally, since the absorption of cholesterol is reduced by PS, this reduction would lead to a compensatory increase in de novo synthesis of cholesterol [71]. Indeed, cholesterol biosynthesis is upregulated after consumption of diets containing phytosterols, although this increment is insufficient to offset the beneficial effects of phytosterol [28, 49, 77].

4 Other Biological Activities

The beneficial effect of PS has been traditionally ascribed to their cholesterol-lowering properties. However, recent research reveals that their biological role has been underestimated. Several in vitro and in vivo studies have reported that PS can act as immunomodulatory and anti-inflammatory agents and reduce the risk of several diseases such as cancer [13, 78, 79].

4.1 Cancer Preventive Agents

The second major beneficial effect of PS is based on their role as cancer preventive agents [78, 80–82]. The activity of a large number of phytochemicals (alone or combined with other factors) as cancer preventives has been largely reviewed and discussed [80, 83]. Some authors have suggested that PS can reduce cancer risk, although there is still a lack of data in humans, similar to those manifested by other phytochemicals [81]. PS have been proposed to prevent cancer development through several mechanisms of action such as inhibition of carcinogen production, cancer-cell growth, angiogenesis, and promoting apoptosis [80]. Emerging evidence suggests that PS can consequently play an important role in the prevention of several types of cancer such as lung, stomach, prostate, ovarian, and breast cancer [80].

One of the first studies suggesting the preventive effect of PS on cancer showed that Seventh-Day Adventists, having a high dietary intake of PS, presented low rates of colon cancer [84]. The PS intake in this population could reach 344 mg day^{-1}, which was considerably high in comparison with the average intake of the USA population. This preventive effect was mainly attributed to the reduced bile acid excretion of this population after PS intake [85], as it is known that high levels of bile acids in the bowel can increase the risk of colon cancer [86]. In contrast, contradictory results have been reported with regard to decreased bile acid excretion due to PS intake [14]. Moreover, these findings are limited by the possible modulating effect coming from other components of the diet. Ileostomy studies are more accurate to determine their effect on reducing bile acid levels in the bowel as the variability attributed to side factors can be minimized or even eliminated [87]. Revision of the available studies on this subject reveals that the magnitude of the effect attributed to PS on the reduction of bile acid excretion can be highly dependent on other dietary factors that must be taken into account. In addition, the effect on bile acid excretion can vary according to the molecule of the PS studied [81].

Some authors have proposed that other mechanisms could be involved in the cancer preventive effect of PS. Awad and Fink [88] proposed a hypothesis based on the inhibition of cell growth through stimulation of apoptosis (programmed cell death). In vitro studies have also shown the inhibitory effect of certain PS on breast- and colon-cancer cell cultures and, in a lower extent, on prostate-cancer cells [88, 89]. Another proposed mechanism is based in the capacity of PS to stimulate the sphingomyelin cycle. For instance, sitosterol seems to have a clear in vitro modulatory effect on this cycle. The PS molecule can be incorporated into the cell wall, thus reducing sphingomyelin and increasing ceramide levels in the cell membrane, which can consequently increase cell apoptosis [89, 90]. Finally, changes in testosterone concentrations can also be accounted as an alternative mechanism involved in the prevention of prostate cancer [88]. It has been also reported that diets containing 2% PS reduce the activity of 5α-reductase in liver and prostate and thus the testosterone levels in plasma [91]. However, this hypothesis has not yet been confirmed in human studies.

Furthermore, PS have also been associated as agents capable to reduce angiogenesis and metastasis [80]. In vitro studies reveal that a reduction in the invasiveness and adhesiveness of cancer cells can be responsible, at least in part, of a lower metastasis capacity of cancer cells [92, 93]. However, further clinical studies are necessary to corroborate the anti-angiogenic properties of PS.

In a similar way than other phytochemicals, comparison between animal and human studies is controversial as it is difficult to extrapolate the effective doses necessary to reach clinical relevance. In general terms, extrapolation of doses from animals to human suggests that very high intakes would be necessary to reach significant effects.

4.2 Modulation of the Immune System and Anti-inflammatory Properties

Modulation of the immune system and reduction of inflammatory disorders have also been proposed as other beneficial effects of PS consumption [13, 79].

First evidences suggested that PS can modulate the immune system by improving the activity of T lymphocytes and natural killer cells [94]. Further clinical studies have investigated the immunomodulatory effect of PS under clinical trial situations [94, 95]. The findings reveal that PS consumption can improve the clinical recovery of pulmonary-tuberculosis patients and ameliorate the adverse effects caused by immune suppression induced by immunodeficiency viruses or stress [95]. It has been recently reported that β-sitosterol can enhance the action of vitamin D on the immune function of macrophages [96]. In addition, research conducted in human Jurkat T cells has revealed that campesterol, β-sitosterol, and β-sitostanol can suppress mitogen-induced IL-2 production in a dose-dependent manner [97]. This interaction with IL-2 could be useful for patients requiring immunosuppressive effects, although further research is needed to elucidate its clinical relevance.

The role of PS as anti-inflammatory agents is commonly ascribed to their capacity to modulate cytokine production. However, how this production is modulated remains unclear. Some authors have reported that PS can reduce the production of pro-inflammatory cytokines such as IL-6 or TNF-α [94, 98], whereas others have reported the opposite effect [96, 99]. Other results show that the induced production of cytokines IL-10, IL-4, and gamma interferon in Jurkan T cells is not altered by PS [97]; however, this observation is not devoid of controversy as this effect could not be confirmed in animals [100]. However, regardless of their mechanism, different animal and human studies provide a reasonable body of evidence supporting the anti-inflammatory properties of PS [13, 100–102].

Altogether, these beneficial effects on immune and inflammatory functions seem promising as they can also be involved in the development of other pathologies such as cancer or atherosclerosis. Nevertheless, current evidence is not consistent enough, and further research is necessary to elucidate the clinical implications of sterol supplementation.

4.3 Antidiabetic Effect

PS may play an important role in ameliorating obesity or diabetic-associated disorders [13], despite the evidence is scarce. Misawa et al. [103] reported that oral administration of two types of antidiabetic PS isolated from *Aloe vera* (lophenol and cycloartenol) improves hyperglycemia in Zucker diabetic fatty rats [103]. Moreover, these PS can downregulate the expression of hepatic genes involved in the expression of gluconeogenic enzymes (glucose-6-phosphatase, phosphoenolpyruvate carboxykinase, Pepck) and upregulate that of β-oxidation enzymes such as peroxisome proliferator-activated receptor alpha (Ppar-α) [104]. Likewise, PS have been proposed to be one of the main compounds responsible of the antidiabetic effect of some plant extracts [13, 105], although further clinical evidence is necessary.

5 Side Effects

The hypocholesterolemic effect of PS at high doses is well known, and several nutraceutical products have been approved until now by the administrations of the EU, USA, and other countries. However, much less is known about the possible toxicity or undesirable side effects of this high intake.

5.1 Toxicity

It is generally accepted that consumption of PS is safe due to their negligible rate of absorption in the upper small intestine. However, it is still in debate whether toxicological effects could appear at very high and continuous intake of some plant sterols and stanols [16].

Several studies conducted in animals [106, 107] and humans [108, 109] did not find negative physiological effects at high and/or continuous intake of plant sterols and stanols. However, other reports have reported that some toxicological effects, mainly related to the possibility of anomalous accumulation of PS in some tissues, must be taken into account [110, 111]. For instance, the study of Lees et al. [111] on hypercholesterolemic patients treated with plant sterol preparations found high serum levels of campesterol (mean 16 mg dL^{-1}) in five patients, suggesting the possibility of iatrogenic atherosclerosis due to PS accumulation. However, another study conducted in rabbits fed with semi-purified diets containing sitosterol or sitostanol esters revealed that while serum cholesterol was present at levels of milligrams dL^{-1}, serum PS were present at levels of micrograms dL^{-1} [112]. In the same study, aortic cholesterol and PS were found in microgram and nanogram quantities, respectively, and no aortic lesions were observed. One of the major concerns regarding the PS accumulation in tissues is based on their accumulation in the brain. Jansen et al. [110] reported that increased circulating levels of plant sterols, as a result of intake of a plant sterol-enriched diet in wild-type mice or as a consequence of ABCG5 or ABCG8 deficiency, was associated with elevated levels of plant sterols in the brain. More recently, Vanmierlo et al. [113] reported that mice fed with a plant sterol ester-enriched diet for 6 weeks displayed increased concentrations of plant sterols in serum, liver, and brain. In addition, the authors observed that after stopping plant sterol intake for a period of 6 months, brain PS levels remained unaffected. Interestingly, this accumulation was not found when animals received plant stanols. However, the clinical implications of these are still to be established.

5.2 Sitosterolemia (Phytosterolemia)

It has been estimated that a maximum of 5% of the plant sterol intake is absorbed, resulting in very low levels in plasma (0.5 mg dL^{-1},representing less than 0.5% total neutral sterols in plasma) [16]. However, there is a very restricted group of patients presenting a rare autosomal recessive disease called phytosterolemia [114]. These subjects can absorb up to 60% of the dietary plant sterols whereas the rate of absorption of cholesterol seems to be normal [115, 116]. This disease is characterized by mutations occurring in ABCG genes controlling the efflux of PS at intestinal level and the delivery of PS by the liver [117, 118]. Several studies reported that these patients have PS plasma levels from 18 to 72 mg dL^{-1}, which represents 7–30% of total neutral sterols in plasma [119].

With this disease there is an accumulation of PS not only in plasma but also in adipose tissue, skin, aorta, and other tissues. As a result, main symptoms of this disease include xanthomatosis and atherosclerosis [120]. This accumulation is not only related by hyperabsorption of PS but also by impaired biliary secretion. Some authors have found that phytosterolemia patients present around 20% reduction of PS biliary excretion and around 50% reduction of the whole-body cholesterol synthesis [30, 121, 122]. It has been also found that in sitosterolemic patients, the hepatic conversion of cholesterol to bile acids is blocked, which can result in cholesterol accumulation and atherosclerosis [115].

New interest in the development of sitosterolemia has arisen from the fact that several studies found relationships between anomalous high levels of PS in plasma and CHD in non-sitosterolemic subjects [120]. For instance, Glueck et al. [123] found that plasma cholesterol levels of 7 mmol L^{-1} and 40 μmol L^{-1} of PS were associated with a higher deposition of PS in the aorta in seven subjects. Likewise, Stalen et al. [124] reported that lethal atherosclerosis is related to increases in plasma PS levels. Therefore, PS levels in phytosterolemia patients must be carefully controlled.

5.3 Phytosterol Oxides

Although cholesterol oxides and their biological effects have been studied for many years [125, 126], much less is known about the biological effects of phytosterol oxides (PSO). However, the approval to supplement several food products with high doses of PS has generated the need to determine in which extent PSO can be present or formed in these products and whether they can constitute a risk for the consumer. As PS are very closely related to cholesterol in their molecular structure, it seems logical to hypothesize that they can undergo similar oxidative reactions. Thus, hydroxy-, keto-, epoxy-, and triol-derivatives of sterols would be expected to be the most abundant oxides found in food products. In contrast, plant stanols are lacking the nucleus double bound, which indicates that their oxidative pathways would not be analogous to those of cholesterol when they are subjected to processes involving reactive oxygen and free radical species, as well as irradiation and heating [127]. For stanols, the main ways of oxidation involve enzymatic reactions, which can affect the side chain [128].

The attribution of biological effects to PSO is controversial as studies reporting reliable values of their concentrations in food products are scarce and very recent [126, 129]. In addition, the values reported for PSO from food, plasma, or tissues are not easy to compare between studies due to the different analytical methods used for quantification, the lack of availability of PSO standards, the similarity of their structure, and their presence in trace amounts [130]. Thus, a better validation and standardization of analytical procedures is the main concern for future research in this field as higher amount of reliable results would help to elucidate the biological effects of PSO.

In phytosterol-enriched spreads, the content of PSO ranges from 12 to 68 μg g^{-1} [131, 132]. This would correspond to a possible ingestion of less than 1.7 mg PSO day^{-1}, according to the recommended daily intake of 20–25 g of spread. Abramsson-Zetterberg et al. [133] estimated that in the Swedish adult population, the intake of PSO, which are originally from heated vegetable oil, should be less than 0.7 mg day^{-1}. This value would be clearly lower than that estimated for the intake of cholesterol oxides (3.0 mg per day) in the context of a low-cholesterol intake population (<300 mg of cholesterol day^{-1}) [127]. The total amount of PSO in the body is still controversial, and correlations between PSO intakes and PSO levels are difficult to establish as PSO levels in the body not only come from dietary sources but also from endogenous formation [134–136]. The first reliable data regarding plasma PSO levels were reported by Plat et al. [137]. These authors were able to detect sitostanetriol and 7-keto, 7α- and 7β-OH, and α-epoxy derivatives from β-sitosterol in phytosterolemia patients, although they did not correlate these levels with adverse health effects. Some other studies were able to measure PSO in plasma of healthy volunteers [132, 138]. In all cases, β-sitosterol oxides seem to be predominant, which suggests that the absorption of β-sitosterol oxides is higher than that of other PS oxides or that the oxidation of circulating β-sitosterol in plasma is higher than that of other PS [127].

Several studies have reviewed the biological effects of PSO [126, 127, 130], although it remains questionable whether PSO can exert undesirable or beneficial effects. Some authors have proposed that PSO can be pro-inflammatory, pro-atherosclerotic, and cytotoxic [139, 140]. In contrast, others have reported beneficial effects, including modulation of cholesterol homeostasis and anti-inflammatory, lipid-lowering, and antidiabetic properties [126, 127, 130]. Moreover, for a long time, oriental traditional folk medicine has been using extracts from plants belonging to the genera Euphorbia, Urtica, and Bombyx for the treatment of some cancer-type pathologies. Recently, it has been reported that, in these extracts, PSO are the most abundant steroid compounds [141]. It has been demonstrated that PSO can induce cell death by apoptosis in different type of cell models [126]. Some observations suggest that the biological effects of PSO are similar to that of cholesterol oxides, but being five times less active [142]. Therefore, although PSO can modulate the human metabolism in some extent, it is difficult to conclude whether they are responsible of any relevant toxic effect.

5.4 Decrease in Plasma Levels of Carotenoids

Several studies have reported associations between high doses of plant sterol and stanol ester intakes and decrease in plasma carotenoid concentrations. The first problem in understanding the relevance of this effect is that no standard levels of plasma carotenoids can be clearly established [16]. Several studies comparing high and low intakes of PS have reported a parallel decrease in plasma carotenoid levels when high amounts of PS are consumed. Kritchevsky [16] compiled nine different studies in humans that were administered with pure stanols (between 0.8 and 3.2 g day^{-1}), pure sterols (between 0.8 and 3.6 g day^{-1}), wood-derived stanols (2.3 g day^{-1}), or vegetable-derived stanols (2.6 g day^{-1}) during a variable period. Results of these studies showed that in all cases, relevant dose-dependent decreases in plasma total cholesterol and LDL-c were found, which was correlated with a parallel decrease in carotenoid concentrations. The reduction was up to 20% in some cases. However, results between studies are not easy to compare as the carotenoids determined are not always the same. Even though, most of these intervention studies showed that the decrease in plasma carotenoid levels, which was accompanied by α-tocopherol decreases, disappeared when values were corrected for total cholesterol [143]. In other cases, this decrease in carotenoid and tocopherol was not observed [34]. In addition, certain studies reported that basal plasma levels of these carotenoids can be maintained by supplementing with carotenoids a high-PS diet [144]. Given these evidences, Kritchevsky [16] explained the disparity of results from different studies by differences in the carotenoid and vitamin levels present in the basal diets.

It is worth mentioning that reductions in plasma carotenoids up to 10–20% of plasma carotenoids could not be associated with negative physiological effects [145, 146]. However, it has been hypothesized that a reduction on carotenoid plasma levels could induce some disturbance in the antioxidative pathways associated with the prevention of cancer development [81]. Glutathione-*S*-transferases (GST) are enzymes with antioxidant properties which can be partly involved in the prevention of some cancers [147]. In prostate cancer, a reduction of GST1 expression may promote the susceptibility to the carcinogenic effect of chemicals, while induction of GST (i.e., by carotenoid supplementation) in early-stage prostate cancer can be a useful as a protective strategy [148]. Data existing at this moment reveal that only a slight reduction of GTS activity can be observed after PS intake [81]. Moreover, no clinical data showing a direct relationship between PS intake and risk of prostate cancer is available.

Nonetheless, since there is a parallel reduction in plasma cholesterol and carotenoid levels, it is advised to supplement the diet with these microcomponents in order to avoid the risk of side effects.

5.5 Other Safety Aspects

Other unfavorable effects have been proposed for PS intake at high doses. For instance, it is well known that PS intake increases the excretion of coprostanol and cholesterol [149]. Some recent data have shown that this increased excretion can promote the development of colon cancer [150]. However, this association was found in studies where the population consumed low-quality, high-fat diets. Therefore, it is difficult to investigate the direct relationship between high levels of PS intake and a higher colon cancer risk [81]. Further, some authors have suggested that PS could also participate as promoters of colon cancer by a possible mutagenic effect on gut bacteria. Studies on the mutagenic potential effect of PS and their esters have been conducted in bacterial in vitro cell gene mutation and in vivo rat mutagenicity assays [151]. Negative results have been obtained in all cases for PS, phytosterol esters, and for several metabolites of cholesterol (4-cholesten-3-one and 5β-cholestan-3-one). Some authors have also suggested that a high intake of PS and their esters can lead to higher levels of oxides, which can accelerate lipid autoxidation [81]. However, there is not enough information to conclude on the relevance of this oxidation process in promoting mutagenicity.

On the other hand, some studies, mainly performed in animals, have shown certain interesting and noteworthy effects of high PS intakes. Studies conducted in stroke-prone spontaneously hypertensive rats (SHRSP) demonstrated that dietary cholesterol and PS clearly affect the development of stroke and the survival of rats after the stroke [152]. According to these authors, certain level of plasma cholesterol is needed after the stroke in order to maintain the integrity of red blood cells. In contrast, high levels of PS in plasma can lead to a higher fragility of these cells and a shorter life span.

In addition, another safety aspect of relevant interest is the existence of a population of hypercholesterolemic patients with normal diets that also show hyperphytosterolemia [153]. This fact was observed in a study conducted in the USA with 595 subjects that constituted the top serum cholesterol quintile among a total population of 3,472 subjects. Approximately a 3.5% of these subjects showed anomalous high campesterol and stigmasterol levels, being considered "hypercholesterolemic-hyperphytosterolemic." This fact was associated with a personal or familiar history of premature CHD (<55 years old). However, a relevant fact reported in a follow-up study was that the levels of phytosterolemia can be normalized in this type of patients by eating a low plant sterol diet [123].

Other studies have reported similar observations [154, 155], supporting the conclusion that subjects with low endogenous cholesterol synthesis are at increased risk for coronary heart disease if they do not restrict PS intake in their diets. For these subjects, a careful control of the ratio of cholesterol/plant sterols in the diet and in plasma is recommended.

6 Conclusion

CHD is one of the main causes of mortality in developed countries. Elevated blood cholesterol concentration is known to be a major risk in the development of CHD. LDL-c in plasma can be reduced by 10% by consuming 2 g day^{-1} of PS. Although it has been suggested that higher doses can lead to undesirable side effects, the consumption of PS is generally considered safe. Current research is providing valuable insights with regard to the pathways associated to the beneficial effects of PS, although their exact mechanisms are not yet fully understood. Recently, some studies have suggested that these compounds may be able to prevent diseases such as cancer, diabetes, and inflammatory and immune disorders. Nevertheless, more studies are necessary to confirm their clinical relevance. The combination of PS with other bioactive compounds, drugs, or therapies also seems promising as their beneficial effects can be complementary or synergic.

Therefore, the incorporation of PS into functional foods or nutraceutical products can be of relevant interest not only to reduce the risk of CHD but also to prevent the development of many other diseases.

Acknowledgments Authors are grateful to Gerard Bryan Gonzales for the linguistic revisions of the manuscript.

Abstract

Withanolides are a group of naturally occurring C_{28} steroidal lactones with ergostane-based skeleton. They are highly oxygenated natural products, and the oxidation at various sites of skeleton is responsible for the structural variations in different classes of withanolides. Withanolides possess a wide range of biological activities including antitumor activity. The extracts of withanolide-containing plants have been used for the treatment of various types of cancers and tumors. However, the antitumor activity of a purified withanolide was first reported in 2004. Since then, many withanolides have been evaluated for their anticancer and antitumor activities by using a number of bioassays. The chapter deals with the structural classes of withanolides and their biological activities. The reported antitumor activity of withanolides (covering the period till early January 2012) is discussed in detail, along with other biological and pharmacological activities of withanolides.

Keywords

Anticancer • antitumor • cyclooxygenase • cytotoxic • ergostane • immunomodulatory • quinone reductase • steroidal lactones • withanolides

Abbreviations

ESI-QqTOF-MS/MS	Positive ion electrospray ionization quadrupole time-of-flight mass spectrometry
CID-MS/MS	Collision-induced dissociation tandem mass spectrometry
COX-1	Cyclooxygenase-1
COX-2	Cyclooxygenase-2
EI-MS	The electron impact mass spectrum
IC_{50}	Concentration which causes 50 % inhibition of activity

UV	Ultraviolet spectrometry
M^+	Molecular ion
MS/MS	Mass-mass or tandem spectroscopy
m/*z*	Mass to charge ratio
NMR	Nuclear magnetic resonance spectroscopy
ROS	Reactive oxygen species
SAR	Structure-activity relationship

1 Introduction

The withanolides are a group of naturally occurring steroids with an ergostane-type of skeleton having δ- or γ-lactone-containing side chain of nine carbons, attached at C-17 of main steroidal skeleton [1–5]. The rearranged ergostane framework of withanolides (**1**) is commonly known as the "22-hydroxyergostan-26-oic acid 26,22-lactone." Withaferin A (**2**), the first member of this group, was isolated from *Withania somnifera* by Lavie and coworkers in 1965, and the name withanolide was accordingly given based on the name of the source genus [4, 6]. In the last three decades, a number of reviews focusing on the structural properties, biosynthesis, synthetic approaches, and biological properties have been published [2–5]. However, this chapter is the first comprehensive review on the antitumor and anticancer properties of withanolides reported in last three decades, covering the literature up to early January 2012.

Since 1965, a large number of withanolides were isolated from the plants of Solanaceae, Taccaceae, Leguminosae, Labiatae, and Myrtaceae, as well as from some marine organisms [1–5, 7, 8]. Among all these plant families, the Solanaceae is the richest source of withanolides, containing 14 genera, namely *Acnistus, Datura, Deprea, Dunalis, Discopodium, Exodeconus, Hyoscyamus, Iochroma, Jaborosa, Larnax, Lycium*, *Nicandra, Physalis, Salpichroa, Trechonaetes, Tubocapsicum, Vassobia, Withania*, and *Withanergia* [2].

In addition to the plants of Solanaceae family, certain withanolides named "minabeolides" have been reported from the sea soft coral belonging to the genus *Paraminabea*, representing the first class of marine withanolides [7, 9]. Minabeolides were reported three decades ago and found to be structurally similar to the simple withanolides such as withaferin A (**2**). However, recently they have attracted attention because of numerious reports of their cytotoxic properties.

2 Classes of Withanolides

Oxidation at different sites of the steroidal skeleton is responsible for the rearrangement of the basic skeleton of withanolides to the following classes:

2.1 Withaphysalins

The oxidation of the C-18 methyl into carboxylic acid leads to the formation of an additional lactone ring by the linkage between C-18 carboxylic acid and C-20 hydroxyl group in the basic skeleton of withanolide [10, 11]. Such withanolides are known as “withaphysalins.” Examples include withaphysalins A (**3**) and E (**4**) [11–13].

2.2 Physalins and Neophysalins

Physalins are the steroidal lactone constituents of *Physalis minima* and other closely related genera, corresponding to 16,24-cyclo-13,14-*seco* steroidal structures [14, 15]. The highly oxidized skeleton of physalins is biogenetically related to the withanolides, with (a) an oxidized 13,14-bond ring cleavage yielding a nine-membered ring, (b) formation of a new six-membered carbocycle between C-16 and C-24, and oxidation of the C-13 methyl group into a carboxylic acid which results in 18,20-lactonization [11]. Examples include physalins A (**5**) [16, 17] and B (**6**) [17].

The further rearrangement of the skeleton of physalin due to the C-15/C-16 bond cleavage, followed by the C-14/C-16 bond formation, leads to the formation of neophysalin. Physalin P (**7**) was the first neophysalin isolated from *Physalis alkekengi* [18].

2.3 Ring D Aromatic Withanolides

The withanolide having unique structural feature, aromatic ring D, example is nicandrenone (**8**), only reported from *Nicandra physalodes* [19, 20].

2.4 Ring A Aromatic Withanolides

Many withanolides, such as jaborol (**9**), reported from plants of genus *Jaborosa*, have a skeleton with aromatic ring A [21].

2.5 Acnistins

Acnistin-type withanolides have a bicyclic system, instead of a lactone ring at the C-17 side chain. The linkage between C-21 and C-24 of the lactone ring is responsible of the formation of a five-membered ring, attached to the lactone ring as in acnistin E (**10**), isolated from *Acnistus ramiflorus* [22].

2.6 Ixocarpalactones or Perulactones

These are the withanolides with a characteristic modification in the side chain to form 26,23-γ-lactone. Examples include ixocarpalactone A (**11**) [23, 24] and perulactone B (**12**) [25].

2.7 Withajardins

Structurally, withajardins closely resemble the acnistin-type withanolides with the difference that the bicyclic side chain contains a six-membered ring, instead of a five-membered ring, obtained by the linkage between C-21 and C-25 of the lactone ring. Examples include withajardin A (**13**) isolated from *Deprea orinocensis* [26, 27].

2.8 Withametelins

These withanolides are only reported from plants of genus *Datura*. They are closely related to the withajardin- and acnistin-types with the difference that the C-21 and

C-24 of the lactone ring are linked through an ether bridge to form another six-membered ring, along with the presence of an exocyclic double bond between C-25 and C-27 [28]. Examples include withametelinol (**14)** and withametelinone (**15**) [29].

2.9 Norbornane-Type Withanolides

These withanolides have an additional ring that arises by the linkage of C-15 and C-17 of ring D. Jaborosalactol 18 (**16**) is among the first members of the norbornane-type of withanolides, isolated from the aerial parts of *Jaborosa bergii* [30].

2.10 Sativolides

Withanolides having six-membered hemiketal, obtained by the linkage between keto (oxidized C-12) and hydroxylated C-21, are known as sativolides [5]. Jaborosalactone 37 (**17**) is an example of this class of withanolides, isolated from the plants of genus *Jaborosa* [31].

2.11 Spiranoid δ-Lactones

These withanolides are formed by the double oxidation of C-22, leading to the formation of an ether linkage between C-12 and C-22 and a spiranoid δ-lactone at C-22. Examples include jaborosalactones 27 (**18**) and 28 (**19**), isolated from *Jaborosa rotacea* [31].

3 Spectral Generalization of Withanolides

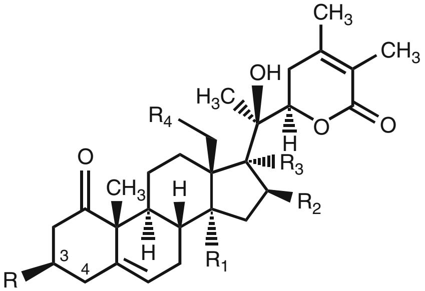
The withanolides exhibit characteristic spectroscopic behavior, which can help in their structural elucidation.

3.1 Ultraviolet and Infrared Spectra

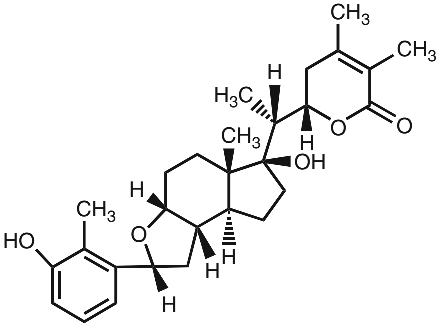
The majority of withanolides possess two types of chromophores:

1. An enone (2- or 5-ene-1-one) such as **2**, **14**, and **15**
2. An α,β-unsaturated δ-lactone, such as in withanolide E (**20**) and 3β-hydroxy-2,3-dihydrowithanolide F (**21**)

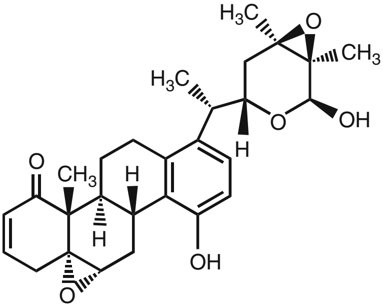
The UV absorptions due to these chromophores generally appear in the range of 218–230 nm [38]. The compounds have aromatic rings in their skeleton that generally absorb in the range of 224–301 nm, as in (+)-jaborol (**22**) [32] and salpichrolide G (**23**) [33].



21 $R=R_1=R_3=OH$, $R_2=R_4=H$
78 $R=R_1=R_3=H$, $R_2=R_4=OH$, $\Delta^{3,4}$



22

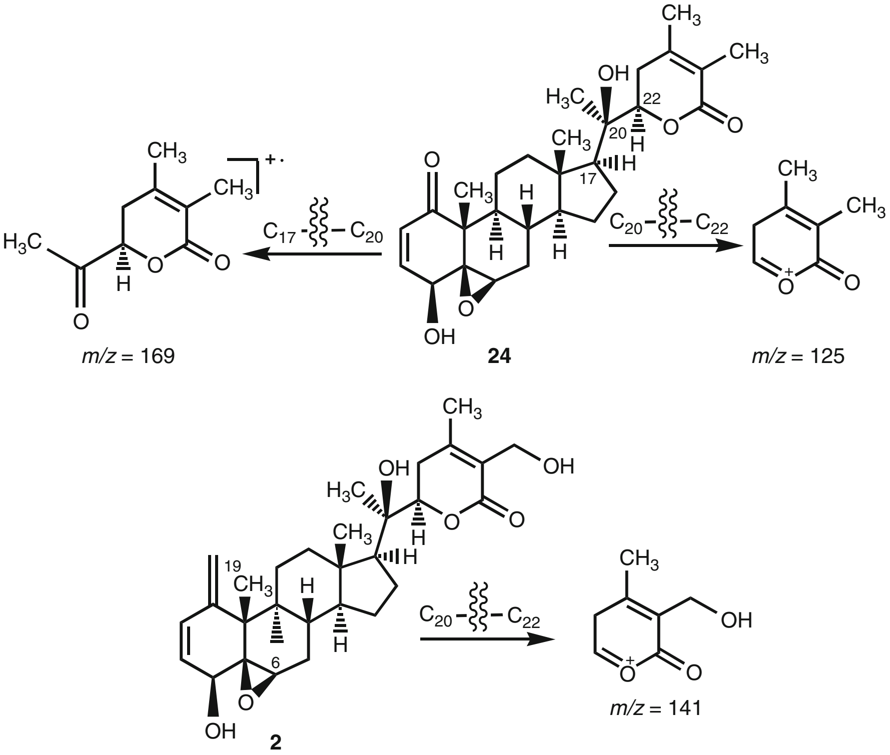


23

Almost all types of oxygen functionalities are present in this class of steroidal lactones, and the characteristic IR spectral bands for various functionalities appear in the spectra. The characteristic enone and *α,β*-unsaturated *δ*-lactone moieties of withanolides show absorptions at or near the 1,660 and 1,710 cm^{-1}, respectively. An IR absorption at 1,778 cm^{-1} is due to carbonyl stretching vibrations in five-membered lactone ring, found in all physalins and other classes of withanolides with modified skeleton [34–36].

3.2 Mass Spectra

Mass spectrometry is a powerful tool in structure determination of withanolides. The M^+ in electron impact mass spectra (EI-MS) is either weak or absent in various types of withanolides. The EI-MS spectra of withanolides are more informative, as compared to those having modified withanolide skeleton. A base peak at *m*/*z* 125 is formed by fission of the C-20/C-22 bond and is considered to be a diagnostic feature for withanolides with an unsubstituted *α,β*-unsaturated *δ*-lactone moiety [37] (Scheme 114.1). However, the presence of a hydroxyl group at C-20 facilitates the cleavage of the C-17/C-20 bond and gives rise to a peak at *m*/*z* 169



Scheme 114.1 The characteristic EI-MS fragmentation pattern of withanolides

(Scheme 114.1) [38]. The presence of a hydroxyl group in the lactone part of the molecule shifts the peak from *m*/*z* 125 to *m*/*z* 141 [39–41].

Gas-phase fragmentation of withanolides studied by ESI-QqTOF-MS/MS established a rapid method for the identification of low quantities of withanolides in complex plant extracts, herbal formulations, and pharmaceutical products [42]. Structure-fragmentation relationship (SFR) of ten standard withanolides was studied. The withanolides with hydroxyl groups at C-4, C-5, C-17, C-20, and C-27 and an epoxy group between C-5 and C-6 were evaluated for their characteristic fragmentation pattern. The CID-MS/MS analysis indicates the multiple removal of water molecules and the removal of C-17 lactone moiety as a major pathway. However, C-24 hydroxylated withanolides, such as withaferin A (**2**), exhibit diagnostic ions at *m*/*z* 95 and 67, generated due to the cleavage of *δ*-lactone moiety (Scheme 114.2). A generalization based on MS/MS fragmentation was developed for the rapid identification of withanolide in the complex plant extract by employing LC-MS/MS analysis.

The mass spectra of other types of withanolides exhibit no systemic fragmentation pattern, which may be due to their highly complex and oxygenated skeletons.

3.3 Nuclear Magnetic Resonance Spectra

3.3.1 ^{1}H-NMR

The C-22 proton of a simple withanolide shows a characteristic pattern, resonating in the range of δ 4.00–4.90 and referred as the withanolide "fingerprint." It is a diagnostic doublet of triplets in typical withanolides, which have unsubstituted C-20 and C-23 [43], as in withaferin A (**2**), and as a double doublet when either C-20 or C-23 is substituted [44–46], as in **24**.

A typical withanolide exhibits characteristic singlets for five methyl groups in the range of δ 0.99–2.00, two angular methyls (C-18 and C-19), two vinylic methyls (C-27 and C-28), and one secondary methyl (C-21). In the case of unsubstituted C-20 compounds, the C-21 methyl appears as a doublet between δ 1.00 and 1.02, with the coupling constant (J) of 6.4–6.7 Hz. The characteristic one proton doublet, appearing at δ 3.22 ($J_{6\alpha,7\beta} = 2.1$ to 2.4 Hz), is due to an oxirane ring between C-5 and C-6, commonly found in withanolides of diverse classes [47, 48].

The ^{1}H-NMR spectral data of physalins display several characteristic signals. These include three characteristic methyl singlets at δ 1.25, 1.35, and 1.99 Hz, which are due to C-28, C-19, and C-21 tertiary methyls, respectively [34, 49]. The presence of a C–O bridge between C-14 and C-27 is inferred from the appearance of a pair of characteristic signals for the C-27 methylene protons, resonating at δ 3.75 as a doublet ($J_{AB} = 13.5$ Hz) and at δ 4.53 as a double doublet ($J_{AB} = 13.5$ Hz, $J_{27,25} = 4.4$ Hz) [34, 50, 51].

3.3.2 ^{13}C-NMR

The ^{13}C-NMR spectral data of withanolides has been found to be very useful in the structural and conformational analysis of withanolides. The downfield singlets between δ 202–216 and 166–168 are attributed to the carbonyl group at C-1 and the lactone carbonyl at C-26, respectively. Two signals around δ 149 and 121 correspond to the olefinic C-24 and C-25 of the lactone ring. The C-22 bearing the δ-lactone oxygen, appears between δ 74 and 78 in all members of this class. Three methyl carbon signals at δ 26.5, 21.2, and 14.5 are due to the C-21, C-19, and C-28 quaternary methyl carbons of physalins, respectively. The C-27 methylene carbon appears at δ 60.7, as in other members of physalins [34, 49–51].

4 Pharmacological Importance of Withanolides

The withanolides containing plants of the family Solanaceae possess a wide range of pharmacological properties and are well-known sources of medicinal agents, stimulants, and poisons [52].

Withanolide-containing plants are widely used for hair care. *Datura metel*, or Datura, is a widely recommended remedy for the treatment of dandruff. *Withania somnifera*, also known as ashwagandha or Indian "ginseng," is the most widely used withanolide-containing plant in the Ayurvedic medicinal system for therapeutic purposes. The flowers of the *Withania somnifera* are recommended in the Siddha system of medicine as an exclusive hair remedy [53–55].

The methanolic extracts of different parts of *W. somnifera* exhibit therapeutic potential against various types of cardiovascular problems and are also effective against hyperlipidemia, obesity [56], aging, and copper-induced pathophysiological conditions [57]. This plant is reputed to promote vitality during recovery from chronic illnesses [58] and is also useful for the pain management in arthritic conditions [59].

Withania somnifera has a calming effect on mind and thus promotes sound sleep. In bronchial asthma and spasmodic cough, the ash of its burnt roots is given with honey and oil to liquify the phlegm. The black root ash of the plant, mixed with sesame oil, helps in removing skin depigmentation and minor skin ailments [54]. Ashwagandha also helps to maintain the heart in good condition and is reputed to be a blood purifier. It is considered to be beneficial in blood diseases [54].

Similarly, *Physalis minima* is widely used in folk medicines for the treatment of bronchitis, inflammation, enlargement of spleen, urinary disorders, abdominal troubles, and headache [53, 60]. The roots are used as a vermifuge and febrifuge and for the treatment of diabetes. In Guatemala, the plant is popularly used for the treatment of gonorrhea [61]. The fruits of *Physalis minima* are said to be an appetizer and have also been recorded as an ingredient of medicinal oil for spleen disorders. The fruits are also considered as a tonic, diuretic, and purgative in different areas of the Punjab, Pakistan [12, 53, 62, 63].

The Mundas (a tribe) of Nagpur (India) mix the juice of the leaves with water and mustard oil and use it as a remedy against earache [60]. Similarly, *Physalis philadelphica* is used by the people of Guatemala for the treatment of gastrointestinal disorders and in Mexico for the treatment of leprosy [64].

A wide range of the biological activities of the plants having withanolides as principle constituents have attracted the attention of the researchers and led to the isolation of the therapeutically active constituents, the withanolides, followed by the pharmacological evaluation of these compounds to validate their traditional uses.

4.1 Antitumor Activity of Withanolides

The antitumor potential of withanolides has been extensively investigated by the researchers all around the world, which led to the identification of diverse properties such as cytotoxicity, cell differentiation induction, cancer chemoprevention, and COX-2 and quinine reductase enzymes inhibition potential of withanolides. Recently, over 80,000 natural and synthetic compounds were evaluated by Santagat and coworkers for their anticancer activity, targeting protein homeostasis. They concluded that many active compounds were natural products belonging to the five classes, limonoids, celastraloids, colletofragarones, curvularins, and withanolides [65].

4.1.1 Cytotoxicity of Withanolides

The cytotoxicity of withaphysalin-types of withanolides was first reported in 2004 by Veras and his coworkers. They evaluated the cytotoxic potential of ethanolic extract of leaves of *Acnistus arborescens* and isolated withaphysalins M (**25**) and O (**26**), active against human lung cancer (Lu1), hormone-dependent human prostate cancer (LNCaP), and estrogen-dependent human breast cancer (MCF7) cell lines, and showed the potent cytotoxic abilities [66, 67]. They further studied the incubation of withaphysalin F (**27**) on the leukemia cells and found a reduction in 5-bromo-2′-deoxyuridine incorporation after 24 h of incubation. Furthermore, studies have also showed that withaphysalins M and O are cytotoxic and seemed to induce apoptosis and necrosis in tumor cells [68]. In vitro cytotoxic activity of physalin D (**28**) against human cancer lines was reported by Cordero et al. in 2009. The compound showed weak cytotoxicity against normal human fibroblast cultures (Fib04) [69]. The cytotoxic activities of withaphysalins M and O and physalin D thus validate the folk uses of *A. arborescens* as a remedy to suppress the growth of cancer.

The cytotoxic activity of a series of withanolides, isolated from *Physalis angulata*, was evaluated against various human cancer cell lines. Strong cytotoxicity was exhibited by withangulutin B (**29**) and physalins B (**6**), D (**28**), F (**27**), and U (**30**) [67, 68] against DU-45, 1A9, HCT116, LNCAP, KB, KB-VIN, A431, A549, HCT-8, PC-3, and ZR751 human tumor cell lines [70, 71].

39 R=R$_1$=R$_2$=H, R$_3$=OH
40 R=R$_1$=H, R$_2$=R$_3$=OH

A series of ten withanolides, isolated from *Physalis minima*, were evaluated for their cytotoxic properties against HCT-116 and NCI-H460 cell lines. It was found that withaphysalin C (**31**) was active against both the cell lines [72]. The structure-activity relationship (SAR) studies of the cytotoxic withanolides from *Physalis minima* and *Physalis angulata* indicate that the α,*β*-unsaturated ketone moiety in ring A and 5*β*-6*β* oxirane moiety in ring B are important contributors in the cytotoxicity of withanolides. The absence of these two structural features may result in a loss or reduction of the cytotoxicity of withanolide [4].

The evaluation of cytotoxic activity of 17 withanolides against various human cancer cell lines, such as hepatocellular carcinoma (Hep G2, Hep 3B), breast carcinoma (MDA-MB-231, MCF-7), lung carcinoma (A-549), and embryonic lung (MRC-5) cell lines, disclosed the significant cytotoxic potential of withanolides **32–42** [73]. The SAR studies showed that the C-4 hydroxyl group apparently has no contribution to their activity. 6-Chloro withanolides **34** and **42** are found to be less cytotoxic, as compared to their hydroxyl analogues **33** and **41**. This initial inference is further supported by the significant cytotoxic potential of 5-chloro substituted physagulin B (**43**) [74] and physalin H (**44**) [21, 75, 76]. The cytotoxic potential of the chlorinated (**45**) and diepoxide-containing withanolide (**46**) was also evaluated by our group against the human lung cancer cell line (NCI-H460), along with withaferin A (**2**). All compounds exhibited cytotoxicity and growth inhibition activity which further support the role of C-5 Cl group in antitumor activity of withanolides. Withaferin A (**2**) was found to be the most potent withanolide against lung cancer cell line [77].

The cytotoxic behavior of the withanolides, having 7*β* or 16α acetoxy group, was evaluated by Minguzzi in 2002. They observed that above-mentioned functionalities have no contributions in the cytotoxicity of the withanolides [78]. However, the C-17-oxygenated withanolides with C-16α hydroxyl or acetoxy group showed enhanced the cytotoxicity [79].

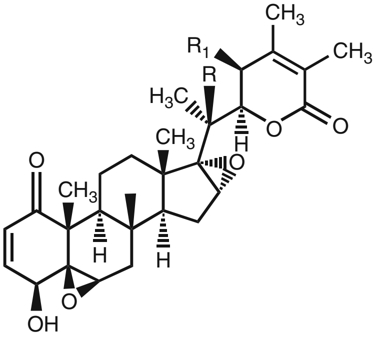
34 R=OH, R$_1$=Cl



35 R=R$_1$=H
36 R=OH, R$_2$=H
37 R=H, R$_2$=OH

The cytotoxic potential of a series of 14 withalongolides was evaluated by using a MTS viability assay, and it was found that eight withanolides **47**–**54** and four acetylated derivatives **47a**, **47b**, **48a**, and **48b** showed potent cytotoxicity against human head and neck squamous cell carcinoma (JMAR and MDA-1986), melanoma (B16F10 and SKMEL-28), and normal fetal fibroblast (MRC-5) cells. The results further support the role of an acetyl group in the antitumor activity of **47a**, **47b**, **48a**, and **48b**. However, the contribution of the acetoxy functionalities to the cytotoxic potential of withanolides needs to be further evaluated [80]. The cytotoxicity of withanolide-type steroids, isolated from Tunisian *Datura metel*, against human lung carcinoma cells (A549) and human colorectal adenocarcinoma cells (DLD-1) [81] has been observed. Discorolides A (**55**) and B (**56**) showed promising results against tumor cell lines (A549, SK-OV-3, SK-MEL-2, and HCT15) for further studies [82].

Cytotoxicity of six new withanolides was evaluated against human liver carcinoma Hep G2 cell lines, and it was found that peramenolide A (**57**) and minabolides-1 (**58**) were cytotoxic withanolides [6].

4.1.2 Cell Differentiation Inducing Activity

Kuroyanagi and his coworkers evaluated a series of sixteen withanolides, isolated from *Withania somnifera*, for their cell differentiation inducing ability and found that withaferin A (**2**), withanolide D (**24**), dihydrowithanolide D (**59**), and 27-hydroxywithanolide D (**60**) were potent cell differentiation inducers against the MI cells [83]. It was further concluded that all these withanolides have a similar 4*β*-hydroxy-5*β*-6*β*-epoxy-2-ene-1-one moiety in ring A, apparently responsible for their cell differentiation inducing activity.

4.1.3 COX-2 Inhibition and COX-1 Non-inhibition Activity

The overexpression of COX-2 enzyme in various types of tumor cells indicates the role of this enzyme in the onset of tumors. On the other hand, the inhibition of COX-1 enzyme is responsible of the formation of ulcers. The COX-2 inhibition ability of twelve withanolides from *Withania somnifera* was evaluated, along with their lipid peroxidation missing ability. Compounds **61, 62, 63**, and **64** and **65** were found to be the inhibitors of COX-2 enzyme at 50 μg mL^{-1} concentration. These withanolides were found to be noninhibitors of COX-1 even at a concentration of 500 μg mL^{-1}. The selective inhibition of COX-1 by the sulfur-containing dimeric withanolides, ashwagandhanolides (**66**) and thiowithanolide (**67**), was also investigated by the same group, along with the growth inhibition potential of both compounds against various cancer cell lines [84–86]. The results of the COX-2 inhibition assay by withanolides provided the scientific validation for the traditional uses of *Withania somnifera* leaves as remedy for cancers.

4.1.4 Radiosensitizing Activity

Effective tumor control can be achieved by the use of substances that can increase the sensitivity of the tumor cells for chemotherapeutic agents and therefore reduce the side effects for the normal cells. Withaferin A (**2**), the major constituent of the *Withania somnifera*, was found to be a potent radiosensitizing agent when administered before radiotherapy. The effect was studied on B16F1 melanoma and fibrosarcoma mouse tumors grown in C57BL and Swiss albino mice, respectively. The study concluded that the radiotherapy response of both tumors increased substantially on administration of withaferin A (**2**) [87].

4.1.5 Quinone Reductase Inducing Activity

Induction of quinine reductase enzymes is considered as an important mechanism to study the protection against toxic effects of many carcinogens. Therefore, the quinine reductase inducers are important chemoprotective agents against cancer.

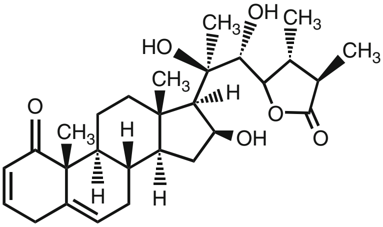
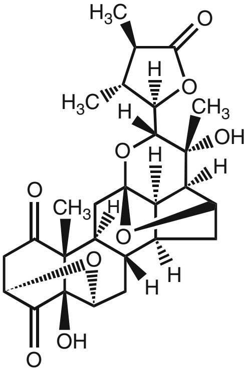
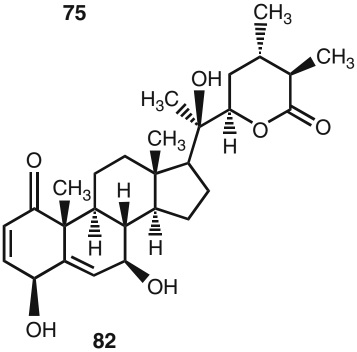
A series of withanolides was evaluated by Su and coworkers for their ability to stimulate quinine reductase induction with cultured mouse hepatoma, Hepa 1c1c7 cells. It was found that philadelphicalactones A (**68**) and B (**69**), ixocarpalactones A (**11**) and B (**70**), withaphysacarpin (**71**), 18-hydroxywithanolide D (**72**) and withanone (**73**), subtrifloralactones A (**74**) and F (**75**), subtrifloralactones K (**76**) and L (**77**), and 3*β*-hydroxymethylsubtrifloralactone E (**78**) are effective inducers of quinine reductase enzyme [64, 88–90]. Gu and coworkers also evaluated the significant quinine reductase potential of 2,3-dihydro-3*β*-methoxyixocarpalactone A (**79**), 2,3-dihydro-3*β*-methoxyixocarpalactone B (**80**), 2,3-dihydroixocarpalactone-B (**81**), and 4*β*,7*β*,20*R*-trihydroxy-1-oxo-with a-2,5 diene-22,26-olide (**82**) for their ability to induce quinine reductase in Hepa 1c1c7 cells [23].



75



76



82

4.1.6 Mechanism of Antitumor Activities of Withanolides

The mechanism of antitumor activity of three withanolides, withaferin A (**2**), physalin B (**6**), and tubocapsanolide A (**35**), was studied by different research groups. Withaferin A, the major constituent of *Withania somnifera*, was found to be able to bind with and inactivate Hsp90 (heat shock protein 90) through ATP-dependent mechanism, and it results in HsP90 protein degradation which contributes to its anticancer activity against pancreatic cancer [91]. The induction of the ROS generation and mitochondrial dysfunction of cancer cells are responsible for both mitochondrial-dependent and mitochondrial-independent apoptosis by withaferin A as reported by Singh and coworkers [92]. The inhibition of Notch-1 signaling and downregulation of Akt/NF-kB/Bcl-2 pathway in HCT-116, 5 W-480, and Sw-620 colon cancer cell lines have also been reported. In addition to this, the downregulation of pS6K and p4E-BPI and activation of c-Jun-NH_2-kinase-mediated apoptosis of colon cancer cells by withaferin A further supports the potential of withaferin A as a useful chemotherapeutic agent to treat colon cancer [93]. Withaferin A is also known to induce the aggregation of vimentin filaments through inhibition of F-actin, required for vimentin expression. The capillary growth induction in corneal neovascularized mouse model is also known to be reduced by the use of withaferin A in vimentin-deficient mice. Thus withaferin A has therapeutic potential to treat angioproliferative and malignant health disorders [94].

Ubiquitin-proteasome pathway, involved in the degradation of tumor growth proteins, plays an important role in the treatment of cancer. Physalin B (**6**), the major steroidal lactone of *Physalis angulata*, is known to produce the ubiquitinated protein accumulation and inhibit the TNFa-induced activation of NF-KB in DLD-1 4Ub-Luc cell assay. Physalin B does not inhibit purified proteasome catalytic activities but interferes with the cellular catalytic activities of the proteasome proteins at 4–8-fold high concentration, which is required to produce significant rise in bioluminescence and ubiquitinated protein accumulation in DLD-1 4Ub-Luc cells. The results indicate that physalin B is cytotoxic and works as an apoptotic triggering agent in DLD-1 4Ub-Luc cells [95].

The cancer-preventing ability of the tubocapsanolide A (**35**) against Skp2 overexpressed cells was checked by the immunoprecipitation assay. The results suggest that the mechanism involves the Skp2 suppression by blocking the Rel A binding site of nuclear factor-kB of Skp2 gene promoter by tubocapsanolide A [96]. The inhibitory potential of tubocapsanolide A against Hsp90-Hsp70 chaperone complex was investigated by Wu and coworkers. The mechanism proceeds through the oxidation of the thiol group which leads to the depletion of Hsp90 client proteins and thus arrest apoptosis in MDA-MB-231 cells [97]. The inhibition potential of tubocapsanolide A against TAK1 to suppress NF-kB-induced CCR7 breast cancer cell expression further supported the potential of tubocapsanolide A to prevent lymphocyte invasion of breast cancer cells [98].

The antitumor and anticancer potential of withanolides against various cancer cell lines and in different biological assays has been summarized in Table 114.1.

Table 114.1 The antitumor/anticancer potential of withanolides

S. no.	Withanolides	Anticancer activity	References no.
		Cytotoxicity	
	25, **26**	Cytotoxic against human lung cancer (Lu1) cell line	[66–68]
	28	Weak cytotoxicity against normal human fibroblast cultures (Fib04)	[69]
	27, 28, 29, 30	A strong cytotoxicity was exhibited against DU-45, 1A9, HCT116, LNCAP, KB, KB-VIN, A431, A549, HCT-8, PC-3, and ZR751 human tumor cell lines	[70, 71]
	31	Cytotoxic against HCT-116 and NCI-H460 cell lines	[72]
	32-42	Cytotoxic against hepatocellular carcinoma (Hep G2, Hep 3B), breast carcinoma (MDA-MB-231, MCF-7), lung carcinoma (A-549), and embryonic lung (MRC-5) cell lines	[73]
	43 and **44**	Cytotoxic against the human lung cancer cell line (NCI-H460)	[21, 75, 76]
	45 and **46**	Cytotoxic against the human lung cancer cell line (NCI-H460)	[77]
	47-**54** and **47a**, **47b**, **48a**, and **48b**	Cytotoxic against human head and neck squamous cell carcinoma (JMAR and MDA-1986), melanoma (B16F10 and SKMEL-28), and normal fetal fibroblast (MRC-5) cells	[80]
	55 and **56**	Cytotoxic against tumor cell lines (A549, SK-OV-3, SK-MEL-2, and HCT15)	[82]
	57 and **58**	Cytotoxic against human liver carcinoma Hep G2 cell lines	[6]
		Cell differentiation inducing activity	
	2, 24, 59 and **60**	Potent cell differentiation inducers against MI cells	[83]
		COX inhibitors	
	61, 62, 63, **64** and **65**	COX-2 inhibitors	[84, 85]
		COX-1 non-inhibitors	
	66 and **67**	COX-1 non-inhibitors	[86]
		Radiosensitivity inducers	
	2	Increase the radiosensitivity of B16F1 melanoma and fibrosarcoma mouse tumor grown in C57BL and Swiss albino mice	[87]
		Quinine reductase inducers	
	11, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82	Effective inducers of quinine reductase enzyme in cultured mouse hepatoma, Hepa 1c1c7 cells	[64, 88–90]

	Bracteosin A, B, and C Withaferin A 2,3-Dihydrowithaferin A 6α,7α -Epoxy-5α,20β-dihydroxy-1- oxo-witha-2,24-dienolide	Acetyl- and butyrylcholinesterase inhibitors	[1, 113]
	4β,7β,20α-Trihydroxy-1-oxo-witha-2,5,24-trienolide Jaborosalactol 18 Jaborosalactones 29, 30, 31, 33, 38 12-*O*-Methyljaborosalactone 38 12-*O*-Ethyljaborosalactone 42	Phytotoxic activity	[30, 31, 103, 118]
	Withaferin A Witharistatin	Diuretic activity	[119]
	Coagulanolin C and L 17β-Hydroxywithanolide K Withanolide F	Significant inhibition of postprandial rise in hyperglycemia	[4, 120]

5 Other Pharmacological Activities of Withanolides

In addition to antitumor activities, withanolides exhibited a wide range of other biological activities, including antifeedent, insecticidal (such as **23**) [84, 85], trypanocidal (such as **25, 26**) [29, 87, 88], antileishmanial [51, 99, 100], antimicrobial [98, 101], phytotoxic [31, 102, 103], and diuretic [4]. Anti-inflammatory [104] and immunomodulatory properties [104–109] of steroidal lactones have been extensively investigated by different groups, along with the study of their mechanism of action. The significant inhibition of postprandial rise of hyperglycemia and fall in fasting blood glucose level in diabetes rate models has also been studied [4].

Withanolides have also been evaluated by a number of groups, including us, for their potential to treat various neurodegenerative disorders, such as Alzheimer's, Parkinson's, and Huntington's diseases [1, 110–112]. Our group has reported for the first time the anti-Alzheimer's potential of withanolides as acetyl- and butyrylcholinesterase inhibitors [1]. Docking studies on these withanolides by us further supported their drug-like potency to treat Alzheimer's and associated complications [113].

A list of pharmacologically active withanolides, other than antitumor/anticancer potential has been presented in the Table 114.2.

6 Conclusion

Withanolides are among the most common classes of natural products with tremendous potential to treat various health disorders including tumors and cancers.

The purification, structure elucidation, and pharmacological studies on different classes of bioactive withanolides further validate the traditional uses of withanolide-producing plants to treat various ailments by local and traditional people. Diverse structural features, low toxicity, and novel and diverse mechanism of action make them suitable drug candidates for the treatment of various cancers and tumors. However, there is a need of extensive studies at the interface of chemistry and biology to fully explore the potent anticancer activity of withanolides, an essential step toward anticancer drug development with enhanced activity and lower toxicity, as compared to the available chemotherapeutic agents.

Abstract

Ginseng is also known as "The King of All Herbs." It not only possesses superior status in the field of traditional Chinese medicine and being extensively used in Chinese communities for thousands of years, it is one of the most popular herbs in the world and accounts for over 800 million US dollar of international market. Many scientific approaches (e.g., bioassays and omics studies) have been used to

unlock the mechanisms behind the biological effects of ginseng. Frequently, ginsenosides are being said to be the most pharmacologically active constituents in ginseng. In this chapter, we will cover the basic biochemistry and pharmacology of ginsenosides, as well highlight how ginsenosides work in human body with respect to various pathological conditions, including cancer and age-related disorders. Lastly, we will discuss the possibilities of developing ginsenosides into targeted therapeutic agents to benefit the human society.

Ginseng • ginsenosides • steroidal hormone receptors

Abbreviations

ER	Estrogen receptor
GR	Glucocorticoid receptor

1 Introduction

The word “ginseng” is translated from the pronunciation of the Chinese words “人蔘” (Renshen) that means “essence of men,” and is conventionally referring to the Asian ginseng (*Panax ginseng*). The botanical name *Panax* means “all-healing” in Greek, which is first coined by the Russian botanist Carl A. Meyer in 1843 (Image 115.1). The *Panax* family consists of at least nine species, and are mostly named by their geographic origins, although they could be cultivated and processed elsewhere. For example, American ginseng (*Panax quinquefolium*) was discovered by a Jesuit priest Father Joseph Francois Lafitau near Montreal/Ottawa, Canada, in 1716. Later, he started to export wild American ginseng to China and experiment on ginseng cultivation technique. As time goes by, China now becomes the second largest producer and exporter of the American ginseng. Other members of the family include *Panax notoginseng* (Sanqi 三七/ Tian-qi 田七), *Panax japonicus* (Japanese ginseng), *Panax vietnamensis* (Vietnamese ginseng), and *Panax trifolius* (Dwarf ginseng).

Siberian ginseng (*Eleutherococcus senticosus*) is also frequently found in the market. However, Siberian ginseng is only distantly related to the Panax family and can be considered as an entirely different plant. It contains a different set of active components that leads to distinct biological activities. Therefore, Siberian ginseng is now more commonly known as Eleuthero to avoid confusion.

Ginseng is a slow-growing perennial herbaceous plant that grows to about a half meter tall. Wild ginseng could be found in cold (optimal growing temperature is 8–15 °C) and well-shaded areas of moist hardwood forests. It takes the plant approximately 10 years to grow into maturity (has 4–5 long leaves with red berries) (Image 115.2). Because of the increasing popularity of this powerful herb, wild ginseng is almost being ripe off. Both wild Asian and American ginsengs are now protected under the Convention on International Trade in Endangered Species of

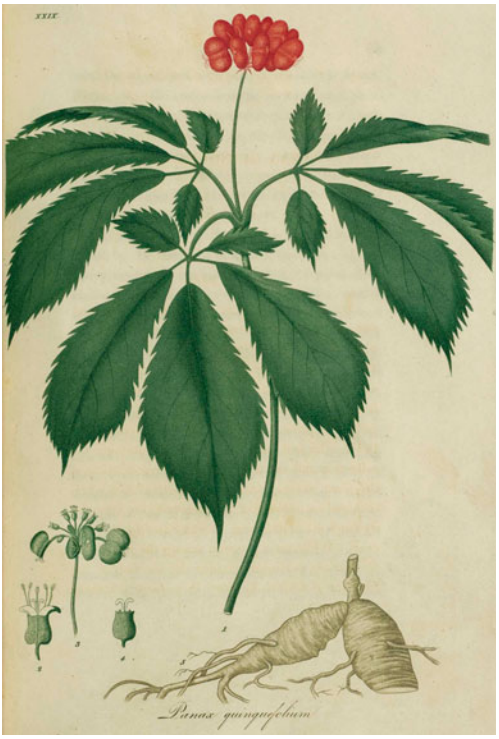

Image 115.1 The drawing depicts American ginseng adopted from the book of American Medical Botany: (1817) [1]

Image 115.2 A mature ginseng plant. (The image is adopted from http://www.herbs.org/)

Wild Fauna and Flora (CITES), an international trade agreement that is signed by 135 nations in 1973 and went into effect in 1975 (Image 115.3).

To meet demand of trade needs from the whole world, many countries start growing ginseng using systematic farm cultivation and wood grown wild-simulation approaches. Farm cultivated ginsengs usually grow faster (4–6 years to maturity) and

Image 115.3 The image shows a typical ginseng root. The shape of the root resembles a "little human" with a head, a body and four limbs. A wild Panax ginseng roots grown in a desirable shape can worth tens of thousands of dollars

lost the "man-like" appearance compared to the wild-simulated ginsengs (8–10 years to maturity). China is the main producer (50 %) of the cultivated ginseng, followed by South Korea (32 %), the United States (7.5 %), Japan (2.3 %), Canada (2.2 %), North Korea (1.2 %), and all others (4.6 %). Annual world production of cultivated ginseng is over 5,000 t [2], and accounts for over half a billion US dollar of international market value. Hong Kong SAR, China, acts as the world's clearing-house for ginseng, which imports 3,895 t in 1990 [2]. Apart from a substantial consumption within Hong Kong, significant amount of ginseng is redistributed to China, Taiwan, Japan, Malaysia, Singapore, North America, and Europe.

The ginseng species share more or less the same set of active components, although each has a unique composition prolife to give its unique biological properties. The constituent composition of a ginseng species can also be affected by a range of factors, such as age and part of the plant, cultivation method, harvesting season, and preservation method [3, 4]. The ginseng roots air-dried after harvested appear to be white, while the darker-colored red roots are produced by steaming at 98–100 °C for 2–3 h before drying [5]. The steaming process transforms the major medicinal constituents of ginseng into novel compounds that adds unique therapeutic values to these red roots [6–10]. In 2001, some roots are steamed at an even higher temperature (120 °C for 4 h) to enhance the antitumor properties of the ginseng, and this new type of ginseng is known as Sun ginseng [11–16]. The Sun ginseng is also found to possess enhanced anxiolytic effects compared to white and red ginsengs [17].

2 Chemical Constituents of Ginseng

Ginseng has been widely used in Chinese community for thousands of years. It is generally believed that consuming ginseng or ginseng extracts can support overall health and boost the immune system. It is accepted by the European countries and the United States to be used in complementary and alternative therapies [18, 19]. However, the mechanisms of ginseng's biological actions are still not fully understood. Identifying and characterizing the pharmacological active components of ginseng is a key area in ginseng researches. To date, majority of the effects of ginseng points to three categories of constituents, they are polysaccharides, phenolics, and flavonoids, and saponins.

2.1 Polysaccharides

The polysaccharides of the ginseng comprised 40 % (by weight) of the root. This class of compound was first isolated and documented in 1966 [20]. Most biologically active carbohydrates in ginseng are acidic polysaccharides, known as ginsan, which have the typical structure of pectin [21, 22].

Ginseng polysaccharides have both stimulating and suppressive actions on the immune system. It was found that ginseng polysaccharides increases serum IgG levels, activates the reticuloendothelial system (RES), and anti-complementary and alkaline-phosphatase-inducing activities [21]. At the same time, ginseng polysaccharides are reported to calm down enteric immune responses by activating Peyer's patch lymphocyte [23]. Ginseng polysaccharides also possess anticancer, antimutagenic, and radioprotective effects [22, 24, 25].

2.2 Phenolics and Flavonoids

Phenolics and flavonoids are powerful plant-derived antioxidants. These compounds demonstrate radical-scavenging and ferrous ion–chelating activities. Ginseng's phenolics and flavonoids comprised 2–7 % (by weight) of the root [26], in which quercetin and kaempferol are the most abundant ones [27]. Quercetin and kaempferol can also be found in *Ginkgo biloba* and St. John's wort, and ginseng-specific phenolics and flavonoids have not been identified.

2.3 Saponins

Ginseng triterpene saponins are also known as Ginsenosides. This class of compounds accounts for most of the ginseng's biological activities. Ginsenosides

	R_1	R_2	Formula	T_{melt} (°C)

Fig. 115.1 Images depicted the structures of protopanaxadiol (*PPD*) and protopanaxatriol (*PPT*) (Figure adopted from Leung et al. [82]. *glc* glucosyl, *ara*(*p*) pyranosyl arabinosyl, *ara*(*f*) furanosyl arabinosyl, *rha* rhamnose

can be found in all parts of the plants – the roots, stems, leaves, as well as flowers. Each part of the plant contains distinct ginsenoside profiles [28]. Being the most concentrated region, the root contains 3–6 % (by weight) of ginsenosides, and the overall saponin content is directly proportional to the age. On average, the root saponin content reaches peak levels at around 6 years of age for cultivated ginseng, and at least 10 years for the wild ones [29, 30].

To date, more than a 100 naturally occurring ginsenosides have been isolated from roots, leaves, stems, fruits, and flower heads of ginseng [31]. The triterpenoid core of ginsenosides is a four-ring structure with various sugar moieties (e.g., glucose, rhamnose, xylose, and arabinose) attached to the C-3, C-6, and C-20 positions. Ginsenosides are named according to the chromatographic polarity in alphabetical order with a prefix "R" that stands for the root [32]. Therefore, Ra is the least polar ginsenoside and Rg3 is more polar than Rg1. The presence or absence of the C-6 carboxyl group categorize ginsenosides into two groups – the 20(S)-protopanaxatriol (PPT) (Re, Rf, Rg1, Rg2, Rh1) and the 20(S)-protopanaxadiol (PPD) (Rb1, Rb2, Rb3, Rc, Rd, Rg3, Rh2, Rs1), respectively [33] (Fig. 115.1).

Besides the common ginsenosides (Rb1, Re, Rg1, Rg3), ginsenoside composite varies among ginseng species. For example, ginsenoside Rf is unique to Asian ginseng and F11 is found exclusively in American ginseng. Thus, the Rf/F11 ratio is used as a phytochemical marker to distinguish American ginseng from Asian ginseng [34, 35]. Such differences can generally correlate with the physiological properties of the ginseng – American ginseng is described to be cooling and soothing to body conditions, while Asian varieties are thought to be "hot" and stimulating – although detailed ginsenoside property identification is still under investigation. The heat-processed red ginseng contains multiple unique ginsenosides, including Rg3, Rg5, Rk1, Rk2, Rk3, Rs4, Rs5, Rs6, and Rs7 [36]. It is these unique ginsenosides to produce the signature effects of the red ginseng.

3 Ginsenosides Are Part of the Defense Mechanisms in Ginseng

Over evolution, plants eliminate most of the non-necessary biological pathways and reserve those benefit to its own survival. Thus, we ask what is the purpose for ginseng to make the saponins called ginsenosides?

Plants produce antibiotic substances to defense themselves from insect and microbial attack, such as nicotine from tobacco leaves [37], rotenone from derris tree roots [38], pyrethroids from chrysanthemum flowers [39], and triterpenoids from neem tress [40]. Evidence indicated that ginsenosides are one of the phytoanticipins to protect the ginseng plant.

Ginsenosides are constantly synthesized by the ginseng plant prior to pathogenic invasion, and defensive stress signals, such as methyl jasmonate and salicylic acid, can enhance ginsenoside production and accumulation by 3–4 times, as illustrated in ginseng root cells' in vitro culture [41–44]. Ginsenosides are found to possess antimicrobial and fungitoxic properties [45–47], and the bitter taste keeps insects and animals from feeding on them [48]. Ginsenosides share high degree of molecular structure similarity with the insect molting and metamorphosis hormone ecdysteroids, suggesting ginsenosides may be an agonist to the ecdysteroid receptor. Thus, ginsenosides may protect the plant by interfering with the life cycle of herbivorous insects [49] (Fig. 115.2). These lines also verify the folk belief that wild ginsengs grown in a more challenged environment contain larger amount of ginsenosides and have greater biological effects compared to the cultured ginseng, thus are sold at a much high price range. To reproduce the quality of wild ginseng, ginseng growers developed the "wild simulating cultivation" approach to provide a more natural environment for the plants.

4 The "Yin and Yang" Actions of Ginseng

Ginsengs are described as an "adaptogens." The concept of "adaptogen" was first proposed by a Soviet pharmacologist and toxicologist, Dr Nikolai Vasilievich Lazarev (1895–1974). At that time, adaptogen is a substance that can be administrated to individuals of any health condition to increase nonspecific resistance to various kinds of biological stresses. However, adaptogenicity can hardly be proved by scientific evidence. Here I reframe it and elaborate this property of ginseng in the yin and yang concept.

The "yin and yang" concept in Chinese is the coexistence and balance of opposing forces, such as light and dark, good and evil, calm and irritation. Unlike most of the other herbs, ginseng is commonly taken by its own. This would be explained by the coexistence of ginsenosides of various properties, and consumption of ginseng alone can lead to a combination of effects, which resemble "Fufang" (複方) in Chinese medicinal concept, or the cocktail therapy in the Western approach. Taking angiomodulation effects as an example, angiogenic properties of ginseng are related to the compositional ratio between ginsenosides Rg1 and Rb1. Asian ginseng with

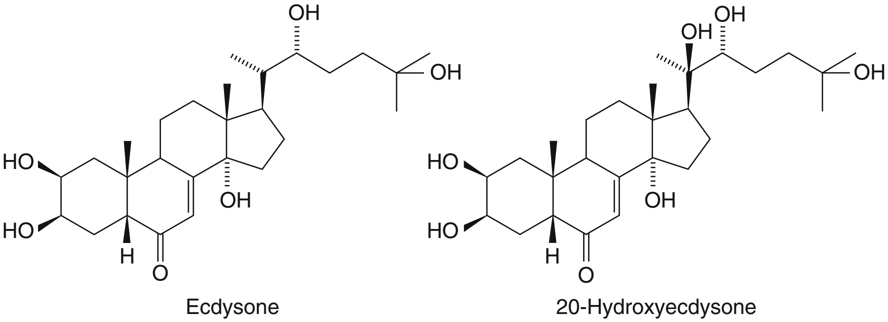

Fig. 115.2 Molecular structures of the insect molding hormones ecdysone and 20-Hydroxyecdyson. Structural similarities between ginsenosides and the ecdysone suggest ginsenosides maybe analogs to ecdysone receptors

higher Rg1 levels is found to promote growth of blood vessels and consumption of Asian ginseng can reduce hypertension. In contrary, American ginseng that contains more Rb1 is found to suppress angiogenesis, and is used in cancer treatment. The coexisting Rg1 and Rb1 interact with different receptors and give ginseng the ability to balance the dynamic equilibrium of human physiological processes. We will discuss the ginsenoside-receptor interactions later in this chapter.

5 Standardized Ginseng Extracts

Because of complex composition of the ginseng and some of the ingredients are having contrasting actions, variations in composition will lead to inconsistent experimental results. For this reason, standardized extracts are made and are commercially available to minimize variability among preparations. Two commonly used standardized extracts are G115 from *P. ginseng* (total ginsenoside adjusted to 4 %) (Pharmaton SA, Switzerland) and NAGE from *P. quinquefolius* (total ginsenoside content adjusted to 10 %) (Canadian Phytopharmaceuticals Corporation, Canada). Studies on these two ginseng extracts using high-performance liquid chromatography (HPLC) found ginsenosides Rb1, Rb2, Rc, Rd, Re, and Rg1 in both G115 and NAGE, and ginsenoside Rg2 in G115 only. Comparing G115 and NAGE: G115 has higher Rg1, but NAGE has higher in Rb1 and Re [50–52].

Moreover, the butanol-soluble fraction of Sun ginseng is formulated into KG-135 which contains Rk3 Rs3, Rs4, Rs5, Rs6, and Rs7 in addition to the major antitumor ginsenosides [16, 53].

6 Biotransformation of Ginsenosides

As a group of defensive phyto-compounds, ginsenosides may require certain degree of transformation to gain its full activity in mammalian system. In fact, major

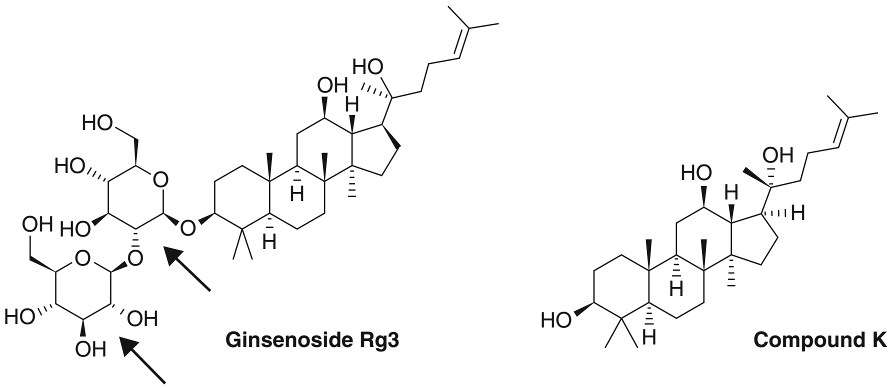

Fig. 115.3 Molecular structures of ginsenoside Rg3 and its metabolite Compound K. *Arrows* indicate the C3 glucoses to be deglycosylated by the microflora

ginsenosides, such as Rg1, Rg3, Rb1, Re, and Rc, are bulky molecules that are poorly membrane permeable. Moreover, these ginsenosides are antigenic in the circulatory system. Antibodies against these ginsenosides can be purified from immunized animals and are commercially available [54–57].

Ginsenosides in orally consumed ginseng preparations are subjected to acid hydrolysis, glycosyl elimination, and intestinal microflora-driven sugar moiety cleavage [58–60]. Following biodegradation, PPDs are converted to compound K (also known as M1 or IH901) and panaxadiol, while ginsenoside F1 and panaxatriol are the major metabolites of PPTs. Several bacterial strains are identified and selected transforming enzymes are overexpressed using recombinant DNA technique for in vitro ginsenoside modification [61].

Studies have shown that ginsenoside metabolites indeed have greater biological effects compared to the naturally occurring ginsenosides [62–64]. Ginsenoside Rh2, compound K, and panaxadiol, the metabolites of Rg3, are found to have greater antitumor activities than ginsenoside Rg3 itself [62, 65]. Similarly, compound K, panaxatriol, and panaxadiol possess the human liver enzyme cytochrome P450 inhibitory effects that are not found in the bulk ginsenosides Rb1, Rb2, Rg1, and Re [64] (Fig. 115.3).

7 Bioavailability of Ginsenosides

Multiple systematic actions of ginsenosides are reported and intensively investigated, but how ginsenosides are absorbed from the digestive system and reach the systemic organs remains largely unknown.

Although ginsenosides have the basic structure of a steroid, the sugar side chains increase the hydrogen bond count and polar surface area that hurdle effective permeability of these compounds across the membranes. The side chains are prone to degradation via hydrolytic cleavages and deglycosylations. Thus, availability of intact ginsenosides from the intestine is extremely low [58, 66, 67]. To detect the ginsenosides in the blood samples after consumption using high-performance liquid chromatography, only 3.29–18.4 % Rg1 and 0.64–4.35 % Rb1 are detected in rat serum after oral administration of the ginsenosides [67–71].

Ginsenosides are shown to be transported across the intestinal mucosa in an energy-dependent and non-saturable manner [68, 69, 72]. The sodium-dependent glucose co-transporter-1 may be involved in this process [73]. Several approaches has been tested to increase the bioavailability of ginsenosides, including coadministration of ginsenosides with adrenaline [74], emulsification of ginsenosides into lipid-based formulation [75, 76], micronization of the ginsenoside particle and consequently increase the dissolution rate [77], and suppression of p-glycoprotein efflux system [78]. However, not a single approach is proved to enhance the bioavailability of all ginsenoside.

After absorption, ginsenosides continue to be biologically modified, such as oxidation and small degree of deglucosylation at the tissue levels [79]. As well, circulating ginsenosides and their deglycosylated products were subject to rapid and extensive biliary excretion through active transport, resulting in short biological half-lives and low systemic exposure levels [79].

8 Physiological Effects of Ginseng

Being crowned as the King of Herbs, ginseng has diverse activities on multiple organ systems in human regardless of the low bioavailability. In this chapter, biological effects on cardiovascular system, cancer, diabetes, immune system, and neurological system will be reviewed.

8.1 Pro- and Anti-angiogenesis

Ginsenosides are found to be able to modulate angiogenesis in both directions via altering genes involved in cell architectural dynamics, adhesion, and migration. For example, ginsenoside Rg1 interacts with glucocorticoid receptor (GR) and stimulates angiogenesis through augmenting the production of nitric oxide (NO) and vascular endothelial growth factor (VEGF) in endothelial cells [80, 81]. Angiogenesis promotion can accelerate wound healing and support stroke recovery. At the same time, ginsenoside Rb1 interacts with estrogen receptor-beta (ER-β) and enhances the production of anti-angiogenic pigment epithelium-derived factor (PEDF) from the endothelial cells [82]. Since tumor mass attracts blood vessels, suppressing angiogenesis ginsenosides is then exploited as part of the anticancer treatment.

8.2 Anticancer

American ginseng has been shown to have powerful anticancer properties, and heat-processed red ginseng has more potent inhibition on tumor growth compared to the untreated white ginseng. Patients with stage-3 gastric cancer taking red ginseng were observed to have a higher 5-year disease-free survival rate and better restoration of immune functions during adjuvant chemotherapy compared to control patients [83]. Regular consumption of ginseng also demonstrates a dose-dependent decrease in risk of cancer in Korea [84, 85]. Besides the anti-angiogenic properties of certain class of ginsenosides that have been exploited as an anticancer modality, ginsenosides Rg3 and Rh2 are shown to inhibit growth of several cancer cell lines [86, 87] and capable in reversing the multidrug resistance properties of cancer cells by inhibiting the efflux transporter P-glycoprotein (P-gp) [88–90]. Inhibition of P-gp leads to the improvement of bioavailability of several orally administrated anticancer drugs and could be taken to assist cancer chemotherapy [91, 92]. “Anticancer capsules” of Rg3 alone or in combination with ginsenoside Rh2 are available in Mainland China as over-the-counter drugs.

8.3 Combat Diabetes

In genetically obese diabetic KK-CA model, intraperitoneal injection of ginseng root extract can significantly lower blood glucose levels [93, 94]. As well, total ginseng berry extract reduces body weight and improves glucose homeostasis in type-2 diabetic ob/ob mice [95]. Particularly, treatment with ginsenoside Re lowers the elevated fasting blood glucose to normal levels and enhances glucose tolerance capacity in diabetic mice, but has no effects in the nondiabetic littermates [95]. Yet the mechanism of such effects is unclear. In human studies, consumption of 3 g of American ginseng root 40 min before the test meal significantly lowered blood glucose level in both nondiabetic subjects and diabetic patients [96].

8.4 Immune System Enhancement

Ginseng is shown to be an immunostimulant. It activates macrophages of healthy and fungal-infected mice [97, 98], as well as in mice exposed to the cold-water swim stress [99]. Ginseng also assists recovery of natural killer (NK) cells function in immunosuppressed mice [100, 101]. In a randomized, placebo-controlled double-blind trial, volunteers were treated with an influenza vaccine plus either placebo or a standard ginseng extract G115 over a 3-month period [102]. The frequency of upper respiratory infections (i.e., colds and flus) was significantly reduced by three times in the ginseng group compared to the placebo. In addition, antibody titers and NK activities were significantly higher in the ginseng group [102]. In a study, hot-water wild ginseng extracts resulted in increased lymphocyte proliferation both in vitro and in mouse model, while extracts from cultured ginseng had no effect [103]. This finding paralleled to the folk belief that wild ginseng has stronger immunomodulating effects compared to the cultured or domesticated ones.

Besides the cancer-combating potential, ginseng is often taken by patients in advance stage tumor for its immune stimulation properties. Cancer patients are inherently immunosuppressive due to tumor-derived factors and the standard treatments, such as chemotherapy [104, 105]. Thus, many patients choose ginseng preparations to complement their standard cancer treatments.

9 Cellular Signal Transduction Pathways

Given the steroidal structure of ginsenosides, it has been shown to interact with the ligand binding sites of various steroid hormone receptors – ginsenosides Rg1 [82, 106] and Re [107] are functional ligands of the glucocorticoid receptor (GR), whereas ginsenosides Rh1 [108] and Rb1 [82] are functional ligands of the estrogen receptor (ER). However, the effects elicited by the ginsenoside-receptor complex are not as prominent as the native agonist of the steroidal receptors, i.e., the glucocorticoid and estrogen for the GR and ER, the ginsenosides may therefore function as partial agonists, which ginsenoside compensate for the insufficient steroidal activities when the intrinsic ligand is absent or inadequate in the system, while reversibly occupying the steroidal receptor with low affinity to modulate the steroidal effects when large amount of intrinsic ligand is present. This hypothesis also explained the adaptogenic properties of ginseng to bring extreme physiological conditions back to balance.

Moreover, each ginsenoside is able to bind to multiple steroid hormone receptors with different affinity. In addition to GR, ginsenosides Rg1 acts through ER and elicits cross-talking with insulin-like growth factor-1 receptor (IGF-IR) in neuronal cells [109]. Effects of ginsenoside Re on cardiac myocytes are related to ER alpha isoform, androgen receptor, and progesterone receptor [110]. The end metabolites PD and PT bind and activate both GR and ER in endothelial cells [111]. The multi-target properties of ginsenosides may explain why ginseng has a wide range of beneficial effects.

On the other hand, taking ginseng preparation enhances the mood and health-related quality of life in menopausal women with no change in female hormone–related physiological parameters, e.g., follicle-stimulating hormone (FSH) and estradiol levels, endometrial thickness, maturity index, and vaginal pH were not affected by the treatment [112], indicating some of the beneficial effects of ginseng are not mediated via steroidal hormone receptors. Other studies showed that ginsenosides can modulate expressions and functions of receptors, such as receptor tyrosine kinases (RTK) [113], serotonin receptors (5-HT) [114], NMDA receptors [115], and nicotinic acetylcholine receptors (AChR) [116]. Thus, ginsenosides are involved in a very complicated network of actions and more research is required to acquire thorough understanding.

10 Conclusion

Although ginsengs come in many different varieties and different molecular composition, the active effective compound is ginsenosides. The structural analyses, binding studies, and functional investigations demonstrated the steroidal hormone receptor partial agonist properties of ginsenosides and explained the multiple therapeutic effects of this group of molecules. At the same time, ginsenosides modulate the activities of other cellular signaling pathways that awaits further investigations. This allelopathic property of ginseng attracts growing attention since many diseases, such as cancer, neurodegenerative disorders, and metabolic syndromes, are not isolated conditions of a single organ, and promising cure are currently unavailable. Therefore, unraveling the action mechanisms of the natural occurring systemic modulatory compounds, like ginsenosides, would be beneficial to the overall community welfare.

Abstract

Plants have a long history as therapeutic tools in the treatment of human diseases and have been used as a source of medicines for ages. In addition, plants play a role in disease prevention. For example, reduced risk of cancer is associated with high consumption of vegetables and fruits. Thus, the cancer chemopreventive cytotoxic potential of naturally occurring phytochemicals is of immense interest. There is an urgent need to develop new anticancer chemotherapeutic agents to overcome the development of multidrug resistance tumors. Essential oils exhibit many potential activities such as cytotoxicity, antimicrobial, anti-inflammatory, analgesic, and insect repellant. Most of the essential oils are extracted from plants by hydrodistillation so they contain a variety of volatile molecules such as terpenes and terpenoids, phenol-derived aromatic components, and aliphatic components. Essential oils act on via apoptotic pathway, affecting mitochondrial functions. This may impart free radical scavenging potential which could be controlled and targeted. This property makes the terpenoids favorable anticancer agents. Depending on type and concentration, they exhibit cytotoxic effects on living cells but are usually nonmutagenic and nongenotoxic. In some cases, changes in intracellular redox potential and mitochondrial dysfunction induced by essential oils can be associated with their ability to exert antigenotoxic, antimutagenic, and anticancer effects. These findings suggest that the encountered beneficial effects of essential oils are due to pro-oxidant effects on the cellular level. This chapter focuses on the cytotoxic activity of sesquiterpenes and their derivatives.

Keywords

Apoptosis • cytotoxicity • essential oil • sesquiterpenes

Abbreviations

3-HMGCoA	3-Hydroxy-3-methylglutaryl-coenzyme A
DAG	Diacyl glycerol
DMAPP	Dimethylallyl pyrophosphate
EPA	Environmental protection agency
ERK	Extracellular signal-regulated kinase
FADD	Fas-associated death domain
FPP	Farnesyl pyrophosphate
FTase	Farnesyltransferase
GC-MS	Gas chromatography-mass spectrometry

GGPP	Geranylgeranyl pyrophosphate
IPP	Isopentenyl pyrophosphate
MDR	Multidrug resistance
NFkB	Nuclear factor kappa B
NMR	Nuclear magnetic resonance
PARP	Poly (ADP-ribose) polymerase
PKC	Protein kinase C
ROS	Reactive oxygen species
SLs	Sesquiterpene lactones
TNF	Tumor necrosis factor

1 Introduction

Plants produce primary and secondary metabolites which encompass a wide array of functions. Primary metabolites are the compounds which play an important role in the regulation of cellular and physiological processes, for example, carbohydrates, lipids, and proteins. Secondary metabolites are the compounds produced in response to stress, such as the case when acting as a deterrent against herbivores [1]. Plants can manufacture many different types of secondary metabolites, which have been subsequently exploited by humans for their beneficial role in a diverse array of applications [2]. Often, plant secondary metabolites may be referred to as plant natural products, in which case they elicit effects on other organisms. Although this review focuses on plant terpenes, it should be realized that other organisms are able to synthesize terpenes. For example, the endophytic fungus isolated from *Hypericum perforatum* has been producing hypericin and emodin, terpene lactones [3]. There are three broad categories of plant secondary metabolites as natural products: terpenes and terpenoids (~25,000 types), alkaloids, and phenolic compounds [4].

Essential oils are secondary metabolites produced in the plants as volatile aromatic principles. They are colorless and rarely colored and soluble in organic solvents. It is found in all part of the plants and is stored in epidermal cells, trichomes, secretory cells, canals, and cavities. They are extracted by the use of liquid carbon dioxide or microwaves, expression and mainly steam or hydrodistillation process. Due to their biological, nutritive, and pharmaceutical properties, they are more attractive alternatives to synthetic chemical products to protect the equilibrium.

The extraction process, collection of drug material, plant parts, age of the plant, and geographical and climatic conditions affect chemical profile and stereochemistry of the essential oil products [5, 6]. Most of the commercialized essential oils are analyzed by gas chromatography (GC), mass spectrometry (MS), or a combination of GC-MS technique [7].

Essential oils have been largely employed for their properties already observed in nature, that is, for their cytotoxicity, antimicrobial, anti-inflammatory, analgesic, and insect repellant activities. At present, approximately 3,000 essential oils are known, out of which 300 are commercially important especially for the agriculture, food, pharmaceutical, cosmetic, and perfume industries. Moreover, essential oils are used in massages as mixtures with other oils (aromatherapy). Some essential oils exhibit particular medicinal and therapeutic properties and have been used in the prophylaxis and treatment of acute and chronic disorders.

Terpenes are a large class of natural hydrocarbon secondary metabolites built up from five-carbon isoprene units linked together most commonly in a head to tail arrangement, but can be constructed in other configurations with varying degree of unsaturation, oxidation, reduction, functional groups, and ring closure, giving rise to a rich diversity of structural classes, with novel skeleton being continuously discovered. These modified hydrocarbons are referred to as terpenoids, which are primarily found to occur in a wide variety of higher plants. They can also be found in insects and marine organisms. The name terpene is derived from the word turpentine, a product of coniferous oleoresins.

The terpenes or terpenoids are classified or grouped according to the number of isoprene units found in parent nucleus ranging from one to many. Terpenoids are the chemically modified products of terpenes. Terpenes and terpenoids are made up of isoprene unit $(C_5H_8)n$. Chemically isoprene is 2-methylbuta-1,3-diene and commercially used for the preparation of rubber. As with any class of compounds, not all terpenoids contain even number of intact isoprene units, with a few being degraded isoprene moieties with missing carbons such as C_{19} diterpenoids. The simplest type of terpenoids is hemiterpenes consisting of single five-carbon isoprene unit. Their occurrence is rare and is not biologically significant. Monoterpenes consist of two isoprene units that can be found in acyclic, monocyclic, and bicyclic forms and in various state of oxidation. Sesquiterpenes are C_{15} compounds containing three isoprene units, occurring in simple acyclic to macromonocyclic rings as well as simple and complex bicyclic and tricyclic forms. The structural diversity of sesquiterpenes is such that the number of carbon skeletons having been reported far exceeds 100. C_{20} terpenoids are the diterpenes which contain four isoprene units. Their structural diversity ranges from simple acyclic to complex polycyclic rings. Sesquiterpenes are rare C_{25} compounds. Triterpenes are C_{30} compounds numbering more than 4,000 distributed in more than 40 different carbon skeletons, arising from the cyclization of an oxidized form of squalene, the linear parent triterpene and carotene. Natural rubber which contains long chain of many cis isoprene units, and gutta-percha which contains many trans isoprene units. These natural products are the members of polyterpenoids [8].

Biosynthetically, majority of terpenoids are formed via the mevalonic acid, but they may also be formed through methyl-erythritol-4-phosphate (MEP) pathway. The C_5 isoprene unit which can be linked together “head to tail” to form linear chains or cyclized to form rings is considered the building blocks of terpenes. Rather the C_5 units exist as isopentenyl pyrophosphate or its isomer dimethylallyl pyrophosphate by enzymatic conversion and phosphorylation from mevalonic acid. The IPP may be considered as the precursor of hemiterpenes. In the biosynthesis of mono- and higher terpenes/terpenoids, the starting molecule is DMAPP, which condenses with an IPP unit to form geranyl pyrophosphate, leading to the formation of monoterpenoids. Condensation of GPP with and IPP leads to the formation of farnesyl pyrophosphate (FPP), the precursor of sesquiterpenoids. FPP and IPP form geranylgeranyl pyrophosphate, the precursor of diterpenes. GGPP and IPP lead to the formation of sesquiterpenoids. Dimerization of two molecules of FPP gives rise to squalene, precursor of triterpenes and steroids. Condensation of intermediate precursor and IPP leads to tetra- and polyterpenoids. Chemical and biological studies have shown that the terpenoids possess a variety of chemical, physical, and biological activities. Biologically, the terpenoids possess anticancer, antimicrobial, cytotoxic, anti-inflammatory, and analgesic activities [8].

2 Terpenes and their Classification

Terpenes (turpeen) are a large and diverse group of organic compounds, produced by a variety of plants, particularly conifers, though also by some insects such as termites or swallowtail butterflies. They have characteristic odor and thus may have had a protective function [9]. Terpenes and terpenoids are the primary constituents of the essential oils of many types of plants and flowers. Essential oils are used widely as natural flavor in food additives, as fragrances in perfumery, and in traditional and alternative medicines such as aromatherapy. Terpenes are released by trees more actively in warmer weather, acting as a natural form of cloud seeding. The clouds reflect sunlight, allowing the forest to regulate its temperature.

2.1 Classification of Terpenes

Classes	No. of isoprene unit	No. of carbon atoms
Hemiterpenes	1	5
Monoterpenes	2	10
Sesquiterpenes	3	15
Diterpenes	4	20
Triterpenes	6	30
Tetraterpenes	8	40
Polyterpenes	n	Cn

3 Sesquiterpenes and their Classification

Sesquiterpenes are a class of terpenes that consist of three isoprene units and have the molecular formula $C_{15}H_{24}$. Sesquiterpenes may be acyclic or contain rings, including many unique combinations. Biochemical modifications such as

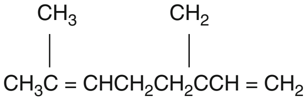

Fig. 116.1 Structure of isoprene unit

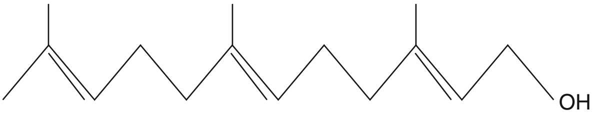

Fig. 116.2 Farnesol

oxidation or rearrangement produce the related sesquiterpenoids which are naturally found in plants and insects, as defensive agents or pheromones (Fig. 116.1).

Sesquiterpene lactones are secondary metabolites that belong to the group of C_{15} terpenoids. They are formed from three isoprene units. One of their methanol groups, a part of the isoprene group, was oxidized to lactones [10]. It constitutes an important group of secondary metabolites which play an important role in plant defense, as antimicrobials and insecticides. This group of secondary metabolites shows allelopathic prospective.

In recent years, there is an increasing demand of sesquiterpene lactones, mostly because of their high therapeutic potential as cytotoxic and anticancer agent. This is a large group of secondary metabolites. More than 90% of lactones were isolated from the members of Asteraceae family, while members of Magnoliaceae, Lauraceae, and Apiaceae family were the more primitive representatives of sesquiterpene lactones. Lipophilic solvents or supercritical fluid technology are used for the extraction of sesquiterpene lactones from plant material. The purification and structure elucidation was performed using chromatographic techniques and NMR and mass spectroscopy [11]. The presence of α,β-unsaturated γ-lactonic ring in sesquiterpene lactones has distinguishing therapeutic activity. Some sesquiterpene shows an allelopathic potential. The sesquiterpene shows an antibacterial, antimicrobial, antiviral, antiprotozoal, cytotoxic, and anticancer activity.

3.1 Acyclic

When geranyl pyrophosphate reacts with isopentenyl pyrophosphate, the result is the 15-carbon farnesyl pyrophosphate, which is an intermediate in the biosynthesis of sesquiterpenes such as farnesene. Oxidation can then provide sesquiterpenoids such as farnesol and juvenile hormone (Fig. 116.2).

3.2 Monocyclic

With the increased chain length and additional double bond, the number of possible ways that cyclization can occur is also increased, and there exists a wide variety of cyclic sesquiterpenes, for example, abscisic acid, fumagillin, germacrene, dendrolasin, and trans-y-monocyclo farnesol. In addition to common six-membered ring systems such as in zingiberene, a constituent of the oil from ginger, cyclization of one end of the chain to the other end can lead to macrocyclic rings such as humulene.

3.3 Bicyclic

In addition to common six-membered rings such as in the cadinenes, one classic bicyclic sesquiterpene is caryophyllene, which has a nine-membered ring and cyclobutane ring. Additional unsaturation provides aromatic bicyclic sesquiterpenoids such as vetivazulene and guaiazulene. Examples are caryophyllene, y-muurolene, petasin, lporneamarone, carotol, helminthosporal, avocettin, alkaloids of Nuphar, and mycophenolic acid.

3.4 Tricyclic

With the addition of a third ring, the possible structures become increasingly varied. Examples are longifolene, copaene, patchoulol, illudins, hirsutic acid, corlolins, trichothecin, helicobasidin, picrotoxinin, dendrobine, sativene, and santonin.

3.5 Tetracyclic

These compounds have four-membered rings. Examples are gossypol and marasmic acid.

3.6 Pentacyclic

These compounds have four-membered rings, for example, siccanochromenes (Fig. 116.3).

3.7 Functions of Sesquiterpenes in Plants

Sesquiterpene lactones have been isolated from all plant parts. However, most commonly they are obtained from glandular trichomes in leaves. They are bitter

in taste and are not a good food candidate for herbivorous animals. These animals include herbivorous insects as well as mammals [10]. It protects plant material and makes its defense system stronger.

4 Cytotoxicity and Apoptosis

Cytotoxicity is the quality of cellular toxicity and the causative agents are cytotoxic agents. Cytotoxic agents are chemical substances, cells of immune system, and some venom (e.g., spider toxin). Treating cells with the cytotoxic compounds may undergo necrosis, in which they lose their membrane integrity and die rapidly as a result of cell lysis. The cells can stop actively growing and dividing (a decrease in cell viability), or the cells can activate a genetic program of apoptosis (controlled cell death).

Cell death occurs by two alternative and basically different modes: necrosis and apoptosis. Necrosis, the “ordinary” cell death with the characteristics of a passive process, is traditionally associated with inflammation, occurs in response to severe forms of physical or chemical types of injury, or results from severe depletion of cell energy and nutrition stores [12]. Apoptosis (programmed cell death) is a fundamental and complex biological process that enables an organism to kill and remove unwanted cells during any stage of development, therefore maintaining normal homeostasis and eliminating infected or malignant cells. In the development of new anticancer agents, apoptosis is considered the paramount form of pathophysiological cell death [13].

Apoptosis is one of the most important regulatory functions whereby a living organism maintains homeostasis. In some diseases, this regulation is disturbed, and the rate of apoptosis is increased (e.g., neurodegenerative diseases) or decreased (e.g., cancer).

4.1 Morphological and Biochemical Alterations

The onset of apoptosis is characterized by the shrinkage of cell and nucleus and by the condensation of nuclear chromatin into sharply delineated masses. Later, the nucleus progressively condenses and breaks up. The term budding has been coined for a process whereby the extensions separate and the plasma membrane seals to form a separate membrane around the detached solid cellular material. These apoptotic bodies are crowded with closely packed cellular organelles and fragments of the nucleus. The apoptotic bodies are rapidly phagocytosed into neighboring cells, including macrophages and parenchymal cells. Apoptotic bodies can be recognized inside these cells, but eventually they become degraded. If the fragmented cell is not phagocytosed, it will undergo degradation, which resembles necrosis, in a process called secondary necrosis. Apoptotic shrinkage, disassembly into apoptotic bodies, and engulfment of individual cells characteristically occur without associated inflammation [14].

Biochemical events lead to characteristic cell changes (morphology) and death. These changes include blebbing, cell shrinkage, nuclear fragmentation, chromatin condensation, and chromosomal DNA fragmentation. Unlike necrosis, apoptosis produces cell fragments called apoptotic bodies that phagocytic cells are able to engulf and quickly remove before the contents of the cell can spill out onto surrounding cells and cause damage [15–17]. Activated nucleases are responsible for DNA degradation. As a consequence, some of the cells contain a decreased amount of DNA and can be detected as a subdiploid population in the cell cycle distribution by flow cytometry.

In the early stages of apoptosis, plasma membrane alterations occur at the cell surface, and PS translocates from the inner side to the outer layer of the plasma membrane. PS and phosphatidylethanolamine are actively confined to the inner cytofacial leaflet of the plasma membrane by the aminophospholipid translocase. This has been identified as a trigger for stimulation of the phagocytosis of apoptotic cells by macrophages, thus preventing secondary necrosis and inflammation of the surrounding tissue.

4.2 Caspases

Caspases are a family of specific proteases, present as inactive precursors in growing cells which trigger apoptosis [18]. These proteases use a cysteine residue for catalysis and only cleave substrates at Asp-Xxx bonds [19]. Caspases are synthesized as zymogens with an N-terminal prodomain, followed by a large and a small subunit. The mature enzyme contains two heterodimers and two active sites [20]. In apoptosis, caspases function in both cell disassembly and in initiating this disassembly in response to proapoptotic signals. More than ten different caspases have been identified in mammalian tissues [21]. Caspase 3 is activated by other caspases, and it can cleave many cellular targets, resulting in the attainment of apoptotic morphology. Activation of this caspase generally results in an irreversible commitment to cell death. Caspases are responsible for cleaving numerous cellular targets, including structural elements, nuclear proteins, and signaling proteins, leading to the morphological hallmarks of apoptosis [20].

4.3 TNF Pathway

TNF is a cytokine produced mainly by activated macrophages and is the major extrinsic mediator of apoptosis. Most cells in the human body have two receptors for TNF: TNF-R1 and TNF-R2. The binding of TNF to TNF-R1 has been shown to initiate the pathway that leads to caspase activation via membrane proteins, TNF receptor-associated death domain and Fas-associated death domain (FADD.) proteins [22]. Binding of this receptor can also indirectly lead to the activation of transcription factors involved in cell survival and inflammatory responses [23].

4.4 Fas Pathway

The Fas receptor (CD95) binds the Fas ligand (FasL), a transmembrane protein part of TNF family. The interaction between Fas and FasL results in the formation of death-inducing signaling complex (DISC), which contains the FADD., caspase-8, and caspase-10. In some types of cells, processed caspase-8 directly activates other members of the caspase family and triggers the execution of apoptosis of the cell. In other types of cells (type II), the Fas-DISC triggers the release of proapoptotic factors from mitochondria and the amplified activation of caspase-8 [24].

4.5 Other Components

A balance between proapoptotic (BAX, BID, BAK, or BAD) and anti-apoptotic (Bcl-Xl and Bcl-2) members of the Bcl-2 family is recognized. The proapoptotic members are required to make the mitochondrial membrane permeable for the release of caspase activators such as cytochrome c. Control of proapoptotic proteins under normal cell conditions of non-apoptotic cells is incompletely understood, generally Bax or Bak are activated by the activation of BH3 proteins [23].

5 Cancer

Cancer, neoplasm, involves uncontrolled and unregulated cell division. In cancer, cells divide and grow uncontrollably, forming malignant tumors, and invade nearby parts of the body. The cancer may also spread to more distant parts of the body through the lymphatic system or blood stream (metastasis).

The causes of cancer are complex. Many things are known to increase the risk of cancer, including tobacco use, certain infections, radiation, lack of physical activity, poor diet and obesity, and environmental pollutants [25]. These can directly damage genes or are entirely hereditary [26].

Cancer can be detected symptomatically and through screening tests or medical imaging. Once a possible cancer is detected, it is diagnosed by histological examination. Cancer is usually treated with chemotherapy, radiation therapy, and surgery. The chances of surviving the disease vary greatly by the type and location of the cancer and the extent of disease at the start of treatment. While cancer can affect people of all ages, and a few types of cancer are more common in children, the risk of developing cancer generally increases with age. In 2007, cancer caused about 13% of all human deaths worldwide (7.9 million). Rates are rising as more people live to an old age and as mass lifestyle changes occur in the developing world [27]. The vast majority of cancer risk factors are due to environmental (including lifestyle) factors, and many of these factors are controllable. Thus, cancer is largely considered a preventable disease [28]. Greater than 30% of cancer is considered preventable by avoiding risk factors including tobacco, overweight/obesity, insufficient diet, physical inactivity, alcohol, sexually transmitted infections, and air pollution. Not all environmental causes can be prevented completely such as naturally occurring background radiation.

Cancer cells are the descendants of a normal cell in which something has gone wrong. In this normal cell, some kind of internal or external stress causes a mix-up in its genetic code. This event is said to “initiate” the cell to a precancerous state. After its DNA has been damaged, the cell withdraws from close communication with its neighboring cells. Interrupted cell-to-cell communication is a common result of DNA damage or other forms of cellular damage. Separated from the regulatory controls of its community, it is now at the mercy of its environment. The environment around this cell contains a promoting agent that stimulates cell proliferation. In response to the promoting agent, this precancerous cell divides to produce daughter cells, and these daughter cells divide to produce more daughter cells, and so on. All are proliferating only in response to the promoting agent. The promoting agent may be a chemical foreign to the body, or it could come from a natural process such as inflammation. The genetic instabilities passed down through the generations finally result in one cell that becomes capable of self-stimulation, and on this day an autonomous cancer cell is born. This cell no longer requires the promoting agent to stimulate its proliferation. The role of the promoting agent is made obsolete by the cell’s ability to make proteins such as growth factors that stimulate proliferation. This original cancer cell divides to produce daughter cells; these cells also divide, and soon there is a population of cancer cells. As they divide, they develop malignant characteristics, such as the ability to invade and metastasize. They also develop other characteristics that help assure survival, for example, the ability to evade the immune system, to mutate when faced with adverse conditions, and to induce the growth of new blood vessels through the process called angiogenesis. The development of these characteristics marks the third stage in carcinogenesis, the first two stages being initiation and promotion, respectively.

5.1 Approaches for Cancer Inhibition

5.1.1 Reduction of Genetic Instability

Genetic instability is provoked by oxidative stress (free radicals). High oxidative stress results in mutation and more destructive cancers. Thus, one way of reducing genetic instability is by reducing oxidative stress.

5.1.2 Inhibit Irregular Gene Expression

Gene expression can be normalized through modifying the activity of transcription factors. Genes that inhibit cancer progression are underexpressed and genes that facilitate cancer are commonly overexpressed in cancer cells. Therefore, cancer can be inhibited by normalizing the activity of those transcription factors that control gene expression.

5.1.3 Inhibit Abnormal Signal Transduction

The signal transduction from outside the cell to the nucleus depends on several proteins (kinase enzymes and ras proteins). Signal transduction is a normal process needed by healthy cells, but in cancer cells excessive signal transduction favors proliferation and metastasis. So cancer can be inhibited by normalizing signal transduction.

5.1.4 Cell-to-Cell Communication

Normal cell-to-cell communication can be promoted by improving gap junction communication and by normalizing CAM activity.

5.1.5 Inhibit Tumor Angiogenesis

Angiogenesis is a normal process that is required during wound healing and in other situations. Angiogenesis in tumors is uncontrolled which can be regularized by regularizing the factors that control it. Angiogenesis is most successful in presence of angiogenic factors and certain environmental conditions, such as hypoxia. Cancer can be inhibited by inhibiting the release of angiogenic factors or altering the local environment to inhibit tumor angiogenesis.

5.1.6 Inhibit Invasion and Metastasis

Invasion requires enzymatic digestion of the healthy tissue surrounding the tumor and can be reduced by inhibiting tissue digestive enzymes, by protecting normal tissues from the enzymes, and by reducing the ability of tumor cells to migrate.

Metastasis requires that cells detach from the primary tumor, enzymatically digest blood vessel walls to gain access to and exit from the blood circulation, and evade the immune system while in the circulation.

5.1.7 Increase the Immune Response

Cancer is an immune disorder. The immune response against cancer cells can be increased by stimulating the immune system and by reducing the ability of cancer cells to evade immune attack. The healthy, fundamental immune cells can destroy cancer cells, if it can be recognized antigen in the body [29]. Nowadays, immunomodulator is an emerging concept to combat against cancer.

5.2 Natural Compounds as Inhibitors of Cell Proliferation

The flow of information leading to cell proliferation is mediated through proteins. Abnormal gene expression is the most prominent feature, which results in four types of protein signals that support proliferation or malignant behavior. All four of these primary protein signals can be inhibited by natural compounds (herbal drugs).

1. Fault in the p53, Bax, and Bcl-2 gene can produce proteins that fail to induce apoptosis in cancer cells and protect cancer cells from apoptosis.
2. Abnormalities in some genes can produce excessive amounts of proteins that support angiogenesis, metastasis, or elusion of the immune system. It affects proliferation and apoptosis.
3. Overexpression of oncogenes such as *fos*, *jun*, and *myc* can produce large amounts of *fos* proteins which act as transcription factors to induce the expression of cyclin genes, whose proteins make the cell cycle proper.
4. Abnormal genes produce proteins like growth factors, growth factor receptors, kinase enzymes, ras proteins, and others several proteins that facilitate signal transduction. Overproduction of these proteins results in increased signal transduction, which stimulates abnormal activity of transcription factors such as NF-kB. Abnormal transcription factor activity stimulates gene expression, resulting in the overproduction of cyclin proteins that drive the cell cycle and the overproduction of other proteins that assist angiogenesis, invasion, and metastasis. Their actions include lowering mutation rates by scavenging free radicals, normalizing p53 activity, or both; inhibiting abnormal transcription factor activity; inhibiting kinases or other proteins involved in signal transduction; inhibiting the activity of cyclin proteins, which drive the cell cycle; and increasing cell-to-cell communication, which sends signals that normalize gene expression. Natural compounds that inhibit signal transduction can play a dual role in inhibiting cancer. In addition to proliferation signals, cancer cells also require signals to prevent apoptosis. In cancer cells, these signals come in part from both growth factors and increased signal transduction. Therefore, natural compounds that reduce signal transduction not only inhibit proliferation but also induce apoptosis [29].

6 Description of Cytotoxicity of Sesquiterpenes and their Derivatives

The plants of the genus *Taraxacum* contain a number of sesquiterpenes including eudesmanolides, taraxacolide, guaianolides, ixerin D, and germacranolide esters, taraxinic acid derivatives, and ainslioside [30, 31]. Furthermore, the two germacranolides and guaianolide glycosides sonchuside and vernoflexuoside were isolated from roots of *Taraxacum bicorne* and *Taraxacum hondoens* [32]. Eudesmanolides derivatives and taraxinic acid were isolated from *Taraxacum linearisquameum; Taraxacum coreanum* shows significant cytotoxicity against human leukemia-derived cell lines [33]. The recently discovered cytotoxic sesquiterpene lactones deacetylmatricarin and 2-oxo-guaianolides were present in *Taraxacum platycarpum*, *Taraxacum obovatum*, *Taraxacum hondoense*, and *Taraxacum bessarabicum* [34]. The taraxasterol and taraxerol from *Taraxacum japonicum* exhibited strong inhibitory effects in the carcinogenesis of mouse skin tumors [35]. The increased amounts of TNF-α and IL-1 contributed to dandelion (*Taraxacum officinale*)-induced apoptosis in hepatoma cell lines [36].

Eupatorium perfoliatum L. (Asteraceae), boneset also known as Indian sage, produces a number of sesquiterpene lactones possessing cytotoxic and immunostimulant activities [37, 38]. The sesquiterpenes lactones are guaianolides such as euperfolid, 11,13-dihydroeuperfolid, eufoliatin, eufoliatorin, or germacranolides such as euperfolitin and euperfolin [39].

Great burdock (*Arctium Lappa* L.) is widely used in folk medicine. The root extracts of Burdock shows antitumor properties against colon, ovarian, prostate, and renal cancer. The burdock seeds contain sesquiterpenes, lactucopicrin [40].

Telekin from the roots of *Telekia speciosa*, helenin from the roots of *Inula helenium* L., and sesquiterpene alcohol ledol from the aerial parts of *Ledum palustre* L. show cytotoxicity [41]. Bisabolol, a nontoxic sesquiterpene alcohol, was isolated from *Matricaria chamomilla*, *Carthamus lanatus*, and *Matricaria recutita* and exhibits a cytotoxic apoptosis-inducing effect [42] against human glioblastoma and pancreatic carcinoma cell lines.

A new guaianolide derivative, which possesses cytotoxic activity, was obtained from leaves and stems of *Chrysanthemum boreale*. It is effective in kidney carcinoma, melanoma, colon adenocarcinoma, prostate adenocarcinoma, and lung carcinoma. *Chrysanthemum morifolium* effectively inhibited the cytotoxicity and improved cell viability. It also stimulates the elevation of reactive oxygen species (ROS) level, increase in Bax/Bcl-2 ratio, cleavage of caspase-3, and PARP proteolysis [43, 44].

Xanthium strumarium L. (Asteraceae), locally called Bandaa, exhibits in vitro cytotoxic activities against various cancer cell lines like adenocarcinoma. Several other species of the genus *Xanthium* produce sesquiterpene lactones termed xanthanolides, xanthatin, 8-epi xanthatin, and 8-epi tomentosin, which are responsible for most of the biological activities. Regarding lung cancer, a methanolic extract of *X. strumarium* leaves exhibited a strong inhibition of tumor cell proliferation. The active constituents responsible for cytotoxic effect include

8-epi-xanthatin and its epoxide, two xanthanolides, and sesquiterpene lactones. The two xantholides show promising farnesyltransferase (FTase) inhibitory effect. Farnesylation of certain oncoproteins (especially Ras proteins) is required for their oncogenic activity. Moreover *X. strumarium* extracts effectively inhibit tubulin polymerization in mammalian tissues [45]. The maximum caspases 3/7 activity was observed with xanthatin. It seems that the induction of apoptosis was effected by activation of caspase-3. DNA fragmentation was also observed in human leukemia cell line. Sesquiterpene lactones trigger mitochondrial membrane transition, loss of mitochondrial membrane potential, and release of proapoptotic mitochondrial proteins leading to caspase activation and apoptotic cell death [46]. Xanthatin also caused a programmed cell death like in trypanosomes as evidenced by a reduction in mitochondrial membrane potential [47].

Farnesol, a sesquiterpene present in orange peel, lemon grass oil, and strawberries, has been considered as promising anticancer drug by affecting apoptotic pathway [48–50]. The extrinsic apoptotic pathway involves the activation of death domain receptors and downregulation and activation of caspase-3, while the intrinsic apoptotic pathway enhances the degradation of mitochondria and activation of caspase-9 pathway, which induces caspase-3 activation. The HSP27 protein which is associated with cancers and resistance to therapy found to be downregulated [51]. Farnesol induces an inhibition of cell growth and promotes apoptosis in squamous cell carcinoma through the induction of caspases, inhibition of survivin, and downregulation of various cellular proteins, for example, keratin 5A, RAN, heat shock protein, and glutathione S-transferase [52–54]. It also interferes with a phosphatidylinositol-type signaling pathway, leading to decreased levels of intracellular diacyl glycerol (DAG), and results in the activation of caspases and inhibition of survivin, leading to cell disassembly and growth inhibition. Its effect on mevalonic acid metabolism may account for antitumor activities in pancreas, colon, and cervix and cancer of lymphatic gland [55].

Parthenolide (PRT) is a sesquiterpene lactone obtained from feverfew (*Tanacetum parthenium*). It inhibits NF-kB and induces ROS production [56, 57]. The cytotoxicity of PRT inhibits DNA binding of NF-kB, signal transducer, and transcription activators, as well as reduction in MAPK activity and the generation of reactive oxygen [58, 59]. Its anticancer activity was established in multiple myeloma, lymphocytic leukemia, and stem cells [60]. The proapoptotic activity of PRT includes stimulation of intrinsic apoptotic pathway with the higher level of intracellular ROS, conformational changes of Bcl-2 family proteins, and poly (ADP-ribose) polymerase degradation. Treatment with parthenolide led to G1 phase cell cycle arrest by modulation of cyclin D1 and phosphorylated cyclin-dependent kinase. Parthenolide also inhibited the invasive ability of bladder cancer cells. PRT amplifies the apoptotic signal through the sensitization of cancer cells to extrinsic apoptosis, induced by TNF-α. PRT is a promising metabolic inhibitor to retard tumor formation and suppress tumor growth.

The members of genus Vernonia (*V. scorpioides*, *V. cinerea*, *V. lasiopus*, *V. amygdalina*) are good sources of sesquiterpene lactones (SLs). It contains highly oxygenated germacranolides, such as glaucolides and hirsutinolides, which possess cytotoxic property [61, 62]. The cytotoxic SLs, pulchellin E and gaillardin, from Inula oculus-christi [63] and guaianolides were also obtained from the leaves of *Achillea depressa* [64]. The crude extracts, chloroform and hexane-derived fractions of *Vernonia scorpioides*, Asteraceae, are a good source of sesquiterpene lactones (SLs), highly oxygenated germacranolides, such as glaucolides, hirsutinolides, and cadinanolides [65]. Hirsutinolides and glaucolides show cytotoxic property [66]. Phytochemical analysis of the leaves of *Vernonia amygdalina* yielded two cytotoxic sesquiterpene lactones: vernolide and vernodalol [67].

Ginkgo biloba L., living fossil, is among the most sold medicinal plants in the world. A number of secondary metabolites have been isolated from the plant. However, are terpenes and flavonoid glycosides considered the main bioactives [68]? The leaf extract may have cytotoxicity, related to their antioxidant, antiangiogenic, and gene regulation property. The extract changes gene expression that regulates cell proliferation, cell differentiation, or apoptosis; enhances antioxidant status; and inhibits DNA damage. It inhibits the formation of radiation-induced chromosome-damaging factors and ultraviolet light–induced oxidative stress effects that may also be associated with anticancer activity. Synergism is found between terpenoid and other constituents to elicit optimum effects [69, 70]. In vivo study suggests that Ginkgo may promote apoptosis of cancer cells by caspase-3 activation in mouth and stomach cancer [71, 72].

Guaiazulene is a bicyclic sesquiterpene obtained from guaiac wood oil, *Callis intratropica* Blue, and *Matricaria chamomilla* [73]. Guaiazulene showed cytotoxicity against cancer and normal cells by inducing an intrinsic apoptotic pathway and caspase-3 activation [74].

Rolandra fruticosa (L.) Kuntze (Asteraceae) has been placed in the subtribe Rolandrinae. Bioactivity-guided fractionation of methanol extract *Rolandra fruticosa* results in the isolation of sesquiterpene lactones which was active against colon cancer cell [75].

Laurus nobilis L. (Lauraceae) is a native to southern Mediterranean region and is widely cultivated mainly in Europe and the USA. The plant contains sesquiterpenes lauroxepine, costunolide, gazaniolide, and four sesquiterpene lactones including santamarine, reynosin, 11,13-dehydrosantonin, and spirafolide as a cytotoxic principle against leukemia and ovarian and gastric cancers [76].

The genus *Lactuca* (*L. perennis*, *L. tatarica*, *L. indica*, *L. capensis*, *L. tenerrima*) has been shown to produce sesquiterpene lactones including guaianolides, germacranolides, and some eudesmanolides. Two new eudesmane sesquiterpene lactones show anticancer activity against epithelial carcinoma and colon carcinoma cell lines [77].

The leaves of *Helianthus annuus* are the source of sesquiterpene annuolide E, leptocarpin, sesquiterpene heliannuols A–I, bisnorsesquiterpene, annuionone E, heliannuol L, helibisabonol A, and helibisabonol B. Sesamol seems to be an almost equally potent chemopreventive agent. Sunflower oil offered protection in skin tumor [78, 79].

Achillea species have been widely applied in folk medicine for the treatment of different cancers. The cytotoxic or cytostatic effects of *A. alexandri-regis* [80], *A. clavennae* [81], *A. ageratum* [82], and *A. millefolium* [83] extracts have been established against breast, lung, and colon cancer. The SLs, guaianolide, 1,10-seco-guaiane, seco-pseudoguaianolides (paulitin and isopaulitin) responsible for the antitumor activity [84].

The acetone extract of *Ambrosia* species *A. artemisiifolia*, *A. psilostachya*, *A. trifida*, and *A. tenuifolia* contains cytotoxic sesquiterpene lactone, ambrosin, isabelin, psilostachyn [85, 86], cumanin, and peruvin [87]. The steroidal lactone blocks cells in mitosis and acts as a novel checkpoint inhibitor of the G_2/DNA damage [88], suggesting that these compounds can easily bind covalently to the target proteins [89]. The Compositae family is known to possess antitumor, cytotoxic, antimicrobial, and phytotoxic activities due to the presence of α, β-unsaturated-γ-sesquiterpene lactones (ridentin and santonin). These compounds may explain many of the observed pharmacologic activities of *Artemisia tridentata* (sagewood). The antitumor and cytotoxic activities may be due to the alkylation of enzymes that regulate cell division [90]. Many sesquiterpene lactones bearing methylene-7-lactone group include germacranolides, elephantin, elephantopin, costunolide, tulipinolide, guaianolides, gaillardin, euparotin acetate, and its companions, the pseudoguaianolide, damsin, elemanolide, and vernolepin show significant antitumor or cytotoxic activity [91]. *Artemisia vulgaris*, commonly known as mugwort, is a perennial weed native to Asia, Europe, and North America [92]. It shows anticancer effect against sarcoma cell lines. The extract of *Artemisia* species shows antimutagenic and antitumor effect [93].

Artemisia annua (annual wormwood) is the source of 20 known sesquiterpenes including artemisinin (arteannuin A), arteannuin B, artemisitene, and artemisinin acid. Artemisinin (qinghaosu) is an important natural sesquiterpene lactone with antimalarial effect against susceptible and multidrug resistant *Plasmodium* spp. Current research also shows that artemisinin drugs are effective against cancer [94, 95]. It inhibits cancer proliferation, metastasis, and angiogenesis, also reduces tumor volume and progression. Interestingly, the potent anticancer action of artemisinin can also be ascribed to the endoperoxide bond [96]. Generally, iron and heme or heme-bound proteins activate artemisinin [97]. Preloading of cancer cells with iron activates artemisinin cytotoxicity [98]. Moreover, artemisinins tagged to iron-carrying compounds exhibit greater activity compared to artemisinin alone [99]. Induction of heme oxidase and downregulation of the heme synthesis genes may also inhibit cytotoxicity of artemisinin. Continued proliferation and growth of malignant cells require higher iron metabolism which can be fulfilled by increase in transferring receptors (TfR). Blocking the TfR increases artemisinin activity [100]. It is reported that the cytotoxicity of iron-activated artemisinin due to the release of highly alkylating carbon-centered radicals and radical oxygen species (ROS). In artemisinin-treated cancer cells, radicals cause apoptosis, arrest growth, inhibit angiogenesis, and cause DNA damage. Artemisinin cytotoxicity associated with impaired cytokinesis enhanced levels of oxidative stress, inhibition of tumor invasion, migration, and metastasis [101]. Hence, increasing oxidative stress is a common anticancer mechanism of antitumor agents [102].

The sesquiterpene lactone, helenalin, is a component found in the aerial part of *Arnica montana* L (sneezeweed). Helenalin induces apoptosis in leukemia cells by the cleavage of caspase-3-like substrate as well as proteolysis of procaspase-3 and procaspase-8. It also induces the release of cytochrome c from mitochondria which leads to caspase activation. Overexpression of Bcl-xL or Bcl-2 proteins failed to give resistance to helenalin-induced apoptosis. It is reported that helenalin induces a mitochondria-dependent pathway. Thus, helenalin is a promising cytotoxic agent that overcomes apoptosis resistance attributable to overexpression of anti-apoptotic Bcl-2 proteins [103]. Furthermore, helenalin dramatically inhibits periodic Skp2 protein accumulation, p27 degradation, and S phase progression resulting in cell cycle arrest at G1 phase [104]. Helenalin inhibits nuclear factor kappa B (NF-kB) DNA-binding activity. Protein kinase C (PKC) and extracellular signal-regulated kinase (ERK) inhibitors significantly inhibited HL-60 cell differentiation induced by helenalin. Moreover, helenalin enhanced PKC activity and also increased the level of ERK. The enhanced levels of cell differentiation closely correlated with the decreased levels of NF-kB binding activity by helenalin. These results indicate that PKC, ERK, and NF-kB may be involved in HL-60 cell differentiation induced by helenalin [105].

Ixeris sonchifolia (Asteraceae) contains 20 sesquiterpene lactones and shows potential chemopreventive and chemotherapeutic application of sesquiterpene lactones [106]. Methanolic extract inhibits the proliferation of Ehrlich carcinoma cells [107].

Centaurea deflexa is a perennial plant belonging to the Asteraceae family. In vitro cytotoxic activity against different pancreatic and colon cancer cell lines has been also reported for several *Centaurea* species [108]. The major constituents identified in *Centaurea* L. species, responsible for most of their pharmacological properties, are sesquiterpene lactones which induce apoptosis in cancer cells [109].

Ginger, the rhizome of *Zingiber officinalis*, one of the most widely used species of the Zingiberaceae family, is a common condiment for various foods and beverages [110]. The volatile oil components in ginger consist mainly of sesquiterpene hydrocarbons, predominantly zingeberene (35%), curcumene (18%), and farnesene (10%), with lesser amounts of bisabolene and β-sesquiphellandrene [111]. Zerumbone exhibits antiproliferative and anti-inflammatory activities [112]. It inhibits the activation of NF-kB and NF-kB-regulated gene expression, which may provide a molecular basis for cancer treatment by zerumbone. The ethanol extracts of ginger have antitumor-promoting effects in mouse skin tumorigenesis model [113]. The prevention of tumor initiation and promotion process occurs through the induction of antioxidant, metabolizing enzymes and suppression of proinflammatory signaling pathways. Antitumor promoter activity of gingerol and paradol was established by inhibition of cell transformation and protein-1 activation [114, 115].

6.1 Sesquiterpene Coumarins

Sesquiterpene coumarins constitute an interesting family of natural products. They are a group of molecules whose structures are based on a C_{15} terpene moiety linked through either an ether linkage with the 7-hydroxy group of umbelliferone, scopoletin, or isofraxidin or through a C–C bond with carbon 3 of 4-hydroxycoumarin. These are found in some plants of the families Umbelliferae, Asteraceae, and Rutaceae [116].

6.2 Sesquiterpene Umbelliprenin

Umbelliprenin is found in the plants of Apiaceae and Rutaceae family. It includes genera Angelica, Ferula, Heptaptera, Heracleum, Peucedanum, and Haplophyllum [117]. Umbelliprenin shows cytotoxicity against fibrosarcoma cell line [118], and its effect can be increased in combination with Fe_3O_4 nanoparticles [119]. The extract of the aerial parts of *Ferula vesceritensis* contains two sesquiterpene coumarins: farnesiferol and feselol having potential role in multidrug resistance cancer. Umbelliprenin isolated from the flowers of *Magydaris tomentosa* was reported to inhibit growth of pathogenic bacterial strains [120].

6.3 Sesquiterpene Ethers

Sesquiterpene ethers (scopoletin) scopofarnol and scopodrimol were also isolated from *Achillea* and *Artemisia* species and are potential modulators of MDR in tumor cells [121].

6.4 Prenylated 4-Hydroxycoumarins

Ferulenol was isolated from the extract of *F. communis*. Ferulenol displays microtubule interacting properties as indicated by its cytotoxic effects toward breast, colon, and ovarian cancers and leukemia. The cytotoxic effect of ferulenol may be related to the impairment of microtubule dynamic and mitochondrial function [122] (Fig. 116.4).

7 Allelopathic Potential of Sesquiterpenes

Allelopathy is a biological phenomenon by which an organism produces one or more biochemicals that influence the growth, survival, and reproduction of other organisms. These biochemicals are known as allelochemicals and can have beneficial (positive allelopathy) or detrimental (negative allelopathy) effects on the target organisms. Allelochemicals are a subset of secondary metabolites, which are not required for metabolism of the allelopathic organism. Allelochemicals with negative allelopathic effects are an important part of plant defense against herbivory [123, 124].

Allelopathy is characteristic of certain plants, algae, bacteria, coral, and fungi. Allelopathic interactions are an important factor in determining species distribution

and abundance within plant communities and are also thought to be important in the success of many invasive plants. Allelopathic potential was found in the members of Asteraceae family [125]. The sesquiterpene lactones and a flavonoid compound isolated from this plant inhibit seedling growth in *Brassica parachinensis*. The isolated lactones deoxymikanolide, dihydromikanolide, mikamicranolide, and tetrahdroxyflavone derivatives show a great phytotoxicity on *B. parachinensis* seedlings. These compounds reduce the root and shoot growth in seedlings. The invasive effect of lactones is more than that of flavonoids.

8 Specificity of Sesquiterpenes

A particular sesquiterpene exhibits a particular biological activity, that is, cytotoxicity, genotoxicity, mutagenicity, stimulation, and suppression of genes. They are also specific in their mode of action relating to production of free radicals. This change in biological activity depends on the composition of sesquiterpenes, which are affected by endogenous and exogenous factors. The endogenous factors are related to anatomical and physiological properties of the plant material as well as their biosynthetic pathways, which might change in either the different tissues of the plants or in different seasons but also could be influenced by DNA adaptation. The exogenous factors might affect genes responsible for the formation of essential oil. Moreover, methods of drying, size reduction, and extraction methods affect the yield of volatile components. The concept of chemotypes in the same plant species is also gaining popularity. Chemotaxonomy classifies essential oils containing plant material characterized by species-specific chemical polymorphism. With reference to antigenotoxic and mutagenic effects, the sesquiterpenes and their oxygenated derivatives show similar type of protection, while the mechanism of protection does not depend on the composition of oil, but it depends on the type and nature of mutagens, type of enzymatic reactions, and programmed cell death or necrosis [126–128].

9 Synergism and Antagonism Among Sesquiterpenes

Chemically essential oil is terpenoids and their oxygenated derivatives. It contains a large number of molecules in their composition. We know that the presence or absence of other molecules in combination with the main molecules affects the biological and therapeutic property of essential oil. So it is very mandatory to study the effect of all constituents of essential oil. Sometimes, the other less available or less important constituents improve the biological properties of main molecule (synergism) so that the net effect will be more than the individual effect or vice versa (antagonism). On the basis of literature survey in most cases, generally, the main constituents of essential oil bisabolol, carvacrol, carvone, cinnamaldehyde, citronellol, eucalyptol, eugenol, farnesol, farnesene, geraniol, limonene, linalool, nerol, safrole, santalol, terpineol, and thymol were analyzed. Usually, the main components reveal good enough biochemical, biophysical, and therapeutic potential of the essential oils from which they were isolated [129], but the therapeutic effectiveness depends on the concentration of main component alone and in combination with the essential oil [130–132]. Furthermore, it is likely that several components, the cell penetration, cell distribution, hydrophilic and lipophilic magnetism, fixation on cell walls and membranes, color, density, fragrance, texture, of the essential oils were also affected by other constituents [133]. The cell penetration and cell distribution is very important because the distribution of the oil in cell compartment determines the intensity of the therapeutic effects. So for biological and therapeutic purposes, it is more meaningful to study entire oil rather than some of its individual components because the concept of synergism and antagonism seems to be more significant.

10 Regulatory Issues

The essential oil industry adopted the latest legislation from Europe on the safety aspect of essential oils. Any industry which deals with the selling of essential oils must now match to the latest CHIP-2 regulations, and this is a significant change in essential oils sold. At the current time, few companies adhere to even putting the “best before” and “batch number,” the most notable being the band of aromatherapy companies. However, it is likely to be enforced as the time goes. Most “trading standards officers” are overworked with other things to worry too much about the new legislation. However, once something hits the press or media, then they tend to swing into action. It also affects anyone selling bottles of essential oils to “the public.” Estimating the “best before” date is far more complex than may be seen at first examination. Some years ago, the “NORA program” researchers spent a lot of time for testing the oxidization of essential oils and gave the concept of decay time. It is not feasible to give a standard time to oils because of production date, oil composition, and storage condition. Some oils such as the citrus have a short shelf life especially in hot weather.

The most important part of the new CHIP regulations concerns the labeling of essential oils, and this will affect the insight of oils. The new definition of R65 (Risk Phrase) affects some oils and is the latest piece of legislation to emerge from the European Union. Briefly, it means that oils have to be labeled as “harmful and may cause lung damage if swallowed” followed by the S62 (Safety Phrase) “If swallowed do not induce vomiting; seek medical advice immediately and show this container or label.” It would appear to end the “internal uses” school of thought once bottles have got the orange and black harmful logo. One important point from the legislation is the all pure essential oils sold to the public must be in child-resistant closures. The warning labels need to be rewritten to cover the “harmful” aspect. There are some moves afoot to try and challenge this new legislation, but it depends upon aromatherapy organizations. A lesson can be learned from the MCA’s attempt to dragoon the Health Food Industry recently where public reaction forced it to abandon and rethink its legislation. No opposition and it becomes law. The EPA (environmental protection agency) regulates the use of pesticides and insect repellents. Even if they approve an essential oil such as lemon eucalyptus or citronella for use as an insect repellent, products making such claims must be registered and approved by the EPA before they can be sold. Many cosmetic and aromatherapy companies have tried to adopt structure/function claims in their labeling. However, structure/function claims are only applicable to dietary supplements and do not apply to cosmetics. So claims such as “provides support during cold and flu season” are not allowed for aroma therapy or cosmetic products [134].

11 Therapeutic Potential and Future Prospects

The cytotoxicity property of terpenoids can make them exceptional antioxidant, antiseptic, and antimicrobial agents. This property can be used for aromatherapy, purification of air, food and crop preservation, antiaging, as well as for various ailments like cancers. The main advantages associated with the use of terpenoids are as follows: generally free from long-term genotoxic and mutagenic risks, environmentally friendly, target specificity, ability to overcome resistance, low cost, and easy accessibility. Additionally, some terpenoid shows a very clear antimutagenic effect may be one of the mechanisms of anticancer activity of the drug. The antioxidant activity of terpenes and their derivatives, as well as polyphenols, is very efficient in reducing tumor weight, tumor volume, or tumor cell proliferation by apoptotic and necrotic effects [135–142].

The cytotoxic activity of sesquiterpene lactones in species *Ajania przewalskii Poljakov* and *Ligularia platyglossa* was also reported [143, 144]. The volatile principles of *Citrus aurantifolia* inhibit proliferation inhibition of human colon cancer cells by apoptosis. The volatile sesquiterpenes showed DNA fragmentation and induction of caspase-3 [145]. The antiproliferative and anticancer activity of *Nigella sativa* was established [146]. Sesquiterpene lactone from *Schistochila glaucescens*, *Laurencia majuscula*, *Curcuma parviflora*, and Liverwort shows cytotoxicity [147–150]. The antiproliferative activity of Thai medicinal plants and eugenol against murine leukemia and skin carcinoma cell lines was established [141]. Geraniol inhibits DNA synthesis and reduces the tumor volume [151]. The in vitro and in vivo antiangiogenic potential of β-eudesmol from *Atractylodes lancea* was reported [152].

Essential oils act via apoptotic pathway, affecting mitochondrial functions. This may impart free radical scavenging potential which could be controlled and targeted. This property makes the terpenoids favorable anticancer agents. The controlled-release formulations like liposome, nanosome, neosome, and nanoparticle are becoming popular day by day. These formulations not only control the release rate of essential oil but also target drug to the specific body tissue or organs. These formulations enhance the duration of action and minimize the side effect of drug [153, 154]. Thus, terpenes and their oxygenated derivatives could build their approach from the traditional system of medicine to the modern system of medicine. The therapeutic use of essential oils in treating several diseases like cancers, inflammation, neurodegenerative disorders, cardiovascular diseases, and bacterial and fungal diseases seems to be ignored. Very less information regarding pharmacokinetics, pharmacodynamics, and nutritional properties of essential oil is known. Therefore, more studies should be performed in this area. The possible relationship between therapeutic effectiveness and most active constituent of essential oil should also be performed. The essential oils used for food preservation, nutritional and therapeutic purposes, and issues of safety and toxicity should also be considered.

Abstract

Tanshinones are a series of abietane-type norditerpenoid quinones isolated from the roots of *Salvia miltiorrhiza* ("*tanshen*"), a well-known traditional Chinese medicine (TCM) with varied pharmacological activities such as antibacterial, antioxidant, anti-inflammatory, and antineoplastic. This chapter summarized about the biosynthesis and structural properties of tanshinones and the bioactivities against a variety of tumors and cardiovascular diseases and also provides our views on future trends.

1 Introduction

Tanshinones are a series of abietane-type norditerpenoid quinones isolated from the roots of *Salvia miltiorrhiza* (“*tanshen*”), a well-known traditional Chinese medicine (TCM), by Nakano and Fukushima for the first time in 1930 [1, 2]. As its Chinese name implies, the *S. miltiorrhiza* root *tanshen* is characterized by the abundance of red pigments, which are largely ascribed to the tanshinones and related quinones. In other words, tanshinones are named after the source plant for “the quinone of *tanshen*.” *Tanshen* is an annual sage plant and has been used in TCM for the treatment of coronary heart diseases, particularly angina pectoris and myocardial infarction [3]. It has been used for hemorrhage, dysmenorrhea, miscarriage, swelling, insomnia, and inflammatory diseases such as edema, arthritis, and endangitis [4–6]. *Fu Fang Dan Shen* (a mixture of *S. miltiorrhiza*, *Panax notoginseng*, and *Cinnamomum camphora*) is registered as a drug in several countries outside China including Vietnam, Russia, Cuba, Korea, and Saudi Arabia. In 2010, *tanshen* was the first traditional Chinese medicine to pass US phase II clinical trials for cardiovascular indications.

Diterpenoid tanshinones were found exclusively in the genus *Salvia* and attracted particular attention from many researchers for their wide-ranging pharmacological activities such as antibacterial, antioxidant, anti-inflammatory, and antineoplastic [3]. Tanshinone I (Tan-I) (**1**), tanshinone IIA (Tan-IIA) (**11**), and cryptotanshinone (1**3**) are the major constituents of *S. miltiorrhiza*. A related plant *S. columbariae*, which has been used by California Indians in the treatment of strokes, also contains tanshinones, especially cryptotanshinone [7, 8]. This chapter will summarize about the structural properties, the activities against a variety of tumors and cardiovascular diseases, and biosynthesis of tanshinones.

2 Tanshinones Isolated from Natural Sources

Tanshinones are generally composed of four rings, including naphthalene or tetrahydronaphthalene rings A and B, an ortho- or para-quinone or lactone ring C, and a furan or dihydrofuran ring D. Based on their structural properties, tanshinones documented in this chapter were divided to five classes, types I–V.

Type I tanshinones (Fig. 117.1) contain four rings of naphthalene rings A and B, ortho-quinone ring C, and furan or dihydrofuran ring D. Tan-I (**1**) was isolated and identified by Nakano and Fukushima from *S. miltiorrhiza* Bunge [1, 2]. Przewaquinone B (**2**) [9], tanshinol I (**3**) [10], 3-hydroxymethylenetanshinone (**4**) [11], nortanshinone (**5**) [12], tanshinaldehyde I (**6**) [13], methylenedihydrotanshinone (**7**) [13], dihydronortanshinone (**8**), dihydrotanshinone I (**9**) [14], and 1,2,15,16-tetrahydrotanshinone I (**10**) [13, 15] are serial type I tanshinones isolated from *S. miltiorrhiza* in the last two decades.

Type II tanshinones (Fig. 117.2) are structurally similar to type I tanshinones, except that the naphthalene rings A and B in type I tanshinones were instead of

tetrahydronaphthalene in type II tanshinones. The representative compounds of type II tanshinone are Tan-IIA (**11**), tanshinone IIB (**12**), and cryptotanshinone (**13**), which are the major constituents of *S. miltiorrhiza*. The oxygenation of the ring A produces a series of analogs such as 1-hydroxytanshinone IIA (**14**) [16], 3-hydroxytanshinone IIA (**15**), tanshindiol A (**16**), tanshindiol B (**17**), tanshindiol C (**18**) [12], przewaquinone C (**19**), przewaquinone F (**20**), methyl tanshinate (**22**), and methyldihydrotanshinate (**23**) [17]. The oxygenation occurs in ring D of tanshinone IIA to afford przewaquinone A (**24**), which was found in TCM *S. przewalskii* Maxim only [9]. Dehydrogenation of tanshinone IIA results in two other analogs: dehydrotanshinone IIA (**25**) and dimethoxyltanshinone IIA (**21**) [18].

The significant property of type III tanshinones (Fig. 117.3) is the 1,4-quinone moiety, which is different from the 1,2-quinone moiety in the structures of types I and II tanshinones. These serial tanshinones are named “isotanshinone” in general, including isotanshinone I (**26**), isodihydrotanshinone I (**27**), 2-hydroxy

isodihydrotanshinone I (**28**), isotanshinone IIA (**33**), isocryptotanshinone (**34**), and isotanshinone IIB (**35**) [19–21]. The concentration of most of these analogs is low in plants, and few studies have been done on them.

Type IV tanshinones (Fig. 117.4) are a type of tricyclic diterpenoid quinones, and they share the isopropyl substitution C-13 of the structure in common. Among these compounds, miltirone I (**33**, Ro-09-0680) and miltirone (**38**) showed significant antiplatelet and antioxidant activity [22–25].

The other tanshinone-like compounds were classified as type V tanshinones (Fig. 117.5) which are the intermediates or postmodified products in the biosynthetic pathway [26–37]. Among these compounds, neo-tanshinlactone (**65**) and its analogs show the most promising potentials for antitumor drug discovery and will be discussed later in this chapter.

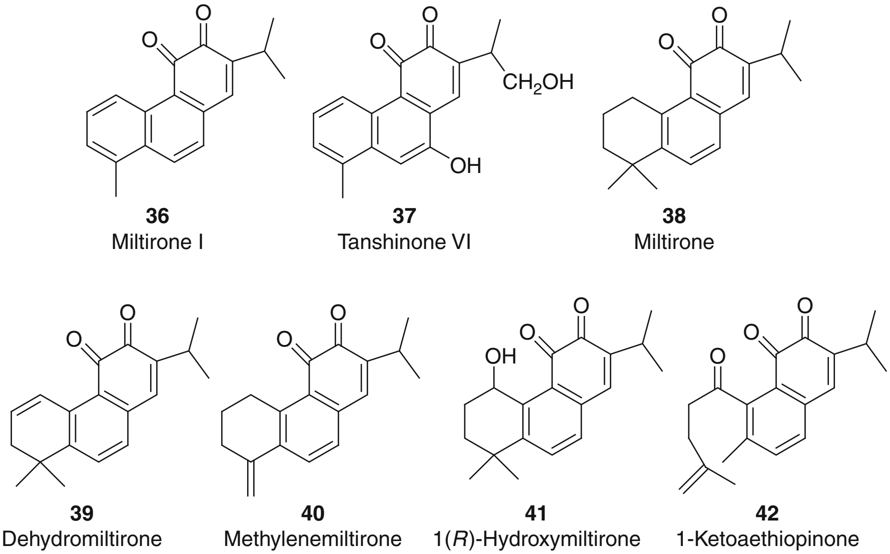

Fig. 117.4 Type IV tanshinones (tricyclic diterpenoid quinones)

3 Biological Activity of Tanshinones and their Mode of Action

3.1 Antitumor Activity and their Mode of Action

Tanshinones showed a broad spectrum of cytotoxic effects on cell lines derived from human carcinomas of the colon, ovary, lung, mouth, and breast [3, 38, 39] (Table 117.1). The mode of action (MoA) for antitumor activity has been studied for different tanshinones. Tan-I (**1**) and IIA (**11**) have been studied efficiently for their cytotoxic activity and induced differentiation and apoptosis [45, 46]. Przewaquinones A (**24**) and B (**2**) showed promising antitumor activity in mice [47]. This section will outline antitumor activity of tanshinones, especially Tan-I, Tan-IIA, and neo-tanshinlactones in vitro and in vivo, and their MoA.

Tan-I (**1**) was discovered; the activities on several cancer cell lines and their MoA were listed in Table 117.2.

Tan-I inhibited cell growth dose dependently at concentrations ranging from 0.5 to 25 μM and induced apoptosis in activated T-HSC/C-6 hepatic stellate cells. Tan-I increased caspase-3 activation via cytochrome c release and loss of mitochondrial membrane potential [48]. Nizamutdinova and coworkers investigated the effect of Tan-I on the induction of apoptosis in human breast cancer cells (MCF-7 and MDA-MB-231) in vitro. Tan-I inhibited cell proliferation of MCF-7 and MDA-MB-231 cells in a dose- and time-dependent manner and significantly induced apoptosis in MCF-7 and MDA-MB-231 cells. The induction of apoptotic cell death was mediated by the activation of caspase-3; the downregulation in the level of the

antiapoptotic protein, Bcl-2; and the upregulation of the level of the proapoptotic protein, Bax [39]. Further investigation by Nizamutdinova et al. showed the effect of Tan-I on cancer growth, invasion, and angiogenesis on human breast cancer cells MDA-MB-231, both in vitro and in vivo. Tan-I exhibited the strongest inhibitory effect on TNF-α-induced adhesion molecules in endothelial cells. The role of cell adhesion molecules has been studied extensively in the process of inflammation, and these molecules are critical components of carcinogenesis and cancer metastasis. Tan-I regulated adhesion molecules in human MDA-MB-231 breast cancer cells, with a concentration ranging from 1 to 50 μM, on the expression of intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) in tumor necrosis factor-alpha (TNF-alpha)-stimulated endothelial cells. Tan-I can significantly reduce adhesion of either monocyte

Table 117.2 Antitumor activities of tanshinone I and their MoA

Cell lines	IC_{50}	MoA	Reference
T-HSC/C-6 hepatic stellate cells	0.5–25 μM	Increased caspase-3 activation	[48]
Human breast cancer MCF-7 and MDA-MB-231	1–50 μM	Increased caspase-3 activation, downregulation of Bcl-2, and upregulation of Bax	[39]
Human breast cancer MDA-MB-231	5–50 μM	Regulated adhesion molecules	[49]
Human colon cancer Colo 205 cells	1–10 μg/mL	Increased activation of caspase-3, bax, p53, and p21	[50]
Human nonsmall-cell lung cancer CL1-5 cells	10 μg/mL	Reduced metastasis and tumorigenesis by inhibiting NF-κB and AP-1, suppressing the expression of the angiogenic factor IL-8	[51]
Monocytic leukemia cells (U937, THP-1, and SHI 1)	10–50 μg/mL	Activation of caspase-3, reduction of hTERT mRNA expression and telomerase activity, and downregulation of survivin expression	[52]

U937 or MDA-MB-231 cells to HUVECs. Furthermore, Tan-I effectively inhibited TNF-alpha-induced production of vascular endothelial growth factor (VEGF) and VEGF-mediated tube formation in HUVECs. At 10 and 50 μM, Tan-I inhibited more than 80% invasion of cancer cells. Additionally, reduction of tumor mass volume and decrease of metastasis incidents of MDA-MB-231 breast cancer cells to lung tissue by Tan-I were observed in vivo [49].

Su and coworkers investigated the induction of apoptosis by Tan-I at 1–10 μg/mL in human colon cancer Colo 205 cells. Tan-I reduced cell growth in a concentration-dependent manner, inducing apoptosis accompanied by an increase in TUNEL-stained cells in the sub-G1 fraction. The treatment with Tan-I at 0, 1, 2.5, 5, and 10 μg/mL for 72 h increased the percentage of cells in sub-G1 phase from 3.83% to 7.22%, 8.68%, 14.4%, and 32.98%, respectively. The expression of p53, p21, bax, and caspase-3 increased in Tan-I-treated cells. The authors suggested that Tan-I induces apoptosis in Colo 205 cells through both mitochondrial-mediated intrinsic cell-death pathways and p21-mediated G0/G1 cell cycle arrest [50].

Lee and coworkers investigated the anticancer effects of tanshinones on highly invasive human lung adenocarcinoma cell line, CL1-5. The results revealed that Tan-I significantly inhibited migration, invasion, and gelatinase activity in macrophage-conditioned medium-stimulated CL1-5 cells in vitro and also reduced the tumorigenesis and metastasis in CL1-5-bearing severe combined immunodeficient mice. They indicated that Tan-I did not have direct cytotoxicity, which is unlike Tan-IIA that induces cell apoptosis. Further investigation suggested that the anticancer effects of Tan-I might be mediated through the interleukin-8, Ras-mitogen-activated protein kinase, and Rac1 signaling pathways [51].

However, Liu et al. discovered the growth inhibition and apoptosis-inducing effects of Tan-I on three kinds of monocytic leukemia cells (U937, THP-1, and SHI 1) and found that Tan-I could inhibit the growth of these three kinds of leukemia cells and cause apoptosis in a time- and dose-dependent manner. They concluded that the induction of apoptosis by Tan-I in monocytic leukemia U937 THP-1 and SHI 1 cells was highly correlated with activation of caspase-3 and decreasing of hTERT mRNA expression and telomerase activity as well as downregulation of survivin expression [52].

The antitumor activity of Tan-IIA (**11**) has been studied a lot on many cells, tissues, and animal models. These studies revealed that Tan-IIA showed antitumor activity on inducing apoptosis, inhibiting invasion and metastasis, inhibiting angiogenesis, and downregulating epidermal growth factor receptors both in vitro and in vivo [53]. Different human cancer cell lines, glioma cells, THP-1 leukemia cell lines, MDA-MB-231 breast cancer cell lines, HL60 promyelocytic cell lines, K562 erythroleukemia cell lines, MKN-45 gastric carcinoma cell lines, human colon carcinoma (CRC) cell lines HT29 and SW480, and hepatocellular cancer (HCC) cell lines, were used [54–59].

Apoptosis is a new therapeutic target of cancer research, and recently, Tan-IIA has been reported to have apoptosis-inducing effects on a large variety of cancer cells. There are various MoA reported and revealed that Tan-IIA could induce apoptosis through activation of caspase-3, downregulation of the antiapoptotic protein bcl-2, and upregulation of the proapoptotic protein bax.

Wang and coworkers evaluated the inhibitory effect of Tan-IIA on cell growth of human glioma cells, and it showed an IC_{50} value of 100 ng/mL. After the treatment with 25–100 ng/mL of Tan-IIA, the apoptotic cells increased significantly ($P < 0.01$), the cells in G(0)/G(1) phase increased ($P < 0.01$) and decreased in S phase, and ADP-ribosyltransferase (ADPRTL1) and CYP1A1 mRNA expression increased one- to twofold. Their findings suggested that Tan-IIA exhibited strong effects on growth inhibition and induction of apoptosis and differentiation in human glioma cells [56]. Further study on Tan-IIA demonstrated a dose- and time-dependent inhibitory effect on human breast cancer cell growth ($IC_{50} = 0.25$ μg/mL) and suggested that ADPRTL1 might be the main target at which Tan-IIA acted [60]. Tan-IIA was observed to induce apoptosis in HL60 human premyelocytic leukemia cell line and human breast cancer. Tan-IIA-induced apoptosis in HL60 human premyelocytic leukemia cell line was accompanied by the specific proteolytic cleavage of poly(ADP-ribose) polymerase (PARP) and the activation of caspase-3, a major component in apoptotic cell-death mechanism [55]. Zhou et al. revealed that Tan-IIA could arrest HeLa cells in mitosis by disrupting the mitotic spindle and subsequently triggered cells to enter apoptosis through the mitochondria-dependent apoptotic pathway. Tan-IIA destroyed only the mitotic spindle during the M phase but not the microtubule structure in interphase cells. Tan-IIA could trigger the mitotic-arrested cells to enter apoptosis faster than vincristine or Taxol [61].

Pan et al. reported Tan-IIA exhibited strong growth inhibition against human cervical cancer cells (HeLa cells) in dose- and time-dependent manners with a 50% cell growth inhibition with 2.5 μg/mL (8.49 μM). The authors executed a bioinformatics analysis of proteins to survey global protein changes induced by Tan-IIA treatment on HeLa cells. Significant changes in the levels of cytoskeleton proteins as well as stress-associated proteins were observed. Their further analysis suggested that Tan-IIA treatment regulated the expressions of proteins involved in apoptotic processes, spindle assembly, and p53 activation including vimentin, maspin, alpha- and beta-tubulins, and GRP75. The authors concluded that Tan-IIA might strongly inhibit the growth of cervical cancer cells through interfering in the process of microtubule assembly, leading to G(2)/M phase arrest and sequent apoptosis [62].

Dong and coauthors revealed that Tan-IIA upregulated expression of p53 gene and downregulated expression of bcl-2 gene in human gastric carcinoma MKN-45 cells. A significant inhibition of Tan-IIA on the growth and proliferation of MKN-45 cells was observed in a dose- and time-dependent manner ($P < 0.05$). Tanshinone A arrested MKN-45 cells in G(2)/M phase which resulted in apoptosis of MKN-45 cells, and the apoptosis rate was as high as 43.91% after treatment with 2.0 μg/mL Tan-II A for 96 h [63].

Liu and coworkers studied the antiproliferation and apoptosis-inducing effect of Tan-IIA as well as its influence on cell adhesion to and invasion through the extracellular matrix (ECM) on acute promyelocytic leukemia (APL) NB4 cells in vitro. Their investigation showed that Tan-IIA exhibited induction of apoptosis by activation of caspase-3, downregulation of antiapoptotic proteins bcl-2 and bcl-xl, and upregulation of proapoptotic protein bax, as well as disruption of the mitochondrial membrane potential. They also revealed that Tan-IIA could reduce cell adhesion to and invasion through ECM in leukemia NB4 cells [57]. Shan et al. found that Tan-IIA significantly inhibited tumor invasion and metastasis in human colon carcinoma (CRC) cell lines HT29 and SW480121 in vitro (0.5–2.5 mg/mL) [64]. In addition, Xu and coworkers reported that Tan-IIA inhibited both the invasion and metastasis of HCC cells in vitro (0–2 mg/mL) [65].

Since antineovascularization has generally been regarded as an effective strategy for anticancer therapy, researchers showed great interests on investigation of the activity of Tan-IIA on human endothelial cells. Fu et al. studied the effects of Tan-IIA on apoptosis and the expression of VEGF in the SMMC-7721 HCC cell line and revealed that Tan-IIA not only induced apoptosis but also reduced the expression of VEGF [66]. Yang and coworkers demonstrated that Tan-IIA elicits human endothelial cell death independent of oxidative stress and suggested that Tan-IIA-mediated cytotoxicity might occur through activation of NAD(P)H: quinone oxidoreductase (NQO1), which induces a calcium imbalance and mitochondrial dysfunction, thus stimulating caspase activity [67] (Fig. 117.6).

Chiu et al. studied the effects of Tan-IIA on the cell cycle, mitochondrial membrane potential (MMP), and calcium and reactive oxygen species (ROS) released in human lung cancer; A549 cells were detected by flow cytometry. They revealed that Tan-IIA inhibited the proliferation of nonsmall-cell lung cancer A549 cells, possibly by decreasing the MMP and inducing apoptosis due to the induction of a higher ratio of Bax/Bcl-2 [68].

Many Chinese researchers have studied the antiangiogenic, antiproliferation, and antimigration effects of Tan-IIA and resulted in the conclusion of multitarget interactions of mechanism. Xu et al. reported that Tan-IIA inhibited the

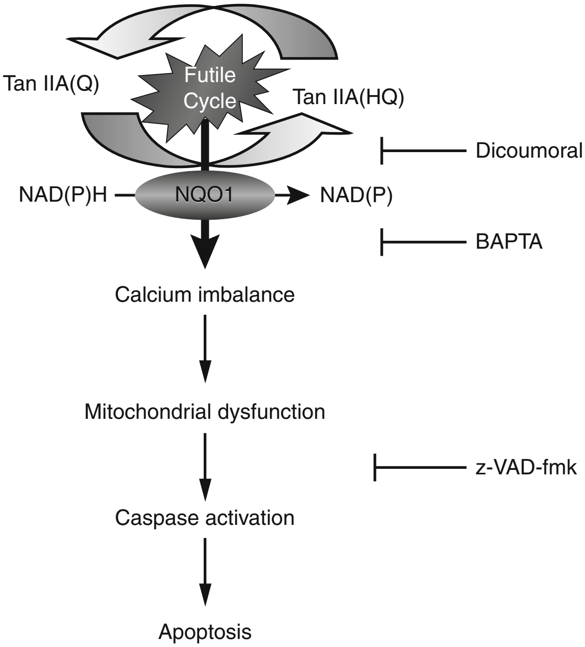

Fig. 117.6 A proposed model for tanshinone IIA-induced human endothelial EAhy926 cell apoptosis. Tanshinone IIA is reduced from quinone to hydroquinone in the presence of NQO1. The hydroquinone form of tanshinone IIA is quite unstable and autooxidizes to its original parent form. This futile cycle causes the rapid and severe loss of cellular NADP (H) and induces the sequestration of Ca^{2+} from ER causing a rise in cytosolic Ca^{2+} levels. The perturbation of the Ca^{2+} pools leads to cytochrome c release and mitochondrial membrane depolarization, which then stimulates the activation of caspases, ultimately resulting in apoptosis [67]

proliferation of the human MDA-MB-435 breast cancer cell line with an IC_{50} value of 21 nM and prevented breast cancer cell migration at 5 and 6 nM in a wound-healing assay and a Transwell migration assay, respectively. Further studies revealed that Tan-IIA inhibited the tube formation of newborn cattle aortic endothelial cells (NCAECs) after 2-h coincubation with MDA-MB-435 and mRNA expression of VEGF and two transcription factors (HIF-1a/c-Myc) in a dose-dependent manner [69]. More studies have been done and revealed that the downregulation of HIF-1a expression could be observed in SGC-7901 gastric cancer cells treated with Tan-IIA. In addition, the expression of c-Myc protein was inhibited by Tan-IIA in SGC-7901 gastric cancer and MDAMB-231 breast carcinoma cells [70–72].

Tan-IIA not only showed strong activity on different tumor cell lines in vitro but also showed promising activities in vivo. Seven nude mice bearing human breast infiltrating ductal carcinoma orthotopically were tested for anticancer activity and expression of caspase-3 in vivo by s.c. injection of Tan-IIA at a dose of 30 mg/kg, 3 times/week for 10 weeks. A 44.91% tumor mass volume reduction and significant increase of casepase-3 protein expression were observed in vivo [60].

Shan et al. found two significantly inhibited tumor invasions and metastasis in CRC cell lines HT29 and SW480 in vivo (0–80 mg/kg/day for 4 weeks). The results revealed that Tan-IIA showed the activity by reducing levels of urokinase plasminogen activator (uPA) and matrix metalloproteinases (MMP)-2 and MMP-9 and by increasing levels of tissue inhibitor of matrix metalloproteinase protein (TIMP)-1 and TIMP-2 [64]. Xu and coworkers also reported that Tan-IIA inhibited the invasion and metastasis of HCC in vivo (0–13.5 g/kg/day for 5 consecutive weeks in male athymic BALB/c nu/nu mice) [65]. Su et al. found that Tan-IIA caused upregulation of TNF-α and caspase-3 and downregulation of ErbB-2 protein expression as compared to the controls in male SCID mice xenografted with Colo 205 cells [73].

Lee research group identified a new compound, neo-tanshinlactone (**65**), from the root of *S. miltiorrhiza* [74]. Serial neo-tanshinlactone analogs have been synthesized, and their antibreast cancer activities have been fully evaluated [75–81].

Neo-tanshinlactone (**65**), with strong and selective antibreast cancer activity, was identified and synthesized by Lee et al. [74]. Structure **65** showed strong activity against estrogen receptor positive (ER+) human breast cancer cell lines (MCF-7 and ZR-75-1) with ED50 values of 0.6 and 0.3 μg/mL, respectively. Otherwise, **65** was inactive against two ER− cell lines (MDA MB-231 and HS587-1) with ED_{50} values beyond 10 μg/mL (Table 117.3). Structure **65** also showed good activity against an HER-2-overexpressing breast cancer cell line (SK-BR-3 HER++) [74]. Since **65** showed significant inhibition against the two ER+ human breast cancer cell lines and was tenfold more potent and 20-fold more selective as compared to tamoxifen citrate, serial analogs have been studied in Lee's lab aimed at developing novel and promising antibreast cancer drug candidates from neo-tanshinlactone. Wang et al. developed serial strategies to provide different types of neo-tanshinlactone analogs with potent activity against different breast tumor cell lines. These strategies included the following modification of the structure **65**: (1) substitution of rings A and B and/or ring D, (2) modification of ring D, (3) cleavage of each ring [75, 80], (4) preparation of nonaromatic ring A [76], (5) structural simplification like getting rid of rings B or D [77, 78], and (6) bioisosteric replacement of the oxygens [78].

Synthesis of different compounds with variously substituted rings A and B or a modified ring D of the structure **65** was done, and **66** with an ethyl group at position-4 showed the most potent activity and selectivity with ED50 values of 0.45 and 0.18 μg/mL against MCF-7 and ZR-75-1 (ER+) and 13.5 and 10.0 μg/mL against MDA MB-231 and HS 587-1 (ER−), respectively. In addition, **66** showed potent activity against SK-BR-3 (ER−, HER2++) with an ED50 value of 0.10 μg/mL.

In general, a complex lead compound may have a simpler pharmacophoric moiety buried within its structure. If this pharmacophore can be clearly defined, the resulting biologically active, simpler molecules may improve synthetic tractability and be more useful as a scaffold for further drug development. In the other hand, the structural complexity of natural products, such as intricate ring systems and numerous chiral centers, may lead to limited supplies and hamper mechanism of action studies and clinical applications [82]. For this reason, structural simplification of natural products is a powerful and highly productive tool for lead development and analog design [83]. Dong et al. studied the individual contribution of the rings A, B, C, and D of **65** to the selective activity against breast cancer cells. Only compound **67**, with an opened ring C, showed primary antibreast cancer

TAM tamoxifen citrate, *NA* not tested or not available activity in vitro. Further optimization led to a novel class of antibreast cancer agents, 2-(fura-2-yl) naphthalen-1-ol (**FNO**) derivatives. Interestingly, compounds **68** and **70** showed decreased cytotoxic potency but better selectivity than neo-tanshinlactone analog **66**. Compound **69** showed broad cytotoxicity against human cancer cell lines, which suggested a different MoA from its structural derivatives. The authors suggested that intramolecular hydrogen bonding was important to form a rigid conformation and improved the in vitro anticancer selectivity of **68** [75]. The C11-esters **71** and **72** showed broad antitumor activity (ED50 1.1–4.3 μg/mL against several cancer cell lines), and C11-hydroxymethyl **73** showed unique selectivity against the SK-BR-3 breast cancer cell line (ED50 0.73 μg/mL). **74** and **75** displayed potent and selective antibreast cancer cell line with ED50 values of 1.7 and 0.85 μg/mL, respectively. In in vivo experiments, **68** significantly inhibited the proliferation of mammary epithelial cells and branching of mammary glands in both wild-type and *Brca1*/p53-deficient mice [80].

Neo-tanshinlactone analogs with nonaromatic ring A, tetrahydroneotanshinlactone (**TNT**) and tetrahydronaphthalene-1-ol (**TNO**), have been designed, and their antibreast cancer activity has been evaluated as well. Cyclohexene ring A could dramatically affect the antitumor activity and selectivity. Among the obtained analogs, compound **76** showed the highest potency with ED50 values of 0.7 and 1.7 μM against SK-BR-3 and ZR-75-1 breast cancer cell lines, respectively. Neo-tanshinlactone analogs with nonaromatic ring A provided the promising new lead compounds with a novel skeleton for further development toward a new potential clinical trial candidate [76]. A serial simplified neo-tanshinlactone analog has been discovered by Dong et al.; **77** and **78** showed the highest cancer cell line selectivity, being approximately 100–250-fold more potent against SK-BR-3 (ED50 0.28 and 0.44 μM, respectively) compared with other cancer cell lines tested. In addition, **77** displayed low cytotoxicity against normal breast cell lines 184A1 and MCF10A. The results indicated that the nonaromatic ring A of these structures is critical to both potency and cancer cell line selectivity. This case revealed two promising compounds (**77** and **78**) for further development as clinical trial candidates for antibreast cancer treatment, and the skeletal planarity is not indispensable for the entire molecule [77].

Further discovery revealed a new class of neo-tanshinlactone analogs, 4-amino-2*H*-benzo[h]chromen-2-one (**ABO**) and 4-amino-7,8,9,10-tetrahydro-2*H*-benzo[h] chromen-2-one analogs (**ATBO**), which were designed by combined structural simplification and bioisosteric replacement strategies [78, 79, 81]. Among all 4-substituted **ABO** analogs, the 4′-methoxyphenyl derivative (**79**) and 3′-methylphenyl derivative (**80**) showed the most potent antitumor activity against a broad range of cancer cell lines with ED50 values of 0.01–76 μM [79]. Among those **ATBO** analogs, compounds **81** and **82** with a 4-methoxyphenyl group at position C-4 were extremely potent with ED50 values of 0.008–0.064 and 0.035–0.32 μM, respectively [81]. Based on SAR study results on **ABO** and **ATBO** analogs, which displayed much higher potency than **65** analogs, Dong et al. designed a new class of **APO** analogs. Among these analogs, **83** and **84** were the most potent compounds with an ED50 range between 0.059 and 0.163 μM [84].

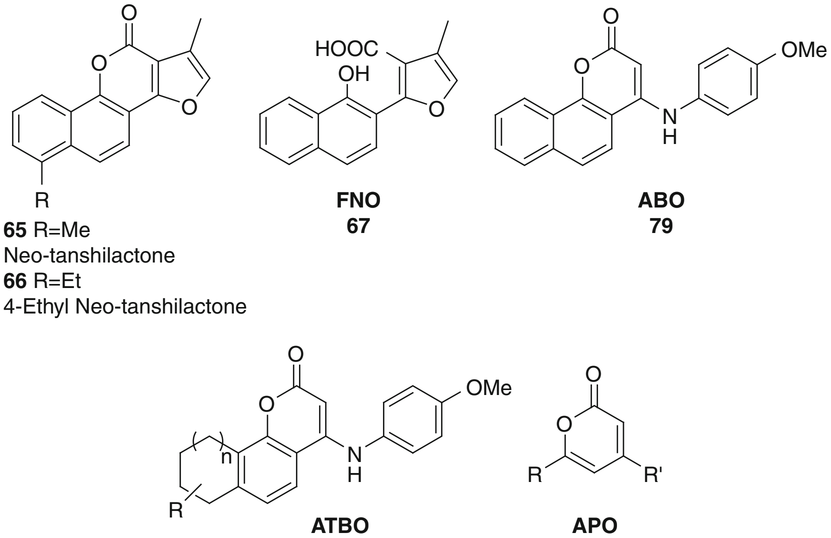

Fig. 117.7 Structure of different scaffolds of synthetic neo-tanshinlactone analogs

In conclusion, Lee research group discovered serial antibreast cancer neo-tanshinlactone analogs, and SAR studies have been fully addressed. The aromatic rings A and D were found to be important for antibreast cancer activity, and certain ring C-opened analogs retained activity and had increased selectivity toward specific breast cancer subtypes. The lead compound **66** was also tested in vivo against cancer cell xenografts in mice. At 10 mg/Kg, it remarkably delayed tumor growth compared to control against the human ZR-75-1 breast ductal carcinoma xenograft [38] (Figs. 117.7 and 117.8).

3.2 Anticardiovascular Activity of Tanshinones and their Mode of Action

The root of *Salvia miltiorrhiza* has been used as Chinese folk medicine for the treatment of cardiovascular diseases, such as ischemia, angina pectoris, coronary heart disease, myocardial infarction, and hypertension. Many studies on the secondary metabolites from *Salvia miltiorrhiza* revealed that tanshinones were a group of compounds responsible for these biological activities, especially for the treatment of coronary artery disease and hypertension.

Park et al. revealed that 15,16-dihydrotanshinone I inhibited collagen-induced aggregation of rabbit washed platelets with IC_{50} value of 8.7 ± 5.6 μM, which is sevenfold greater of potency than EGCG, an active green tea catechin component (IC_{50} 56.6 ± 48.7 μM). The authors revealed that 15,16-dihydrotanshinone I exerted potent antiplatelet activity via suppression of intracellular calcium mobilization and arachidonic acid liberation [85]. Tan-IIA was found to inhibit the

Fig. 117.8 Structure of neo-tanshinlactone analogs

migration of human aortic smooth muscle cells through an AKT and matrix metalloprotease-9 pathway [86].

The in vivo experiments have been studied on Tan-IIA as well. A similar rat coronary artery ligation experiment found that Tan-IIA reduced monocyte chemoattractant protein I expression, thereby blocking inflammation. Macrophage infiltration and transforming growth factor (TGF)-beta secretion were also blocked [87]. The previous study has demonstrated that p38 MAPK played an important role in ischemia-induced signaling in mammalian cells, and an increase in phosphorylation of p38 MAPK contributed to myocyte injury. Zhang and coworkers revealed that Tan-IIA decreased p38 MAPK activation in MI rats. Tan-IIA could reduce the transcription factor SRF and MEF2 levels which could promote the miR-1 expression. This explains the reasons why Tan-IIA protects cardiac myocytes from ischemic injury [88].

Clinical evidence has shown that Tan-IIA increases coronary blood flow and protects heart against ischemia/reperfusion (I/R) injury. In order to explore the mechanism of its therapeutic action, Zhang and coworkers investigated the protective effects of Tan-IIA on I/R injury in diabetic rats and the underlying mechanism. Their study indicated that Tan-IIA pretreatment reduces infarct size and improves cardiac dysfunction after I/R injury. This was accompanied with decreased cardiac apoptosis and inflammation. They also found that Tan-IIA could inhibit inflammatory responses by inhibiting inflammatory factors including TNF-α and IL-6 production. Moreover, the specific PI3K inhibitor wortmannin can abolish the cardiac protective effects of Tan-IIA. In summary, the mechanism responsible for the effects of Tan-IIA is mediated, at least in part, by the PI3K/Akt-dependent pathway [89].

Liu and coworkers explored the protective effects of Tan-IIA in the acute stage of ischemic stroke and revealed that TORC1 nuclear accumulation and BDNF transcription are implicated in the early stage of ischemia. They concluded that TORC1 signal pathway, which controls the dynamics of CRE-target gene transcription, might be one of the Tan-IIA's effective therapeutic targets for cerebral ischemia [90].

Inflammation has been confirmed to play an important role in the pathogenesis of brain injury secondary to ischemia. Wang's studies evaluated the Tan-IIA's protective role in cerebral ischemia and its potential mechanism. After systemic administration of Tan-IIA, the infarct volume, neurologic deficits, and brain water content could be diminished in a dose-dependent manner, and the upregulation of HMGB1, NF-κB, RAGE, and TLR4 was significantly suppressed. They concluded that HMGB1 associated with NF-κB activation pathway might be one of the Tan-IIA's effective therapeutic targets for cerebral ischemia [91].

Hei and coworkers found that Tan-IIA reduced the hypoxic ischemic brain damage (HIBD)-caused downregulation of phosphor-NR1 S879 and the HIBD-caused [Ca^{2+}]. The neuroprotective effect of Tan-IIA may be related to influencing NMDA receptor expression and decreasing intracellular free-calcium aggregation [92].

Tan and coworkers discovered that Tan-IIA could protect cardiac hypertrophy induced by ISO. It is well known that the Ca^{2+}-activated Ser/Thr protein phosphatase calcineurin and the downstream transcriptional effectors of calcineurin, NFATcs, have been implicated as a key-signaling pathway in the hypertrophic response of the myocardium. In their study, they demonstrated that Tan-IIA inhibited the increased expression of calcineurin and NFATc3 induced by ISO, which indicates that Tan-IIA protects against cardiac hypertrophy in a calcineurin/NFATc3-dependent pathway [93].

Intimal hyperplasia is a key event of atherosclerosis and restenosis after PCI; smooth muscle cell migration and proliferation are thought to be central to the development of intimal hyperplasia. Li and coworkers demonstrated that Tan-IIA could significantly decrease intimal thickening, suppress cell proliferation and BrdU incorporation into DNA, and block cell cycle in G0/G1 phase. Mitogen-activated protein kinases (MAPK) cascade is one of the well-known signal transduction pathways for vascular smooth muscle cell (VSMC) proliferation and migration. Tan-IIA-decreased ERK1/2 activity and downregulation of c-fos expression in a dose-dependent manner were found, suggesting that TA inhibits VSMC proliferation by decreasing MAPK signaling pathway and downregulation of c-fos expression [94].

Yagi and coworkers demonstrated that tanshinone VI has two effects on heart. The first is that tanshinone VI can protect the heart against hypoxia/reoxygenation injury and improve the posthypoxic cardiac function, and the second one is about the decrease in the fibrosis of cardiac fibroblasts [95].

Yang and coworkers found that sodium Tan-IIA sulfonate (STS) can inhibit cardiomyocyte hypertrophy induced by angiotensin II (Ang II). The results indicated STS inhibited Ang II-induced increases in myocyte diameter and decreased the LVW/BW (left ventricular weight/body weight) ratio independent of decreasing systolic blood pressure. Therefore, STS may have some pharmacological properties similar to angiotensin-converting enzyme inhibitors or Ang II receptor antagonists, which need further research. It is also found that MEK inhibitor U0126 (20 μM) markedly enhanced STS-induced effects on cardiomyocyte. So we can conclude that MEK/ERK pathway plays a significant role in the antihypertrophic activities of STS [96].

The pathogenesis of sepsis is mediated in part by bacterial endotoxin, which stimulates macrophages/monocytes to sequentially release early (e.g., TNF, IL-1, and IFN-γ) and late (e.g., high-mobility group box 1 (HMGB1) protein) proinflammatory cytokines. Li and coworkers demonstrated that STS could selectively abrogate endotoxin-induced HMGB1 cytoplasmic translocation and release in a glucocorticoid receptor-independent manner. Interestingly, STS does not affect the release of most other cytokines, distinguishing itself from all previously known HMGB1 inhibitors [97].

Dihydrotanshinone relaxed isolated rat coronary arteries stimulated with 5-hydroxytryptamine (5-HT). The effect was blocked by the guanylate cyclase inhibitor ODQ, indicating a mechanism involving inhibition of calcium influx in smooth muscle cells of the vasculature [59].

With intact spontaneously hypertensive rats, Tan-IIA lowered systolic blood pressure when given *i.p.* at 10 mg/kg. The same dose had no effect on blood pressure in normotensive rats. Oral administration had the same effects, and in vitro experiments with isolated arteries implicated ATP-sensitive calcium channels in the mechanism [98].

4 Biosynthesis of Tanshinones

The extraction of diterpenoids from plants has been tedious and inefficient and requires substantial sacrifice of natural resources. Tanshinones show a broad spectrum of activities; the studies on biosynthesis of tanshinones are helpful to understand the biosynthetic pathway and the relationship between the properties of their scaffold and activities and produce new active analogs via genetic engineering. The biosynthetic pathways of the tanshinones have been explored for more than two decades, and work is still ongoing to determine the exact transformations and related enzymes.

Terpenes or isoprenoids are synthesized via at least two different pathways in higher plants, the mevalonate (MVA) pathway occurring in the cytosol and the non-MVA, 2-*C*-methyl-D-erythritol 4-phosphate (MEP) pathway in the plastids of cell (Fig. 117.9) [99–101]. The MVA pathway is responsible for the synthesis of sesquiterpenes, triterpenes, sterol, and the side chain of ubiquinone. The MEP pathway takes part in the production of monoterpenes, diterpenes, carotenoids, and the side chains of chlorophylls and plastoquinone. These terpenoids are all derived from two common precursors, isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAP) [99]. In the MVA pathway, HMGR catalyzes the formation of MVA from 3-hydroxy-3-methylglutaryl-CoA, an initial and important step in the MVA pathway, followed by the formations of IPP and DMAP [102]. In the MEP pathway, DXP synthase (DXS) and DXP reductoisomerase (DXR) are the first two enzymes. Pyruvate and glyceraldehyde-3-phosphate (GA3P) initially form 1-deoxy-D-xylulose-5-phosphate (DXP) through the action of DXS. DXP is subsequently catalyzed by DXR to form 2-*C*-methyl-D-erythritol 4-phosphate (MEP). MEP then undergoes several steps catalyzed by a series of enzymes to afford IPP and DMAP [100, 103]. Chain elongation starts after the synthesis of IPP and DMAP via MVA or MEP pathway (Fig. 117.9). The carbonium ion is a potent alkylating agent that can react with IPP to produce GPP. GPP has the active allylic phosphate group to further react with IPP, giving FPP. GGPPS catalyzes the consecutive condensation of three IPP molecules with DMAPP to give C_{20} compound GGPP, a precursor of diterpenes [99, 104–108].

The biosynthesis and biotechnological production of tanshinones have been studied over two decades. Diterpenes in plants are presumably derived from the MEP pathway. In the MEP pathway, DXS plays an important role and is a rate-limiting enzyme for the synthesis of IPP and DMAP [109–111]. A full-length cDNA encoding DXR has been isolated from *S. miltiorrhiza* hairy roots [112]. Tissue expression pattern analysis revealed that the expression level of a cDNA encoding DXR (*Sm*DXR) was the highest in leaves, followed by roots and stems subsequently in *S. miltiorrhiza* plants [113]. The above studies provide the evidences for the biosynthesis of tanshinones via the MEP pathway.

Mevinolin and fosmidomycin are inhibitors of HMGR and DXR, respectively)

Although there are some evidences that supported the biosynthesis of tanshinone in *S. miltiorrhiza* mainly via MEP pathway, this process may also depend on cross talk between the MVA and MEP pathways, based on some key enzymes and genes detected in the early steps of these pathways. Ge et al. revealed that elicitor-induced tanshinone accumulation in *S. miltiorrhiza* hairy roots was mainly synthesized through the MEP pathway (involving DXS) but also depended on a cross talk with the MVA pathway involving HMGR [100]. Hao et al. also detected an EST fragment of HMGR from a full-length cDNA library constructed with *S. miltiorrhiza* roots [114].

Diterpene synthases or cyclases are responsible for the cyclization of GGPP. Tanshinones belong to the abietane-type diterpenoids, and a sequential pair of cyclization reactions uniquely initiates the biosynthesis. The characteristic fused bicyclic hydrocarbon structure is formed from the diterpenoid precursor (*E*,*E*,*E*)-geranylgeranyl diphosphate (GGPP) in an initial carbon-carbon double-bond protonation-initiated reaction catalyzed by class II diterpene cyclases such as *syn*- and *ent*-copalyl diphosphate synthases (CPS). At this step, the initial stereochemistry is established, which is designated by comparison to that of the analogs A/B ring substructure in sterol biosynthesis [115]. Additional stereocenters are generally formed in the subsequent cyclization and/or rearrangement reaction catalyzed by CPP-specific class I diterpene synthase, kaurene synthase like (KSL), which is

similar to the kaurene synthase found in all higher plants for the requisite biosynthesis of gibberellin phytohormones [116]. As a subsequent of this step, miltiradiene is formed. The structure of miltiradiene has been determined by means of different NMR experiments. Because the cyclohexan-1,4-diene in the structure of miltiradiene is relatively unstable, the authors proposed that miltiradiene may undergo aromatization to ferruginol, followed by further introduction of different groups to give miltirone and neocryptotanshinone. The authors revealed that miltiradiene existed only transiently and its content decreased in correlation to an increase of Tan-IIA, suggesting that miltiradiene is an intermediate in the biosynthetic route to tanshinones. Based on the above evidences, Gao et al. proposed a biosynthetic pathway for tanshinones (Fig. 117.10) [53, 104, 105, 117]. This research has provided various methods to increase the production of tanshinones in *S. miltiorrhiza*, such as by elicitation with a yeast elicitor and transformations of cells [118–120].

Although a number of microorganisms have been engineered to produce isoprenoids as well as their intermediates [121–123], the overall efficiency remains low. Previous strategies commonly focus on the mevalonic acid (MVA) or methyl-D-erythritol phosphate (MEP) pathways that are at the early stage of terpenoid biosynthesis [122–124]. The conservation and interactions of diterpenoids synthases attracted little attention. Recently, Zhou et al. described the modular pathway engineering (MOPE) strategy and its application for rapid assembling synthetic miltiradiene pathways in the yeast *Saccharomyces cerevisiae*. They analyzed the molecular interactions between SmCPS and SmKSL and engineered their active sites into close proximity for enhanced metabolic flux channeling to miltiradiene biosynthesis by constructing protein fusions. The results revealed that the fusion of SmCPS and SmKSL, as well as the fusion of BTS1 (GGPP synthase) and ERG20 (farnesyl diphosphate synthase), led to significantly improved miltiradiene production and reduced by-product accumulation. The MOPE strategy facilitated a comprehensive evaluation of pathway variants involving multiple genes, and the diploid strain YJ2X reached miltiradiene titer of 365 mg/L in a 15-L bioreactor culture. Zhou's findings provided that the strategies of pathway assembling could be applied to engineering microbial hosts for the production of other valuable metabolites [125].

5 Conclusion

Tanshinones are a series of abietane-type norditerpenoid quinones isolated from TCM *S. miltiorrhiza* with wide-ranging pharmacological activities such as antibacterial, antioxidant, anti-inflammatory, and antineoplastic. Antitumor activities of tanshinones, especially Tan-I, Tan-IIA, and neo-tanshinlactone, have been studied both in vitro and in vivo against a variety of different human cancer cells such as glioma cancer, leukemia tumor, breast cancer, promyelocytic cancer, erythroleukemia cancer, gastric carcinoma, human colon carcinoma, and hepatocellular cancer. Their molecular mechanisms have been investigated in inducing apoptosis, inhibiting invasion and metastasis, inhibiting angiogenesis, and downregulating epidermal growth factor receptors. Tanshinones were reported as a group of compounds isolated from *S. miltiorrhiza* responsible in the treatment of coronary artery disease and hypertension.

Several tanshinones, such as Tan-I, Tan-IIA, and neo-tanshinlactone, might serve as the leads for the development of promising anticancer and anticardiovascular diseases, and further research needs to be focused on the preclinical evaluations. In addition, recent studies revealed tanshinones as the promising leads for anti-TB pharmaceutics development (Data not published, Liu XT et al.). These findings will extend the clinical uses of tanshinones, and further MoA against TB is in progress.

Chemical modifications of tanshinone analogs will improve the pharmacological profiles for preclinical testing. And considerable research efforts have been made in the last two decades to understand the tanshinone biosynthesis in *S. miltiorrhiza* at the protein and molecular levels which will help to develop biotechnological processes for tanshinone production. Our lab is striving in systematics-guided investigation of anti-infectious microbial natural products, such as anti-MRSA, anti-TB, and synergic antifungal, and led to a series of active natural products [69, 126–128]. Zhuo et al. adopted a successful proprietary approach to improve the yield of avermectin B1a (with 52% production improvement) and provide a route to optimize production in these complex regulatory systems. The engineered strain A56 was cultured in a 180-m^3 fermentor, in which the production has reached to 6,382 μg/mL [129]. These findings shed light on genetic engineering aimed at producing more secondary metabolites and increasing the yields of specific products, which provides an example for further study of tanshinones on synthetic biology.

Acknowledgments We sincerely thank Dr. Krishna Bolla for valuable discussion. This work was supported in part by grants from National Natural Science Foundation of China (30911120483, 81102356, 81102369, 30901849, 30973665, 30911120484), the CAS Pillar Program (XDA04074000), and the Ministry of Science and Technology of China (2011ZX11102-011-11, 2007DFB31620). Abstract

Strigolactones (SLs) are carotenoid-derived plant terpenes which function in the rhizosphere and in planta. In the rhizosphere, SLs induce seed germination in root parasitic plants and hyphal branching in arbuscular mycorrhizal (AM) fungi, therefore mediating both parasitic and symbiotic interactions with SL-producing plants and root parasitic plants and AM fungi, respectively. In planta, SLs are a group of plant hormones regulating shoot as well as root architecture. In this

1 Introduction

Among plant secondary metabolites, strigolactones (SLs) discussed in this chapter are unique as their new but probably original biological functions have been unveiled nearly 40 years after the isolation and structural determination of the first SL, strigol, from cotton root exudate as a seed germination stimulant for a root parasitic weed witchweed, *Striga lutea* (syn. *S. asiatica*), in 1966 [1]. Following this discovery and structural determination [2], strigol analogs collectively called “strigolactones” [3] have been isolated from root exudates of various plant species [4–6]. So far, more than 15 natural SLs have been characterized, and the total number of natural SLs may exceed 100 as they exist not only as structural isomers but also as stereoisomers. In addition, all plant species examined to date were found to produce and exude not a single SL but mixtures of several SLs. Compositions of these SL mixtures vary with plant species and among cultivars within the same genus, change with growth stage, and seem to be affected by growth conditions [4].

Since SLs induce seed germination of root parasitic weeds, SLs had been considered as wastes or harmful metabolites until their function as a host-recognition signal for arbuscular mycorrhizal (AM) fungi with which more than 80% of land plants form symbiotic relationship was uncovered in 2005 [7]. However, non-mycotrophic plant species such as Arabidopsis (*Arabidopsis thaliana* L.) [8], white lupin (*Lupinus albus* L.), and spinach (*Spinacia oleracea* L.) were found to produce SLs [9], indicating that SLs have important biological functions in SL-producing plants themselves. Within a few years, SLs or their further metabolites were identified as a novel class of plant hormones inhibiting shoot branching [10, 11]. Accordingly, SLs released from plant roots to the rhizosphere function as host-recognition signals for root parasitic plants and AM fungi and in plants as a plant hormone regulating aboveground architecture. In addition to these functions, SLs have been shown to be involved in the regulation of root architecture [12–14], photomorphogenesis [15], secondary growth [16], and rhizobia colonization [17, 18]. Furthermore, SL production by the moss *Physcomitrella patens* [19] and liverwort [20] indicates that SLs evolved before the first colonization of land by plants. Ubiquitous presence of SLs in the rhizosphere implies that any organisms in the rhizosphere are exposed to SLs, and thus, it is likely that SLs have other hidden roles in the interactions between SL-producing plants and other organisms in the rhizosphere.

In this chapter, diverse chemical structures of natural SLs, biosynthetic pathway and its regulation, analytical methods, biological activities, and potential agronomical uses are discussed.

2 Chemistry of Strigolactones

Most of SLs have been characterized as germination stimulants for root parasitic plants (weeds) of the family Orobanchaceae, including witchweeds (*Striga* spp.), broomrapes (*Orobanche* and *Phelipanche* spp.), and *Alectra* spp. *Striga* spp. are hemiparasites as they have functional chloroplasts but cannot survive without parasitizing to their hosts and thus regarded as obligate parasites. They parasitize important food crops including sorghum, maize, millet, and rice. *Orobanche* and *Phelipanche* spp. are holoparasites lacking chlorophylls and depend entirely on their hosts for the supply of water and nutrients. *Alectra* spp. are hemi- and obligate parasites like *Striga* spp. These root parasites are causing significant crop losses all over the world [21–23]. The seeds of these root parasites will not germinate unless they are exposed to chemical stimuli germination stimulants released from plant roots [24]. Majority of germination stimulants so far characterized are SLs [4, 25, 26].

All natural SLs identified to date contain a tricyclic lactone (ABC-part) which is connected to a butenolide moiety (the D ring) via a vinyl ether linkage [4–6]. These SLs have different substituents on the A and B rings but the same CD moiety (Figs. 118.1 and 118.2). Strigol **1**, along with its acetate (strigyl acetate), was isolated from root exudate of cotton (*Gossypium hirsutum* L.), nonhost of *Striga* [1, 2], and then its presence was confirmed in root exudates from *Striga* hosts, sorghum [*Sorghum bicolor* (L.) Moench], common millet (*Panicum miliaceum* L.), and maize (*Zea mays* L.) [27]. Sorgolactone **2** and alectrol **3** were identified as *Striga* germination stimulants from genuine hosts of *Striga* sorghum [28] and cowpea [*Vigna unguiculata* (L.) Walp.] [29], respectively. The structure originally proposed for alectrol **3** was disproved by comparison of spectral data with those of synthetic standard [30] and then identified as orobanchyl acetate [31–33]. Orobanchol **4a**, the first *Orobanche* germination stimulant, was isolated from red

clover (*Trifolium pratense* L.) root exudate [34, 35]. Structure of orobanchol was revised recently [33]. Red clover plants also produce orobanchyl acetate and an isomer of didehydro-orobanchol [36]. Sorgomol **5** was isolated from sorghum root exudate [37, 38] and then detected in some Fabaceae plants such as Chinese milk vetch (*Astragalus sinicus* L.) and white lupin (*Lupinus albus* L.) [9]. Sorgomol appears to be the biosynthetic precursor of sorgolactone because further oxidation of the hydroxymethylene group to carboxylic acid and the subsequent decarboxylation would afford sorgolactone [38, 39]. 5-Deoxystrigol **6a** was first identified

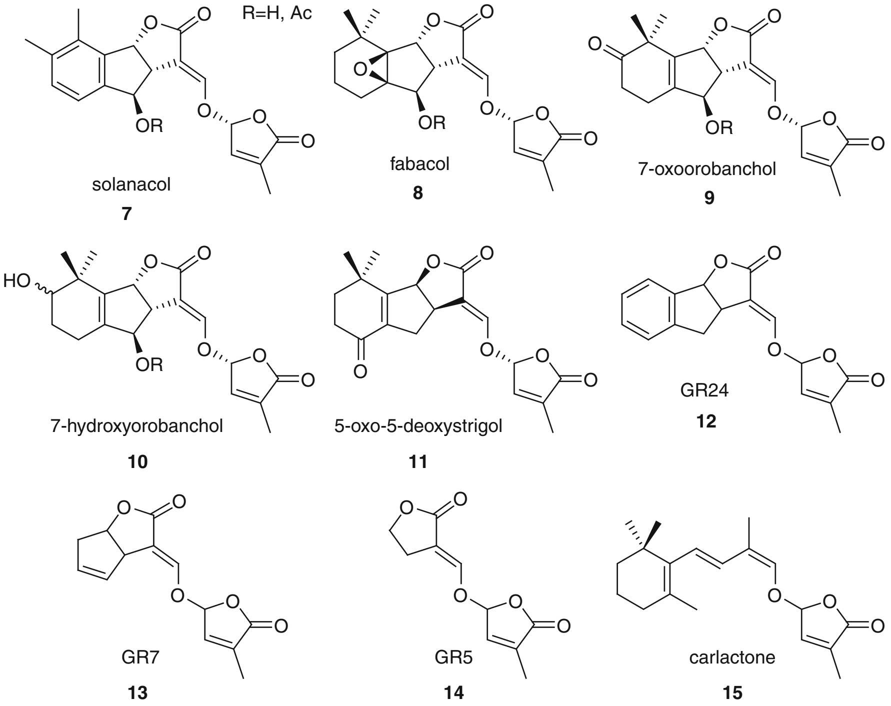

Fig. 118.2 Natural strigolactones, synthetic analogs, GR24, GR7 and GR5, and carlactone

from *Lotus japonicus* L. root exudates as a branching factor for AM fungi [7] and then as a germination stimulant in various plant species. One of its diastereomers, *ent*-2′-*epi*-5-deoxystrigol **6b**, was identified as a major SL in rice (*Oryza sativa* L.) plants [11] (Xie et al. unpublished data). Solanacol **7**, a unique SL containing a phenyl group, was purified from tobacco *(Nicotiana tabacum* L.) root exudates [40] and identified in tomato (*Solanum lycopersicum* L.) root exudates [41]. The structure of **7** was established by synthesis [42]. Tobacco plants also produce orobanchol **6a**, *ent*-2′-*epi*-orobanchol **4b**, orobanchyl acetate, *ent*-2′-*epi*-orobanchyl acetate, solanacyl acetate, 5-deoxystrigol **6a**, *ent*-2′-*epi*-5-deoxystrigol **6b**, and three isomers of putative didehydro-orobanchol whose structures have not yet been identified (Xie et al. unpublished data). Fabacol **8** and fabacyl acetate were originally purified from pea (*Pisum sativum* L.) root exudates [43]. 7-Oxoorobanchol **9** and 7-hydroxyorobanchol **10** and their acetates were found in root exudates of flax (*Linum usitatissimum* L.) and cucumber (*Cucumis sativus* L.) [4, 44]. 5-Oxo-5-deoxystrigol **11** was purified from root exudates of dokudami (*Houttuynia cordata* Thunb.) and detected in strawberry (*Fragaria grandiflora* Ehrh.) (Kisugi et al. unpublished data). This SL is one of the didehydro-orobanchol(-strigol) isomers but different from those detected in red clover [36], tobacco [40], tomato [41], and *Medicago truncatula* L. [45].

The CD moiety in the SL molecules has been suggested to be essential for the three representative biological activities – stimulation of seed germination in root parasitic plants [46, 47], induction of hyphal branching in AM fungi [48], and inhibition of shoot branching [4]. In fact, in the stimulation of parasite seed germination and hyphal branching of AM fungi, removal of the A ring of GR24 **12** as in GR7 **13** resulted in a reduction of the activity, and further removal of the B ring as in GR5 **14** brought about a significant (parasite seed germination) or complete loss of the activity (hyphal branching) [4, 47, 48]. For the inhibition of shoot branching (tillering) in rice plants, GR5 and GR7 were more active than GR24 when applied to growth media (Umehara et al. unpublished data). Therefore, natural SLs whose structures have not yet been identified would contain the ABC-part and the D ring. However, since carlactone **15** lacking the B and C rings, a possible intermediate in the SL biosynthetic pathway, could induce *Striga* seed germination [49], novel SLs without the B or C ring or carlactone analogs may exist.

To date, only acetates of hydroxy-SLs have been identified. Conjugation with amino acids and sugars may also occur and may be important in regulation of endogenous levels of biologically active SLs [4].

3 Biosynthetic Pathway and Regulation

3.1 Biosynthetic Pathway

SLs had long been recognized as sesquiterpene lactones until Matusova et al. suggested that SLs would be derived from carotenoids [50]. Although they did not quantify SLs, the reduction in *Striga* seed germination stimulation activity of root exudates from carotenoid-deficient maize mutants and from maize, cowpea, and sorghum plants treated with carotenoid biosynthesis inhibitors well supported their hypothesis. This was then confirmed by the finding that SLs are a long-sought, carotenoid-derived, novel class of plant hormones inhibiting shoot branching [10, 11].

To date, four enzymes – D27, an iron-containing isomerase [49]; two carotenoid cleavage dioxygenases CCD7 and CCD8; and a cytochrome P450 monooxygenase, MAX1 in Arabidopsis – have been identified in the SL biosynthetic pathway (Scheme 118.1) [51, 52]. These enzymes are distributed widely in the plant kingdom, and even the moss *Physcomitrella patens*, although it lacks *MAX1* ortholog, was found to produce SLs [19]. In the biosynthetic pathway proposed recently, the C9–C10 double bond in all-*trans*-β-carotene is converted by the isomerase D27 to 9-*cis*-β-carotene [49]. This is the key step in the SL biosynthesis, since CCD7 is stereospecific for the 9-*cis* configuration and cleaves the C9′–C10′ double bond of 9-*cis*-β-carotene to afford 9-*cis*-β-apo-10′-carotenal and β-ionone. Then, CCD8 converts 9-*cis*-β-apo-10′-carotenal to carlactone [49]. These reactions occur in plastids since these enzymes and the starting materials – carotenoids – are located in plastids. MAX 1 and probably some other proteins in endoplasmic reticulum then catalyze the conversion of carlactone to 5-deoxystrigol and its

stereoisomers, which includes dioxygenation, dehydrogenation, and closure of the B and C rings [49]. These reactions may proceed without very strict stereochemical control and thus may afford all four stereoisomers of 5-deoxystrigol **6a–d**. In *L. japonicus*, 5-deoxystrigol **6a** is the major isomer but *ent*-2′-*epi*-5-deoxystrigol **6b** in rice plants [4]. Although *ent*-5-deoxystrigol **6c** and 2′-*epi*-5-deoxystrigol **6d** have not yet been detected so far, it is likely that plants produce all stereoisomers at different levels so that only major and/or accumulated ones have been detected [4].

Based on the stereochemistry or orientation of the C ring, natural SLs identified to date are divided into two groups [4]. One is "strigol series" starting from 5-deoxystrigol and including strigol, sorgomol, 5-oxo-5-deoxystrigol, and sorgolactone. The other is "orobanchol series" starting from *ent*-2′-*epi*-5-deoxystrigol, to which orobanchol, 7-hydroxyorobanchol, 7-oxoorobanchol, fabacol, solanacol, and probably most of didehydro-orobanchol isomers belong. In both SL series, an *R*-configuration at the C-2′ seems to enhance biological activities [4, 47]. Plants appear to produce both SL series.

3.2 Regulation of Biosynthesis

Various environmental factors have been shown to influence production and exudation of SLs. In particular, nutrient availability has profound effects on SL production and exudation. It has long been known that root parasitic weeds prevail on nutrient-deficient soils and fertilizer applications often alleviate crop damages caused by these parasites [53]. In addition, root exudates from plants grown under phosphate starvation are more active in AM hyphal branching than those from plants grown with sufficient phosphate supply [54]. Therefore, nutrient starvation, especially phosphate deficiency, was expected to enhance or stimulate SL production and exudation. Indeed, in red clover (*Trifolium pratense* L.), a host of *O. minor*, reduced supply of phosphorus (P) but not of other mineral elements (N, K, Ca, Mg) greatly promoted production of orobanchol, the major SL in red clover [55]. In the case of sorghum, a host of *S. hermonthica*, N deficiency as well as P deficiency profoundly increased the exudation of 5-deoxystrigol, the major SL in sorghum [56]. In both cases, SL contents in the roots were comparable to the increase in the root exudates, indicating that SLs may be rapidly secreted after their production in the roots. Similar results have been observed with tomato [41]. In petunia (*Petunia hybrida* L.), involvement of ATP-binding cassette (ABC) transporter PDR1 in SL exudation from roots and root-to-shoot transportation has been reported [57]. By contrast to these mycotrophic plant species, in non-mycotrophic white lupin (*Lupinus albus* L.), SL production responded to neither N nor P deficiency [9]. These results indicate that the regulation of SL production and/or exudation appears to be closely related to the nutrient acquisition strategy of the plants. More detailed analyses of the effects of N and P deficiencies on SL exudation in Fabaceae, Asteraceae, Solanaceae, and Poaceae plants suggested that the P status of the shoot regulates SL exudation [58, 59].

Major SLs produced by Chinese milk vetch (*Astragalus sinicus* L.) are sorgomol, 5-deoxystrigol, and orobanchyl acetate. Sorgomol is derived from 5-deoxystrigol but orobanchyl acetate (orobanchol) from *ent*-2′-*epi*-5-deoxystrigol. Exudation of sorgomol and 5-deoxystrigol was significantly enhanced by N and P deficiencies, whereas neither P nor N deficiency promoted orobanchyl acetate exudation [59]. These results imply that plants produce all SLs but may promote exudation of particular SLs in response to environmental stresses including nutrient starvation. In addition, the two different biosynthetic pathways for SLs starting from either 5-deoxystrigol to strigol series SLs or *ent*-2′-*epi*-5-deoxystrigol to orobanchol series SLs appear to be regulated somewhat independently under N and P deficiency, and the former pathway seems to be more sensitive than the latter to N and P deficiency in this plant [59].

Deficiency of other elements also affects SL production and exudation but to a lesser extent. Of course, enhancement of SL production and/or exudation under nutrient deficiency would be temporal and would last within several days to a few weeks when the plants exhaust their stocks. These responses, however, may vary with plant species and their growth stages.

Light is one of the environmental factors suggested to influence SL production and exudation in plants [60]. Light quality, intensity, and irradiation period seem to affect SL production and exudation directly or indirectly through its effects on biosynthesis, transport, and signaling of the other plant hormones, auxin, cytokinins (CKs), ethylene, gibberellins (GAs), abscisic acid (ABA), and brassinosteroids (BR). Other environmental factors including nutrient availability would also influence SL production and exudation indirectly in a similar manner. In general, auxin promotes but CKs and GAs suppress SL biosynthesis. ABA which antagonizes with SL in seed germination of parasitic plants [61] was suggested to regulate SL biosynthesis [62].

Seeds of root parasitic plants need to be kept in a warm–wet environment for several days prior to the exposure to germination stimulants including SLs. During this period – called conditioning period – the seeds become responsive to the stimulants [24]. Although it has not yet been confirmed by chemical analysis, root parasitic plants appear to have ability to produce their own SLs as genes for SL biosynthesis and signal transduction are preserved in their genome [63]. Expression analysis of genes for SL biosynthesis during seed conditioning and germination suggests that SL biosynthetic activity decreases to the minimum level toward the end of conditioning period, creating SL starvation in the seeds, and thus renders the seeds sensitive to exogenous SLs (Westwood et al. unpublished data). Inclusion of GAs in the conditioning media has been known to increase sensitivity of parasite seeds to germination stimulants [64, 65]. This may be due to the inhibition of SL biosynthesis by GAs. GA treatment further reduces endogenous SLs during the conditioning period and therefore enhances the sensitive to exogenous SLs.

4 Analytical Methods for Strigolactones

4.1 Bioassays

The most sensitive and selective detection methods for SLs are germination test with seeds of root parasitic plants and hyphal branching assays with AM fungi. For example, SLs are active at as low as 10^{-12} M in *Orobanche minor* seed germination [66] and at 0.1 pg/disc in hyphal branching of *Gigaspora margarita* [48]. Of course, only bioactive SLs and related compounds (precursors and metabolites) can be detected by these bioassays. Since these bioassays are very sensitive and specific, it is possible to detect SLs even in crude extracts without any purification. Semiquantitative analysis may be possible with these bioassays especially by the seed germination test, but inhibitors present in the crude extracts may mask the activity of SLs [24, 67]. This may be avoided by conducting bioassays using fractions after HPLC separation of crude extracts. By comparing retention times of germination stimulants with those of synthetic and/or natural SL standards, SLs present in the sample may be estimated. However, in the case of parasite seed germination, not only SLs but also other plant metabolites have been shown to be active to some parasite species. For example, *P. ramosa* germination stimulants produced by rapeseed (*Brassica napus* L.) are isothiocyanates [68], and dehydrocostuslactone produced by sunflower (*Helianthus annuus* L.) is the germination stimulant for *O. cumana* [69].

4.2 UV Absorption

All the natural SLs have weak to moderate UV absorption with a maximum at around 240–250 nm [1] and thus can be detected by UV or PDA (photodiode array) detector only when their concentration ($>10^{-6}$ M) and purity are high enough. In the case of plant root exudates collected and thus concentrated by absorption on activated charcoal, it is sometimes possible to detect SLs without any purification by HPLC equipped with a UV detector. Of course, various compounds have rather strong absorption in this UV region, and concentrations of SLs in plant root exudates are generally quite low. Consequently, it is quite difficult to analyze SLs in crude samples with HPLC–UV detector system.

4.3 GC–MS

In the first isolation of orobanchol, purified samples were analyzed by GC–MS after conversion to their TMS ethers [34]. Since decomposition of SLs and their TMS ethers occurs in the capillary column, column length should be shorter than 5m (DB-5). Most of natural SLs have been analyzed by GC–MS without derivatization, but sensitivity for hydroxy-SLs is rather low. Although detection limit of GC–MS (~ ng) is more than 1,000 times higher than that of LC–MS/MS (~ pg), fragment ions and fragmentation patterns obtained from GC–MS analysis provide more rich information on structural features of SLs than LC–MS/MS. In addition, SL isomers that cannot be differentiated by LC–MS/MS often have distinct retention times in GC–MS analysis. Unfortunately, crude samples cannot be analyzed by GC–MS, and extensive purification steps are required.

4.4 LC–MS

The most simple and highly sensitive analytical method for SLs is LC–MS/MS with multiple reaction monitoring (MRM) mode [36, 70]. Even crude samples can be directly analyzed by LC–MS/MS for the detection of known and unknown SLs with known or estimated molecular formulae. This is possible because all natural SLs contain the essential structure, the CD part. Electrospray ionization (ESI) of SLs results in the formation of their $[M + H]^+$ and $[M + Na]^+$ ions, and these ions give rise to characteristic product ions on collision-induced dissociation (CID) with argon due to the loss of the D-ring moiety. In general, reversed-phase HPLC equipped with a C_{18} column with solvent system of methanol–water or acetonitrile–water is used for the separation of SLs. In the first report on SL analysis by LC–MS/MS, only the transitions of sodium adduct ions $[M + Na]^+$ to the fragment ions losing the D-ring moiety $[M + Na - 97]^+$ were selected [36, 70]. Then it has become possible to set two or more MRM transitions for each SL for more accurate identification of known SLs. Development of ultrahigh-performance liquid chromatography (UPLC) has enabled clearer separations of SL isomers in shorter analytical time. For example, a single peak of monomethoxy-SL was detected in rice root exudates by a conventional HPLC (C_{18} column, 3 μm) connected to MS/MS, whereas the same sample gave four peaks in UPLC–MS/MS (C_{18} column, 1.8 μm) (Xie et al. unpublished data).

Although crude samples can be analyzed by LC–MS/MS, it is better to remove acidic compounds which strongly interfere with electrospray ionization of SLs. Therefore, direct comparison of peak areas in MRM chromatograms among different samples which contain different levels of matrices may lead to over- and/or underestimation of SLs in the samples. In particular, root exudates from plants grown under nutrient deficiency contain relatively large amounts of organic acids. In addition, for extracts of plant tissues, it is preferable to subject them to a simple purification step using a silica gel or C_{18} cartridge. For accurate quantifications of SLs, internal standards should be employed.

Instability of natural SLs in particular under basic conditions has been described repeatedly. In fact, natural SLs may decompose within a day in aqueous solutions [48]. In general, hydroxy-SLs are less stable than their acetates and SLs without hydroxyl substituents. Furthermore, it is better not to store root exudate or plant material in a freezer for a long period. Lyophilization (freeze drying) of these samples results in a partial or a complete decomposition of SLs (Kisugi et al. unpublished data). These samples should be extracted with ethyl acetate or other appropriate organic solvents immediately after collection.

5 Biological Activities

SLs exhibit biological activities in the rhizosphere and in plants. In the rhizosphere, SLs are signaling compounds involved in the communications between the SL-producing plants and other organisms including root parasitic plants and AM fungi. In plants, SLs work as a class of plant hormones regulating shoot branching. Hence, biological activities of SLs in the rhizosphere and in plants are discussed separately.

5.1 Strigolactones as Rhizosphere Signaling Molecules

Once released into the rhizosphere, SLs induce seed germination of root parasitic plants and hyphal branching of AM fungi. Since plant roots continuously release SLs into the rhizosphere, all soilborne organisms are exposed to SLs when they are in close vicinity to the root. SLs appear to diffuse only to a limited area as they decompose rapidly in soil, and thus, SLs are good cue of the presence of living plant roots nearby.

5.1.1 Germination Stimulants for Root Parasitic Plants

Natural SLs identified to date contain the same CD moiety but different substituents on the A and B rings. These substituents affect biological activity of SLs. In the case of *O. minor* seed germination, approximately 1,000-fold differences in activity were observed among 11 natural SLs [66]. Monohydroxy-SLs including orobanchol are most active and induced >80% germination at 10^{-11} M. In general, acetates of monohydroxy-SLs are approximately tenfold less active than the corresponding monohydroxy-SLs, while 7-oxoorobanchol is less active than its acetate, probably due to its instability. By contrast, rather lipophilic SL 5-deoxystrigol and sorgolactone are the least active SLs and induce 80% germination at 10^{-8} M. The synthetic SL GR24 (mixture of four stereoisomers) is 100-fold less active than the least active natural SLs. These results indicate that germination stimulation activity of natural SLs on *O. minor* seeds depends on the lipophilicity of SL molecules and their stability also affects activity. It is likely that seeds of different root parasitic plants have different sensitivities to each SL. Since plants produce and exude mixture of SLs, it is intriguing to understand which SL in the mixture contributes most to host-specific seed germination. For example, it has been known that only host plant root exudates can induce germination of host-specific root parasites such as *O. hederae* (ivy broomrape), whereas ivy root exudate was found to contain known SLs including orobanchol (Xie et al. unpublished data). Therefore, in addition to the germination tests with individual SL, various mixtures of SLs need to be examined for germination stimulation of host-specific root parasites.

Root parasitic weeds *Striga* and *Orobanche* (*Phelipanche*) spp. are causing devastating damages to agricultural production worldwide [21–23]. One of the most promising approaches to alleviate these damages is breeding of resistant genotypes. Although there are multiple layers of incompatibility to the parasitic weeds [71, 72], reduced production of SLs is a simple and straightforward characteristic for the resistance since genotypes with such a trait are expected to induce only a few parasite seeds located very closely to the host roots [73]. Indeed, root exudates from SL-deficient mutants of rice [11] and tomato [74] induced only low germination of root parasitic weeds.

In sorghum, *Striga*-resistant genotypes with reduced or no stimulant production were selected by comparing the germination stimulation activity of root exudates [73]. Therefore, quantitative and qualitative differences in SL production between *Striga*-resistant and *Striga*-susceptible sorghum cultivars were examined [5]. Unexpectedly, when they were grown hydroponically, root exudates from *Striga*-resistant sorghum cultivars induced *S. hermonthica* and *O. minor* seed germination at levels similar to those induced by *Striga*-susceptible cultivars. All of these sorghum cultivars produced sorgomol, sorgolactone, and 5-deoxystrigol as major SLs. The only difference was that *Striga*-resistant cultivars exuded lower amounts of more stable 5-deoxystrigol than did *Striga*-susceptible ones. Similar results were obtained with *Striga*-resistant and *Striga*-susceptible maize genotypes (Yoneyama et al. unpublished data). In the case of NERICA (new rice for Africa) cultivars, there was a positive relationship between the amount of SLs in the root exudate and *Striga* germination, attachment, and emergence rates [75]. Among the SLs detected in the root exudates, there was a strong correlation between *Striga* germination and amounts of more stable methoxy-5-deoxystrigol isomers and (*ent*-)2′-*epi*-5-deoxystrigol, whereas attachment, emergence, and dry biomass of *Striga* correlated best with orobanchol. These results indicate that more stable SLs are mainly involved in germination stimulation of *Striga* seeds and other less stable SLs also contribute to processes after germination including radicle elongation toward host root and subsequent attachment.

5.1.2 Signaling Molecules for Soilborne Microbes

AM symbiosis is the most widespread and common symbiosis on earth and evolved 460 Ma ago. AM fungi are soilborne microorganisms that form symbiotic relationship with more than 80% of land plants. They penetrate and colonize plant roots and develop branched structure called arbuscules, the sites of nutrient exchange. AM fungi uptake water and nutrients mainly phosphate and nitrogen through their network of fine hyphae and supply them to their hosts, and in turn the fungi receive photosynthates from their hosts. Like rhizobium–legume interaction, the interaction between plants and the AM fungi is initiated by mutual exchange of signaling molecules – branching factor (BF) and myc factor [76, 77]. 5-Deoxystrigol was the first BF identified in *L. japonicus* root exudate [7]. All natural SLs examined so far are active as BF at 1–100 pg/disc [48]. Synthetic SL GR24 is active at 100 pg/disc, but the karrikin KAR_1 (3-methyl-2*H*-furo[2,3-*c*]pyran-2-one), a germination stimulant in smoke [78], is totally inactive. Structure–activity relationships of natural and synthetic SLs have been reported [48]. SLs-deficient mutants of pea showed reduced AM colonization, which was rescued by SL application, suggesting SLs influence only presymbiotic phase of AM colonization [10]. On the other hand, AM colonization reduces SL production and/or exudation and thus renders the host plants less susceptible to root parasitic weeds [26, 79].

Several other soilborne pathogenic and nonpathogenic fungi have been examined for their response to the synthetic SL GR24. Steinkellner et al. reported that GR24 did not affect hyphal branching in *Rhizoctonia solani, Fusarium oxysporum*, and *Verticillium dahliae* [80]. In another report [81], GR24 inhibited growth of *F. oxysporum* f. sp. *melonis, F. solani* f. sp. *mango, Sclerotinina sclerotiorum, Macrophomia phaseolina*, *Alternaria alternata*, *Colletotrichum acutatum*, and *Botrytis cinerea*. Hyphal branching was promoted in *S. sclerotiorum, C. acutatum*, and *F. oxysporum* f. sp. *melonis* and also slightly in *Alternaria alternata*, *F. solani* f. sp. *mango*, and *B. cinerea*. GR24 was inhibitory on hyphal branching in *M. phaseolina*. These observations suggest that SLs would influence growth and development of broad range soilborne fungi. Since GR24 used in these studies consist of four (or two) stereoisomers, optically pure natural SLs may induce different responses.

SLs have been shown to regulate rhizobia nodulation. GR24 promoted nodulation in alfalfa (*Medicago sativa* L.) inoculated with *Sinorhizobium meliloti* without affecting bacterial growth or *nod* (nodulation) gene expression [17]. A similar promotive effect of GR24 on nodulation was observed in pea (*Pisum sativum* L.) inoculated with *Rhizobium leguminosarum*. Significantly reduced nodulation in the SL-deficient mutant *rms1* could be increased by GR24 application which also promoted nodulation in wild-type plants [18]. Grafting experiments with using wild type and *rms1* revealed that SLs are positive regulators of nodulation. SLs in roots appear to regulate nodule number but not nodule formation. Such an effect of SLs only on presymbiotic phase is similar to that observed in AM colonization where SLs play an important role in AM fungi infection but not in arbuscule formation. Recently, the GRAS-type transcription factors NODULATION SIGNALING PATHWAY1 (NSP1) and NSP2, which are functioning in Nod factor-induced signaling and thus essential for rhizobium symbiosis (NSP2, also for mycorrhizal symbiosis), have been shown to be indispensable for SL biosynthesis [45]. NSP1 and NSP2 are functionally conserved in nonlegume higher plants including non-mycotrophic *Arabidopsis*, and thus, the regulation of SL biosynthesis is considered an ancestral function.

It is difficult to simulate natural conditions in the soil as plant roots continuously release SLs into the rhizosphere, but artificially applied SLs would rapidly disappear due to degradation. It is likely, however, that SLs released from plant roots influence soil biota, and in turn some microbes utilize this rhizosphere signal for their growth and development.

5.2 Strigolactones as Plant Hormones

5.2.1 Inhibition of Shoot Branching

Inhibition of shoot branching or bud outgrowth by SLs has been reviewed extensively, and thus, we will not go into details here. Other plant hormones, in particular auxin and cytokinin, also influence shoot branching directly or indirectly through their effects on SL production and/or signaling [51, 82–84].

So far, all genes in the SL biosynthesis and signaling have been cloned from mutants with excessive branching (tillering in rice) [52]. The genes for SL biosynthesis are *RMS5*/*MAX3*/*D17(HTD1)* and *RMS1*/*MAX4*/*D10*/*DAD1* (RMS, MAX, D, and DAD are from pea, *Arabidopsis*, rice, and petunia, respectively) encoding carotenoid cleavage dioxygenase (CCD)7 and CCD8, respectively; *MAX1* in *Arabidopsis* encoding a cytochrome P450 (CYP711A1); and *D27* encoding an iron-containing isomerase [49]. *RMS4*/*MAX2*/*D3* encoding an F-box protein and *D14* encoding an α/β-hydrolase are required for perception and signaling of SLs [51, 52, 85].

Karrikins are smoke-derived germination stimulants which contain a butenolide structure similar to SLs [78]. Karrikins strongly elicit seed germination of fire-prone plant species but not those of root parasitic weeds [86]. They are active neither in hyphal branching of AM fungi nor inhibition of shoot branching [4, 48]. In *A. thaliana*, karrikins and SLs exhibit somewhat similar biological effects, for example, light-dependent inhibition on hypocotyl elongation, and MAX2 is required in the response to karrikins and SLs [87]. It has been demonstrated that *Arabidopsis D14* ortholog *AtD14* is necessary for SL response but *D14* paralog (*D14-like*) *KARRIKIN INSENSITIVE 2* (*KAI2*) is required for response to karrikins [88]. Both D14 and KAI2/D14-like homologs are distributed widely in the plant kingdom, and thus plants have two distinct signaling systems for karrikins and SLs.

5.2.2 Other Biological Functions

SLs have been shown to regulate not only shoot but also root architecture by controlling lateral root formation and root-hair elongation in a MAX2 dependent manner [12–14, 89]. As in the regulation of shoot architecture, SL–auxin cross talk seems to be involved in these root responses.

SLs appear to function in various processes of plant growth and development. For example, SLs induce seed germination of crops and weeds [90], promote photomorphogenesis [15], and restore germination in thermoinhibited seeds [91]. It is likely that additional functions and effects of SLs will be identified in the near future.

In addition to the effects of SLs on plants and microbes, they may influence other living organisms including human beings. Natural SLs were detected in fresh cucumber and coconut juice (Xie et al. unpublished data), and thus we would have a chance to receive SLs. SLs might protect us by inhibiting development of breast cancer [92]. Further study is needed to clarify effects of SLs on plant growth and development and also on other organisms including human beings.

6 Agronomical Uses

Root parasitic weeds are causing devastating damages to agriculture worldwide. They attach to host roots and spend most of their life cycle underground. The parasites become visible only after they emerge aboveground when growth of host plants had already been severely stunted. Single root parasitic weed can produce several hundreds of thousands of tiny seeds which remain viable for decades in soil. Therefore, the most important strategy in root parasite management is to decrease the number of parasite seeds (seed bank) in soil. As SLs can induce germination of parasite seeds in the absence of host plants and the germinated seeds will die unless they attach appropriate host roots within a few days, SLs and their synthetic analogs have been tested as inducers of seed germination in the absence of hosts – termed “suicidal germination” [93, 94]. Although natural SLs are not stable enough to induce acceptable levels of germination under field conditions, synthetic analogs like Nijmegen-1 provided promising results under field conditions [95–98]. Recently, novel types of SL mimics and nonmimics have been reported to be active on parasite seed germination, AM hyphal branching, and inhibition of shoot branching [99–101]. In general, these synthetic compounds are different from natural and synthetic SLs in that they have only one or two of the three biological activities – parasite seed germination, AM hyphal branching, and shoot branching. Therefore, it is likely to find useful compounds for the induction of suicidal germination of parasite seeds, for promotion of AM symbiosis, and for regulation of shoot and root architecture in plants.

7 Conclusion

Production of SLs by liverworts, the most basal land plants, and Charales, green algae closest to the land plants, suggests that SLs evolved before land colonization by plants and their primitive function may be regulation of rhizoid elongation because both liverworts and Charales have orthologs of D14-like which is involved in SL signaling [20]. Then, diffused or actively released SLs from tissue would be utilized by soilborne microbes including AM fungi as a cue of host presence nearby. Therefore, it is likely that SLs still have other functions in rhizosphere communications and in plant growth and development. In addition, it is intriguing to understand why and how plants produce and exude various SLs and their mixtures and how individual SL contributes to host recognition by root parasites and by AM fungi and to the regulation of shoot and root architectures in plants. Further studies are needed to answer to these questions.

Acknowledgments We would like to thank Kohki Akiyama, Junko Kyozuka, Shinjiro Yamaguchi, Tadao Asami, Harro Bouwmeester, Daniel M. Joel, Pierre-March Delaux, Guiliaume Bécard, and Nathalie Séjalon-Delmas for sharing information. Abstract

Investigation of the biological effects of olive oil/leaf/fruit phenolic extracts and, more recently, of the isolated compounds oleuropein and hydroxytyrosol has revealed their health beneficial action opening the way for a potential pharmacological utilization as single drug or after enrichment of olive oil or other food component. After a brief description of the chemical structure, biosynthesis, and the enzymatic degradation of oleuropein, which generates other biological active derivatives (i.e., hydroxytyrosol), the present review will focus on the

VOO	Virgin olive oil

1 Introduction

The Mediterranean diet has been associated with longevity and low incidence of chronic and degenerative diseases as shown in the Seven Countries Study [1–4] and several others studies, which attribute to the virgin olive oil (VOO) many of the healthy advantages of this diet [5–7].

The olive is an important crop in the Mediterranean basin, which produces 98% of the world total (approximately 11 million tons) [8]: it is estimated that seven million hectares is planted with around 600 million productive olive trees including more than 1275 autochthonous cultivars. Many customers identify olive oil as a food product that perfectly combines nutritional and sensory values, so that the production and consumption of olive oil are moving slowly but inexorably beyond the Mediterranean countries, and olive trees are being planted in countries as far from the Mediterranean basin as New Zealand and Argentina [9]. Historically, the healthful effects of VOO have been attributed to its high content of monounsaturated fatty acids (MUFAs), such as oleic acid, which represents 70–80% of fatty acids present in VOO [3]. However, several seed oils (including soybean, sunflower, and rapeseeds) rich in MUFA do not possess the same beneficial properties [10, 11]. Noteworthy, contrary to majority of edible oils, VOO can be consumed in crude form, conserving all the beneficial properties typical of its minor components. This unsaponifiable fraction of olive oil represents about 2% of the total weight

and includes a number of heterogeneous compounds (more than 230): some nonchemically related to fatty acids such as hydrocarbons, alcohols, sterols, volatile compounds, and antioxidants and fatty acid derivatives such as phospholipids, waxes, and sterol esters, as the most important [12, 13].

Virgin olive oil is a premium and highly priced product thanks to the nutraceutical properties of its antioxidant components. The most abundant antioxidants in VOO are lipophilic and hydrophilic phenols that affect the healthy and sensory characteristics of VOO and improve its resistance to oxidation [14]. Further, they are produced as a consequence of the reactivity to pathogen attacks and the response to insect injuries in the olive tree, thus playing an important role in the plant physiology [3, 15, 16]. Among the antioxidant compounds in VOO, the hydrophilic phenolic alcohols and their secondary metabolites are of paramount importance to keep a long oil shelf life and provide excellent organoleptic characteristics (taste and color) and beneficial effects on human health [14, 17, 18]. The main phenolic alcohols in VOO are 3,4-dihydroxyphenyl ethanol, also known as 3,4-DHPEA or hydroxytyrosol (HT), and *p*-hydroxyphenyl ethanol (*p*-HPEA or tyrosol) and their secoiridoid derivatives [3, 14].

The most abundant secoiridoids in intact olive fruit are oleuropein (OL), demethyloleuropein, ligstroside, and nüzhenide. During mechanical oil extraction, several hydrolysis reactions of OL, demethyloleuropein, and ligstroside take place due to the activity of endogenous β-glucosidases [19], and aglycone derivatives originate known as VOO secoiridoids. Thus, the most abundant in VOO are the dialdehydic form of decarboxymethyl EA (elenolic acid) linked to HT or tyrosol termed 3,4-DHPEA-EDA and *p*-HPEA-EDA, an isomer of OL aglycone (3,4-DHPEA-EA) and the ligstroside aglycone (*p*-HPEA-EA) (Fig. 119.1) [19].

The concentration of secoiridoids is largely affected by agronomic factors (cultivar, ripening stage, geographic origin of olive fruit, and olive trees irrigation) and by oil extraction conditions during crushing, malaxation, and VOO separation [20–22]. These compounds are present in olive fruit and are released to VOO during the mechanical extraction process. OL, discovered in 1908 by Bourquelot and Vintilesco, is a heterosidic ester of elenolic acid and HT [23]. HT is its principal degradation product [24]. OL is present in high amounts in unprocessed olive fruit and leaves, while HT is more abundant in the processed olive fruit and olive oil. The decrease in the concentration of OL and the increase in the concentration of HT occur due to chemical and enzymatic reactions that take place during maturation of the fruit or as a result of olive processing (e.g., oil production) [17, 19].

Among the all above-mentioned compounds, it is possible to consider the OL and its derivatives as the molecules of major interest for their biological and pharmacological properties and resulting among the most investigated antioxidant natural compounds [7, 14, 24].

2 Chemistry and Analysis of Oleuropein and its Derivatives

2.1 Chemical Structure, Biosynthesis, and Enzymatic Degradation of Oleuropein

Oleuropein (OL) and ligstroside are the major phenolic compounds in the olive fruit. OL belongs to the family of secoiridoids, which are abundant in *Oleaceae*, *Gentianaceae*, *Cornaceae*, as well as many other plants. Iridoids and secoiridoids are compounds that are usually glycosidically bound and are produced from the secondary metabolism of terpenes as precursors of various indole alkaloids. The secoiridoids in *Oleaceae* are usually derived from the oleoside type of glucosides (oleosides), which are characterized by an exocyclic 8,9-olefinic functionality, a combination of EA and a glucosidic residue. OL is an ester of HT and has the oleosidic skeleton that is common to the secoiridoid glucosides of *Oleaceae*, mainly in its aglycone form, which makes the sugar moiety insoluble in oil [24].

Probably, the biosynthesis of OL in *Oleaceae* proceeds via a branching in the mevalonic acid pathway in which terpene synthesis (oleoside moiety) and phenylpropanoid metabolism (phenolic moiety) merge [25–28], giving in the *Oleaceae* family the plausible biosynthetic route proposed, which, starting from deoxiloganin acid, produces ligstroside and then oleuropein oleosides [26–28]; thus, the biosynthesis of oleosides is similar to that of secologanin-derived secoiridoids in *Gentianales* and *Cornales*. In these compounds, the carbon skeleton is derived from mevalonic acid. Geraniol, 10-hydroxygeranoil as well as 10-hydroxynerol, and iridoidal are known precursors of loganin. Later, deoxyloganic acid, 7-epiloganic acid, and loganic acid are incorporated into ligustroside, a direct precursor of oleuropein, via a 7-ketologanic acid intermediate. The sequences of the steps between deoxyloganic acid and 7-ketologanin may differ between plant species and times of the year [28]. In *Olea europaea*, both

Scheme 119.1 Proposed biosynthetic pathway for OL in *Oleaceae* (From [7]) possible epoxides of secologanin and secoxyloganin can be precursors for OL [27], and a plausible biosynthetic route from deoxyloganic acid, 7-epiloganic acid, 7-ketologanic acid, 8-epikingisidic acid, oleoside 11-methyl ester, 7-β-1-D-glucopyranosyl-11-methyl oleoside, and ligustroside to OL was proposed by Damtoft et al. for *Oleaceae* (Scheme 119.1) [27, 29].

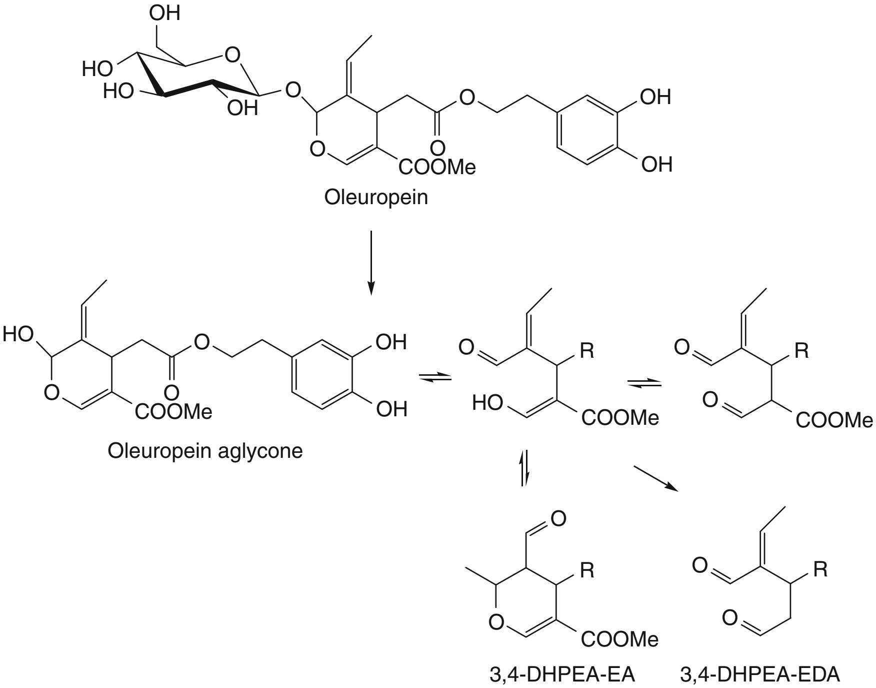
Phenols, particularly secoiridoids, generally decrease during VOO storage due to its hydrolysis in HT, tyrosol, and EA and formation of oxidized phenols. This reaction leads to a decrease in bitterness and pungent intensity, positive attributes that are characteristics of fresh VOO [30]. In the development of the olive fruit, three phases are usually distinguished: a growth phase, during which accumulation of OL occurs; a green maturation phase that coincides with a reduction in the levels of chlorophyll and OL; and a black maturation phase characterized by the appearance of anthocyanins and decrease of the OL levels [31]. Therefore, OL is very abundant in the early stages, and in young fruits, it can reach 14 % of dry matter [7]. Although lower, its levels are still very important at harvest for green picked cultivars [31]. In black cultivars, its levels decline rapidly during maturation [31, 32] in some varieties (*Olea europaea* var. *leccino*), falling to zero when the fruits are completely black [33]. Degradation of OL during maturation is accompanied by accumulation of demethyloleuropein and EA glucosides. The former replaces OL in about the same amount and constitutes the major components of black olive fruit [26, 31, 34–37].

So, EA glucoside and demethyloleuropein reach their maximum during black maturation, until demethyloleuropein becomes the major constituent of black olives [33]. It is possible that these two compounds are formed from OL by the action of esterases because esterase activity increases considerably during the first phase of maturation and reaches a maximum during the black maturation phase.

The degradation of OL occurs by two pathways: the first involves cleavage of OL to EA or demethyloleuropein by specific endogenous esterases, which are both found in mature olive fruit, which may produce the aglycone from the glycoside [38]; the second includes activation of β-glucosidases during crushing and malaxation of the fruits, which may produce the aglycone from the glycoside (Scheme 119.2) [39]. It is presumed that demethyloleuropein acts as a precursor for the formation of 3,4-DHPEA-EDA during crushing. However, high concentrations of the latter are found in cultivars characterized by low demethyloleuropein concentration. These results indicate that the concentration of 3,4-DHPEA-EDA is dependent not only on the concentration of demethyloleuropein but also on that of OL decomposed by methylesterase. During malaxation, the final composition of secoiridoid derivatives is mainly controlled by the activity of β-glucosidase.

2.2 Analytical Methods for Oleuropein Derivative Determination

Several different analytical approaches for the characterization of the secoiridoid profile, from both a qualitative and quantitative point of view, have been studied and applied in the last decade. Essentially two basic steps are required for analysis



Scheme 119.2 Degradation pathway of OL

of OL derivatives: extraction from the sample and separation/detection. The choice of the specific extraction method strongly depends on the sample characteristics, while the analytical technique to apply depends on the degree of information demanded [32, 40]. Besides the classical OL derivative sources (olive fruits and leaves, VOO), there are other cheaper sources coming from wastes of olive oil production, such as the olive mill wastewater (OMW) [41] and the alperujo, a semisolid residue obtained from the two-phase decantation used in olive oil industry [32]. Table 119.1 summarizes the analytical methods for quantification and identification of OL derivatives pointing out the average concentration of the most abundant derivatives in different matrix.

2.2.1 Extraction from the Matrix

With liquid samples as oils, OL isolation has been realized by two main techniques: liquid-liquid extraction (LLE) and solid-phase extraction (SPE) [14, 73]. LLE is based on transfer of the phenolic fraction from VOO to a more hydrophilic phase such as pure methanol or methanol-water mixtures with different alcohol concentrations [42–44]. Ultrasounds can be used as auxiliary energy to accelerate and improve LLE. The main advantages of ultrasound-assisted LLE are shortened extraction time, reduced reagent and sample volume, and improved extraction efficiency [32, 48]. After extraction, cleanup and pre-concentration steps are

required to isolate OL derivatives [42]. SPE is based on the separation of the hydrophilic compounds of VOO from the lipophilic matter by fractionation between an unpolar sorbent packed in a cartridge and a polar solvent as methanol. SPE is a versatile technique thanks to the range of different sorbents and eluents [45, 49, 51]. The main advantage of SPE is its dual action of extraction and cleanup.

For solid samples, a time-consuming protocol is generally required. Olive leaves are normally extracted as dry powered matter, and the temperature in the drying step is strictly controlled, as OL is relatively thermolabile. The extraction methods used are maceration at room temperature or Soxhlet extraction (SE) using different solvents [59–61]. Super Heated Liquid Extraction (SHLE) [62, 63] and pressurized liquid extraction (PLE) using food-grade solvents [65] are some of the new techniques to valorize this cheap waste of oil production in a greener way. Moreover, olive leaves can be extracted using classical methanol/water mixture with a nonconventional microwave-assisted extraction (MAE) [64]. The whole olive fruits are normally blended and dried, but the OL derivative profile and the quantity of the extracted desired product strongly depend on the pretreatment and extraction procedure applied. The highest quantity of OL is obtained when the fruits are frozen before blending, to avoid the hydrolytic β-glucosidases action, and then extracted by maceration in a solvent [69]. When an acid or basic pretreatment is done to leach secoiridoids from the olive mesocarp, OL aglycone and hydroxytyrosol are the derivatives obtained in higher quantity [67]. Ultrasound-assisted extraction (UAE) applied on freeze-dried fruits was able to increase OL amount up to 33 % [66].

Semisolid matter, such as alperujo, has rarely been exploited for obtaining OL derivatives. The samples may be taken directly from the production line and stored at 20 °C until analysis. The extraction is realized using microwave or ultrasound assistance [70]. In particular, in the continuous UAE method, the sample is located in the leaching chamber, which is subjected to the action of an ultrasound probe; meanwhile, the leaching liquid is recirculated in a closed circuit for proper mass transfer to the liquid phase. No degradation of the target compounds was observed under the optimal working conditions for leaching [70].

Olive mill wastewater, generated by the oil extraction industry, represents a severe environmental problem due to its highly polluting organic load. However, with its more than 30 phenolic compounds, OMW is also regarded as a potent source of natural antioxidants [72]. Several techniques are used individually or in combination form to recover the phenolic compounds from olive OMW. Among them, solvent extraction is the most widely used technique for recovering OL and OL aglycones avoiding its hydrolysis to HT [72]. Emmons et al. [71] patented a process for collecting OL aglycone from OMW that involves addition of citric acid to the raw material, subsequent heating in order to precipitate the solids, and extraction of OL aglycone with a nonpolar organic solvent mixture. More recently, Cardoso et al. [41] proposed a method where the OMW was firstly freeze-dried, then defatted with n-hexane, and the residue was extracted with methanol.

2.2.2 Separation, Identification, and Quantification

The individual separation, identification, and quantification of OL derivatives from natural extracts have been realized basically by chromatographic separation or capillary electrophoresis methods. Both gas and liquid chromatographies have been exploited, combined with several detection methods such as UV, fluorescence, and mass spectrometry (MS) [14]. Soft spectroscopic techniques as midium infrared spectroscopy have been recently explored for rapid quantification of OL [61], while high-resolution spectroscopic techniques as nuclear magnetic resonance are considered interesting application in the analysis of the OL derivative structures [14].

Gas chromatography (GC) is a high-resolution separation technique based on the interaction of the sample components with a stationary phase and along a temperature gradient. GC assumes that the analytes are volatile at the temperature of the analysis and remain stable during analysis. Due to the low volatility and thermal stability of phenolic compounds, a suited derivatization step is mandatory in order to increase volatility and thermostability of the analytes. Derivatization of phenolic compounds is mostly based on silylation reactions: phenolic compounds are separated as more volatile trimethylsilyl esters, thus decreasing the temperature required for chromatographic separation. Ríos et al. proposed a simple and versatile method for silylation of phenolic compounds in VOO after an SPE diol cartridge extraction and cleanup procedure. Oxidation products coming from the aldehydic and dialdehydic forms of OL aglycones were detected [46]. In general, MS supported this technique as an excellent tool for identification [74]. Further improvement to GC-MS was obtained by the introduction of the ion trap (IT) and GC-tandem MS (GC-MS/MS) that provide excellent sensitivity and selectivity for target compound analysis [47, 75].

Liquid chromatography (LC) is nowadays the most popular technique for VOO phenols analysis because of the combination of high resolution and applicability to nonvolatile compounds. Among the different chromatographic modes, reverse-phase LC is the preferred option for phenols separation [76]. Over the past few years, various liquid chromatographic methods with fluorescence, UV-Vis (ultraviolet-visible) or DAD-UV (diode array detector-ultraviolet) absorption, and, more recently, with MS detection have been developed for the analysis of phenols [44, 45, 68, 76]. Using traditional approaches based on high-performance liquid chromatography (HPLC)-DAD or UV detection, spectra of phenolic compounds are very similar, and the possibility of unambiguous identification does not exist. Mass spectrometry coupled to HPLC or UPLC (ultra performance liquid chromatography) enables the collection of significant data on the structures of those compounds that show similar UV-Vis spectra [44, 76]. At present, in LC-MS analysis of phenolic compounds, atmospheric pressure chemical ionization (APCI) [50] and electrospray ionization (ESI) [49] are used almost exclusively, and both positive and negative ionizations are applied. The selection of the analyzer is determined by the required sensitivity and selectivity. IT or triple quadrupole systems (QqQ) provide the possibility of doing MS/MS or MS^n [77]. Di Donna et al. have recently applied a UPLC-ESI-MS/MS analysis to the separation and identification of the dialdehydes affording from the enzymatic hydrolysis of OL and of its demethylated analogue [78]. Finally, TOF (time of flight) MS, which is one of the most advanced MS analyzers, provides excellent mass accuracy and allows measurements of the correct isotopic pattern [79].

Capillary electrophoresis (CE) is a good alternative to GC and LC techniques for profile determination of OL derivatives. CE requires minimal sample preparation and represents a good compromise between analysis time and satisfactory characterization. The most efficient operative mode to separate phenolic compounds is the borate-based CE, which makes use of a borate run buffer at alkaline pH [52]. To date, the most widely used detector in CE is based on UV absorption [53, 54], although the coupling to MS analyzers such as QqQ, IT, TOF has revalorized the potential of this technique [55].

A new perspective for determination and quantification of OL in natural extracts is represented today by the medium infrared spectroscopy (MIR). It achieves high analysis speed and requires little or no sample preparation. Aouidi et al. have developed a direct and rapid tool to quantitative determination of OL in olive leaves by MIR associated to chemometric treatment [61].

Raman spectroscopy coupled to theoretical methods was also used to fully characterize OL derivative profile of olive oils. The Raman data, assisted by the theoretical simulations, allowed obtaining the main spectroscopic features of the olive oil constituents which determine their antioxidant and chemoprotective properties [58].

Finally, high-resolution proton nuclear magnetic resonance (^{1}H-NMR) has been a useful technique for identification and structural assignment of several OL derivatives. In the past, ^{1}H-NMR has permitted to elucidate the hydrolysis mechanism of OL that gives rise to aglycone contributing to recognize its five different isomeric forms in solution [66, 80]. Nevertheless, NMR identification of complex mixture of different derivatives in natural extracts is affected by several problems such as signal overlap or diversity of intensity due to various concentrations, finally leading to an incomplete assignment [56]. A useful approach to overcome this problem involves the combination of ^{1}H-NMR and chromatography. A good agreement of HPLC-DAD/MS and 1D and 2D NMR spectroscopy has been obtained by Valli et al. [57], by comparing the sum of monoaldehydic and dialdehydic forms of OL derivatives after microwave heating in VOO. The most promising application of ^{1}H-NMR is targeted to qualitative analysis by generation of characteristic fingerprinting registers to improve VOO quality [81].

3 Bioavailability

In addition to their effect on VOO stability and human health, phenolic and volatile compounds are the main responsible for the sensory attributes of VOO (e.g., bitter, astringent, pungent, throat catching), providing this oil with its delicate and unique flavor highly appreciated by costumers [6, 82, 83]. Recent studies showed that the sensory intensity of the bitterness attribute in VOO is associated mainly to secoiridoid derivatives of hydroxytyrosol, particularly 3,4-DHPEA-EDA and 3,4-DHPEA-EA [79]. Most importantly, VOO phenols are well adsorbed by the intestine and enter the blood circulation [84] to constitute one of the bases of nutritional and therapeutic effects of VOO. Recent papers have pointed out that HT, OL, and 3,4-DHPEA-EA reach human blood concentrations ranging from 1 to 18 μM [85, 86]. The structural similarity of 3,4-DHPEA-EA and 3,4-DHPEA-EDA with OL and their higher lipophilicity [log P(3,4-DHPEA-EDA) = 1.02; log P (OL) = 0.13] [87] suggest that these compounds may also be adsorbed into the bloodstream, according to the "Lipinski rule of 5" [88]. Moreover, both 3,4-DHPEA-EDA and 3,4-DHPEA-EA show good stability after 48 h at acidic pH values (pH 3.5 and 5.5) and do not change significantly in acidified water up to 4 h [89]. These studies suggest that these compounds may survive the acidic conditions of stomach and be available for absorption.

Vissers et al. found that absorption of administered HT and OL aglycone was 55–60 % in human subjects [90]. They also suggested that an important step in the metabolism of olive oil phenolics OL and ligstroside aglycones is their transformation into HT or tyrosol. This hypothesis was supported by finding that 15 % of OL supplement administered to healthy human subjects was excreted in urine as HT [90]. OL is rapidly absorbed after oral administration with a maximum plasma concentration occurring 2 h after administration. Both compounds (OL and HT) are rapidly distributed and excreted in urine mainly as glucuronides or in very low concentrations as free forms [91, 92]. Many other reports confirmed that HT is renally excreted: while part of HT is unchanged, an aliquot is also metabolized, and over 90 % of the urinary metabolites are conjugated [90, 93–96], mainly glucuronide metabolites, yet free phenols and methylconjugates, with or without glucuronidation, were also excreted in human urine. Sulfoconjugates of HT, tyrosol, or their metabolites (methyl or glucuronide conjugates) have been observed only in animal experiments [94, 97, 98].

Tuck et al. investigated the in vivo fate of HT after intravenous and oral dosing of either tritium labeled compound to rats [97]. The elimination of radioactivity in urine within 24 h for the intravenously and orally administered oil-based dosing was significantly greater than the oral, aqueous dosing method. HT is quantitatively transported into the small-intestinal epithelial cells by passive diffusion [99]. Data from in vivo experiments with animals and humans have confirmed that olive oil phenolics are well absorbed at the intestinal level [97]. Not the entire quantity of tyrosol and HT that was given was subsequently found in the urines; whether the remaining amount is not absorbed, excreted with the feces, destroyed in the gut, accumulated in organs or circulating cells such as red blood cells, or excreted after 24 h remains to be elucidated. Anyway, tyrosol and HT are absorbed by humans in a dose-dependent manner [93]. These observations indicate that the first-pass intestinal/hepatic metabolism of the ingested phenolics is extensive [100]. However, data regarding the metabolism of olive oil phenolics in the human body are very limited, and contrasting results have been obtained regarding the amounts and forms in which they are present in plasma and excreted in urine [92, 94–98, 101, 102]. HT appeared in plasma minutes after oral administration, with maximal concentrations of HT obtained in the 5–10-min period and minimal concentrations of HT observed after 60 min [103].

In situ intestinal perfusion on the absorption of OL showed that OL was absorbed under iso-osmotic conditions, with a permeability coefficient of 1.47×10^{-6} cm/s [104], and it was postulated that this increase was due to an enhancement in paracellular movement facilitated by opening of the paracellular junctions. OL could be poorly absorbed from the isolated perfused rat intestine [104].

Limited metabolism of olive oil phenols was observed using Caco-2/Tc7 cells as model of human intestinal epithelium: the methylated conjugates were the major metabolites detected [105]. Manna et al. investigated the kinetics of ^{14}C-labeled HT intestinal transport and metabolism in Caco-2 cells [99]. They observed that the rate of HT was linear, the intestinal transport system was not saturable, and transport occurred by a passive diffusion mechanism. It is likely that HT will be 100 % absorbed in humans. The only labeled metabolite found in this study was homovanillic alcohol (4-hydroxy-3-methoxy phenylethanol), a methylated derivative of HT which is a product of intestinal catechol-*O*-methyl-transferase activity [99]. A recent article by D'Angelo et al. investigated the fate of radiolabelled HT (^{14}C) in rats [106]. Pharmacokinetic analysis revealed that the HT is quickly absorbed. Over 90 % of the administered radioactivity is excreted in urine after 5 h indicating that renal excretion represents the preferential disposition, whereas about 5 % of radioactivity was observed in feces and gastrointestinal tract [106]. HT is converted to four oxidized and/or methylated derivatives. These metabolites were tentatively identified as homovanillic alcohol, homovanillic acid, 3,4-dihydroxyphenylacetic acid, 3,4-dihydroxyphenylacetaldehyde, and sulfoconjugated derivatives.

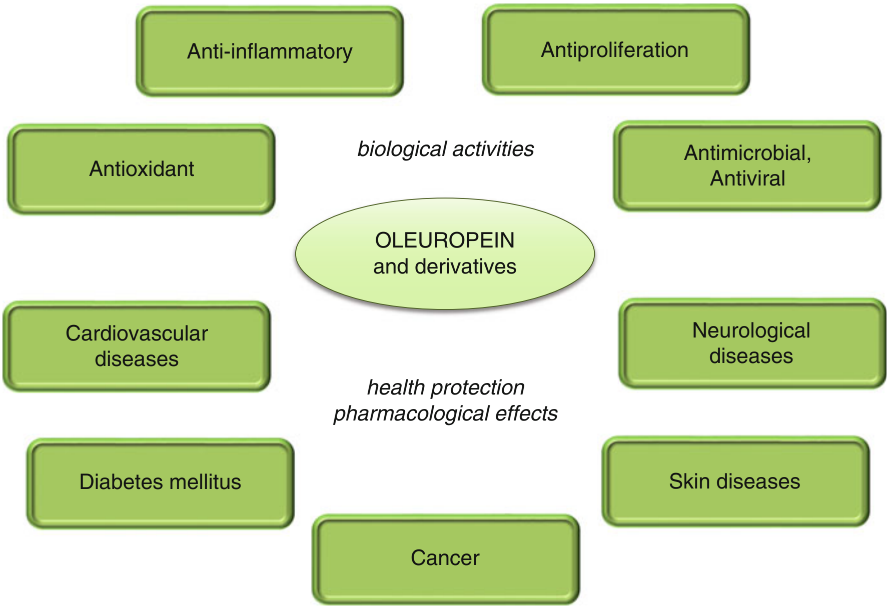
To study the potential hepatic metabolism of olive oil phenols, human hepatoma HepG2 cells were incubated for 2 and 18 h with HT and HT acetate. Methylated and glucuronidated forms of HT were detected at 18 h of incubation, together with methylglucuronidated metabolites. HT acetate was largely converted into free HT and subsequently metabolized, yet small amounts of glucuronidated HT acetate were detected. The absence of the formation of sulfated metabolites in vitro is in agreement with data from human studies, in which methylated and glucuronidated metabolites were the only conjugates observed in plasma and urine samples [90, 93, 95, 96, 98, 99]. Sulfate metabolites were detected in urine from animals only after intravenous administration of HT [10, 94, 97], indicating that rat hepatocytes are capable of sulfation of this phenol. Nevertheless, when the in vitro sulfation of olive oil phenolics was attempted using microsomes obtained from rat liver, no metabolites could be detected after 2 h of incubation [107].

4 Biological Activity and Pharmacological Properties

In the last decades, many biological properties have been assigned to the olive tree phenols, investigated both as whole oil/leaf/fruit extracts and isolated compounds [7, 108–110]. The effects of the latter are of particular interest in view of a pharmacological use of the purified/neosynthesized compounds as single drug or after enrichment of olive oil or other food component. OL and its derivatives have shown antioxidant, anti-inflammatory, antiproliferative, antimicrobic, and antiviral activity, so representing promising pharmacological agents for the protection against/treatment of many human diseases, including cardiovascular diseases, cancer, and many others (Fig. 119.2). Some differences have been reported in the observed effects when single phenols were tested in comparison with “oil phenolic extracts” probably because some biological effects may derive from the mixture of various derivatives generated by enzymatic hydrolysis. In the following paragraphs, only the effects of OL, 3,4-DHPEA-EA, and HT will be examined, focusing on the molecular mechanism underlying their action, as resulting from in vitro and in vivo experimentation performed using isolated compounds.

4.1 Antioxidant Activity

Oxidation is a process naturally occurring during VOO storage by reaction with air. Initially, lipids are oxidized to hydroperoxides which decompose through homolytic cleavage of the hydroperoxide group, giving rise to volatile oxidation products responsible for typical unpleasant sensory characteristics [111, 112]. Moreover, oxidation is a degenerative process in biological systems due to the endogenous reactive oxygen species (ROS). ROS are the result of normal metabolic processes, and they can damage cellular macromolecules as proteins or DNA, possibly leading to the development of degenerative diseases. Phenolic compounds in general and OL derivatives in particular can act as natural antioxidant in various ways, thus becoming important molecules both for the food stability and the human health [3]. The antioxidant activity in food can be explained by the so-called polar paradox: in



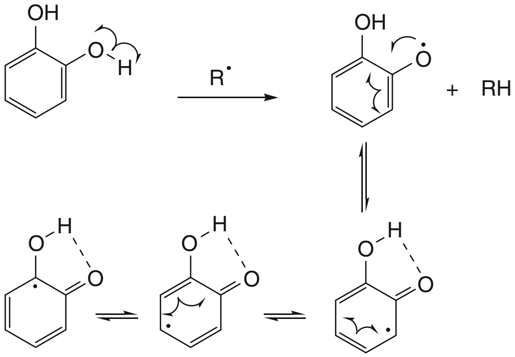
Anti-inflammatory
Antiproliferation
Antioxidant
biological activities
Antimicrobial, Antiviral
OLEUROPEIN and derivatives
Cardiovascular diseases
Neurological diseases
health protection pharmacological effects
Diabetes mellitus
Skin diseases
Cancer

Fig. 119.2 Biological and pharmacological effects of oleuropein and derivatives

a bulk oil system, the hydrophilic antioxidants such as OL derivatives are oriented in the air-oil interface, thus protecting lipophilic molecules against oxidation [113]. Endogenous defense against ROS includes the action of protective enzymes as superoxide dismutase, catalase, and glutathione peroxidase. When the defensive mechanism cannot balance the action of the free radicals, the subsequent cellular damages contribute to the pathogenesis of various diseases, as atherosclerosis and cardiovascular diseases, diabetes mellitus and metabolic syndrome, and skin and neurodegenerative diseases. In addition, the genotoxic effects of ROS have been correlated with the onset of cancer [114, 115]. Both natural and synthetic antioxidants are therefore of great interest for the disease prevention and treatment. The antioxidant activity of phenols in vivo is strictly correlated to their bioavailability, absorption, metabolism, and pharmacokinetics [116]. Depending on their action, the antioxidant can be classified as (a) free radical scavengers and radical chain breaking (primary antioxidants), (b) anti oxygen radicals (reducing and antioxidant molecules), and (c) metal chelators. OL derivatives can cover all of these three roles. They can both break the chain of reaction triggered by free radicals and scavenge the peroxyl radicals thanks to their catecholic structure: the ortho-diphenolic group in the HT moiety has the ability to form intramolecular hydrogen bonds between the hydroxyl group and the phenolic radical (Scheme 119.3). From the study of the resonance structures formed, the ortho-disubstituted radicals have higher stability than the meta-disubstituted and mono-substituted phenols [3].

The antioxidant properties of OL and its derivatives have been demonstrated in several in vitro and in vivo experimental models [7, 108, 109]. A strong chelating

Scheme 119.3 Resonance structures of phenolic radical



effect on metals as iron or cupper has been reported to diminish the appearance of ROS derived from reactions associated with these metals [117, 118]. In addition, the antioxidant activities of OL and HT have also been demonstrated using metal-independent oxidative systems [119] or measuring stable free radicals, such as 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical [120, 121]. In particular, the ability to scavenge or reduce the generation of ROS has been reported in intact leukocytes treated with phorbol 12-myristate 13-acetate as well as in a hypoxanthine/xanthine oxidase cell-free system using a chemiluminescence method to detect ROS generation [103, 122]. Finally, a scavenging effect of OL and HT was demonstrated in a model of hypochlorous acid (HOCl)-mediated inactivation of catalase [103].

Particular attention has been focused on the scavenger ability of inhibiting the process of low-density lipoprotein (LDL) cholesterol oxidation, since it represents a major prevention mechanism against atherosclerosis (see next paragraph). Various experimental evidences, using in vitro and in vivo preclinical models, showed a strong action of both OL and HT [109, 117]. Moreover, OL and HT were able to reduce 5-lipoxygenase-driven cellular recruitment of leukocytes and the damaging consequences of their ability to release ROS while leaving unimpaired the generation of prostaglandins, which promote microvascular blood flow and act as immunomodulators [122].

It has been suggested that protection by HT against oxidative stress is also conferred by the simultaneous activation of two critically important pathways, phase II detoxifying enzymes (a set of enzymes, such as glutathione S-transferase, heme oxygenase-1, NAD(P)H quinine oxidoreductase-1, and γ-glutamyl cysteine ligase, that lead to an increase in levels of endogenous antioxidants) and mitochondrial biogenesis [123]. Recently, Domitrovic et al. [124] have demonstrated that OL, in vivo, induces the antioxidant enzyme heme oxygenase in the liver. This enzyme catalyzes the degradation of heme into iron, carbon monoxide, and bilirubin, the latter of which provided with cytoprotective activity. Interestingly, 3,4-DHPEA-EA has revealed to be even stronger than oleuropein, as antioxidant as well as in other activities [125].

4.2 Anti-inflammatory Activity

The anti-inflammatory effects of olive oil phenolics, and particularly OL and HT, in humans have been described in many studies [7, 108–110]. When added to murine macrophages stimulated with a bacterial lipopolysaccharide (LPS), OL enhanced the functional activity of these immune-competent cells, as evaluated by a significant increase in the production of nitric oxide [126]. This increase was the consequence of a direct tonic effect of OL on the inducible form of the enzyme nitric oxide synthase (iNOS), as demonstrated by Western blot analysis of cell homogenates and by co-incubation of LPS-challenged cells with the iNOS inhibitor L-nitromethylarginine methylester. Also, OL elicited anti-inflammatory effects inhibiting leukocyte lipoxygenase activity and reducing the production of proinflammatory molecule leukotriene B4 [122]. Similarly, Maiuri et al. [127] reported that HT impeded the synthesis of prostaglandin E2 by indirectly blocking the enzymes iNOS and cyclooxygenase (COX)-2. This effect arose from the prevention of the activation of mouse macrophages subsequent to block of transcriptional activation of NF-kB, interferon regulatory factor-1, and transducer and activator of transcription 1. Suppression of COX-2 and iNOS expression was also described in human monocytes treated with HT [128]. To test the anti-inflammatory effect of OL and HT, De la Puerta et al. [129] studied a mouse model with inflammation induced in the ear by arachidonic acid and/or phorbol esters. These researchers found that the topical application of the two phenols inhibited the edematous tissue with a reduction of swelling related to the lower infiltration of neutrophils, as measured by the inhibition of myeloperoxidase. In another in vivo model of acute inflammation induced by intravenous injection of carrageenan, Gong et al. [130] demonstrated that a preparation containing HT (22 %) was able to inhibit both the acute inflammation as well as the pain: the analgesic action was not dose dependent, and levels of mRNA of the inflammatory cytokines interleukin-1β and tumor necrosis factor alpha (TNF-α) lowered without raising those of the anti-inflammatory cytokine interleukin-10 [130]. More recently, to gain insight into the mechanism of action and pharmacological value of OL on the inflammatory bowel disease, Giner et al. evaluated its efficacy in a dextran sulfate sodium-induced colitis in mice, associated with the inhibition of proinflammatory protein expression and release as well as block of NF-κB signaling [131].

Considering the functions of the prostaglandins and leukotrienes, the results of these studies have important implications not only for the genesis of the inflammatory response but also for the thrombotic processes, in particular platelet aggregation (see next paragraph). Thus, HT was found to inhibit in vitro platelet aggregation induced by collagen and thromboxane B2 production [132]. Moreover, González-Correa et al. [133] found a reduction in the synthesis of thromboxane A2 measured by the reduction of its metabolite, thromboxane B2, mainly due to the inhibition of activity of the COX. For these authors, the antithrombotic effects would be caused by decline in the production of vascular prostacyclin, effects similar to those determined by acetyl salicylic acid.

Recently, it has been shown that ligstroside aglycone (oleocanthal) inhibits COX-1 and COX-2 activity in the same way as the anti-inflammatory drug ibuprofen does [134]. Starting from these results, we speculated a similar activity for 3,4-DHPEA-EA, and for this reason, many efforts have been spent in our laboratory to design synthetic protocols that, starting from renewable sources of primary matter and adopting sustainable synthetic strategies, may give rise to biologically more active derivatives of OL [135]. By using a synthetic protocol to obtain 3,4-DHPEA-EA and HT from OL and their acetylated derivatives in good yields and very mild conditions, we demonstrated that peracetylation of OL and its derivatives may improve their capacity to permeate the molecular membrane. HT, peracetylated HT, and 3,4-DHPEA-EA were the strongest inhibitors of COX-1 and COX-2 activity as demonstrated by in vitro test and confirmed in vivo using the carrageenan-induced paw edema [5, 136]. In addition, 3,4-DHPEA-EA ameliorated development of arthritis caused by injection of collagen type II in mice, an effect associated with decreased iNOS and COX-2 expression and reduced levels of prostaglandin E-2, metabolite of COX-2, in the serum of treated mice. Amelioration of joint disease was associated with full inhibition of cytokines as well as of neutrophil infiltration [137]. The anti-inflammatory effect of 3,4-DHPEA-EA was recently demonstrated in the secondary injury associated with the mouse model of spinal cord trauma, in which this treatment significantly decreased histological damage and motor recovery [138]. Again, there was observed inhibition of proinflammatory enzymes COX-2, lipoxygenase, and iNOS and also of phosphoinositide 3-kinase.

Table 119.2 summarizes the molecular mechanisms involved in the anti-inflammatory action of OL, HT, and 3,4-DHPEA-EA.

4.3 Cardiovascular Protection

For decades, research on the health-promoting effects of Mediterranean diet has revealed that olive oil consumption is a key factor in the cardiovascular protection found in Mediterranean countries [139]. It is well established that the healthful properties of olive oil depend mostly on its high oleic acid content. However, many arguments demonstrate that in olive oil there are minor bioactive components, other than oleic acid, responsible for its cardiovascular protective properties: among them, the phenolic fraction of olive oil, and in particular OL and HT, has demonstrated antioxidant, anti-platelet aggregation, vasodilatatory, and anti-inflammatory effects, all involved in this health beneficial action [7, 108–110].

Oxidation of LDL cholesterol is one of the key steps in the initiation of atherosclerotic lesions by promoting injury to the arterial wall through several mechanisms, including growth factor and chemotactic protein expression, inflammation, and increased local macrophages [140]. Visioli et al. [117] have demonstrated that OL and HT strongly inhibit copper sulfate-induced oxidation of LDL, as result of measure of various indexes of lipid oxidation (vitamin E content, formation of thiobarbituric acid-reacting substances, lipid peroxides, levels of

polyunsaturated fatty acids, protein modification, conjugated diene formation). Production of chloramines via the myeloperoxidase-catalyzed formation of HOCl and subsequent chlorination of apoB-100 is an initiating agent in LDL lipid peroxidation [141]. As previously mentioned, OL and HT exert a scavenging effect toward HOCl, and this action, jointly to their protection against oxidation of LDL, plays a role in retarding the onset of the atherosclerotic damage. Postprandial lipemia is a well-known risk factor for atherosclerosis: OL, 3,4-DHPEA-EA, and HT promoted hypocholesterolemia, lowering LDL plasma levels and total cholesterol in rats fed a cholesterol-rich diet; also, they increased high-density lipoprotein levels and antioxidant enzyme activity reducing LDL oxidation [142, 143].

Although reduction of plasmatic cholesterol and LDL is the major mechanism underlying the antiatherogenic action of OL and HT, additional effects are also involved. It is well established that local leukocyte and monocyte recruitment into the vessel wall is an early step in atherogenesis; this event is correlated with the expression in the endothelial cells of adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1) and vascular adhesion molecule-1 (VCAM-1). OL and HT showed capacity to reduce LPS-stimulated expression of VCAM-1 in human vascular endothelial cells inhibiting its mRNA levels. Simultaneously, they were able to decrease monocyte cell adhesion to endothelial cells [144]. Moreover, Dell'Agli et al. [145], investigating the action of OL in TNF-α-stimulated human monocyte cell line, have demonstrated that OL prevents the expression of matrix metalloproteinases (MMP), which contribute to atherosclerotic alteration of the vessels wall.

Platelet aggregation often accompanies and aggravates atherosclerosis development, since the damage to the vascular endothelium stimulates platelet activity and aggregation [146]. Recently, Dell'Agli et al. [147] have reported that OL inhibits platelet aggregation blocking cAMP and cGMP phosphodiesterases. Other anti-aggregate effects of OL and HT derive from their anti-inflammatory action, by reducing the production of eicosanoids derived from arachidonic acid, as result of inhibition of COX enzyme (see previous paragraph).

Analysis of the in vitro effects of OL on vascular smooth muscle cell (SMC) has revealed that OL inhibits proliferation of SMC acting through the extracellular-signal regulated kinase-1/2, an effect that participates in atherogenesis progression [148].

Furthermore, direct effects on myocardiocytes have also been reported. Manna et al. [149] analyzed OL effects in myocardial injury induced by ischemia, measuring in isolated rat heart perfused with OL before induction of ischemia the levels of creatine kinase, a biochemical marker of cellular damage, and oxidize glutathione, a marker of heart's exposure to OS and a key factor in the pathogenesis of atherosclerosis. OL significantly decreased levels of both markers suggesting a cardioprotective effect in the acute events that follow coronary occlusion. The impact of OL has been studied also in vivo in normal and hypercholesterolemic rabbits subjected to ischemia and reperfusion [150]. Treatment with OL for 3 or 6 weeks considerably reduced the infarct size in normal rabbits subjected to regional ischemia followed by reperfusion, while a higher dose reduced the infarct size. In this experimental model, OL protection of reperfused myocardium was associated with decreased total cholesterol and triglyceride levels. Finally, the cardioprotective effects of HT have been supported in a study conducted with cardiomyocytes extracted from rats treated with this phenol, in which administration of HT reduced the expression of proteins related to aging as well as the infarct size and cardiomyocyte apoptosis [151].

4.4 Antidiabetic Activity

A protective role for OL extracted from olive leaves against diabetic disease was first postulated by Gonzalez et al. in the early 1990s [152]. In that study, the hypoglycemic effect of OL in animals with alloxan-induced diabetes was attributed to a potentiation of glucose-induced insulin release and parallel increased peripheral uptake of glucose [152]. Subsequent studies evidenced a stronger link of the antidiabetic action with the antioxidant effects of OL. The role played by OS for diabetes complications such as retinopathy, nephropathy, and coronary heart disease is well established, so that the use of dietary antioxidant compounds was able to protect from the damages of oxidative stress and free radicals in diabetic patients [153].

In animal experimental models of alloxan-induced diabetes, both antioxidant and hypoglycemic effects of OL have been demonstrated. By treating alloxan-diabetic rabbits with 20 mg/kg body weight of OL for 16 weeks, Al-Azzawie and Alhamdani [154] found a significant decrease of blood glucose levels as compared with diabetic control rabbits. Such a hypoglycemic activity was related to its strong antioxidant potential: in fact, in parallel, the rabbits treated with OL showed also restoration of the levels of malondialdehyde and most of the enzymatic and nonenzymatic endogenous antioxidants [154]. A direct interaction of OL with free radicals was proposed as a possible explanation of this activity (see previous paragraph). Similar results were obtained in alloxan-diabetic rats: the administration, for 4 weeks, of OL- and HT-rich extracts exhibited significant hypoglycemic, hypolipidemic, and antioxidant effects in all of the tested diabetic rats [155]. In a similar experimental model, HT caused a decrease in glucose level in plasma and an increase in superoxide dismutase, catalase, and glutathione peroxidase activities in liver and kidney. Furthermore, a protective action against hepatic and renal toxicity in diabetic rats was also observed [156]. A close relationship between antioxidant and hypoglycemic activity of olive leaf extracts (OLE) was confirmed by Poudyal et al. [157] using a high-carbohydrate, high-fat diet-induced model of the metabolic syndrome in rats. Supplementation with OLE containing polyphenols such as OL and HT improved glucose tolerance and normalized abdominal fat deposition as well as plasma triglyceride and total cholesterol concentrations. Such effects were accompanied by reduced plasma uric acid and malondialdehyde concentrations, therefore suggesting a decrease in OS.

Recently, the effects of olive leaf polyphenols have been investigated also in insulin-secreting pancreatic β-cells, whose OS-induced alterations contribute to the pathogenesis of diabetes [158]. Cumaoglu et al. [159, 160] found that OL significantly suppressed cell death induced by cytokine- or H_2O_2-mediated apoptosis and/or necrosis and was able to inhibit ROS generation and to preserve insulin secretion in INS-1 cells. These effects were accompanied by the maintenance of intracellular glutathione content and the activity of antioxidant superoxide dismutase suggesting an involvement of the preservation of redox homeostasis in the protective action [159, 160].

An additional molecular mechanism of the protective action of OL against diabetes has been recently revealed by Rigacci et al. [161]. Using a rat insulinoma cell model, they demonstrated the ability of 3,4-DHPEA-EA to inhibit cytotoxic amyloid aggregation of amylin, a hallmark of type II diabetes. Moreover, by using gene expression profiling analysis in the liver of obese mice treated with OL, Kim et al. have found that the hepatic mRNA levels of lipocalin 2 (LCN2) (0.33-fold) were downregulated in the livers of the OSD-fed mice [162]. Since a recent study suggested that LCN2 deficiency protects mice from developing aging- and obesity-associated insulin resistance and hyperglycemia [163], the effect on this protein may represent an additional target of OL action.

4.5 Anticancer Activity

For a long time, the polyphenols of the olive oil of the diet have been considered to play a role for the prevention of certain types of cancer in the Mediterranean countries [164, 165]. Even more than in olive oil, constituents present in OLE have shown strong antioxidant potency and inhibition of cancer cell proliferation, thus suggesting the protection against the genotoxic action of the ROS as one of the mechanisms explaining the anticancer effects of these compounds. Indeed, either OLE or the isolated constituents OL, HT, and HT acetate exerted free radical scavenging activity and growth inhibition at low micromolar concentration on human breast cancer and urinary bladder carcinoma cells [166]. Such findings were further confirmed by other in vitro reports, testing the effects of OL or HT against human cancer cell lines [167–170]. Furthermore, Hamdi et al. demonstrated a regression of tumors caused by orally administrated OL in mice that developed spontaneous soft tissue sarcomas [171].

Several in vitro experiments support an action of OL or HT on diverse molecular pathways involved in human tumorigenesis; growth inhibition has in fact been associated with (a) induction of apoptosis [167, 172–177]; (b) upregulation of cyclin-dependent protein-kinase inhibitors $p21^{WAF/Cip1}$ and $p27^{Kip1}$ [178]; (c) blockage of messengers of pathways involved in cell proliferation, as inhibition of ERK1/2 activation [179], depletion of HER2 and reduction of its tyrosine autophosphorylation [180], and inhibition of fatty acid synthase enzyme [181]; and (d) inhibition of angiogenesis [182]. Interestingly, as for the antioxidant effect, 3,4-DHPEA-EA has shown a stronger activity than OL, when tested on cancer cells of various origins [168, 183, 184]. Moreover, semisynthetic peracetylated derivatives of OL and HT were also more effective to inhibit the growth of two breast cancer cell lines [185]. Finally, another mechanism active for cancer cell growth inhibition may derive from HT metabolism and interaction with hydrogen peroxide: production of catechol quinones, in fact, exerts anticarcinogenic properties, probably through the inhibition of NF-kB [186]. It must be remembered that, although very promising as anticancer agents, at present only one study [171] demonstrated the in vivo effectiveness of these compounds in blocking tumor proliferation.

4.6 Protection Versus Infectious Diseases

For thousands of years, folk medicine has used olive leaf for the treatment of infections. Such protective properties have been confirmed by several studies performed in the last decades using OLE [187] or isolated compounds [188–190]. Gram-positive and Gram-negative bacteria, as well as mycoplasma and also *Toxoplasma gondii*, resulted sensitive to the antiproliferative action of OL and its derivatives [188–192]. At present, the exact mechanism responsible for the antimicrobial activity of OL is still not completely clarified, although an interaction with the bacteria membrane determining a disruption of cell peptidoglycans involving the ortho-diphenolic system (catechol) of the molecule has been suggested [190].

Effective interference with the protein synthesis by altering the production of amino acids necessary for the growth of specific microorganisms has also been proposed [7]. Alternatively, nonspecific antimicrobial effects may derive from the direct stimulation of phagocytosis resulting from the activation of the immune system [7].

OL and its derivatives have demonstrated strong in vitro antimicrobial activity against several strains of bacteria causing intestinal and respiratory diseases. In fact, they were able to inhibit the development and production of enterotoxin B by *Staphylococcus aureus* [193, 194], the development of *Salmonella enteritidis* [195, 196], and the germination and consequent growth of spores of *Bacillus cereus* [197]. OL and other phenolic compounds completely inhibit the development of *Klebsiella pneumoniae, Escherichia coli*, and *Bacillus cereus* [189]. Interestingly, a synergistic growth inhibition effect of OL against *Salmonella enteritidis* has been reported when mixed with other phenolic compounds contained in olive leaves, as probably occurring in vivo [196].

Also, antiviral effects have been described for OL, and a US patent claims for a possible use of OL against herpes mononucleosis, hepatitis virus, rotavirus, bovine rhinovirus, canine parvovirus, and feline leukemia virus infections [198]. Antiviral activity of OL has been reported against respiratory syncytial virus and parainfluenza type 3 virus [199]: interestingly, in this study, the antiviral effects were not correlated with the antioxidative potency. Finally, OL and HT inhibition of cell-to-cell transmission of human immunodeficiency virus (HIV) as well as block of in vitro HIV replication has been reported [200, 201]. In the latter study, computational analysis complemented the corresponding experimental investigation proposing a direct interaction between OL and the HIV-1 surface glycoprotein subunit gp41, which is responsible for HIV entry into normal cells [201].

4.7 Neuroprotective Activity

As a consequence of their antioxidant and cardioprotective activity, including antiatherogenic and hypocholesterolemic effects, OL and its derivatives result effective also for protection against human neurodegenerative disease. In fact, a close link does exist between cardiovascular diseases caused by abnormal accumulation of metabolites like cholesterol and/or amyloid beta peptide (Aβ) and Alzheimer's disease (AD), so that modulation of such metabolites represents an outcoming therapeutic strategy currently explored even in this disorder [202, 203]. Furthermore, also inflammatory processes are clearly involved in the clinical manifestations of AD [204]. In this context, OL and HT have been proven to interact with Aβ preventing its aggregation [205, 206], thus protecting neural cells against Aβ-induced toxicity [207]. In addition, HT, OL, and 3,4-DHPEA-EA were able to prevent Tau aggregation into fibrillary tangles, an alteration proposed for playing a causative role in AD neurodegeneration [208]. Finally, neuroprotective effects of OL [209] and of 3,4-DHPEA-EA [138] were recently demonstrated in an experimental model of spinal cord injury. Further studies will clarify whether a neuroprotective action may be effective even against other neurodegenerative disorders (Parkinson's disease, vascular dementia, schizophrenia).

4.8 Skin Protection

The OL action as a free radical scavenger has opened the way to investigation of its protective effects also at the skin level. After the early report of Budiyanto [210] who demonstrated a protective effect of topically applied olive oil against photocarcinogenesis following UVB exposure of mice, a direct antioxidant action of OL on skin was first reported by Ancora et al. [211]. Subsequently, Perugini et al. [212] described the lenitive property of OL against UVB-induced erythema, suggesting a utilization in association with other active ingredients in cosmetics to repair UV damages. By using male hairless mice exposed to UVB irradiation, Kimura and Sumiyoshi [213] found that OL administered orally significantly inhibited increase of skin thickness and reduction of skin elasticity, as well as skin carcinogenesis and tumor growth, and that such an effect was associated with inhibition of the expression of VEGF, MMP-2, MMP-9, and MMP-13 through a reduction in COX-2 levels. The same authors confirmed such finding in another experimental model, proposing that the preventive effects on UVB-induced skin damage might be caused in part by inhibiting the degradation of extracellular matrixes in the corium and the proliferation of epidermal cells through reduction of MMP-13 and ROS levels induced by irradiation [214]. Interestingly, a set of HT conjugates with fatty acids at different molecular weights, synthesized under mild conditions, have shown optimal topical delivery features as a function of their permeation profiles through the human stratum corneum and viable epidermis membranes, appearing as novel promising agents in both anti-inflammatory and antioxidant topical therapies [215].

5 Conclusions

The beneficial health effects of olive oil phenolic compounds have also been proven by many randomized, crossover, controlled, human studies on biomarkers of health performed in the last years [165]. Several preclinical studies suggest that such beneficial effects may be mainly ascribed to the phenolic compounds OL and HT. However, at present, there are not final reports of studies using direct administration of OL or HT on humans; animal studies demonstrated an absolute absence of both acute and subchronic toxicity [106, 216], although it has been reported that OL may undergo CYP3A-mediated oxidation to reactive metabolite(s) capable of binding and inactivating CYP3A4, acting as inhibitor of androstenedione 6 beta-hydroxylase activity [217, 218].

With the demonstration of the intraluminal stability of OL in human gastric and small-intestinal contents [219] and considering their high bioavailability, attempts to enrich the olive oil with isolated/purified phenolic compounds are in progress [220].

In this regard, however, it should be taken into consideration, in addition to the evaluation of the phenolic content, also other important factors such as the feasibility of implementing the preparation process in the food industry. Noteworthy, recent results obtained with 3,4-DHPEA-EA or some semisynthetic derivatives [64, 185] suggest that attempts to improve the effects of OL by modifying the molecule to increase some advantageous pharmacological properties (stability, bioavailability) represent promising strategies in view of therapeutic use of these compounds. Further studies are necessary to better define the in vivo effects of individual OL derivatives used as single agents or in mixture, including their safety profile on humans. Moreover, a better characterization of their molecular mechanism of action may open the way to a larger utilization in human pharmacology.

Abstract

Bacosides are the putative bioactive component of the Indian medicinal plant *Bacopa monnieri* which was placed second in the most important medicinal plants' list by the Export-Import Bank of India. Among the bacoside components, bacoside A was found to be more pharmacologically active than bacoside B. Traditionally, *Bacopa* has been used in ayurvedic medicines as a cure for mental disorders and loss of memory. Later on, other pharmacological properties like antioxidant, antidepressant, antiulcer, hepatoprotective, anticancerous, vasodilator, smooth muscle relaxant, mast cell stabilizer, and various other functions are revealed. Increasing clinical trials indicate the potential role of bacosides even in Alzheimer's disease and in epilepsy. Bacosides attribute to the neuroprotective function mainly through modulating antioxidant enzymes, namely, SOD, catalase, etc. Bacosides also regulate the levels of different neurotransmitters in the brain. Interestingly, bacosides do not exert any side effects as proven both in animal models and in human volunteers. These features render *B. monnieri* as well as bacosides pharmacologically immensely important.

SOD	Super oxide dismutase

1 Introduction

Bacosides are the mixture of different triterpenoid saponins isolated from the plant *Bacopa monnieri* Linn., traditionally known for its immense therapeutic value. In ayurvedic medicine in India, it has been used for almost 3,000 years and is classified as medhya rasayana, a drug used to improve memory and intellect (medhya). On the basis of their medicinal importance, commercial value, and potential for further research and development, *B. monnieri* was placed second in a priority list of the most important medicinal plants by the Export-Import Bank of India. Bacoside A and bacoside B are the major bacosides found in *B. monnieri*. Bacoside A and bacoside B were elucidated as mixtures of triglycosidic and diglycosidic saponins, respectively. Bacoside A fraction was found to be more biologically active compounds.

B. monnieri is a rich source of many secondary metabolites, namely, alkaloids, glycosides, flavonoids, and triterpenoid saponins (Fig. 120.1). Although different triterpenoid compounds are well distributed in plant kingdom, *B. monnieri* (popularly known as Brahmi) is the only herbal source of bacosides. *B. monnieri* is a herbaceous plant, belongs to the family Scrophulariaceae, and grows naturally in the Indian subcontinent. Authentic ayurvedic treatise like Charaka Samhita and Sushruta Samhita, written in the first century AD, prescribed Brahmi as a cure for mental disorder leading to insanity and also beneficial in loss of intellect and memory [1]. Brahmi is recommended in formulations for the management of a range of mental conditions including anxiety, poor cognition, and lack of concentrations [2]. Besides this, it has the potential to act as antioxidant [3], antidepressant [4], antiulcer [5], hepatoprotective, anticancerous [6], Ca^{+2} antagonist, smooth muscle relaxant [7], vasodilator [8], and mast cell stabilizer [9].

Bacosides are most popular for their effect on nervous system mainly because of their neuroprotective activities. Neuroprotection signifies the mechanisms and strategies used to protect neuron from degeneration or malfunctioning. Various factors may involve in neuron malfunction (Fig. 120.2). Some of these factors are neuronal injury, exposure to chemical agents, adverse physiological conditions, and different disorders or diseases either decreasing efficiency of proper nervous

functions or causing degeneration of neuron. These factors are finally affecting the normal functions of the central nervous system (CNS) in various ways.

The goal of neuroprotection is to limit neuronal malfunction or to prevent neuronal death and to maintain the highest possible integrity of cellular interactions in the brain resulting in an undisturbed neural function. There is a wide range of chemical agents available or under investigation, which can potentially be used as neuroprotectant. An immunosuppressive calcineurin inhibitor, NOS inhibitor, σ-1 modulator, AMPA antagonist, and Ca^{2+} channel blocker have all demonstrated to show neuroprotective activity. An estrogen agonist and two glycoprotein IIb/IIIa antagonists also exhibit neuroprotective activity [10]. Effect of different neuroprotective agents can be achieved by different ways, as shown in the Fig. 120.3.

Bacosides have been experimentally shown to act as anti-inflammatory agents and free radical scavengers through modulating antioxidant enzymes. Recent studies revealed that bacosides also facilitate proper functioning of CNS through GABA receptor function regulation in the cerebellum, inhibition of acetylcholinesterase, and enhancement of kinase activity in damaged neurons. Unlike other synthetic

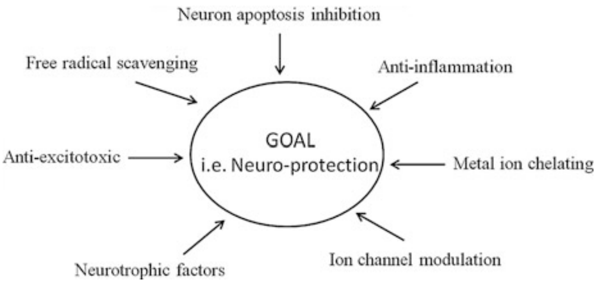

Fig. 120.3 Various strategies to achieve neuroprotection

neuroprotective drugs, bacosides show no apparent toxic effect in experimental animal models as well as in human volunteers. Bacosides are also shown to stimulate thyroxin hormone secretion, have protective function against gastric ulcer, and even have potential to be used as anticancerous agent.

2 Pharmacological Applications

Bacosides are well known for their neuropharmacological effects. Most of the studies on the pharmacological properties were made with the alcoholic extract of whole plant of *Bacopa monnieri* which chiefly constituted of bacosides A and B [1].

2.1 Memory-Enhancing Ability of Bacosides

B. monnieri extract (BME) has been traditionally used in ayurvedic medicine for the treatment of a number of memory-related disorders, particularly those involving intellect and poor memory [1]. Although bacosides A and B were reported to be active in facilitating effects on learning schedules [11], later on it was found that bacoside A alone was responsible for the facilitation of memory [12].

Bacosides promote the capacity for mental retention and were active in both positive and negative reinforcement experiments [13]. Bacosides are also reported to enhance retention of newly acquired information [14]. Kishore and Singh [15] described that bacosides facilitate anterograde memory and attenuate anterograde experimental amnesia induced by scopolamine and sodium nitrite possibly by improving acetylcholine level and hypoxic conditions, respectively.

2.2 Protective Role of Bacosides in Chronic Cigarette Smoke

Bacoside A was observed to exhibit protective role against chronic cigarette smoke. Cigarette smoke exposure disturbs the tissue defense system by enhancing oxidative stress, inducing mitochondrial dysfunction and membrane damage. Bacoside A works by exerting antioxidant role and maintaining level of trace elements like copper, zinc, and selenium [16]. Moreover, bacoside A maintains the structural and functional integrity of the mitochondrial membrane potential and impulse propagation which depends on membrane enzymes. Disturbances in the electrolyte balance due to cigarette smoke also contribute to membrane damage in brain. Anabarasi and coworkers [17] reported that bacoside A inhibits lipid peroxidation, improves the activities of ATPase, and maintains the ionic equilibrium.

2.3 Antioxidant Properties

The brain is extremely vulnerable to oxidative stress mainly because of abundance of nonheme iron in brain, which involves in the catalysis of oxygen free radical production. Besides, brain also possesses a relatively high amount of polyunsaturated fatty acids that are particularly good substrates for peroxidation reactions [18].

Antioxidant properties of bacoside A were studied by S. K. Bhattacharya [3], and he showed that it increases the activities of antioxidant enzymes like superoxide dismutase (SOD), catalase, and glutathione peroxidase in the brain. The results also suggested that the increase in oxidative free radical scavenging activity of bacosides may be associated with cognition-facilitating action. Such cognition-enhancing effects of bacosides were revealed by Vohra et al. [19] and Stough et al. [20]. Both acquisition and retention of memory improvement was found to be associated with bacoside treatment, and the observed cognitive effects were noted to be independent of motor stimulation [19]. The later group of scientists suggested that the bacosides may improve higher-order cognitive processes that are critically dependent on the input of enforcement from the environment such as learning and memory.

2.4 Antistress Effect of Bacosides

Antistress effect of bacosides was studied by Shukia et al. [21] and Sheikh et al. [22]. The first group demonstrated that bacosides of *Bacopa monnieri* have been postulated to modulate the activities of Hsp70, cytochrome P450, and SOD allowing the brain to be prepared to act under adverse condition such as stress. The later group showed that treatment with bacosides attenuated the stress-induced changes in levels of serotonin and dopamine in cortex and hippocampus regions. The adaptogenic activity of bacosides might be due to the normalization of stress-induced changes in plasma corticosterone and levels of monoamines like noradrenaline, dopamine, and serotonin in cortex and hippocampus region of brain.

2.5 Bacosides as Remedy for Epilepsy and Cognitive Dysfunctions

BME has been indicated as a potential remedy for epilepsy in ayurvedic medicine. Bacoside A was reported to have beneficial effect on epilepsy-associated behavioral deficits [23]. High doses of BME were reported to exhibit anticonvulsive effect.

Hypobaric hypoxia-induced memory impairment has been attributed to several factors including increased oxidative stress, depleted mitochondrial bioenergetics, altered neurotransmission, and apoptosis. Hota et al. [24] expressed that administration of bacosides could be a useful therapeutic strategy in ameliorating hypobaric hypoxia-induced cognitive dysfunctions and other related neurological disorders.

2.6 Other Neuropharmacological Applications

Neuroprotective effect of bacosides was reported by Jyoti and group [25] against aluminium-induced changes in peroxidative products such as thiobarbituric acid-reactive substances and protein carbonyl contents and SOD activity. It was clearly observed that bacoside significantly prevented the aluminium-induced decrease in SOD activity as well as the increased oxidative damage to lipid and proteins. Neuroprotective effects of bacosides were shown to be comparable to those of l-deprenyl at both biochemical and microscopic levels.

It was found to have antidepressant activity and was comparable to that of standard antidepressant drug imipramine [4]. Bacoside was also known to possess potent adaptogenic property.

The role of bacosides on prevention of Alzheimer's disease has been exclusively studied by Holcomb et al. [26] and Singh et al. [27] concluding that these compounds have potential application in Alzheimer's disease. Anxiolytic activity of bacosides is also well established.

3 Mechanism of Action

Action of drugs is the biochemical and physiological mechanisms by which the chemical produces a response in living organisms. One major problem of pharmacology is that majority of the drugs produce single effect. The primary effect is the desired therapeutic outcome, and the secondary effects are all other consequences other than the desired effect which may be either beneficial or harmful (popularly known as side effects). The biological effects observed after a drug has been administered are the result of an interaction between that chemical and some part of the organism. Mechanisms of drug action can be viewed from different perspectives, namely, the site of action, the general nature of the drug-cell interactions, etc.

The bacosides aid in repair of damaged neurons by enhancing kinase activity, neuronal synthesis, and restoration of synaptic activity. Ultimately, nerve impulse transmission is relived, and a boost in the synthesis of new proteins in the brain is also observed [1].

Bacosides express antioxidant effect by increasing SOD, catalase (CAT), and GPx activities in all brain regions [3]. Bacoside A has a protective activity against nicotine-induced toxicity by reducing lipid peroxidation (LPO) and restoring SOD (superoxide dismutase), CAT, GSH, ALP, and GST levels [28], protecting the brain from damage by maintaining the structural and functional integrity of the

mitochondrial membrane, inhibiting lipid peroxidation, improving the activities of ATPases, and maintaining the ionic equilibrium [17]. Figure 120.4 summarizes mechanism of oxidative damage on nerve cell. Neuroprotective activity of bacosides is mainly attributed to its ability to scavenge ROS.

Bacosides exhibit antistress effects modifying Hsp70 expression, superoxide dismutase, and cytochrome P450 activity in rat brain. During stressed condition, Hsp70 expression and cytochrome P450–dependent 7-pentoxyresorufin-o-dealkylase (PROD) and 7-ethoxyresorufin-o-deethylase (EROD) activity increase in all brain regions. As a result, the activity of SOD was found to decrease for lower dose of bacosides but increase for higher dose [29].

Bacosides have a positive effect in Alzheimer's disease. The levels of acrolein (one of the by-products of lipid peroxidation) and amyloid β peptide are much higher in vulnerable brain regions of the patients. This toxicity is due to oxidative stress generation in brain region. BME pretreatment significantly reduces intracellular reactive oxygen species (ROS) generation in the human neuroblastoma cell line SK-N-SH. Additionally, it preserves the mitochondrial membrane potential and activity of several redox-regulated proteins, i.e., NF-kappa β, Sirt1, ERK1/2, and p66Shc, to support cell survival in response to oxidative stress [27].

Shukia B. and coworkers [21] suggested that bacosides protect central nervous system from the nociceptive effect, electroshock seizures, and chemoconvulsions through GABAergic system. Additionally, Das et al. [30] showed that bacosides exert inhibitory effect on acetylcholinesterase activity and anti-dementia properties.

Bacosides have different effects on acute stress (AS)- and chronic unpredictable stress (CUS)-induced changes in plasma corticosterone and monoamines – noradrenaline (NA), dopamine (DA), and serotonin (5-HT) – in cortex and hippocampus regions of brain in rats. AS significantly elevates plasma corticosterone and 5-HT levels in both the brain regions, while DA content significantly increases only in cortex region. On the contrary, AS decreases NA content in both the brain regions and DA content in hippocampus regions. However, treatment with BME lowered the plasma corticosterone levels and increased the levels of 5-HT in both brain regions and DA in cortex. But it decreases DA in hippocampus regions and is also unsuccessful in normalizing the NA levels. CUS causes significant increase in plasma corticosterone levels and decrease in NA, DA, and 5-HT in cortex and hippocampus regions of rat brain. In summary, bacoside treatment weakens the stress-induced changes in levels of 5-HT and DA in cortex and hippocampus regions [22].

Bacosides were found to have a protective effect on morphine-challenged liver toxicity in rats. Also, it protects liver by controlling antioxidant enzyme levels [31].

4 Toxicity

In experimental studies, bacosides did not show any endocrine, metabolic, gastrointestinal, anabolic, or behavioral side effect; no lethality was observed on the oral administration also. Phase I clinical studies confirmed the safety of the bacosides in healthy male volunteers at both single and multiple doses administered over a period of 4 weeks [1]. In addition, bacosides showed no adverse effect on reproductive system in male mouse [32].

5 Bioavailability and Metabolism

Sivaramakrishna et al. [33] used column chromatography to obtain 12 pure saponin compounds from hydroalcohol extract of *B. monnieri*. Figure 120.5 represents all the saponins reported from *B. monnieri*. Table 120.1 compiles the chemical names of different saponins.

The neuroprotective actions of *B. monnieri* are mainly attributed by bacosides, which are dammarane type of triterpenoid saponins [34]. Bacosides were initially thought to be the mixture of bacoside A (melting point 250 °C) and B (melting point 203 °C). But later on, it was revealed that they are the stereoisomers of the same compound, where bacoside A was found levorotatory and bacoside B dextrorotatory [35]. The other active agents as extracted from this medicinal plant, namely, bacopasaponins A, B, C, D, E, and F [36] and also bacopasides I, II, III, IV, and V, were isolated and characterized [37, 38]. Figure 120.6 depicts chemical structures of some important saponins obtained from *B. monnieri*.

Bacoside A and B fractions were further enriched and elucidated as mixtures of triglycosidic and diglycosidic saponins, respectively. Bacoside A fraction

Saponins are a class of triterpene (C_{30}) glycosides, produced by many plant species as secondary metabolite. Like most triterpenoid compounds found in adaptogenic plants, saponins possess an aglycone (glycoside-free) portion, termed as sapogenins, along with various sugar molecules attached to the triterpene unit [39]. Glucose and arabinose are the glycone part, whereas jujubogenin and pseudojujubogenin are the aglycone part in the saponins obtained from *B. monnieri*.

Terpenoids are classified by the number of five-carbon units they contain like hemiterpenes (C_5), monoterpenes (C_{10}), sesquiterpenes (C_{15}), diterpenes (C_{20}), triterpenes (C_{30}), tetraterpenes (C_{40}), and polyterpenes (more than 8 isoprene units). All terpenoids are derived by repetitive fusion of branched five-carbon units based on isopentane skeleton, i.e., isoprene units. At suitable chemical conditions, isoprene undergoes polymerization to generate numerous terpenoid skeletons.

At the turn of the twentieth century, structural investigations of many terpenoids led Otto Wallach to formulate the “isoprene rule,” which postulated that most terpenoids could be constructed hypothetically by repetitively joining isoprene units. This principle provided the first conceptual framework for a common structural relationship among terpenoid natural products. Wallach’s idea was refined in

the 1930s when Leopold Ruzicka formulated the “biogenetic isoprene rule,” emphasizing mechanistic considerations of terpenoid synthesis in terms of electrophilic elongations, cyclizations, and rearrangements. This hypothesis ignores the precise character of the biological precursors and assumes only that they are “isoprenoid” in structure. As a working model for terpenoid biosynthesis, the biogenetic isoprene rule has been proved to be essentially correct [40].

Despite great diversity in form and function, the terpenoids are unified in their common biosynthetic origin. The biosynthesis of all terpenoids from simple, primary metabolites can be divided into four overall steps: (a) synthesis of the fundamental precursor IPP; (b) repetitive additions of IPP to form a series of prenyl diphosphate homologs, which serve as the immediate precursors of the different classes of terpenoids; (c) elaboration of these allylic prenyl diphosphates by specific terpenoid synthases to yield terpenoid skeletons; and (d) secondary enzymatic modifications to the skeletons (largely redox reactions) to give rise to the functional properties and great chemical diversity of this family of natural products. As bacosides are triterpenoid derivatives, they may probably follow the common biosynthetic pathway of terpenoid production [40].

Proper metabolic pathways that lead to the biosynthesis of bacosides are still not known. But most likely, as soon as the aglycone triterpenoid part is synthesized,

the glycone part of the bacosides is then added to the aglycone part to yield different types of saponin molecules.

The following mechanism was proposed by James and Dubery [41] for the catabolism of bacosides. The sugar part of bacosides can easily be cleaved off in the gut by bacteria, allowing the aglycone (triterpene) to be absorbed. This allows them to be inserted into cell membranes and subsequently influence membrane fluidity, which can potentially affect many signaling pathways.

6 Other Biological Activities

6.1 Anti-inflammatory Role of Bacosides

Mast cells play a key role in the inflammatory process. A mast cell quickly releases its granules and various hormonal mediators into the interstitium when activated. Mast cell stabilizers are cromone medications (cromones prevent and relieve swelling of the airways and buildup of mucus. These are used to prevent asthmatic conditions) used to prevent or control certain allergic disorders. They block a calcium channel essential for mast cell degranulation, stabilizing the cell and thereby preventing the release of histamine and related mediators. Bacosides exhibit anti-inflammatory actions by stabilizing mast cells and inhibiting superoxide release from polymorphonuclear (PMN) cells [42].

6.2 Protective Effect of Bacosides Against Heart and Kidney Damage

B. monnieri along with four other herbs shows a considerable reduction of serum markers of heart and kidney damage. In addition, a decrease in lipid peroxidation with a concomitant increase in the enzymatic (SOD and CAT) and nonenzymatic antioxidants (reduced glutathione) suggested a protective effect against both damaged heart and kidneys [43]. Also, *B. monnieri* possesses broncho-vasodilatory activity, which is mainly characterized by interference with calcium ion movement [8].

6.3 Protective Role Against Gastric Ulcer

Bacoside A has a curative as well as protective effect in gastric ulcer. Sairam and coworkers [44] showed dose-dependent antiulcerogenic effect on various gastric ulcer models promoted by ethanol, acetic acid, aspirin, etc. This effect is due to increased mucin secretion and decreased cell shedding in stressed animals. But the extract does not have any effect on acid-pepsin secretion or cell proliferation. Bacosides were also shown to possess antimicrobial activity against *Helicobacter pylori*, a bacterium responsible for chronic gastric ulcers in vitro [45]. Accumulation of well-known protective agent for gastric mucosa, namely, prostaglandin E and prostacyclin, was also noted when *H. pylori*–infected human colonic mucosa cells were incubated with BME [45].

6.4 Bacosides Stimulate Thyroid Hormone Secretion

High doses of bacosides were found to increase thyroid hormone T4, but T3 remained unaffected. This data indicates that bacosides have the potential to induce thyroid stimulation, but probably they have no role in T4 to T3 conversion. Interestingly, this enhanced T4 secretion took place without increasing hepatic lipid peroxidation (LPO). This property of the extract suggests that it can be used as a thyroid-stimulating drug [46].

6.5 Potential Use as Antifertility Agent

Antifertility potential of bacosides has recently been demonstrated. In male mice, bacosides were shown to induce reversible suppression of spermatogenesis and fertility without causing toxic effect [32].

6.6 Anticancerous Property

Elangovan et al. [6] conducted in vitro studies on the anticancer activity of *Bacopa* extract. They saw that bacosides have cytotoxic activity for sarcoma-180 cells. This might be due to inhibition of DNA replication induced by bacosides in the cancerous cell line. Besides, in vitro studies demonstrated protective role of *B. monnieri* against DNA damage in astrocytes [47] and fibroblasts [48], which protects them from becoming cancerous.

7 Clinical Trials

Clinical trials are a set of procedures in medical research and drug development that are conducted to allow safety (or information about adverse drug reactions and adverse effects of other treatments) and efficacy data to be collected for health interventions (e.g., drugs, diagnostics, devices, therapy protocols). These trials can take place only after satisfactory information has been gathered on the quality of the nonclinical safety, and health authority/ethics committee approval is granted in the country where the trial is taking place. Clinical trials have different phases like phase I, phase II, phase III, and phase IV. After completion of different phases of clinical trial, a potential drug is available in markets for public use.

7.1 On Antioxidant Properties

It is reported that different salts of aluminium caused oxidative damages of lipids, proteins, and nucleic acids. Jyoti et al. [25] experimentally demonstrated that BME at a dose of 40 mg/kg/day shows similar antioxidant properties like l-deprenyl, a standard drug against $AlCl_3$ toxicity, in 8-month-old male Wistar rats. The extract significantly protects lipid and protein in cerebral cortex of rat brain from damage. It also restored the activity of endogenous antioxidant enzymes associated with aluminium administration. It extensively inhibits intraneuronal lipofuscin accumulation and necrotic alteration in the CA1 region of the hippocampus of rat brain [25].

Chronic cigarette smoke exposure also disturbs the tissue defense system by enhancing oxidative stress. Anbarasi and coworkers [16, 17] showed that when adult male albino rats and male Wistar albino rats were exposed to cigarette smoke for a period of 12 weeks, it induced mitochondrial dysfunction in rat brain by the production of ROS molecules. For assay of mitochondrial functional capacity, they used lipid peroxides, cholesterol, phospholipid levels, cholesterol/phospholipid (C/P) ratio, and the activities of isocitrate dehydrogenase, alpha-ketoglutarate dehydrogenase, succinate dehydrogenase, malate dehydrogenase, NADH dehydrogenase, and cytochrome c oxidase as a marker. Aqueous extract of *Bacopa monnieri* also protects from nicotine-induced toxicity by reducing lipid peroxidation (LPO) and restoring SOD (superoxide dismutase), catalase, GSH, ALP, and GST levels in mice liver [28].

When rats are administered with bacoside A (10 mg/kg), levels of glutathione, vitamin C, vitamin E, and vitamin A were reduced. The activities of superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase were also assayed. Copper, iron, zinc, and selenium levels in brain and serum ceruloplasmin activity were also measured. Administration of bacoside A improved the antioxidant status and maintained the levels of trace elements [16].

7.2 On Cognitive Function

One of the significant effects of bacosides is to improve higher-order cognitive processes in human beings. Cognition helps people to function in day-to-day life. It includes concentrating, learning, strategizing, executing plans, comprehending language, etc. When it failed to work properly, people find difficulties in processing information quickly, remembering or recalling information, paying attention in work, solving problems, etc.

Stough and coworkers [20] studied the effect on a double-blind, placebo-controlled independent group. Subjects were indiscriminately assigned to one of two treatment conditions, ethanolic extract of *B. monnieri* (300 mg) or placebo. Neuropsychological status was monitored pre- and postdrug administration. Subjects were tested for speed of visual information processing, learning rate and memory consolidation, and state anxiety. Treated subjects were significantly improved above neurophysiological conditions compared to placebo.

Bacoside's capacity to improve cognitive effect has also been studied in Indian children. Tests were performed on 40 children (ages between 6 and 8). Children were grouped into control and treated. One teaspoon *Bacopa* syrup (350 mg *Bacopa* powder/teaspoonful) three times daily for 3 months was given to the children undergoing treatment. Visuomotor and perceptual abilities and memory span were measured before and after the treatment. Major improvements were noted in perceptual images of patterns, increased perceptual organization, and reasoning ability [49].

Another trial was done by another group of scientists to prove cognitive effect of bacoside. A double-blind, randomized, placebo-controlled trial was performed on 36 children with diagnosed attention deficit/hyperactivity disorder over a period of 16 weeks. Nineteen children were given *Bacopa* extract (containing 20 % bacosides) at a dosage of 50 mg twice daily for 12 weeks against a placebo. A significant improvement was observed in *Bacopa*-treated subjects at 12 weeks proven by an upgradation on sentence repetition and logical memory. Assessment showed that these improvements were maintained at 16 weeks [50].

7.3 On Memory-Enhancing Function

Roodenrys et al. [14] showed that bacosides also have chronic effect on human memory. In a double-blind, randomized, placebo-controlled study, they tested various memory functions and levels of anxiety in 76 adults (aged between 40 and 65 years). This study showed that bacosides help to retain new information, decrease the rate of forgetting newly gained information, increase verbal and short-term memory, and help in recovery of preexperimental knowledge.

7.4 On Anti-inflammatory Function

Carrageenan, a linear sulfated polysaccharide, induces paw edema in mice and rats which is an acute inflammatory model. The ethanolic extract of *B. monnieri* is injected intraperitoneally (100 mg/kg, 10 ml/kg) into right hind paw of mice. After 30 min, paw edema was induced by a single subplantar injection of 0.1 ml of arachidonic acid (0.5 %, w/v), bradykinin (20 μg/ml), histamine (1 mg/ml), prostaglandin E2 (0.01 μg/ml), or serotonin (1 mg/ml) into the right hind paw of rats. Three hours later, the animals were sacrificed, and paws were quickly amputated at the ankle-joint level and weighed. The edema in the right paw was determined by subtracting its weight from the weight of the left paw [51]. The extract (50 and 100 mg/kg) resulted in a considerable decrease in paw edema (33–95 %) which was 1.6 times more powerful than that caused by aspirin (28–60 %). Hence, *B. monnieri* has anti-inflammatory action toward paw edema.

7.5 On Gastrointestinal Disorders

Some in vitro animal and human studies have investigated the effect of bacosides on gastrointestinal tract. It has direct spasmolytic activity on intestinal smooth muscle, via inhibition of Ca^{2+} influx across cell membranes. Also, a similar effect was observed in rabbit's blood vessels and jejunum.

Bacosides have prophylactic and healing effects in five models of gastric ulcers. BME considerably healed penetrating ulcers induced by acetic acid at a dose of 20 mg/kg for 10 days, notably strengthened the mucosal barrier, and reduced mucosal exfoliation. The extract also reportedly reduces lipid peroxidation and balances SOD and catalase levels in rat gastric mucosa [44, 45].

In vitro studies on animal and human subjects regarding the effect of bacosides on gastrointestinal tract showed that they may have a positive effect on irritable bowel syndrome (IBS). Experiments showed that it has a direct spasmolytic effect on intestinal smooth muscle. A double-blind, randomized, placebo-controlled trial of 169 patients with IBS was done for both standard therapy (clidinium bromide, chlordiazepoxide, and psyllium) and Bacopa extract. Subjects were divided into five subgroups based on type of IBS and randomly assigned to standard drug treatment, BME therapy, or placebo for 6 weeks (5 g of each drug administered orally thrice daily). It was exposed that standard drug therapy is better than BME, except in IBS patients with diarrhea [52].

7.6 On Diabetic Neuropathy

A common complication of diabetes is diabetic neuropathy. It damages the nerves that allow feeling sensations such as pain. Recent treatments are insufficient to provide relief from pain and also cause side effects. Streptozotocin stimulates diabetes in 80 % of animals. Male Sprague Dawley rats were injected streptozotocin (65 mg/kg, i.p.) and subjected to thermal (cold and hot) and chemical (formalin) stimuli. Six weeks after streptozotocin administration, blood glucose levels increased and hyperalgesia developed. Hyperalgesia is an increased sensitivity to pain, which may be caused by damage to nociceptors or peripheral nerves. Ethanolic extract of *Bacopa monnieri* leaf (500 mg/kg, i.p.) containing bacoside A as main composition significantly set back the responses to thermal and chemical stimuli in diabetic rats [53].

7.7 On Anxiety and Depression

Traditionally, *Bacopa* was used as antianxiety remedy in ayurvedic medicine and is justified by both animal and clinical research. Lorazepam which is an antianxiety drug has amnesia as side effect. But BME having the same effect did not stimulate amnesia [54]. Thirty five patients diagnosed with anxiety neurosis were treated with Brahmi syrup with a dose of 30 mL twice daily. After this treatment the patients showed significant decrease in level of anxiety, disability, and mental fatigue whereas increase in immediate memory span. Some other positive changes that also occurred during treatment were increased body weight, decreased respiration rate, and decreased systolic blood pressure [55].

7.8 Clinical Trials on Synthetic Drug-Bacosides Interaction

Carbamylcholine chloride (carbachol) exerts bronchoconstrictor action. It is noticed that carbachol significantly increases inspiratory and expiratory pressures and decreases blood pressure and heart rate. Bronchodilation was monitored in anesthetized male albino rats, and ethanolic extract of *B. monnieri* (50 mg/kg) was administered before and after. The effects of carbachol were reversed within 2–5 min. At a dose of 25 mg/kg, the plant extract repressed the inspiratory pressure, while the doses 37 and 50 mg/kg inhibited both inspiratory and expiratory pressures, respectively. Increase in tracheal pressure due to carbachol reversed in the presence of the plant extract (50 mg/kg). Hence, the ethanolic extract antagonizes the bronchoconstrictor effects of carbachol [7].

Scopolamine is frequently used as amnesic agent. But being a synthetic drug, it has some undesirable effects. Oral dose (at 120 mg kg^{-1}) of ethanolic extract of *Bacopa monnieri* inverted scopolamine (0.5 mg kg^{-1} i.p.)-induced adverse effects. The ethanolic extract also stopped scopolamine (0.5 mg kg^{-1} i.p.)-induced retrograde amnesia [56].

8 Conclusion

With the increasing knowledge on pharmacological applications of bacosides, researchers are now also trying BIOTECHNOLOGICAL tools to obtain higher yields of bacosides from the plant as it is the exclusive source of these immensely useful compounds [57]. Diverse array of neuropharmacological functions of bacosides have the prospect to end the long quest for a neuroprotective drug which has no or minimal side effects. The therapeutic effects of BME were gradually established both in animal models and in human volunteers. But the detailed mechanism through which bacosides execute neuroprotective function or enhance memory is still not clear. Also, the exact functional component of BME as well as its metabolism is yet to be elucidated. Many studies indicated that there may exist interactions between herbal medicines and synthetic drugs. So, stringent clinical trials are necessary to negotiate these issues.

Abstract

Globally, there is an increasing prevalence of cardiovascular diseases (CVD) and is still maintaining its apex position. It includes elevation in low density lipoproteins cholesterol (LDL-C), increase in LDL-C oxidation, irregular clumping of blood platelets, and increase in C-reactive proteins and homocysteine. These abnormalities are also associated with atherosclerosis, high blood pressure, and hypercholesterolemia. Garlic (*Allium sativum* L.) is among the world's oldest cultivated plants, popular in food and for medicinal purposes. Commercially available garlic preparations in the form of garlic oil, powder, and pills are widely used for therapeutic purposes. The water-soluble and insoluble sulfur compounds in garlic showed beneficial effects in all these cardiac abnormalities, especially for the treatment of hypercholesterolemia and prevention of arteriosclerosis through antioxidant ability involving induction and inhibition of various metabolic enzymes and via chelating activity. There is continuous investigation being carried out to find out the other potent bioactive constituent in garlic. Likewise, phenolic compounds have emerged as minor but potent compounds, which are responsible for its antioxidant activity. Most of the studies are in the preliminary stage and need to be clarified in clinical trials.

Keywords

Atherosclerosis • cardiovascular disease • garlic • hypercholesterolemia • sulfur compounds

Abbreviations

AA	Arachidonic acid
ACE	Angiotensin converting enzyme
ADP	Adenosine diphosphate

VT	Ventricular tachycardia

1 Introduction

Garlic, scientifically known as *Allium sativum*, is a close relative of onions, leeks, and chives. The word *Allium* is derived from the Celtic word *al*, meaning pungent, burning, or stinging and *sativum* meaning planted, cultivated, or sown. The English name "garlic" comes from the Anglo-Saxon *gar-leac* or spear plant, which refers to its flowering stalk. It is one of the oldest cultivated plants with its origin in central Asia. It has also been found in Egyptian pyramids, ancient Greek temples, and on Sumerian clay tablets dating from 2600 to 2100 BC [1, 2]. Garlic was used as medicine by the ancient Egyptians especially for the working class involved in heavy labor and is listed in the Egyptian medical papyrus *Codex Elsers* (1500 BC). The ancient medical manuscript of India, *Charaka-Samhita*, recommends garlic for the treatment of heart disease and arthritis, and another ancient Indian medical textbook, *Bower Manuscript* recommends garlic for fatigue, parasitic disease, digestive disorder, and leprosy [2]. During World Wars I and II, the injured soldier wounds were dressed with garlic, and it was used as an antiseptic in the prevention of gangrene.

Garlic and its preparations are prescribed in many pharmacopeias around the world, including Ph Eur 6 [3], USP 31 [4], and BP 2007 [5]. Garlic is also incorporated in the list of German Commission E, which is a therapeutic guide in herbal medicine, complied by a special expert commission of the German Federal Institute of Medicines and Medical Inventions. German Commission E recommends usage of an average dose of 4 g of fresh garlic or equivalent preparations of garlic as a dietary supplement to hyperlipidemic patients and in prevention of vascular alterations caused by aging. Garlic is popularly used as one of the major spices, and its medicinal use is both widespread and growing due to proven potential health benefits, which have been published in more than 3,000 research articles. Studies suggests that garlic and its components not only prevent cardiovascular disease (including lowering of serum cholesterol level, inhibition of platelet aggregation, and increased fibrinolysis) but also other chronic diseases associated with aging, stimulation of immune function through activation of macrophages, induction of T cell proliferation, reduction of blood glucose level, radioprotection, improvement of memory and learning deficit, and protection against microbial (viral and fungal infections) and anticancer effects.

2 Bioactive Constituents and Preparations

Garlic bulbs develop and grow entirely underground and are composed of several bulbils structure called cloves. Each clove is enclosed in a white or pink skin of the parent bulb, mainly consists of active secondary plant metabolites, which are responsible for taste, flavor, and health benefits. There are over 600 cultivated subvarieties of garlic available in the world, and scientifically, all the true garlic comes under the species *Allium sativum* with two most common subspecies, *ophioscorodon* or hard-necked garlic (ophios for short) and *Sativum* or soft-necked garlics.

Fresh raw garlic bulbs contain ~65% of water, ~28% carbohydrate, ~2% proteins, ~1.2% amino acids, ~1.5% fibers, fatty acids, phenols, and trace elements, as well as more than 33 (~2.3%) sulfur (Fig. 121.1)-containing compounds [6, 7]. Hundred grams of garlic provides ~149 kcal energy, 33.07 g of carbohydrate, 6.93 g of protein, and 0.5 g of fat. It has been estimated that ~97% of chemical constituents in garlic are water soluble, and very small amounts of oil-soluble constituents which vary from 0.15–0.7% (Table 121.1). The major trace elements found in the fresh garlic cloves are shown in Table 121.2. Further compounds present in a small amount are flavonoids, steroids, and triterpene saponins from the β-sitosterol or F-gitogenin.

The sulfur-containing compounds are generally classified into nonvolatile precursor and organosulfur compound. δ-glutamyl-*S*-allyl-L-cysteines and *S*-allyl-L-cysteine sulfoxides (alliin) are abundant in intact garlic and serve as a precursor of allicin, methiin, (+)-*S*-(*trans*-1-propenyl)-L-cysteine sulfoxide, and cycloalliin. When there is any mechanical injury to the garlic bulb then, there is formation of thiosulfinate compound called allicin through enzymatic reaction of sulfur-substituted cysteine sulfoxides, which are present in the cytoplasm with alliinase in the vacuole, via sulfur-substituted sulfenic acids. Key studies by Cavallito and Bailey [9] and Stoll and Seebeck [10] identified the compound allicin. Allicin further decomposes into diallyl disulfide (DADS), diallyl sulfide (DAS), diallyl trisulfide (DTS), and sulfur dioxide. In addition, there are other thiosulfinates present in garlic homogenate, including allyl methyl, methyl allyl, and *trans*-1-propenyl thiosulfinate, that are also unstable like allicin.

There are various available brands of garlic products in stores/on shelves that provide a convenient way to obtain the health benefits of garlic. The most commonly used garlic preparations are raw garlic per se, aged garlic, garlic oil, allicin extract powder (Table 121.3) and commercially prepared lyophilized garlic powder, garlic oil, garlic oil macerate, and aged garlic extract (AGE) [11, 12]. Among the popular commercial garlic preparations investigated in trials are KWAI® (Lichtwer Pharma, Berlin, Germany), Garlicin® (Nature's Way, Springville, UT, USA), and Kyolic-100® (Wakunaga of America, Mission Viejo, CA, USA).

3 Garlic and Cardio Protection

Globally, CVD remain the biggest cause of death and disability. According to WHO report 2011, 17.3 million people died from CVD in 2008, which accounts for over 80 % of deaths in low- and middle-income countries. It is estimated that by 2030, almost 23.6 million people will die from CVD [13]. CVD refers to a group of disorders of the heart and vascular system and includes coronary heart disease, congestive heart failure, stroke, congenital heart defects, myocardial infarction, and high blood pressure. Imbalance between free radicals production and scavenging leads to oxidative damage of membrane lipids, proteins, carbohydrates, and finally

Vitamin C	5 mg
Zinc	1.8–3.1 mg

to DNA which brings changes in the structural, mechanical, electrical, and biochemical properties of the heart. Nowadays, natural herbal drugs are gaining greater acceptance from the researchers and public due to advances in understanding the mechanism of action, fewer side effects, and lesser cost effective therapy. Extensive in vitro, in vivo, and clinical studies showed that garlic with its sulfur and nonsulfur bioactive compounds is involved in the prevention and treatment of CVD.

Table 121.3 Commonly available and used garlic preparations

Preparation	Major sulfur constituents	Preparation process	Properties
Raw garlic per se	δ-glutamyl-*S*-allyl-L-cysteines, *S*-allyl-L-cysteine sulfoxides, allicin, adenosine	Intact clove with the white or pink skin by simple pull off	Precursor of allicin, methiin, (+)-*S*-(*trans*-1-propenyl)-L-cysteine sulfoxide, and cycloalliin
Garlic essential oil	Diallyl disulfide (DADS), diallyl sulfide (DAS), diallyl trisulfide (DTS), methyl allyl disulfide, methyl allyl trisulfide, vinyldithiins, and ajoenes	Steam distillation or ether extracted	Most potent source of garlic odor and causes body odor, used in perfumery and cosmetic industry
Garlic oil macerate oil	DAS, allyl methyl dimethyl, mono-to hexasulfides, allyl 1-propenyl and methyl 1-propenyl di-, tri-, and tetrasulfides	Cold extraction method (maceration) and steam distillation	Manufactured as capsule in diluted form for therapeutic use
Garlic powder	Alliin accumulates naturally during storage of the bulbs at cool temperature	Simply dehydrated, pulverized garlic clove with (<60 °C) temperature control	Commercially available for household use
Allicin powder extract	Allicin	Specialized patented extraction process produces allicin liquid that is spray dried	Stable at cool temperatures but at high temperature allicin degraded
Aged garlic extract (AGE)	Stable and water-soluble organosulfur compounds, such as *S*-allylcysteine, *S*-allylmercaptocysteine, with allixin, selenium, and *N*-alpha-(1-deoxy-D-fructos-1-yl)-L-arginine	Sliced raw garlic is stored in 15–20 % ethanol, fermented bulb of age ~2 years	Highly bioavailable and shown to be superior to raw garlic in terms of its antioxidant properties

4 Hypolipidemic Effects

Hyperlipidemia, which is characterized by an increase in the level of cholesterol or lipids (LDL, triglycerides) in the blood, serves as a major risk factor of atherosclerosis. The growing interest in complementary and alternative medicine has led to an increasing number of nonpharmacological therapies for lipid management and treatment of hyperlipidemia/hypercholesterolemia with dietary intervention. These include garlic, which reduces total cholesterol (TC), low density lipoprotein cholesterol (LDL-C), and triglyceride (TG) levels; furthermore, it increases high density lipoprotein cholesterol (HDL-C), which has been confirmed in several research studies.

Preparations of garlic including garlic paste, garlic oil, allicin, and ajoene have been found to significantly reduce cholesterol biosynthesis in rat hepatocytes via inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase and

14-α-demethylase [14, 15] and human HepG$_2$ cells [16]. After measurement of the enzyme activity, it has been indicated that garlic and its constituents inhibit human squalene monooxygenase along with HMG-CoA reductase, the enzymes involved in cholesterol biosynthesis [8, 17]. In addition, garlic supplementation significantly decreased the cholesterol 7-α-hydroxylase activity [18]. Augusti et al. [19] in 2005 confirmed the inhibition of HMG-CoA reductase by garlic. Some authors postulate that garlic's trace minerals, such as tellurium (Te), are involved in the inhibition of hepatic cholesterol synthesis [20]. It was found that the more water-soluble compounds like *S*-allylcysteine (SAC) present in aged garlic extract are less cytotoxic but more efficient in inhibiting cholesterol biosynthesis; in contrast the lipid-soluble sulfur compounds such as diallyl sulfide (DAS) are less efficient [16]. In rabbits that were fed with a high-cholesterol diet and supplemented with garlic or allicin, it was found that hypercholesterolemia was significantly inhibited by 50% and showed a decrease in tissue cholesterol and LDL-C concentrations and raised HDL-C concentrations along with reduced atheromatous changes [21]. Koch [22] indicated that the cholesterol-lowering effect of garlic was probably due to the nonsulfur component, saponin. In addition, another study [23] also supported the saponin fraction from methanolic raw garlic extracts, which mainly contains spirostanol saponins produced by the conversion of furostanol saponins via β-glucosidase. It lowered TC and LDL-C cholesterol without changing HDL-C levels in hypercholesterolemic animal models. A recently published animal study results showed that garlic significantly reduced TC, TG, LDL-C, very low density lipoprotein (VLDL-C), liver triglyceride, plasma malondialdehyde (MDA), and elevated plasma antioxidant in garlic-treated rats along with decrease in liver phosphatidate phosphohydrolase (PAP) activity [24].

4.1 Clinical Studies

Several clinical trials on garlic preparation have investigated, but only a few of them have showed significant hypolipidemic effects. In a meta-analysis on 28 clinical trials, Warshafsky et al. [25] found only five randomized, placebo-controlled studies that met their criteria for inclusion in the meta-analysis. The analysis result showed that treatment with garlic or garlic preparations caused decrease an approximately 9% in TC level. In addition, another meta-analysis of 16 published studies [26] in 1994, revealed that treatment with garlic preparations resulted in nearly a 12% decrease in TC and a similar decrease in LDL-C. Out of 16 studies, only 8 studies included the data on TG; when analyzed together, they revealed a 13% decrease in TG levels. A 12-week, randomized, placebo-controlled study [27] using Kwai garlic powder (900 mg/day) showed a reduction in TC and LDL-C levels by 6% and 11%, respectively, in the garlic supplement group, while TC and LDL-C levels decreased by 1% and 3%, respectively, in the placebo control group. In a long-term (10 months) randomized, double-blind, crossover study [28] in moderately hypercholesterolemic men, using AGE versus placebo, the measurements were made six times during the first intervention (AGE or placebo) and five times over the 120 days of crossover to the alternate treatment. AGE resulted in a maximum TC reduction of 6% for all study subjects compared with placebo and 7% compared with their baseline values. While the LDL-C reduction was 4.5% and 4% compared against placebo and baseline, respectively. A comparative study [29] was reported in 1997, in which garlic (900 mg powder/day) and fish oil (12 g fish oil/day) were used as dietary supplements. This was a randomized, placebo-controlled (partially double-blind) study with four arms: garlic with fish oil placebo, fish oil with garlic placebo, garlic and fish oil, and both placebos. Potential subjects began a 3-week run-in period for dietary stabilization. During this run-in period, TC level had to exceed 5.2 mmol/L (200 mg/dL). They reported that garlic significantly reduced both TC and LDL-C levels, whereas fish oil also significantly decreased TG and increased LDL-C levels as expected. An interesting outcome by Zhang et al. [30] showed that gender might be affect the action of garlic on plasma cholesterol and glucose levels of normal subjects. Alder et al. [31] in 2003 published a systematic review of the effectiveness of garlic as an antihyperlipidemic agent. They included ten studies and found that in six studies garlic was effective in reducing serum cholesterol levels. The average drop in total cholesterol was 9.9%, LDL-C 11.4%, and triglycerides 9.9%. In a study, consumption of enteric-coated garlic supplements, standardized to produce 9.6 mg allicin, significantly decreased TC (4%) and LDL-C (7%) in mild to moderated hypercholesterolemic patients when combined with a low-fat diet [32]. A clinical study confirmed the hypolipidemic effect of raw garlic in hyperlipidemic subjects and reported significantly reduction of TC and TG along with significantly increase in HDL-C [33]. Recently published meta-analysis studies, in which 13 trials including 1,056 subjects, do not produce any statistically significant reduction in serum total cholesterol level from garlic [34]. In addition, another recently published meta-analysis of 29 trials suggested intake of garlic causes significant reduction in TC and TG but does not exhibit any significant effect on LDL-C or HDL-C [35].

4.2 Proposed Mechanism

There are four possible mechanisms through which garlic inhibit the cholesterol synthesis and enhance the cholesterol excretion from the body (Fig. 121.2). The first one is that garlic decreases cholesterol absorption in the intestine, as shown in hypercholesterolemic rat models [23]. Second, experiments using cultures of rat hepatocytes have shown that garlic inhibits the enzymes involved in cholesterol synthesis [16, 36, 37]. Third, Borek [38] has suggested that the cholesterol-lowering effect of garlic is caused by deactivation of HMG-CoA reductase, involved in the synthesis of cholesterol. Fourth, garlic also increased the excretion of cholesterol, as manifested by enhanced excretion of acidic and neutral steroids after garlic feeding [39].

5 Antioxidant Effects

There is a continuous production of free radicals from the body's metabolic process that use oxygen, such as respiration and some cell-mediated immune functions. The LDL oxidation in the artery wall gives rise to thrombosis, atherosclerosis, and CVD. Besides reactive oxygen species (ROS) and reactive nitrogen species (RNS), hypochlorous acid (HOCl) is also a strong endogenous oxidant and is excessively produced in inflammatory, degenerative, and neoplastic disorders; thus, effective therapies and/or prophylaxes using exogenous scavengers of high specificity are required. Homeostasis and self-defense system of the body maintain a balance between the amount of generated free radicals in the body and body internal antioxidants glutathione (GSH) to quench and/or scavenge or even detoxify them

and finally protect the body against their harmful effects. Nowadays, commercially available synthetic antioxidants such as BHA (butylated hydroxyanisole) and BHT (butylated hydroxytoluene) are being replaced with natural origin antioxidants because of their toxicity and carcinogenicity. Garlic and its preparations show antioxidant action by scavenging ROS, enhancing the cellular antioxidant enzymes superoxide dismutase, catalase, and glutathione peroxidase, and increasing glutathione in the cells (Fig. 121.3). It has been observed that aqueous extracts from raw garlic and unpeeled cloves treated with distinct thermal processes were able to differentially scavenge HOCl and that SAC was the only effective garlic compound [40].

Alliin scavenges superoxide, while allyl cysteine and allyl disulfide do not react with superoxide. Allicin suppress the formation of superoxide by the xanthine/xanthine oxidase system, probably via a thiol exchange mechanism. It is now concluded that alliin, allyl cysteine, and allyl disulfide all scavenges hydroxyl radicals ($OH^{\bullet}$). Allyl disulfide, alliin, allicin, and allyl cysteine exhibit different patterns of antioxidant activities as protective compounds against free radical damage [41–43] and appear in fresh garlic approximately 1,000 times more potent as antioxidants than those found in aged garlic extract, while whole garlic and aqueous garlic extract exhibit direct antioxidant effects and enhance the serum levels of two antioxidant enzymes: catalase and glutathione peroxidase [44]. Several studies have been performed to test the antioxidant activity of raw and boiled garlic by using different assays: β-carotene linoleate model system (β-carotene), radical scavenging activity by 1, 1-diphenyl-2-picrylhydrazyl (DPPH), scavenging activity against nitric oxide (NO) with 2, 29-azinobis (3-ethylbenzothiazoline-6-sulfonic acid) radical cation ($ABTS^+$), ferric-reducing/antioxidant power (FRAP), and Cu^{2+}-induced LDL-C oxidation [45–49]. It has been investigated that an aqueous extract obtained from 1 mg of a garlic preparation was as effective as an antioxidant as 30 nmol ascorbic acid and/or 36 nmol α-tocopherol [50]. In rat liver microsomes, garlic extract prevented formation of thiobarbituric-acid-reactive substances in cell membranes during lipid peroxidation in a dose-dependent manner [51]. In an in vitro and animal study, there was a significant improvement in the plasma lipid levels in rats fed cholesterol-containing diets and an increase in the plasma antioxidant activity in groups of rats fed cholesterol-free diets supplemented with raw and boiled garlic at 100°C for 20 min [52, 53]. A concentration-dependent inhibition of LDL-C oxidation was observed with the oil-soluble garlic compound, allixin [54]. In another in vitro study, AGE significantly reduced Cu^{2+} and 15-lipoxygenase-mediated lipid peroxidation of isolated human LDL-C by 81% and 37%, respectively [55]. Aqueous garlic extracts have the ability to scavenge superoxide anion ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH^{\bullet}$) in the following aqueous preparations: (a) extracts of boiled garlic cloves (BG), (b) extracts of microwave-treated garlic cloves (MG), and (c) extracts of pickled garlic (PG) and heated extracts of (a) garlic powder (HGP) and (b) raw garlic (HRG). The data were compared with the unheated raw garlic (RG) or with the unheated garlic powder (GP). Extracts of GP and RG scavenged $O_2^{\bullet-}$, H_2O_2, and $OH^{\bullet}$ in a concentration-dependent way. The ROS scavenging capacity was not decreased in the aqueous garlic extracts except in MG and HRG (for $O_2^{\bullet-}$) and in HGP and PG (for H_2O_2), while the heating before or after garlic cutting was unable to eliminate the capacity of the extracts to scavenge H_2O_2, $O_2^{\bullet-}$, and $OH^{\bullet}$ [56]. Moreover, it was also found that fresh garlic, subjected to a cooking regimen of 100 °C during 20 min, preserves its bioactivity: the decrease in the contents of the studied compounds and the decrease in the total antioxidant potential were statistically not significant [53]. Recently, Lei et al. [57] suggested that DADS and DATS protect eNOS activity against ox-LDL-C insult. This protection can be attributed partly to their mediation of phosphatidylinositol 3-kinase/protein kinase B signaling and prevention of eNOS degradation. Subsequently, another recent study [58] suggested that SAC, *S*-benzylcysteine (SBC), and *S*-propylcysteine (SPC) to be excellent hydroxyl radical (•OH) scavengers, while SAC only as a modest peroxyl radical (HOO•) scavenger. As described, the sulfur content in garlic responsible for antioxidant activity, furthermore some recent studies reported the abundance of phenolic compound in garlic leaves including gallic acid and quercetin, contributing the antioxidant activity [7, 59, 60].

6 Clinical Studies

In a randomized, double-blind, placebo-controlled study with three parallel arms [61], 17 participants consumed garlic oil (4 mg), 18 participants consumed garlic powder (0.5 g), and 17 participants consumed placebo for 11 weeks. Garlic oil caused a relatively rapid (4 weeks) rise in total antioxidant capacity compared with placebo or garlic powder. However, at 6 weeks, a significant rise also could be seen with garlic powder; by 11 weeks, it reached the same level as that obtained with garlic oil. Moreover, in a randomized, double-blind, placebo-controlled crossover trial [62], in which 10 normolipidemic subjects (5 males, 5 females) took six capsules each day containing either 100 mg of garlic powder/tablet or placebo followed by a 1-week washout period and then another 2 weeks on the alternate substance. The study data indicated that, for individuals taking garlic, there was increased antioxidant status as evidenced by an increase in the resistance of LDL-C to oxidative stress as compared with participants taking placebo [62]. However, the TBARS assay used in this study did not use purified LDL-C, and it is now known that the use of purified LDL-C yields more reliable data. In a small-scale preliminary double-blind, placebo-controlled, crossover study [54] involving eight subjects (4 men and 4 women), four subjects took 1.2 g AGE three times a day for 2 week, then 2 week of no garlic (washout period), followed by 2 week of placebo. The use of the garlic supplement was found to significantly increase the resistance of LDL-C to oxidation [54]. A study [63] showed that after short-term garlic supplementation in essential hypertensive patients (EH) regarding indices of oxidative stress, there is a significant reduction in ox-LDL-C and 8-iso-PGF2α levels. In a study [64] on six organosulfur compounds, derived from garlic showed marked antioxidative and antiglycative effects in partially oxidized (or glycated) LDL-C and plasma against further deterioration in 36 diabetic patients. Durak et al. [65] showed that consumption of 10 g of garlic/day for 4 months causes significant increase in blood antioxidant capacity and improved blood lipid profile in hypertensive patient. Dhawan and Jain [66] in 2005 demonstrated in a clinical trial of hypertensive patients, supplementation with garlic leads to significant reduction in 8-Hydroxy-2′-deoxyguanosine (8-OHdG), nitric oxide (NO) levels and lipid peroxidation along with an increase in vitamin levels (A, E, and C) and total antioxidant status (TAS).

7 Proposed Mechanism

Many authors suggest various possible garlic antioxidant mechanism of action, in which scavenging of ROS is most common mechanisms whereby garlic derivatives confer its important health care benefits. Vaidya et al. [67] suggested that the peroxyl-radical-trapping activity of garlic is primarily due to 2-propenesulfenic acid formed by the decomposition of allicin. Thus, sulfenic acids are very probably the most potent of all peroxyl-radical-trapping antioxidants. New insights on the antioxidant mechanism of garlic derivatives *S*-allylcysteine and its corresponding sulfoxide (alliin) showed the highest and lowest HOCl-scavenging capacities [68]. This scavenging activity is enhanced by increasing the number of S atoms or by the alanyl group ($-CH_2CH–NH_2–COOH$) and decreased in the absence of the C=C bond or in the presence of a sulfoxide group in the thioallyl group [68]. Recently, Miron et al. [69] showed that the allicin diffuses through cell membranes and exerts its biological effects by rapidly reacting with intracellular free thiols, such as reduced glutathione (GSH), cysteine, and sulfhydryl groups of proteins. The reaction of the allylthio group with those cellular components constitutes the major beneficial effects of allicin. The first product is most likely that of the *S*-allylthio-mixed disulfide (AS-SX) with GSH. Another recent study [58] suggested the mechanism by which SAC, SBC, and *S*-propylcysteine (SPC) scavenge •OH and ROO• due to amelioration when the allyl group was replaced by benzyl or propyl groups.

8 Antihypertensive Effects

Hypertension is a collective risk factor for cerebrovascular disease, ischemic heart disease, peripheral vascular disease, and renal disease characterized by systolic blood pressure of 140 mmHg or greater, and/or a diastolic blood pressure of 90 mmHg or greater, in people who are not taking antihypertensive medication. A number of studies have documented the hypotensive effect of garlic and their bioactive preparations. In 1973, Chanderkar and Jain [70] reported the hypotensive (10–50 mmHg) effect of alcoholic garlic extract (2.5–25 mg/kg) after oral administration in experimentally induced hypertension. Some studies [71, 72] showed a slight decrease in both systolic and diastolic pressures after intravenous injection of garlic extracts in experimental animals. Gastric administration of encapsuled garlic powder to anesthetized dogs induced a dose-dependent (2.5–15 mg/kg) prolonged decrease in arterial blood pressure [73]. Single or multiple doses of 0.5 mL of aqueous extract of garlic were given orally to two-kidney-one-clip (2K–1C) model rats that showed a maximum antihypertensive effect at 2–6 h after administration [74]. Experimental rats who were fed a 2% high-cholesterol diet exhibited a 23.50% increase in systolic blood pressure which was significantly reduced when the rats were fed an aqueous extract of garlic powder containing allicin on a daily basis [75]. In another study [76], chronic feeding of diets containing either AGE or raw garlic (RG) powder for 10 weeks resulted in a reduction of the increase of systolic blood pressure compared with the control group from 4 weeks after beginning the experimental diets. The effect of AGE was accompanied by a decrease of pulse pressure (PP), suggesting an improvement of the pliability of the artery, although RG did not affect PP. In a recent animal study [77], combination of fresh garlic homogenate compound *S*-allyl cysteine sulfoxide and captopril exerted super-additive (synergistic) interaction with respect to fall in blood pressure and angiotensin converting enzyme (ACE) inhibition and suggested the combination of garlic with captopril should be avoided. Continuous researches have been carried out on animals and have repeatedly documented the significant hypotensive activity of garlic. Another recent study [78] demonstrated that garlic homogenate in moderate dose (250 mg/kg) with added hydrochlorothiazide possesses synergistic cardioprotective and antihypertensive properties against fructose- and isoproterenol-induced toxicities in albino rats.

9 Clinical Studies

Evidence has been found that people's belief in continuing garlic use for the management of hypertension is justified and well documented. A very early research in 1921 showed the hypotensive effect of garlic tincture [79]. Allimin tablets containing 4.75 g of garlic concentrate (0.31 g of desiccated garlic and 2.375 g of desiccated parsley) administered to 26 hypertensive patients three times daily for 3 days resulted in reduction of systolic and diastolic blood pressure (12.3 mmHg and 6.5 mmHg) in 85% of the patients [80]. Intake of about 900 mg/day garlic powder in hypercholesterolemic [81], mild hypertension patients [82], and normotensive subjects [83] resulted in reduction of diastolic blood pressures as compared to the nongarlic consuming groups. In another study [28], there was a 5.5% decrease in systolic blood pressure and a modest reduction of diastolic blood pressure in response to 900 mg/day aged garlic consumption. Short-term consumption of garlic supplementation (250 mg/day for 2 months) in essential hypertensive patients resulted significant decline in both systolic and diastolic blood pressures [63]. Garlic extract consumption for 4 months caused significant reductions in systolic and diastolic blood pressures in 13 hypertensive patient [65]. A study [84] showed that the undamaged garlic (swallowed) had no lowering effect on lipid level of serum, while crushed garlic (chewed) reduces cholesterol, triglyceride, MDA, and systolic and diastolic blood pressures. In a double-blind parallel randomized placebo-controlled trial [85] involving 50 patients, receiving four capsules of aged garlic extract (960 mg containing 2.4 mg SAC) daily for 12 weeks resulted in lowering of systolic blood pressure similar to current first-line medications in patients with treated but uncontrolled hypertension. Recently, a randomized, placebo-controlled parallel feeding trial [86] showed a significant reduction in both systolic and diastolic blood pressures in hypertensive subjects after taking two 500 mg capsules of processed garlic for 8 weeks. There was one meta-analysis performed by Silagy and Neil in 1994 [87] which included eight trials using the same dried garlic powder preparation (Kwai). The results from the data of 415 subjects after analysis showed only three of the trials were specifically conducted in hypertensive subjects, and out of the seven trials that compared the effect of garlic with that of placebo, three showed a significant reduction in systolic blood pressure (SBP) and four in diastolic blood pressure (DBP). In 2008, a study [88] searched the databases for studies published between 1955 and October 2007 in which 11 of 25 studies included in the systematic review were suitable for meta-analysis. The author suggested that garlic preparations are superior to placebo in reducing blood pressure in individuals with hypertension. Another meta-analysis study [89] was published in the same year 2008 which included ten trials in the analysis. The result showed that garlic reduced SBP by 16.3 mmHg and DBP by 9.3 mmHg compared with placebo in patients with elevated SBP in the three trials. However, the use of garlic did not reduce SBP or DBP in patients without elevated SBP. A very recently published meta-analysis [90] containing the data from January 1994 to December 2010 including 13 studies included 659 subjects. The result of all studies showed a mean decrease of 4.2 ± 2.4 mmHg for SBP in the garlic group compared to placebo, while the mean decrease in the hypertensive subgroup was 7.3 ± 2.2 mmHg for SBP and 6.7 ± 1.4 mmHg for DBP. There were no statistically significant effects of garlic (compared to placebo) observed for DBP of all subjects and the nonhypertension subgroup.

10 Possible Mechanism

Many authors proposed the possible mechanism by which garlic influences antihypertensive effects. Early investigation [72] proposed that prostaglandin-like activity responsible for antihypertensive action of garlic decreases peripheral vascular resistance. Whenever, the body increases production of angiotensin II converting enzyme (ACE), blood pressure increases. Garlic showed blood pressure reducing properties which have been linked to its hydrogen sulfide (H_2S) production [91]. It has been demonstrated that garlic and garlic-derived organic polysulfides, such as diallyl trisulfide (DATS) and diallyl disulfide (DADS), induce H_2S production in a thiol-dependent manner and allicin content liberated from alliin and the enzyme alliinase which has angiotensin II inhibiting and vasodilating effects in in vitro [92], animal [93] studies. Nitric oxide (NO) is a well-recognized vasodilator and vasorelaxant for endothelial and smooth muscle cells. Garlic extract and *S*-allyl-γ-cysteine significantly increase NO production in endothelial cells [94, 95] which results in lowering blood pressure [96]. In addition, in in vitro [97] and animal studies [98], garlic shows nitric-oxide-dependent relaxation in pulmonary arteries. Amino acid analysis of garlic powder demonstrated that it is a rich source of arginine, the precursor of NO. This was explained by the fact that NG-nitro-L-arginine methyl ester (L-NAME, a NOS inhibitor) abolished the vasodilatory effect of garlic. In a single in vitro study [99], garlic opens K^+ channels, which can reduce calcium influx and cause vasodilation which was ultimately responsible for the antihypertensive activity.

11 Antithrombotic and Fibrinolytic Effect

Blood platelets are mainly responsible for maintaining the hemostatic integrity of blood vessels and to stop bleeding after injury. Due to coronary artery disease and rupture of atherosclerotic plaque, there is increase in the platelet count and activation of the coagulation cascade with platelet thrombus formation, and that finally leads to vessel embolism. Garlic inhibits the platelet aggregation and prevents the thrombosis in in vitro animal models, and clinical studies. During the 1970s, there were three animal studies which reported the antiplatelet activity of garlic. The essential oil was more effective than clofibrate in the usual clinical dose of 33 mg/kg/day prevent lipid accumulation in the rabbit aorta [100], and essential oils of garlic protect against experimental atherosclerosis by preventing the fall in the alpha lipoprotein fraction and by enhancing fibrinolytic activity [101]. Sainani et al. [102] in 1979 showed enhanced fibrinolytic activity in albino rabbits when administered with garlic juice (0.25–25 g/day) in 10 mL distilled water. Aqueous garlic extracts inhibit platelet aggregation in vivo when added to plasma rich platelet at a concentration of 10 μM, suggesting allicin as principle inhibitor [103]. ADP-, epinephrine-, collagen-, and arachidonate-induced platelet aggregation is inhibited in vitro by garlic extract in a dose-dependent manner by inhibition of the prostacyclin biosynthesis in rat aorta [104]. Diallyl disulfide and diallyl trisulfide are mainly responsible for the prevention of acute platelet thrombus formation in stenosed canine coronary arteries model [105]. Several in vitro and in vivo studies were continuously performed and have proven the previous work with proposed mechanism hypothesis. In an ex vivo study [106], infusion of different garlic extract (10, 2, 5 and 100 mg/kg) in the ear vein of the rabbit significantly inhibits serum TXB_2 production in a distinct dose and time-dependent pattern. Chloroform/acetone extracts of fresh garlic have been shown to inhibit cyclooxygenase activity directly in in vitro, with the acetone extract being more effective [107]. In 1992, Lawson et al. [108] suggested that the antiaggregatory activity of garlic clove homogenates (*S*-allyl cysteine sulfoxide) in platelet rich plasma was due to adenosine; however, in whole blood neither adenosine nor the polar fraction had any effect, and all of the antiaggregatory activity was due to allicin and other thiosulfinates compound. Ajoene is a well-established antiplatelet agent in garlic, and its inhibitory effect on platelet aggregation has been extensively studied and documented both by in vivo and in vitro experiments [109, 110] including inhibition of baboon platelet aggregation in vitro (75 μg/mL) and in vivo (25 mg/kg) induced by adenosine diphosphate (ADP) or collagen [111]. Diallyl trisulfide inhibited platelet aggregation and Ca^{2+} mobilization induced by thrombin without affecting the production of IP_3 [112]. Another study suggested that garlic component sodium 2-propenyl thiosulfate modulated cyclooxygenase activity in canine platelets in a dose-dependent manner, thus preventing their aggregation [113]. Administration of the garlic in a rat in situ loop model,suggested that odorless garlic not only activates fibrinolytic activity by accelerating tPA-mediated plasminogen activation but also suppresses the coagulation system by downregulating thrombin formation [114]. Recently, an in vitro study [115] suggested the alcoholic wild garlic extract is more potent, while *Allium sativum* and *Allium ursinum* exert similar antiaggregatory effects in a dose dependant manner and inhibit platelet aggregation induced via the ADP pathway.

12 Clinical Studies

Several clinical studies done by Bordia and colleagues [116, 117] in the late 1970s and early 1980s reported that a garlic oil preparation rich in vinyldithiins, sulfides, and ajoene could inhibit platelet aggregation and result in increased fibrinolytic activity. In 1977, study on 10 healthy individuals, 10 patients with old myocardial infarction, and 20 patients with acute myocardial infarction showed garlic (1 g/kg b.w.) significantly increased fibrinolytic activity in all subjects especially in healthy group [116]. Later on, Bordia et al. [118] showed that garlic oil preparation inhibits platelet function in both healthy subjects and in patients with coronary heart disease. A randomized, double-blind, placebo-controlled crossover study [119] of 12 healthy subjects reported that garlic powder (Kwai, 900 mg/day) inhibited platelet aggregation induced by ADP and collagen. Administration of garlic in a daily dose of 2 × 2 capsules (each capsule containing ethyl acetate extract from 1 g peeled and crushed raw garlic) showed antiplatelet activity and also inhibited platelet thromboxane formation [120]. In another study [121] of garlic powder, it was found that feeding 7.2 g of AGE powder/day (~25 mL/day of liquid AGE) to hypercholesterolemic men resulted in inhibition of epinephrine (another platelet aggregating agent) and collagen-induced aggregation, but not ADP-induced aggregation. A 13-week study [122] involving normolipidemic subjects who ingested 5 mL of aged garlic extract per day significantly inhibited both the total percentage and initial rate of platelet aggregation at concentrations of ADP up to 10 μmol/L. Besides sulfur containing compound, other nonsulfur compounds, such as β-chlorogenin and quercetin, have also been shown to inhibit platelet aggregation [123]. A meta-analytical survey based on 11 electronic databases study [124], which included 1,798 pertinent records, 45 randomized trials, and 73 additional studies, reported cardiovascular-related effects were limited to randomized controlled trials lasting at least 4 weeks, and it has been found that in comparison with placebo, garlic preparations lead to a significant reduction in platelet aggregation [124]. Cavagnaro et al. [125] describe the effect of cooked garlic on antiplatelet activity on the blood sample from two healthy subjects, who had abstained from eating *Alliums* or other known platelet inhibitory foods for at least 1 week. The result showed oven heating at 200 °C or immersing in boiling water for 3 min or less did not affect the ability of garlic to inhibit platelet aggregation (as compared to raw garlic), whereas heating for 6 min completely suppressed in vitro antiaggregatory activity in uncrushed, but not in previously crushed, samples [125]. Prolonged incubation (more than 10 min) at these temperatures completely suppressed in vitro antiaggregatory activity, while microwaved garlic had no effect on platelet aggregation. A randomized, double-blind, placebo-controlled, crossover study involving 14 healthy subjects showed one large dose of garlic oil (~9.9 g garlic) slightly but significantly affected adrenaline but not ADP or collagen-induced platelet aggregation [126]. In a recently published report, it was shown that there was reduction in adenosine-induced platelet aggregation by garlic diallyl sulfide (2.2 μg) compound in women participants with type 2 diabetes mellitus [127].

13 Proposed Mechanism

Arachidonic acid (AA) is an essential fatty acid precursor in the biosynthesis of leukotrienes, prostaglandins, and thromboxanes (Fig. 121.4). Various platelet agonists mobilize calcium through G-protein-coupled receptors. Calcium activates phospholipase A_2, which liberates arachidonic acid from phosphatidylcholine and phosphatidylethanolamine. Calcium also activates myosin light-chain kinase. AA is liberated from phospholipids and, in the presence of the enzyme cyclooxygenase, incorporates oxygen to form the endoperoxide prostaglandin G_2 (PGG_2). PGG_2 is then quickly transformed to prostaglandin H_2 (PGH_2). PGH_2, in the presence of thromboxane synthase, produces thromboxane A_2 (TXA_2) which further mobilizes calcium from intracellular storage sites. TXA_2 and activated myosin light-chain kinase together lead to platelet coagulant activation by stimulating secretion of products of platelet granules, allowing tenase and prothrombinase formation [128]. TXA_2 is a vasoconstrictor and platelet aggregating compound which serves as precursor for inactive thromboxane-B_2 (TXB_2). Ajoene strongly inhibits the metabolism of arachidonic acid by both cyclooxygenase and lipoxygenase pathways [129, 130], thus inhibiting the synthesis of TXA_2, AA metabolite, and

12-hydroxy-eicosatetraenoic acid (12-HETE). AGE has been shown to reduce thromboxane formation [106]. It has also been reported that *N*-ethylmaleimide causes the disaggregation of both ADP and thrombin-induced platelet aggregation and that this disaggregation is a result of the removal of calcium ions (Ca^{2+}) from the platelet cytosol. Therefore, the effects of AGE on calcium mobilization were investigated in both A23187 and ADP-stimulated platelets [131]. In the presence of AGE, the initial concentration of calcium ions was significantly less than when the experiments were performed in the absence of AGE. This could be due to the metal chelation properties of AGE, as reported earlier [55]. In support of this, garlic extract has been shown to strongly inhibit calcium binding, suppressing the influx of calcium ions by chelating calcium within platelet cytosol and arteriosclerotic nanoplaque formation [132, 133]. AGE may inhibit phospholipase A_2, thus reducing levels of lysophosphatidic acid, which causes platelet aggregation and increases intracellular calcium ions [131]. Antiaggregatory effect of ajoene may also be causally related to its direct interaction with the putative fibrinogen receptor (GPIIb/IIIa) in a dose-dependent manner [134]. The GPIIb–IIIa receptor has a high content of –SH groups, and binding of fibrinogen is inhibited by the organosulfur compound ajoene [135]. AGE has been reported to enhance NO production by activating cNOS, but not iNOS [136], which may increase the GTP concentration and ultimately induces platelet aggregation.

14 Antiatherosclerotic Effect

Atherosclerosis is a result of an interaction between fat and cholesterol within the cellular components of the arterial wall and buildup in the walls of arteries to form hard structures called plaques, the pathogenic substratum of many cardiovascular diseases. Various in vitro and clinical studies have shown and confirm the effect of garlic in the prevention and treatment of atherosclerosis. Early studies on experimental animals showed the reduction in aortic lipid content of garlic fed animals by 72%, while in the control group there was no significant reduction. The data suggests that cholesterol is depleted from experimentally induced atherosclerosis by garlic administration [137, 138]. Treatment with aged garlic extract reduces fatty streak development, vessel wall cholesterol accumulation, and the development of fibro fatty plaques in neointimas of cholesterol-fed rabbits, thus providing protection against the onset of atherosclerosis [139]. In cell cultures, aqueous solutions of dried garlic powder containing allicin and ajoene significantly inhibit the proliferative activity of smooth muscle cells from atherosclerotic aortic plaques [140, 141]. In hypercholesterolemic rabbits, garlic supplements significantly reduced the aortic lesions and lipid content of existing fatty plaques [142]. AGE exerts antiatherogenic effects through inhibition of smooth muscle phenotypic change and proliferation and by another (unclarified) effect on lipid accumulation in the artery wall [143]. Garlic exerts hypocholesterolemic and antiatherogenic activity by inhibition of plasma cholesteryl ester transfer protein (CETP) activity, which may delay the progression of atherosclerosis, thereby supporting the atherogenicity of CETP and the inhibitory activity of garlic supplementation against CETP [21]. An in vitro study's results show the formation of the ternary proteoheparan sulfate HS-PG/LDL/Ca^{2+} complex, which is initially responsible for the "nanoplaque" composition and ultimately for the arteriosclerotic plaque generation, where the garlic extract strongly inhibits Ca^{2+} binding to HS-PG [132]. A notable restoration of arterial blood pressure; significantly enhanced vasorelaxant response to adenosine, acetylcholine, and isoproterenol; and reduction in atherogenic properties of cholesterol were seen in animals on garlic-supplemented diet [144]. Daily dietary supplement of allicin, 9 mg/kg body weight, reduced the atherosclerotic plaque area by 68.9% and 56.8% in apolipoprotein E-deficient and low density lipoprotein (LDL) receptor knockout mice, respectively, as compared with control mice and also by using pure allicin preparation; an in vitro study results showed that allicin may affect atherosclerosis not only by acting as an antioxidant but also by other mechanisms, such as lipoprotein modification and inhibition of LDL uptake and degradation by macrophages [145]. A recent in vitro study suggested that AGE inhibit monocyte differentiation into macrophages, CD36 expression, and oxidized LDL-C (oxLDL-C) uptake into macrophages induced by the cardiovascular risk factor homocysteine (Hcy) [146].

15 Clinical Studies

In a randomized, placebo-controlled trial in ten healthy adults, there was a significant improvement in plasma viscosity and capillary blood flow within 5 h after taking 900 mg of standardized garlic powder [147]. Another randomized placebo-controlled double-blind crossover study in healthy volunteers showed increased erythrocyte velocity results from vasodilation of precapillary arterioles which increased diameter of erythrocyte column by an average of 8.6 % along with simultaneous inflow of interstitial fluidity accompanied by a significant decrease in hematocrit and plasma viscosity (rheoregulation) [148]. In a placebo-controlled trial of patients with stage II peripheral arterial occlusive disease, garlic powder supplements (800 mg/day) were associated with a significant increase in walking distance by 46 m; the improvement started after the fifth week of treatment mainly by simultaneous decrease in spontaneous thrombocyte aggregation [149]. A cohort study including 101 healthy adults who took at least 300 mg daily of dried garlic powder for at least 2 years were compared with 101 age and gender matched controls who were not taking supplements; pulse wave velocity and elastic vascular resistance (two measures of arterial elasticity) were significantly lower in the garlic group than in the control group, even after controlling for age and systolic blood pressure, that is, chronic garlic powder intake was associated with an attenuation in age-related increases in aortic stiffness [150]. In a prospective, 4-year clinical trial of patients treated with 900 mg daily of standardized garlic powder, there was a 9–18 % reduction in plaque volume, a 4 % decrease in LDL-C levels, an 8 % increase in HDL-C concentrations, and a 7 % decrease in blood pressure [151]. Similar results were reported in a 4-year German trial in 152 older adults; those who took high-dose garlic for 4 years, demonstrated reduced atherosclerotic plaque in both carotid and femoral arteries by 5–18 % [152]. A study of 11 atherosclerotic patients with oxidative stress showed prevention of oxidation reaction by eliminating this oxidative stress and significantly lowered plasma and erythrocyte malondialdehyde (MDA) levels after the ingestion of garlic extract [153]. A placebo-controlled, double-blind, randomized pilot study indicates the potential ability of AGE to inhibit the rate of progression of coronary calcification in 19 patients, as compared to placebo over 1 year [154]. AGE consumption increases plasma nitric oxide synthase (NOS) activity in 11 atherosclerotic patients and suggested that AGE may arise from its NOS-inducing and nitric-oxide (NO)-producing activities [155].

16 Proposed Mechanism

The exact molecular mechanism of garlic by which it shows antiatherosclerotic effect is not fully understood. The development of atherosclerotic plaque or lesions is a result of endothelial dysfunction induced by elevated and modified LDL and ox-LDL, free radicals, toxins, homocysteine, hypertension, and other unknown risk factors. It has also seen that disturbance in immune system supports the formation of atherosclerotic plaques. Diets supplemented with garlic are able to restore endothelial function in experimental laboratory animals [144] and investigations of humans [156]. It has been shown that raw garlic possibly works via its active metabolite allicin action on coronary endothelial function and vasoreactivity [157]. The electrophysiological correlation to vasodilatation in human coronary arteries under the influence of garlic extract showed decrease in the isometric wall tension. Allicin and ajoene hyperpolarized the cell membrane and relaxed the vascular strips in a concentration-dependent manner and suggested that garlic extract and its compounds can be classified as phytopharmacological K^+ channel openers [99]. OxLDL-C, but not native LDL-C, contributed to atherogenesis and promoting vascular dysfunction by exerting direct cytotoxicity toward endothelial cells, by increasing chemotactic properties for monocytes, by transforming macrophages to foam cells via scavenger receptors, and by enhancing the proliferation of endothelial cells, monocytes, and smooth muscle cells. Garlic compounds can effectively suppress LDL-C oxidation in vitro and that short-term supplementation of garlic to humans increases resistance of LDL-C to oxidation [54, 158]. Hcy, a metabolite from methionine, serves as an independent cardiovascular disease risk factor, which causes thrombosis and oxidative-stress damage and is often associated with atherosclerosis and a higher risk of coronary heart disease, stroke, and peripheral vascular disease by damaging the inner lining of arteries and promoting blood clotting. Hcy has an inverse relationship with folate deficiency and decreased NO production. AGE may at least partly prevent a decrease in bioavailable NO and endothelium-derived hyperpolarizing factor during acute hyperhomocysteinemia [159] and also decrease plasma total hcy concentration by 30 % without changing the protein-bound/free hcy ratio [160]. Coronary arterial calcification (CAC), a marker of plaque formation in human coronary arteries and atherosclerosis, has been linked to an increased risk for cardiovascular events such as myocardial infarction, fatal arrhythmia, and congestive heart failure. AGE inhibits the rate of progression of coronary calcification as compared to placebo over 1 year [154]. C-reactive protein (CRP) is one of the strongest predictors for the risk of atherosclerosis and cardiovascular events in subjects with and without cardiovascular disease. But there was only one study which showed that 12 weeks of treatment with a high-dose, chemically well-characterized, production-controlled garlic powder had no significant effect on CRP protein in normolipidemic subjects with risk factors for CVD [161].

17 Other Cardioprotective Activity

Cardiac arrhythmias are any abnormality or perturbation in the normal activation sequence of the myocardium. Some earlier studies showed beneficial effects of garlic in cardiac arrhythmias. Garlic powder (1 % corresponding to Kwai/Sapec added to a standard chow for a 10-week period) significantly reduces the incidence of ventricular tachycardia (VT) and fibrillation (VF) in isolated perfused rat heart [162]. Another study in the same manner using garlic powder (1 % added to a standard chow for an 8-week period) also showed significantly reduced ischemia reperfusion-induced ventricular fibrillation (VF) in isolated perfused rat heart and suggested that an intact alliin–alliinase system is important for this activity of garlic [163]. Garlic dialysate decreased the positive inotropic and chronotropic effects of isoproterenol in a concentration-dependent manner and suggesting via β-adrenoceptor blocking action produced by the garlic dialysate [164]. Another study by same author suggested that garlic dialysate has a significant antiarrhythmic effect in both ventricular and supraventricular arrhythmias [165]. Aqueous garlic extract increased the amplitudes of atrial complex "p" wave and the ventricular complex "QRS" of the rat ECG. This is suggestive of increase in voltage output of the atria and ventricles probably in accordance with positive inotropism [166]. A recent animal study suggested that garlic cannot alter the ventricular fibrillation threshold (VFT), but it significantly decreases the upper limit of vulnerability (ULV) in a dose-dependent pattern, indicating that it can reduce the range of the stimulation strength between the VFT and ULV (vulnerability window) during the vulnerable period of a cardiac cycle [167].

A few studies have shown the beneficial effect of garlic and its active constituents in conjugation with some drugs. Allylmercaptocaptopril is an example of a conjugate of the ACE inhibitor drug captopril with garlic allicin. Allylmercaptocaptopril prevented progressive weight gain, without a detectable effect on food intake, lowered blood pressure, and improved cardiac hypertrophy, as indicated by heart weight and ventricular-wall thickness [168]. Garlic therapy in animals with myocardial infection showed improved survival and cardiac function by add-on captopril [169, 170] and propranolol [171]. Garlic juice inhibited the contractions of rabbit and guinea pig aortic rings induced by norepinephrine in Ca^{2+}-free and Ca^{2+}-containing Krebs–Henseleit solutions and indicated that it produces concentration-dependent synergistic effect by its calcium-blocking property [172]. Beneficial effects of combined therapy of garlic and hydrochlorothiazide were also demonstrated and confirmed in the recent past [173, 174]. The same author also reported that combination of *S*-allyl cysteine sulfoxide (SACS) from fresh garlic homogenate and captopril exerted super-additive (synergistic) interaction with respect to fall in blood pressure and ACE inhibition [77]. In one preliminary study, in which pretreatment with aged garlic extract for 27 days ameliorated the effect of an active anticancer agent doxorubicin (DOX) administration on cardiac tissue; cardiomyocytes looked more or less similar to those of control and suggested that aged garlic extract is potentially protective against doxorubicin-induced cardiotoxicity [175].

18 Bioavailability and Metabolism

Very few studies have been conducted on the bioavailability of garlic compounds. An animal study [176] showed that in a very short time (10 min) after orally administering alliin (10 mg/mouse), it was observed in the stomach (7.2%), intestine (22.4%), and liver (2.5%) without the production of allicin and its degradation compounds such as DADS, vinyldithiins, and allyl-SS conjugated compounds, suggesting alliin is not metabolized to respective organosulfur compounds without an appropriate enzyme (allinase). In a pharmacokinetic study using synthesized 35S-labeled alliin, 60–70% was absorbed in rats [177]. Alliin along with DADS has been detected in the perfusate after the isolated rat liver passage, while there was absence of allicin [178] even in human serum or urine from 1 to 24 h after ingesting 25 g of raw garlic containing a significant amount of allicin [108]. These findings indicate that alliin itself is never converted to allicin in the body and metabolized into various organosulfur compounds such as DADS by liver enzymes. When allicin is added to fresh blood, it is quickly transformed into allyl mercaptan, but this compound was not found in blood or urine of people who consume garlic, also demonstrating that the level of allyl methyl sulfide (AMS) in the exhaled air depended on amount of the ingested allicin or its derivatives [179]. Vinyldithiins, 2-vinyl-4H-1,3-dithiin, and 3-vinyl-4H-1,2-dithiin, have been detected in the serum, kidney, and fat tissue >24 h after oral ingestion, while only 1,3-vinyldithiin was found in the rat liver [180]. The metabolic fate of [^{35}S]-labeled DADS in rats after intraperitoneal injection with the maximum concentration of [^{35}S]-labeled DADS by mice livers occurred 90 min after treatment, and about 70% of the radioactivity was distributed in the liver cytosol, of which 80% was metabolized to sulfate [181]. The pharmacokinetics of SAC is well established in animal studies, which is detected in the blood, and its pharmacokinetic parameters are well associated with oral dose administration. Significant concentration of *N*-acetyl-*S*-allyl-L-cysteine is also identified as a metabolite of SAC in the urine. This indicates that SAC could be transformed into *N*-acetylated metabolite by *N*-acetyltransferase in the body. The bioavailability of SAC is 103.0 % in mice, 98.2% in rats, and 87.2% in dogs [182]. SAC was found also in human blood after ingestion of AGE, the main component of which is SAC [183]. DAS could be metabolized by one of the cytochrome P_{450} isoenzymes to form diallyl sulfoxide (DASO) and then diallyl sulfone ($DASO_2$) [184]. After GC–MS analysis, two major peaks, which were identical to allyl mercaptan and DADS after ingesting grated garlic, could be detected in human breath without other organosulfur volatiles [185]. There is a need of major clinical trial which confirm the bioavailability of sulfur and nonsulfur compounds in garlic.

19 Side Effects and Toxicity

According to the suggested doses from the studies and optimum pharmacological responses, the following doses are recommended: 2–5 g of fresh raw garlic, 0.4–1.2 g of dried garlic powder, 2–5 mg garlic oil, and 300–1,000 mg of garlic extract (as solid material). Other preparations should correspond to 4–12 mg of alliin or approximately 2–5 mg of allicin, an active constituent of garlic. Various studies have been investigated in search of toxicity from garlic, but till now there is no known toxic constituents in garlic and its preparations. Garlic is considered to have very low toxicity and is listed as Generally Recognized as Safe (GRAS) by the US Food and Drug Administration (FDA). The most common side effects produced by intake of small amounts of garlic are bad breath and body odor. When garlic is taken in a high dose by a sensitive individual, it is known to cause gastric irritation. A clinical trial showed side effects which include heartburn, nausea, vomiting, diarrhea, flatulence, bloating, mild orthostatic hypotension, flushing, tachycardia, headache, insomnia, sweating, and dizziness as well as offensive body odor [186]. In some cases, people are allergic to sulfur-based compounds and reported allergic reactions to garlic; namely, contact dermatitis, asthma, rhinitis, conjunctivitis, urticaria, anaphylaxis, and angioedema [187–189]. Garlic may be used safely in pregnant and breast-feeding mothers. Consumption of garlic enhances the pharmacological effects of anticoagulants (warfarin, fluindione) but reduces the efficacy of anti-AIDS drug saquinavir [190]. A clinical trial reported that coadministration of garlic did not significantly alter warfarin pharmacokinetics or pharmacodynamics [191].

20 Conclusion

Evidence from in vitro, in vivo, and clinical studies support the beneficial effects of garlic consumption in various preparations in the prevention of cardiovascular disease. The raw garlic and AGE are the most important among the available preparation and showed maximum pharmacological effect in low dose. The present report suggests that garlic has the ability to prevent excess free radical production, maintain the oxidative balance via increase in antioxidant status and increase in bioavailability of nitric oxide, prevent vascular inflammation, reduce cholesterol content and plaque formation, and inhibit platelet aggregation.

Evidence suggests that garlic may produce modest but not clinically significant effects in the treatment of hyperlipidemia and hypertension via reduction in DBP. Indeed, the results from clinical trials are very few and inconsistent, probably due to differences in garlic preparations, unknown active constituents and their bioavailability, and small sample size. Systematic reviews are available for the possible antilipidemic, antihypertensive, antithrombotic, and chemopreventive effects. However, the clinical evidence is far from compelling. Garlic appears to be generally safe, although some allergic reactions may occur [192]; therefore, it would be a safe tool for the treatment and prevention of CVD. In conclusion, the proposed in vitro, in vivo, and animal models should be further verified in human studies in order to establish a causative link between molecular properties and the role of garlic active constituents in the prevention and treatment of CVD.

Acknowledgments I wish to thank CSU library for databases, Kathryn Koromilas for valuable suggestion and Dr. Basit Iqbal for abstract drafting. I can't finish without my family inspiration, including My Parents, Saba and Ariba.

Abstract

Ginkgo biloba is commonly known as maidenhair tree, available as a popular herbal supplementary in Asian, European, and American countries. Extensive in vitro, in vivo, and clinical studies demonstrated and confirmed the neuroprotective effects of a commercial standard ginkgo extract formulation known as EGb-761. Terpene trilactone comprises 5–7 % in EGb-761, collectively called as ginkgolides (G-A, G-B, G-C, G-J, G-K, G-L and G-M) and bilobides. Its clinical application gained popularity in herbal medicine due to treatment of early-stage Alzheimer's disease, cerebrovascular disorders, PAF antagonism, and vestibular disorders. In addition, ginkgolides showed potent antioxidant activities via scavenging of reactive oxygen and nitrogen species. The physiological dosage of ginkgo extracts ranges between 120 and 240 mg/day in humans, and it is readily available as an over the counter product/supplementary product. According to the recent clinical findings, EGb-761 did not confirm its effect on long-term cognitive functioning, while it showed effectiveness and enhancement in shor-term cognitive and related activities. Ginkgo is generally well tolerated, but in a high dose, it can cause gastric upset, skin allergy, and increase the risk of bleeding in patients with risk factors (anticoagulant or antiplatelet treatment, surgery, etc.). Neuropharmacology, clinical issues of safety and usage are addressed in this book chapter.

Keywords

Ginkgo • ginkgolides • neuroprotection • PAF antagonism • terpenoids

1 Introduction

Ginkgo biloba, maidenhair tree, is one of the ancient tree classified in its own division called, Ginkgophyta which belongs to family Ginkgocea, the only species still surviving and found in Asian countries (China, Japan, and Korea) [1]. There are unequivocal representatives of the genus Ginkgo which have been described as a new species, *Ginkgo yimaensis* and another extinct "species," *Ginkgo adiantoides* [2]. Genus, *Ginkgo* has been derived from the Japanese name Yin-Kwo, meaning silver fruit and the species *biloba*, describes the bilobed shape of the leaves. *G. biloba* is also known as a living fossil because of the finding of the fossil plants quite similar to *G. biloba* which date back to 180 million years ago [3]. In the ancient period, ginkgo seeds were used against cough, asthma, enuresis, alcohol misuse, pyogenic skin infections, and worm infestations in the intestinal tract. This is first mentioned in the great herbal Pen Ts'ao Kang Mu of 1596 by Li Shih-chen [4]. The leaf extracts were used for the improvement of the blood circulation, both peripherally and centrally. This started in the 1960s in Germany [5]. The draft monographs on ginkgo folium and extract mentioned in the USP [6, 7] and ginkgo folium and standardized ginkgo extract are in the European Pharmacopeia [6]. The positive monographs on *G. biloba* were published in the German Commission E, which are available in an English translation as well [8]. In addition to the Commission E, WHO also published a positive monograph on *Ginkgo* leaf extracts, which is in principle comparable [9]. This chapter will summarize the beneficial effects and provide an update on gingkolides, mostly in the form of EGb-761 preparation in the various neurological conditions and diseases.

2 Major Bioactive Constituents and Preparations

The commonly used parts of *G. biloba* are the seeds and leaves, which contains most of their pharmacologically important constituents and makes them medicinally important. The seeds contain mainly polysaccharide and protein (ginkbilobin), which stimulates apoptosis of human hepatoma SMMC-7721 cells and exhibit antifungal activity. However, seed also contains 4-*O*-methylpyridoxine, a ginkgotoxin, a poisonous compound whose primary mode of action is to antagonize the activity of vitamin B_6 [10]. The leaf extract is generally categorized into two types: full extracts and standardized extracts. The full leaf extracts are usually prepared with alcohol and contain all alcohol soluble constituents. The standardized extracts are EGb-761 and LI-1370, but EGb-761 is more common in use and contains a variety of active constituents. The major bioactive compounds in EGb-761 are classified as flavonol glycosides (24 %), terpene trilactones (5–7 %), proanthocyanidins (7 %), carboxylic acids (13 %), catechins (2 %), non-flavonol glycosides (20 %), alkylphenols (5 ppm), and other (unknown 28 %) shown in Fig. 122.1. Other preparation like ginkgo extract (P8A) that is approximately 10-fold enriched in terpene trilactones and contains bilobalide and the four ginkgolides (G-A, G-B, G-C, G-J) extracted from the leaves of the plant [11]. While the preparation BN-52021 is specific for ginkgolide B and used as ginkgolides activity.

3 Ginkgolides

Ginkgolides were first isolated by Furukawa in 1932 from the root bark of *G. biloba* [12]. Maruyama et al. [13–17] and Nakanishi [18] isolated and elucidated the structure of ginkgolides G-A, G-B, G-C, and G-M from the root bark. Meanwhile, Okabe and Sakabe independently determined the structures of G-A, G-B and G-C from leaves of *G. Biloba* by means of X-ray crystallography [19, 20]. Later, ginkgolide G-J [21] and two new traces ginkgolide G-K and G-L have been identified [22]. From the total of 5–7 % terpene trilactones, 2.8–3.4 % are ginkgolides A, B, and C, and 2.6–3.2 % are bilobalides, ginkgolides contributes 50–60 %. Chemically, ginkgolides (Fig. 122.2) are diterpene trilactones consist of C-20 terpenes, 6 five-membered rings, that is, a spiro[4, 4]-nonane carbocylic ring, three lactones, and a tetrahydrofuran ring. The presence of a tertiary butyl group makes ginkgolides unique among natural products. All are pharmacologically active; however, ginkgolide B is by far the most potent and has received far more attention from researchers due to their distinguishing structure, specific occurrence, and broad pharmacology.

4 Ginkgolides Pharmacology

A number of studies have been conducted on the pharmacological activities of *G. biloba* crude extract, commercial available extract (EGb-761), and leaf extract. G-B and ginkgolide extract (EGb-761) have received more attention due to their higher potency, broad action, and versatile constituents [23]. The in vitro, in vivo, and clinical studies demonstrated the anti-inflammatory, cardioprotective, anticancer, antidiabetic, antioxidant, and gastroprotective activities as shown in Table 122.1. Out of the various beneficial studies, few of them have not been confirm by further researcher, in animal models, and which are confirmed in animals did not further conducted in human (clinical trial).

5 Neuroprotective Activities of Ginkgolides

Neuroprotection refers to maintaining the intactness of cellular interactions/intercellular communication in the brain resulting in an overall undisturbed

function [45]. Both prevention and delayed onset of neurological disorders would have a large impact in terms of reducing both suffering and costs. Nowadays, researcher interest in herbal medicine has grown in several countries. Moreover, efforts have been made to find new therapeutic agents from these natural products for the prevention or treatment of memory disorders, such as the gradual impairment of memory in aging or in neurodegenerative pathology and even lifestyle factors. Ginkgolides from *G. biloba*, especially G-B and preparation EGb-761, have emerged as natural/herbal source of neuroprotective agents. Various in vitro/in vivo and preclinical/clinical studies confer their neuroprotective activities (Fig. 122.3).

6 CNS Effects of *Ginkgo Biloba*

6.1 Cerebral Blood Flow

Interruption or inclusion in cerebral blood flow leads to a decrease in supply of oxygen and nutrient to the brain, which ultimately leads to several neurodegenerative diseases. Table 122.2 showed the protective effect of EGb-761 in cerebral blood flow disorder animal models.

There are various mechanisms involved in decrease in cerebral blood flow. Research studies suggested three major events including increase uptake of glucose or decrease tissue glucose content, leads to increase glucose utilization and cerebral embolism which have cumulative effects on the cerebral blood flow (Fig. 122.4).

Table 122.1 Common pharmacological activities of *G. biloba* (Ginkgolides)

Pharmacological activities	Preparations	Effects	References
Anti-inflammatory	Ginkgolide B, A, C and J	Inhibit the increase of T-helper 2 cytokines, such as interleukin IL-5 and IL-13, in bronchoalveolar lavage fluid (BALF), suppression of extracellular regulating kinase/MAPK (mitogen activated protein kinase) pathway; ginkgolide B, A, C, and J inhibited PAF-mediated aggregation of human platelets at concentrations of 2.5, 15.8, 29.8, and 43.5 μg/mL,	[24, 25]
Antiarrhythmic	EGb-761	Dose-dependently reduction in ventricular fibrillation (VF) and ventricular tachycardia (VT) in the hearts of rats	[26]
Anticancer	EGb-761	Dose-dependent decreases in xenograft growth of both MDA-MB-231 breast cancer and U-87 glioma cell lines in nude mice; suppress proliferation and increase cytotoxicity in HepG2 and Hep3B cells	[27, 28]
Antidiabetic	EGb-761 and G-B	Ingestion of *G. biloba* extract by an NIDDM subject may increase the hepatic metabolic clearance rate of not only insulin but also the hypoglycemic agents; protect beta cells	[29–31]
Anti-ischemic reperfusion	EGb-761	preventive effect on ischemia-reperfusion injury in rat urinary bladder; reduced hydroxyl-deoxyguanosine (8-OHdG) formation in the DNA from liver undergoing ischemia-reperfusion	[32, 33]
Anti-atherosclerotic	EGb-761	Significantly suppressed the proliferation and migration of VSMCs, promoted apoptosis and reduced inflammatory processes	[34]
Antimicrobial	G-A, G-B, and the standardized Ginkgo leaf extracts	Exhibited antimicrobial activity against *Streptococcus pyogenes*; crude extracts of Ginkgo leaves (7.8 μg/mL) possess inhibitory activity against Gram-positive and Gram-negative bacteria	[35, 36]
Antioxidant	*G. biloba* extract; G-A & G-B	Inhibit NF-κB activation induced by H_2O_2; antagonize iNOS-mediated NO production in macrophages stimulatory effect via antioxidation and attenuation of NF-κB activation	[37–39]
Antithrombotic	EGb-761	In a rat model of thrombosis, the antithrombotic effects of EGb-761 combination therapy were more effective than with ticlopidine alone; combinative therapy of G-B and cilostazol enhanced antithrombotic efficacies without increasing side effects	[40, 41]

6.1.1 Clinical Trials

In a double-blind randomized placebo-controlled trial of 72 outpatients with cerebral insufficiency of at least 24 weeks duration, EGb-761 improved mental/mnestic performance [53]. A meta-analysis was conducted to evaluate *G. biloba* (120–240 mg/day) effectiveness in treating cerebrovascular insufficiency [54]. All of the seven studies included in the analysis were double-blind, placebo-controlled

trials that showed significant improvements compared to placebo on all of the individual symptoms that were analyzed (one study was inconclusive) [54]. Recently, in a pilot study [55] of 9 healthy subjects, the dynamic susceptibility contrast-enhanced magnetic resonance imaging (DSC-MRI) showed a significant increase of non-normalized cerebral blood flow after *G. biloba* extract capsule (15 % in white and 13 % in gray matter).

Table 122.3 Beneficial effects of ginkgolides in animals models of cognitive disorders

Compound	Study	Action	References
EGb-761	Mice	Oral administration (100 mg/kg) facilitate memory processes, acquisition, and improved the performance	[56]
EGb-761	Mice	100 mg/kg dose per day showed improvement in short-term memory but only in the aged group mice	[57]
EGb-761	Mice	a daily i.p. injection (40 mg/kg) cause enhancing effect on the performance of a learning task as observed in both group of mice (adult and aged)	[58]
EGb-761	Rats	200 mg/kg dose showed significant improve in continuous learning and delayed nonmatching to position tasks in aged rats	[59]
EGb-761	Rats	Chronic (60 mg/kg/day i.p.) and acute (60 or 120 mg/kg i.p.) injections enhanced olfactory recognition in young rats and facilitative effects in aged rats that received a single 60 mg/kg i.p. injection	[60]
EGb-761	Chicks	(3 mg/mL) dose facilitate memory in chicks with poor long-term retention	[61]
EGb-761	Rats	high doses (150 mg/kg/b.w./day) significantly improved considerable memory, cognitive performance, and exploratory behavior	[62]
Leaf extract (gingkoselect)	Rats	(100 mg/kg/day, orally, 21 days) normalized cognitive deficits in rats chronically treated with corticosterone and improved memory in the chronically stressed rats	[63]
EGb-761	Rats	50 or 100 mg/kg doses per day protect against intermittent hypoxia-induced memory impairment, oxidative stress, and neuronal DNA damage	[64]

6.2 Cognition

Cognitive abilities include perception, memory, judgment, perceptual speed, spatial manipulation, and reasoning. These declines as part of normal aging. Dementia is a loss of cognitive abilities in multiple domains that results in impairment in normal activities of daily living and loss of independence. AD is the most common cause of dementia, responsible for 60–80 % of all dementia. *Gingko* extract has been involved in improvement of cognitive disorder in various animal models (Table 122.3).

6.2.1 Clinical Trials

Numerous clinical studies have been conducted that showed the *G. biloba* has a beneficial effect in age-related decrease in cognition.

A double-blind, crossover comparative trial [65] with healthy female volunteers documented the ability of EGB ability to improve short-term memory. There was no any significant effect observed at lower doses (120 and 240 mg). However, when the women were given 600 mg of EGB and tested 1 h later, the results showed a very significant improvement in short-term memory compared to women taking a placebo [65]. In a double-blind, randomized placebo-controlled long-term study (24 weeks) involving 72 outpatients with cerebral insufficiency using EGb-761, it showed statistically significant improvement in the short-term memory after 6 weeks and of the learning rate after 24 weeks were observed in the ginkgo group, but not in the placebo group (longitudinal analysis) [53]. In a randomized, double-blind, placebo-controlled study [66] on aged patients receiving either *G. biloba* alcohol/water extract in a high dose (RD), a low dose (LD) or a placebo (PL) for 24 weeks resulted increase in short-term visual memory by 18 %, 26 %, and 11 % in the RD, LD, and PL groves respectively and indicating that the use of ginkgo extracts in elderly individuals with cognitive impairment might be promising. In contrast, another double-blind, placebo-controlled study [67], in 30 healthy male subjects who were receiving 260-mg tablets of Bio Ginkgo (LI-1370) daily for 5 days did not showed any significant results, furthermore another 24-week, randomized, double-blind, placebo-controlled, parallel-group, multicenter trial [68] did not show any statistically significant differences in mean change of scores between ginkgo (either 240 mg/day or 160 mg/day) or placebo. In a 6-week, double-blind, fixed-dose, placebo-controlled trial on intact persons over the age of 55 years who received EGb-761 (180 mg/day) [69], results showed significantly more improvement on a task, assessing speed of processing abilities (i.e., Stroop Color and Word Test color-naming task) and improved overall abilities to remember by the end of treatment as compared to participants who received placebo [69]. A placebo-controlled, multi-dose, double-blind, balanced, crossover trial of 20 healthy subjects who received 120, 240, and 360 mg of a standardized extract of ginkgo (GK501, Pharmaton, SA) or a matching placebo [70] was conducted. The results showed a number of significant changes on the performance measures after administration of ginkgo. The most striking of these was a dose-dependent improvement of the "speed of attention" factor following both 240 mg and 360 mg of the extract, which was evident at 2.5 h and was still present at 6 h. Additionally, there were a number of time and dose-specific changes (both positive and negative) in performance of the other factors [70]. In a very short-term study [71] on healthy postmenopausal, women aged 53–65 years, of one week of ginkgo treatment, showed improved performance in three of the cognitive tasks – the tests of short-term nonverbal recognition memory, mental flexibility, and sustained attention. In another placebo-controlled double-blind design study [72] on young healthy volunteers showed an acute dose of ginkgo significantly improved performance on the sustained attention task and pattern recognition memory task. In a prospective community-based cohort study involved 3,534 subjects aged 65 years and older [73], the results showed that initial consumption of EGb-761 did not modify the risk of dementia, whereas the consumption of other treatments for memory impairment was associated with a higher risk of dementia. Subjects who took *G. biloba* had a significantly lower risk of mortality in the long-term, even after adjustment for potentially confounding factors [73]. In a placebo-controlled, multi-dose, double-blind, balanced-crossover study [74] where combination treatment of 120 mg EGB complexed with phosphatidylserine resulted both in improved secondary memory performance and significantly increased speed of memory task performance across all of the post-dose testing sessions. In a small randomized, double-blind, placebo-controlled trial [75] of GB, 120 mg significantly improves the cognitive performance of subjects with multiple sclerosis (MS) via the Stroop test. In a meta-analysis study [76], which included 6 randomized placebo-controlled trial. Considering baseline risk in the assessment of treatment effect, EGb was found to be effective for cognitive functions in dementia with the treatment of 6 months [76]. Recently, Kaschel [77] showed that the EGb-761 (240 mg once daily) improves free recall of appointments in middle-aged healthy volunteers, which requires high demands on self-initiated retrieval of learned material.

6.3 Neurotransmitter System

Neurotransmitters are the chemical messengers in the nervous system, which relay information across synapses via excitation or inhibition of the next neuron or effector tissue. Neurotransmitters can be classified into two broad categories, small-molecule neurotransmitters and neuropeptides. Small-molecule neurotransmitters, such as acetylcholine and the monoamines, are synthesized in the axon terminal of the neuron and larger neuropeptides, such as somatostatin and vasopressin, are synthesized in the neuron's cell body. It has been shown that *G. biloba* and its gingkolides produces effect on a number of neurotransmitter systems, including serotonergic, adrenergic, dopaminergic, and cholinergic systems.

6.3.1 Adrenergic Transmission

A neurotransmitter formed in sympathetic postganglionic synapses, known as noradrenaline. Very few studies have been conducted to show the effect of *G. biloba* on adrenergic system. Chronic treatment with *G. biloba* extract on rat cerebral cortex resulted in increase in noradrenaline release along with decrease in the density of cerebral β-adrenoceptors and suggested as an adaptive mechanism (after 27 days or 2 months) [78]. The age-related decrease of α-2-binding-sites in rat cerebral cortex was prevented by EGb-761 treatment, indicating a relative increase of noradrenergic neurotransmission in aged rats, while the reduction in binding affinity was unaffected [79]. Oral administration of *G. biloba* extract at a dose of 90 mg/kg for seven consecutive days on rat brain modulate the β-adrenoceptors and implicated in the favorable effects of *G. biloba* extracts on learning and memory [80]. After 14 days of daily oral treatment with 100 mg/kg of EGb-761, which resulted significantly only in decrease of NE uptake in mice [81].

6.3.2 Cholinergic Transmission

Choline is a precursor for biosynthesis of the neurotransmitter acetylcholine; any modulation in the cholinergic system is known to influence cognitive processes, learning processes, and working memory [82]. Indeed, increases in cholinergic transmission are known to enhance working memory performance [83] and vice versa [84]. *G. biloba* extracts have been shown to enhance cholinergic processes in various cortical regions. In vitro studies indicate that EGb-761 (100 μg/mL) increases acetylcholine (ACh) release in hippocampal synaptosomes [85]. In vivo studies showed that EGB attenuate the amnesia induced by scopolamine [86], and chronic oral treatment with an extract of *G. biloba* increases the apparent muscarinic receptor population in the hippocampus of the aged rat [87].

6.3.3 Dopaminergic Transmission

Dopamine (DA) is a monoamine neurotransmitter which has a number of important physiological roles and influences on brain function, including playing a role in regulating attention, cognition, movement, pleasure, and hormonal processes. Studies have shown the benefits of *Gingko* extract in the improvement of DA neuron or its physiological function under the influences of neurotoxicity. Administration of EGb-761 (20, 50, 100 mg/kg/day i.p.) for 7 days before or after MPTP treatment effectively protects against MPTP-induced nigrostriatal dopaminergic neurotoxicity and suggesting that the inhibitory effect of EGb-761 on brain MAO may be involved in its neuroprotective effect [88]. Another study showed the significant recovery of rats observed after EGb (50, 100, and 150 mg/kg) treatment for 3 weeks in 6-OHDA induced decrease in the level of DA and its metabolites and an increase in the number of dopaminergic D_2 receptors in striatum [89]. The neuroprotective effect of EGb-761 against MPTP neurotoxicity in mice, receiving EGb-761, had significantly attenuated MPTP-induced loss of striatal dopamine levels and tyrosine hydroxylase immune staining in the striatum and substantia nigra pars compacta. Moreover, the author suggested that the neuroprotection was associated with blockade of lipid peroxidation and reduction of superoxide radical production (indicated by a downregulation of Mn-superoxide dismutase activity) [90]. Chronic (100 mg/kg/14 days/once daily) treatment with EGb-761 showed dose-dependent increases in frontocortical dopamine levels and, to a lesser extent, in the striatum [91]. A recent study results suggest that administration of EGb-761 increases dopaminergic activity in the paraventricular nucleus (PVN) and the mesolimbic system to facilitate noncontact erection (NCE) in male rats [92].

6.3.4 Glutamateric and GABAergic Transmission

Glutamate is the major excitatory neurotransmitter of the cortex and hippocampus, released from vesicles in presynaptic terminals by a Ca^{2+}, and is involved in many aspects of higher mental function. In particular, loss and dysfunction (hyperactivity) of both the pre- and postsynaptic glutamatergic system have been linked to neurodegenerative disorders. *Gingko* extract treatments have shown the positive effect in the glutamate transmission either from loss or excitotoxitcity. Ginkgolide B reduced excitotoxic damage in cultured chick embryo telencephalic neurons overexposed to glutamate [93]. Furthermore, BN-52021 (100 mM) showed protection against glutamate toxicity when it was added to rat neuronal cultures 24 h after glutamate exposure [94]. EGb (2.5 mg/L) and its constituent G-B (2 mg/L) protected the neuronal viability against glutamate-induced injury and prevented the glutamate-induced elevation in the intracellular free calcium (Ca^{2+}) concentration. EGb (3–10 mg/kg) attenuated the decrease of nucleus areas in arcuate nuclei induced by glutamate (1 g/kg, s.c.) [95]. In contrast, another study showed an increase in protein kinase A (PKA) activation by G-B, which subsequently enhances the Ca^{2+} entry through voltage-dependent N and P/Q-type Ca^{2+} channels to cause increase in evoked glutamate release from rat hippocampal nerve terminals [96]. Recently, EGb-761 showed neuroprotection at a concentration 200 μg/mL to the spinal cord neurons from glutamate excitotoxicity and oxidative stress-induced cell death [97]. Kynurenic acid (KYNA) belongs to the group of low-affinity metabotropic glutamate receptor (mGluR) antagonists and interferes with the glycine B site of the NMDA receptor. An earlier study showed that EGb-761 modulating the glutamatergic systems are KYNA and 6-hydroxykynurenic acid (6-HKA) [98]. Ginkgolides are selective and potent antagonize at a concentration 10 μM the glycine receptor action and at IC_{50} 73 μM inhibit gamma-aminobutyric acid ($GABA_A$) receptors activity [99]. Ginkgolides A, B, and C noncompetitive inhibit the direct action of α, β, and γ $GABA_A$ receptor [100]. In vivo treatment of rats with EGb and its bioactive components G-A and G-B reduces the ligand-binding capacity, protein, and messenger RNA expression of the adrenocortical mitochondrial peripheral-type benzodiazepine receptor (PBR) [101].

6.3.5 Serotoninergic Transmission

Serotonergic neurotransmission plays a pivotal role in the etiology and expression of stress and anxiety disorders. In vitro EGb-761 (4–16 μg/mL) significantly increase the 5-HT uptake (23 %) and also similar effects have been found in ex vivo synaptosomes preparation from the cortex of mice treated orally (100 mg/kg/day) with EGb-761 [102]. It was found that an age-related decrease in $5\text{-}HT_{1A}$-receptor binding density in human cerebral cortex. Intraperitoneally administration of EGb-761 (5 mg/kg) resulting significantly (33 %) increase the binding density in aged rats [103]. These findings indicate that changes in $5\text{-}HT_{1A}$ receptors may reflect changes in the brain that are responsible for the impaired cognition that occurs with aging. *G. biloba* extract (14 mg/kg p.o.) restored restraint stress-induced elevation in whole brain levels of catecholamines (NE, DA), 5-HT, and plasma corticosterone to near normal levels [104]. The administration of EGb-761 (50 mg/kg per o.s./14 days) antistress property via enhancing the stimulation of $5\text{-}HT_{1A}$ receptors and preventing their desensitization after subchronic cold stress [105]. In addition another study showed the anti-aggressive effect of EGb-761 may be mediated by $5\text{-}HT_{2A}$ receptors in the MAO-A deficient mice [106]. EGb-761 also induces a stimulus control similar to that of $5\text{-}HT_{1A}$ receptor agonists, and indeed, changes in behavior induced by EGb-761 (10 mg/kg i.p.) were antagonized by the selective $5\text{-}HT_{1A}$ receptor antagonist WAY 100635 [107].

6.4 Free Radical Scavenging

Oxidation and reduction process is one of the cellular activity occurred in each and every kind of cells, whereas reactive oxygen and nitrogen species (RONS) are the major by product formed. Whenever the rate of formation of RONS is more than the

rate of clearance from the cells then the oxidative stress environment created, which cause a number of neurodegenerative disorders including cerebral ischemia, neuronal hypoxia, and AD. Extensive research have been conducted and shown the antioxidant activity of *G. biloba* constituent (Fig. 122.5). In vitro, EGb-761 is a potent free radical scavenger via inhibition of NADPH-oxidase, decreased in the concentration of superoxide anion (O^{-2}) and hydrogen peroxide (H_2O_2) along with the reduction of hydroxyl radical generation ($OH^{\cdot}$) at concentrations as low as 15.6 μg EGb/mL [108, 109]. EGb-761 showed the dose-dependently inhibition of nitric oxide (NO) production in lipopolysaccharide/gamma interferon (LPS/IFNγ)-activated macrophages by concomitantly scavenging NO and inhibiting inducible nitric oxide synthase (iNOS) mRNA and enzyme activity [110, 111]. Excessive iron deposition and mitochondrial insufficiency are responsible for aging and degenerating nervous system. Heme oxygenase-1 (HO-1) is the rate-limiting enzyme that degrades heme to biliverdin, free iron, and carbon monoxide; its immunoreactivity is enhanced greatly in neurons and astrocytes of the hippocampus and cerebral cortex of Alzheimer subjects and co-localizes to senile plaques and neurofibrillary tangles (NFT) [112]. A study showed that EGb-761 induces HO-1 in a dose-dependent manner (0, 10, 50, 100 and 500 μg/mL) and suggested the protective activity in ischemia [113]. In an in vitro study, EGb-761 also displayed protective effects against toxicity produced by either H_2O_2 or nitric oxide which possibly mediate Aβ toxicity and completely blocked Aβ-induced events, such as reactive oxygen species accumulation and apoptosis [114]. Recently, EGb-761 pretreatment (100 mg/kg/o.s.) significantly increased the protein expression levels of Nuclear factor E_2 (Nrf2), HO-1, GAPDH, β-actin,

$CRMP_2$, and histone H_3 during t-BuOOH-induced oxidative stress and showed antioxidant as well as neuritogenic potential and suggesting the beneficial effect of extract in stroke and ischemic brain injury [115]. EGb-761 has been shown to increase the protein level and activity of antioxidant enzymes such as superoxide dismutase (60 %) and catalase (22 %) in rat hippocampus [116] and rat ileum [117] as well as of glutathione (GSH) reductase in mouse liver specifically from G-A [118]. Similarly, the activity of γ-glutamylcysteinyl synthetase, the rate-limiting enzyme of GSH synthesis, was enhanced by EGb-761 (200 μg/mL) in a dose-dependent manner [119]. In vitro study on human neuroblastoma cell line (SK-N-SH), where G-A, and G-B inhibit the NO-induced cytotoxicity in SK-N-SH cells via scavenging [120].

6.5 Apoptosis

EGb-761 (100 mg/L), G-J (100 mM/L), and G-B (10 mM/L) reduces apoptosis from staurosporine-induced apoptotic chick embryonic neurons to 24 %, 62 %, and 31 %, respectively [121]. It is well established that ROS may trigger apoptosis in various types of cells including T cells and neuronal cells. Mice were treated daily with 100 mg/kg EGb-761 per o.s. over a period of 2 weeks showed significantly reduction in ROS-induced apoptosis and protects spleen T-lymphocyte [122]. In vitro study showed that EGb-761 (100 mg/mL) prevented the hydroxyl radical-induced thymocyte apoptosis [123]. In contrast, in vivo study using EGb-761 (250 μg/mL) shown to effectively decrease oral cavity tumors by inducing apoptosis via caspase-3 activation [124]. In addition, another study also support and showed that treatment of mouse blastocysts with 5–10 μM G-A and G-B dose-dependently induced five- to eightfold increases in apoptosis and suggesting their pro-apoptotic activity [125]. Moreover, a recent animal study revealed after administration of 10 and 20 mg/kg G-B significantly suppress gene expressions of TLR-4 and NF-κB, lessen concentrations of TNF-α, IL-1β and IL-6 as well as reduce number of apoptotic neuronal cells in haemorrhagic rat brain tissues [126].

7 *Ginkgo biloba* in CNS Disorders

7.1 Alzheimer's Disease

Alzheimer's disease (AD) is a progressive neurodegenerative disorder, pathologically characterized by deposition of amyloid beta (Aβ) plaques and neurofibril tangles ultimately leads to decline cognitive function and memory. A number of researches have been done on anti-Alzheimer's activity of ginkgo extract, and most of them have shown significant beneficial effect (Fig. 122.6). But also there were some studies which do not show any beneficial activity of ginkgo extract. Even though the results of nonsignificant, we cannot neglect the plenty of significant outcomes from the ginkgo extract. EGb-761 (100 μg/mL) was even able to protect (up to 8 h)

Fig. 122.6 Alzheimer's disease pathogenesis and ginkgolides effect: amyloid precursor protein found in the cytosol and upon action of various enzymes forms soluble nontoxic amyloid and toxic amyloid beta via nonamyloidogenic and amyloidogenic pathway. Secretase involved in non-toxic amyloid formation and ginkgolides enhances this enzyme activity and protect the brain. While amyloid beta from the amyloidogenic pathway induces toxicity by increasing NMDA excitotoxicity, increase in ROS accumulation, increase in apoptosis, inhibition of cholinergic transmission and aggregation. These all events are inhibited ginkgolides and showed neuroproecion against demetia and AD

hippocampal cells against toxicity induced by $A\beta_{25–35}$ and $A\beta_{1–40}$ [127]. Diffusible, nonfibrillar ligands derived from $A\beta_{1–42}$ are potent central nervous system neurotoxins, and these ADDLs soluble oligomers of Aβ have been found in AD brains. An in vitro study [128] showed that EGb-761 inhibits the formation of amyloid beta-derived diffusible neurotoxic soluble ligands (ADDLs) in a dose-dependent manner. Alpha-secretase (α-secretase), the enzyme regulating the non-amyloidogenic processing of APP (cuts within the Aβ segment) and the release of α-APPs, EGb-761, enhance the effect on the α-secretase pathway observed at low concentrations (5 and 25 μg/mL) in hippocampal slices could be counterbalanced by an α-secretase PKC-dependent pathway at higher concentration (100 and 200 μg/mL) [129]. Free cholesterol may be involved in the production of APP and Aβ peptide, key events in the development of AD. EGb-761 (50 mg/kg) lowered circulating free cholesterol and inhibited the production of brain APP and Aβ after 28 weeks of treatment, as compared with controls rats [130]. As Aβ elicit its neurodegenerating effects by interfering with the central cholinergic system, therefore an in vitro study [131] results showed that G-B (0.01–10 μM) caused a concentration-related reversion of the inhibitory effect elicited by the effective concentration of Aβ (1 μM) and suggesting its anti-amnesic effect by minimizing the inhibitory effect of Aβ peptides on cholinergic transmission. Chronic *G. biloba* extract (similar to EGb-761) treatment (70 mg/kg/day) block an age-dependent decline in spatial cognition without altering Aβ levels and without suppressing protein oxidation in a transgenic mouse model of AD [132]. EGb-761 (100 μg/mL) directly inhibits amyloid fibril formation in solution in vitro and in the cell culture medium, moreover G-J also inhibit (72 %) the Aβ aggregation [133]. In a (SH-SY5Y) neuroblastoma cell line study [134], ginkgolides (A and B) inhibit PAF and that platelet-activating factor antagonists block the toxicity of amyloid-$\beta_{1–42}$ or sPrP106. The results suggested that PAF antagonists such as the ginkgolides may be relevant treatments for prion or AD [134]. Furthermore, pretreatment with ginkgolides A or B protects neurons against A$\beta_{1–42}$-induced synapse damage, reduced the effects of PAF, and suggested that the ginkgolides are active components of *G. biloba* preparations and may protect against the synapse damage and the cognitive loss seen during the early stages of AD [135]. There is also evidence which showed suppression of Aβ-related pathological behaviors. Among six single components of EGb-761, only G-A and G-J (100 μg/mL) exhibited a statistically significant delay of Aβ-induced paralysis in transgenic worms [136]. Transthyretin plays an important role in hormone transport in the brain and possibly a neuroprotective role by Aβ sequestration. The only gene on the array whose expression was upregulated more than threefold that encodes transthyretin in the hippocampus by dietary supplementation with EGb-761 in a dose of 36 mg/kg [137]. Aβ_{1-42} induces cell apoptosis, reactive oxygen species (ROS) accumulation, mitochondrial dysfunction and activation of c-jun N-terminal kinase (JNK), extracellular signal-regulated kinase 1/2 (ERK1/2), and Akt signaling pathways. In a double-transgenic mouse model (TgAPP/PS1) study [138], EGb-761 (100 mg/kg) significantly increases cell proliferation in the hippocampus of both young (6 months) and old (22 months) TgAPP/PS1 mice, and the total number of neuronal precursor cells in vitro in a (0–120 μg/mL) dose-dependent manner. Furthermore, Aβ oligomers inhibit phosphorylation of cAMP response element-binding protein (CREB) and cell proliferation in the hippocampus of TgAPP/PS1 mice. Administration of EGb-761 (100 mg/kg) reduces Aβ oligomers and restores CREB phosphorylation in the hippocampus of these mice and suggesting therapeutic potential for the prevention and improved treatment of AD [138]. In other transgenic mice for human APP (Tg2576) model study [139], long-term treatment (16 months) with EGb-761 (300 mg/kg diet) significantly lowered human APP protein levels by approximately 50 % as compared to controls in the cortex but not in the hippocampus. However, APP levels were not affected by EGb-761 in young mice, suggesting the potential neuroprotective properties of EGb-761 may be, at least partly, related to its APP lowering activity [139]. An in vitro study [140] revealed that EGb-761 prevent the activation of NF-κB, ERK1/2, and JNK pathways induced by Aβ in neuroblastoma cell line N2a. Another human neuroblastoma SH-SY5Y cell line study [141] showed that EGb-761 (50–200 μg/mL) constituents G-B (5–20 μg/mL) along with quercetin (1.5–6 μg/mL) involved in the inhibitory effects on Aβ_{1-42} induces cell apoptosis, reactive oxygen species (ROS) accumulation, JNK, ERK1/2, and Akt signaling pathways. While only G-B helped to improve mitochondrial functions. Decreased clearance of Aβ from brain is the main root cause of their deposition in sporadic AD. However, the mechanisms underlying ischemia-mediated AD pathogenesis remain unclear. The receptors for advanced glycation end products (RAGE) and low-density lipoprotein receptor-related protein-1 (LRP-1) expressed at blood–brain barrier (BBB) are actively involved in Aβ clearance. In vitro study [142] suggested that EGb-761 favor clearance of Aβ via regulating the expression of RAGE and LRP-1 during brain ischemia. Synaptic dysfunction is likely to occur at early stages of AD. Low levels of oligomeric Aβ alter mechanisms underlying the excitatory response at single synapses producing synaptic dysfunction before synapse loss, cell death, and a complex series of events including inflammation, deposition of Aβ in senile plaques and within the walls of the cerebral microvasculature and appearance of neurofibrillary tangles. A new *G. biloba* extract P8A, 70 % enriched with terpene trilactones, prevents Aβ_{1-42} induced inhibition of long-term potentiation in the region I of hippocampus proper (CA1) in mouse hippocampal slices and also capable of inhibiting cell death of rodent hippocampal neurons caused by Aβ_{1-42}, which is attributed in large part to G-J (1–5 μM) that completely replicates the effect of the extract [143]. EGb LI-1370 (100 μg/mL) significantly improved oxidative phosphorylation system performance and was able to restore Aβ-induced mitochondria failure [144]. An in vitro study [145] showed that G-B (40 μg/mL) significantly dampens Aβ_{25-35}-induced apoptosis, and the neuroprotective effects may be intimately associated with brain-derived neurotrophic factor upregulation caused by G-B. The *N*-methyl D-aspartate receptor (NMDA) plays a pivotal role in the process of glutamate-induced excitotoxicity associated with many neurological disorders including AD. Studies in isolated rat hippocampal neurons indicated that the modulatory effects of EGB on NMDA-activated currents may contribute to the neuroprotective effects of two solvent preparations that is mEGB (0.1 mg/mL, dissolved in DMSO) and nEGB (0.1 mg/mL) either dissolved in DMSO or dissolved in standard extracellular solution where the modulatory effect of nEGB on NMDA-activated current was greater than that of mEGB [146].

7.1.1 Clinical Trials

In a randomized, double-blind, placebo-controlled, multicenter study (24 weeks) on 156 (222 patients at entry) outpatients with presenile and senile primary degenerative dementia of the Alzheimer type (DAT) and multi-infarct dementia (MID) [147], where patients received a daily oral dose of 240 mg of EGb-761 or placebo. There was a significant difference in the number of responders at the end of the treatment (28 % for EGb-761 compared with 10 % for placebo), suggesting that EGb-761 is of clinical efficacy in the treatment of outpatients with dementia. Furthermore a placebo-controlled, randomized, double-blind clinical trial [148] of 40 patients with moderate dementia received intravenous infusions of either

EGb-761 or placebo 4 days per week for 4 weeks. The result showed in an improvement of psychopathology and cognitive performance, which is reflected in an increased ability to cope with the demands of daily living. In addition, placebo-controlled, double-blind, randomized trials [149], 137 patients (327 patients at entry) were treated for 52 weeks with 120 mg of EGb-761. The patients showed significant improvement in learning, memory, visual and spatial orientation, and social behavior. A meta-analysis of effect size on the results of the 4 studies of more than 50 studies considered that met the author's inclusions criteria [150]. This analysis revealed a highly significant overall effect of ginkgo compared with placebo. The results showed that there is a small but significant effect of 3- to 6-month treatment with 120–240 mg of *G. biloba* extract on objective measures of cognitive function in AD [150]. In a long-term (26 weeks) study [151] on mild to severe AD patient, EGb-761 treatment with a 120-mg dose (40 mg t.i.d.) and the placebo group showed a statistically significant worsening in all domains of assessment, while the group receiving EGb-761 was considered slightly improved on the cognitive assessment and the daily living and social behavior. A retrospective analysis [152] explored whether the therapeutic effect of EGb-761 (120 mg) in AD depends on baseline severity. Treatment effect favorable for EGb-761 could be observed with respect to cognitive performance and social functioning, regardless of the stage of dementia. However, improvement was observed only in the group of patients with very mild cognitive impairment, while in more severe dementia, the mean effect of EGb-761 should be considered in terms of stabilization or slowing down of worsening [152]. An interesting result of a 6-week study [153] on healthy volunteers (203 completed out of 230) indicates that ginkgo (40 mg, t.i.d.) did not facilitate performance on standard neuropsychological tests of learning, memory, attention, and concentration or naming and verbal fluency in elderly adults without cognitive impairment. The ginkgo group also did not differ from the control group in terms of self-reported memory function or global rating by spouses, friends, and relatives. These data suggest that ginkgo provides no measurable benefit in memory or related cognitive function to adults with healthy cognitive function [153]. In a randomized controlled trial [154] of 359 dementic patient aged 50 years or above, treated with EGb-761 (240 mg/day) or placebo for 22 weeks. Their short syndrome test (SKT) score improved by −3.0+/−2.3 and −3.4+/−2.3 points in patients with AD and VaD, respectively, whereas the patients on placebo deteriorated by +1.2+/−2.5 and +1.5+/−2.2 points [154]. Another, randomized, double-blind exploratory trial [155] of 96 outpatients, aged 50 years or above, where EGb-761 (240 mg/day), donepezil (initially 5 mg, after 4 weeks 10 mg/day) or EGb- 761 and donepezil combined (same doses) were administered for 22 weeks. The results showed no significant difference in the efficiency between EGb-761 and donepezil, but a combination therapy will be superior to a mono-therapy with one of both substances with fewer side effects under a combination therapy than under monotherapy with donepezil [155]. In a German study [156], it was reported that the efficacy of EGb-761 has its place in the treatment of dementia. EGb-761 in the treatment of dementia (AD and VD) had been studied in 10 randomized controlled, double-blind clinical trials. In 3 of the

4 large trials conducted in accordance with recent recommendations, EGb-761 was significantly superior to placebo with respect to cognitive performance and one or more further (global, functional, or behavioral) outcomes demonstrating the clinical relevance of the findings. The findings from the 6 smaller trials were in line with those of the large trials [156]. Recently, published systematic review and meta-analysis [157] using 9 relevant trials were found statistically significant advantage of *G. biloba* extract compared to placebo in improving cognition for the whole group of patients with AD, vascular, or mixed dementia. While regarding activities of daily living, there was no significant difference for the whole group. However, in the subgroup of patients with AD, there was a statistically significant advantage of *G. biloba* extract compared to placebo [157]. Moreover, a recent multicenter trial [158] of 410 outpatients with mild to moderate dementia (AD, VD, or mixed form) with neuropsychiatric features, where the patients were treatment with 240 mg of EGb-761 or placebo once daily for 24 weeks. The results showed significantly superior to placebo in the treatment of patients with dementia with neuropsychiatric symptoms [158]. More recently, in a multicenter, double-blind, randomized, placebo-controlled, 24-week trial [159] with 410 outpatients, treatment with EGb-761 at a once daily dose of 240 mg was safe, confers the previous study findings, which is resulted in a significant clinically relevant improvement in cognition, psychopathology, functional measures, and quality of life of patients and caregivers.

7.2 Parkinson's Disease

Parkinson's disease (PD) is characterized by the degeneration of the dopaminergic nigrostriatal pathway, as indicated by the severe loss of substantia nigra neurons and by the decrease in striatal dopamine (DA) concentration. N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and 6-hydroxydopamine (6-OHDA) selectively causes degeneration of the nigrostriatal dopaminergic neuronal pathway and used as lesion model in several studies to investigate the possible protective effect of EGb-761. Semi-chronic ingestion of EGb-761 for 17 days (100 mg/kg/day) prevents MPTP-induced reduction (approximately 25 %) in the striatal dopaminergic nerve endings in mice [160]. The 2 mono-amino oxidase (MAO) isoforms (A and B) regulate levels in the brain of most biogenic amines (e.g., dopamine, serotonin, and norepinephrine), and it is also well established that MAO-B activity increased with age and that some MAO-B inhibitors may improve quality of life in the elderly. Interestingly, 2 *G. biloba* extracts different from EGb (dried leaved extract) have been reported to induce reversible inhibition of both MAO-A and MAO-B activity in rat brain mitochondrial extracts [161]. Moreover, EGb-761 administered before (20, 50, 100 mg/kg/d i.p.) or after (50 mg/kg/d i.p.) MPTP treatment effectively protects against MPTP-induced nigrostriatal dopaminergic neurotoxicity and that the inhibitory effect of EGb-761 on brain MAO may be involved in its neuroprotective effect in mice [88]. EGb (100 mg/kg/d) decreased the duration and frequency of the rotation of rats ($P < 0.05$, $n = 10$) while EGb (50 or 100 mg/L) inhibited the decreases of dopamine (DA) and superoxide dismutase (SOD) and the increase of malondialdehyde (MDA) induced by MPTP [162]. 6-OHDA-induced rat models of PD study suggested that levodopa (50 mg/kg/day for 3 days, 5 days, 7 days, L-dopa group) had neurotoxic effect, and EGb (100 mg/kg/day) decreases the toxicity of levodopa [163]. EGb-761 (100 mg/kg/day) was investigated on 6-OHDA-induced neurotoxicity in the nigrostriatal dopaminergic system of the rat brain and reduces the behavioral deficit in 6-OHDA lesions in rat and also indicates a possible role for the extract in the treatment of PD [164]. Rats were treated with 50, 100, and 150 mg/kg EGb for 3 weeks showed dose-dependent protection against 6-OHDA-induced Parkinsonism in rats [89]. EGb-761 attenuates MPTP-induced neurodegeneration of the nigrostriatal pathway and suggesting that an inhibitory effect against oxidative stress possibly partly responsible for its observed neuroprotective effects [90]. Recently, chronic treatment with EGb-761 (100 mg/kg/14 days/once daily) showed dose-dependent increases in frontocortical dopamine levels [91].

7.2.1 Clinical Trials

The in vitro and animal data suggesting the beneficial effect of EGb-761 in PD, but there is no any clinical trial conduct to investigate the protective effect in human. Therefore, there is a need of conduction of such trials.

7.3 Anxiety

Anxiety is a condition which describes a normal feeling person experience when faced with threat, danger, or when stressed and the anxious condition makes a person upset feeling, uncomfortable, and tense. EGb-761 (100 mg/kg in 5 % ethanol) treatment group inhibited the development of polydipsia in rats due to the stress of daily handling and intubation [165]. In a 20 days of oral treatment with an extract EGb-761 (50 or 100 mg/kg/day) showed that auditory perturbation (stress) during the discriminative phase of learning decreased the percentage of correct responses and increased the number of errors in young as well as old rats [166]. Chronic administration of EGb-761 (50 or 100 mg/kg p.o. daily for 14 days) inhibits stress-induced corticosterone hypersecretion through a reduction in the number of adrenal peripheral benzodiazepine receptors [101]. Another, long-term EGb-761 (50 or 100 mg/kg p.o. daily for 14 days) administration study [167] on rats resulted in a decreased basal corticosterone secretion and an attenuation of the related increase in corticotropin releasing hormone (CRH) and arginine vasopressin (AVP) gene expression, while chronic i.p. injection of G-B reduced basal corticosterone secretion without alteration in the subsequent CRH and AVP increase. Under intense surgical stress CRH, ACTH, and corticosterone plasma concentrations were markedly elevated in control animals but significantly less so in EGb-761 treated animals. These findings confirm that the administration of EGb-761 and G-B reduces corticosterone secretion suggest that EGb-761 interferes with the regulation of the activity of the hypothalamic-pituitary-adrenocortical (HPA) axis [167]. There were few studies conducted and showed the anxiolytic effect of EGb-761 in combinational therapy. Hasenohrl et al., in the year 1996 and 1998 [168, 169], showed the anxiolytic effect of a combination preparation of standardized extracts of *G. biloba* and *Zingiber officinale*. Ginkgolic acid conjugates (GAC), isolated from the *G. biloba* leaf, having similar profile with EGb-761, GAC (0.6 mg/kg) significantly increased ambulation and reduced the immobility time, suggesting the anxiolytic activity [170]. EGb-761 (100 mg/kg/day) serve as an antistress buffer, showed attenuating the increase in anxiety in mice after cold water exposure [171]. EGB (0.125 g/kg, p.o.) produces a significant anxiolytic-like effect following repeated administration and that G-A (1 or 2 mg/kg, p.o.) is most likely responsible for this effect [172]. It was found that *G. biloba* extract (14 mg/kg p.o.) restored restraint stress-induced elevation in whole brain levels of catecholamines (NE, DA), 5-HT, and plasma corticosterone to near normal level [104]. In prevention and treatment of the post-stress memory dysfunctions study [173], repeated administration of EGb-761 (100 mg/kg) prevents stress and corticosterone-induced impairments of information retrieval in rats.

7.3.1 Clinical Trials

A few clinical studies have conducted to evaluate the anxiolytic activity of ginkgolides. An early German studies, patients enrolled with cerebrovascular disease induced cognitive impairment, in which anxiety was one of the noncognitive symptoms relieved significantly by EGb-761 treatment [174]. In a pilot study [175], EGb (240 mg/day) significantly improved sleep pattern by an increase of sleep efficiency and a reduction of awakenings especially in the treatment of the depressive syndrome with sleep disturbance. In a trial on healthy volunteers [176], single treatment with EGb-761 (120 mg) reduced stress-induced rise in blood pressure without affecting the heart rate and influence salivary cortisol release in response to some stress stimuli. A randomized, double-blind, placebo-controlled trial [177] suggested that EGb-761 (240 and 480 mg/day) has a specific anxiolytic effect that is dose-dependent and significantly exceeds the placebo effect commonly seen in trials of psychoactive drugs.

7.4 Cerebral Insufficiency/Ischemia and PAF

Cerebral insufficiency refers to describe the people with age-related decline in mental function and decrease blood flow to the brain cause by clogged arteries. Platelet activating factor (PAF) is an inflammatory mediator, plays an important role in allergy, inflammatory processes, coronary, and cerebral vasoconstriction [178]. The production and release of PAF in the brain under various pathological conditions, including oxidant stress-induced ischemic injury [179]. The efficiency of EGb-761on cerebral circulation and metabolism has been demonstrated in various models of cerebrovascular insufficiency and showed beneficial effect like cerebral edema in rats intoxicated with triethyltin chloride (TET) [180]. Moreover, oral or intravenous administrations EGb decrease cerebral edema development in gerbils [181]. In an animal study [182], EGb-761 and an extract of local ginkgo leaf (LGb) improved spatial memory function with chronic cerebral insufficiency (produced by bilateral common carotid artery ligation) from the second week after operation, but only EGb-761 delayed deterioration of motor functions from the fifth week after operation.

EGb enhanced the local cerebral blood flow as well as the blood glucose level dose-dependently but decreased the cortical glucose concentration without other substrate levels being changed in rat [180]. EGb-761 (110 mg/kg/day) could prevent the ischemia-induced impairment of the Na,K-ATPase activity [183]. Pretreatment (15 days) with oral administration of *G. biloba* extract (Ph-GB; 37.5–150 mg/kg) significantly and in a dose-dependent way reduced post-ischemic brain MDA (malondialdeide) levels and post-ischemic brain edema in gerbils [184]. Oral administration of EGb-761 at a dose of 25, 50, and 100 mg/kg/day protects against ischemia-induced neuron death and reductions in mitochondrial gene expression in gebrils [185]. In addition, EGb-761 (100–200 mg/kg) protects against transient and permanent focal cerebral ischemia and was effective after a prolonged reperfusion period even when therapy is delayed up to 2 h in rats [186]. EGb-761 (100 mg/kg) also showed protection of neuronal cells against ischemic brain injury by preventing injury-induced decreases in p70S6 kinase and S6 phosphorylation in rats [187]. In contrast, a recent study showed that after p.o. administration of G-B (6 mg/kg) once daily for 7 days does not cause acute increase in cerebral blood flow after reperfusion, especially in hyperglycemia condition but effective in reactive oxygen species or MDA control in hyperglycemia ischemic rats [188]. G-B protects against cerebral ischemic injury by inhibiting excitotoxicity by modulating the imbalance of excitatory amino acids versus inhibitory amino acids, which may support the traditional use of *G. biloba* leaves for the treatment of stroke [189]. Pretreatment with G-K (2, 4, and 8 mg/kg (i.v.) once a day for 5 days) significantly diminished the volume of infarction and brain water content and improved neurological deficit score [190]. Moreover, G-K markedly reversed the level of MDA, NO, NOS, and SOD to their normal state in serum or cerebral ischemic section. Another recent in vitro (brain slices) and in vivo study [191] revealed that administration of EGb-761 (300 mg/kg) strongly reduces cellular edema formation and neurodegeneration under conditions of ischemia possibly via reduction of excitotoxicity because ischemia-induced release of glutamate was strongly suppressed.

Administration of ginkgolide B (BN-52021) in dose of 10 mg/kg/day via i.p. or oral-improved stroke index scores (determined by symptoms ranging from piloerection to seizures) and protect brain against hypoxic damage with their PAF antagonistic properties following bilateral carotid artery occlusion in the gerbil [192]. Free fatty acids, diacylglycerols, and polyphosphoinositides were accumulated in ischemic condition. BN-52021 (10 mg/kg, i.p.) inhibited the maturation of ischemic injury; increased cerebral blood flow and increased free fatty acid levels were reduced likely by inhibition of phospholipase A [193]. Moreover pretreatment with BN52021 (10 mg/kg, i.p.) reduces the injury-induced activation of phospholipase A2 and lysophospholipase, which mediate the accumulation of FFA in mice brain [194]. A temperature-controlled model of transient forebrain ischemia in the rat receiving BN-52021 (25 mg/kg, s.c.), 1 h before and 1 h after the induction of transient forebrain ischemia, exhibited a significant reduction in hippocampal and neocortical damage and proposed that PAF plays an important role in the pathophysiology of ischemic/excitotoxic neuronal injury via a direct action on neurons [93]. A comparative study [25] confirmed that induction of aggregation of human platelets by PAF requires at least 200 times higher concentration when compared to rabbit cells. Under the chosen experimental conditions, PAF-mediated aggregation of human platelets was half-maximally inhibited by ginkgolide B, A, C, and J at concentrations of 2.5, 15.8, 29.8, and 43.5 μg/mL, respectively [25]. In an animal study [195], both pre- and posthypoxic treatment with BN 52021 (25 mg/kg/dose, two serial doses) decreased the incidence of cerebral infarction from 90 % to about 30 %. The result suggested either prophylactic or rescue administration of PAF antagonists decreases the incidence and severity of brain injury associated with an episode of perinatal cerebral hypoxia-ischemia [195]. In a photochemically induced thrombotic cerebral ischemia in tree shrews model, G-B (5 mg/kg, i.v.) 6 h after photochemical reaction, cortical NA, DA, and 5-HT contents recovered to control levels and water, and calcium contents decreased significantly [196]. The results suggested that PAF may play an important role in inducing calcium overload, brain edema, and secondary brain damage in penumbra and that G-B produces its neuroprotective effects by inhibiting the pathological manifestation of PAF [196]. A recent animal study [197] showed that administration of G-B (10 or 20 mg/kg) before ischemia reduced the ischemia-induced elevation of levels of glutamate, aspartic acid, and glycine, increased the elevation of extracellular GABA, decreased the excitotoxic index, and diminished the volume of cerebral infarction. The results suggested the protection against cerebral ischemic injury by G-B-induced inhibition excitotoxicity by modulating the imbalance of excitatory amino acids versus inhibitory amino acids [197].

7.4.1 Clinical Trails

There were numerous clinical trial conducted between 1980s and 1990s, and most of them were shown a significant result. In an open one year German trial [198], *G. biloba* extract at a dose of 120 mg/day showed a statistically significant regression of the major symptoms of vertigo, headache, tinnitus, short-term memory, vigilance, and mood disturbance in 112 outpatient with chronic cerebral insufficiency. In a multicentric, double-blind, EGb versus placebo French trial [199] involving 166 patients confirmed that *G. biloba* extract is effective in 3 months against cerebral disorders due to aging. Moreover, in double-blind, randomized placebo-controlled study [53] of 24 weeks duration in outpatients with cerebral insufficiency showed statistically significant improvement in the short-term memory after 6 weeks and of the learning rate after 24 weeks in the test substance group. A critical review identified 40 such trials included small patient numbers [200]. Nevertheless, 8 out of 40 trials were found to be well performed, and the qualities of trials were sufficient enough to make credible conclusions. In these 8 trials, patients were typically given 120- to 160-mg *G. biloba* extract daily for at least 4–6 weeks. All 8 trials reported positive results and supported the conclusion that *G. biloba* extracts reduce the symptoms of cerebral insufficiency to the extent that is clinically relevant [200]. A meta-analysis including 11 clinical trials revealed the usefulness of the *G. biloba* extract, Kaveri (LI-1370), in cerebral insufficiency [54]. Three studies were excluded due to methodological inadequacies. In one study, the findings were inconclusive, but the pooled data from the remaining trials confirmed the effectiveness of the extract compared to placebo controls. Patients received Kaveri (150 mg per day, oral) for a period of 12 weeks, and the results support the clinical use of *G. biloba* extracts for cerebral insufficiency [54]. The results suggested the further need of clinical evaluation investigation in healthy as well as cerebral insufficiency/ischemic patient.

7.5 Retinal Degeneration and Glaucoma

The lens of the eye focuses an image of an object on a portion of the retina called the *macula*, the area of finest visual perception. *Gingko* extract have shown beneficial effect in macular degeneration, reduced intraocular pressure, and reduced ocular blood flow and glaucoma. Early studies showed that EGb reduces ischemia-reperfusion injury in rat retina [201, 202] as well as inhibits the preretinal proliferation in experimental tractional retinal detachment [203]. In an isolated rat retina model study suggested the existence of PAF-acether-specific receptors inside the retina. Simultaneous administration of ginkgolide B (BN 52021; 2×10^{-5} M) inhibited an irreversible decrease of the electroretinogram β-wave amplitude [204]. EGb-761 (50 mg/kg, per o.s.) was administered in a daily dose for 10 days showed significantly reduction in the maldistribution of ions induced by ischemia and reperfusion in rat retina obtained from normotensive and spontaneously hypertensive rats [205]. It was reported that EGb-761 (40 mg/kg) protects against susceptibility of rabbit retinal cells from proteolytic enzymes [206]. EGb have a protective effect against the progression of diabetic retinopathy and neuropathy [207]. Pretreatment and early posttreatment with EGb-761 protect and effective against neurotoxicity of retinal ganglion cells of rats with chronic moderately elevated intraocular pressure (IOP) [208]. Intraperitoneal injection of EGb-761 enhances the antioxidation ability of retina and partially inhibits the apoptosis of photoreceptors and exerts a protective effect on photoreceptors [209]. Intragastral administration of a *G. biloba* extract applied after an experimental and standardized optic nerve crush in rats were associated with a higher survival rate of retinal ganglion cells in a dosage-dependent manner [210]. Intraperitoneal injections of a *G. biloba* extract given prior to and daily after an experimental and standardized optic nerve crush in rats were shown associated with a higher survival rate of retinal ganglion cells [211]. In a recent study [212], pretreatment with EGb-761 prevented the focal cerebral ischemic injury-induced decrease in PEA-15 (phosphoprotein enriched in astrocytes 15) expression in rats.

7.5.1 Clinical Trials

In a 6-month, double-blind, placebo-controlled study of 10 people with macular degeneration, use of ginkgo at a dose of 160 mg daily resulted in a statistically significant improvement in long-distance visual acuity [213]. In a French double-blind trial, in 29 diabetic subjects with an early diabetic retinopathy (6 months period) showed an improvement tendency was evidenced in EGb treated subjects [214]. Phase I crossover trial [215] of with either EGb 40 mg or placebo 3 times daily orally in 11 healthy volunteers was treated for 2 days showed significantly increased end diastolic velocity (EDV) in the ophthalmic artery (OA). EGb-761 was investigated in a controlled, double-blind trial involving 99 patients with impaired vision due to senile, dry macular degeneration for 6 months [216]. Both the dosages (240 mg/day or 60 mg/day) of EGb-761 results in increase therapeutic efficacy of EGb-761 in patients with senile, dry macular degeneration, with obvious benefits in everyday life [216]. A small double-blind, placebo-controlled trial found that use of ginkgo extract at a dose of 120 mg daily for 8 weeks significantly improved vision in people with glaucoma [217]. In a randomized, double-masked, placebo-controlled, two-way crossover study [218] included 15 healthy male volunteers, before and up to 3 h after oral intake of 240 mg EGb-761 cause significantly decreased retinal venous diameters, but there was no significant difference between the two groups. The optic nerve head blood flow was significantly increased in response to *G. biloba*, but this effect was not significant compared with that of placebo. However, the results suggesting the drug may influence ocular blood flow in patients with ocular vascular disease after long-term treatment [218]. In a case study [219], 11 months after commencing *G. biloba* (120 mg/day) treatment, visual acuity improved to 20/80 OD and 20/40 OS, and subsequently at 30 months follow-up, his visual acuity improved further to 20/40 OD and 20/30 OS.

7.6 Vestibular Dysfunction

Vertigo is a type of dizziness characterized by “spinning” sensation in the head and is usually brought on by sudden changes in position. Ginkgo extract have shown significant beneficial influence on the vestibular system, particularly on compensation after vestibular lesions in experimental animals. In a chemical-induced labyrinthectomy rats, EGb-761 (50 mg/kg per day, i.p.) administration for 73 days post-surgery significantly accelerated compensation of static postural symptoms and spontaneous nystagmus compared with non-treated controls [220]. But there was a limitation of all of these studies that control animals have not received vehicle injections. Due to missing in conduction of a dose–response analysis, there was no evident whether 50 mg/kg/day i.p. was the optimal dose [220]. In an animal study, postoperative administration of EGb-761 (50 mg/kg/day, i.p.) for 30 days following UVD in cats has been shown to accelerate the compensation of postural, locomotor dysequilibrium, and oculomotor symptoms [221]. EGb-761 was administered over 30 days at daily doses of 50 mg/kg i.p. in cat strongly accelerated postural and locomotor balance recovery and demonstrated that EGb-761 acts on recovery mechanisms considered as key processes in vestibular compensation [222]. Guinea pig vestibular nuclei perfused with EGb-761 has a direct excitatory effect on the lateral vestibular nuclei (LVN) neurons and also i.p. administration of EGb-761 led to a reversible, dose-dependent decrease of the horizontal vestibule-ocular reflex (HVOR) gain without affecting the phase of the reflex [223]. In a comparative study [224] of EGb-761 components (terpenes vs. flavonoids) contained extract, examining on equilibrium function recovery in the unilateral vestibular neurectomized cat. Administration of EGb-761 orally (p.o./2 groups; 40 mg and 80 mg/kg) or intraperitoneally (i.p/2 groups; 50 mg and 25 mg/kg), whereas the 2 others received only a special extract that did not contain the terpenes (i.p. administration: 25 mg and 10 mg/kg) significantly improved the locomotor balance recovery in all the experimental groups as compared to the control groups [224]. There was also significant pharmacological activity of the extract when given i.p. as compared to the p.o. route of administration, and dose-dependent effects were evidenced with the i.p. administration of the special extract without the terpenes, with a lower efficacy for the lowest dose (10 mg/kg) [224]. In an animal study [225], G-B was investigating for the behavioral recovery process (vestibular compensation) which occurs following surgical removal of the vestibular receptor cells in one labyrinth (unilateral labyrinthectomy, UL). Guinea pigs received a single i.p. injection of G-B at the time of the UL (25, 50, or 100 mg/kg), and the effects were evaluated on the compensation of the UL symptoms, spontaneous ocular nystagmus (SN), yaw head tilt (YHT), and roll head tilt (RHT). A single i.p. injection of G-B (25 mg/kg) at the time of the UL produced an acceleration of SN compensation [225].

7.6.1 Clinical Trials

In a randomized, placebo-controlled, double-blind trial in patients (out of 50, 33 completed) with vertigo and ataxia symptoms using EGb-761 (120 mg/day) for 12 weeks showed lateral sway amplitude in the cranio-corpography (CCG) and proportion of subjective improvement [226]. In another randomized, placebo-control, double-blind trial on 35 patients with peripheral vestibular vertigo treated with EGb-761 (160 mg/day) for 12 weeks resulted in sway amplitude in posturography and suggesting combinational therapy with *G. biloba* [227]. In a double-blind trial extending over a 3-month period, the patient (out of 70, 67 completed) with vestibular vertigo were given either EGb-761 (160 mg/day) or a placebo. At the end of trial 47 % of the patients treated were rid of their symptoms as against 18 % of those who received the placebo [228]. In a non-vestibular group of trial, 80 patient receiving EGb-761 (160 mg/day) for 12 weeks showed proportion of the patients free from the symptoms and greatly improved [229]. An open, randomized study of 45 patients suffering from vertigo induced by peripheral vestibular lesions is interesting [230]. All patients participated in a physical training program, 23 patients received EGb-761 in addition. In these patients, posturographic investigations showed a more rapid reduction in sway amplitude [230]. A systematic review published in 2007 showed the beneficial effect of EGb-761 on vestibular compensation in various preclinical and clinical studies [231]. The author suggested the presence of efficacy of EGb-761 for the treatment of vertiginous syndromes in the available studies [231].

7.7 Other Neuroprotective Activities

Neuroinflammation is characterized by activation of local glial cells and production of various pro-inflammatory mediators which lead to the abnormalities in neurons and astrocytes. Cytokine IL-1β has been implicated in the extensive inflammation and progressive neurodegeneration that occurs after ischemia. Brain ischemia induces production of both TNF-α and IL-1β which may disrupt phosphatidylcholine homeostasis by increasing its hydrolysis and inhibiting the synthesis. In a trial of 79 patients suffering from chronic, age-related neurological disorders, treatment with 9.6 mg of EGB (ginkgo extract) twice daily for 8 weeks shown a statistically significant decline IL-6 level to near normal values, but there were no significant changes observed in serum levels of IL-1β and TNF-α [232]. In a pilot study [233] of 10 multiple sclerosis patients in acute relapse were treated with a 5-day course of intravenous G-B. 8 patients had improvement of their neurological score, beginning 2–6 days after the initiation of therapy of G-B [233]. In contrast, a randomized double-blind placebo-controlled trial [234] on 104 multiple sclerosis patients, 43 received placebo, 29 received 240 mg/day G-B, and 32 received 360 mg/day ginkgolide B for 7 days. The result does not showed any significant result, and suggesting G-B is not an effective treatment of exacerbations of multiple sclerosis [234]. Treatment with BN-52021 (10 mg/kg) attenuates the development of early posttraumatic cerebral edema in rats subjected to a mild traumatic insult [235]. The author suggested that PAF may be involved in the pathogenesis of posttraumatic cerebral edema [235]. Moreover, administration of BN-52021 (1 or 10 mg/kg i.v.) 15 min prior to, and 120 min after, fluid percussion-induced traumatic brain injury resulted in the reduction of neurological deterioration due to traumatic brain injury [236].

8 Ginkgolides Pharmacokinetics

Ginkgolide B showed about 50 % of metabolism in vivo and suggesting its hydroxyl metabolites its principal metabolites [237]. A dosage of 40-mg G-B twice daily (every 12 h) is accompanied by a significantly longer half-life ($t_{1/2}$) and mean residence time (MRT) than a single 80-mg dose, even though the latter causes a higher concentration peak (C_{max}). The maximum concentration time (T_{max}) is 2.3 h after administration in both treatments [238]. After each single dose of G-A, G-B and bilobalide ranging from 0.90 mg to 3.36 mg, blood and urine samples were collected for up to 36 h and 48 h, while fasting, the extents of bioavailability are high, as shown by bioavailability coefficients (FAUC) mean (+/− SD) values equal to 0.80 (+/− 0.09) and 0.88 (+/− 0.21) for G-A and G-B respectively [239]. In short, G-A and G- B are nearly completely bioavailable [240].

9 Side Effect

As *G. biloba* is one of the very popular herbal supplementary in dose range of 120–240 mg/day due to its versatility in human health benefits and safer efficacy. But, there were few cases have been reported the side effect of *G. biloba* including minor (stomach upset, skin reaction and headache or dizziness) and severe (haemorrhage). At a higher dose of ginkgo extract in initial supplementary or therapy dose leads to stomach upset. It is recommended to start with a lower dose and titrate as tolerated to minimize or ovoid the gastrointestinal side effects. In some cases, allergic skin reactions is caused by the herbal remedy *G. biloba* extract and that resolve after discontinuing ginkgo therapy [241]. There is also a case of Stevens-Johnson syndrome reported in a patient after their second dose of a combination herbal product containing EGB [242]. Ginkgo seeds contain ginkgo toxin, which can cause seizures, difficulty breathing, loss of consciousness, and shock when consuming more than 10 roasted seeds daily. It is also found that the availability of ginkgo toxin is much higher concentrations in ginkgo seeds than in ginkgo leaf extract. There is an evidence of about 20 detailed reports of hemorrhage (usually cerebral, ocular, or postsurgical) in patients using *G. biloba* extracts have been published [243]. One third of these patients were also taking drugs that increase the risk of bleeding (anticoagulants or antiplatelet drugs). Therefore there is a cautionary recommendation established in practice, patients with risk factors for bleeding (anticoagulant or antiplatelet treatment, surgery, etc.) should avoid using *G. biloba* extracts [243].

10 Conclusion

Aging, which is a fate of all creatures, is a challenge to every living being. There is a cellular, structural, and functional changes occur in the brain during aging. Nerve cells may respond to these changes adaptively, or they may succumb to neurodegenerative cascades that result in disorders such as AD and PD. Neurodegenerative diseases have drawn a lot of attention due to their irreversibility, lack of effective treatment, and accompanied social and economic burdens. *G. biloba* showed various pharmacological effects, among them multiple researches have been demonstrated their neuroprotective effect in the prevention and recovery of cognition, ischemic, antioxidant, anti-amyloidogenic, and PAF inhibitory abilities. It maintains blood vessel health, reduces blood viscosity, and enhances blood supply to the brain, which has recently been implicated as a causative factor for stroke.

At the present time, there are no definitive prevention and treatments for dementias or age-related cognitive decline. The significance of these neurological disorders mandates that every therapeutic option should be investigated with rigorous scientific methodology. There is a major portion (28 %) of unknown or unidentified compounds in ginkgo extract which are need to be investigating because it may be possible that they exhibit the same effects like ginkgolides or other active constituents. Moreover the basic pharmacology and therapeutic potential of *G. biloba* extracts (EGB-761) in neuroprotection have understood and also the activity of ginkgolide has also been evaluated separately in neurological disorders. But there is a lack of clinical research in PD which is one of the major neurodegenerative disorders. The question is EGb-761 does not contains only ginkgolides at a major constituents, it contributes about 6–7 % of the total components. Moreover, it may be possible that the other bioactive constituents also participating in neuroprotection activities. Even though the gingkolides were used combination and fewer in the total content, we cannot underestimate their role in neuroprotection. Therefore, the complete neuropharmacological potential of ginkgolides will be understood through coordinated in vitro/in vivo animal investigations and should be confirmed with human placebo-controlled, double-blinded research designed to objectively measure relevant functional parameters including their safety parameters.

Acknowledgements I wish to thank CSU library for databases and Prof. Patrick Ball for valuable suggestion. I cannot finish without my family inspiration, including my parents, Saba and Ariba.

Abstract

Cardiac glycosides (CGs) which are composed of aglycone moiety and glycone moiety occur mainly in plants. CGs increase cardiac contractility by inhibiting the sodium-potassium-adenosine triphosphatase (Na^+/K^+ ATPase) of plasma membrane and are widely used in the treatment of chronic heart failure. New findings within recent years have revealed that CGs are involved in selective control of tumor proliferation. Inhibition of Na^+/K^+ ATPase by CGs induces antiproliferative downstream effects which are related to cell growth and apoptosis. As anticancer effects of CGs occur also below their cardiotoxic concentration, Na^+/K^+ ATPase independent pathways are also proposed. Some CGs are almost completely nontoxic to rodent-derived tumor cell lines but potently inhibit proliferation human tumor cell lines. Some of the CGs, in nontoxic concentrations, are able to induce apoptosis in human promyelocytic leukemia cells (HL60) but not in normal leukocytes. The anticancer effects of CGs are found to be related to the inhibition of tissue kallikrein expression, anoikis sensitizers, inhibition on topoisomerase, blockade of NF-kB activation, and suppression of general protein synthesis. However, the viewpoint and evidence of CGs as anticancer agents in clinical application are still controversial.

Keywords

Anticancer activity • cardiac glycosides • clinical implication • mechanism

Abbreviations

bcl-2	B cell lymphoma/leukemia-2
Ca^{2+}	Calcium ion
c-FOS	FBJ osteosarcoma oncogene
CGs	Cardiac glycosides
c-myc	v-myc myelocytomatosis viral oncogene homolog (avian)
DNA	Deoxyribonucleic acid
EDLC	Endogenous digitalis-like compounds
ER	Estrogen receptor
ERK	Extracellular signal-regulated kinase
HL60	Human promyelocytic leukemia cells
IkBa	I kappa B alpha
JAK2	Janus kinase 2
JNK	c-Jun NH_2-terminal kinase
KLK	Kallikreins
MAPK	Mitogen-activated protein kinase
MCF-7	Michigan Cancer Foundation – 7

MEK	MAPK/ERK kinase
mRNA	Messenger ribose nucleic acid
Na^+/Ca^{2+} exchanger	Sodium-calcium exchanger
Na^+/K^+ ATPase	Sodium-potassium-adenosine triphosphatase
NF-κB	Nuclear factor kappa-light-chain enhancer of activated B cells
p21	Protein 21
p53	Protein 53 or tumor protein 53
PI3K	Phosphoinositide-3 kinase
PPC-1	Primary prostatic carcinoma cell line
PSA	Prostate-specific antigen
PUMA	p53 upregulated modulator of apoptosis
Rac1	Ras-related C3 botulinum toxin substrate l
SCID	Severe combined immune deficiency
Src	Sarcoma
$t_{1/2}$	Half-life
TNFR	Tumor necrosis factor receptor

1 Introduction

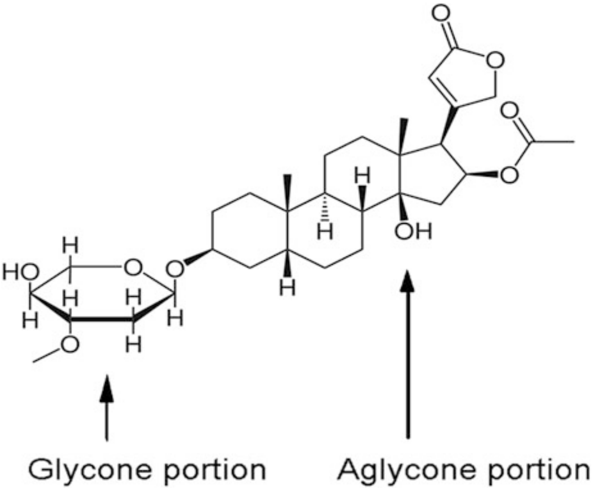
1.1 Sources of Cardiac Glycosides

Cardiac glycosides (CGs, digitalis-like compounds, cardenolides) occur mainly in plants, such as *Digitalis purpurea, Digitalis lanata, Strophanthus gratus*, and *Strophanthus kombe*. Plants containing CGs have been used as poisons and heart drugs at least since 1500 B.C. CGs are found in amphibian, e.g., toad venom, such as bufadienolides, and in mammals, e.g., endogenous digitalis-like compounds (EDLCs). EDLCs are identified in mammalian tissues, e.g., ouabain and digoxin, which are purified from human plasma and hypothalamus.

1.2 Structure Activity Relationship

CGs are composed of two structural features. Aglycone (steroid, nonsugar portion) moiety is responsible for biological activities, e.g., positive inotropic action on cardiac muscle. Glycone moiety (sugar portion, 1–4 sugars present in most CGs) possesses no biological activity; however, the polarity differences caused by the number of sugars differ markedly in their degree of absorption, half-life ($t_{1/2}$), and the time to maximal effect. For instance, ouabain which contains one sugar molecule has a $t_{1/2}$ of 21 h, and digoxin, which possesses a three-sugar side chain, has $t_{1/2}$ of 36 h (Fig. 123.1).

Fig. 123.1 Chemical structure of cardiac glycosides



1.3 Mechanism of Action of CGs

The most widely accepted mechanism of action of CGs involves the ability to inhibit the activity of the membrane-bound sodium-potassium-adenosine triphosphatase (Na^+/K^+ ATPase) pump (Fig. 123.2).

CGs inhibit the cardiac myocyte membrane Na^+/K^+ ATPase causing intracellular sodium concentration to increase. The increased intracellular Na^+ reduces the concentration gradient driving Na + into the cell across the Na^+/Ca^{2+} exchanger, thereby decreasing the activity of the exchanger, which lowers the movement of Ca^{2+} out of the cell. The increased intracellular Ca^{2+} results in more Ca^{2+} to be released by the sarcoplasmic reticulum, thereby making more Ca^{2+} available to bind to troponin C, increasing contractility.

1.4 Major Clinical Application of CGs

CGs are widely used in the treatment of chronic heart failure owing to their cardiotonic effects and are also used for patients with atrial fibrillation, especially if they are diagnosed with congestive heart failure via vagal activation.

2 Anticancer Activity of CGs

It is known that the inhibition of Na^+/K^+ ATPase activates tyrosine kinase sarcoma (Src), phosphoinositide-3 kinase (PI3K), and phospholipase C signalosome complex, which can induce many antiproliferative downstream effects related to cell growth and apoptosis [1–3]. Since some anticancer effects of cardiac glycosides

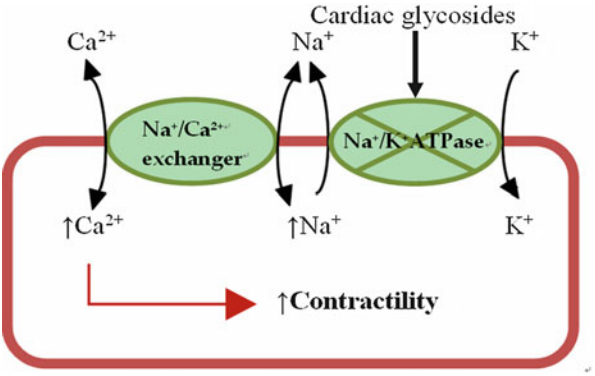


Fig. 123.2 Inhibition of plasma membrane Na^+/K^+ ATPase by cardiac glycosides

occur below their cardiotoxic concentration, many Na^+/K^+ ATPase independent pathways are also proposed [1, 4].

New findings within recent years have revealed that CGs are involved in complex cell-signal transduction mechanisms, resulting in selective control of tumor rather than normal cellular proliferation. As such, CGs are promising in cancer chemotherapy.

2.1 In Vivo Efficacy of Ouabain in a Xenograft Model of Retinoblastoma

Anticancer activity of CGs ouabain is found on a xenograft model of retinoblastoma. Three groups of two 8-week-old ICR/SCID male mice bearing Y79 tumors implanted in the flank are treated with vehicle only, 1.5 and 15 mg/kg ouabain, respectively [5]. The results show that the average tumor size for the control group reached 1,000 mm^3 at day 14 and in animals treated with 15 mg/kg ouabain, the tumors are nearly eradicated by day 14 (18 mm^3 in average). At a lower dose of 1.5 mg/kg, ouabain also reduces the tumor burden compared with that in the control. However, the average body weight of treated and control animals does not differ significantly, implicating that even at the high dose of 15 mg/kg, ouabain does not induce any significant toxicity.

2.2 Anticancer Selectivity of CGs

2.2.1 Characteristics of the Species-Related Sensitivity

Some CGs, such as oleandrin, bufalin, and digitoxin, are almost completely nontoxic to rodent (mouse and rat)-derived tumor cell lines but potently inhibit proliferation of monkey and human tumor cell lines at nanomolar concentration [6, 7]. The species-dependent disparity in tumor cell sensitivity to antitumor agents is unusual. The difference in response of murine as compared to human tumor cell lines implicates that a fundamental difference in drug targeting exists and, thus, serves as a probe or model for reexamination of the pharmacologic role of this class of compounds in treatment of human cancers [7].

A difference in the subunit composition of Na^+/K^+ ATPase might explain the differential species-dependent sensitivity and selectivity to human tumor cell to CGs [8]. Human tumor cells commonly express both $\alpha1$ and $\alpha3$ subunits; however, all rodent tumor cell lines now known only express the $\alpha1$ subunit. Recent studies indicate a clear selective binding of CGs to the $\alpha3$ form over that of the $\alpha1$ or $\alpha2$ isoforms [9]. For instance, a 1,000-fold difference in binding of ouabain to the $\alpha3$ isoform over that of $\alpha1$ is found in the study [9]. The increased expression of $\alpha3$ over $\alpha1$ subunits is also noted in human colon or colorectal cancer [7], whereas no significant expression of the $\alpha3$ isoform protein is noted in the normal kidney [10]. Human tumor cell lines with a low ratio of $\alpha3{:}\alpha1$ are relatively resistant to growth inhibition with CGs, and the tumor cell lines with high $\alpha3{:}\alpha1$ ratios are very sensitive to CGs.

2.2.2 Cardiac Glycosides Selectively Inhibiting Tumor Cells

Selectively Inducing Apoptotic Effects on Tumor Cells

The different effects of CGs on human tumor compared to normal cells are observed. For instance, oleandrin inhibits the activation of certain transcription factors and potentiates ceramide-induced apoptosis in human tumor cells rather than in normal, primary human cells [11]. Researchers also [12] indicate that CGs sensitize human tumor but not normal cells to subsequent radiation treatment. These data suggest that it may be possible to exploit differences in the Na^+/K^+ ATPase pumps of normal as opposed to tumor cells to improve the therapeutic index of radiation therapy.

CGs have been shown to induce apoptosis in different malignant cell lines [13, 14]. In light of the pivotal role of apoptosis in cancer development and progression and this new experimental finding concerning CGs, it seems probable that the apoptosis-inducing capability is explained by mechanisms other than just Na^+/K^+ ATPase inhibition. The role of sustained $[Ca^{2+}]$ increases in the cells, persistent activation of the mitogen-activated protein kinase (MAPK) pathway, altered expression of the c-myc and B cell lymphoma/leukemia-2(bcl-2) genes involved in apoptosis, and activation of ras-related C3 botulinum toxin substrate 1 (Rac1), protein 21 (p21)-activated kinase, and c-Jun NH_2-terminal kinase (JNK) pathway have all been considered as potentially involved.

Malignant cells in general are more susceptible to CGs than normal cells. It may be due to the fact that in many cases, Na^+/K^+ ATPase activity is different in tumor or transformed cells compared to their normal counterparts. For instance, one of the CGs, bufalin, in nontoxic concentrations, is able to induce apoptosis in human promyelocytic leukemia cells (HL60) but not in normal leukocytes. Therefore, bufalin seems to act as a potent differentiation and apoptosis-inducing agent in cancer cells. Also, oleandrin [15] is found to increase the expression of Fas and tumor necrosis factor receptor 1 (TNFR1), resulting in potentiation of apoptosis in tumor cells but not in normal primary cells, such as peripheral blood mononuclear cells or neutrophils. Oleandrin also initiates apoptosis in non-small-cell lung cancer cells by increasing the expression of death receptors 4 and 5 [16] with little if any toxicity to normal cells.

Inhibiting Mutant-Protein 53 Containing Sensitive Cancer Cells

Protein 53 (p53) can prevent tumor formation through transcriptional-dependent mechanism, which is mainly mediated by p53 upregulation of its downstream targets. Upon activation by a variety of stimuli, p53 induces the expression of proarrest genes such as p21, to induce growth arrest or pro-apoptotic genes, and p53 upregulated modulator of apoptosis (PUMA), to induce apoptosis [17]. p53 acts as a guardian of the genome by inducing growth arrest to allow cells to repair the damage or apoptosis, if the damage is too severe and irreparable.

As p53 plays a pivotal role in controlling abnormal cell growth and is inactivated by point mutations in more than 50 % human cancers, p53 has been a central target for mechanism-driven cancer drug discovery [17, 18]. CGs such as digoxin and ouabain selectively kill mutant p53 containing sensitive cancer cells via a synthetic lethal mechanism [19]. CGs sensitivity to p53 reduction is cancer cell line dependent, but independent of p53 status of a wild type or mutants. CGs are completely inactive in reducing wt p53 in normal "immortalized" cells. CGs-induced p53 decrease occurs not at the messenger ribose nucleic acid (mRNA) levels but at the protein levels, as a result of reduced synthesis rather than enhanced degradation. The drug-induced p53 reduction can be rescued by the inhibitors of Src and MAPK/ERK kinase (MEK), suggesting an involvement of Src/MAPK signaling pathways, initiate upon the drug binding to Na^+/K^+ ATPase.

2.3 Inhibitors of Human Tissue Kallikrein Expression

Human tissue kallikrein (KLK) comprises a subgroup of 15 homologous-secreted serine proteases. KLK is used as cancer biomarkers (e.g., prostate-specific antigen (PSA)) and is directly implicated in cancer-related invasion, angiogenesis, and tumor growth [20]. Acting at low concentrations (10–50 nmol/L), CGs are found to inhibit KLK expression and induce marked decrease in c-myc and c-FBJ osteosarcoma oncogene (c-FOS) expression, in a dose-dependent manner that is correlated the KLK inhibition, suggesting a transcriptional mechanism of regulation of KLK expression.

2.4 Anoikis Sensitizers to Decrease Tumor Metastasis

Normal epithelial cells undergo apoptosis upon detachment from the extracellular matrix, a process termed "anoikis" [21]. However, malignant epithelial cells with metastatic potential resist anoikis and can survive in an anchorage-independent manner. One study is carried out to identify novel anoikis sensitizers in anoikis-resistant PPC-1 prostate adenocarcinoma cells. CGs ouabain is found as anoikis sensitizers. The underlying mechanisms of ouabain to sensitize cells include initiation of mitochondrial pathway of caspase activation, inhibition of Na^+/K^+ ATPase pump, and induction of hypoosmotic stress. Ouabain is found to inhibit tumor metastases but rather than alter the growth of subcutaneous tumors. Since the resistance to anoikis permits cancer cells to metastasize to distant organs, to sensitize resistant cells to anoikis using ouabain can be considered as a novel mechanism to decrease tumor metastasis. The clinical evidence also implicates the reduction in metastasis and relapse in breast cancer patients who have undergone treatments with CGs. CGs peruvoside, digoxin, digitoxin, and strophanthidin are also anoikis sensitizers.

2.5 Inhibitory Effects on Topoisomerase

Topoisomerases are key cellular enzymes that adjust DNA's topological structure, transcription, replication, and chromosome structure. Apoptosis of certain type of cancer cell is induced when topoisomerases are inhibited. Topoisomerase inhibitors are among the most active anticancer agents.

Topoisomerase II enzymes are important for cancer chemotherapy, especially since overexpression of these proteins has been demonstrated in many human tumor types, such as breast cancer [22, 23]. Digoxin, ouabain, and proscillaridin exert significant inhibitory effects on the proliferation of the tested MCF-7 breast cancer cells. The degree to which these compounds inhibited cell growth in breast cancer cells is correlated to topoisomerase II-inhibiting activity. Ouabain and digoxin inhibited topoisomerase II catalytic activity at nanomolar concentrations (100 nM), but neither agent inhibited topoisomerase I catalytic activity even at concentrations as high as 100 mM. On the other hand, proscillaridin A was a potent inhibitor of both topoisomerase I and II activities at nanomolar drug concentrations (30, 100 nM, respectively), suggesting that this agent may produce its cytotoxic activity by targeting both enzymes simultaneously [13].

2.6 Anticancer Activity via Blocking NF-kB Activation

Nuclear factor kappa-light-chain enhancer of activated B (NF-κB) cells were first discovered in the lab of Nobel Prize laureate David Baltimore via its interaction with an 11-base pair sequence in the immunoglobulin light-chain enhancer in B cells [24]. NF-κB is a protein complex that controls the transcription of DNA. NF-κB is found in almost all animal cell types and is involved in cellular responses to stimuli. Active NF-κB turns on the expression of genes that keep the cell proliferating and protect the cell from conditions that would otherwise cause it to die via apoptosis. NF-kB is activated in response to various inflammatory stimuli including cytokines, mitogens, bacterial products, viral proteins, and apoptosis-inducing agents [25]. Incorrect regulation of NF-κB has been linked to cancer, inflammatory and autoimmune diseases, septic shock, viral infection, and improper immune development.

NF-kB is an ideal target for anticancer drug development for several reasons [26] described as follows. (a) In tumor cells, NF-κB is active either due to mutations in genes encoding the NF-κB transcription factors themselves or in genes that control NF-κB activity (such as IκB genes); some tumor cells secrete factors that cause NF-κB to become active. (b) Activation of NF-kB has been shown to block apoptosis and promote proliferation, and blockade of NF-κB causes tumor cells to stop proliferating or to become more sensitive to the action of antitumor agents. (c) Constitutive expression of NF-kB in tumor cells induces proliferation, and NF-kB activation induces resistance to chemotherapeutic agents. Thus, NF-κB is the subject of much active research among pharmaceutical companies as a target for anticancer therapy.

The CG oleandrin is found to block tumor necrosis factor (TNF)-induced activation of NF-kB in a concentration- and time-dependent manner [25]. Oleandrin blocked NF-kB activation induced by phorbol ester and lipopolysaccharide. The inhibitory effect of oleandrin on NF-kB is mediated via suppressing phosphorylation and degradation of I kappa B alpha (IkBa), an inhibitor of NF-kB; however, these effects of oleandrin were not cell-type specific, because it blocked TNF-induced NF-kB activation in a variety of cells.

2.7 Anticancer Activity by Inhibiting General Protein Synthesis

Studies proposed that inhibition of the Na^+/K^+ ATPase pump was responsible for the inhibitory effects of CGs on protein synthesis. They expressed the naturally cardiac glycoside-resistant alpha1 chain of the murine Na^+/K^+ ATPase pump, which is about 1,000 times less sensitive for CGs than the human alpha1 subunit, in human cells [27]. Expression of the murine but not the human alpha chain largely rescued the inhibitory effects of digitoxin on intracellular protein expression. The other study also further indicates that inhibition of the Na^+/K^+ ATPase pump is responsible for the inhibition of CGs on protein synthesis. For instance, Na^+/K^+ ATPase pump activity is inhibited by digitoxin in incubating cells for 4–8 h in a sodium-free buffer. The Na^+-free buffer inhibited both murine and human Na^+/K^+ ATPase pump activity as determined by intracellular K^+ levels and did not affect cell viability in the timeframe of the experiment, resulting in a decreased expression of relatively short-lived proteins such as p53 and Janus kinase 2 (JAK2).

3 Estimation of Clinical Anticancer Property of CGs

3.1 Beneficial Effect of CGs in the Treatment of Breast Tumors

An unusual finding was reported in 1979 that breast cancer of women ($n = 142$) [28, 29] who were taking CGs (mostly digoxin) at the time of their breast cancer diagnosis had tumors with less aggressive phenotypes than breast tumors of women not taking CGs [30]. They later reported a higher recurrence rate among the women not taking CGs after 5 years and approximately 22 years of follow-up [28, 31]. These observations suggested a beneficial effect of CGs for women with breast tumors.

A 5-year follow-up study indicates that the recurrence rate of breast cancer in patients not on digitalis was 9.6 times higher than in patients treated with digitalis. In the subsequent 20-year follow-up, the death rate from breast carcinoma (excluding other causes of death and confounding factors) was 6 % (2 of 32) among patients on digitalis compared with 34 % (48 of 143) among patients not on digitalis ($p = 0.002$); the study confirmed these results by conducting a retrospective study of 127 cancer patients in their records. Of a total of 21 deaths, they found only one cancer death among those who had taken digitalis. Additionally, a study with 9,271 patients showed a relationship between high plasma concentrations of digitoxin and a lower risk for leukemia lymphoma [30].

3.2 Negative Effect of CG Reported in the Treatment of Breast Tumors

After comparison of site-specific cancer incidence rates among digitalis-treated Norwegian patients with expected rates in the general population [32], the results showed that several cancers, including female breast cancer, occurred at higher rates among those treated with digitalis compared with the general population [32], showing the association between digoxin treatment and breast tumor incidence rate in a population-based prospective case-control study of postmenopausal Danish women.

3.3 Digoxin and Estrogen-Sensitive Cancer

Among women given digoxin, breast and uterus cancer incidences are significantly increased (risk ratios is about 1.3–1.5); both cancers are estrogen sensitive [33]. In contrast, ovary and cervix cancers are relatively estrogen insensitive, and incidence is unaffected by digoxin administration. These phenomena parallel those of estrogen, suggesting that digoxin works via estrogen receptor (ER)-stimulated proliferation, accelerating the growth of nascent cancers. Also consistent with an estrogenic effect, men using digoxin have a small but significant reduction in prostate cancer (risk ratio, 0.76).

3.4 Prospect of Clinical Implication

Whether CGs may sound as potential anticancer agents is still controversy [27–29].

3.4.1 CGs not Expected as Potential Anticancer Agents

As described in the previous sections, reports about CGs are controversial in clinical observations, and successful randomized trials have thus far not been reported. Since it is found that normal diploid fibroblasts, non-tumorigenic breast epithelial cells MCF10A, and peripheral blood mononuclear cells are equally sensitive to CGs as neoplastic cells, and also the mechanism of cytotoxicity is correlated to general protein synthesis inhibition, CGs should not be considered to possess specific anticancer activities.

3.4.2 CGs Expected as Potential Anticancer Agents

The changes occur in Na^+/K^+ ATPase activity in premalignant mucosa, months before gross tumors develop, and these changes may partially explain the altered levels of Na^+ and K^+ in the cytoplasm of premalignant and malignant colonocytes; the changes in the transmembrane transport of cations during the course of malignant cell transformation are due to increases in Na^+/K^+ ATPase activity [29, 34].

Studies indicate that digitoxin may be one of the most promising anticancer CGs since it shows significant anticancer effect against several types of cancer including lung cancer, pancreatic cancer, leukemia, and breast cancer, all at therapeutic concentrations.

4 Conclusion

The major characterization of the anticancer activities of CGs is as follows. (a) Some of the CGs are found almost completely nontoxic to rodent-derived tumor cell lines but potently inhibit proliferation of human tumor cell lines at nanomolar concentration, some of the CGs induce apoptosis in human tumor cells rather than in normal, and some of the CGs can selectively kill mutant p53 containing sensitive cancer cells. (b) KLK is directly implicated in cancer-related invasion, angiogenesis, and tumor growth; CGs are found to inhibit KLK expression. (c) Some of the CGs are found to inhibit tumor metastases by acting as anoikis sensitizers because some malignant epithelial cells have metastatic potential resist anoikis. (d) Topoisomerase inhibitors are among the most active anticancer agents, and some of the CGs inhibit topoisomerase II catalytic activity at nanomolar concentrations. (e) Constitutive expression of NF-kB in tumor cells induces proliferation, and NF-kB activation induces resistance to chemotherapeutic agents; some of the CGs are found to block tumor necrosis factor (TNF)-induced activation of NF-kB in a concentration- and time-dependent manner. (f) Clinical evidence for whether CGs may sound as potential anticancer agents is still controversy. Comparing with those women with breast cancer not taking CGs, both a higher and a lower recurrence rate among the women taking CGs are reported by follow-up study. (g) Further study is needed for whether and in what condition CGs can be used as anticancer agents in clinics.

Abstract

The human skin itself hinders the widespread use of transdermal drug delivery (TDD) for administration of medications. Despite the different strategies devised and employed to reversibly overcome the skin barrier, this noninvasive delivery mode is restricted to potent, low molar mass therapeutic agents. As most drugs would not be able to penetrate the skin in a sufficient quantity to reach the desired therapeutic level, chemical penetration enhancers (CPE) are commonly used to breach the skin barrier and increase drug permeation. Over the years, extensive screening and testing have identified different classes of chemicals as potential

adjuvants. Among these, terpenes, which are constituents of plant essential oils, have been widely investigated as skin penetration enhancers for both hydrophilic and hydrophobic drugs. Their enhancing effects on human skin and interactions with skin lipids have been extensively studied. The mechanisms of action of terpenes on excised human skin as determined by several analytical techniques were found to be the extraction and phase separation of stratum corneum intercellular lipids. The enhancing efficacies of terpenes with various physicochemical properties for lipophilic and hydrophilic drugs could be compared and ranked, while their enhancing effects on the skin were found to be reversible and the in vitro permeability of skin recovered once they were removed from the excised skin. Terpenes have been incorporated as adjuvants in the form of penetration enhancers or sorption promoters for improved drug delivery from various dosage forms including solutions, gels, and transdermal therapeutic systems.

1 Introduction

The human skin barrier hinders the widespread use of transdermal drug delivery (TDD) for drug administration. Despite the range of strategies devised and employed to reversibly overcome the skin barrier, TDD is restricted to potent and low molar mass therapeutic agents. Nonetheless, this noninvasive delivery mode offers advantages such as sustained and controlled drug release, reduced side effects, improved bioavailability, better patient acceptance and compliance, and easy termination of drug therapy. The use of chemical penetration enhancers (CPE) is the conventional approach to modify the skin structure and lower its resistance, so as to allow sufficient drug to reach desired therapeutic levels for systemic effects. Over the years, extensive screening and testing have identified different classes of chemicals as potential adjuvants. Among these, terpenes, the natural volatile oils extracted from plant sources, have been widely used as CPE by permeating into the human skin and reversibly decreasing its barrier resistance.

2 Structure of the Human Skin

The skin, with a surface area of ca. 1.72 m^2, is the most accessible organ of the human body and continues to be the preferred site for the application of topical dosage forms [1]. It consists of three main histological layers: the epidermis, dermis, and subcutis as show in Fig. 124.1 [2]. The stratum corneum (SC) of the epidermis, the outermost part of the skin [3, 4] is a remarkable transport barrier which effectively retards the diffusion of exogenous and endogenous moieties into and out of the host and may be regarded as the rate-limiting layer [5]. Superficial SC is formed in the final stage of differentiation from several layers of dead cells embedded in a lipid matrix, and its morphology resembles a “brick and mortar” array [6].

The protective quality of the skin is firmly attributed to the unique composition and structural configuration of the intercellular SC lipids. Lipid bilayers of ceramides, fatty acids, cholesterol, and cholesterol esters are arranged into a continuous semicrystalline and crystalline interconnecting domain [7–9]. As sweat glands and hair follicles occupy a fractional skin area of 0.1% [3], absorption across the SC layer can be geometrically subdivided into transcellular and intercellular routes. Tortuous intercellular pathway is supposedly the principal route [10–12].

3 Human Skin Permeation and Transdermal Drug Delivery

The continuous SC has been the usual target in TDD. In recent years, researchers have employed physical and chemical methods to temporarily disrupt its elegant molecular structure. Physical methods such as low-frequency ultrasound (sonophoresis) and electrical current (iontophoresis and electroporation) may facilitate absorption of drug molecules by physically altering the skin morphology [13]. Ultrasound causes cavitation, and the shock waves from the collapsing vacuum bubbles increase the free volume space within the lipid lamellae [14, 15]. Iontophoresis electrically drives or repels ionized drug molecules and peptides through current-induced defects [16, 17]. Skin electroporation creates transient aqueous pores in the lipid bilayers.

The conventional strategy of disrupting the skin barrier and improving the skin permeation of poorly absorbed drugs is to incorporate CPE into drug preparations [10, 18]. Lipid-protein-partitioning (LPP) model [19] theorizes that CPE intensifies TDD by increasing drug solubility in the donor formulation, increasing drug partitioning between the formulation and the skin, or disrupting the intercellular SC lipids [13, 20]. At clinically acceptable concentrations, most CPE interact with

the lipoidal domains. These interactions include lipid fluidization, polarity alteration, phase separation, and lipid extraction as illustrated in Fig. 124.2 [10, 20]. Compounds such as sulfoxides, pyrrolidones, fatty acids, terpenes, and alcohols are potential enhancers. The ideal CPE would be pharmacologically inert, nontoxic, nonirritating, nonallergenic, and compatible with other components of the transdermal formulation and device as well as upon removal, the skin barrier properties would be restored rapidly and fully. In addition, the onset and duration of the action of a CPE should be predictable and reproducible [21].

4 Terpenes

4.1 Source, Nomenclature, Classification, and Uses of Terpenes

Terpenes are constituents of essential oils which are the volatile and fragrant substances present in flowers, fruits, and leaves of plants. They are named “terpenes” after “turpentine” as turpentine oil is a mixture of these compounds [22, 23]. They are usually named after the plants from which they were first isolated. Some terpenes share the same composition by percentage, and some have even the same molecular

weights and similar boiling points. However, they smell different, have different optical properties, and behave differently in chemical reactions, they are not identical.

The term "terpene" is used to describe a compound, which is a constituent of an essential oil containing carbon and hydrogen or carbon atoms, hydrogen, and oxygen atoms, and is not aromatic in character [24, 25]. This definition is usually extended to include other compounds called terpenoids, which are not of natural occurrence but are very closely related to the natural terpenes. Most terpenes, which include terpenoids, are invariably hydrocarbons, alcohols, aldehydes, ketones, or oxides, and they may be solids or liquids. Terpene hydrocarbons are usually liquids, while terpenes of higher molecular weights, mostly obtained from the natural gums and resins of plants and trees, are not steam volatile.

Terpenes are defined and classified by the so-called isoprene rule, introduced by Wallach in 1887 [22]. Two isoprene units make one "terpene unit." They are grouped according to the number of isoprene units, for example, monoterpenes [C_{10}], sesquiterpenes [C_{15}], diterpenes [C_{20}], triterpenes [C_{30}], and tetraterpenes [C_{40}] contain 2, 3, 4, 6, and 8 isoprene units, respectively. A subsidiary classification is based on the number of carbon rings present in the terpene;

monoterpenes, for example, may be acyclic, monocyclic, or bicyclic. Each group is further broken down into chemical divisions of hydrocarbons, alcohols, oxides (ethers), and ketones.

Terpenes have been utilized for a number of therapeutic purposes, such as in antispasmodics, carminatives, and perfumery. They have been found to be useful when incorporated into topical and transdermal pharmaceutical formulations as they act as chemical penetration enhancers facilitating the permeation of drugs through the skin barrier, both healthy and diseased in comprehensive reviews [26, 27].

4.2 Terpenes as Chemical Penetration Enhancers

Terpenes, in particular monoterpenes (Fig. 124.3), are generally recognized as safe (GRAS) adjuvants as indicated by high percutaneous enhancement [28–30], reversible effect on skin lipids, and mild cutaneous irritancy at low concentrations (1–5%w/v) [31, 32]. No skin irritation or sensitization was noted in humans for formulations containing hydrophobic limonene [31] and oxygen-containing anethole, linalool, carvacrol, thymol, and menthol [33, 34]. Sesquiterpenes (Fig. 124.4), probably due to a more bulky molecular structure, tend to be less effective and favorable. They are less active [21] and have a longer duration of action, implying poor reversibility, that is, they do wash out of the skin readily [29]. However, in a recent work by Nokhodchi et al. [35], sesquiterpenes (farnesol and nerolidol) were found to be more potent enhancers than monoterpenes (carvone, limonene oxide) for diclofenac sodium.

The activity of terpenes is dependent on terpene concentration, but there is no clear activity-concentration relationship. Kunta et al. [32] examined the influence of terpene concentration on propranolol permeation. The terpenes investigated were carvacrol, linalool, menthol, and limonene. In general, propranolol transport initially increased and subsequently remained constant with terpene concentration. This phenomenon was also documented by Krishnaiah et al. [34], for menthol in the delivery of nicardipine hydrochloride. Probable reasons are limited terpene solubility in the vehicle and terpene saturation in the skin. In a study by Kararli et al. [33], the permeation flux of zidovudine dropped significantly as thymol and carvacrol concentrations increased from 5% to 10% w/w. Similarly, Babu and Pandit [36] noted a decrease in bupranolol permeation as menthol concentration increased from 2% to 5%w/v. No clear explanations were given for the reduced activities with terpene concentration. Many researchers have chosen a terpene concentration of around 5%w/v in their preparations, and at this level, significant improvements in drug permeation were obtained [28, 37–40]. The bottom line is that the enhancer concentration should be high enough to produce an adequate skin penetration but not high enough to elicit an irritating cutaneous response.

Oxygen-containing terpenes were more potent for hydrophilic drugs (Table 124.1) such as 5-fluorouracil [41], propranolol [32, 49], and zidovudine [33, 45]. Hydrocarbon terpenes apparently gave a better enhancement for lipophilic drugs (Table 124.1) such as ketoprofen [1] and indomethacin [20]. These collectively give rise to the

general rule of thumb – the use of hydrophilic terpenes for polar drugs and the use of hydrocarbon terpenes for nonpolar drugs. Evidently, there are exceptions to the rule. Font et al. [37] and Ueda et al. [50] showed that hydrophobic limonene improved the deliveries of hydrophilic sumatriptan succinate (Table 124.1) and aminopyrine

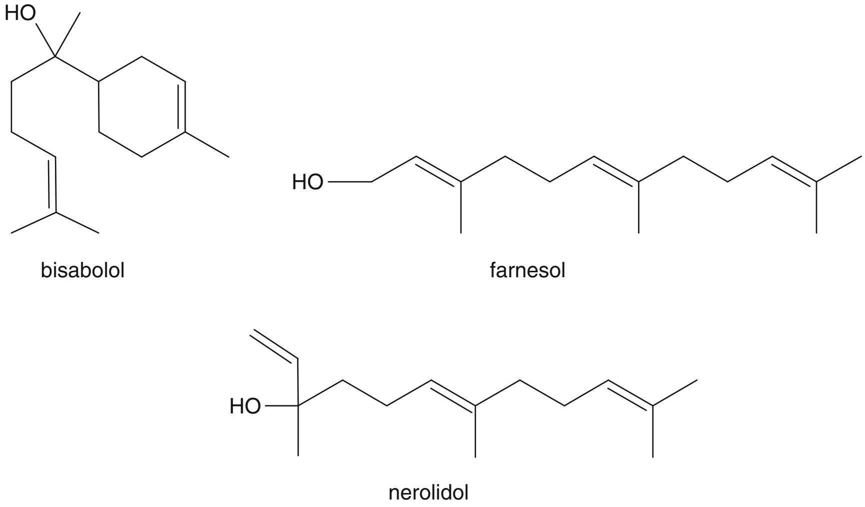

Fig. 124.4 Molecular structures of sesquiterpenes tested as skin penetration enhancers. Sesquiterpenes (C_{15}) are made up of three isoprene units

through excised animal skins the most as compared to oxygen-containing terpenes. The generic trend acts as a guideline for the screening of terpenes, but it does not provide any information on the enhancement level.

The use of terpenes in conjunction with physical enhancers aims to further enhance drug permeation. Ueda and coworkers explored the coupled effect of ultrasound and several chemical enhancers on the percutaneous delivery of aminopyrine [50]. A greater enhancement in aminopyrine flux was obtained when ultrasound was used with monoterpenes (menthol, carvone, and limonene); the coupled effect was much greater than the sum of its individual effects. Rastogi and Singh [51] demonstrated a similar synergistic effect when iontophoresis was combined with limonene pretreatment in the percutaneous absorption of insulin through porcine epidermis.

4.3 Mechanisms of Skin Permeation of Terpenes

Penetration enhancers are applied onto the skin in an amount that is many times more than the skin lipid molecules beneath the area of administration. This means that there are possibly multiple mechanisms taking place at the same time, making it difficult to determine the relative importance and contribution of each mechanism [52, 53].

4.3.1 Techniques to Investigate the Mechanisms of Skin Permeation of Terpenes

Analytical techniques are used in elucidating changes in lipid conformation and composition caused by skin enhancers [54]. Differential scanning calorimetry (DSC),

Table 124.1 Terpenes as skin penetration enhancers for hydrophilic and hydrophobic drugs

Drug	Log *P* of drug	Terpene	Log *P* of terpene	Class and type of terpene	Ref.

Fourier transform infrared (FTIR), and isothermal calorimetry (ITC) are techniques which have been utilized to examine macroscopic and molecular transitions of the skin.

DSC is sensitive to the thermal effects accompanying phase changes or transitions of the components of the SC layer. DSC thermograms of human SC, extracted lipids, and protein residue showed three endotherms at ca. 65 °C, 75 °C, and 95 °C [55]. The first is due to the melting of lipids. The second is believed to be the melting of lipid-protein complexes and the last represents protein denaturation. A decrease in lipid melting transition of the enhancer-treated skin denotes a plausible phase separation [39, 56, 57]. Phase separation involves the formation of interfacial defects in the SC lamellae, resulting in decreased diffusional path length or resistance. Based on the lowered lipid endotherms, Vaddi and our fellow researchers suggested that alcoholic terpenes in ethanol-water could exist as pools of fluid within the intercellular lipids [39]. The presence of fluid terpenes at physiological temperatures presumably aids molecular transport. Moghimi et al. reported some degree of phase transformation, the replacement of the lamellae by a reversed viscous isotropic phase, in limonene-treated matrices [57]. These macroscopic defects within the lipid structure may lead to enhanced drug permeation.

To better understand the effects of the terpenes on the permeability of a drug through the skin, the interactions of the terpenes with SC intercellular lipids were studied using the isothermal titration (ITC) method by our research group [58]. Cholesterol, palmitic acid, and stearic acid were found to be the most soluble among all the lipids in propylene glycol, and they were further significantly solubilized upon the addition of farnesol. The interactions between farnesol and four representative lipids, that is, cholesterol, behenic acid, ceramide 3, and ceramide 9 were studied using the ITC method. The binding ratios of farnesol to cholesterol, behenic acid, ceramide 3, and ceramide 9 were found to be 1, 2, 2, and 2, respectively. All were endothermic and entropy driven except for that between farnesol and behenic acid, which was exothermic and enthalpy driven. Hydrogen bonding may be the driving force of these interactions. The results suggested that the skin permeation enhancement mechanism of farnesol, the terpene of interest, could be due to lipid extraction and/or triggering lipid phase transition of the SC lamella. This finding was also consistent with the permeation study results, which showed the permeability coefficients of the drug increased as the lipophilicities of monoterpene and sesquiterpenes increased. It is perceivable that terpenes with high lipophilicities will have more interactions with skin lipids.

Infrared spectra bands of the SC can be attributed to the lipid or protein molecular vibrations. The hydrocarbon chains of SC lipids give rise to asymmetric and symmetric CH_2 stretching vibrations at 2,920 and 2,850 cm^{-1}, respectively [39]. The shift of these bands to a higher frequency occurs when the methylene groups change from a trans to a more energetic gauche conformation, and this shift is associated with lipid fluidization. The absorbance of the CH_2 stretching bands is proportional to the amount of SC lipids, and thus, the extraction of lipids by a skin enhancer results in a decrease in absorbance [5, 39, 53, 59]. SC proteins give rise to CN stretching and NH bending vibrations at 1,550 cm^{-1}, and $C = O$ stretching vibration at 1,650 cm^{-1}. The shift of these bands to either a higher or lower frequency signifies a change in the protein conformation [45, 53]. FTIR findings of several research groups identified partial lipid extraction as a dominant mechanism for alcoholic, oxide, and hydrocarbon terpenes [39, 40, 60, 61] and showed that delipidization was consistent with enhanced drug permeation.

After the permeation behaviors of the model drug and the enhancers have been investigated by studying the interactions between skin lipids and terpene enhancers, the modeling of drug permeation process through excised skin using both Franz cell and flow-through cell was used to compare the effects of terpenes on drug permeation [62]. A mathematical solution based on finite outflow volume was derived from Fick's law. It can serve as a statistical model to estimate the permeability coefficient from in vitro skin permeation study with the accumulation of penetrants in the receptor compartment of the static diffusion cells. The model is suitable to describe the in vitro drug or chemical permeation studies using Franz cells. However, the flow-though cells have infinite outflow volume, so a different model that could enable the parameter estimation without impairing the integrity and quality of the original permeation data was proposed. The nonlinear regression model derived from Fick's law is appropriate.

Bootstrap sampling is useful for checking the precision of parameter inference based on the large-sample theory. For the in vitro permeation study that we conducted with flow-through cells, the method proved to be robust. The estimates of permeated drug/chemical are important in that, unlike in vivo environment where stratum corneum is replenished by the adjacent live stratum granulosum through keratinization, the excised stratum corneum, though composed of dead corneocytes, will deteriorate after days in contact with solvents, which will cause overhydration of stratum corneum that can destroy the lamella and decomposition that will leave highly permeable passages in the stratum corneum. The predictions are relevant for transdermal drug delivery, the cosmetic industry, and regulatory risk assessment on dermal exposure to toxic substances.

4.3.2 Comparison of the Skin Permeation Effects of Terpenes

The effects of a terpene as a CPE are very much dependent on its physicochemical properties and molecular structure. Increases in the skin transports of propranolol [32, 45], haloperidol [39], and zidovudine [33] were partially attributed to the hydrogen-bonding ability of oxygen-containing monoterpenes. The ether and hydroxyl groups of terpenes interact with the polar head groups of skin ceramides and fatty acids, thereby disrupting the lateral/traverse hydrogen bonding of the lipid bilayers [45, 49]. On the contrary, hydrocarbon terpenes would reside preferentially and cause structural perturbation in the alkyl tail regions of the lipid bilayers [61].

Cornwell and Barry [29] obtained a positive, linear relation between skin conductivity ratio and 5-fluorouracil enhancement ratio for eight terpenes (limonene, terpineol, carvone, pulegone, nerolidol, menthone, ascaridole, and cineole) with oxygen-containing cineole and hydrocarbon limonene positioned at the higher and lower ends of the curve, respectively. Increases in both skin conductivity and permeability after treatment with terpenes suggest the creation of new polar channels through which both ions and polar molecules traverse. These polar routes would be confined in the aqueous regions near the head groups of SC lipids [45], and their formation is possibly linked to the hydrogen-bonding potential of hydrophilic terpenes.

The enhancing effects of 49 terpenes were compared by in vitro drug permeation studies of haloperidol through excised human epidermis by our research group [62]. The derived multiple linear regression models which provided estimations of the permeability coefficients of a drug or chemical through the human skin were found to be useful for the preliminary screening of CPE. The authors reported that for monoterpenes and sesquiterpenes, the permeability coefficients of haloperidol increased as the lipophilicities of terpenes increased. For all terpenes studied, their enhancing abilities decreased as their molecular weights increased. Melting points and boiling points of terpenes were negatively correlated with the permeability coefficients of haloperidol. Sesquiterpenes were better than monoterpenes when only their enhancing effects were considered. The effects of the skin permeation enhancement by terpenes were ranked as follows: ester > aldehyde > oxide > hydrocarbon > alcohol > ketone > phenol > acid (Table 124.2).

Table 124.2 The second column is the name of each terpene, its CAS entry, and purity. The third column T indicates the terpene category (key: 1 monoterpene, 2 sesquiterpene, 3 diterpene, 4 triterpene, 5 tetraterpene). The fourth to seventh columns are molecular weight, melting point, boiling point, and logP of each terpene. The boiling point of (−)-isolongifolol is not available and is estimated at 300 °C to be similar to the boiling points of other sesquiterpenes. The eighth column, Sol, is the solubility of HP in PG at 37 °C with or without 5 % (w/v) enhancer. The last column *LogKp* is the in vitro permeability coefficient of HP though human stratum corneum. Data are given as mean ± SD. For columns 8 and 9, the data were determined experimentally in our lab. The other data were obtained from SciFinder Scholar® and original product information

4.4 Reversible Effects of Terpenes

In addition to the enhancing effects, the reversibility of the effects of terpenes on the skin is also an important characteristic of an ideal CPE. The permeability of the pretreated epidermis was comparable to that of the control, so the insult to the barrier function of the skin caused by the enhancers was restored as reported by our research group [43]. As an in vitro study was performed, the recovery of the epidermal barrier function could not be due to the physical barrier being restored via cellular regeneration of the horny layer. The mechanism for this reversible enhancement would be attributed to the insertion of these enhancers within the SC intercellular lipid lamella. The disruptions in the lipid lamella eased the permeation of the lipophilic drug through the tortuous pathway, hence resulting in enhancement of drug permeation. Likewise, once the enhancers were removed, bonds between the lipids could start to re-form, and the depletion of the enhancers could allow the packing of the lipids to revert back to its original alignment. Of the terpenes studied, (R) – (−) carvone had a much faster elution profile out of the epidermis than eucarvone. The results also showed that (R) – (−) carvone, rather than eucarvone, retained more drug, haloperidol, within the epidermis, which suggests that (R) – (−) carvone could be useful as an enhancer for depot HP therapy. Both (R) – (−) carvone and eucarvone were shown to be effective and reversible enhancers for the in vitro permeation of haloperidol through the human epidermis.

4.5 Terpenes in Transdermal Formulations

The transdermal drug formulations could be in the form of a suspension, solution, gel, ointment, or multilayer transdermal patch. A controlled drug release from the patch is usually achieved by changing the properties of either the rate-controlling membrane or the drug matrix.

Lim et al. [42] demonstrated a controlled drug release by varying the gelator content of an organogel vehicle which presented different degrees of resistance to drug diffusion. He also went on to show the effect of CPE, such as terpenes, on the physical, rheological, and chemical characteristics of a model pharmaceutical formulation for topical and transdermal drug delivery [63] by examining the effects of three terpenes (linalool, cineole, limonene) on the rheology and chemical stability of an organogel composed of dibutyllauroylglutamide (GP1) and propylene glycol (PG). At a given GP1 concentration, oxygen-containing linalool and cineole decreased gel moduli (elastic and viscous) and brittleness, and the reverse was obtained for hydrocarbon limonene. Probably, linalool and cineole interfered with hydrogen bonding between GP1 molecules, while limonene could have initiated a phase separation-mediated gelation, changing the gel morphology. Microcalorimetry detected minute heat endotherms for gels (with and without terpenes) subjected to accelerated heat testing. These heat changes could arise from a small degree of structural disruption of the gel network. Heat endotherms normalized with respect to GP1 content were used to assess gel chemical stability. Although the terpenes altered rheology, they did not significantly affect the chemical stability of the gels. This is the first literature report on the effect of penetration enhancers, such as terpenes, on the physical, rheological, and chemical characteristics of a model pharmaceutical formulation for topical and transdermal drug delivery.

The enhancing effect of a selected enhancer, farnesol, incorporated into gels containing small molecule gelling agents (SMGA), was reported by our research group [38]. The SMGA gels developed for application on the skin retained their characteristic aesthetic and rheological properties with the incorporation of the drug and enhancer. These in vitro human skin permeation studies showed that the gels possessed desirable properties for both topical and transdermal delivery. The translucent lipophilic gels with ISA were stable and the permeation of the drug reached the pseudo steady state in less time compared to the PG-based gel. The latter, opaque white in color, delivered the drug at a faster rate with the addition of the enhancer. The gelator, GP1, did not influence the drug permeation rate but increased its permeation lag-time.

Experimental transdermal patches have also been fabricated by flanking a solution or gel containing the test drug and other excipients between an impermeable backing laminate and a rate-controlling membrane. A pressure-sensitive adhesive coated on the membrane ensures an intimate patch-skin contact. The patch is kept in a sealed aluminum pouch to minimize solvent loss [31, 62, 64].

Krishnaiah et al. [31] designed a transdermal therapeutic system (TTS) for nimodipine. The drug reservoir was an ethanolic gel with 4%w/w limonene as the penetration enhancer. A copolymer film (rate-controlling membrane) was coated with a pressure-sensitive adhesive. In vivo study performed on human volunteers showed that the TTS provided a steady-state nimodipine plasma level with minimal fluctuations for around 20 h and a much-improved bioavailability relative to a tablet dosage form of nimodipine. The intersubject variation in the drug plasma level was observed to be significantly lower for the transdermal route than for the oral route. Hepatic first-pass metabolism, differences in gastric emptying, and gastrointestinal absorption among the subjects are the key causes of a low bioavailability and a less reproducible pharmacokinetics, commonly associated with oral administration. Also, the absence of any local irritation at the application sites of the volunteers demonstrated that the components of the TTS patch (drug, terpene, vehicle, and adhesive) were well tolerated by the skin. Similar findings and conclusions were obtained for the TTS for nicardipine hydrochloride and nicorandil with menthol and nerolidol as the penetration enhancer, respectively [34, 65, 66].

5 Conclusions

Terpenes, as constituents present in plant essential oils, have been investigated as chemical enhancers in transdermal drug delivery. In particular, monoterpenes were generally more efficacious probably due to their small molecular sizes. The main mechanisms of action of terpenes on the skin as determined by several analytical techniques were lipid extraction and phase separation. Terpenes such as limonene and menthol in experimental patch formulations were demonstrated to be safe on the skin and effective in improving drug delivery across the skin.

Abstract

Quassinoids were initially isolated as bitter principles of plants of the Simaroubaceae family. These natural products are formed by oxidative degradation of triterpene derivatives. Since the 1970s, these molecules have attracted attention because of their promising biological activities, especially in the context of research regarding active anticancer and antimalarial principles. In this chapter, the structural diversity of quassinoids and their botanical and geographical occurrence are described, combining a historical perspective from the literature references regarding these two major biological activities and focusing on the results obtained in vivo with the most promising compounds; in vitro studies are less relevant and have already been extensively reviewed in the literature. The biological activities with respect to the uses of the corresponding Simaroubaceae in traditional medicine are also analyzed.

Species names have been transcribed according to the nomenclature system used by The Plant List (http://www.theplantlist.org). Full names of species with determinant are given when cited for the first time only.

1 Introduction

1.1 Structural Diversity and Natural Occurrence of the Quassinoids

Quassinoids are natural products formed by oxidative degradation of triterpene derivatives; their biosynthetic precursors are similar to those of limonoids but the biosynthetic pathways of quassinoids have not been established so far [1]. At least 351 different natural quassinoids have been described in the literature (Fig. 125.1), and a large number of semisynthetic and synthetic analogues have been prepared for synthesis or medicinal chemistry purposes, mostly in last 30 years [see, for example, 2–4]. Several base skeletons have been described in the literature, and these can be classified into five distinct groups according to the number of atoms of the main chain (Fig. 125.1).

The C_{18} quassinoids comprise laurycolactones A and B, eurycolactone B-D, and samaderin A and derivatives. Here, the lactone linkage between carbon atoms C-15

and C-12 is always present, and rings A and B are oxidized with carbonyl groups at positions 1 and 7. In samaderin A, carbon atoms C-20 and C-13 are interconnected with an ether moiety.

The C_{19} quassinoids can be subdivided into three structural groups (Fig. 125.2). The first includes eurycolactone A and samaderolactone A. The second is more diverse, with 33 compounds, including eurycomalactone, eurycomalide, and

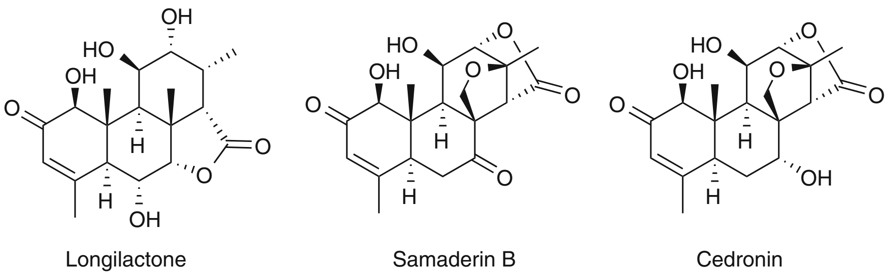

Fig. 125.2 Examples of C_{19} quassinoids

longilactone derivatives, more samaderin derivatives and eurycolactones E and F, indaquassin A, and cedronin. The first representatives of this series were the samaderins B and C, isolated and characterized in 1962 from *Quassia indica* (Gaertn.) Noot. by Polonsky [5].

In this series, longilactones have a lactone linkage between C-15 and C-7, while all others have a lactone ring closure between carbon atoms C-15 and C-12. The only exceptions are eurycolactone F and eurycomaoside, which should have been named after longilactone. In addition, cedronin and samaderins have an ether linkage between C-20 and C-13. The third group of C_{19} quassinoids is smaller. It is composed of 15 different compounds with a contracted B ring. In general, C-16 is linked to C-7, forming a six-membered lactone ring. The A ring is always a γ-butyrolactone and is almost always unsaturated.

More than 75 % of all natural quassinoids described in the literature have a C_{20} skeleton. In the first type of C_{20} quassinoids, a lactone is usually formed between C-16 and C-7 (as represented here), although some members of this group are lactonized between C-16 and C-12. All positions can be oxidized with double bonds or oxygenated functional groups, and again, an ether moiety linking C-20 to C-13 and sometimes C-11 can be encountered. When the C-15 atom is hydroxylated, the hydroxyl group is often esterified with small lipophilic side chains. Quassin, the first isolated quassinoid, belongs to this C_{20} group, and most in vivo studies and clinical trials with quassinoids were conducted on compounds of that group. Quassin is used as natural insecticide and bitter food flavoring. The C_{20} quassinoids that have attracted most attention in the literature for their pharmacological interest are ailanthone and its analogues (ailanthinone, glaucarubinone, chaparrinone, 15-desacetylundulatone, and peninsularinone), bruceins, brusatol, bruceolide, bruceantin, and simalikalactones D and E (Fig. 125.3).

The second group of C_{20} quassinoids with a contracted C ring is represented by shinjudilactone and ailantinol D, and the third group with a cleaved C ring is composed of vilmorinines A-F isolated from *Ailanthus vilmoriniana* (Dode) [6].

The three C_{22} natural quassinoids known in the literature have a butenolide moiety attached to the A ring, presumably originating from the aldol cyclization of a α-acetoxycarbonyl moiety from the normal C_{20} skeleton. In this series, sergeolide has attracted much attention due to its very good antimalarial potential (Fig. 125.4) [7].

Fig. 125.3 Examples of naturally occurring C_{20} quassinoids

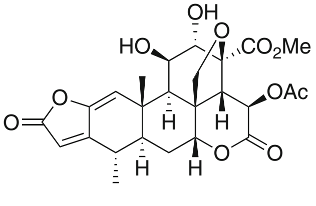

Fig. 125.4 Structure of sergeolide

C_{25} quassinoids are rather rare. Simarolide was the first member of this group to be isolated and characterized by Polonsky in the early 1960s [8, 9]. The side chain consisting of carbon atoms C-22 to C-26 is always lactonized, either forming an O–C-22 or a O–C-24 bond. In this series, the C-15 position is never hydroxylated so the side chain that seems to impact on the biological activity of the C_{20} quassinoids is absent. Also, C-20 is always a methyl group, whereas, the A ring of soulameolide and indaquassin F does bear the α,β-unsaturated ketone with the carbonyl functional group on C-2.

Quassinoids are natural products occurring in the Simaroubaceae family and are known as the bitter principles of these plants. The Simaroubaceae belong to the Sapindales order and are considered as emerging from a protorutaceous stock because of the presence of tryptophan-derived alkaloids (canthinones and β-carbolines) common to the Rutaceae and the Simaroubaceae. The major metabolic difference with Rutaceae species originates from the presence of limonoids in Rutaceae, whereas the Simaroubaceae generate quassinoids [10–12]. The correlation between the presence of alkaloids and quassinoids and the geographical distribution of the species has also been studied to clarify the phylogenetic relationships within the Simaroubaceae family [11].

Nevertheless, some exceptions to this rule must be highlighted, with the examples of the genera *Samadera* and *Harrisonia*. In 1997, the first example of joint occurrence of quassinoids and limonoids was uncovered in a new Australian Simaroubaceae species SAC-2825, tentatively assigned as aff. *Samadera bidwillii* Oliv. [12]. The genus *Harrisonia* was also shown to contain both families of molecules [13]. However, with the evolution of botanical nomenclature, *Samadera bidwillii* is considered unresolved and some *Samadera* species have been placed in synonymy with *Quassia* species, whereas the genus *Harrisonia* is now included in the Rutaceae family. These examples of species containing simultaneously limonoids and quassinoids could illustrate the chemistry of primitive Rutales, before the metabolic separation between the two families, and quassinoids therefore appear to be of chemotaxonomic relevance.

Currently, the Simaroubaceae family includes 16 genera divided into 102 species exclusively distributed in tropical and subtropical areas, with the exception of the *Ailanthus* and *Picrasma* genera, the distribution area of which extends to temperate Asia. The most species-rich genera are *Quassia* (37 species), followed by *Castela* (17), *Simaba* (12), and *Brucea* (10). *Armoria*, *Gymnostemon*, *Iridosma*, *Leitneria*, and *Simarouba* are monospecific. Some genera have distribution areas restricted to Asia (*Eurycoma*) or southwest Africa (*Odyendyea* and *Hannoa*). *Brucea* is present in East Africa and Asia, *Picrasma* and *Quassia* are considered cosmopolitan, and *Castela* is essentially neo-tropical [14]. A biogeographic study of the Simaroubaceae family suggested that this family may originate from North America with a migration through the Bering Strait by ancestral taxa [15].

Morphologically, species of this family are trees of medium to small size, or branched and bushy shrubs, sometimes spiny. The leaves are alternate, compound, rarely simple, without stipules. The bitter taste of all parts of the plants of this family is also a criterion for botanic identification. The scientific names and even

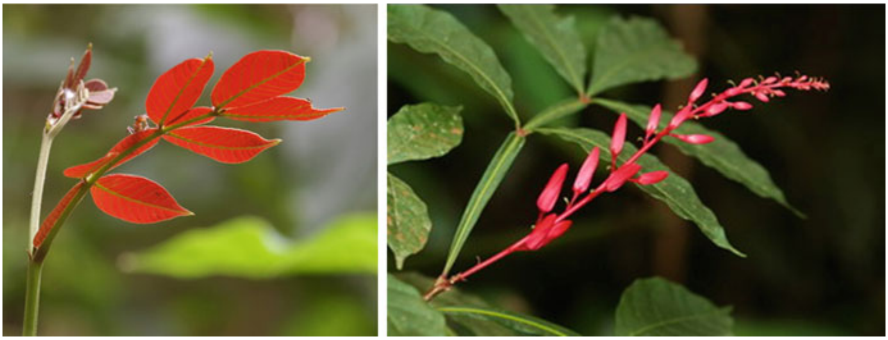

Fig. 125.5 Young leaf (*left*) and mature leaf and flower (*right*) of *Quassia amara* L. (Picture: G. Bouchon)

more the vernacular names of these species bear witness to this feature. For example, *Quassia africana* (Baill.) Baill., an African Simaroubaceae, is known in Congo under the name of "simalikali" which means "bitter than everything else" [16].

1.2 From Kwasi to Quassin, or How a Traditional Pharmacological Application Led to a New Promising Family of Molecules

The history of quassinoids began in the mid-eighteenth century, after the discovery in 1760 of the febrifuge properties of a Simaroubaceae, *Quassia amara* L. (Fig. 125.5). The medicinal property of the roots of this species was revealed to Carl G. Dahlberg, a Dutch army officer, by a Suriname slave and famous healer named Kwasi. This recipe was subsequently made public by Daniel Rolander, a Swedish naturalist. Linnaeus, excited by the discovery of this plant and its uses, named it in honor of the healer. The botanist, however, committed an error in its description, corrected in 1763 by his disciple C.M. Blom [17–20].

Under the name of "quassia" or "quassia wood" (*Quassiae lignum*), two indiscriminate species were then sold in Europe: *Quassia amara* (mainly root, wood and stems) and *Picrasma excelsa* (Sw.) Planch. (formerly *Picraena excelsa* (Sw.) Lindley) or Jamaican quassia (trunk wood) [17, 18, 20]. Quassia wood was initially used as an antiseptic, for meat preservation and as antipyretic. But because of its bitter principles its main recommendation was as a digestive and tonic [17, 21]. *Q. amara* was rapidly registered in various European pharmacopoeias, alone or with other Simaroubaceae species with the same reputation, such as *Picrasma excelsa* or *Simarouba amara* Aubl. [22–25]. The reputation of quassia wood then spread to the United States, where the medicinal use of cups mostly made of *Q. amara* wood became popular [26]. Meanwhile, a few Simaroubaceae were registered in North American official pharmaceutical documents, such as the King's American Dispensatory [27] or the United States Dispensatory [28].

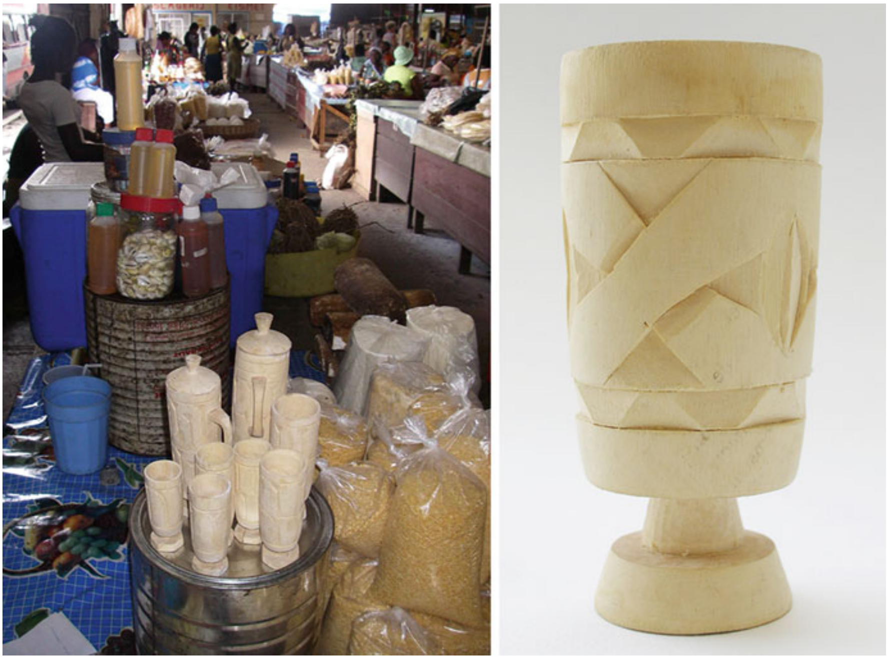

Fig. 125.6 *Left*: *Middags Markt* stall, Paramaribo, Suriname, with a choice of bitter-cups (Picture: G. Odonne) – *Righ*t: close-up view of a bitter-cup (Picture: E. Deharo)

These cups, called tonic- or bitter-cups, are still in use for their tonic properties in Suriname today (Fig. 125.6), where they are also known under the name "Kwasi bita beker" [29].

The bitter substances of *Quassia amara* were first named quassin by Thompson in the beginning of the nineteenth century [17 ,21] and were obtained in crystalline form by Winckler in 1835 [30]. It was more than a century later that a method for preparation and purification of quassin and neoquassin was described, highlighting that the crude extract was, in fact, a mixture of these two components [31, 32]. Studies on quassinoids from *Quassia amara* and *Picrasma excelsa* – mainly quassin, neoquassin, and isoquassin, the latter initially named picrasmine – then continued until the 1950s [33–36]. In particular, their structures were partially determined by Robertson et al. based on physical and chemical observations. The authors also synthesized norquassine, isolated thereafter and named simalikalactone B or picrasine B [37]. The complete structure of these molecules (quassin and neoquassin) and their stereochemistry, however, were only fully established in the early 1960s, when nuclear magnetic resonance techniques could be applied to them [38, 39]. This step marked the beginning of many studies leading to the isolation of quassinoids from natural sources.

Technical advances in structural analysis also initiated subsequent advances in synthesis of quassinoids, leading in particular to the first total synthesis of quassin

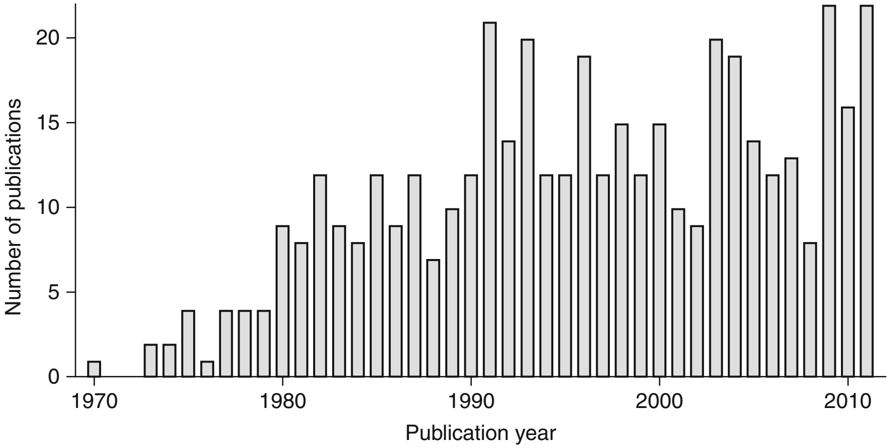

Fig. 125.7 Yearly number of publications related to quassinoids between 1970 and 2011 (Source Scopus + Science Direct)

by Grieco et al. in 1980 [40]. This milestone contribution to the study of quassinoids and the marked antileukemic activity of some of them – especially quassinoids with the C_{20} skeleton – initiated a considerable increase in publications related to quassinoids in the 1980s [41].

A literature search conducted for the terms "quassinoid" and "simaroubolide" (a term used in the 1970s to designate these molecules isolated from plants of the Simaroubaceae family) on the search engines Scopus and Science Direct provided a total of 453 references from 1970 to 2011; Fig. 125.7 illustrates the yearly profile.

This graph highlights the growing interest in quassinoids between the 1970s and 1980s. This trend could be explained simply by the increasing number of scientific publications at the time, but a study of the literature shows clearly that it is also correlated with the discovery of the anticancer properties of these molecules. Since 1990, the number of articles on this family of molecules has remained stable.

1.3 Pharmacological Activities: A Focus on Cancer and Malaria

The quassinoids are renowned for two major pharmacological activities: their anticancer and their antiplasmodial potential. Looking more closely at the evolution of publications on these two major classes of biological activities, we obtained the curves shown in Fig. 125.8. The linear regressions represented here demonstrate an early interest in their anticancer activities (1970–1985) and the increasing interest in their antimalarial potential (since 1990). Subsequent sections will therefore focus on these two pathologies.

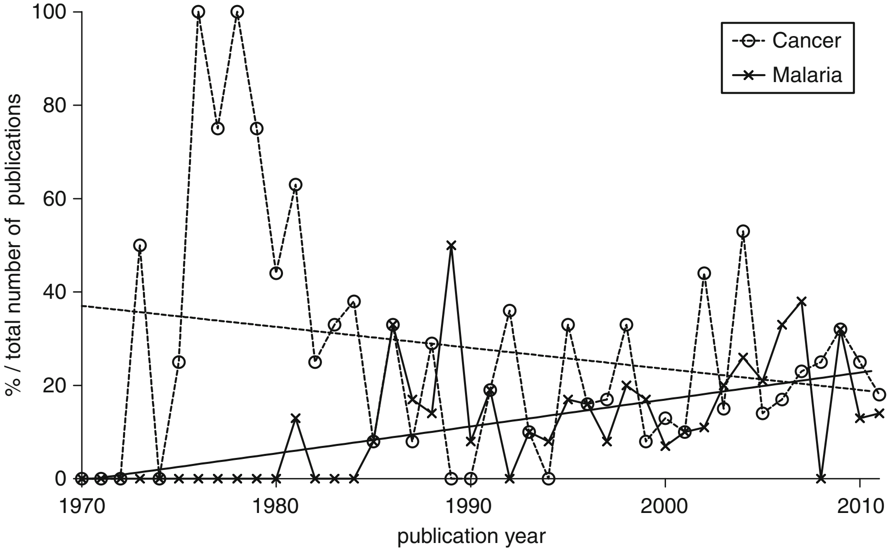

Fig. 125.8 Trends in numbers of publications on anticancer and antimalarial activities of quassinoids from 1970 to 2011

2 Pharmacological Applications

2.1 Historical Perspective and In Vitro Cytotoxic Activities

The decade that followed the discovery of the antileukemic activity of bruceantin is marked with a strong interest of the scientific community for the study of the anticancer properties of quassinoids. Bruceatin was isolated in 1973 by Kupchan from the stem bark of *Brucea antidysenterica* Mill. and identified as the active ingredient of this tree used against cancer in Ethiopia [41]. Following this discovery, many plants of the Simaroubaceae family were studied, and more than twenty molecules with high in vitro cytotoxic activity were isolated between 1973 and 1985, including dehydroailanthinone from *Pierreodendron kerstingii* (Engl.) Little [42], quassimarin extracted from *Quassia amara* [43], bruceoside A from *Brucea javanica* (L.) Merr. [44], samaderine E from *Samadera indica* Gaertn. (syn. *Quassia indica*) [45], and sergeolide from *Picrolemma pseudocoffea* Ducke (syn. *Picrolemna sprucei* Hook.f.) [7]. Quassinoids' in vitro anticancer activity has been broadly compiled in excellent reviews [46, 47]. Bruceantin was the first quassinoid introduced in clinical trials (see Sect. 2.2), but the unsatisfactory results obtained led to a decline in interest in research on anticancer activity of quassinoids. Since 2000, new results on bruceantin have suggested that the activity of this molecule towards certain types of cancer (leukemia, lymphoma, myeloma) deserves further investigation [48]. To date, the quassinoids therefore remain a family of molecules with potential in the context of the search for anticancer compounds.

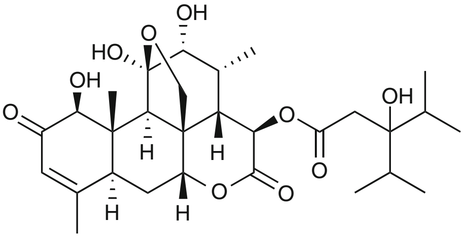

Fig. 125.9 NBT-272

2.2 In Vivo Anticancer Assays with Quassinoids, Clinical Trials

Quassinoids have been widely studied for their anticancer activity in vitro, however, only a few of them have shown interesting activity. Bruceantin was active in animal models against melanoma, colon cancer and leukemia [41, 48]. According to Cuendet et al. (2004), male mice seemed to be more sensitive to bruceantin than females, independent of the age of the treated mice. It was claimed that doses of 2.5 and 5.0 mg kg^{-1} promote the regression of earlier and advanced tumors (multiple myeloma, RPMI 8,226 cells) without apparent toxicity [49]. Phase I and II clinical trials were conducted with this compound. Unfortunately, no objective regression of the proliferative process was observed in humans, whereas a relative toxicity was noticed (hypotension, nausea, and vomiting at low dose, thrombocytopenia at higher dose) [50–53].

NBT-272, a semisynthetic analogue of bruceantin (Fig. 125.9), was found to be two to tenfold more potent than the original compound in inhibiting the cellular proliferation of a variety of cancer cell lines [54]. It also prevented tumor progression in a xenograft model of neuroblastoma cells with coinciding reduction of MYC expression and ERK activation in treated tumors [55].

Peninsularinone extracted from *Castela peninsularis* Rose, has been shown to be very active against pancreatic adenocarcinoma at 4.3 mg kg^{-1} and against colon adenocarcinoma (3.2 mg kg^{-1}) in animal models. The most surprising observation was that a lethal dose of peninsularinone could be administered safely in previously treated animals with low non-toxic concentrations a few days before the injection of the lethal dose. Interestingly, this molecule could be synthesized from glaucarubolone (isolated from *Castela polyandra* Moran & Felger) [56], which also showed activity in this model. Chapparinone, a related compound, also showed potential clinical application according to National Cancer Institute standards in the treatment of colon adenocarcinoma due to its activity against C38 cells implanted in mice [56].

15-desacetylundulatone, isolated from *Hannoa klaineana* Pierre & Engl root bark, which has free hydroxyl functions at C-l, C-11, and C-12 and an ester chain at C-6, was active against P388 leukemia in mice at doses up to 100 mg kg^{-1}. Remarkably, when the carbonyl group in C-2 was reduced, the activity dropped dramatically [57].

Administration of simalikalactone E (SkE) to nude mice implanted with K562-luc human leukemia cells resulted in leukemia regression at 1 mg kg^{-1}

SkE [58]. New assays against leukemia should be conducted with quassinoids as SkE and/or bruceantin are strongly active against leukemia cell lines in which Ras/Raf/MEK/Erk and c-MYC are activated.

2.3 Historical Perspective and In Vitro Antiplasmodial Activities

The emergence of resistance of the human malaria parasite *Plasmodium falciparum* to all commercialized antimalarials is of great concern for mankind. The wide use of Simaroubaceae species against malaria in areas of endemism stimulated the study of quassinoids and derivatives against *Plasmodium species*. As early as 1930, a quassinoid glycoside isolated from the seeds of *Simaba cedron* Planch. demonstrated an interesting potential for the treatment of malaria via the parenteral route, but renal secondary effects at high doses were recorded [59]. In 1947, the pharmaceutical company Merck screened around six hundred plant extracts on bird malaria models in vivo to find new antimalarials [60]. From the Simaroubacea family many plants were found to have excellent activity against *Plasmodium gallinacaeum* in chickens: *Castela spinosa* Cronquist, *Castela tortuosa* Liebm., *Castela tweediei* Planch., *Mannia africana* Hook. f. (syn. *Pierreodendron africanum* (Hook.f.) Little), *Picrolemma sprucei*, *Simaba cedron, Simaba cuneata* A.St.-Hil. & Tul., *Simaba insignis* A.St.-Hil. & Tul., *Simarouba amara*, *Simarouba berteroana* Krug & Urb., *Simarouba glauca* DC., *Simarouba tulae* Urb. Unfortunately, at the end of the World War II, the company stopped the project and no further study was conducted on these plants.

The investigation of the antimalarial properties of quassinoids then restarted at a significant rate in the mid-1980s and has remained relatively constant since then. Review articles on the antimalarial activity of quassinoids were published by Muhammad and Samoylenko in 2007 [59] and Guo et al. in 2005 [47].

The discovery of antiparasitic activities of quassinoids (see Sect. 4) prompted some authors to study the antimalarial potential of these molecules [61]. Among the quassinoids highlighted as potential antimalarials by Trager and Polonsky were simalikalactone D, identified as the most active molecule with complete inhibition of parasite growth at a dose of 2 μg ml^{-1}, as well as glaucarubinone and soularubinone. Other compounds, such as sergeolide [62] and bruceantin [63], also showed significant antiplasmodial activity.

Studies based on traditional use of Simaroubaceae continued in the 1980s, especially by Phillipson et al. [63–67]. Many articles on this subject followed, with, for example, the reisolation of simalikalactone D and the isolation and characterization of gutolactone from the bark of *Simaba guianensis* Aubl., a species used by people in the Amazon Basin [68]. Also, cedronin was isolated from the bark of *Simaba cedron*, a species used in Central and South America for the treatment of malaria [69], and samaderines B, E, X, and Z were isolated from *Quassia indica* branches used in the Indonesian traditional pharmacopeia [70]. In our work, it was chosen to test the traditional remedies as prepared by local people. This approach highlighted the remarkable activity of a decoction made from the leaves of *Quassia amara* [71, 72]. Later, it was shown that the antimalarial activity of this remedy could originate from the presence of two quassinoids: simalikalactone D (SkD) isolated from an optimized young leaf tea and simalikalactone E (SkE) isolated from a mature leaf decoction [73–76]. SkD was shown to be responsible for both the antimalarial activity and the cytotoxicity of the young leaf preparation. Overall, these studies take all their importance within the framework of the World Health Organization's recommendations on the evaluation of traditional medicines.

2.4 In Vivo Antimalarial Activity of Quassinoids in Murine Models

We will focus herein on compounds harboring antimalarial activity in vivo in a mouse model. Because that model requires more facilities than culture and larger amount of compound, only a few quassinoids have been studied against murine malaria. Among them, less than 20 quassinoids showed interesting activity. They were isolated from six species (*Ailanthus altissima*, *Brucea javanica*, *Hannoa chlorantha* Engl.& Gilg. (syn. *Quassia undulata* (Guill. & Perr.) D.Dietr.), *Picrolemma pseudocoffea*, *Quassia amara*, *Simaba cedron*) or were semisynthesized from quassinoids extracted from *B. javanica* (Table 125.1).

They can be separated into the following two classes derived from a core C_{20} carbon skeleton as suggested by Muhammad and Samoylenko [59]:

- Class A: quassinoids with the C-8(13)-oxymethylene bridge in the C ring isolated from *Brucea*, *Quassia*, *Simaba*, *P. pseudocoffea*, and semisynthetic bruceolide derivatives.
- Class B: quassinoids with the C-8(11)-oxymethylene bridge reported from *Ailanthus* and *Hannoa*.

The authors claimed that the quassinoids with a C-8(13)-oxymethylene group were five to tenfold more potent than C-8(11)-oxymethylene analogs in vitro. In vivo, this scheme does not appear so clear.

In class B derivatives, the activity seems to be influenced by the presence or absence of a hydroxyl group or a side chain at the C-15 position. Hence, 15-hydroxy-ailanthone isolated from *A. altissima* is very active (ED_{50} 0.76 mg kg^{-1} day^{-1} when administered orally); while chaparrine, which lacks function in the C-15 position, is inactive [66]. Interestingly, carbonyl group in C-2 is also important; when position 2 is occupied by a hydroxyl substituent (chaparrine) instead of a ketone (chaparinone) the activity disappears. The difference between in vivo activity of glaucarubin (with a C-2 hydroxyl group) inactive and glaucarubinone (=O) very active (ED_{50} 0.86 mg $kg^{-1}day^{-1}$ upon oral administration) is another example. It seems that the length of the C-15 substituent does not influence the antimalarial activity because ailanthone, ailanthinone, and glaucarubinone present the same antimalarial potential. Montjour et al. [77] showed that glaucarubinone was ineffective against *P. berghei* when administrated once by oral route at 2.5 mg kg^{-1} and was effective by intraperitoneal route at 0.5 mg kg^{-1} day^{-1} for

Table 125.1 In vivo antimalarial activity of natural and semisynthetic quassinoids against murine *Plasmodium*

			Oral	1	
Simaba cedron Planch. (Stem bark)	Cedronin	*P. vinckei*	Intraperitoneal	1.8	[71]

12 days. The authors also observed toxicity at doses > 2.5 mg kg^{-1} (oral) and 0.5 mg kg^{-1} (intraperitoneal). According to François et al. [78] among the quassinoids isolated from *Hannoa chlorantha*, the most active one was 15-desacetylundulatone but the EC$_{50}$ was not calculated. Nevertheless, the administered doses (50 mg kg^{-1}) were high and close to the toxic range. Authors proposed to split the treatment in several lower doses, but further such experiments have not been described so far. Interestingly, 15-desacetylundulatone is functionalized in position C-6 as SkE, a very active class A compound (see below).

In class A, brucein derivatives are almost all equally potent; the presence of either a hydroxyl or a short acyloxy substituent in C-15 does not influence the antimalarial activity. Nevertheless, with a too long/bulky acyloxy group, the activity drops dramatically (brucein A vs brucein C) [65]. Semisynthetic derivatives of bruceolide [79] were found more potent than chloroquine, increasing by four times the life span of treated mice without noticeable signs of toxicity even at doses of 3 mg kg^{-1}. For example, ED_{50} for 3,15-*O*-diacetylbruceolide was 0.46 mg kg^{-1}, but this compound was unable to remove malaria parasites in the blood stream of infected mice completely [80]. Authors suggested that the 15-acetoxy substituent was critical to the in vivo antimalarial efficiency. Nevertheless, to the best of our knowledge, no other semisynthetic quassinoid derivative has been studied for antimalarial purposes.

SkE seems to be almost four times more active in vivo than SkD [73, 76], but the *Plasmodium* species used for the test were different: *P. vinckei* for SkE and *P. yoelii* for SkD, *P. vinckei* being usually almost ten times more sensitive to treatment than *P. yoelii* [81].

Sergeolide isolated from roots of *Picrolemma pseudocoffea* had an original structure with a butenolide function attached to the ring A. It had been shown to be active in vivo against *P. berghei* (ED_{50} 0.2 mg $kg^{-1}day^{-1}$), unfortunately with a poor therapeutic index (median lethal dose LD_{50} 1.8 mg kg^{-1}) [62].

Compared with the plethoric studies on antiplasmodial activity against *P. falciparum* in vitro, in vivo antimalarial assays dedicated to quassinoids are scarce and hardly comparable. Nevertheless, the excellent antimalarial activities highlighted in those studies should open the way to complementary studies of their pharmacokinetics and toxicity. Association with other antimalarials should also be investigated in order to define new therapeutic schemes and to lower the administered doses, increasing drugs' tolerability.

3 Mechanisms of Action

Anticancer activity is one of the most striking biological properties of quassinoids. It has been particularly well documented and is still a source of discoveries. Many mechanisms of action have been proposed, including inhibition of phosphoribosyl pyrophosphate aminotransferase of the de novo purine synthesis pathway [82], inhibition of aerobic respiration [83], mitochondrial membrane depolarization, activation of caspase-3 [84], and alteration of microtubules [85]. It is also generally well accepted that quassinoids restrain protein synthesis, inhibiting the polypeptide chain elongation that prevents the first round of peptide bond establishment prior to polysome formation [86–88], this inhibition being reversible [87]. In particular, bruceantin binds to the peptidyl transferase center on ribosomes [89]. Brusatol has been claimed to decrease c-MYC oncoprotein expression at the post-transcriptional level [90] and to up-regulate mRNA levels of transcription factor NF-kB [91] and phosphorylate NF-kB inhibitors promoting NK-kB translocation into the nucleous. On the contrary, brucein D has been shown to inhibit NF-kB, increasing the protein level of IkB-alpha, known to sequester NF-kB in the cytoplasm and prevent its nuclear translocation. It has also been shown to generate oxidative stress depleting GSH and to activate p38-MAPK pathway. Some authors suggested that discrepancies between these related molecules are due to different methodologies [46].

Quassinoids also impair the protein synthesis mediated by the translation initiation factor 4E [92]. A liphophilic extract of *Nothospondias staudtii* Engl. inhibited Activator Protein-1 (AP-1), a transcription factor found in cellular nucleus, known to promote tumoral progression under certain conditions [93]. A quassinoid analogue, NBT-272, was reported to induce down-regulation of c-MYC in medulloblastoma-derived cells [54]. Castelletti et al. [55] showed that this molecule interferes with AKT and MEK/extracellular signal-regulated kinase pathways. The authors suggested that the depleting effect of NBT-272 on MYC protein expression occurred via indirect mechanisms, rather than selective inhibition. Crude extract and fractions of *Eurycoma longifolia* have been shown to induce apoptosis via a caspase-9-independent pathway in MCF-7 breast cancer cells [94]. This finding was corroborated by Zakaria et al. [95], who showed that an eurycomanone-enriched fraction was able to induce apoptosis via the p53 pathway in HepG2 liver cancer cells. More recently, Wong et al. [96] found that eurycomanone reduced the abundance expression of the following lung cancer cells markers: heterogeneous nuclear ribonucleoprotein A2/B1, p53 tumor suppressor protein and other cancer-associated genes including prohibitin, annexin 1, and endoplasmic reticulum protein 28 but not the housekeeping genes. Another bruceantin analog has been shown to inhibit the phosphorylation of upstream elements of HIF-1alpha (ERK1/2, MNK1 and eIF4E), a clue mediator of cellular responses to low oxygen, over-expressed in certain cancers [97]. It has been suggested that its effect was the consequence of the inhibition of this dependent MAPK cascade (HIF-1 alpha upstream elements) and/or the inhibition of the phosphorylation of eIF4E, which inhibits HIF-1 alpha translation.

In the case of *Plasmodium*, the main accepted mechanism of action is that quassinoids target plasmodial protein synthesis [98]. Arnot and Gull [99] showed that throughout *P. falciparum* growth inside the red blood cell, protein synthesis increases rapidly while the DNA synthesis peaks between the 20 and the 38 h of its blood cycle. Afterwards, DNA, RNA, and protein synthesis decrease dramatically at the schizont stage announcing the end point of the cycle. Interestingly, when SkE was pulsed every 6 h in a *Plasmodium falciparum* synchronous culture, it was found more effective at stages when DNA synthesis occurs [76]. This finding was corroborated by Bertani et al. [100], who showed that when SkD was pulsed every 4 h, the half-inhibitory concentration (IC_{50}) dropped to 10 nM at the 30 h, when the production of plasmodial DNA is maximal and rate of protein synthesis still elevated. SkD targets a very particular moment of *Plasmodium* growth. It is almost inactive on young and old stages while it is strongly active on mature cells at the DNA replication stage. Mata-Greenwood et al. [101] showed in 2001 that some quassinoids are able to inhibit DNA synthesis with greater efficacy when these molecules possess a C-15 ester side chain; that is the case for SkD.

Bertani et al. [100] also showed that SkD was inactive against heme biomineralization process and did not affect permeability pathways induced by a parasite in the host erythrocyte membrane. They also showed that SkD enhanced the activity of atovaquone on *Plasmodium* mitochondrial membrane potential, while it had an additive effect when combined with other commercial antimalarials.

4 Other Biological Activities and Ethnopharmacological Relevance

An extensive search for antimalarial compounds among the quassinoids was inspired by the discovery in the 1950s of the antiparasitic properties of these compounds, especially towards *Entamoeba histolytica* [61]. Glaucarubine's amoebicide property, isolated from *Simarouba glauca*, had been discovered a few years earlier [102]. Many antiparasitic activities would later be identified for extracts and molecules from the Simaroubaceae: amoebicidal (bruceantin [103], *Castela texana* (Torr. & A. Gray) Rose (syn. *Castela tortuosa*) [104]), nematicide (chaparrinone, klaineanone, and glaucarubolone [105], samaderins B and E [106]), antibabesial (*Brucea javanica* extract, and brusatol, bruceantin, brucein, abruceantinol, dehydrobrusatol, and dehydrobrucein A isolated from this species [107, 108]).

Many other activities were also recorded for quassinoids: insecticidal, antiviral, anti-inflammatory, and so on. These were extensively reviewed by Guo et al. and Almeida et al. [47, 109], thus justifying the interest in drawing parallels between the biological activities identified in vitro or in vivo for these molecules and the traditional uses of species from which they come.

Species belonging to the Simaroubaceae family are widely referenced in the pharmacopoeias of different medical systems around the world, whether they be of contemporary or ancient use, transmitted orally, or from written sources. For example, *Ailanthus altissima*, the area of natural distribution of which extends from Manchuria to Malaysia, is one of the most cited species in ancient Chinese medical treatise for a wide range of indications. One of the oldest recipes for this species has been recorded in a book in China dating back to 732 AD for the treatment of mental illness [110]. Its bark is still registered in actual Chinese and Asian pharmacopoeias, and it is traded across China. The same applies to *Brucea javanica* fruits in Southeast Asia and to *Ailanthus excelsa* Roxb. bark, mentioned in ancient and contemporary ayurvedic medicine books [111]. The use of *Brucea antidysenterica* bark has also been documented since the sixteenth century in ancient Arabic medical pharmacopoeias [112].

Moreover, some species have been introduced, naturalized, cultivated, and marketed outside their original distribution area with respect to their therapeutic value. This is the case for *Simarouba amara*, introduced in India; *Ailanthus altissima*, introduced as an ornamental and medicinal plant in North America, then in Europe; *Brucea javanica*, now cultivated in Africa; and *Quassia amara*, a few specimens of which were introduced in Africa and India. In their country of origin, *Ailanthus altissima*, *Ailanthus excelsa*, *Brucea javanica*, *Castela tortuosa*, *Eurycoma longifolia*, *Picrasma excelsa*, *Quassia amara*, *Quassia indica*, *Simaba cedron*, and *Simarouba amara*, among others, are still prepared under more or less advanced galenic forms and some are even for sale on the Internet.

Within the 102 Simaroubaceae species, an exhaustive bibliographic investigation (Table 125.2) highlights about twenty of most used species in traditional medicine. The most cited genera worldwide are *Ailanthus*, *Brucea*, *Castela*, *Eurycoma*, *Hannoa*, *Picrasma*, *Picrolemma*, *Quassia*, *Simaba*, and *Simarouba*. Despite the multiplicity of species, their geographic distribution range, and therefore the extreme cultural diversity that underlies their use, there is a marked homogeneity in the uses made of these species. Much of the uses of Simaroubaceae are first centered on the gastrointestinal sphere and the corresponding organs (stomach, liver, small intestine, colon). *Ailanthus triphysa* (Dennst.) Alston, *Brucea antidysenterica*, *Eurycoma longifolia*, *Picrasma excelsa*, *Quassia amara*, and *Simarouba amara* are recommended for their invigorating "tonic" and stimulating effect and used to increase appetite, in cases of dyspepsia, and for indigestion. *Ailanthus altissima*, *A. excelsa*, *Hannoa klaineana*, *Picrasma crenata* Engl. in Engl. & Prantl., *Picrasma quassioides* (D. Don) Benn., *Quassia africana*, *Q. gabonensis* Pierre, *Simaba cedron*, and *Simarouba amara* are prescribed as intestinal antispasmodics and in cases of acute colic with or without diarrhea.

Simple diarrhea, without blood, can be treated with *Ailanthus altissima*, *A. excelsa*, *Brucea antidysenterica*, *B. javanica*, *Castela coccinea* Griseb., *Eurycoma longifolia*, *Quassia amara*, *Q. undulata*, and *Simarouba amara*; bloody dysenterical diarrhea is treated by the administration of *Ailanthus altissima*, *A. excelsa*, *A. triphysa* (Dennst.) Alston., *Castela coccinea*, *C. erecta* Turpin, *C. tortuosa*, *Eurycoma longifolia*, *Picrasma excelsa*, and *Simaba cedron*. The most widely used species, the effectiveness of which has been demonstrated for this indication, is *Simarouba amara* (bark and seeds), together with the fruits of *Brucea antidysenterica* and *Brucea javanica*. Stomach pains are treated with *Brucea antidysenterica*, *Castela tortuosa* (syn. *Castela texana*), *Picrasma excelsa*, *Picrolemma sprucei*, *Quassia amara*, *Q. gabonensis*, *Q. indica*, *Q. undulata*. The seed kernels of *Simaba cedron* have an effect on hepatic colic and liver tropism. This is justified in the context of traditional medicine by their bitterness. Indeed, most Simaroubaceae are extremely bitter [72], as it is the case for *Brucea antidysenterica*, *Castela tortuosa*, *Eurycoma longifolia*, and *Quassia amara*, used in cases of jaundice and other chronic liver diseases. Antidiabetic and/or lipolytic remedies *Castela tortuosa*, *Picrasma crenata*, *Picrolemma sprucei*, *Quassia amara*, and *Simaba orinocensis* Kunth. may also target liver.

Ailanthus altissima, *Brucea antidysenterica*, *Picrasma excelsa*, *Quassia africana*, *Quassia undulata*, *Simaba cedron*, and *Simarouba amara* are also used as anthelmintics.

Simaroubaceae are broadly used against dermatological conditions from bacterial origin (furuncles, superinfected wounds, erysipelas, acne, abscesses), parasitic origin (leishmaniasis), related to the presence of dermatophytes (ringworm), to those described as warts or "cancerous tumors of the skin," tropical ulcers, and

Table 125.2 Medicinal uses of Simaroubaceae species (Part of plant used: *AP* aereal part, *Bd* bud, *Ft* fruit, *L* leaf, *Bk* bark, *RBk* root bark, *R* root, *Res* resin, *S* seed, *SBk* Stem bark, *St* stem, *Wd* wood)

Species and main geographic distribution of registered uses	Uses (part of plant used)
Ailanthus altissima (Mill.) Swingle (China, South east Asia)	Anthelmintic (Bk), cutaneous parasitic ulcers (L, Bk, Rbk), kala azar (Bk), intestinal hemorrhage (Bk, RBk), spermathorrea (Bk) [113]; Cardiovascular disease (L), asthma (Bk, R), epilepsy (L), antispasmodic (gastro-intestinal) (L) [114]; Dysentery (Bk, L, RBk) [113–115]; Diarrhea (Bk, RBk) [113, 115]; Leucorrhea (Bk) [115, 116];
	Menstrual disorders (Bk, RBk) [113, 116];
	Uterine hemorrhage (Bk, RBk) [115]
Ailanthus excelsa Roxb. (India)	Asthma (SBk), antispasmodic (gastro-intestinal) (SBk) [117];
	Affection of the mouth (L), cough (L), leucorrhea (L), skin ulcers (BK, L), uterine hemorrhage (L) [116];
	Contraceptive effect (L, SBk) [118];
	Diarrhea (Bk, L), dysentery (BK, L), menstrual disorders (Bk, L) [111, 116]
Ailanthus integrifolia subsp. calcynia (Pierre) Noot. (Nepal, North India)	Furunculosis (Res) [119]
Ailanthus triphysa (Dennst.) Alston (South East Asia)	Dysentery, dyspepsia, bronchitis (Bk, Res) [113]
Brucea antidysenterica J.F.Mill.	Asthmatic disorders (L, R), digestive (Bk, Ft, L, R, S), cancerous tumor of the skin (L, S) [120];
Southern and Eastern Africa, Tropical Africa	Diarrhea (Bk, Ft, L, R, S) [112, 114, 120];

	Malaria (L) [71]

[a]Bourdy G. 2003, unpublished data from French Guiana

other skin diseases (psoriasis, eczema, pruritus, rash), together with affections of the oral mucosa. Seventeen species are applied locally to treat these conditions: *Ailanthus altissima*, *A. excelsa*, *A. integrifolia* subsp. *calcynia* (Pierre) Noot., *Brucea antidysenterica*, *B. javanica*, *Castela emoryi* (A.Gray) Moran & Felger, *C. erecta*, *Eurycoma longifolia*, *Picrasma javanica* Blume, *P. quassioides*, *Quassia africana*, *Q. amara*, *Q. gabonensis*, *Q. indica*, *Q. undulata*, *Simaba cedron*, and S*imarouba amara*.

The Simaroubaceae find their field of election in the treatment of malarial fevers, which makes these species a major therapeutic recourse in places where the disease is endemic. The species most used against malaria worldwide are *Brucea javanica*, *Eurycoma longifolia*, *Hannoa klaineana*, *Picrasma excelsa*, *Picrasma javanica*, *Picrolemma sprucei*, *Quassia africana*, *Q. amara*, *Q. indica*, *Simaba cedron*, and *Simarouba amara*. As a corollary to the antibacterial and antiparasitic activities of quassinoids, the Simaroubaceae *Brucea antidysenterica*, *Castela erecta*, *C. tortuosa*, *Eurycoma longifolia*, *Picrasma excelsa*, *P. quassioides*, *Quassia africana*, *Q. amara*, *Q. indica*, *Q. undulata*, *Simaba cedron*, and *Simarouba amara* in particular are widely used against febrile illnesses of various etiologies.

Another major indication of the Simaroubaceae also focuses on the respiratory system, and *Ailanthus altissima*, *A. excelsa*, *A. triphysa*, *Brucea antidysenterica*, *Hannoa klaineana*, *Quassia africana*, *Q. gabonensis*, and *Q. undulata* are prescribed in case of serious pulmonary infections (bronchitis, asthma, cough, emphysema, bronchopneumonia).

Some Simaroubaceae also display therapeutic actions on the male or female reproductive system: *Simaba cedron* and *Simarouba amara* are used during childbirth and in the postpartum period; *Ailanthus altissima* and *Simarouba amara* are known to stop uterine bleeding; *Ailanthus excelsa* is contraceptive; and *A. altissima*, *A. excelsa, Quassia indica*, *Q. africana*, *Picrasma crenata*, and *Simarouba amara* regulate menstruation and are sometimes used in cases of vaginal leucorrhea, some of which may be due to the presence of vaginal parasites. For the male reproductive tract, *Ailanthus altissima* cures spermatorrhea; *Eurycoma longifolia* and *Quassia undulata* are reportedly aphrodisiacs; and *Picrasma crenata* and *Quassia africana* are used against syphilitic venereal diseases.

Lastly, three Simaroubaceae species are described as antivenom (*Brucea antidysenterica*, *Quassia amara*, and *Simaba cedron*, with a very strong convergence of use for the cotyledons of *Simaba cedron* seeds in South America). *Brucea antidysenterica*, *Brucea javanica*, *Eurycoma longifolia*, *Quassia undulata*, and *Picrasma javanica* are known as antidotes to food poisoning or other types poisoning. Central nervous system troubles, such as dementia, nervousness, and epilepsy, and alcohol addiction are treated with preparations of *Ailanthus altissima*, *Quassia undulata*, *Simarouba amara*, or *Picrasma excelsa*.

Used for centuries to treat frequent, sometimes life-threatening, medical tropical conditions (malaria, amoebic dysentery, infectious diarrhea in young children), the Simaroubaceae have demonstrated a real therapeutic interest with remarkable convergence of practice undoubtedly linked to the strong antiparasitic, antibacterial, and antiproliferative activities of quassinoids. Moreover, functional activities justifying organ tropisms also contribute to the effectiveness of Simaroubaceae medicinal plants, making them an invaluable resource and justifying their inscription in national pharmacopoeias.

5 Conclusion

Quassinoids are a family of molecules with a broad range of remarkable pharmacological activities (anticancer, antimalarial, ameobicide, nematicidal, anti-inflammatory, antiviral, and so on), the most of which is being made through the still active use of the Simaroubaceae in traditional medicines. Quassinoids' pharmacological potential has been largely demonstrated in the laboratory both in vitro and in vivo. Nevertheless, no drug has been developed so far from these substances. With respect to their anticancer activity, these compounds have not been up to expectations against cancers for which they were tested (breast cancer and melanoma). They are likely to be more efficient against hematological cancers but this remains to be demonstrated. Also, the antimalarial activity seems to be associated with some toxicity, and these compounds have never been placed into clinical trials for their antimalarial potential. However, the results described in the literature speak in favor of the search for new active and less toxic quassinoids and the parallel development of further structure-activity relationship studies aiming at improving the antimalarial selectivity of these natural products. The discovery of synergistic interactions between quassinoids and other clinical antimalarial drugs can also contribute to circumvent the obstacle of their toxicity. Finally, considering the structural complexity of these highly oxygenated molecules containing multiple stereocenters, quassinoids' total synthesis also remains an interesting challenge.

Acknowledgments The authors have written this review under the auspices of CaP (Chemotherapy against Parasites / Consortium antiParasitaire). The authors wish to thank Pr Hagai Ginsburg for illuminating intellectual support.

Abstract

Glycyrrhizic acid (GA), an active compound extracted from *Glycyrrhiza glabra*, has been demonstrated to specifically lower blood glucose and improve insulin sensitivity and lipid profile in normal lean rats and rats on high-sucrose or high-fat diet. Blood pressure was not affected by GA during the duration of the experiment. Aspartate aminotransferase, alanine aminotransferase, and γ-glutamyltransferase in the liver and creatine kinase in muscles were normal as well in lean rats given GA. 11β-Hydroxysteroid dehydrogenase activities were lower in the kidneys, liver, adipose tissues, and muscles in treated rats, while glucose-6-phosphatase activities and phosphoenolpyruvate carboxykinase activities in the liver and kidneys were reduced ($p < 0.05$) but induced in the visceral and subcutaneous tissues. Upregulation of lipoprotein lipase was seen in both the high-fat-fed and high-sucrose-fed rats, while peroxisome proliferator-activated receptor γ was also upregulated in high-fat-fed rats.

In conclusion, this work showed that GA could improve hyperglycemia and hyperlipidemia in lean, high-fat-fed, and high-sucrose-fed rats.

Keywords

Glycyrrhizic acid • Metabolic syndrome • Dyslipidemia • Lipoprotein lipase • Lipid profile • Gluconeogenic enzymes

Abbreviations

11β-HSD	11β-Hydroxysteroid dehydrogenase
ALT/AST	Alanine aminotransferase/aspartate aminotransferase
AM	Abdominal muscle
CK	Creatine kinase
FFA	Free fatty acid
G6Pase	Glucose-6-phosphatase
GA	Glycyrrhizic acid
GC	Glucocorticoids
H	Heart
H6PDH	Hexose-6-phosphate dehydrogenase
HDL	High-density lipoprotein
HOMA-IR	Homeostasis model assessment of insulin resistance
K	Kidney
L	Liver
LDL	Low-density lipoprotein
LPL	Lipoprotein lipase
Met S	Metabolic syndrome
PEPCK	Phosphoenolpyruvate carboxykinase
PPAR	Peroxisome proliferator-activated receptor
QF	Quadriceps femoris
SAT	Subcutaneous adipose tissue

T2DM	Type 2 diabetes mellitus
TAG	Triacylglycerol
VAT	Visceral adipose tissue
VLDL	Very-low-density lipoprotein
γGT	γ-Glutamyltransferase

1 Introduction

1.1 Glycyrrhizic Acid: A Natural Product from Licorice Roots

Plants are abundant sources of natural products with biologically active molecules that play an important role in pharmacology. Licorice (*Glycyrrhiza glabra*) is a tall shrub of the Leguminosae family. Commercial licorice products are often derived from extracts of the licorice root. Glycyrrhizic acid (GA) which is also known as glycyrrhizin or glycyrrhizinate is considered the primary active ingredient in licorice root extract and constitutes 10–25 % of the root extract [1]. It is also known as Gan Cao in Chinese (Fig. 126.1).

Licorice is mainly used as a condiment in food and confectionery industries. It is widely used as a sweetener in diet coke, candies, chewing gum, gelatin, pudding, cream, and alcoholic beverages [2]. The sweetness of GA can mask the bitter taste

Fig. 126.1 Root of licorice shrub

of medicines. Hence, GA in ammoniated form is also used in the production of cough syrups, linctus, and other medicines [3].

Therapeutic uses of licorice have been demonstrated for over 4,000 years in ancient Assyrian, Egyptian, Chinese, and Indian culture. A Greek botanist and pharmacologist, Theophrastus, used licorice to treat respiratory problems such as asthma and dry cough [4]. Apart from that, in China and India, it was used to treat pharyngitis, cough, palpitation, gastric pain, and gastric ulcer. GA was also prescribed as a folk medicine to diabetic patients [5] consistent with current findings that GA improves glucose tolerance in noninsulin-dependent diabetes model mice [6]. Additionally, GA also exhibits antineoplastic, anticarcinogenic, antidote, and antioxidant properties. Licorice was observed to cause apoptosis in melanoma and gastric cancer cells [4]. A registered Japanese medicine, Stronger Neo-Minophagen C (SNMC), is used to treat chronic viral hepatitis [7]. Other Asian nations use GA for treatment of allergic dermatitis and urticaria [8].

2 Pharmacokinetics of GA

GA is a saponin compound, which contains one molecule of triterpenoid aglycone (glycyrrhetic acid, GE) conjugated to two molecules of glucuronic acid (Fig. 126.2).

GE exists as 18α- or 18β-stereoisomeric forms [1]. However, GA has poor oral bioavailability in both rats and humans. Upon oral ingestion of GA into the gastrointestine, it undergoes presystemic deglucuronidation by specialized β-glucuronidase from intestinal flora (*Eubacterium* sp., *Ruminococcus* sp., and *Clostridium innocuum*) and is completely absorbed as GE [1]. GA is only detectable in rats and human plasma after high oral doses of 50–500 mg/kg and 100–1,600 mg/kg, respectively [1, 9].

GE binds extensively to both specific and nonspecific binding sites of human and rat plasma albumin. GE is distributed mainly into the liver and minimally to other body compartments such as heart, spleen, pancreas, kidney, muscle, adipose tissue, and small intestines in rats. Such distribution profile may be similar in human as well [3].

In the liver, a saturable capacity-limited carrier protein mediates rapid hepatic uptake of GE which subsequently undergoes hepatic biotransformation, producing glucuronyl and sulfate conjugates such as 18β-glycyrrhetyl-3-O-hydrogensulfate, 18β-glycyrrhetyl-3-O-monoglucuronide, or 18β-glycyrrhetyl-30-monoglucuronide [10]. GE may also undergo hepatic dehydrogenation to form 3-ketoglycyrrhetic acid.

These metabolites are later excreted into the bile via the canalicular multispecific organic anion transporter (cMOAT) and subsequently re-metabolized by the intestinal flora. This enterohepatic recirculation is responsible for the slow terminal plasma clearance of GE. However, the major elimination pathway for GA is in feces [1, 2]. The summary of the pharmacokinetics of GA is depicted in Fig. 126.2.

Fig. 126.2 Metabolism of glycyrrhizic acid (*GA*); GA is converted to GE either completely (*1*) or through a two-step process (*2a*, *2b*). Glycyrrhetic acid (*GE*) is absorbed (*3*) and undergoes hepatic biotransformation (*4*) to produce 18β-glycyrrhetyl-3-O-hydrogen sulfate (*B*), 18β-glycyrrhetyl-3-O-monoglucuronide (*C*), or 18β-glycyrrhetyl-30-monoglucuronide (*D*). GE may also undergo hepatic dehydrogenation (*5*) to form 3-ketoglycyrrhetic acid (*A*) [1]

3 Biological Effects of GA

3.1 11β-Hydroxysteroid Dehydrogenase (11β-HSD)

Glycyrrhetinic acid (GE), which is deglucuronidated from GA by intestinal flora upon ingestion, has been found to inhibit 11β-HSD and was known to have modulation on the regeneration of glucocorticoids and confers ligand specificity to mineralocorticoids. It is therefore recognized to have antidiabetic properties in terms of its ability to inhibit the enzyme 11β-HSDs [11].

Substantial experimental evidence pointed out that both GA and GE have inhibitory effects on 11β-HSDs but GE is 200–1,000 times more potent than GA [1]. Both 11β-HSD1 and 11β-HSD2 are suppressed by GA and GE since they are nonselective inhibitors of this enzyme. However, GE exerts higher degree of inhibitory effect on 11β-HSD1, favoring the reaction direction that drives the conversion of active GCs into inactive GCs [12].

As elevated 11β-HSD activities and the resulting increased GC production have been reported to impair the glucose and lipid homeostasis and lead to the development of insulin resistance, inhibitory effect of GA could represent a potential therapeutic intervention in the treatment of type 2 diabetes mellitus (T2DM) and metabolic syndrome (MetS) [13–18].

11β-HSD is an enzyme complex that catalyzes the reversible conversion of active glucocorticoid (cortisol in human, corticosterone in rodents) to inactive glucocorticoids (cortisone in human, 11-dehydrocorticosterone in rodents) [2]. Clinical studies on obese individuals have demonstrated elevated levels of 11β-HSD1 mRNA, decreased levels of 11β-HSD2 mRNA, and increased GC levels in the adipose tissues [17]. Hyperinsulinemia and elevated FFA levels induce an acute increase in 11β-HSD activity in the adipose tissues of humans [19]. The association between elevated levels of 11β-HSD1 mRNA and metabolic abnormalities such as visceral obesity, IR, and hypertension has prompted the design of 11β-HSD inhibitors for the treatment of MetS [20].

3.2 Lipoprotein Lipase (LPL)

LPL is the major enzyme responsible for the hydrolysis of circulating TAG moiety of both classes of TAG-rich lipoproteins: the chylomicrons and VLDL, generating FFA, that are either oxidized in the muscles or reesterified in the adipose tissues, and glycerol that is returned to the liver. LPL plays a central role in overall lipoprotein metabolism, where (1) the successive interaction of VLDL with LPL generates the LDL that are involved in forward cholesterol transport and (2) the remnant lipoprotein particles so formed from LPL catalysis contributes to the maturation of HDL precursors, the latter of which is then involved in reverse cholesterol transport [21, 22]. Perturbation in LPL activity could therefore lead to significant metabolic consequences, and LPL has been implicated in pathophysiological conditions characterized by marked hypertriglyceridemia, such as that observed in the metabolic syndrome (MetS).

Stimulation of LPL activity by either the use of transgenic overexpression or the administration of LPL-raising drugs has been shown to ameliorate the observed dyslipidemia and hyperglycemia. Interests over GA studies rose further as triterpenoids had been discovered to act as PPAR agonists, and this may suggest that GA could also potentially act to activate the PPAR class of nuclear receptors and may therefore be proposed to be a candidate for raising LPL [23, 24].

3.3 Peroxisome Proliferator-Activated Receptor Class of Nuclear Receptors (PPAR)

In addition, GA has also been suggested to possibly transactivate nuclear receptor peroxisome proliferator-activated receptor (PPAR) class of nuclear receptors; triterpene compounds (such as 2-cyano-3,12-dioxooleana-1,9-dien-28-oic acid (CDDO) and dehydrotrametenolic acid) have been found to bind to and transactivate PPARγ [25, 26]. This may suggest that GA, a triterpenoid compound, could also possibly transactivate (PPAR) class of nuclear receptors.

Studies of the past few years have identified the therapeutic utility of PPARγ agonists in T2DM and MetS treatment due to their ability to improve hyperglycemia and insulin resistance [27–29]. PPARγ and were also reported to be transcriptional factors that control several genes for the key enzymes involved in lipid and glucose metabolism, for example, LPL, PEPCK, and G6Pase. The gene promoters of these enzymes have also been found to contain PPARγ response element (PPRE) [30, 31]. Therefore, the potential ability of GA as a ligand for PPARγ transactivation may provide another additional molecular mechanism for the GA-induced improvement in the glucose and lipid metabolism other than the GA-induced 11β-HSD inhibition.

3.4 Effects of GA on the Aforementioned Parameters

The metabolic syndrome is a cluster of metabolic disorders characterized by hyperglycemia, dyslipidemia, obesity, hypertension, and insulin resistance. These are risk factors for the development of diabetes mellitus type 2 and cardiovascular diseases [32]. Dyslipidemia is a hallmark of the syndrome and is associated with a reduction in LPL activities, an enzyme involved in lipid metabolism. Functionally, GA inhibits 11β-HSD1 that catalyzes the activation of GC. GC plays a role in the regulation of PEPCK and G6Pase [33, 34]. Our earlier studies have indicated that GA could improve dyslipidemia and insulin sensitivity in lean rats fed on normal rat chow. As obesity is one of the risk factors in the development of diabetes mellitus type 2, we decided to investigate the effects of GA on PEPCK, H6PDH, and G6Pase; 11β-HSD and LPL involved in lipid and carbohydrate metabolism in lean rats; as well as rats on a high-fat or high-sucrose diet.

The following synopsis summarizes the observed enzyme activity involved in the lowering of glucose and improvement in insulin sensitivity and lipid profiles in GA-treated rats under various physiological conditions.

To determine the effects of GA on different tissues, the following tissues were examined, namely, liver (L), kidney (K), visceral and subcutaneous adipose tissues (VAT and SAT), quadriceps femoris (QF), and abdominal muscles (AM).

4 GA on Blood Pressure

No effect on blood pressure was seen between the lean rats given GA and control rats even for a period of three months. Rats on a high-fed diet showed increased blood pressure between the test groups and the control rats. However, no difference was noted between rats on high fat and given GA and rats on high-fat diet only, thus indicating that GA did not cause the rise in the observed blood pressure [35].

Similar observations were seen in rats on high-sucrose diets [36].

5 GA on Liver and Muscle Enzymes

Determination of liver enzymes in the lean rats given GA showed no increase in ALT, AST, and γ-GT. No increase was also observed in CK activity. This may indicate that 100 mg kg^{-1} of GA within the studied period did not affect the liver or muscle [37].

6 GA on Glucose Metabolism

Elevated intracellular GC level is one of the factors in the development of MetS. Studies in our laboratory on lean rats have revealed that administration of 100 $mgkg^{-1}$ of GA orally improved glucose metabolism in rats with effects on enzymes such as PEPCK and H6PDH which reduce blood glucose by increasing insulin sensitivity through a reduction in HOMA-IR [38, 39]. Improved insulin sensitivity HOMA-IR (<0.05) and blood glucose reduction ($p < 0.05$) were observed with the administration of GA. HSD1 and 2 activities decreased significantly in all tissues ($p < 0.05$) except in the AM and QF ($p > 0.05$) [38]. Gluconeogenic enzymes like PEPCK showed a reduction in the L ($p < 0.05$) and K ($p > 0.05$) but an increase in VAT ($p < 0.05$) and SAT ($p > 0.05$). However, H6PDH activities were significantly reduced only in the liver ($p < 0.05$).

Oral administration of 100 mg kg^{-1} of GA to high-fat- or high-sucrose-induced obese rats led to significant reduction in blood glucose concentration and improvement in insulin sensitivity as indicated by improvement in HOMA-IR ($p < 0.05$) [35, 36].

11β-HSD1 activities were significantly higher in SAT, VAT, AM, QF, and L for the high-fat-fed rats compared to the control. When treated with GA, the 11β-HSD1 activities in these tissues were lower compared to the high-fat-fed rats. GA inhibited 11β-HSD2 activities in AM, QF, and L in the GA-treated rats compared to the high-fat-fed rats. However, in the SAT, VAT, and K of the high-fat-fed GA-treated rats, no 11β-HSD2 activities inhibition was found [40].

In both the high-fat- and high-sucrose-fed rats, significant (1) decrease in H6PDH activities was seen in the aforementioned tissues ($p < 0.05$), (2) reduction in G6Pase activities in the L and K ($p < 0.05$), (3) decrease in PEPCK activities in the L and K ($p < 0.05$), and (4) increase in SAT and VAT ($p < 0.01$) was also observed in the GA-treated rats [36, 41].

In GA-treated high-sucrose-induced obese rats, significantly lower blood glucose, serum insulin, and HOMA-IR ($p < 0.05$) and improved lipid parameters ($p < 0.05$) with no elevation in blood pressure were seen. LPL activities were upregulated in all tissues ($p > 0.05$) with significant upregulation in the L ($p < 0.01$). 11β-HSD activities were lower in all tissues in GA-treated rats compared to those on high sucrose alone ($p < 0.05$). A smaller increase in H6PHD activities was observed in the L, SAT, AM, and QF ($p > 0.05$). PEPCK activities were elevated in the L and K ($p < 0.05$) but increased more in the SAT and VAT ($p < 0.01$), while increases were seen in the hepatic and renal G6Pase activities ($p < 0.05$) [36].

Histological analysis on all the studied tissues using hematoxylin and eosin as well as periodic Schiff stain indicated that GA-administered lean rats on normal diet had more intense magenta coloration compared to the control rats indicating increased deposition of polysaccharide, glycogen in the cells. Similar observations were seen in tissues from rats on high-sucrose or high-fat diet with GA [35, 36].

7 GA on Lipid Metabolism

In lean rats given GA, significant increase in LPL expression in the QF ($p < 0.05$) but nonsignificant increase in AM, K, L, heart, SAT, and VAT were seen ($p > 0.05$). Consistent improvement in serum lipid parameters was also observed with decrease in serum FFA, TAG, and total cholesterol and elevated LDL cholesterol ($p > 0.05$). Histological staining using Oil Red O showed significant decrease in lipid deposition in the AM and QF ($p < 0.05$) but nonsignificant decrease in the H, K, and L ($p > 0.05$) [42].

Upregulation of total PPARγ, PPARγ1, and PPARγ2 expressions in VAT, SAT, AM, QF, L, and K was seen in rats given GA ($p > 0.05$). Significant upregulation of total PPARγ ($p < 0.01$) was observed in the QF. Upregulation, albeit nonsignificantly, of total PPARγ, PPARγ1, and PPARγ2 expression in all the studied tissues with improved insulin sensitivity was seen [43, 44].

GA was found to be effective in improving dyslipidemia in rats on high-fat diet via increased tissue PPARγ and LPL expression, together with a positive shift in lipid profile and serum FFA as well as reduced tissue lipid accumulation [35, 45].

Also, GA given to high-fat-induced obese rats led to significant reduction in blood pressure and improvement in HOMA-IR ($p < 0.05$). LPL expression was upregulated in the K, H, QF, AM, VAT, and SAT but downregulated in the L – a condition seen in reverse to that seen in high-fat diet-induced obese rats without GA. Lipid profile showed significant hypotriglyceridemic and HDL-raising effects ($p < 0.05$) with a consistent reduction in serum FFA, total cholesterol and LDL cholesterol and significant decrease in lipid deposition across all tissues studied ($p < 0.01$).

In the high-sucrose-fed rats, consistent decrease in FFA, TAG, total cholesterol, and LDL cholesterol ($p > 0.05$) and an increase in HDL cholesterol ($p < 0.05$) were seen [36]. LPL expression was upregulated in the K, H, QF, AM, VAT, and SAT ($p > 0.05$) but downregulated in the L ($p > 0.05$) [36].

GA administration to high-fat-induced obese rats increased PPARγ2 expression significantly in the K, AM, QF, VAT, and SAT ($p < 0.05$) but insignificantly in the liver ($p > 0.05$). PPARγ2 expression was induced in the L, K, QF, and AM in both the high-fat-fed rats with and without GA with the VAT and SAT showing the highest expression in both groups [46].

Serum leptin levels were also significantly higher in rats fed on high-sucrose diet compared to the rats fed on high-sucrose diet with GA administration ($p < 0.01$) [43]. No significant difference was seen between the normal control and rats fed on high sucrose with GA.

Analysis on both the subcutaneous and visceral adipocytes indicated a decrease in the mean cell area in the rats given GA compared to the control rats with a larger reduction in the subcutaneous adipocytes compared to the visceral adipocytes [38].

8 Reported Side Effects

Chronic consumption of GA has been reported to be associated with corticosteroid-like effects and changes in cortisol metabolism in tissues which may lead to hypermineralocorticoid-like effects such as electrolyte imbalance, hypertension, and depression of the renin-angiotensin-aldosterone system [1, 2]. However, the effects are reversible upon withdrawal of GA [1].

Interest in GA arose following findings that have implicated the role of increased activation of GC receptors in the development of MetS symptoms such as central obesity and hyperlipidemia. Overexpression of 11β-HSD type 1 (11β-HSD1) in white adipose tissue of mice, for example, resulted in increased intracellular GC level, abdominal obesity, insulin resistance, hypertension, hyperglycemia, and dyslipidemia [47].

9 Discussion

9.1 High-Sucrose Diet and Glucose and Lipid Metabolism

It has been widely accepted that high-sucrose diets lead to undesirable metabolic abnormalities such as hypertension, hyperglycemia, insulin resistance, and dyslipidemia. Several studies have utilized animal models such as rabbits [48], mini-pigs [49], mice [50], and rats [51] fed on high-sucrose diet to examine mechanisms underlying diabetes-accelerated dyslipidemia and atherosclerosis. It has been established that overfeeding of animals with more than 50 % of calories from sucrose for approximately 4 weeks is sufficient to initiate moderate obesity and often results in dyslipidemia and T2DM [52]. In our studies, rats were fed a high-calorie diet with high (60 %) calories from sucrose obtained from cane sugar and low amount of calories from fat and protein for 4 weeks. These rats on high-sucrose diet consumed significantly more calories "per day" compared to the controls which were fed on standard rat chow.

The increased blood pressure observed in high-sucrose-fed subjects may be attributed toward the association between hyperinsulinemic state and sympathetic nervous system, accumulation of intracellular glyceraldehyde and dihydroxyacetone phosphate, and increased level of angiotensin-converting enzyme (ACE) [53]. GA administration has also been implicated with mineralocorticoid-like effects characterized by sodium retention, hypokalemia, hypertension, suppression of renin-angiotensin system, and low aldosterone level. This is due to nonselective nature of GA which inhibits both 11β-HSD1 and 11β-HSD2 [3]. However, in our studies, no elevation in the blood pressure in rats on high-fat diet with GA administration was seen. This suggests that the increase in blood pressure in rats from this group is due to the high-sucrose intake and therefore GA administered at 100 mg/kg for 28 days did not contribute toward this increase.

The positive shift in lipid parameters following GA treatment in sucrose-induced obese rats was similar to that previously reported by Lim et al. [42] in lean rats and Eu et al. [35] in high-fat-induced obese rats. The hypertriglyceridemia observed in patients with the MetS and T2DM originates from (1) lipolysis of TAG store from adipose tissue that causes elevated FFA flux to the liver and, hence, increased hepatic TAG synthesis and (2) inhibition of lipolysis of chylomicrons and VLDL due to decreased LPL levels [54]. Our present study indicated that GA treatment has effectively prevented such development through induction of LPL expression in all tissues which promotes catabolism of circulating TAG-rich lipoproteins. More importantly, GA induced a significant increase in HDL levels in the sucrose-induced obese rats. Esterification of free cholesterol is mediated by lecithin-cholesterol acyltransferase (LCAT) which is bound to HDL cholesterol. This key antiatherogenic mechanism facilitates removal of excess free cholesterol from the cells in the peripheral tissues and is returned to the liver and excreted in the bile [55]. Hence, various pharmacological interventions have been focused on raising HDL cholesterol levels [56]. Thus, the increase in HDL concentration could possibly be a more promising avenue to hinder lower coronary heart disease (CHD) instead of lowering LDL cholesterol [57].

Fructose, the monosaccharide component of sucrose, is highly lipogenic. Fructose provides large amount of hepatic triose-phosphate as precursors for fatty acid synthesis. It has indeed been observed in several studies that hepatic de novo synthesis is stimulated after acute fructose ingestion, with fructose contributing to the synthesis of both the glycerol- and the fatty-acyl parts of VLDL triglycerides [58]. Fructose may, in addition, increase the expression of key lipogenic enzymes in the liver [59].

Reduced LPL activities in the kidney, heart, and SAT were observed in high-sucrose-fed subjects. In agreement with our studies, LPL activities in muscle and adipose tissues were seen to be reduced with the onset of IR [60]. The absence of insulin-mediated suppression of lipolysis in adipocytes by hormone-sensitive lipase (HSL) promotes the release of fatty acids which in turn inhibit LPL activity [52]. Fatty acids, when in excess, are postulated to bind to LPL and displace it from its binding sites, thereby rendering them nonfunctional [53]. Therefore, the responses of both LPL and hormone-sensitive lipase (HSL) are blunted [61].

Fructose may also modulate intracellular lipid deposition known as "ectopic lipids," that is, deposition of TAG in the cytoplasm of nonadipose cells, such as hepatocytes and muscle fibers. In rodents, a high-sucrose diet rapidly increased intrahepatic fat deposition within 1 week and intramyocellular lipids on prolonged feeding [62]. This effect of fructose may involve stimulation of de novo lipogenesis through an enhanced intrahepatic synthesis of triose-phosphate precursors, an increased expression of lipogenic genes and LPL in the liver and muscle tissues [63]. Overfeeding promotes increased malonyl-CoA which in turn serves as an immediate precursor to promote de novo fatty acid synthesis. Malonyl-CoA also acts as an allosteric inhibitor of the rate-limiting enzyme, carnitine palmitoyl-transferase-1 (CPT-1), in the transport of long-chain acyl-CoAs (fatty acids) into the mitochondria for β-oxidation. As a result, they are diverted away from mitochondrial oxidation toward biosynthetic enzymes such as glycerol phosphate acyltransferase (GPAT1), diacylglycerol acyltransferase (DGAT1), and serine palmitoyltransferase (SPT1) which promote fatty acid reesterification into TAGs [64].

Inhibition of 11ß-HSD1 by GA caused a reduction in active glucocorticoids, and PPAR agonism properties of GA could be the reasons for the increased LPL expression in all tissues following GA administration. PPARα, once activated, leads to a direct upregulation of LPL expression and also downregulates apolipoprotein C-III (apoC-III), a protein which inhibits TAG hydrolysis by LPL. This results in increased fatty acid uptake and thus reduced serum TAG level as shown by the results from our studies [65, 66]. Elevation of PPARα was observed in 11ß-HSD1 knockout mice by Morton et al. [67]. PPARα is physiologically induced by glucocorticoids, and its elevation following 11ß-HSD1 inhibition may have arisen from increased circulating plasma glucocorticoids due to impaired negative feedback from the hypothalamic-pituitary-adrenal axis [67]. Therefore, GA-mediated direct or indirect activation of PPAR in concert with inhibition of 11ß-HSD1 may have contributed toward the upregulation of LPL expression in all tissues.

Contrary to fructose-mediated increase in LPL expression which led to tissue lipid accumulation, this GA-mediated increase in LPL expression in all tissues neither leads toward ectopic lipid depositions nor insulin resistance. In addition, the significant upregulation of LPL activities in the liver is probably because the liver is centrally involved in metabolism. This may have the highest distribution of GA. Studies on distribution of intravenous (IV) administration of GA in rats have confirmed that GA distribution is highest in the liver [68], thus further supporting this postulation. Similarly, LPL expression in the liver was significantly higher in GA-administered rats fed on high-fat diet as well [35].

In our studies, the mean blood glucose concentration was markedly raised with sucrose feeding. This was in accordance with studies on prolonged feeding on high-sucrose diet which increased glucose and insulin responses to a sucrose load [69] and increased fasting glycemia, thereby leading to hepatic insulin resistance in healthy men [70]. Insulin resistance is closely linked to lipid metabolism disorders. Elevated circulating FFA level and high ectopic lipid deposition in IR subjects lead to increased toxic lipid-derived metabolites, such as diacylglycerol, fatty acyl-CoA, and ceramides. The presence of these metabolites in the intracellular environment leads to higher serine/threonine phosphorylation of insulin receptor substrate-1 (IRS-1), which has been shown to reduce insulin signaling by decreasing GLUT4 translocation to plasma membrane. This in turn reduces insulin-stimulated glucose uptake in peripheral tissues [71].

However, this increase was moderated down in GA-treated rats on high-sucrose diet. The lower fasting blood glucose may be due to the increased glucose uptake into the adipose tissues and muscles by transporter GLUT4. Saltiel and Kahn [72] reported that insulin sensitizing PPARγ agonist increased the expression of Cb1-associated protein (CAP) which mediates downstream signaling molecules in activating GLUT4 protein mainly in the adipose tissue due to its high expression in this tissue. The enhanced GLUT4 activity in muscles was found to be predominantly mediated by 11β-HSD1. According to Vegiopoulos and Herzig [73], GC-induced IR in muscles resides in the suppression of glucose uptake mainly through inhibiting translocation of GLUT4 to the cell surface. Studies on 11β-HSD1 gene knockout mice also suggest that 11β-HSD1 inhibition could decrease blood glucose concentrations without risk of hypoglycemia. Besides increasing insulin-stimulated glucose uptake in tissues, blood glucose concentration was greatly reduced due to the decrease in hepatic glucose production. In T2DM, as much as 90 % of the hepatic glucose output can be due to accelerated gluconeogenesis. Both the inhibition of 11β-HSD1 and activation of PPARγ have been demonstrated to decrease expression of gluconeogenic enzymes [12]. Both actions promote gene expressions of fatty acid binding protein (FABP), LPL, acyl-CoA synthase (ACoAS), and PEPCK. This will lead to increased reesterification of FFA and enhance fat storage in the adipose tissues. Both 11β-HSD1 inhibition and PPARγ activation also suppress the genes that induce lipolysis and the release of FFAs, such as β3-adrenergic receptor, leptin, and TNF-α. This causes reduced circulating FFA levels and amelioration of FFA-induced hepatic and peripheral IR, resulting in increased hepatic and peripheral insulin sensitivity and improved glucose disposal [73].

Results from our studies have revealed that high-sucrose diet resulted in higher H6PDH activities in all six tissues. This result is in agreement with London et al. [74] who observed increased H6PDH mRNA levels in the liver and adipose tissues of Sprague-Dawley rats. High sucrose increases the substrate glucose-6-phosphate (G6P) and the availability for H6PDH, thereby leading to increased production of cofactor NADPH via the pentose phosphate pathway. The increased NADPH subsequently promotes the reductase activity of 11β-HSD1, resulting in elevated production of active GCs [75]. This postulation is further confirmed by elevated 11β-HSD1 activity observed in all tissues. Moreover, fructose enhances glucose phosphorylation in the liver. Fructose, derived from high-sucrose diet, is converted to fructose-1-phosphate which then binds to glucokinase regulatory protein (GKRP) and causes the dissociation of glucokinase (GK) from the glucokinase binding protein (GKBP). GK is translocated from the nucleus to the cytoplasm, resulting in an increase in the conversion of glucose to G6P [76]. This increases the substrate availability for H6PDH activity [77]. Lower H6PDH activities observed in rats with GA administration are probably due to the inhibitory effect of GA on 11β-HSD1. This leads to a reduction in the generation of cofactor $NADP^+$, thereby decreasing the H6PDH activity [36]. GA administration leads to reduced PEPCK and G6Pase expression, which subsequently decrease the rate of hepatic gluconeogenesis. GA's activation of PPARγ also improves hepatic and peripheral insulin sensitivity and glucose uptake. Both effects of GA lead to reduced hepatic glycogen store and circulating blood glucose, leading to a decrease in the production of G6P from glucose and glycogen through glycolysis and glycogenolysis. As a consequence, the availability of G6P for H6PDH decreases, contributing to a reduction in H6PDH activity [36].

As aforementioned, PEPCK is a key regulatory enzyme involved in two metabolic processes: gluconeogenesis, which occurs in the liver and kidney, and glyceroneogenesis, which occurs in the adipose tissues [78]. Our studies showed elevated PEPCK activities in all tissues with sucrose feeding. Increased expression of hepatic PEPCK gene was also observed in diabetic mice, characterized by elevated hepatic glucose output [79]. This could be due to increased production of GCs which stimulates the hepatic and renal PEPCK activities by promoting the assembly of several transcription factors (TFs), hepatocyte nuclear factors (HNF-3β and HNF-4α), Ccaat-enhancer-binding proteins (C/EBP β), and forkhead box protein O1 (FOXO1), on the PEPCK gene promoter [80]. However, Cassuto et al. [81] found that PEPCK activities are only stimulated by GCs in the liver and kidneys but are suppressed in adipose tissues. Our results are contrary to the above, where significantly increased PEPCK activities were observed in all tissues of the group on high-sucrose diet alone. Increased PEPCK activities in SAT and VAT in this group could be attributed to the FFA-induced activation of PPARγ. PPARγ is predominantly expressed in adipose tissues. During high-sucrose feeding, elevated GC-induced lipolysis causes activation of reesterification to prevent an all-out release of FFA into the bloodstream. As a consequence, glyceroneogenesis is activated to produce G3P, which is required for fatty acid reesterification. Under this condition, elevated circulating FFA would activate PPARγ, which binds as a heterodimer complex with RXRα to the PPAR response element (PPRE) on the PEPCK gene promoter. This results in increased PEPCK gene transcription and a corresponding increase in its activities in the adipose tissues [82].

The group on high-sucrose diet and given GA had increased hepatic and renal PEPCK activities compared to the control rats on normal diet, but the elevations were smaller compared to the rats on high-sucrose diet alone. This indicated the ability of GA to improve hyperglycemia through GC-stimulated PEPCK activity in gluconeogenesis. GA administration leads to reduced production of active GCs. This results in a downregulation in the PEPCK gene transcription, thereby decreasing PEPCK activity and gluconeogenesis rate [12]. In addition, activation of PPARγ was also found to downregulate the gene expression of PEPCK in the liver and kidneys, resulting in decreased gluconeogenesis [27]. GA, which is a triterpenoid saponin, has been found to be an agonist of PPARγ [43]. Therefore, GA's activation of PPARγ would lead to downregulation of PEPCK gene transcription, and this would also account for the reduced PEPCK activities observed in GA-treated rats compared to non-GA-treated rats.

G6Pase is mainly expressed in gluconeogenic tissues such as the liver and kidneys. It is a membrane-bound enzyme with a multicomponent system consisting of G6PC and G6PT which are located in the ER [83]. Similar to H6PDH, G6Pase requires G6P as substrate. It catalyzes the final step of gluconeogenesis and glycogenolysis, which is the hydrolysis of G6P to glucose [84]. Following high-sucrose feeding, an increase in six-carbon sugars (glucose and fructose) would increase the availability of substrate G6P for G6Pase. This would lead to increased G6Pase activities and elevated glucose output [85]. In addition, increased production of active GCs during high-sucrose feeding has been found to induce the gene transcription of G6Pase. This involves the binding of GR and cofactors to G6Pase gene promoter and increased coactivation of PGC-1α with GR, FOXO1, and HNF-4, which promote the G6Pase gene transcription [86]. High circulating FFA has also been associated with increased G6Pase mRNA and activities in diabetic condition. Elevated circulating FFA exerts a PPAR-dependent allosteric stimulation on G6Pase, resulting in increased G6Pase expression and gluconeogenesis [87]. Smaller elevation in G6Pase activities were observed in GA-treated rats compared to nontreated rats on high-sucrose diet. Besides the reduction in active GCs, another possible mechanism which might account for reduced G6Pase activities in the liver and kidneys could be the actions of PPARα in improving glucose and lipid metabolism and enhancing whole-body insulin sensitivity. Treatment with PPARα agonist was found to significantly reduce the mRNA level of G6Pase, leading to decreased gluconeogenesis. This suggests the possible role of GA as a PPARα agonist in the modulation of G6Pase activities [74].

Despite significantly higher serum insulin level in sucrose-fed rats, insulin failed to suppress the PEPCK and G6Pase activities in all the studied tissues. This could be due to reduced responsiveness of the tissues to insulin action due to increased circulating FFA levels. This will impair the insulin-stimulated suppression of PEPCK and G6Pase activities [87].

9.2 High-Fat Diet and Glucose and Lipid Metabolism

Numerous studies have revealed that high-fat diets promote hyperglycemia and whole-body IR. It is generally accepted that high-fat diets can be used to generate rodent model for MetS with IR [88]. Overfeeding of animals with high fat of more than 50 % of calories as fat for approximately 5 weeks is sufficient to initiate moderate obesity and often results in IR [89, 90]. Our work on rats fed on high fat showed that these rats consumed significantly more calories on a per day basis compared to the controls which were fed only standard rat chow.

In the insulin-resistant state, the decrease in insulin-mediated suppression of lipolysis in adipocytes promotes the release of fatty acids which inhibit LPL activities [91]. When supply of fatty acids exceeds tissue demand, fatty would probably bind to LPL and displace it from its binding sites, thereby rendering them nonfunctional [92]. LPL expression of rats fed on high fat without GA was downregulated in all nonhepatic tissues compared to the control rats on normal diet. The downregulation of LPL in the adipose tissues, muscles, and kidney may be due to inflammatory mediators such as tumor necrosis factor-alpha (TNF-α) which are found to be elevated in obesity and insulin-resistant states [93]. Its inhibition of LPL gene transcription is suggested to be mediated in part by blocking the nuclear-factor Y/CCAAT interactions with LPL promoter [94, 95]. However, the increase in TNF-α levels renders the opposing effect in the liver. According to Wang and Eckel [96], LPL is not normally expressed in the adult liver of animals but can be expressed under specific physiological and pathological conditions. A single dose of TNF-α can cause a significant increase in LPL mRNA levels in the liver. However, the detailed mechanism of such induction is not well understood. The increase in hepatic LPL activities and their concomitant decrease in the nonhepatic tissues could have resulted in greater partitioning of plasma TAG and apolipoprotein B100 (apoB100) from the liver [97] and hence may account for the observed hypertriglyceridemia in the rats on high fat without GA compared to the control rats on normal diet.

In rats on high-fat diet given GA, LPL expression was upregulated in all nonhepatic tissues, condition that opposes that seen in rats on high-fat diet without GA. It was postulated that GA results in upregulation of LPL via the activation of PPAR class of nuclear receptors since LPL gene is found downstream of the transcriptionally active PPRE [98]. Of the tissues in which LPL expression was upregulated, the highest upregulation occurred mainly in the muscles (AM, QF, and H) compared to SAT and VAT. This suggests that GA may exhibit a higher potency in activating PPARα than PPARγ; PPARα is highly expressed in the heart, liver, and kidney in which it has a crucial role in controlling fatty acid oxidation [99], while PPARγ is highly expressed in the adipocytes which trigger adipocyte differentiation and lipogenesis [94]. The activation of PPARα may lead to a direct upregulation of LPL expression and also downregulate apo-III, an inhibitor of LPL [65] that is upregulated in the insulin-resistant state [54]. The downregulation of LPL expression in the liver might be due to the reduction in macrophage-derived TNF-α in the adipose tissues. According to Jeong and Yoon [100], PPARα activation in adipose tissue mRNA levels of TNF-α production subsequently downregulates LPL in the liver. The end effect of these is that GA promotes partitioning of lipids away from the liver into the oxidative tissues.

Improvement in lipid profile following GA treatment was seen in all GA-treated rats. In the high-fat-fed rats, more prominent hypotriglyceridemic and HDL-raising effects were seen. The hypertriglyceridemia observed in patients with MetS and T2DM originates from (1) lipolysis of TAG store from adipose tissue that causes elevated FFA flux from the liver and, hence, increased hepatic TAG synthesis and inhibition of lipolysis of chylomicrons and VLDL due to decreased LPL levels [54]. Our study on high-fat-fed rats indicated that GA given to these obese rats could curb such development by selective induction of LPL expression in the nonhepatic tissues to promote catabolism of circulating TAG-rich lipoproteins and prevent further uptake of FFA into the liver by downregulating hepatic LPL expression. More importantly, GA induced a significant increase in HDL levels in the obese rats. Elevating HDL cholesterol may serve as a more attractive treatment alternative instead of lowering LDL cholesterol as dyslipidemia is often characterized by a normal range of serum LDL cholesterol but with a predominance of the more atherogenic small, dense LDL rather than the less atherogenic large, buoyant LDL particles [101]. The atheroprotective effect of HDL is exerted through its ability to counteract LDL oxidation, the major initiating event that prompts the development of the atherosclerosis. The HDL particle, by virtue of the antioxidative properties of its attached apo A-1 paraoxidase and glutathione peroxidase, reduces the oxidative modification of LDL by quenching the oxygen-derived free radicals generated from LDL oxidation [56]. Hence, various pharmacological interventions have been focused on raising HDL-induced levels [56].

Obesity-induced IR results in profound dysregulation in the glucose homeostasis and produces elevations in fasting and postprandial glucose levels [54]. The mean glucose levels increased in rats on high-fat diet alone compared to the control rats which are on normal rat chow. With the development of visceral obesity, the high circulating FFA leads to IR that promotes a dual effect to enhance hyperglycemia by downregulating the insulin-sensitive glucose transporter 4 (GLUT 4) via the Randle cycle and thus promotes an accumulation of glucose in the circulation and (2) stimulating hepatic gluconeogenesis by antagonizing the action of insulin in the liver (hepatic IR) [54]. GA-treated rats on high-fat diet demonstrated a significant decrease in fasting blood glucose compared to the rats on high-fed diet alone. The reduction in fasting blood glucose of the high-fat diet rats given GA is proposed to be accounted for by increased tissue glucose uptake via GLUT 4. PPARγ activation in the adipose tissue has been shown to increase the expression of c-Cbl-associated protein (CAP) that is important for the translocation of GLUT4 to the cell surface [54], and inhibition of 11β-HSD1 may also exhibit similar effect by attenuating the inhibition muscle GLUT4 translocation by active glucocorticoids [73]. These effects may therefore increase glucose disposal, giving a decrease in circulating glucose level. More importantly, both 11β-HSD1 inhibition and PPARγ agonism have also been associated with the reduced expression of PEPCK and G6Pase [12, 74], the two rate-limiting enzymes of the gluconeogenesis pathway that are aberrantly induced in T2DM patients [73]. Uncontrolled accelerated gluconeogenesis accounts for 90 % of hepatic glucose output in T2DM patients and is thus a significant contributor to hyperglycemia [12].

Besides a significant reduction in blood glucose concentration in rats on high-fat diet given GA, mean serum insulin level was also reduced compared to rats on a high-fat diet alone. This may be due to improved glucose-sensing proteins in the pancreatic β-cells since β-cells control insulin secretion in response to blood glucose levels [102]. Both GLUT2 transporter and glucokinase are components of the glucose-sensing apparatus of the β-cells whose expressions are both decreased in diabetes. With this, the glucose threshold for insulin secretion is also decreased, leading to aberrant insulin secretion and hyperinsulinemia. PPARγ activation is shown to restore both GLUT2 and glucokinase expression [36]. Thus, the glucose threshold for insulin secretion is increased, thereby reducing insulin secretion. The HOMA-IR is used for assessment of insulin sensitivity from basal (fasting) glucose and insulin levels, a higher value indicating lower insulin sensitivity (higher insulin resistance) and vice versa [103]. The HOMA-IR index decrease in rats on high-fat diet given GA was significant compared to those on high-fat diet alone – indicating an improvement in insulin sensitivity in rats on high-fat diet given GA.

Chromic obesity has been associated with nonadipose tissue lipid accumulation – a condition known as tissue steatosis [54, 104]. During conditions of chronic caloric excess, a compensatory mechanism first occurs in the leptin-responsive state where the surplus FFA upregulates PPARα and promotes the compensatory oxidation of the surplus FFA, with the excess energy dissipated as heat. As such process continues, such caloric excess is no longer compensated, and in the leptin-unresponsive state, the surplus FFA activated PPARγ instead, leading to upregulation of the lipogenic enzymes that causes ectopic TAG accumulation [104]. Leptin resistance has been shown to occur in late phases in both rat and human diet-induced obesity [104]. In our work, lipid deposition in all tissues from rats on high-fat diet given GA was significantly reduced compared to the rats on high-fat diet alone. Thus, it could be that the GA activation of PPARα expression which in turn induced the expression of lipid-catabolizing genes such as carnitine palmitoyltransferase-1 CPT-1, acyl-CoA oxidase (AC), and uncoupling protein (UCP-2) that is induced normally in the state of compensated caloric excess in the above tissues. Tissue lipid accumulation has been associated with obesity-related IR [105, 106], and these are mediated by TAG-derived metabolites and inhibit signal transduction [64]. Thus, our observation of GA-mediated improvement in insulin sensitivity may be related to such decrease in tissue lipid as well.

10 Conclusion

In conclusion, our group has demonstrated that glycyrrhizic acid:

- Not only lowered blood glucose significantly but also improved insulin sensitivity and caused a positive shift with respective to lipid parameters in rats under various physiological conditions. Besides, blood pressure was not affected during the studied period, with the given dosage of GA at 100 mg kg^{-1}
- Did not affect liver enzymes AST/ALT, γ-GT, and muscle CK as their activities were similar to that of the control rats.
- Exerted selective induction/repression of LPL expression, upregulation of PPARγ, increased/decreased of 11β-HSD types 1 and 2, and the activities of PEPCK, G6Pase, and H6PDH in the studied tissues.

The above observations therefore suggested that GA acts via the above regulatory gluconeogenic enzymes as well as LPL and HSD1 to give the observed glucose and lipid effects. GA could therefore be considered as a potential compound in ameliorating dyslipidemia and hyperglycemia in rats.

Abstract

At this moment, more than 450 ecdysteroids are identified, most of them found in different plant species. They are biosynthesized via the mevalonic acid pathway as C-27, C-28, and C-29 steroid structures. The isolation of new phytoecdysteroids is a still ongoing process. Phytoecdysteroids can play a taxonomic role. They are thought to play a role as growth regulators, and they may protect plant species against phytophagous insects. They can be considered as possibly interesting structural templates for different therapeutic indications. However, up to now, no real therapeutic applications have been materialized. They are actually used for dermatological purposes in cosmetology, and putative anabolic activity is highly promoted via Internet, without too much evidence. The large variety of substances may hamper the making of synthetic derivatives that can be patented as original therapeutic entities.

1 Introduction

Ecdysteroids (also called ecdysones) are a group of natural polyhydroxysteroids present in plants (phytoecdysteroids) and animals (zooecdysteroids). Some ecdysteroids, such as ecdysone, 20-hydroxyecdysone (ecdysterone), and ajugasterone C, can be found in plants and animals [1]. The phytoecdysteroid profile varies in amount and composition between plant species but also depends on plant organs, season, origin, and habitat [2].

The chemical structure of α-ecdysone was elucidated by physiochemical studies and chemical transformations by Karlson et al. [3], and the stereochemical structure was determined by Huber and Hoppe [4] by X-ray analysis. Closely related molecules were discovered in plant species soon thereafter. Galbraith and Horn [5] isolated ecdysterone, a phytoecdysone with insect-molting properties from the fern *Polypodium elatus*. Simultaneously, Nakanishi et al. [6] identified ponasterone from another gymnosperm, namely, *Podocarpus nakaii*. Jizba et al. [7] isolated crustecdysone from *Polypodium vulgare*, whereas Takemoto et al. [8] extracted insect-molding substances from mulberry leaves. These first discoveries triggered further efforts to investigate the distribution of ecdysones in plants. They were also discovered in red algae which contain closely related pinnasterols [9], [10] and later in fungi [11]. Dinan and Lafont [12] made a compilation of the literature for the screening of plant species, among others vascular plants, algae, and fungi. In the beginning, the focus was on the discovery of possible natural antitumoral agents, but very soon, the target moved from human therapy to insecticidal activity. As these molecules interfered with insect development and reproduction, there was hope for development of a new class of natural pesticides as alternative for purely chemical agents. However, the complexity of the molecules makes them difficult to synthesize. They hardly can penetrate in the living insects, and their stability is limited in a natural environment. Up to now, no natural ecdysteroids have made their way in pest control [13].

This chapter deals with a review of the biodiversity of phytoecdysteroids, the possible biosynthetic pathways of these molecules, and the hypothesized functions of this class of secondary metabolites for plants and humans.

2 Distribution of Phytoecdysteroids

Ecdybase (http://www.ecdybase.org) is a good resource for chemical and biological data for ecdysteroid analogues and literature data on the occurrence of phytoecdysteroids in plants. Ecdysteroids seem to occur not only in a wide variety of species but also as a wide variety of structures. Glucosyl-ferulate conjugates are among the newer classes of conjugates discovered in *Microsporum membranifolium* [14]. The question emerges whether phytoecdysteroids are synthesized by the plant species themselves or whether they are taken up and subsequently modified by species like fungi [13].

Another question is related to the capacity of a larger group of plants to synthesize ecdysteroids. In the beginning, ferns were thought to be the species representative for ecdysteroid synthesis, but this was due to the high number of ferns screened [13]. Ecdysteroids were also found in species like *Arabidopsis thaliana*, originally considered as ecdysteroid negative [15]. The actual concept is that few plant families do not contain ecdysteroid species within their members. Some species contain huge amounts of phytoecdysteroids, i.e., 2–3 % of their dry weight (e.g., seeds of *Rhaponticum carthamoides* and stalks of *Diploclisia glaucescens*, inflorescences of *Serrulata inermis* and roots of *Cyanothis arachnoides*), but in general, the steroid content in plants is normally in the order 0.01–0.1 % of the plant dry weight [16]. There may be a relationship between the presence or absence of phytoecdysteroids and the taxonomic position of plant species, e.g., the within the family of the *Chenopodiaceae* and within the genus *Silene* [13].
